TiS_2 in LiCl (saturated) LiAlCl_4 .—The behavior of TiS_2 was also studied in LiAlCl_4 at 175°C , in the voltage window $1.28\text{-}0.15 \text{ V}$ (*vs.* Al). The material is stable in this medium, and at this temperature and no dissolution or chemical reaction was observed.

Fig. 5. TiS_2 (+ graphite 50%) galvanostatic discharge at different current densities in $\text{BpCl}(31.2)\text{-LiCl}(13.3)\text{-AlCl}_3$ (55.5 m/o) at 60°C (curves 1, 2, and 3) and without LiCl (curve 4).

Fig. 6. Galvanostatic discharge-charge cycle of TiS_2 in $\text{BpCl}(31.2)\text{-LiCl}(13.3)\text{-AlCl}_3$ (55.5 m/o) at 0.5 mA cm^{-2} . $T = 60^\circ\text{C}$.

Fig. 7. TiS_2 galvanostatic discharge in LiCl (sat) + AlCl_3 at 175°C at various current densities.

The galvanostatic discharge curves of TiS_2 electrodes at various current densities are reported in Fig. 7. By comparison with the behavior of this material in an $\text{AlCl}_3\text{-BpCl-LiCl}$ mixture at 60°C , the effect of current densities is quite negligible and the faradaic capacity is the same (1 F/mol TiS_2) between 0.1 and 0.5 mA cm^{-2} . A decrease of capacity (11% smaller than in $\text{BpCl-AlCl}_3\text{-LiCl}$) is observed when the discharge is carried out at 2.5 mA cm^{-2} for the same voltage cutoff. A first voltage plateau appears at the middle-discharge voltage ($\sim 0.65 \text{ V}$), and another small plateau appears at about 0.28 V . This last one is better defined at low current densities.

Fig. 8. Galvanostatic charge-discharge cycles of TiS_2 in LiCl (saturated) + AlCl_3 (49.5 m/o) at 0.5 mA cm^{-2} . $T = 175^\circ\text{C}$. Voltage window: 1.28-0.15V.

Discharge-charge cycles.—Discharge-charge cycle curves at 0.5 mA cm^{-2} in the voltage window 1.28-0.15V are shown in Fig. 8. The two plateaus at 0.70 and 0.28V are well defined in each cycle. The faradaic capacity is 1 F/mol^{-1} for the first discharge. It falls to about 77% in the second cycle, and then stays quite constant (between 98% and 100% of the preceding discharge) during the following ones.

A comparison between the results in $\text{BpCl}_3\text{-LiCl}$ at 60°C (Fig. 6) and in LiAlCl_4 (49.25 m/o AlCl_3) at 175°C (Fig. 8) is shown in Fig. 9. It shows that the yield is higher in the all-inorganic molten salt. As an example, the observed faradaic capacity at the fiftieth cycle is 120 Ah kg^{-1} in LiAlCl_4 and only 81 Ah kg^{-1} in $\text{BpCl-AlCl}_3\text{-LiCl}$. This comparison is illustrated by the decrease of the capacity of TiS_2 as a function of cycle number in both molten salts (Fig. 8). The capacity appears to be better in the first cycles in $\text{BpCl-AlCl}_3\text{-LiCl}$, but the higher reversibility observed in LiAlCl_4 shows that, after the 20th cycle, the faradaic capacity is higher in this medium.

The successive cycles of TiS_2 in LiAlCl_4 clearly show that the voltage plateau at around 0.27V is reversible. The shapes of the successive charge-discharge curves demonstrate that the voltage plateau at 0.27V has no influence on the earlier reduction step or on the subsequent recharge. Recovered capacity during the second discharge is 81% of the first. This means that the greatest part of the observed capacity loss during the second cycle is due to a relatively small irreversible process in the discharge. After the fifth cycle, the irreversible process appears to be insignificant and the recovered capacity at twentieth discharge is still 92% of the fifth cycle and 83% of the second one.

Conclusion

Experimental results show that, in spite of the strong ability of chloroaluminates to dissolve oxides and sulfur compounds, V_2O_5 and TiS_2 are stable enough to be used as cathodic materials in these molten salts. A chemical oxidation of chloroaluminate by the cathodic material was observed in only one case: V_2O_5 in LiCl-AlCl_3 at 175°C . Chemical oxidation at ambient temperatures has not been observed under the experimental conditions.

Whatever the cathodic material is, the reduction process with Li^+ insertion seems to occur the same in molten chloroaluminates as in organic electrolytes (5-10) or in LiCl-KCl (15-19). As has been reported, a complete initial reduction is always necessary in order to obtain good reversibility of the charge-discharge cycle.

In the case of V_2O_5 at low current density, the Li^+ insertion proceeds in four steps like in an organic solvent. These steps correspond to the following stoichiometry (reference: Al electrode)

- | | |
|--|--|
| (1) $\text{V}_2\text{O}_5\text{Li}_{0.25} \approx 1.3\text{V}$ | (3) $\text{V}_2\text{O}_5\text{Li} \approx 0.35\text{V}$ |
| (2) $\text{V}_2\text{O}_5\text{Li}_{0.5} \approx 1.0\text{V}$ | (4) $\text{V}_2\text{O}_5\text{Li}_3 \approx 0.10\text{V}$ |

Fig. 9. Comparison of the galvanostatic discharge (as percentage of the initial recovered capacity) of TiS_2 in $\text{BpCl} + \text{LiCl}$ at 60°C and in LiAlCl_4 at 175°C . Current density: 0.5 mA cm^{-2} .

The maximum capacity is about 2.5 Li^+ per V_2O_5 unit.

Curves in Fig. 2 show that the modification of the crystal lattice which is necessary for the reversibility occurs at + 0.30V.

The decrease of the capacity with successive charge-discharge cycles becomes very small at high cycle numbers.

While it is still necessary to limit this decrease, V_2O_5 appears to be a good cathodic material in molten chloroaluminates at a temperature not far from the ambient.

As has been previously observed, the reversible insertion of Li^+ during the TiS_2 reduction is rigorously dependent on the quality of TiS_2 . With titanium sulfide prepared as described, the insertion process in both chloroaluminate melts (BpCl-LiCl-AlCl_3 and LiCl-AlCl_3) gives the same results as in organic media or in LiCl-KCl at 450°C . The capacity is about $1 \text{ Li}^+/\text{TiS}_2$.

Nevertheless, the best reproducibility is obtained in LiAlCl_4 at 175°C ; in this electrolyte, the loss of capacity during the successive cycles is lower than in the presence of BpCl . The Li^+ capacity is less dependent on the current density because of the combined effect of temperature increase and viscosity decrease.

Work is in progress to increase the yield of Li^+ cycling and to find anodic lithium compounds compatible with the cathodic lithium insertion compounds.

The Anodic Reaction of Sulfide Ions at Graphite Electrodes in Molten Cryolite

Nguyen Quang Minh* and Neng-Ping Yao*

Argonne National Laboratory, Chemical Technology Division, Argonne, Illinois 60439

ABSTRACT

The anodic reaction of sulfide ions at graphite electrodes in molten cryolite has been studied by cyclic voltammetry at 1323 K. The anodic reaction is found to proceed via a quasi-reversible mechanism, *i.e.*, one in which the current is controlled by both diffusion and charge transfer kinetics

The transfer coefficient β and the standard rate constant k_s are estimated to be 0.5 and 4.2×10^{-3} cm/s, respectively. The apparent diffusion coefficient for sulfide ions in cryolite at 1323 K is about 3.93×10^{-5} cm²/s.

Since the early work of Delarue (1, 2) on the anodic oxidation of sulfide ions in molten salts, many investigations and reviews (3-5) have been published on the subject. However, several important questions about the mechanism of the electrochemical reaction and the sulfide species present remain unanswered.

From the fundamental viewpoint, the electrochemical reaction of sulfide ions in molten salts offers an area of challenging research. The mechanism of the reaction is still controversial and cannot be interpreted in an unambiguous manner. It is also of technological interest since metal sulfides have been proposed as cathode materials in molten-salt batteries (6) and the extraction of metals by molten-salt electrolysis of sulfides (electrowinning) has long been of commercial interest and the subject of many investigations (5). Except for some electrochemical studies of the sulfide reaction at very high temperatures (1623-1823 K) in slags (as applied to electroslag remelting of metals) (7-11), most of the investigations on sulfide in melts were carried out in chlorides and in the temperature range 700-850 K. Recently, the present authors have investigated the anodic oxidation of sulfide in both molten chlorides and fluorides (12-14) at a temperature of 1023 K. These studies were carried out as part of the experimental work on the molten-salt electrolysis of Al_2S_3 for the production of aluminum. For MgCl_2 - NaCl - KCl eutectic (12) and AlCl_3 - MgCl_2 - NaCl - KCl melts (13), it has been found that the oxidation of sulfide proceeds via a mechanism based on two steps: $\text{S}^{2-} \rightleftharpoons \text{S} + 2e^-$ followed by $\text{S} + \text{S} \rightleftharpoons \text{S}_2$. The electrochemical reaction is diffusion controlled and reversible. The dimerization is very fast and very much displaced towards S_2 . However, the detailed analysis of the voltammetric results in LiF - NaF eutectic (14) suggests the following mechanism for the anodic oxidation of sulfide ions at 1023 K: $2\text{S}^{2-} \rightleftharpoons \text{S}_2^{2-} + 2e^-$. Since cryolite (Na_3AlF_6) was used as an electrolyte component in previous work (15, 16) on the electrolysis of Al_2S_3 , it is interesting to know how sulfide behaves electrochemically in this system. In the present work, the anodic reaction of sulfide was studied in cryolite at 1323

K using the technique of cyclic voltammetry. The experimental results obtained from the study are presented in this paper.

Experimental

The electrochemical cell for the voltammetric measurements consisted of three electrodes inserted into a pyrolytic boron nitride crucible (5.2 cm diam, 7.2 cm high, Union Carbide) containing molten cryolite (from NaF , ultrapure, Alfa Ventron, and AlF_3 , 99.9% pure, Pennwalt). The boron nitride crucible was dipped into alumina granules held in a stainless steel crucible. The steel crucible was placed inside a furnace tube. The top of the furnace tube was sealed to another flange consisting of inlet ports which provided access to the melt. The upper part of the furnace tube was cooled by water flowing through a soldered-on coil of copper tubing. The furnace tube was heated by a three-zone Mellen high temperature furnace (Model C-2-121) with Mellen temperature controller (Model 919).

A three-electrode system was used for all measurements. The working electrode was a graphite rod (0.63 cm diam, Union Carbide, grade ECV) insulated with hot-pressed boron nitride (Carborundum) so that only a defined surface area was exposed to the molten salt. Another graphite rod immersed in the melt served as the counterelectrode. A Pt wire immersed in the melt was used as a quasi-reference electrode.

The molten salt was prepared from accurately weighed and blended mixtures of cryolite and Al_2S_3 reagent (Cerac Pure) inside a helium atmosphere glove box (Vacuum Atmosphere). The mixture was then charged into the boron nitride crucible, brought out of the glove box, and the cell was quickly assembled under argon. Experiments were started by heating the cell assembly to the experiment temperature of 1323 K. The electrodes were then slowly lowered into the molten salt. An argon atmosphere was maintained above the cell in all experiments. The cell temperature was monitored with a Chromel/Alumel thermocouple. The tip of the thermocouple was placed adjacent to the wall of the boron nitride crucible.

*Electrochemical Society Active Member.

Standard cyclic voltammetric instrumentation was employed. A universal programmer (PAR Model 175) was used to provide an external control voltage for a potentiostat (PAR Model 173) which was connected to the cell. Voltammograms were recorded with an X-Y recorder (Hewlett-Packard Model 7044A).

Results and Discussion

To provide background information, voltammetry of pure cryolite was carried out. A typical voltammogram of the melt with a graphite working electrode at 1323 K is shown in Fig. 1. The voltammetric curves obtained with the graphite working electrode in this study resemble those reported previously in the literature for molten cryolite (17-20) and sodium fluoride (21). The steeply rising cathodic current observed at about -0.5V (all potentials given vs. Pt quasi-reference electrode) can be attributed to aluminum deposition (22). An anodic peak was observed at approximately $+2.5\text{V}$. This anodic peak current represents the critical current density. In general, when a graphite or carbon anode in a molten salt is subjected to a gradually increasing anode potential, the current will eventually reach a maximum, the so-called critical current density, and then decrease abruptly to a low value, which signals the beginning of the anode effect. (The anode effect can be described as a blockage effect which greatly inhibits the current transport between the anode and the melt due to dewetting of the anode by fluorocarbon compounds. Under potentiostatic conditions, it manifests itself by an abrupt decrease in cell current.) It has been suggested that the anodic maximum which leads to the onset of the anode effect corresponds to the electrochemical formation of fluorocarbon compounds, $(\text{CF}_x)_m$, with CF_4 being the predominant species (18-20).

The background current of the molten cryolite in the potential range $+0.6$ to -0.2V is shown in Fig. 2. Within this potential range, the background current is quite small. Voltammograms of the cryolite melt containing Al_2S_3 show two additional peaks associated with the behavior of sulfide ions: a peak representing the anodic oxidation of sulfide, and, on the reverse scan, one repre-

sented the cathodic reduction of its products. Typical voltammograms for sulfide ions are shown in Fig. 3. It can be seen from the figure that the peak potential for the sulfide oxidation shifts anodically with increasing potential sweep. Peak currents, i_p , at different sweep rates were measured and plotted against the square root of the sweep rate, $v^{1/2}$. Plots of i_p vs. $v^{1/2}$ are straight lines, as shown in Fig. 4, for two different Al_2S_3 concentrations. The separations between the anodic peak potential and the cathodic peak potential, $|E_p^a - E_p^c|$, at different sweep rates (uncorrected for ohmic drops) are presented in Table I. Potential separation values corrected for ohmic drops are also shown in Table I. In the present study, because the i_p values are large, it is necessary to correct the potential separations for the ohmic drops caused by uncompensated resistance R_u . This is to ensure that the effect of R_u on the peak separation is eliminated. (Since the ohmic drop at peak potential is approximately $i_p R_u$, each potential separation is corrected for $2i_p R_u$. For this cell, R_u was measured to be about 0.25Ω .) It can be seen from Table I that the separation increases as the sweep rate increases. The above properties of the voltammograms for the oxidation of sulfide ions are in agreement with the criteria for a quasi-reversible charge transfer mechanism (23). A quasi-reversible electrochemical reaction is one in which the current is controlled by both diffusion and charge transfer kinetics. For this type of reaction mechanism, if the sweep rate is slow enough, the reaction approaches reversible behavior (24). Thus, at slow sweep rates, the anodic-to-cathodic peak separation and the peak-to-half-peak separation (ΔE_p) of a quasi-reversible reaction are independent of the sweep rate and approach $2.22 RT/nF$ or $253/n\text{ mV}$ (at 1323 K) and $1.11 RT/nF$ or $126.5/n\text{ mV}$ (at 1323 K) (25), respectively, where R is the universal gas constant, T is the temperature, n is the number of electrons involved in the electrochemical reaction

Fig. 3. Voltammograms of the oxidation of sulfide ions in molten cryolite at different sweep rates. T : 1323 K. Electrode area: 0.32 cm^2 . Al_2S_3 concentration: $1.3 \times 10^{-5}\text{ mol/cm}^3$.

Fig. 4. Plots of i_p vs. $v^{1/2}$ for the anodic oxidation of sulfide ions in cryolite. T: 1323 K. Electrode area: 0.32 cm^2 . ▲: $1.3 \times 10^{-5} \text{ mol/cm}^3 \text{ Al}_2\text{S}_3$, ○: $3.1 \times 10^{-5} \text{ mol/cm}^3 \text{ Al}_2\text{S}_3$.

and F is the Faraday constant. It appears that at sweep rates of 10 and 20 mV/s, the voltammograms obtained for sulfide ions become reversible, and the experimental values for the potential separations (about 120-125 mV for $|E_p^a - E_p^c|$ and about 60-65 mV for ΔE_p) suggest two as the number of electrons involved in the anodic oxidation of sulfide ions.

As the reaction becomes reversible at sweep rates of 10 and 20 mV/s, the Randles-Sevcik equation applies

$$i_p = 0.446 \frac{n^{3/2} F^{3/2}}{R^{1/2} T^{1/2}} A_s D^{1/2} C^0 v^{1/2} \quad [1]$$

where A_s is the electrode area, D is the diffusion coefficient, and C^0 is the concentration of the electroactive species. The diffusion coefficient of sulfide ions can be estimated from i_p at 10 and 20 mV/s using Eq. [1]. The concentration of the diffusing species is the apparent concentration of sulfide ions (i.e., three times the Al_2S_3 concentration). The diffusion coefficients of sulfide ions in molten cryolite at 1323 K are calculated to be $3.95 \times 10^{-5} \text{ cm}^2/\text{s}$ at $1.3 \times 10^{-5} \text{ mol/cm}^3 \text{ Al}_2\text{S}_3$, and $3.92 \times 10^{-5} \text{ cm}^2/\text{s}$ at $3.1 \times 10^{-5} \text{ mol/cm}^3 \text{ Al}_2\text{S}_3$. No data have been reported in the literature on the diffusion coefficient of sulfide ions in cryolite. However, the above calculated values are not unreasonable considering previously reported values for diffusion coefficients of solute species in molten cryolite and other fluorides (26). For example, the diffusion coefficient of Al_2O_3 (2 weight percent) in cryolite is $2.24 \times 10^{-5} \text{ cm}^2/\text{s}$ at 1320 K. In cryolite-NaF melt, the diffusion coefficient of Fe^{3+} is $1.0 \times 10^{-5} \text{ cm}^2/\text{s}$ at 1273 K. The present authors obtained an average value of $1.47 \times 10^{-5} \text{ cm}^2/\text{s}$ for the apparent diffusion coefficient of sulfide in LiF-NaF eutectic at 1023 K (14).

Thus, the voltammetric results obtained suggest a quasi-reversible mechanism for the oxidation of sulfide ions in cryolite with two as the number of electrons involved in the reaction, i.e.

where k_s is the standard heterogeneous rate constant and β is the transfer coefficient.

Table I. Potential separation data for the oxidation of sulfide ions in molten cryolite at 1323 K

v (mV/s)	Al_2S_3 concentration $1.3 \times 10^{-5} \text{ mol/cm}^3$		Al_2S_3 concentration $3.1 \times 10^{-5} \text{ mol/cm}^3$	
	$ E_p^a - E_p^c $ (mV)		$ E_p^a - E_p^c $ (mV)	
	Uncorrected*	Corrected†	Uncorrected*	Corrected†
10	125	125	130	125
20	120	120	130	125
50	190	185	190	180
100	290	285	300	290
200	370	360	360	345
500	510	500	515	490

* Uncorrected for ohmic drops.

† Corrected for ohmic drops. Note: Because the error for potential separation is ± 5 , ohmic drop corrections have been rounded off to nearest multiple of 5; correction of 1 would be considered 0, a correction of 3 would be considered 5, etc.

Table II. Standard rate constants for the oxidation of sulfide ions in cryolite calculated from potential separation data

Al_2S_3 concentration	Sweep rate	$ E_p^a - E_p^c $ (1323 K)	$n E_p^a - E_p^c $ (298 K)	ψ	k_s (cm/s)
$1.3 \times 10^{-5} \text{ mol/cm}^3$	100 mV/s	285	128.4	0.31	0.0045
	200 mV/s	360	162.2	0.19	0.0040

	200 mV/s	345	155.4	0.20	0.0042

The shape of the voltammogram for a quasi-reversible oxidation reaction depends on β and k_s . The ratio of anodic to cathodic peak currents is affected by β . For larger values of β , the oxidation peak is much sharper and the peak current is larger than that of the corresponding cathodic peak. The opposite is true for small values of β . For $\beta = 0.5$, the anodic-to-cathodic peak current ratio is equal to 1. The ratios of anodic-to-cathodic peak currents obtained at different sweep rates and two Al_2S_3 concentrations in this study are approximately unity, suggesting that β is 0.5. For $\beta = 0.5$, the standard heterogeneous rate constant k_s can be derived from the data (at 298 K) given by Nicholson (24), showing variation of the peak separation $|E_p^a - E_p^c|$ with the kinetic parameter ψ , where ψ is defined as

$$\psi = \frac{k_s}{\left(\frac{nFv}{RT} D^{1/2}\right)^{1/2}} \quad [3]$$

The peak potential separations for the sulfide reaction presented in Table I were converted to equivalent values at 298 K (peak potential separations are proportional to the temperature), and the corresponding ψ values were determined. It was found that only the values of peak separation at 100 and 200 mV/s could be used to estimate k_s . The value of 500 mV/s fell outside the range of the data given by Nicholson (24), and the value at 50 mV/s was in the region where ψ is very sensitive to a small change in peak separation in such a way that k_s could not be determined with any confidence. From the peak separation values at 100 and 200 mV/s and the data given by Nicholson, k_s was calculated (Table II), and an average value of about $4.2 \times 10^{-3} \text{ cm/s}$ was obtained for the standard heter-

ogeneous rate constant for the oxidation of sulfide ions in cryolite at 1323 K. This derived value for k_s for the sulfide reaction is compared in Table III with the published data on standard rate constants for some other electrochemical reactions in molten salts.

It should be noted that the use of Eq. [2] to represent the mechanism of the oxidation of sulfide ions at graphite electrodes in molten cryolite is a simplification. At the experimental temperature of the present work (1323 K), besides the formation of sulfur gas, the formation of CS_2 (32) is possible at the graphite electrode. It was not possible to determine the reaction steps for S_2 and CS_2 formation in this electrochemical study. A probable reaction scheme, however, might be

followed by

and/or

Combined Forced and Natural Convection at Vertical Electrodes

Assisting and Opposing Flows

Jacob Jorné*

Department of Chemical Engineering, University of Rochester, Rochester, New York 14627

ABSTRACT

Many electrochemical processes involve combined forced and natural (free) convection. The superimposition of velocity gradients and the Lighthill transformation are used to calculate mass-transfer coefficients for large Schmidt numbers near vertical electrodes where forced and natural convection exist. A distinction should be made between assisting and opposing flows. For assisting flow near a vertical electrode, the third-order correlation for the Sherwood number is a good approximation

$$Sh^3 = Sh_F^3 + Sh_N^3$$

where subscripts F and N represent forced and natural convection if each acts alone. For opposing flow, points of zero shear stress are expected along the electrode length, resulting in flow reversals and boundary-layer separation. An explicit correlation to the limiting forced and natural convection appears more complicated. The combined forced and natural convection near an electrode embedded in a fully developed laminar flow channel is analyzed as well. Again, a distinction should be made between assisting and opposing flows.

Electrochemical processes are usually mass-transfer limited. In order to overcome mass-transfer overpotential, forced convection is introduced via electrolyte circulation, stirring, or gas introduction. However, natural convection (or free convection) is almost an inherent phenomenon in electrochemical systems and in many cases is sufficient to adequately supply and remove reactants and products to and from the electrode-solution interface. Natural convection is the hydrodynamic flow, which results from density variations. In heat-transfer systems, these density variations are the result of temperature differences. In mass-transfer cases, and especially in electrochemical systems, the density variations are due to concentration variations in the electrolyte solution adjacent to the electrode.

In many electrochemical systems, both forced and natural convections exist. The relative magnitudes of the individual convections determine which one dominates. McAdams (1) recommended that the higher transfer coefficient be used. Similarly, Newman (2) recommended that the rule to follow is to calculate the mass-transfer coefficient separately for free convection and again for forced convection and to assume that the higher value applies. Acrivos (3) analyzed the combined effect of natural and forced convection and found that the transition region between predominance of natural convection and predominance of forced convection is usually narrow. However, in many electrochemical reactors, the flow of the electrolyte is relatively low and is determined by the rate of supply and removal of reactants and products, *e.g.*, the chlor-alkali process. In such cases, the magnitudes of the natural and forced convection are quite similar, and a prediction of their combined effect is desirable. Furthermore, in some situations, a balance between opposing natural and forced convection is used in order to minimize undesirable corrosion reaction, such as in the zinc-chlorine battery (4).

In the present communication, the combined effect of natural and forced convection is treated by using the Lighthill (5) transformation which has been extensively used by Newman (2). This transformation is used for two-dimensional convective diffusion in laminar systems where the diffusion boundary layer is much thinner than the hydrodynamic boundary layer due to the large Schmidt number. Based on this solution, an attempt is made to relate, when possible, the combined mass-transfer coefficient (or Sherwood number) to the individual mass-transfer coefficients. The individual mass-transfer coefficients correspond to the two limiting cases where either forced or natural convection exists by itself. The analysis is demonstrated for assisting flow cases

*Electrochemical Society Active Member.

such as vertical wall (electrode) in a free stream, and electrode embedded in a wall of a flow channel in which the flow is fully developed and laminar.

An attempt is made to also include cases of opposed flows where the forced convection is opposed by the natural convection. The opposing flow cases are more complicated, as noted by Churchill (6), Weber (7), and Acrivos (3), because of the fact that at some point along the wall the shear stress (or the velocity gradient) at the wall vanishes, thus causing separation of the boundary layer and flow reversal. In such a case, the analysis is probably valid up to the point of zero shear stress.

Combined Natural and Forced Convection at Vertical Surfaces

The problem of combined natural and forced convection in heat- or mass-transfer has received relatively little attention, mainly because the transition region between the two mechanisms is relatively narrow. McAdams (1) simply recommended using the higher transfer coefficient. Newman (2) advises the same approach in combined convection at electrode surfaces, based on Acrivos' (3) analysis which shows that the transition region is narrow.

Most of the heat transfer correlations that have been proposed are based on the power sum of the individual Nusselt numbers (6)

$$Nu^n = Nu_F^n + Nu_N^n \quad [1]$$

Where the subscripts F and N indicate forced and natural convection, respectively. Churchill (6) chooses $n = 3$ for assisting flows using an empirical correlation procedure. Acrivos (3) proposes $n = 4$ based on his approximate analysis for both assisting and opposing flows. Ruckenstein (8-10) and Ruckenstein and Rajagopalan (11) use a simple algebraic method for obtaining heat- and mass-transfer coefficients under mixed convection. They also calculate the combined coefficients using a similarity solution for the case of assisting and opposing flows. The value $n = 3$ is predicted both from the algebraic method and the similarity transformation. Ruckenstein and Rajagopalan (11) use the algebraic method to correlate mixed convection at vertical plate, entrance region, horizontal cylinder, and magneto-convective mass transfer.

Ruckenstein and Rajagopalan (11) analysis for the opposing flows case is based on the similarity transformation and is limited up to the point of zero shear stress at the wall where flow reversal is expected. However, it appears that their analysis for opposing flows is somewhat oversimplified. It appears that the extension of the correlation to opposing flows is unsuccessful, as pointed out by Weber (7) and Churchill (6).

Attempts at solving the complete transport equations for mixed convection were done by expansions in terms of the ratio of the Grashof number to the square of the Reynolds number (Gr_r/Re_r^2) [Szewczyk, (12) and Eshghy 13]. Merkin (14) obtained a complete solution limited to a Prandtl (or Schmidt) number of 1. Lloyd and Sparrow (15) and Wilks (16) obtained local similarity solutions. The results of Lloyd and Sparrow (15) show in $n = 4$ for $Pr = 10$ and 100. Furthermore, their results break down for $(Gr_r/Re_r^2) > 2$ (11).

Mass-Transfer under Combined Forced and Natural Convection

Electrolytic solutions possess large Schmidt number; therefore, the mass-transfer boundary layer is much thinner than the hydrodynamic boundary layer. Consequently, it is permissible to approximate the velocity components by their first terms in Taylor's expansion in the distance y from the wall

$$u = y \beta(x) \quad v = -\frac{1}{2} y^2 \beta'(x) \quad [2]$$

where $\beta(x)$ is the velocity derivative, $\beta(x) = (\partial u / \partial y)_{y=0}$ at the wall.

The governing laminar boundary layer equations along a vertical plate are

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \nu \frac{\partial^2 u}{\partial y^2} + \alpha g(C - C_\infty) \quad [3]$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad [4]$$

$$u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} = D \frac{\partial^2 C}{\partial y^2} \quad [5]$$

The following boundary conditions are assumed

$$\begin{aligned} u = 0, v = 0, C = C_w \text{ at } y = 0 \\ u = u_\infty, C = C_\infty \text{ at } y = \infty \\ u = u_\infty, C = C_\infty \text{ at } x = 0 \end{aligned}$$

These boundary conditions correspond to a potentiostatic condition where the wall concentration is fixed. Under limiting current condition, the wall concentration vanishes, $C_w = 0$.

Since the diffusion layer is very narrow, it can be further assumed that the actual velocities under combined convection are approximately the sum of the velocities of the forced and natural convection if they exist independently (9)

$$(u_F + u_N) \frac{\partial C}{\partial x} + (v_F + v_N) \frac{\partial C}{\partial y} = D \frac{\partial^2 C}{\partial y^2} \quad [6]$$

Again, the subscripts F and N represent forced and natural convection, respectively, if they exist alone. The velocities are well known for various geometries such as vertical wall in a free stream, and fully developed laminar flow in a vertical channel.

Based on the known superimposed velocities, the local mass-transfer coefficients can be calculated using the Lighthill transformation (2)

$$k_x = \frac{D \sqrt{\beta(x)}}{\Gamma(4/3) (9D)^{1/3} \left[\int_0^x \sqrt{\beta(x)} dx \right]^{1/3}} \quad [7]$$

Where $\Gamma(4/3) = 0.89298$ and

$$\beta(x) = \left(\frac{\partial u_F}{\partial y} + \frac{\partial u_N}{\partial y} \right)_{y=0} = \beta(x)_F + \beta(x)_N \quad [8]$$

x is the distance from the upstream leading edge. The corresponding local Sherwood number is given by

$$Sh_x = \frac{k_x x}{D} = \frac{\sqrt{\beta(x)} x}{\Gamma(4/3) (9D)^{1/3} \left(\int_0^x \sqrt{\beta(x)} dx \right)^{1/3}} \quad [9]$$

The average mass-transfer coefficient is obtained by integration over the length L

$$k_{av} = \frac{1}{6L\Gamma(4/3)} \left[9D \int_0^L \sqrt{\beta(x)} dx \right]^{2/3} \quad [10]$$

and the corresponding average Sherwood number is

$$Sh_{av} = \frac{1}{6L\Gamma(4/3)} \left[9D \int_0^L \sqrt{\beta(x)} dx \right]^{2/3} \quad [11]$$

In the following sections, this method will be applied to several important geometries, and the resultant Sherwood numbers will be interpreted in terms of the individual Sherwood numbers for forced and natural convections. The assisting flows and the opposing flows will be discussed separately.

Assisting Forced and Natural Convection near a Vertical Wall

This situation occurs when an electrode is placed in either an upward free stream and the natural convection is directed upward (e.g., electrodeposition), or in a downward free stream when the natural convection is directed downward (e.g., electrodisolution). The situation is schematically illustrated in Fig. 1.

The superimposed velocity derivative at the wall is given by

$$\beta(x) = \beta(x)_F + \beta(x)_N \quad [12]$$

where

$$\beta(x)_F = \frac{A}{x^{1/2}} \quad \beta(x)_N = Bx^{1/4}$$

and

$$A = \frac{0.332 U_\infty^{3/2}}{\nu^{1/2}} \quad B = 1.92\nu Sc^{-1/4} \left(\frac{g\alpha\Delta c}{4\nu^2} \right)^{3/4}$$

The integration in Eq. [7] can be performed, and the resultant local mass-transfer coefficient is given by

$$k_x = \frac{(B/D)^{1/3} D}{2\Gamma(4/3)} \frac{x^{-1/4}}{\left[1 - \left(x^{-1/2} + \frac{B}{A} x^{1/4} \right)^{-3/2} x^{-3/4} \right]^{1/3}} \quad [13]$$

The local Sherwood number is

$$Sh_x = \frac{(B/D)^{1/3}}{2\Gamma(4/3)} \frac{x^{3/4}}{\left[1 - \left(x^{-1/2} + \frac{B}{A} x^{1/4} \right)^{-3/2} x^{-3/4} \right]^{1/3}} \quad [14]$$

Forced convection alone gives, upon similar integration

Fig. 1. Assisting forced and natural convection near a vertical wall (electrode). (a): Schematic flow pattern. (b): Velocity gradients at the wall.

$$k_F = \frac{D}{\Gamma(4/3) \left(\frac{12D}{A}\right)^{1/3} x^{1/2}} \quad [15]$$

$$Sh_F = \frac{x^{1/2}}{\Gamma(4/3) \left(\frac{12D}{A}\right)^{1/3}} \quad [16]$$

Natural convection alone gives, similarly

$$k_N = \frac{D}{2\Gamma(4/3) \left(\frac{D}{B}\right)^{1/3} x^{1/4}} \quad [17]$$

$$Sh_N = \frac{x^{3/4}}{2\Gamma(4/3) \left(\frac{D}{B}\right)^{1/3}} \quad [18]$$

By defining the ratio G as the cubic ratio between the natural and forced Sherwood numbers (11).

$$G = \left(\frac{Sh_N}{Sh_F}\right)^3 = \frac{3}{2} \frac{B}{A} x^{3/4} \quad [19]$$

and by comparing Eq. [14], [16], and [18], one obtains

$$\left(\frac{Sh_x}{Sh_N}\right)^3 = \frac{\left(1 + \frac{2}{3}G\right)^{3/2}}{\left(1 + \frac{2}{3}G\right)^{3/2} - 1} \quad [20]$$

For the case when

$$\left(1 + \frac{2}{3}G\right)^{3/2} \approx 1 + G \quad [21]$$

one obtains

$$Sh_x^3 = Sh_F^3 + Sh_N^3 \quad [22]$$

This result is identical to Ruckenstein and Rajagopalan's results (11) and in agreement with Churchill's correlation (6), in which the correlating power is $n = 3$. Therefore, for the region when the forced and natural convections are of similar magnitude along a vertical electrode, one can find the combined mass transfer by adding the cubic power of the individual Sherwood numbers. Similarly, the average Sherwood number, upon integration along the height of the electrode, is given by

$$Sh_{av}^3 = Sh_{Fav}^3 + Sh_{Nav}^3 \quad [23]$$

Therefore, the average Sherwood number, or the average mass-transfer coefficient, can be estimated from the corresponding limiting values where either forced or natural convection exist alone.

Opposing Forced and Natural Convection near a Vertical Wall

Consider the situation where the forced convection is opposing the natural convection. If the wall is of length L , the natural boundary layer is developing at the bottom $x = L$, and the forced boundary layer starts at $x = 0$ (see Fig. 2).

Two distinct situations should be considered: (i) when the velocity gradient (shear stress) does not change sign along the electrode height. This is the case when $\beta(x)_F > \beta(x)_N$ and the velocity direction at the wall is the same as that of the forced convection (see Fig. 2a and 2b). (ii) when the velocity gradient at the wall reaches 0 twice along the electrode height (see Fig. 2c and 2d). In this case, flow reversals can occur twice along the electrode surface, and the assumption of superimposition of velocities is probably unrealistic there.

Again, the derivative of the velocity at the wall is given by

$$\beta(x) = Ax^{-1/2} - B(L-x)^{1/4} \quad [24]$$

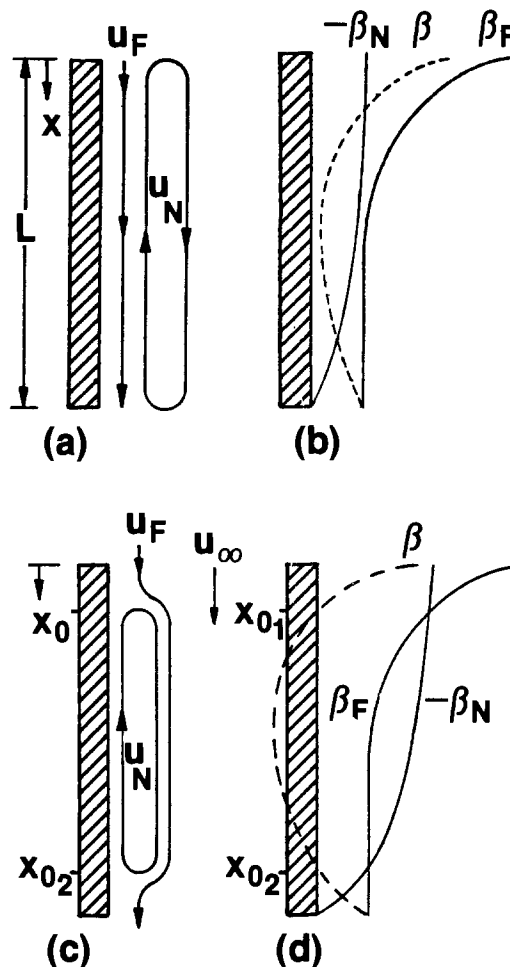

Fig. 2. Opposing forced and natural convection near a vertical wall (electrode). (a): Schematic flow pattern for no point of zero shear stress, $\beta_F > \beta_N$. (b): Velocity gradients at the wall for no point of zero shear stress. (c): Schematic flow pattern for two points of zero shear stress. (d): Velocity gradients at the wall for two points of zero shear stress.

where

$$A = \frac{0.332}{4} \frac{U_x^{3/2}}{\nu^{1/2}} \quad B = 1.92\nu \quad Sc^{-1/4} \left(\frac{g\alpha\Delta C}{4\nu^2}\right)^{3/4}$$

The local mass-transfer coefficient is given generally by

$$k_x = \frac{[Ax^{-1/2} - B(L-x)^{1/4}]^{1/2} D}{\Gamma(4/3)(9D)^{1/3} \left(\int_0^x [Ax^{-1/2} - B(L-x)^{1/4}]^{1/2} dx^{1/3}\right)} \quad [25]$$

However, this expression must be applied carefully for the opposing flows since the velocity derivative changes sign twice along the height of the electrode. The points of zero shear stress can be found by setting $\beta(x) = 0$

$$\beta(x) = Ax_0^{-1/2} - B(L-x_0)^{1/4} = 0 \quad [26]$$

or

$$x_0^2(L-x_0) = (A/B)^4 \quad [27]$$

The two real roots x_{01} and x_{02} represent the points of zero shear stress where flow reversal and separation of the boundary layer occur (see Fig. 2c and 2d). Therefore, the integration in Eq. [25] can be performed only for the upper region $0 < x < x_{01}$. The flow over the surface can be represented by Fig. 2c. For the regions $x_{01} < x < x_{02}$ and $x_{02} < x < L$, it appears unlikely to predict the local mass-transfer coefficients because of the flow reversals and internal circulation.

For the upper edge, the velocity derivative at the wall is given by

$$\beta(x) = Ax^{-1/2} - BL^{1/4} \left(1 - \frac{x}{L}\right)^{1/4} \quad [28]$$

For the case where $x \ll L$

$$\beta(x) = Ax^{-1/2} - BL^{1/4} \quad [29]$$

The integration in Eq. [25] gives

$$\begin{aligned} \int_0^x \sqrt{\beta(x)} dx &= \int_0^x (Ax^{-1/2} - BL^{1/4})^{1/2} dx \\ &= \left(x^{1/2} - \frac{A}{2BL^{1/4}}\right) (Ax^{1/2} - BL^{1/4}x)^{1/2} \\ &+ \frac{A^2}{4(BL^{1/4})^{3/2}} \left[\sinh^{-1} \left(\frac{2BL^{1/4}}{A} x^{1/2} + 1 \right) - \sinh^{-1} 1 \right] \quad [30] \end{aligned}$$

The mass-transfer coefficient is, therefore

$$\begin{aligned} k_x &= \frac{D(Ax^{-1/2} - BL^{1/4})^{1/2}}{\Gamma(4/3)(9D)^{1/3}} \\ &\left\{ \left(x^{1/2} - \frac{A}{2BL^{1/4}}\right) (Ax^{1/2} - BL^{1/4}x)^{1/2} \right. \\ &\left. + \frac{A^2}{4(BL^{1/4})^{3/2}} \left[\sinh^{-1} \left(\frac{2BL^{1/4}}{A} x^{1/2} + 1 \right) - \sinh^{-1} 1 \right] \right\}^{-1/3} \quad [31] \end{aligned}$$

The corresponding Sherwood number is given by

$$\text{Sh}_x = \frac{k_x x}{D} \quad [32]$$

This expression is valid only when $0 < x < x_{01}$, and when the electrode is long enough so the derivative of the velocity of the natural convection becomes almost constant. The mass-transfer coefficient in Eq. [31], or the corresponding Sherwood number (Eq. [32]), cannot be related easily to the limiting cases of individual forced or natural convection.

The individual mass-transfer coefficients (or Sherwood numbers) are calculated similarly to be for forced convection

$$k_F = \left(\frac{A}{12D}\right)^{1/3} \frac{D}{\Gamma(4/3)x^{1/2}} \quad [33]$$

$$\text{Sh}_F = \left(\frac{A}{12D}\right)^{1/3} \frac{x^{1/2}}{\Gamma(4/3)} \quad [34]$$

and for natural convection (in which the origin is at $x = L$)

$$k_N = \frac{D(B/D)^{1/3}}{2\Gamma(4/3)(L-x)^{1/4}} \quad [35]$$

$$\text{Sh}_N = \frac{(B/D)^{1/3}(L-x)^{3/4}}{2\Gamma(4/3)} \quad [36]$$

It appears that a simple relation between the local mass-transfer coefficient (Eq. [31] and [32]) and the individual mass-transfer coefficients (Eq. [33]-[36]) is not obvious as in the case of assisting flows.

The mass-transfer coefficient (Eq. [31]) can be related to the individual mass-transfer coefficients (Eq. [33] and [35]) by defining the ratio G_k , which represents the relative importance of the two individual mass-transfer coefficients

$$G_k = \left(\frac{k_N}{k_F}\right)^3 \approx \frac{3}{2} \frac{B}{A} \frac{x^{3/2}}{L^{3/4}} \quad [37]$$

The local mass-transfer coefficient is then related to the ratio $G_k L/x$ by

$$\left(\frac{k_x}{k_N}\right)^3 = \frac{4}{3G_k} \left(1 - \frac{2}{3} G_k \frac{L}{x}\right)^{3/2}$$

$$\begin{aligned} &\left\{ \left(1 - \frac{3}{4G_k} \frac{x}{L}\right) \left(1 - \frac{2}{3} G_k \frac{L}{x}\right)^{1/2} \right. \\ &\left. + \frac{1}{4} \left(\frac{3}{2G_k} \frac{x}{L}\right)^{3/2} \left[\sinh^{-1} \left(\frac{4G_k}{3} \frac{L}{x} + 1\right) - \sinh^{-1} 1 \right] \right\}^{-1} \quad [38] \end{aligned}$$

For the upper edge of the plate where $x \ll L$, the \sinh^{-1} term can be neglected, and Eq. [38] can be simplified to

$$\left(\frac{k_x}{k_N}\right)^3 \approx \frac{4}{3G_k} \frac{1 - \frac{2G_k}{3} \frac{L}{x}}{1 - \frac{4G_k}{3} \frac{L}{x}} \quad [39]$$

Further approximation when

$$\left(\frac{3}{4G_k} \frac{x}{L}\right) \ll 1$$

gives

$$k_x^3 \approx \frac{4}{3} k_F^3 - \frac{8}{9} k_N^3 \frac{L}{x} \quad [40]$$

It must be kept in mind that all the above correlations are for heights where the natural convection approaches a constant value.

The Sherwood number (Eq. [32]) can be related similarly to the individual Sherwood numbers (Eq. [34] and [36]) by defining the ratio G_{Sh}

$$G_{\text{Sh}} = \left(\frac{\text{Sh}_N}{\text{Sh}_F}\right)^3 = \frac{3}{2} \frac{B}{A} \frac{L^{9/4}}{x^{3/2}} \quad [41]$$

The local Sherwood number is then related to the ratio $G_{\text{Sh}} x^2/L^2$ by

$$\begin{aligned} \left(\frac{\text{Sh}_x}{\text{Sh}_N}\right)^3 &= \frac{4}{3G_{\text{Sh}}} \left(1 - \frac{2}{3} G_{\text{Sh}} \frac{x^2}{L^2}\right)^{3/2} \\ &\left\{ \left(1 - \frac{3}{4G_{\text{Sh}}} \frac{L^2}{x^2}\right) \left(1 - \frac{2}{3} G_{\text{Sh}} \frac{x^2}{L^2}\right)^{1/2} \right. \\ &\left. + \frac{1}{4} \left(\frac{3}{2G_{\text{Sh}}} \frac{L^2}{x^2}\right)^{3/2} \left[\sinh^{-1} \left(\frac{4}{3} G_{\text{Sh}} \frac{x^2}{L^2} + 1\right) - \sinh^{-1} 1 \right] \right\}^{-1} \quad [42] \end{aligned}$$

Again, for the upper section where $x \ll L$ and $3/4G_{\text{Sh}} L^2/x^2 \ll 1$, the correlation can be approximated by

$$\left(\frac{\text{Sh}_x}{\text{Sh}_N}\right)^3 \approx \frac{4}{3G_{\text{Sh}}} \frac{\left(1 - \frac{2}{3} G_{\text{Sh}} \frac{x^2}{L^2}\right)}{\left(1 - \frac{3}{4G_{\text{Sh}}} \frac{L^2}{x^2}\right)} \quad [43]$$

Further approximation yields

$$\text{Sh}_x^3 = \frac{4}{3} \text{Sh}_F^3 - \frac{2}{3} \text{Sh}_N^3 \frac{x^2}{L^2} \quad [44]$$

The above correlations are not as simple as in the case of assisting flow, partially because the natural convection starts at the downstream edge, $x = L$, and the characteristic length in Sh_N is L , while the characteristic length in Sh_x and Sh_F is x .

For both the lower edge of the electrode and the intermediate region, it is not appropriate to use the Lighthill transformation because of flow reversal and boundary layer separation.

The result in Eq. [31] is in disagreement with that of Ruckenstein and Rajagopalan (11) for opposing flows near a vertical wall

$$\left(\frac{Sh_x}{Sh_N}\right)^3 = \frac{(1 - 2/3 G)^{3/2}}{1 - (1 - 2/3 G)^{3/2}} \quad [45]$$

which, upon the simplification $(1 - 2/3 G)^{3/2} \approx 1 - G$, gives

$$Sh_x^3 \approx Sh_F^3 - Sh_N^3 \quad [46]$$

Equations [45] and [46] differ from the equations for assisting flow, Eq. [20] and [22], only by a minus sign. It is not clear how Ruckenstein and Rajagopalan (11) obtained the above results.

Furthermore, the limited experimental data available for opposing forced and natural convections do not agree with the simple relationship given by Ruckenstein and Rajagopalan (11), Eq. [45] and [46].

Vertical Flow Channel

Consider a vertical flow channel in which the flow is fully developed and laminar. An electrode of length L is embedded in the wall starting at point $x = 0$. Natural convection occurs at the electrode due to concentration depletion and density variation. For the case of assisting flows, both forced and natural convection are directed upward. For opposing flows the forced convection is downward while the natural convection is upward.

First consider the assisting flows case. See Fig. 3 for the schematic flow pattern and the velocity gradients at the wall.

The forced velocity is given by

$$u_F = 6\bar{u}_{av} \left(\frac{y}{d} - \frac{y^2}{d^2}\right) \quad v_F = 0 \quad [47]$$

where d is the gap of the flow channel. The velocity can be approximated near the wall to be

$$u_F \approx \left(\frac{6\bar{u}_{av}}{d}\right) y = Ay \quad v_F = 0 \quad [48]$$

The natural convection is given as before by

$$u_N = Bx^{1/4}y \quad [49]$$

and the velocity derivative is

$$\beta(x) = A + Bx^{1/4} \quad [50]$$

Integration gives the mass-transfer coefficient for the assisting flows

$$k_x = \frac{B^4 D z}{8\Gamma(4/3)(9D)^{1/3} \left(\frac{z^9}{9} - \frac{3A}{7} z^7 + \frac{3}{5} A^2 z^5 - \frac{A^3}{3} z^3 + \frac{16}{315} A^{9/2}\right)^{1/3}} \quad [51]$$

where

$$z = (A + Bx^{1/4})^{1/2} \quad [52]$$

The corresponding Sherwood number is

$$Sh_x = \frac{B^4 z x}{8\Gamma(4/3)(9D)^{1/3} \left(\frac{z^9}{9} - \frac{3A}{7} z^7 + \frac{3}{5} A^2 z^5 - \frac{A^3}{3} z^3 + \frac{16}{315} A^{9/2}\right)^{1/3}} \quad [53]$$

For the case of opposing flows, a distinction should be made between two cases: (i) when the velocity derivative at the wall $\beta(x)$ does not reach zero within the electrode length L , and (ii) when the point of zero shear stress occurs on the electrode and flow reversal is expected.

Fig. 3. Assisting forced and natural convection near an electrode embedded in a vertical flow channel. (a): Schematic flow pattern. (b): Velocity gradients at the wall.

The two cases are illustrated schematically in Fig. 4, where both the flow patterns and the corresponding velocity gradients are shown. For case (i), where no zero shear stress occurs at the electrode, the mass-transfer coefficient can be calculated in a similar way as for the case of assisting flows, except the integration starts at the top $x = L$ where the fresh solution approaches the electrode

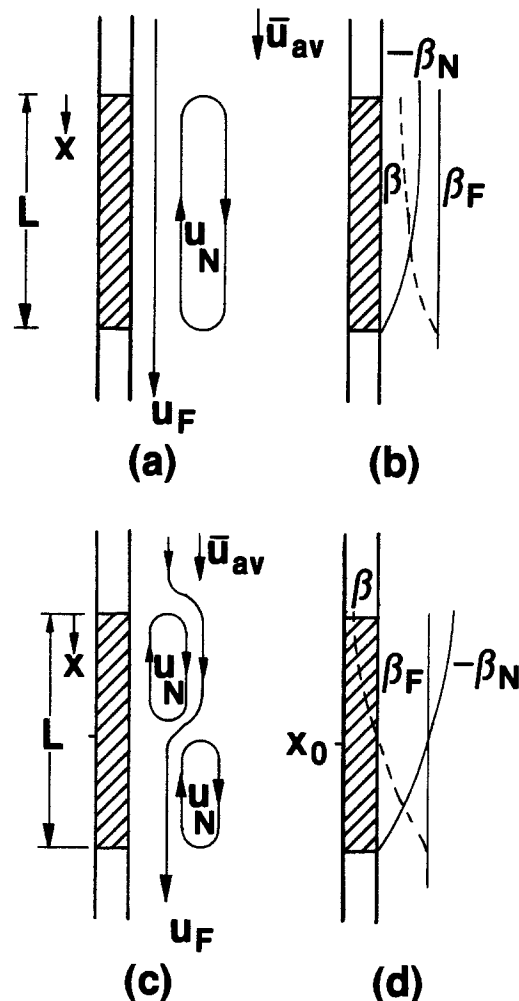

Fig. 4. Opposing forced and natural convection near an electrode embedded in a vertical flow channel. (a): Schematic flow pattern in the case of no zero shear stress at the electrode $\beta_F > \beta_N$. (b): Velocity gradients at the wall in the case of no zero shear stress at the wall. (c): Schematic flow pattern in the case of one point of zero shear stress at the wall. (d): Velocity gradients at the wall for one point of zero shear stress at the wall.

$$k_x = \frac{B^4 D [z(x) - z(L)]}{8\Gamma(4/3)(9D)^{1/3}} \left\{ \frac{z(x)^9 - z(L)^9}{9} - \frac{3A}{7} [z(x)^7 - z(L)^7] + \frac{3A^2}{5} [z(x)^5 - z(L)^5] - \frac{A^3}{3} [z(x)^3 - z(L)^3] \right\}^{-1/3} \quad [54]$$

where

$$z(x) = (Bx^{1/4} - A)^{1/2}$$

$$z(L) = (BL^{1/4} - A)^{1/2}$$

For case (ii), where the point of zero shear stress occurs within the electrode length, $0 < x_0 < L$, the situation is quite complicated, as shown in Fig. 4c and 4d. Flow reversal occurs which results in two circulation patterns. It appears that the present method is too oversimplified for such a case. Nevertheless, if one calculates the mass-transfer coefficients, two regions should be distinguished: the top region, $x_0 < x < L$, where natural convection dominates, and the bottom region, $0 < x < x_0$, where forced convection dominates.

Summary

It has been shown, theoretically, that the local and average mass-transfer coefficients along a vertical electrode where both forced and natural convection exist can be calculated using the superimposition of velocities and the Lighthill transformation. The case of vertical wall in a vertical free flow and the case of electrode embedded in the wall of a vertical flow channel have been treated. A distinction should be made between assisting and opposing flows. In the case of assisting flow, the integration in the Lighthill transformation is straightforward. However, for the cases of opposing flows, points of zero shear stress are expected accompanied by flow reversals. For such complicated cases, the local mass-transfer coefficients can be predicted only for the upstream regions, before flow reversal occurs.

Semiconductor Electrodes

LVII. Differential Photocurrent and Second Harmonic Techniques for *in situ* Monitoring of Surface States on n-MoSe₂ in Aqueous Solutions

Bob L. Wheeler, G. Nagasubramanian, and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Second harmonic ac impedance and differential photocurrent techniques are employed to monitor, *in situ*, the surface states on n-MoSe₂ electrodes in aqueous solutions containing the Fe(CN)₆^{3-/4-} couple. These two techniques are qualitatively more sensitive to the presence of surface states on single-crystal n-MoSe₂ than first harmonic ac techniques. Surface states on this semiconductor electrode were passivated by a thin layer of RuO_x. This film also increased the PEC efficiency of both single-crystal and polycrystalline n-MoSe₂.

Surface states, either intrinsic or extrinsic, are known to affect the performance of photoelectrochemical (PEC) cells and behavior of semiconductor electrodes by promoting Fermi level pinning, acting as recombination centers, and abetting dark current flow (1-3). Several techniques for the study of surface states at electrode surfaces contacting electrolyte solutions are available; these include (i) current-potential methods (3), (ii) photocapacitance spectroscopy (4), (iii) electroluminescence spectroscopy (5-7), (iv) photoluminescence spectroscopy (7), (v) measurements of the subbandgap photoresponse (8-10), (vi) interfacial capacitance (11), and (vii) surface photovoltage (12). Recently, we reported that the ac impedance technique can provide information about both the energy distribution and density of surface states (13, 14). This method could detect the presence of surface states even when their density was too small to cause Fermi level pinning on n-MoTe₂. We report here ac impedance studies of n-MoSe₂ and demonstrate the use of this method as a means of *in situ* monitoring of the semiconductor surface and the effects of surface treatments. In addition, two techniques are described which are qualitatively even more sensitive to the presence of surface states: the second harmonic ac impedance and the differential photocurrent techniques. Deposition of a thin layer of RuO_x on the surface of n-MoSe₂ was shown by all three techniques to passivate the surface states present. Concurrently, the photocurrent-voltage behavior showed a dramatic improvement. This provides strong evidence that all three techniques monitor the semiconductor surface, *in situ*, and that the surface states were responsible for the poor photocurrent-voltage behavior with the untreated surface. The improvement of the single-crystal behavior encouraged us to attempt to improve polycrystalline MoSe₂ films by the same method.

Experimental

Electrodes.—Single crystals of n-MoSe₂¹ were used. The van der Waals surface (\perp C axis) was the face exposed to the solution. Ohmic contacts were made to the back surfaces with Ga/In eutectic. A copper wire lead for electrical contact was attached to the ohmic contacts with silver conductive paint (Allied Product Corporation, New Haven, Connecticut) and then covered with 5 min epoxy cement (Devcon Corporation, Danvers, Massachusetts). A fresh surface was exposed by peeling off the top van der Waals layers with adhesive tape until the surface appeared free of edges or steps upon examination with a microscope. Assemblies were then mounted in 6 mm diam glass tubing and held in place by covering all except the front surface with silicone rubber sealant (Dow Corning Corporation, Midland, Michigan), which also served as a seal against the seepage of the electrolyte to the back contact. The exposed area was ~ 0.06 cm² for all electrodes

*Electrochemical Society Active Member.

¹The single crystals of n-MoSe₂ were obtained from Dr. Barry Miller and Dr. Frank DiSalvo of AT&T Bell Laboratories, Murray Hill, New Jersey.

used. The surfaces of the electrodes were treated with 6M HCl for 1 min and rinsed with distilled water prior to use. The electrolyte consisted of an aqueous solution of 0.2M K₂Fe(CN)₆, adjusted to pH 8 with KOH, and deaerated with prepurified N₂ prior to the experiment. A positive pressure of this N₂ was kept in the cell during the experiments.

Polycrystalline films of MoSe₂ were made from MoSe₂ powder, 99+% (Alfa, Danvers, Massachusetts) using I₂ vapor transport. A quartz tube, 1.5 cm diam + 15 cm length, was rinsed successively with 48% HF, distilled water, aqua regia, distilled water, 48% HF, and distilled water, then dried under vacuum at 150°C. Approximately 3g of the MoSe₂ powder was placed in the tube, and the tube was evacuated ($< 10^{-5}$ torr) for 1h. The tube was filled with He and I₂ was quickly added (~ 20 mg/g MoSe₂). Most of the He was removed and the tube was cooled in liquid N₂ and evacuated and sealed. The MoSe₂ and I₂ were distributed along the tube, which was placed in a split tube furnace (Hevi-duty Electric Company, Watertown, Wisconsin, length 18 in., diam 1.25 in.) and kept at 900°C. The ends of the furnace were plugged with spun alumina to minimize any temperature gradient which could cause growth of single crystals. After three weeks, the tube was removed from the furnace, and a suitable section was cooled under running water to condense the I₂, and then the rest of the tube was cooled. A polycrystalline mass of MoSe₂ had grown above and beneath the original charge. The side of the polycrystalline mass which faced the center of the quartz tube was covered with crystalline platelets protruding perpendicularly to the quartz walls; this was designated as the rough side. The opposite side, which was against the quartz tube, was shiny and was designated as the smooth side. The polycrystalline films were quite sturdy and could be removed easily from the quartz after the tube was broken. Contact to these films was made with silver paint and copper wire. The contact and the rest of the film, except for the area to be exposed to the solution, was covered with 5 min epoxy cement. Since the films had pinholes, the contact had to be kept above the solution level. The electrolyte solution used was an aqueous solution of 1M KBr, deaerated with N₂.

A conventional three-electrode single-compartment cell with a flat Pyrex window for illumination of the semiconductor electrode was used. The cell, which had a volume of about 30 ml, also contained a Pt gauze electrode (area > 40 cm²) which was used as the counterelectrode. The reference electrode was a saturated calomel electrode (SCE) separated from the cell by a KCl-saturated agar bridge. All potentials are reported *vs.* SCE.

Current-potential behavior was obtained with a PAR Model 173 potentiostat with Model 179 digital coulometer plug-in and Model 175 programmer (Princeton Applied Research, Princeton, New Jersey) and recorded with a Model 2000 X-Y recorder (Houston Instruments, Austin, Texas). Polychromatic illumination was obtained from a

450W Xe lamp (Oriel Corporation, Stamford, Connecticut) provided with a water filter. The intensity was 100 mW/cm².

Photodeposition of RuO_x ($x \leq 2$) on the MoSe₂ electrodes was accomplished by a modification of the procedure reported by Anderson and Warren (15). To a solution of 1.7g of RuCl₃ · 3H₂O in 100 ml of 98% aqueous EtOH, 6 ml of 1,3-cyclohexadiene was added (16). The solution was placed in a boiling flask fitted with a reflux condenser and heated to 45°C for 3h. The reflux condenser was then removed, and the solution volume was reduced to 30 ml. The red precipitate of [Ru(η^6 -C₆H₆)Cl₂]₂ was collected by filtration, washed with EtOH, and allowed to dry in air. This species was dissolved in a minimum amount of water, and 4 mol AgBF₄ were added per mole of Ru dimer to obtain Ru(η^6 -C₆H₆)(OH₂)₃²⁺ and a precipitate of AgCl. The solution was filtered, and the filtrate was diluted to give 0.04M Ru. The pH was adjusted to 5 and NaClO₄ was used as supporting electrolyte at a concentration of 0.1M. The aquated species can be oxidized on Pt at +0.9V vs. SCE to give a film of RuO_x (15). On illuminated n-MoSe₂, photo-oxidation starts at +0.2V vs. SCE. The films were produced by illuminating the n-MoSe₂ with white light and biasing at +0.5V while monitoring the charge passed with a coulometer.

AC impedance.—The lock-in technique (13, 14) was used to measure the ac impedance behavior as a function of applied potential. In this technique, a small amplitude sine wave, 12 mV peak to peak, from a wide-range oscillator (Model 200 CD, Hewlett-Packard, Palo Alto, California) is superimposed on a slow (≤ 5 mV/s) dc ramp from the PAR universal programmer by the PAR potentiostat and applied to the cell. The output of the current follower of the potentiostat is input to a lock-in amplifier (PAR Model 5204 or 5206) which separates the signal into the components in and out of phase (90°) with the ac signal from the oscillator. These signals were calibrated by using an RC circuit composed of a resistance substitution box checked with a digital multimeter and a precision decade capacitor (Hewlett-Packard Model 4440 B). The in and out of phase signals as a function of dc potential were plotted on an X-Y-Y recorder (Soltec, Sun Valley, California, Model 6432).

The second harmonic measurements were made by applying the same ac signal at a fundamental frequency (f) and setting the lock-in on the external $2f$ mode. The HP200 CD oscillator was found to have negligible harmonic distortion detectable at the sensitivities used, and, therefore, this oscillator was used for all ac measurements. All other instrumentation was the same as that used in the measurements at the fundamental frequency.

Differential photocurrent.—In this technique, the photocurrent is electronically differentiated with respect to potential as a function of potential (17). The method used the intermodulation frequency of chopped light and ac modulation of the electrode. This method has been described in detail elsewhere (18) and the results are plots of the photocurrent vs. voltage, as well as the differential photocurrent vs. voltage. Instrumentation is identical to that described previously (18).

Results and Discussion

Capacitance-voltage behavior of single-crystal n-MoSe₂.—Mott-Schottky (M-S) plots over the frequency range (f) 0.5-5 kHz are given in Fig. 1 for n-MoSe₂ in aqueous solution containing Fe(CN)₆⁴⁻³⁻ as the redox couple. In this frequency regime, the capacitance values (C) were generally free from the deleterious effects of surface states and yielded values of C which were only slightly dependent on f . The value of flatband potential (V_{FB}) and the average value of the doping density (N_D) obtained from the M-S plots are around $-0.1V$ vs. SCE and $2 \times 10^{17}/\text{cm}^3$. Taking the bandgap as 1.4 eV (19), we estimate that the valence band (VB) and conduction band (CB) edges are located, respectively, at +1.16 and $-0.24V$.

Fig. 1. Mott-Schottky plots for n-MoSe₂ in aqueous 0.2M K₄Fe(CN)₆. a: 500 Hz. b: 1 kHz. c: 5 kHz.

Inflections in the reverse bias region of capacitance (C) or conductance (G) vs. V plots are often associated with excess charge residing in surface states (20). Such inflections will be manifested as dips or humps in the C - V or G - V plots with frequency-dependent peak positions and heights. The shape and size of the humps are determined by the time constant (τ) associated with charge exchange and the density distribution as a function of potential energy (N_{ss} , cm⁻²eV⁻¹). The integrated area under the hump can be used to obtain quantitative information about the total density of surface states. This approach was used previously (14) to obtain a surface-state density of 1.4×10^{10} cm⁻² for n-MoSe₂. This density is too small for pinning the Fermi level (21, 22). In Fig. 2 are shown plots of the equivalent parallel conductance (G_p) and equivalent parallel capacitance (C_p) vs. V for two typical n-MoSe₂ electrodes in aqueous solution containing 0.2M K₄Fe(CN)₆ at two different frequencies, 100 and 500 Hz. While the C_p vs. V plots at 500 Hz show no hump in contrast to that at 100 Hz, the G_p vs. V plots exhibit humps with a frequency-dependent peak height. Different electrodes all gave similar results. This observation, that the in-phase component is more sensitive to the presence of surface states than the 90° component, is in accord with earlier observations (13, 23, 24). In Fig. 3 is shown the second harmonic of the ac impedance of n-MoSe₂ electrode of Fig. 2a in 0.2M K₄Fe(CN)₆ with ac modulation at 500 Hz. Note the absence of any dip or hump in the C_p vs. V at 500 Hz, while the second harmonic (which is related to dC/dV vs. V) exhibits a hump around +0.2V, roughly in the same potential region in which G_p vs. V exhibits a hump. In many devices, the capacitance changes much less rapidly than dC/dV (25, 26, 27) since, while $C_p \propto V^{1/2}$, $dC_p/dV \propto V^{-3/2}$. As with the dC_p/dV behavior, the small hump present in the G_p vs. V curve is greatly amplified in the second harmonic of the conductance (dG_p/dV) (Fig. 3).

Photocurrent and differential photocurrent behavior of n-MoSe₂.—In Fig. 4 are given the photocurrent (j) and the differential photocurrent (Δj) vs. V for two n-MoSe₂ electrodes with monochromatic illumination at 500 nm in aqueous solution containing K₄Fe(CN)₆ as redox couple. The plots in Fig. 4a are for the same electrode as Fig. 2a. Note that the current axis for Δj is given in a logarithmic scale. The $\log \Delta j$ vs. V plots exhibit a large hump in the potential regime in which j vs. V curves exhibit a dip. Similar results were obtained when the two modulating frequencies were varied by $\pm 20\%$ while maintaining the intermodulation frequency constant at 400 Hz for ease of

Fig. 2. AC impedance of n-MoSe₂ in 0.2M K₄Fe(CN)₆. (a) and (b) denote different electrodes. The upper plots are for 100 Hz, and the lower for 500 Hz. G_p , in-phase or equivalent parallel conductance, C_p ; quadrature or equivalent parallel capacitance.

filtering. Since Δj is the differential photocurrent at any potential, information concerning inflections in the photocurrent attributable, for example, to surface recombination and surface states, are amplified in Δj . Even a very small dip or hump in j vs. V will be apparent in Δj vs. V plots. Recall that the in-phase component (Fig. 2) exhibits a peak in the same potential regime in which the j and Δj vs. V plots exhibit a hump. This observation suggests that the differential photocurrent technique can be used as a diagnostic tool to probe the electrode surface for surface states.

The ac impedance and current-voltage behavior of n-MoSe₂ after surface modification with RuO_x.—These techniques, in conjunction with the ac impedance and current-voltage measurements, have been extended to regimes where surface states can be passivated by a thin layer of RuO_x. The thermodynamic potential for RuO_x deposition from Ru(η^6 -C₆H₆)(OH)₂²⁺ complex is about +0.9V vs. SCE. The VB edge of n-MoSe₂ is located at

Fig. 3. Second harmonic ac impedance for n-MoSe₂ in aqueous 0.2M K₄Fe(CN)₆. Fundamental modulation frequency = 500 Hz. Sensitivity for dG_p (second harmonic of G_p) and dC_p (second harmonic of C_p) are 100x and 20x, respectively, G_p and C_p in Fig. 2b. Negative values are plotted upward.

Fig. 4. Photocurrent (j) and log differential photocurrent (Δj) vs. potential for n-MoSe₂ in 0.2M K₄Fe(CN)₆. Monochromatic illumination at 500 nm, j obtained with light modulation at ~ 1.1 kHz, and Δj at the difference frequency (0.4 kHz) between the potential modulation (~ 1.5 kHz) and the light modulation. (a) and (b) denote different electrodes. The plots for (a) are for the electrode of Fig. 2a.

Fig. 5. AC impedance of $n\text{-MoSe}_2/\text{RuO}_x$ in $0.2\text{M K}_4\text{Fe(CN)}_6$. G_p = equivalent parallel conductance, C_p = equivalent parallel capacitance, dG_p = second harmonic of G_p (sensitivity = $5 \times G_p$). Modulation frequency is 25 Hz (left) and 100 Hz (right). Negative values of dG_p are plotted upward.

1.16V vs. SCE. We have photoelectrochemically deposited a thin layer of RuO_x on the surface of the $n\text{-MoSe}_2$ electrode of Fig. 2a held at +0.5V under white light illumination from a 450W Xe lamp. The film appeared golden yellow, and the amount of charge passed was equal to 1.9 mC ($\sim 30 \text{ mC/cm}^2$). In Fig. 5 are given plots of the impedance and the second harmonic ac impedance for two modulation frequencies in $\text{K}_4\text{Fe(CN)}_6$ solution. Both the ac impedance at the fundamental frequency and the more sensitive second harmonic exhibit smooth plots that are indicative of an improved surface. In Fig. 6 is shown the j and Δj vs. V for $n\text{-MoSe}_2$ after depositing RuO_x . Note the significant improvement in the shape of the current-voltage behavior. The photocurrent rises to saturation much more quickly than its counterpart in Fig. 4. This type of steep rise to saturation has been attributed to the absence of surface states and recombination effects (28, 29). At 0.3V, corresponding to the V_{redox} of $\text{Fe(CN)}_6^{4-/3-}$, the photocurrent (roughly corresponding to the short-

circuit photocurrent in a two-electrode PEC cell configuration) of the RuO_x -modified electrode is approximately double that of the untreated electrode. Consider the behavior of the differential photocurrent. Δj decreases more sharply with V than its counterpart in Fig. 4. Further, the hump attributable to the presence of surface states is absent, suggesting the passivation of the surface states. The RuO_x films were found to be stable in the presence of all mineral acids, but could be dissolved by sulfochromic acid. Short treatments in this acid of bare $n\text{-MoSe}_2$ electrodes were found not to affect the ac impedance behavior. In Fig. 7 is given the plot of j and Δj vs. V after partially removing the RuO_x layer by briefly dipping the electrode in chromic acid. Compare Fig. 6 and 7. In both cases, the j vs. V behavior is the same. The lower photocurrent in Fig. 6 is probably due to larger attenuation of the impinging light intensity by a thicker RuO_x

Fig. 6. Photocurrent (j) and log differential photocurrent (Δj) for $n\text{-MoSe}_2/\text{RuO}_x$ in $0.2\text{M K}_4\text{Fe(CN)}_6$. Illumination and frequencies are as in Fig. 4.

Fig. 7. Photocurrent (j) and log differential photocurrent (Δj) for $n\text{-MoSe}_2/\text{RuO}_x$ in $0.2\text{M K}_4\text{Fe(CN)}_6$ after etching RuO_x coating in chromic acid for 5s. Monochromatic illumination and frequencies are as in Fig. 4.

Fig. 8. Current-potential curves for smooth side of polycrystalline MoSe_2 in 1M KBr. Dark (---), illuminated with 450W Xe lamp ($\sim 100 \text{ mW/cm}^2$) (—), and after deposition of RuO_2 under illumination (-.-).

film. However, the Δj vs. V behavior is not the same. This plot exhibits a hump in the same potential regime in which both the ac impedance and differential photocurrent (before RuO_2 deposition) exhibit a hump. This observation indicates that the differential photocurrent method can be used to monitor the presence of surface states even at low levels, where the photocurrent behavior appears normal. In addition, even those states which cannot be charged in the dark but can be charged under illumination (30) are detectable by the differential photocurrent technique. In this respect it is even superior to the second harmonic impedance method for detecting surface states.

In a previous paper (14), we reported that the surface states existing on $n\text{-MoSe}_2$ were not present in sufficient density to cause pinning of the Fermi level in acetonitrile solutions. The possibility that a Schottky barrier exists between the $n\text{-MoSe}_2$ and the RuO_2 is ruled out by the constant onset potential of photocurrent in solutions of iodide, bromide, and ferrocyanide. Formation of insulating layers such as oxides could cause the measured impedance to be no longer equivalent to the combination of

space charge layer and surface states illustrated by Fig. A-1 of Ref. (14). The fact that RuO_2 is a conducting layer, as well as the values of the capacitance away from the potential regime of the surface states before and after RuO_2 deposition (compare Fig. 2a and Fig. 5), strongly suggests that the space charge layer capacitance is being measured. Additional support for this contention lies in the fact that even at frequencies as low as 100 Hz, the Mott-Schottky plots are linear; this would not be the case if the space charge capacitance were not approximately equivalent to the measured capacitance.

PEC behavior of polycrystalline $n\text{-MoSe}_2$.—Recent studies on polycrystalline films of $p\text{-WSe}_2$ (31) and $n\text{-WSe}_2$ (32) have been described. In the latter work, results of a modification procedure with silver and lanthanum ions were discussed. We report here work done on similar polycrystalline films of $n\text{-MoSe}_2$ and results of surface modification with photodeposited RuO_2 films. In Fig. 8 is shown the j - V behavior for the smooth side of polycrystalline $n\text{-MoSe}_2$ in aqueous solution containing 1.0M KBr as the redox couple before and after depositing

Fig. 9. Current-potential curves for rough surface of polycrystalline $n\text{-MoSe}_2$. Dark (---), illumination (—). Conditions are as in Fig. 8.

a thin layer of RuO_x. The conditions are the same as used for the single-crystal n-MoSe₂, except the number of coulombs passed in RuO_x deposition (~420 mC/cm² of projected surface area). (However, the actual surface area could be as much as an order of magnitude greater than the projected area.) The photoperformance is improved after RuO_x deposition; not only is the photocurrent increased, but the onset of photocurrent is located at least 0.3V more negative. Although the *j*-*V* performance appears to be improved after modifying the electrode surface with RuO_x, the photocurrent and efficiency of the polycrystalline material is still much smaller than that of treated single-crystal MoSe₂. Under similar conditions, the untreated rough side of the polycrystalline MoSe₂ gave better photocurrent than the RuO_x-coated smooth side (Fig. 9). However, deposition of the RuO_x on the rough side did not improve the behavior. Thus, the RuO_x treatment appears to help a poor surface more than a good one.

Conclusions

Both the second harmonic and the differential photocurrent methods can be used as diagnostic tools for monitoring the presence of surface states. Even under conditions where the presence of surface states cannot be detected by the photocurrent, the differential photocurrent can be used to detect them. Further, even those states which are not charged in the dark but can be charged under illumination can be detected by the differential photocurrent. In this respect, it is even superior to the second harmonic impedance method. The second harmonic is more sensitive than the ac impedance of the fundamental frequency.

Photoelectrodeposition of a thin film of RuO_x significantly improves both the potential for photocurrent onset as well as the short-circuit photocurrent for single-crystal n-MoSe₂ and the smooth side of polycrystalline MoSe₂. Attempts to study the behavior of similar n-MoTe₂ with RuO_x films were not successful. The Ru(η⁶-C₆H₆)(OH)₂²⁺ redox potential is more positive than the valence band-edge of this material (13) and, therefore, RuO_x films could not be formed by this method.

Acknowledgments

We are indebted to Dr. Barry Miller and Dr. Frank DiSalvo at AT&T Bell Laboratories for the gift of the sample of MoSe₂. The support of this research by the National Science Foundation (CHE8404666) and the Robert A. Welch Foundation is gratefully acknowledged. B. L. W. wishes to acknowledge the generous support of The Electrochemical Society, Inc., in the form of the Colin Garfield Fink Summer Fellowship.

The Voltammetric Response of Solutions of Electroactive Polymers

B. Lionel Funt* and P. M. Hoang

Department of Chemistry, Simon Fraser University, Burnaby, Vancouver, British Columbia, Canada V5A 1S6

ABSTRACT

A series of electroactive polymers was synthesized by incorporating pendant anthraquinone groups on a polystyrene backbone. The spacing between electroactive groups and the overall chain length were varied independently. Symmetrical, reversible cyclic voltammograms were obtained from polymer solutions. Linear plots of current *vs.* (sweep rate)^{1/2} were obtained whose slopes decreased with increase in chain length. Diffusion parameters thus evaluated agree with results obtained by viscometry. The Randles-Sevcik equation was modified to show the dependence of peak current upon polymer molecular weight. The predicted linear dependence of log *i_p* upon log \bar{M}_n was confirmed for polymers whose molecular weights were determined by gel permeation chromatography. The results clearly indicate the presence of independent, noninteracting centers.

The voltammetric behavior of solutions of polymers with pendant electroactive groups reflects the transfer of a large number of electrons to or from a single molecule. Although the electron transfer process may occur solely to the pendant groups, the chain configuration and structure can be expected to exert a profound influence on their diffusion to the electrode and to their interaction with neighboring groups. The size, shape, and location of voltammetric waves reflect the environment in which the electroactive centers are contained, and the extent to which interaction between neighboring groups hinders the process of electron transfer. Moreover, the electrochemical data may be used to characterize the polymers, because the voltammetric current is determined by the rate of diffusion of the macromolecule with its electroactive substituents.

Bard and co-workers investigated poly(2-vinylnaphthalene), poly(1-vinylanthracene) (1), and poly(vinylferrocene) (2), with triangular wave and pulse voltammetry, and found no interference between electroactive centers. We previously reported studies of a series of polymers of poly(vinylbenzophenone) and its copolymers with styrene (3, 4). These encompassed a range of molecular weights for which samples with differing spacings between electroactive groups were prepared. The electrochemical behavior indicated an absence of group-to-group interference for a wide range of copolymer compositions.

Examples of deviation from behavior explicable by this simple model have also been reported. Smith *et al.* (5) investigated poly(vinylferrocene) and estimated that only one in four ferrocene groups ($\bar{M}_n = 1.6\text{--}2.6 \times 10^4$) could be oxidized. Morishima *et al.* (6) investigated polymers and copolymers of 3-vinyl-10-methylphenothiazine (MPT) and found interference between neighboring groups in MPT but not in its copolymers. However, the latter could not be completely oxidized or reduced, and it is suggested that close proximity of electroactive groups is essential for electron self-exchange within the polymer chain and for the occurrence of complete oxidation.

Yap and Durst (7) developed a theoretical analysis of the effects of nearest neighbor interaction in order to quantify the current/potential relationship as a function of interaction parameters and chain length.

We have reported that noninteracting behavior in solution may be used to screen polymeric systems for possible utilization in polymer-modified electrodes (8). Systems which exhibit minimal group-to-group interference in solution are *a priori* expected to show similar tendencies when incorporated in thin films on electrodes.

In this work, we report the preparation and investigation of a series of polymers containing anthraquinone (AQ) and of a model compound for this polymer. The behavior of related quinones is well documented (9, 10), and their use as electrochemical mediators (11-15) prompted this choice.

*Electrochemical Society Active Member.

Experimental

A series of copolymers, of different anthraquinone (AQ) loading and with a range of chain lengths, was prepared.

2-Anthraquinonecarbonylchloride was prepared from 2-anthraquinone carboxylic acid and thionyl chloride by a standard procedure (16). 2-(p-Ethylbenzoyl)-9,10-anthraquinone (EBAQ) was synthesized by reaction of 2-anthraquinonecarbonylchloride (18.8 mM) and aluminum chloride (22.5 mM) with ethyl benzene (200 ml) at room temperature for 3 days. After recrystallization from methanol, the product was obtained as yellow crystals, yield 35%, m.p. 125°-126°C. Elemental analysis was: calculated C 81.18, H 4.71; found C 80.68, H 4.83. Mass spectrum *m/e* (%): 342 ($M^+ + 2$, 1.5), 341 ($M^+ + 1$, 10.5), 340 (M^+ , 35), 235 (9.5), 151 (17.1), 133 (100).

The IR spectrum showed a strong absorption of a quinone group at 1675 cm⁻¹, a β -carbonyl group at 1650 cm⁻¹, an ethyl group at 2970 cm⁻¹, 2930 cm⁻¹, and 2880 cm⁻¹, and a substituted benzene ring at 700 cm⁻¹.

The preparation of polystyrene of narrow dispersity and the determination of the chain length were described previously (3). Poly-[p-9,10-anthraquinone-2-carbonyl]styrene]-co-styrene (PAQ) was synthesized by reacting polystyrene with 2-anthraquinonecarbonylchloride and aluminum chloride in dry nitrobenzene. Polymers of different anthraquinone loading were prepared by changing the relative amounts of 2-anthraquinonecarbonylchloride and polystyrene. The product was purified by repeated precipitation in methanol and finally freeze-dried in vacuum. The IR spectrum showed a quinone band at 1675 cm⁻¹, a β -carbonyl band at 1650 cm⁻¹, a methylene band at 2920 cm⁻¹, and a substituted benzene ring at 700 cm⁻¹. Copolymer compositions were determined from infrared spectra and confirmed by elemental analysis.

Tetraethylammonium perchlorate (TEAP) (Kodak) was recrystallized twice from distilled water and dried under vacuum at 80°C for 3 days. Pyridine (Py) (BDH, analytical grade) was stored over molecular sieves in a nitrogen atmosphere. Dimethylformamide (DMF) (Fisher) was dried over BaO, vacuum distilled, and stored over molecular sieves.

Intrinsic viscosity measurements were performed at 25°C with an Ubbelohde viscometer, on solutions of polymer in 0.3M TEAP/Py-DMF (2/1, v/v). The choice of this solvent system was dictated by the poor solubility of polymers in conventional solvents. Molecular weights

Fig. 1. Cyclic voltammety in 0.3M TEAP/Py-DMF (2/1, v/v) of (a) EBAQ (1.29 mM) and (b) PAQ 40 (1.55 mM anthraquinone residues). Scan rates: 500, 200, 100, 50, 20 mV s⁻¹ for curves 1-5, respectively.

were determined by gel permeation chromatography of the parent polymer. A Waters Model GPC/ALC 301 fitted with five capillary columns was employed.

Solutions of 0.3M TEAP/Py-DMF (2/1, v/v) were transferred to a three-compartment cell maintained under an argon atmosphere.

A ϕ 1.7 mm Pt disk (Bioanalytical Systems, Incorporated) was used as a working electrode with a Pt wire counterelectrode and an Ag/AgNO₃ reference. A PAR Model 170 Electrochemical System was employed for the voltammetric measurements. All potentials are reported relative to the saturated calomel electrode (SCE).

Results and Discussion

The cyclic voltammograms of the model compound EBAQ are shown in Fig. 1a. The peaks are symmetrical: E_{pc} and E_{pa} are independent of sweep rate (ν) for $\nu \leq 0.5$ V s⁻¹; the peak separation is ≈ 60 mV at all scan rates; i_{pa}/i_{pc} is unity, and i_{pc} is proportional to $\nu^{1/2}$. A similar pattern of ideal behavior is shown in Fig. 1b for the copolymer PAQ 40. For the further reduction of the dianion, EBAQ continued to show the characteristics of a simple system, whereas the polymer produces sharp anionic peaks indicative of strong adsorption on the electrode surface. Polymers with a high AQ content, such as PAQ 5(3) and PAQ 200(3), gave evidence of adsorption of the PAQ radical ion and of the PAQ polymer. These samples were excluded from further study, and the investigation on the remaining samples was confined to the first reduction step to the radical anion and of its reoxidation.

The data for a range of polymer chain lengths and for various average spacings of electroactive groups are presented in Table I and Fig. 2. A linear relationship between i_{pc} and $\nu^{1/2}$ is obtained even for samples whose AQ content differs greatly. For example, PAQ 5(1) and PAQ 5(2) each have an average of 51.9 repeat units (\overline{DP}_n) in the polymer chain but have 19.3% and 41.3%, respectively, of pendant AQ groups. The same pattern is evident with the high molecular weight samples [PAQ 200(1) and PAQ 200(2)] with 2170 repeat units in the chain and molecular weights in excess of 300,000. The lower slopes reflect the influence

Table I. Copolymer characterization

Polymers	AQ(%)	\overline{DP}_n	\overline{M}_n	$\overline{M}_w/\overline{M}_n$	$D \times 10^7$ (cm ² /s)	$[\eta]$ (g/100 ml)
EBAQ	1	338.2			78.7	
PAQ 5(1)	19.3	51.9	7.76×10^3	1.20	15.6	0.058
PAQ 5(2)	41.3	51.9	1.04×10^4	1.20	14.2	0.063
PAQ 5(3)	48.9	51.9	1.13×10^4	1.20	—	—
PAQ 8	21.6	72.2	1.12×10^4	1.22	13.4	0.066
PAQ 12	23.1	108	1.71×10^4	1.14	10.9	0.076
PAQ 40	18.0	413	6.06×10^4	1.16	5.84	0.166
PAQ 200(1)	19.5	2170	3.26×10^5	1.35	2.29	0.460
PAQ 200(2)	28.0	2170	3.69×10^5	1.35	2.00	0.483
PAQ 200(3)	47.4	2170	4.68×10^5	1.35	—	—

Fig. 2. Plots of cathodic peak current against (scan rate)^{1/2} for 1 mM anthraquinone residues. Curves from top: EBAQ, PAQ 5(1), PAQ 5(2), PAQ 8, PAQ 12, PAQ 40, PAQ 200(1), PAQ 200(2).

of chain length, but the curves are essentially independent of the number of electroactive groups on the chain.

The relationship between i_p and $\nu^{1/2}$ is given by the Randles-Sevcik equation (17, 18)

$$i_p = 2.69 \times 10^5 n^{3/2} A D^{1/2} C \nu^{1/2} \quad [1]$$

where n is the number of electrons transferred to each electroactive group, A the electrode area, D the diffusion coefficient, and C the bulk concentration of AQ residues (M cm⁻³).

The diffusion coefficients were calculated from the slopes of i_p vs. $\nu^{1/2}$ and are listed in Table I. However, the diffusion coefficients of polymers in solution are a function of the molecular weight and are given by

$$D = K_T M^{-b} \quad [2]$$

where K_T is a constant and the values of the exponent b range from 0.50 for a poor solvent to 0.55 for a good solvent (19). The variation in b results from the changes in chain conformation which occur as the chains coil or become extended in the solvent.

The values of D obtained from the electrochemical data were plotted against the number of average molecular weight, (\overline{M}_n) obtained from gel permeation chromatography of the parent polymers. A straight line whose slope

Fig. 3. Dependence of diffusion coefficient on molecular weight of PAQ copolymers and of EBAQ.

Fig. 4. Intrinsic viscosity-molecular weight relationship for PAQ

yielded $b = 0.52$ was obtained from the double logarithmic plot in Fig. 3.

A further comparison of hydrodynamic behavior may be made with the Mark-Houwink relationship which relates the limiting viscosity number, $[\eta]$ (intrinsic velocity), to the molecular weight

$$[\eta] = K M^a \quad [3]$$

where $b = (1 + a)/3$ (20).

The viscosities of each of the polymer samples were measured at four concentrations and extrapolated to zero concentration. The data in Fig. 4 yield $a = 0.57$ and $K = 3.27 \times 10^{-4}$. This is in remarkable agreement with $a = 0.56$ obtained from the voltammetric data.

The Randles-Sevcik equation can be rewritten in a form which indicates the dependence of diffusion coefficient on the polymer molecular weight

$$i_p = 2.69 \times 10^5 n^{3/2} A \nu^{1/2} C K_T^{1/2} M^{-b/2} \quad [4]$$

A plot of $\log i_p$ vs. $\log \bar{M}_n$ is linear and is presented in Fig. 5. This again illustrates the feasibility of determining molecular weights from voltammetric measurements in these systems (4).

However, the conditions of ideality required for such an application predicate against the general use of this technique. Not only must a Nernstian electrode process occur to satisfy the assumptions of the Randles-Sevcik equation, but there must also be minimal interaction between electroactive centers. The ability to determine molecular weights, even for a limited group of polymers, is a reassuring manifestation of the essential soundness of the physical model.

On average, the electroactive groups were separated by at least one nonactive group along the chain. This does not imply a lack of opportunity for nearest neighbor interaction. The spacing along the chain is random, and it is instructive to calculate the number of sites in which AQ groups are adjacent to one another on a chain at neighboring positions Z_1, Z_2

Let X be the fraction of AQ groups in the polymer, and $(1 - X)$ the fraction of styrene groups. The probability for

Fig. 5. Dependence of peak current at a scan rate of 50 mV s^{-1} on molecular weight of PAQ copolymers and of EBAQ.

structures such as AQ-AQ-AQ is X^2 ; AQ-AQ-STY is $2X(1 - X)$; and STY-AQ-STY is $(1 - X)^2$. Hence, the probability of an AQ group being adjacent to another AQ group is

$$P = 1 - (1 - X)^2 = X(2 - X) \quad [5]$$

For PAQ 5(2), $X = 0.413$ and thus $P = 0.655$. Hence, 65.5% of the AQ groups in the copolymer are adjacent to another AQ group and the opportunity for near-neighbor interaction is high. Despite this, the voltammetric data are indicative of noninteracting centers along the polymer chain. Although the diffusive motion of the electroactive groups is constrained by the relatively slow diffusion of the polymer molecule, the electrochemical behavior is otherwise unchanged from that of free, simple molecular species undergoing oxidation and reduction reactions at an electrode.

The Kinetics of Oxygen Reduction at Porous Teflon-Bonded Fuel Cell Electrodes

R. Holze*¹ and W. Vielstich**

Institute of Physical Chemistry, University of Bonn, D-5300 Bonn 1, Germany

ABSTRACT

Oxygen reduction on porous Teflon-bonded semihydrophobic electrodes has been investigated using the impedance method. Carbon-supported metals and activated carbon have been used as electrocatalysts in neutral and alkaline electrolytes. The results of the impedance measurements agree well with those of galvanostatic double-pulse experiments. Taking into account the internal structure, especially the large inner surface area of the catalyst particles forming the electrode, an attempt is made to calculate exchange current densities from the apparent charge transfer resistance. The values of i_0 support the assumption that hydrogen peroxide is the predominant reduction product formed on the electrocatalysts investigated. The measured polarization resistance is mainly caused by the slow diffusion of oxygen and its reduction products. The rather fast adsorption of oxygen and charge transfer reaction cause only a small contribution to the polarization. The results are discussed with respect to the electrode structure and compared with a general model describing the operation of a semihydrophobic porous electrode.

The reduction of oxygen is the most important cathodic reaction in fuel cells, reactive metal air batteries, and gas-sensitive devices. In the near future, oxygen electrodes may be used in chlor-alkaline electrolysis (1). Many papers related to the kinetics of the oxygen reduction on pure metal or carbon surfaces have been published, *e.g.*, (2).

There is still a lack of information concerning the kinetics of the reduction of oxygen on porous gas-diffusion electrodes, *e.g.*, on metal/carbon or catalyst/carbon electrodes. In recent years Teflon-bonded semihydrophobic electrodes, containing carbon or a catalyst supported on carbon as active material, have been shown to be promising candidates for a widespread application in electrochemical energy conversion. Therefore, it seems necessary to increase our knowledge about these electrodes, not only concerning technical aspects, *e.g.*, lifetime or performance (3), but also fundamental aspects, *e.g.*, exchange current densities, reaction mechanism, and relative influence of diffusion and reaction/adsorption on the overall electrode reaction. A general model of the oxygen reduction kinetics in porous electrodes must include oxygen diffusion, oxygen adsorption, or surface reaction on the active sites of the catalyst, charge transfer, and diffusion of the products.

Wabner demonstrated the possibilities of the impedance method for the investigation of hydrophilic porous gas-diffusion electrodes (4). He separated the polarization resistance of the working electrode into portions attributed to the various steps of the reaction and pointed out the great influence of diffusion polarization. The total electrode overpotential was described as the sum of a large diffusion overpotential due to the diffusion of oxygen and its reduction products, a small overpotential caused by an oxygen surface reaction, and a small charge transfer overpotential.

Using the impedance method, the galvanostatic double-pulse method, and other techniques we tried to develop an appropriate kinetic model describing oxygen reduction in semihydrophobic electrodes. In addition to

information on the kinetics of the electrode reaction, further information should be derived on structural aspects, *e.g.*, the location of the reaction in the porous electrode, the utilization of the electrode, and changes of electrode properties during extended operation.

Experimental

Porous electrodes were fabricated using platinum-carbon (Pt/C, 20 weight percent [w/o] Heraeus), activated carbon (Norit-BRX), silver/carbon (Ag/C, 10-30 w/o, prepared from activated carbon and AgNO₃-solution) and Teflon dispersion (Hoechst). The metal loading was 4 mg/cm² of platinum or 1.4-4.2 mg/cm² of silver with respect to the geometric electrode surface area. The electrodes were dried at 120°C (Pt/C) or 200°C (Ag/C and activated carbon). On one side of the catalyst layer, a silver screen current collector was pressed; on the other side, a porous Teflon backing layer (Berghof, Tuebingen, or Zitex) was pressed to prevent electrolyte leakage when the electrode was operated without feed gas overpressure (Fig. 1). For further details of the preparation, see Ref. (5). Additionally, commercial electrodes without backing layer (Prototech, Fig. 1) and sandwich electrodes, containing two layers of platinum/carbon and activated carbon were measured. Electrolyte solutions were prepared using water purified with a Millipore purification system and reagent-grade NaCl (3M) or KOH (6M). Electrodes were fed with unscrubbed air or oxygen. For electrodes without the porous Teflon backing layer a small feed gas overpressure of 3 kPa was applied. All experiments were performed at room temperature.

All experiments were carried out using a rectangular Plexiglas-cell. The test electrodes were mounted with a screw cap (for rapid replacement), and the counter-electrode was fixed at the opposite side of the cell. A small hole in the wall of the cell near the test electrode served as connection to the reference electrode compartment. In all experiments a saturated calomel electrode (+248 mV vs. SHE) served as a reference. For the impedance measurements, a transfer function analyzer (Model 1172 Solartron-Schlumberger), connected with a potentiostat (Model PCA 72 M, Bank), and a plotter interface (Model 1180 Solartron-Schlumberger) were used (Fig. 2). The measured impedance spectra were displayed on a X-Y plotter (Model HP 7035 B Hewlett-Packard) and

stored on punch cards for further processing. Galvanostatic double-pulse experiments were done using the same cell and a rather simple circuit (Fig. 3), containing a pulse-galvanostat (Model MP-IM 400 Mega-Physik), a transient-recorder (Model B-C 104 Bruker), a CRT display (Model 702 Tektronix), and a custom-designed impedance converter, which contained a circuit for automatic iR_{dc} drop and rest potential correction. During the experiments, the dc current density i_{dc} and feed gas composition were varied. The influence of other experimental conditions is discussed elsewhere (6). To interpret the measured impedances, the equivalent circuit of an oxygen reducing electrode developed by Drossbach (7) was used. The typical properties of porous electrodes which may affect the measured impedance were taken into account according to the results of de Levie (9) and Drossbach (10). After separating the electrolyte resistance R_{so1} and the apparent double layer capacity $C_{D,app}$ from the measured electrode impedance by using a linear regression program, the faradaic impedance was obtained. The kinetic parameters of the elements in the faradaic impedance were fitted using the Marquardt-Levenberg algorithm. All programs were run on an IBM 370/168 computer. A description of the programs and further experimental details are given in Ref. (8).

BET surface areas were determined with a custom-designed apparatus via N_2 adsorption. The porosity of the electrodes was determined from the weight differences between a dry electrode and an electrode soaked with electrolyte.

Results

The polarization curves and the faradaic impedances measured at different dc current densities i_{dc} of electrodes containing platinum carbon in 3M NaCl solution are presented in Fig. 4 and 5. The apparent double-layer capacity

Fig. 2. Schematic wiring diagram of the circuit used for impedance measurements. 1: Cell. 2: Working electrode. 3: Reference electrode. 4: Counterelectrode.

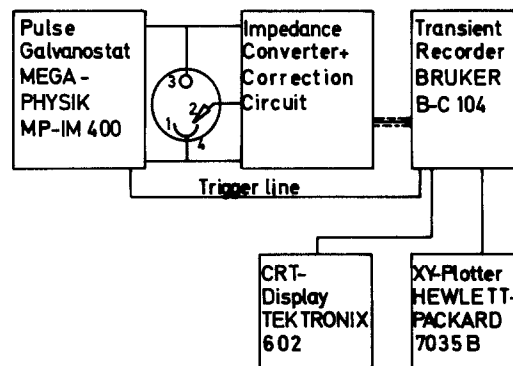

Fig. 3. Schematic wiring diagram of the circuit used for the galvanostatic double-pulse experiments. 1: Cell. 2: Working electrode. 3: Reference electrode. 4: Counterelectrode.

$C_{D,app}$ and the apparent charge transfer resistance $R_{ct,app}$ were measured independently with the impedance method and the galvanostatic double-pulse method, as described above. The results of both methods agreed within experimental error, and the results are given in Table I. Due to changes in the wetting of the electrode, these values were not constant, but time dependent. Using the approximation of the Butler-Volmer equation for small charge transfer overpotentials (*i.e.*, at low charge transfer resistances and small dc current densities) the apparent exchange current density was calculated

$$i_{0,app} = \frac{R \cdot T}{z \cdot F \cdot R_{ct,app}}$$

With $z = 2$ and $T = 298 \text{ K}$, $i_{0,app} = 390 \text{ mA/cm}^2$ (geometric electrode surface area) was obtained. The real inner surface area of the electrode exceeds the geometric surface area by orders of magnitude. In order to obtain a value of the exchange current density i_0 related to the electrochemical active fraction of the inner electrode surface, a surface factor S was calculated. This factor represents the ratio of the electrochemical active surface area of the electrode to the geometric electrode surface. It was obtained by dividing the apparent double layer capacity $C_{D,app}$ obtained for the geometrical electrode surface area by an assumed value of $C_{D,true} = 10 \mu\text{F/cm}^2$ for a smooth carbon electrode. The previously published results leading to the selection of this value will be discussed in detail later in this paper.

With $C_{D,app} = 1.4 \text{ mF/cm}^2$ a surface factor of $S = 140$ was calculated. The $i_{0,app}$ value can be corrected to give an exchange current density per unit true area, $i_0 = 2.85 \text{ mA/cm}^2$. Further interpretation of the impedance spectra is possible with the aid of an appropriate equivalent circuit, containing elements representing the steps of the electrode reaction. According to Drossbach (7), these are as follows. (i) Diffusion of oxygen through the gas phase in the pores and the electrolyte to the reaction sites. (Due

to the small solubility and low diffusivity of oxygen in water and the accumulation of inert gas in the pores, this step should cause a significant contribution.) (ii) Adsorption or heterogeneous surface reaction of the oxygen, coupled with oxygen diffusion. (iii) Charge transfer, reduction of oxygen to H₂O₂ or H₂O. (iv) Diffusion of reduction products into the bulk electrolyte.

These steps in the oxygen reduction process are represented in the faradaic branch of the equivalent circuit of the electrode impedance (Fig. 6). Both diffusion processes are described by diffusion impedances Z_{diff} according to the theory of the Nernstian diffusion impedance (11). They are determined by a diffusion factor $A = 2d/\sqrt{2D}$ (with the diffusion coefficient D and the thickness d of the Nernstian diffusion layer) and a diffusion resistance

$$R_{diff} = \frac{R \cdot T \cdot d}{z^2 \cdot F^2 \cdot a \cdot c_{sur} \cdot D}$$

where c_{sur} is the concentration of the diffusing species at the electrode surface area a . The reaction/adsorption impedance is represented by a resistor and a capacitor in parallel, where $R_{ad/react}$ is given by

$$R_{ad/react} = \frac{R \cdot T}{z^2 \cdot F^2 \cdot c_{sur} \cdot k \cdot a}$$

and $C_{ad/react}$ by

$$C_{ad/react} = \frac{z^2 \cdot F^2 \cdot c_{sur} \cdot a}{R \cdot T}$$

The rate constant of the adsorption/reaction k can be derived by $k = 1/[R_{ad/react} C_{ad/react}]$, and the surface concentration of the reacting/adsorbing species by

$$c_{sur} = \frac{R \cdot T \cdot C_{ad/react}}{z^2 \cdot F^2 \cdot a}$$

Fig. 6. Equivalent circuit of a working oxygen reduction electrode. For description of elements and parameters, see text.

The results of the fitting of the parameters are given in Table II for different values of i_{dc} .

The BET surface area was measured to be 192 m²/g, and the porosity of the electrode was 28%.

At electrodes prepared from silver/carbon, dried at 200°C, $C_{D,app} = 2.6$ mF/cm² and $R_{ct,app} = 0.01$ Ω · cm² were measured with the impedance and the galvanostatic double-pulse method in 3M NaCl electrolyte. With a surface factor $S = 260$, an exchange current density $i_0 = 4.9$ mA/cm² was calculated. The optimization of the parameters of the equivalent circuit yielded data similar to the results obtained at Pt/C electrodes.

At activated carbon electrodes dried at 200°C, much higher values of $C_{D,app}$ and higher values of $R_{ct,app}$ were measured in 6M KOH electrolyte. The current pulses necessary to charge the double-layer capacity of this electrode could not be supplied by the pulse generator used in these experiments; therefore, only the results of the impedance measurements are given in Table I. The relative magnitude of the polarization resistances attributed to the steps of the electrode reaction were nearly the same as they were in the case of the Pt/C electrode. Only the adsorption/reaction impedance was smaller.

The results obtained with the electrode manufactured by Prototech in 3M NaCl solution were $C_{D,app} = 1.5$ mF/cm² and $R_{ct,app} = 0.017$ Ω · cm², and the calculated exchange current density was $i_0 = 4.95$ mA/cm². No further information about metal content and composition of electrode was provided by the supplier, and thus a detailed discussion of the results is difficult. Comparing the data with the results obtained with our electrodes, this electrode seems to contain a rather active electrocatalyst. The thickness of the diffusion layer as well as the diffusion resistance R_{diff} calculated from the impedance attributed to the diffusion process are nearly equal, indicating a relative decrease of the influence of the oxygen diffusion on the total polarization resistance of the electrode (6). This is a result of the different construction of this electrode without the porous Teflon backing layer (Fig. 1). The inert gas accumulation which can take place in the pores of

the backing layer, with the resulting hindrance due to limited gas transport through the layer, thus, was not observed. In addition, the air on the gas chamber in front of the electrode is exchanged rapidly due to the flowing feed gas.

In order to determine the location of the reaction zone within the porous system, the impedance of sandwich electrodes, containing two active layers in different arrangements, was measured. The thickness of these electrodes was nearly doubled: the usual thickness of a single-layer electrode was about 0.6 mm, while the thickness of the sandwich electrodes was about 1 mm.

A reaction zone near the gas-side surface will be favored by a shorter diffusion path for the oxygen, and a reaction zone near the electrolyte side surface will be favored by a shorter diffusion path for the products. Additionally, the reaction could take place in the vicinity of the current collector.

Two types of sandwich electrodes with different layer sequences were investigated: type A (foil-activated carbon-platinum/carbon-current-collector and type B (foil-platinum/carbon-activated carbon-current-collector).

The results are given in Table II. They indicate clearly that the typical properties of the layer at the electrolyte side were measured. The potential difference between electrode A and B demonstrates that the reaction takes place in this zone, since the potential of the electrode is more negative in case of electrode B with less active carbon near the electrolyte. These results were confirmed in experiments with stirred electrolyte. Especially at higher current densities, the potential was more positive if the electrolyte was stirred. This could be explained only by the assumption that the reaction zone must be located near the electrolyte-side surface of the electrode, where the stirring is effective.

Discussion

Although the charge transfer resistance was small for all of the electrodes investigated in our experiments, a detailed discussion of the results is necessary for the understanding not only of the reaction kinetics, but also of the electrode deterioration caused by reaction products.

Taking into account the generally accepted results of research on oxygen reduction catalysis (13) and our numerical values for the exchange current density, two pathways for the reduction of oxygen are important. The first is the $4e^-$ pathway, leading from O_2 directly to H_2O , characterized by low i_0 values ranging from 10^{-6} to 10^{-10} A/cm², with the number of electrons transferred z being 4. The second is $2e^-$ pathway, leading to H_2O_2 , characterized by higher i_0 values, ranging in alkaline electrolytes at carbon electrodes from 10^{-3} to 10^{-4} A/cm² with $z = 2$ (14). Obviously, at our electrodes, the $2e^-$ pathway predominates: calculating i_0 with $z = 4$ leads to i_0 values which are much too high for the $4e^-$ pathway. This verifies the assumed value of $z = 2$ in the calculations described above. In the

case of the activated carbon electrode, no other possibility exists, and the HO_2^- concentration, calculated from the diffusion impedance related to the transport of the product into the bulk electrolyte, confirmed this result. (The HO_2^- concentration calculated from the diffusion resistance is about $10^{-2}M$ in the reaction zone, as discussed below.) At metal/carbon electrodes, the interpretation is more difficult. Both platinum and silver catalyze the $4e^-$ pathway (15). The mechanism via a bridge-like adsorbed oxygen molecule is very sensitive to impurities adsorbed on the electrode surface. With respect to the values obtained i_0 for the metal/carbon electrodes, it has been concluded that oxygen is reduced on these catalysts mostly to H_2O_2 . Obviously, the metal acts as a very active hydrogen peroxide decomposing catalyst: no H_2O_2 could be detected in the bulk electrolyte. The $4e^-$ pathway cannot be excluded, but seems to be of minor importance and may be suppressed by impurities adsorbed on the metal during the preparation of the electrode. Based on our results, a separation of the currents generated at the carbon and at the metal surface is impossible.

The data presented confirm the assumption that the oxygen electrode potential is a mixed potential described by

$$\varphi = \varphi_0 \frac{RT}{zF} \ln \frac{[HO_2^-][OH^-]}{[O_2][H_2O]}$$

Potential differences between different electrocatalysts, e.g., between activated carbon and platinum carbon (e.g., at sandwich electrodes), measured under identical conditions, can be explained at least partially using this equation. With a very active peroxide decomposing catalyst (e.g., platinum), the peroxide concentration is low, resulting in less potential loss.

The most important part of the overpotential (the corresponding diffusion resistances are given in Table II) is due to the diffusion of oxygen to the reaction sites. Various items which are consistent with this view are: (i) low solubility of oxygen in water, about 10^{-3} to $10^{-4}M$ (16), (ii) a small diffusion coefficient, about 0.675×10^{-5} cm²/s (17), (iii) the limited oxygen concentration in air, and (iv) inert gas accumulation in the porous system. Together, these cause a diffusion overpotential of 48%-91% of the total overpotential. According to the theory of the Nernst diffusion impedance, the concentration of the diffusing species as well as the thickness d of the diffusion layer can be calculated with the equations already mentioned

$$d = \frac{A\sqrt{2D}}{2} \quad c_{sur} = \frac{R \cdot T \cdot d}{z^2 \cdot F^2 \cdot R_{diff} \cdot a \cdot D}$$

With the diffusion factors and the diffusion resistances measured in our experiments, values of d ranging from 1 to 275 μm were obtained (depending on i_{DC} , the electrode composition and other experimental conditions) [for details, see Ref. (8)]. These values are in some cases of the same order of magnitude as the thickness of the active layer of the electrode (300-400 μm). This is in disagreement with the classical theory [see e.g., Ref. (11)] of diffusion layers at electrode-electrolyte interfaces, although the values are plausible if one assumes an oxygen concentration gradient from the gas phase outside the electrode to the inner electrode surface. Nevertheless, it seems useful to discuss the diffusion layer theory again for the case of a porous gas-diffusion electrode.

The assignment of the diffusion impedance to the diffusion of the reduction products into the electrolyte is straightforward and depends only on the composition of the catalyst. At platinum/carbon and silver/carbon electrodes, the hydrogen peroxide is decomposed rather fast. The diffusion layer thickness and the concentration of the diffusing species calculated from the impedance parameters can only be associated with the OH^- transport into the bulk electrolyte (3M NaCl). (The OH^- concentration calculated from the results given in Table II is about $10^{-1}M$.) At activated carbon electrodes operating in 6M KOH electrolyte, this diffusion impedance cannot be at-

tributed to the diffusion of OH^- produced during the reduction of oxygen, since the concentration of OH^- obtained from the diffusion resistance would be below the concentration in the bulk electrolyte. Since the product of the reduction of oxygen at smooth carbon electrodes is only hydrogen peroxide (14), this impedance must be attributed to the diffusion of hydrogen peroxide. The concentration values calculated from the measured impedances range from 3.1×10^{-2} to $7.5 \times 10^{-2} M$ (depending on i_{dc}) and agree well with the results obtained at smooth electrodes (14).

Compared with the rather straightforward situation at a planar electrode (with well-defined transport of the reactants) the situation in a porous electrode is more complex. One of the most surprising results concerning the phase boundaries in the gas diffusion electrodes studied in this paper is the low utilization of the inner surface.

The comparison of the electrochemically active surface, the wetted surface, and the total surface area of the electrode obtained from BET measurements has been the subject of many papers published in recent years. Of particular interest are results obtained with activated carbons, graphites, charcoals, and related materials. BET surface areas of these materials range from values as low as $10 \text{ m}^2/\text{g}$ (SP-1 graphite) to as high as $1600 \text{ m}^2/\text{g}$ (Norit-BRX activated carbon). In order to obtain true double-layer capacities, many authors have assumed a complete wetting of the total surface area with the electrolyte. The measured apparent double-layer capacity, in most cases obtained from cyclic voltammograms, was divided by the BET surface area to calculate a true double-layer capacity related to the actual electrode surface. Some representative results are: $3.7 \mu\text{F}/\text{cm}^2$ for Ketjenblack (Armak) (18), $4.3 \mu\text{F}/\text{cm}^2$ for Carpack B, graphitized carbon black (Supelco) (19), $8 \mu\text{F}/\text{cm}^2$ for XC-72 (Cabot) (20), $9.5\text{--}10.7 \mu\text{F}/\text{cm}^2$ for FC-12 (St. Mary's Penn) (28), $10 \mu\text{F}/\text{cm}^2$ [several carbons (22)], $12 \mu\text{F}/\text{cm}^2$ for RB-activated carbon (Calgon) (18), and $19 \mu\text{F}/\text{cm}^2$ for Shawinigan black (Gulf) (18). Unfortunately, there are some inherent limitations and drawbacks in the application of dynamic methods for porous electrodes, as has already been discussed by de Levie (23).

Especially in experiments with high surface area carbons like Ketjenblack or RB, the long relaxation time caused by the extended internal structure of the porous electrode may have affected the results. The assumption of a totally wetted surface is also in obvious contradiction to the results of Momot *et al.* (24) and Lore *et al.* (25), which state that only a small fraction of the BET surface area of the activated carbons and graphites investigated was accessible to the electrolyte and, therefore, at least potentially electrochemically active.

Double-layer capacities obtained at smooth carbon electrodes are not useful in clarifying this contradiction. The published results depend very much on the type of the carbon and the pretreatment. Examples are: $3 \mu\text{F}/\text{cm}^2$ [basal plane of peeled stress annealed pyrolytic graphite (SAPG) (26, 27)], $12 \mu\text{F}/\text{cm}^2$ [ordinary pyrolytic graphite (OPG) basal plane, cleaved (28)], $25 \mu\text{F}/\text{cm}^2$ [glassy carbon, (29)], and $60 \mu\text{F}/\text{cm}^2$ [OPG, basal plane polished (28), and SAPG edge oriented polished (26)].

Using advanced BET-adsorption instruments, the pore volume distribution and the surface area distribution as a function of the pore diameter can be measured. The results can be used for the interpretation of changes in the electrochemical activity of a carbon as a function of changed surface area and surface area distribution for certain electrode reactions (30). However, they are only of limited value for the discussion of the ratio of BET surface area to wetted surface area, unless the microscopic structure of the carbon particle surface and the wetting properties are not well known (31). This situation is further complicated, when electrochemical measurements are done with Teflon-bonded electrodes, *e.g.*, as in Ref. (18), where parts of the carbon may have become hydrophobic.

An additional difficulty is introduced when the double

layer capacity of an operating electrode ($i_{dc} \neq 0$) is determined. According to Schwabe *et al.* (32), only pores of diameter greater than 100 \AA contribute to the current generation during the reduction of oxygen at activated carbon electrodes in alkaline solution. The penetration depth of the electrochemical reaction as well as the penetration depth of the ac signal used in the impedance method into the porous electrode are limited. A detailed discussion with respect to the electrodes used in our experiments is given in Ref. (33).

According to the results and conclusions obtained by Wabner (4) and Holze (33), it is assumed that the measured apparent double-layer capacity resembles the electrochemical active surface area involved in the reduction of oxygen. Since the assumption of a true double layer capacity of $C_D = 10 \mu\text{F}/\text{cm}^2$ seems reasonable with respect to the results published previously and the fact that the carbons used in our experiments are similar to the carbons used in some of the papers mentioned above (18, 19, 22), this value was used to calculate the surface factor S , the surface area involved in the electrochemical reaction, and the exchange current density i_0 .

Only about 0.5% of the BET surface area of the Pt/C electrode is involved in the electrochemical reaction. The wetted surface area may be greater; based on a porosity of 28% and a simplified model of the porous structures assuming cylindrical pores of 100 nm avg diam, it was concluded that about 5% of the BET surface area is wetted. This is in good agreement with, *e.g.*, the value of 2%–5% obtained with Teflon-bonded platinum-black in $1N \text{ H}_2\text{SO}_4$ reported by Austin and Almaula (34).

Kunz and Gruver discussed the utilization of an electrode prepared from carbon-supported platinum (35). From transmission electron microscopy, they calculated a surface area of the platinum of $175 \text{ m}^2/\text{g}$; from the hydrogen adsorption on the platinum, a surface of $70 \text{ m}^2/\text{g}$ was calculated. From the comparison of polarization curves obtained during oxygen reduction experiments in H_3PO_4 on the porous electrodes described with results obtained with smooth platinum electrodes, the authors concluded that about $70 \text{ m}^2/\text{g}$ of the platinum surface was electrochemically active. The discrepancy with the higher values estimated using transmission electron microscopy was attributed to several processes leading to the loss of active surface area. The double-layer capacity and the BET surface area of the electrodes under investigation were not determined; thus, a careful comparison with our results is not possible.

Although several other authors in addition to Austin and Almaula (4, 36, 37) have obtained low utilization values somewhat at variance with the results of Kunz and Gruver, a comparison between different porous electrodes is difficult due to the often poorly understood influence of parameters such as internal structure, surface distribution, degree of interaction between catalyst and Teflon, contact angle, etc., on the actual value of the surface area under discussion.

The active surface area of the electrode can be represented as a very thin reaction zone of, *e.g.*, $1.3 \mu\text{m}$ thickness in case of the Pt/C electrode described. This zone must be localized near the electrolyte-side surface of the electrode. Similar conclusions have been reached by other authors (4, 34, 36, 37).

The results obtained at our electrodes can be explained using the semihydrophobic porous electrode model described by Burshtein *et al.* (38). In this model, Teflon agglomerates form gas channels across the electrode which are surrounded by catalyst-Teflon mixture wetted with electrolyte. At variance with the results given by Burshtein *et al.* (38), in the electrodes investigated here, oxygen reduction obviously occurs preferentially in a small reaction zone located near the electrolyte-side surface of the electrode, probably at the electrolyte-side ends of the gas channels. In this case the diffusion pathways for oxygen and reduction products both are at a minimum. This situation is the most favorable one, since oxygen diffusion in the electrolyte is slower than in the gas-filled channels. If

the reaction zone moves toward the gas side, the diffusion overpotential due to the diffusion of the products will increase. This is demonstrated during the lifetime of the electrode when the loss of hydrophobicity results in flooding of the electrode and increased overpotential due to oxygen diffusion. Additionally, the applicability of this model is favored by the results of our C_p measurements at various Teflon-bonded electrodes of different composition (6).

The situation in the Prototech electrode is slightly different. In this electrode, no porous Teflon backing layer is used. The three-phase boundary is established by the hydrophilic properties of the active layer and a small overpressure of the feed gas. The feed gas was supplied in greater than stoichiometric amounts. This resulted in a diminution of the diffusion overpotential due to gas transport when air was used, since the accumulation of inert gas, which was observed at electrodes with a porous Teflon backing layer, cannot take place. The actual location of the reaction zone in this electrode depends both on the hydrophilicity of the electrode and the feed gas overpressure. Under the experimental conditions applied here, the thickness of the diffusion layer for oxygen as well as that for reduction products, as calculated from the diffusion impedances, is equal. This indicates that the location of the reaction zone is equidistant from both outer-electrode surfaces (6).

Conclusions

The kinetics of oxygen reduction at porous electrodes fabricated from dispersed Teflon and electrocatalysts (Pt/C, Ag/C, activated carbon) as described here are mainly diffusion controlled. In all cases, the reduction of oxygen to hydrogen peroxide prevails, followed by an effective decomposition to water and oxygen in the metal containing electrodes. If the electrode is covered with a porous Teflon backing layer on the gas side, oxygen reduction occurs in a small reaction zone located near the electrolyte side. The thickness of this zone is typically 1.3 μm (compared with a total thickness of the active layer of 0.3-0.4 mm). The utilization of the catalyst is poor.

These results indicate that further development of such electrodes should aim at thin electrodes with homogeneous distribution of the catalyst or at sandwich electrodes with a very thin active layer localized on the electrolyte-side surface. A similar approach has been described by Iliev *et al.* (39). The effectiveness of the electrocatalyst must be judged with respect to parameters such as electrode structure, wetting properties, and Teflon content. These influence the diffusion processes, which produce the major part of the still high overpotential of the porous oxygen electrode.

Electrochemical Deposition, Optical Properties, and Photoelectrochemical Behavior of CdTe Films

Makoto Takahashi, Kohei Uosaki,* and Hideaki Kita

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

ABSTRACT

Electrochemical deposition of cadmium telluride from acidic solutions containing CdSO_4 and TeO_2 is studied and the current-potential expression for this reaction is presented. The electrochemically deposited CdTe films are photoactive, and the maximum cathodic photocurrent due to hydrogen evolution is observed at CdTe films deposited at -0.40V . The photocurrents of the as-grown CdTe films are relatively small compared with those of CdTe single crystals. The major reason for this low efficiency is the effective recombination of hole-electron pairs at grain boundaries and at the surface. The photocurrents are increased significantly by the increase of crystallite diameter by the heat-treatment in a He atmosphere and by the removal of surface Te, which acts as a recombination center, by the etching treatment.

Since cadmium telluride (CdTe) is a direct gap semiconductor with a room temperature energy gap of 1.44 eV (1) and can readily be prepared in both n- and p-type form (2), it is considered to be a promising material for low cost thin film photovoltaic and photoelectrochemical cells. A variety of methods, such as liquid-phase epitaxial growth (3), vacuum evaporation (4), chemical transport (5), and direct combination method (6), have been employed to form CdTe thin films on foreign substrates. CdTe can also be deposited electrochemically from a solution containing CdSO_4 and TeO_2 (7). The electrochemical deposition has the following advantages. The thickness of the film can be controlled by the charge passed during the deposition, both n-type and p-type material can be formed by just changing the deposition potential, and the doping is performed easily by adding the foreign species other than CdSO_4 and TeO_2 in the solution.

Several papers on the photoelectrochemical behavior of CdTe single crystals (8-12) and CdTe thin films (13-16) have been published. Although one of us reported that p-CdTe is a stable photocathode for photoelectrochemical generation of hydrogen (8, 9), most of the work was on n-CdTe in solution containing redox couples as stabilizing agents. Photoelectrochemical studies on electrochemically deposited CdTe films published so far are all on n-CdTe (15, 16), except one, which we published recently as a preliminary note of this work (17).

In this paper, we investigate the electrochemical deposition of CdTe films and report the photoelectrochemical characteristics of the CdTe films deposited at several potentials ($-0.2 \sim -0.6\text{V vs. Ag/AgCl}$) and the effect of annealing and etching treatment on the optical and photoelectrochemical properties of the electrochemically deposited CdTe films.

Experimental

The CdTe films were deposited from aqueous solutions of pH 1.4 containing CdSO_4 and TeO_2 on Ti or Ni (The Japan Lamp Industrial Company, Limited) sheets which were degreased by chloroform and ethanol vapor and washed in purified water before use. The reagent-grade H_2SO_4 , NaOH, CdSO_4 (purity 99.5%), and TeO_2 (purity 99%) were used without further purification. Water was purified by Milli Q water purification system (Millipore Corporation). The usual three electrode cells were used both for the preparation of CdTe films and for the photoelectrochemical measurements. A platinum sheet and a Ag/AgCl electrode were used as a counter and a reference electrode, respectively. A Hokuto Denko HA-301 potentiostat with a Hokuto Denko HB-105 programmable function generator or a Wenking Model 68 FRO.5 potentiostat was used for the potentiostatic deposition of CdTe films and photoelectrochemical measurements. Photoelectrochemical measurements were carried

out in 1M NaOH. A 300 or 500W Xe lamp (Usio Denki Company, Limited) with an IR absorbing filter (Toshiba, IRA-20) was used as a light source. A monochromator (Ritsu Oyo Kogaku Company, Limited) was used to obtain photocurrent action spectra. In all the measurements, currents were recorded on a Rika Denki RW-11T X-Y-t recorder. The electrochemical deposition and photoelectrochemical measurements of the films were carried out at room temperature after the electrolyte solutions were deaerated by passing purified He gas for about 20 min. The heat-treatments of the films were carried out in a quartz tube under a He gas flow. The etching treatment of the films was carried out in a solution containing 0.6M $\text{Na}_2\text{S}_2\text{O}_4$ and 2.5M NaOH at 80°C (18).

The type of semiconductivity of the CdTe films was determined by measuring the potential difference between a hot and a cold contact. The thickness of the films was determined by using a Surfcom 300B surface roughness measuring instrument (Tokyo Seimitsu Company, Limited). The reflection spectra of the films were recorded by a Beckman DK-2 reflectometer. X-ray diffraction measurements were carried out by using a Toshiba XC-40 x-ray diffractometer.

Results

Electrochemical deposition of CdTe.—The current-potential (*i*-V) relation of a Ni sheet electrode in a solution containing 1M CdSO_4 , 1 mM TeO_2 , and 0.05M H_2SO_4 is shown in Fig. 1. Limiting current was observed at potentials between -0.30 and $-0.65\text{V vs. Ag/AgCl}$. The cathodic current increased significantly at potentials more negative than -0.65V . The *i*-V relations were affected by TeO_2 concentration very strongly, and a linear relation was observed between TeO_2 concentration and the limiting cur-

rent, as shown in Fig. 1. However, CdSO_4 concentration affected the i-V relations little. The limiting current was larger when the solution was stirred. The thickness of the film and the charge passed during the deposition, Q_{dep} , are linearly correlated as shown in Fig. 2. The film thickness was found to be uniform throughout the film ($\pm 5\%$). As already reported, x-ray diffraction patterns of the deposited films confirmed the formation of CdTe (19). The x-ray diffraction peak due to Te was also observed in the films deposited at relatively positive potentials. The more positive the deposition potential, the stronger the diffraction peak due to Te (19). Cd deposition was not observed at the potential region employed in this study ($-0.20 \sim -0.60\text{V vs. Ag/AgCl}$). CdTe films deposited at relatively positive potentials were p-type, and those deposited at relatively negative potentials were n-type.

Optical properties and photoelectrochemical behavior of as-grown CdTe films.—A typical example of the diffuse reflection spectra of as-grown CdTe films is shown in Fig. 3. The wavelength dependence of the reflectivity was very small, and the energy gap was not able to be determined.

The photocurrent-potential relations of CdTe films deposited at various potentials are shown in Fig. 4. The most efficient cathodic photocurrent-potential relation was observed at the CdTe films deposited at -0.40V . The films deposited at the potentials at either more negative or more positive than -0.40V gave lower photocurrent, and no cathodic photocurrent was observed at CdTe films deposited either more positive than -0.20V or more negative than -0.55V . Even the highest cathodic photocurrent observed was relatively small compared with that at p-CdTe single crystals (9). The observed cathodic photocurrent at relatively positive potential seemed to be due to hydrogen evolution reaction, as suggested by bubble formation. The photocurrent increased significantly when the potential became more negative than -0.85V , and it seemed to be due to the cathodic decomposition of CdTe, as color of the solution near the electrode became purple, suggesting Te_2^{2-} formation.

Effect of heat-treatment.—By the heat-treatment at 200°C in a He atmosphere, the x-ray diffraction peaks due

Fig. 2. The thickness of the electrochemically deposited films on Ni as a function of charge passed. The deposition was carried out at -0.35V (vs. Ag/AgCl) in a sulfuric acid solution (pH 1.4) containing 1M CdSO_4 and 1mM TeO_2 . Solid line shows the theoretical value calculated by assuming six-electron process.

Fig. 3. Diffuse reflection spectra of the electrochemically deposited films ($3\ \mu\text{m}$ thick) on Ti substrate. The other deposition conditions are the same as those in Fig. 2. Curve 3: Etched in a solution containing $0.6\text{M Na}_2\text{S}_2\text{O}_4$ and 2.5M NaOH at 80°C after heat-treatment in a He atmosphere at 200°C for 12h.

to CdTe became stronger and sharper by the increase of annealing time, but the peak due to Te was not affected by this treatment (17). The crystallite diameter calculated by using Scherrer equation (20) with the value of the full width at half maximum (FWHM) of x-ray diffraction peak due to (311) face of CdTe as well as the photocurrent increased with increase of annealing time, as shown in Fig. 5. By the heat-treatment, the reflection spectra of the CdTe films became clearer, as shown in Fig. 3. The band-edge energy determined from the reflection spectra is 1.45eV and is in good agreement with the value reported for CdTe single crystal (1). The photocurrent-wavelength relation also showed the same energy gap (17).

Effect of etching treatment.—The effect of the etching treatment was studied at p-CdTe films which were deposited at -0.35V and annealed at 200°C in a He atmo-

Fig. 5. Photocurrent at $-0.65V$ (vs. Ag/AgCl) in $1M$ NaOH under illumination of $300W$ Xe lamp and crystallite diameter of the electrochemically deposited films ($3 \mu m$ thick on Ti) as a function of annealing time. Deposition conditions are as same as those in Fig. 2.

sphere for 12h. As shown in Fig. 6, the intensity of x-ray diffraction peak due to Te decreased and that of x-ray diffraction peaks due to CdTe increased with the increase of the etching time. The FWHM of CdTe peaks was not affected by the treatment, suggesting the crystallite diame-

Fig. 6. X-ray diffraction patterns of the films deposited at $-0.35V$ (vs. Ag/AgCl), heat-treated at $200^\circ C$ in a He atmosphere for 12h and etched in a solution containing $0.6M$ $Na_2S_2O_3$ and $2.5M$ NaOH at $80^\circ C$ for several time periods. Curve 1: No etching treatment. Curve 2: 2s. Curve 3: 10s. Curve 4: 40s.

ter did not change during the treatment. The etching treatment also increased the photocurrent. The etching time dependence of the intensity of x-ray diffraction peaks and the photocurrent at $-0.70V$ are shown in Fig. 7. The effect of etching on the reflection spectra is shown in Fig. 3. The absorption edge became much clearer by this treatment. By the too-long treatment, however, the photocurrent as well as the intensity of x-ray diffraction peaks due to CdTe decreased, suggesting that, not only Te, but also CdTe dissolved during the etching treatment.

Discussion

Panicker *et al.* studied the cathodic deposition of CdTe mainly by galvanostatic method (7) and proposed that the following reactions were involved in the formation of CdTe

and that the diffusion of $HTeO_2^+$ preceding reaction [1] is the rate-determining step. The results of the present work also support this mechanism. The current due to reaction [1] at diffusion limited region, i_{Te} , is given by

$$i_{Te} = -\frac{4DFc_{HTeO_2^+}}{\delta} \quad [3]$$

where D and $c_{HTeO_2^+}$ are the diffusion coefficient and the bulk concentration of $HTeO_2^+$, and δ is the diffusion layer thickness. The current due to reaction [2], i_{CdTe} , is given by

$$i_{CdTe} = -2Fk'c_{Cd^{2+}}\theta_{Te}e^{-\alpha F\Delta\phi/RT} \quad [4]$$

where k is the rate constant, $c_{Cd^{2+}}$ is the concentration of Cd^{2+} , θ_{Te} is the surface coverage of Te, α is the transfer coefficient and $\Delta\phi$ is the potential difference across the interface. By considering mass balance, θ_{Te} is given by

$$\theta_{Te} = k'f_{Te} = k' \frac{i_{Te}/4 - i_{CdTe}/2}{i_{Te}/4} \quad [5]$$

where f_{Te} is the fraction of Te at the surface of the films and k' is a proportional constant. From Eq. [3], [4], and [5]

$$\theta_{Te} = \frac{k'Dc_{HTeO_2^+}/\delta}{(Dc_{HTeO_2^+}/\delta) + kk'c_{Cd^{2+}}e^{-\alpha F\Delta\phi/RT}} \quad [6]$$

By using Eq. [3], [4], and [6], the total current, i , is given by

$$i = i_{Te} + i_{CdTe} = -\frac{DFc_{HTeO_2^+}}{\delta} \left(4 + \frac{2kk'c_{Cd^{2+}}e^{-\alpha F\Delta\phi/RT}}{(Dc_{HTeO_2^+}/\delta) + kk'c_{Cd^{2+}}e^{-\alpha F\Delta\phi/RT}} \right) \quad [7]$$

Fig. 7. Etching time dependence of (a) the intensity of x-ray diffraction peaks due to CdTe (111) face (\square) and Te (\circ) and (b) the photocurrent in $1M$ NaOH at $-0.70V$ (vs. Ag/AgCl) under illumination of $500W$ Xe lamp with an IR absorbing filter. Experimental conditions are the same as those in Fig. 6.

Thus, the current should be proportional to the bulk concentration of HTeO_2^+ , i.e., TeO_2 , as observed experimentally. The more negative the potential is, the higher f_{CdTe} and the less free Te are expected from Eq. [6]. Experimental results also confirmed this expectation. When $D_{\text{HTeO}_2^+}/\delta \ll k'c_{\text{Cd}^{2+}}e^{-\alpha F\Delta\phi/RT}$, i.e., the potential is very negative and $\theta_{\text{Te}} \approx 0$, then Eq. [7] becomes

$$i = - \frac{6DFc_{\text{HTeO}_2^+}}{\delta} \quad [8]$$

By assuming that the film is mainly CdTe, that the density of CdTe is 6.2, and that the deposition of CdTe is a six-electron process, as Eq. [8] shows, the current efficiency is calculated as 75% from the data of Fig. 2. The other reaction involved may include the reduction of oxygen, which is left in small amount despite the deaeration before the experiment. The other supporting evidence for this mechanism is that only the films deposited electrochemically at the potentials more negative than -0.25V were photoactive while the standard redox potential of reaction [2] is calculated as -0.155V (vs. Ag/AgCl).

As far as the films deposited at the potentials more positive than -0.40V were concerned, the more negative the deposition potential, the higher the photocurrent. One reason for this seems to be that the amount of free Te left is smaller, and another is that the amount of CdTe is larger in the films deposited at more negative potentials. Free metal is known to act as an electron-hole recombination center and reduce the photoconversion efficiency (21). The higher concentration of CdTe naturally increases the photoresponse. The films deposited more negative than -0.45 are n-type (19), and the more negative the deposition potentials, the lower the cathodic photocurrent.¹

As mentioned before, the photocurrents of the as-grown CdTe films were much smaller than those of CdTe single crystals. Since the usual cause of small efficiency is the effective recombination of hole-electron pairs at grain boundaries and at the surface, the increase of grain size by heat-treatment and removal of surface recombination center by etching treatment are considered to improve the photoconversion efficiency. As shown in Fig. 5, the heat-treatment increases the crystallite diameter as well as the photocurrent. Due to the increase of the crystallite diameter, the number of grain boundaries decreases, and therefore the photoconversion efficiency should be increased. In this case, since the amount of free Te was not affected, only the crystallite diameter affected the photocurrent.

The fact that no diffraction peak due to Te was observed in the x-ray diffraction patterns after the etching treatment suggests that the free Te existed mainly near the surface.² The Te at CdTe surface would act as a surface recombination center which should decrease the photocurrent. As shown in Fig. 7, the photocurrent was increased by removing the surface Te and, thus, it is confirmed that the surface Te was also responsible for the small photocurrent. The fact that the x-ray diffraction peaks due to CdTe were increased and the reflection spectra became much clearer by the etching treatment is explained by the removal of the surface Te-rich layer. This was supported by the fact that FWHM of x-ray diffraction peaks due to CdTe was not changed by the etching treatment.

Conclusion

1. The current-potential expression for the electrochemical deposition of CdTe films is presented.

¹ The anodic photocurrents were observed at potentials more positive than ca. -0.40V .

² The effect of Ar⁺ sputtering on Auger spectra also support this result (19).

2. The electrochemically deposited CdTe films are photoactive, and the maximum cathodic photocurrent which is due to hydrogen evolution reaction is observed at CdTe films deposited at -0.40V (vs. Ag/AgCl). The photocurrents at CdTe films deposited at more positive potentials than -0.40V are smaller because the amount of free Te, which acts as a surface recombination center, is larger, and, accordingly, the amount of CdTe is smaller. The photocurrents at CdTe films deposited at potentials more negative than -0.40V are smaller because the CdTe films deposited at these potentials are n-type.

3. The photocurrents of the as-grown CdTe films are relatively small compared with those of CdTe single crystals. The major reasons for this low efficiency are the effective recombination of hole-electron pairs at grain boundaries and at the surface. The photocurrents are increased significantly by the increase of crystallite diameter by the heat-treatment in a He atmosphere and by the removal of surface Te, which acts as a recombination center, by the etching treatment.

Thermal Decomposition of Dimethoxymethane Electrolyte Solution

J. S. Foos*

EIC Laboratories, Incorporated, Norwood, Massachusetts 02062

Ethereal solutions of LiAsF_6 have shown promise for use as electrolytes in lithium batteries. Solutions of LiAsF_6 in 2-methyltetrahydrofuran (2-MeTHF) and in ether blends with diethylether (DEE) have demonstrated the ability to cycle lithium in high efficiency in Li/TiS_2 laboratory cells (1, 2).

The ability of 2-MeTHF electrolyte to cycle Li well is reflected in its superior thermal stability toward Li in storage tests at 70°C (3). Other electrolytes which react in storage tests give lower Li cycling efficiencies in Li/TiS_2 cells (2, 4). Although the reactivity observed in the above tests can be attributed to reaction with Li, many ether electrolytes also react at elevated temperatures (100°C) in the absence of Li (5).

During the investigation of various ethers for use as electrolytic solvents in lithium batteries, dimethoxymethane (DMM) was chosen for testing. Solutions of LiAsF_6 in DMM allowed the cycling of the Li electrode in high efficiency (6). Unfortunately, this high efficiency was not realized in Li/TiS_2 cells (7). In order to rationalize this discrepancy, investigations into the thermal stability of DMM electrolytes were initiated. Storage tests at 70°C were conducted with solutions of LiAsF_6 in DMM in the presence and absence of Li. The visual results with this ether are similar to those previously reported for other ethers.

However, dramatic differences were observed in ether reactivity which are detected only through analysis of the reaction products. The simple structure of DMM and its decomposition products allow the use of NMR spectroscopy in determining the stoichiometry of its decomposition reaction. A mechanism for the decomposition is proposed based on the identity of the reaction products and the ratio in which they are produced.

Experimental

All purification procedures subsequent to distillation and storage test preparations were conducted at ambient temperature under Ar atmosphere in a Vacuum-Atmospheres Corporation dry box equipped with a Model He-493 Dri-Train. The DMM (Aldrich) was dried with MgSO_4 , followed by molecular sieves. The solvent was then distilled from Na benzophenone ketyl. The lithium hexafluoroarsenate (LiAsF_6) (U.S. Steel Agri-Chemicals, electrochemical-grade) was used as received. Lithium foil (15 mil) was obtained from Foote Mineral Company sealed under Ar.

Activated neutral alumina (Woelm 200 neutral, activity-grade Super 1) was used as received and exposed only to the dry box atmosphere. Approximately 1g desiccant per 5 ml solvent was used in a given purification procedure.

The electrolytes for storage tests were prepared by adding LiAsF_6 with cooling, using Cu shot previously cooled in Dry Ice. The solvents, if treated with alumina, were passed through a column of activated alumina, and the first 10% was discarded.

Generally, the stability tests were conducted by storing a sample of electrolyte (3-10 ml) at 70°C in the absence or presence of Li (1-2 cm^2). The samples were contained in

test tubes with Teflon-lined screw caps. The threads of the test tube were wrapped with Teflon tape. The DMM electrolyte storage test which was analyzed by NMR spectroscopy was conducted in a 5 mm (0.8 mm wall) NMR tube. The sample was placed in the tube in the dry box and then attached to a vacuum line. The sample was outgassed in three freeze-thaw cycles and then the tube sealed under vacuum while the sample was frozen in liquid nitrogen (LN_2).

The test tube storage samples were analyzed by IR spectroscopy (Beckman Acculab 5) using a 10 cm gas cell (at ~ 20 torr). The sample was first frozen (LN_2) and then quickly fitted with an adapter which could be attached to a vacuum line. The sample was then allowed to warm, and aliquots were collected in the IR cell.

The proton NMR analyses were done using a JEOL FX-90Q spectrometer (Biomeasure Incorporated, Hopkinton, Massachusetts). The sample in the 5 mm NMR tube was supported in a 10 mm NMR tube using a Teflon spacer. This outer tube contained the deuteriochloroform for the deuterium lock and the tetramethylsilane (TMS) external standard. The chemical shifts are reported as ppm downfield from TMS. To determine the effect of the external TMS on chemical shift values, spectra of DMM solvent were run with internal and external TMS. The chemical shifts were $\delta 3.26(6\text{H})$ and $\delta 4.47(2\text{H})$ [lit 3.23 and 4.40, Ref. (9)] with internal TMS; and $\delta 2.74(6\text{H})$ and $\delta 3.95(2\text{H})$ with external TMS, giving a change of -0.52 ppm with external TMS. This shift must be due to inhomogeneity in the magnetic field.

Results

Stability tests were carried out with solutions of 1.5M LiAsF_6 in DMM at 70°C with and without Li metal. The samples containing Li showed relatively little reaction, with the best samples showing no reaction after 30 days. The most stable samples appeared to be those prepared from distilled solvent which was subsequently treated with alumina (DA).

In contrast, when samples were stored without Li, the (DA) samples turned dark in 5-7 days. Samples which had not been treated with alumina (D) remained colorless from 11 to 17 days. In either case it is clear that the DMM electrolyte solution is stabilized by Li.

IR analysis.—A sample of DMM electrolyte that had turned dark due to storage at 70°C was analyzed by IR spectroscopy. This analysis was done by slowly warming the cooled sample which was attached to a vacuum line. Aliquots of the vapor which were collected in the vacuum line were then analyzed in an IR gas cell. Surprisingly, the sample was found to contain little or no DMM. The IR spectra contained only absorptions which are attributed to methyl formate and dimethyl ether. The methyl formate absorptions were identical to those obtained from an authentic sample (Eastman). The dimethyl ether absorptions were identical to a published spectrum (8).

Proton NMR analysis.—In order to positively identify the products, to assess the stoichiometry of the reaction, and to search for minor products, the decomposition was

* Electrochemical Society Active Member.

repeated in an NMR tube. A sample of 1.5M LiAsF₆/DMM was sealed in a 5 mm NMR tube which was stored at 70°C. At time intervals, the sample was removed and analyzed by proton NMR spectroscopy. After decomposition, the spectrum show a small amount of residual DMM along with methyl formate and dimethyl ether. All chemical shift values, even after correction for external TMS, show considerable deviation from literature values. This can be attributed to the presence of 1.5M LiAsF₆ in solution.

The chemical shifts for DMM, methyl formate, and dimethyl ether observed above are listed in Table I. This table also shows that when authentic methyl formate is added to DMM electrolyte solution, the chemical shift values of the methyl formate are near those attributed to the methyl formate in the storage test. It can be noted that as the amount of DMM in the sample decreases, the chemical shifts decreases in value. At the end of the experiment, methyl formate and dimethyl ether were present in a 1:2 ratio, as determined from integration of the NMR absorptions. At 5 days storage at 70°C, there was no change in the appearance of the NMR sample and no change in the NMR spectrum. At 9 days, the sample was dark brown, and the NMR analysis showed that the decomposition was 35% complete. At 16 days, a white precipitate appeared, and the reaction was 90% complete (based on the ratio of DMM to methyl formate signals in the NMR spectrum).

This experiment establishes that the decomposition gives almost exclusively 1 mol methyl formate and 2 mol dimethyl ether. The balanced equation for this reaction is shown in Eq. [1]

The brown color may be associated with the beginning of the decomposition of DMM. In contrast, a sample of LiAsF₆/2Me-THF electrolyte solution, which had turned brown as a result of storage at 70°C, showed no trace of 2-MeTHF decomposition when analyzed by proton NMR spectroscopy.

Discussion

The dark coloration is typically observed when LiAsF₆ ether solutions are stored at elevated temperatures. This coloration is not observed in storage tests with LiClO₄ (5), implying that the color is associated with the salt rather than the ether. Additionally, it has been observed that the time of onset of color depends on the purification technique used in preparing solvent, e.g., DMM/LiAsF₆ (DA) reacts more rapidly than DMM/LiAsF₆ (D). These observations imply that the color is a result of decomposition of AsF₆⁻ and that the decomposition of the solution is affected by impurities remaining after solvent purification or due to solvent decomposition. The decomposition products of AsF₆⁻ are expected to be acidic and/or strongly oxidizing. The polymerization of dioxolane is rapid in the presence of LiAsF₆, due to the influence of the AsF₆⁻ anion (10). This polymerization presumably operates in a cationic mechanism.

The above considerations imply that a cationic mechanism might be used to explain the decomposition of

DMM to methyl formate and dimethyl ether. The observation that the presence of Li metal retards the decomposition reaction is consistent with this hypothesis.

Treatment of DMM with an oxidizing agent would be expected to give an oxygen stabilized cation, especially in the absence of a strong nucleophile (11). This oxidation, Eq. [2], as well as the reaction in Eq. [3], are initiation steps in a proposed chain reaction. The oxidation may result from the slow decomposition of LiAsF₆ or from trace impurities, such as O₂. In either case, only a very small amount of oxidation (initiation) can eventually destroy the total amount of DMM. The fact that the solution is stabilized by Li implies that the oxidizer is a trace impurity or produced very slowly.

It is important to note that the prominent nucleophiles in the DMM-LiAsF₆ solution are the AsF₆⁻ anion, which would be poorly nucleophilic (the anion of a strong acid), and the ether itself. The expected cation, I, would be stabilized by the presence of two oxygen atoms, Eq. [2]

Alternately, the cation I could also be formed from acidic impurities. The instability of acetals like DMM is well known in acidic aqueous solution. In the absence of H₂O, an additional molecule of solvent might be expected to react with an acid-base (ether) complex, Eq. [3], to give the dimethyl ether cation (II)

This cation undoubtedly exists in solution in the form of an oxonium ion formed with a molecule of solvent (12). However, it also could react with DMM via hydride transfer to give the same stabilized intermediate, I, described above (see also Eq. [5]). A similar reaction was used to form the 1,3-dioxolan-2-ylum ion (12), (Eq. [4])

The cation I, although relatively stable, may decompose by methyl transfer to a solvent molecule, forming an oxonium ion (III). This oxonium ion could, in turn, decompose giving the intermediate II, which reacts with DMM (with a hydride transfer), regenerating the cation I. These reactions, shown in Eq. [5]-[7], constitute the propagation steps of a chain reaction

Table I. Chemical shifts (ppm, δ) for DMM, methyl formate, and dimethyl ether (corrected to internal TMS)* in 1.5M LiAsF₆/DMM storage test, reference sample, and DMM solvent only

	1.5M LiAsF ₆ /DMM storage sample (70°C)			Reference sample	
	Initial	35% Decomposed	90% Decomposed	Methyl formate added to 1.5M LiAsF ₆ /DMM	DMM solvent only
DMM	3.48(6H) 4.71(2H)	3.44(6H) 4.66(2H)	3.33(6H) 4.54(2H)	3.46(6H) 4.68(2H)	3.26(6H) 4.47(2H)
Methyl formate	—	3.91(3H) 8.22(1H)	3.77(3H) 8.11(1H)	3.93(3H) 8.27(1H)	—
Dimethyl ether	—	3.46(6H)	3.33(6H)	—	—

* A correction factor of 0.52 was added to each of the values observed using external TMS (see "Experimental" section).

This mechanism explains the products and stoichiometry observed. It also explains the reaction-retarding effect of Li metal. It would be expected that cation intermediates would be rapidly reduced on Li to anions which might be insoluble but which would at least disrupt the propagation of the chain reaction. Nucleophilic impurities such as H₂O would be expected to react rapidly with cations to disrupt the chain. Such reactions would be chain-terminating steps.

The alumina while being effective in removing impurities, such as H₂O and peroxides, simultaneously establishes the conditions for the chain reaction. In the presence of Li any residual impurities are scavenged. However in the absence of Li the electrolyte would be more reactive. In Li/TiS₂ secondary cells the electrolyte should be stabilized by the fresh plated Li.

An alternate mechanism for the reaction which might be proposed, is the direct oxidation of DMM by AsF₆⁻ (or by an AsF₆⁻ decomposition product)

It has been suggested that in the case of several ethers (not DMM) that the reactive agent may be AsF₅ produced from the thermal decomposition of LiAsF₆ (4, 5). This could be an initiation step in the proposed chain mechanism. This reaction may become the principal route of decomposition if suitably catalyzed or in the presence of an ether less amenable than DMM to a chain reaction. In our view, this mechanism fails to explain the observed DMM decomposition for several reasons. Although a small amount of white precipitate is observed, it is too little to be the LiF produced if direct oxidation were the major reaction. Actually, the amount of LiAsF₆ in 1.5M LiAsF₆/DMM is insufficient to oxidize the DMM present by this reaction. The IR spectrum of the residual salt left after the decomposition of DMM in a storage test showed a strong peak remaining at 700 cm⁻¹, which corresponds to the AsF₆⁻ absorption. Appreciable oxidation by LiAsF₆ would not be expected in view of its apparently good thermal and solution stabilities (13).

A free-radical mechanism might be proposed as an alternative to the cation mechanism suggested above. However, we do not believe that this is credible. Cation intermediates of the type proposed are known to be stable species, whereas similar free-radical species would be much less stable.

Conclusions

It is observed that DMM electrolyte decomposes thermally to give dimethyl ether and methyl formate. Since methyl formate is unstable towards Li (14), it might be expected that this reaction would seriously degrade the performance of DMM/LiAsF₆ electrolyte in a Li cell. This decomposition reaction may occur during electrolyte preparation or during storage prior to filling the cell.

In the cell, in the presence of the Li negative, the decomposition could be minimized. However, in the bulk

solution, away from the surface of the Li, some decomposition may be initiated by acidic, or oxidizing, impurities introduced during the construction of the cell. If a reaction in the cell, such as AsF₆⁻ decomposition, produces an acid or oxidizing agent, the effects of that reaction will be magnified by the DMM decomposition chain reaction.

Of more general importance, this reaction is an illustration of a type of reaction that can occur only in certain specialized conditions. Such conditions include the presence of a nonreactive, nonnucleophilic anion, i.e., AsF₆⁻, which may stabilize the carbocation intermediates. Required as well is the absence of a reactive nucleophile other than the solvent itself. These conditions are seldom achieved in synthetic organic chemistry but are typical in Li battery electrolytes.

The Role of Oxygen in the Redox Chemistry of Lutetium Diphthalocyanine

M. M. Nicholson*

Rockwell International Science Center, Anaheim, California 92803

T. P. Weismuller

Rockwell International Corporation, Defense Electronics Operations, Anaheim, California 92803

Spectroscopic evidence on the role of oxygen in the redox chemistry of lutetium diphthalocyanine is reported here. The observations indicate an irreversible reaction of oxygen with vacuum-sublimed films of the dye material and a reversible reaction with its solution in dimethylformamide. This behavior can account for several apparent anomalies found in previous investigations.

Since the multicolor electrochromism of lanthanide diphthalocyanine electrode films was reported by Moskalev and Kirin (1), these compounds have been the subject of many chemical and electrochemical investigations (2-11). Although much now is known concerning electron-transfer reactions of the lutetium complex, the exact composition of the green vacuum-sublimed films remains in question. The formula LuHPc_2 , with one labile hydrogen atom, was anticipated from the acidic nature of metal-free phthalocyanine and the strong tendency of rare-earth elements to assume the oxidation state of three.¹ However, Corker *et al.* found that green preparations of lutetium diphthalocyanine were paramagnetic and suggested that this could be due to formation of a salt $\text{LuHPc}_2^+\text{A}^-$ containing an unidentified anion A^- (5). Chang and Marchon confirmed the paramagnetism and reported a mass spectrum corresponding to the composition LuPc_2 (7). For that species, they proposed a radical structure $\text{Lu(III)Pc}_2^{\cdot}$ in which, effectively, one of the organic rings has lost an electron. Collins and Schiffrin subsequently observed the parent masses of both LuHPc_2 and LuPc_2 by field-desorption mass spectroscopy, but they placed more emphasis on finding the mass of LuPc_2 only by the conventional electron-impact technique (9).

Other evidence of the labile hydrogen was obtained by Moskalev and Kirin in a spectrophotometric investigation of tetrasulfonated diphthalocyanines of lutetium, gadolinium, and yttrium in aqueous solutions (2). Spectral changes in the pH range of 6-12 were attributed to a simple acid-base equilibrium involving the imino hydrogen, with the sulfonic acid groups remaining completely ionized. Moreover, two forms of rare-earth diphthalocyanines, one green and the other blue, have been found in chromatographic separations of reaction products from the usual synthesis carried out by heating a rare earth salt with *o*-phthalonitrile. Mackay *et al.* noted that these forms were interconvertible but concluded that a simple acid-base equilibrium relationship between them could be an oversimplification (3).

We proposed, in a 1982 review (8), that the radical and hydrogenated forms could be related through the reaction

Then, in the presence of excess oxygen, the paramagnetic cation could form, in combination with the superoxide anion

Collins and Schiffrin actually found oxygen on the order of stoichiometric amounts in green lutetium diphthalocyanine films by x-ray fluorescence and x-ray photo-

electron spectroscopy (9). They too suggested that O_2^- or OH^- might be the anion in the initial green material. The results presented below offer new insight on the role of oxygen in this system and can be interpreted to account for its influence on certain faradaic processes in diphthalocyanine electrode films.

Film Spectra

Lutetium diphthalocyanine films 0.1-0.2 μm thick were deposited on glass by the usual vacuum-sublimation procedure at $\sim 10^{-5}$ torr. Such films were consistently green and showed no visible change on exposure to air. However, it was found that details of the absorption spectrum could change in air, depending on the substrate temperature during deposition of the film. This behavior is illustrated by Fig. 1 and 2. All spectra reported here were recorded at room temperature. To obtain the film spectrum prior to air exposure, nitrogen at 1 atm was first admitted to the deposition chamber. With an externally controlled manipulator, the dye specimen was then placed in a flat-sided glass cell, and a grease-sealed cover was attached. The protected specimen was promptly transferred to the spectrometer, and its absorption spectrum was determined.

Curve a of Fig. 1 is the typical spectrum of an air-exposed lutetium diphthalocyanine film deposited on an unheated glass substrate. It includes the prominent Q band at the wavelength (λ) of 666 nm, with vibrational

transitions on the short-wavelength side at 575 and 605 nm. The weaker band at 462 nm lies between the Q band and the ultraviolet Soret band characteristic of phthalocyanines.² Curve b of Fig. 1 is the spectrum of the same film recorded under nitrogen before exposure to air. Here, the main peak is lower, at 671 nm, the vibrational transitions are not evident, and the weaker electronic band is slightly shifted to 467 nm. We propose that curve b is the spectrum of solid LuPc_2 , while curve a is that of the paramagnetic oxygen containing species.

Figure 2 indicates the effect of heating the substrate with an infrared lamp in the vacuum-deposition procedure. These data were from different deposition runs which produced somewhat different film thicknesses. Curve a again is for an unheated substrate. Curve b shows the result of preheating the glass under an infrared lamp. This curve, recorded in air, resembles rather closely the curve b spectrum of Fig. 1 for the unheated film before air exposure. When heating was continued during the deposition time of several minutes, the Q band was broadened and shifted slightly, as in curve c of Fig. 2.

The reaction of the fresh green film with air proved to be irreversible. Prolonged evacuation of the air-exposed film at room temperature failed to change the spectrum, subsequently observed under helium. Heating of the exposed film in air converted the spectrum, from curve a of Fig. 1 to one closely resembling curve b of Fig. 1, or curve b of Fig. 2, but the sensitivity to air was lost in the heating process. Briefly, the unheated green films were air-sensitive, while the heated ones were not. The spectral broadening and the loss of air sensitivity on heating may have been due to polymerization or crystallization of LuPc_2 . Unless heated excessively, however, the dye apparently returns to the monomeric vapor state on sublimation.

Solution Spectra

Figure 3 shows a typical spectrum of lutetium diphthalocyanine dissolved in reagent grade dimethylformamide (DMF). The solution was blue, with absorption maxima at 614 and 693 nm. Corker *et al.* noted that this blue form, which was not paramagnetic, could be a reduction product of the green, due to its reaction with aliphatic amine impurities in the DMF (5). In fact, their green solid preparation produced a paramagnetic green solution when dissolved in DMF that had been distilled over CuSO_4 or pre-electrolyzed.

In this investigation, we obtained the same result by adding a small amount of aqueous hydrochloric acid to the blue solution in unpurified DMF. The acidified-solution spectrum, curve a in Fig. 4, matches that of Corker's paramagnetic green. This curve also has features of the

²Electronic spectra of various monophthalocyanines are discussed, for example, in Ref. (12).

Fig. 3. Spectrum of lutetium diphthalocyanine solution in reagent-grade dimethylformamide before acidification.

air-exposed green-film spectrum, although the peaks at comparable heights are sharper for the solution than for the solid film.

A most interesting change occurred on removal of air from the acidified DMF solution. Over several hours, the spectrum shifted from curve a to curve b of Fig. 4, with a corresponding color change from green to blue. Significantly, the spectral change was reversible with addition and removal of oxygen. This appears to be the first clear evidence of reversible oxygen addition to a diphthalocyanine complex. Complete conversions between the

Fig. 4. Effect of oxygen on spectrum of lutetium diphthalocyanine solution in acidified reagent-grade dimethylformamide. Curve a: under oxygen. Curve b: under helium.

curve a and curve b forms occurred in several hours. The spectrum in nonacidified, unpurified reagent-grade DMF remained as in Fig. 3 and was unaffected by addition or removal of dissolved oxygen.

With lutetium diphthalocyanine dissolved in reagent-grade dimethylsulfoxide, a similar spectral change occurred on acidification, but the apparent addition of oxygen was not reversible. Related changes due to oxygen also occurred in acidified acetone, with possible formation of an intermediate state. The spectrum in dichloromethane, without acid, matched that of the oxygenated solution in Fig. 4. The same spectrum was observed in dichloromethane by Chang and Marchon (7).

Interpretations

Before formulation of a unified reaction scheme, it is instructive to distinguish two types of blue-solution spectra and compare them with the spectra of cathodically reduced lutetium diphthalocyanine films, which now are known to be pH dependent (10). Curve b of Fig. 4, for the deoxygenated solution in acidified DMF, differs from the spectrum of the original blue nonacidified solution represented by Fig. 3. It closely resembles, however, the spectrum of a blue solid formed by the one-electron cathodic reduction of a cycled green lutetium diphthalocyanine film in an aqueous electrolyte near pH 3 (10). Moreover, the solution spectrum of Fig. 3, in nonacidified DMF, is similar to the reduced-film spectrum in a pH 7 electrolyte (10). These comparisons support the opinion that the dye was reduced by impurities in the reagent DMF.

For the green forms of lutetium diphthalocyanine, we note the similarity between the spectra of the air-exposed unheated green film, the paramagnetic green in solution with air present, and the electrochemically cycled green film with air absent (10). Several experimental observations can be correlated by assignment of the formula LuHPC_2^+ to the dye species in each of these cases. Reactions 1 and 2 account for its formation from LuPc_2 in the presence of water and oxygen. If LuPc_2 or LuHPC_2^+ is first reduced to LuHPC_2 in the unpurified DMF, the reversible addition of oxygen in solution also can be represented by reaction 2. In this proposed scheme, LuHPC_2 is blue, while LuPc_2 and its protonated form LuHPC_2^+ are both green. The other blue reduction product, obtained at higher pH, probably is the anion LuPc_2^- . The oxygen complex $\text{LuHPC}_2^+\text{O}_2^-$ proposed here is analogous to $\text{MnPc}_2^+\text{O}_2^-$ suggested by Lever *et al.* for the dioxygen adduct formed by MnPc in dimethylacetamide (13). Thermodynamically, the superoxide ion can disproportionate in acidic aqueous media through reaction [3] (14)

This reaction requires a catalyst to proceed rapidly, however, and O_2^- apparently is stabilized in the present system by pairing with the cation LuHPC_2^+ .

With this information, the acid-base equilibrium question can be re-examined. For titrations of the tetrasulfonated rare earth diphthalocyanines in water, the simple acid-base interpretation of Moskalev and Kirin (2) probably is correct, since the acidic anion $[\text{LuHPC}_2(\text{SO}_3)_4]^-$ would not be expected to pair with O_2^- . It appears possible, however, that the pK_a values reported by Moskalev and Alimova for unsubstituted diphthalocyanines of the lanthanide elements (Ln) in DMF-water solutions corresponded to the reaction

rather than the simple equilibrium.

Finally, a discrepancy in the faradaic n values from some of our previous work can be resolved. Nonintegral n 's approaching 2 were typical of anodic moving boundary experiments with the dye on an insulating substrate in air (6), while values close to 1.0 were found by an incremental potential-step technique, using cycled films on tin oxide in the absence of air (10). The color change was from green to orange (or reddish orange) in each case. The difference in the number of electrons lost per molecule of dye is readily explained on the basis that $\text{LuHPC}_2^+\text{O}_2^-$ was the predominant starting material in the boundary propagations. Since the superoxide ion is a relatively strong reducing agent (14), the overall anodic reaction for an air-exposed lutetium diphthalocyanine film in an electrolyte with the anion X^- should be

For a cycled green film in the absence of oxygen, however, the same color conversion would involve only one electron

Calcium/ $\text{Ca}(\text{AlCl}_4)_2$ —Thionyl Chloride High Rate Cell

E. Peled,* R. Tulman, A. Golan, and A. Meitav

Department of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel

The lithium- SO_2 cell shows good performance over a wide range of temperatures and a good shelf life. In addition, it has the highest power density of all commercially available cells (1). For example, a C-size cell is capable of continuously delivering 1.5A at room temperature (2). However, because of hazard limitations, its recommended maximum continuous rate is only 0.36A (2). Recently, both the safety and rate capability of the Li- SO_2 system were improved (3-5), and the recommended maximum continuous rate was doubled. All of this was accomplished by, among other things, the use of balanced Li-to- SO_2 ratio and greater electrode area. The main hazard factors in high rate lithium cells are the deposition of very reactive high surface area lithium during reversal and charging abuses (6-8).

The calcium-thionyl chloride system has recently attracted attention, as a safer alternative to lithium high rate cells (9-17). Encouraging electrical performance was obtained for cells of various sizes - between 3.5 and 2000 Ah - containing LiAlCl_4 electrolyte (15-17).

Recent studies in our laboratory, with the use of small laboratory cells (10 cm^2 electrode area) containing $\text{Ca}(\text{AlCl}_4)_2$ electrolyte, have shown (9-12) good electrical performance and much better safety characteristics. Unlike lithium cells or the $\text{Ca}/\text{LiAlCl}_4$ -TC cell, the $\text{Ca}/\text{Ca}(\text{AlCl}_4)_2$ -TC cell successfully resists charging and reversal abuses (9-12). It behaves like an "electrochemical diode" (11, 12), *i.e.*, it delivers high current densities (up to 50 mA cm^{-2}) in the anodic direction, but operates as a high resistance in the negative direction, and during reversal tests. This seems to result from the facts that the SEI is almost a pure anionic conductor (9-11, 13) and that during cathodic polarization a blocking process of the ionic current takes place. This process most likely results from a sharp decrease in the ionic conductivity of the CaCl_2 -SEI due to depletion of the mobile ionic defects during continuous cathodic polarization. Corrosion tests of calcium in $\text{Ca}(\text{AlCl}_4)_2$ -TC solutions both at 70°C and at room temperature, indicate a projected shelf life of 1.5-2 yr (12). The average corrosion current density of 70°C is 12 $\mu\text{A cm}^{-2}$, and at room temperature it is 0.5 $\mu\text{A cm}^{-2}$ or less.

The goals of this work are: to demonstrate that the $\text{Ca}/\text{Ca}(\text{AlCl}_4)_2$ -TC cells can be scaled up by an order of magnitude with respect to electrode area, while preserving their excellent safety features, and to study the electrical performance of high rate laboratory prototype jelly-roll C-size cells.

Experimental

Details concerning materials and the preparation of solutions have been described in detail in Ref. (9). Calcium (99.9%) 0.5 mm thick foil was purchased from Pfizer. It was degreased in AR petroleum-ether and annealed at 600°-650°C for 2h. The laboratory prototype C-size cell is shown in Fig. 1. It consists of 0.5 mm calcium foil and 0.9-1.0 mm thick Teflon (10% by weight) bonded carbon cathode supported on nickel Exmet. Carbon loading was 1.8g per cathode. The anode and cathode were rolled together with a double 0.18 mm nonwoven glass separator. The effective electrode area was about 100 cm^2 . The cell case was a C-size stainless steel can, which was sealed inside a glass vessel. Connections to the anode and cathode were made with tungsten rods, which were sealed to the glass cap. A ground-glass joint was attached to a side arm of the glass vessel and served as a safety vent. Cells were vacuum filled (to the top of the can) with 1.0M $\text{Ca}(\text{AlCl}_4)_2$ -TC solution. The discharge tests were per-

*Electrochemical Society Active Member.

formed at room temperature by loading the cell with a suitable power resistor. Data were collected by a Fluke Data Logger. Charging and several tests were performed with the use of a Kepco regulated dc power supply.

Results and Discussion

The OCV of freshly filled cells was 2.8-2.9V and increased to 3.1-3.2V within 1-2 days. This OCV is somewhat lower than the OCV of the small glass laboratory cells (9). Cells were discharged through constant loads at current equivalent to 0.125-0.8A, a day or two after filling them with electrolyte. In all tests they exhibited a stable discharge voltage plateau over most of their service life. This plateau voltage decreased from 2.8V at 0.125A to 2.65V at 0.8A. Typical discharge curves are shown in Fig. 2. The initial increase of working potential ("voltage delay") is attributed mostly to the "cleaning" of the anode surface of calcium oxide. In recent experiments (9), a much smaller "voltage delay" was observed, probably

Fig. 2. Constant load discharge curves at room temperature. Curve 1: 2.2. Curve 2: 8.2. Curve 3: 5.5. Curve 4: 3.4.

due to the fact that the anodes were rubbed with sandpaper inside the glove box. This "voltage delay" diminished when the cells were stored for a week or more at room temperature prior to the discharge test. By this time, the thick calcium oxide layer had dissolved by reaction with TC. Cell capacity decreased linearly with current (Fig. 3). It was 3.5 Ah at 0.125A, 2.0 Ah at 0.6A, and 1.5 Ah at about 0.8A.

Capacity per unit area of cathode decreased from 35 mAh cm⁻² at 1.25 mA cm⁻² to 15 mAh cm⁻² at 8 mA cm⁻². These values are 10%-30% lower than those previously obtained for small, flat 10 cm² cells (9). However, the smaller cells had a 10%-20% thicker cathode and a higher concentration of electrolyte (1.3M instead of 1M, in this work).

The small cells exhibited excellent safety features as they resisted abuse charging and reversal tests. Figure 4, 5, and 6 show that these safety features are maintained even when the electrode area is scaled up by an order of magnitude. It should be noted that the initial short-circuit current of these cells is above 10A. Figure 4 describes an abuse "charging" test of a fresh C-size cell at 25V. The initial current is about 150 mA and it decreased to 50 mA after 10 min and to less than 20 mA after 60 min. In a 28V reversal test of a fully discharged C-size cell, the current dropped even faster (Fig. 5). It started at about 120 mA and dropped to 30 mA after 1 min, and then it slowly decreased to less than 20 mA after 200 min. Figure 6 describes the simulation of the reversal of a "weak" cell in a

Fig. 3. The dependence of cell capacity on the discharge current

Fig. 5. Reversal test of a fully discharged cell at a constant voltage of 28V.

Fig. 6. Simulation of a reversal test of a weak cell in a ten cell in series battery, first forced-discharged at constant current and later at constant voltage of 25V.

30V series battery (ten cells in series). At the beginning, a fully discharged cell is forced to discharge at a constant current of 350 mA, till its reverse voltage reaches 25V. This takes about 20 min. Then it is force-discharged at a constant voltage of 25V. The current drops from 350 mA to less than 20 mA after 70 min and stays about constant at this level.

It should be emphasized that any other lithium cell or even a regular nonlithium cell would explode, or at least would vent, under charging or reversal at 25V.

Summary

The Ca/Ca(AlCl₄)₂-TC C-size laboratory cell (with 100 cm² electrode area) exhibits, at low rates, a volumetric energy density close to that of the Li-SO₂ cell. It can deliver a continuous current similar to that permitted for the Li-SO₂ cell. Its energy and power density can be further increased by increasing the electrode area of the cell. It exhibits an excellent safety feature: it successfully resists abuse charging and reversal tests. It is, therefore a very promising candidate for high power multicell battery applications.

Recently, we reported on electrodisolution and passivation phenomena on single crystal electrodes of the III-V compounds InP, InAs, InSb, GaP, GaAs, and GaSb in aqueous electrolytes (1). Considerable differences in the behavior are observed that are particularly pronounced in acid solutions. InAs and InP represent extreme cases: InAs does not passivate at $pH \sim 0$ except at very high current density (c.d.), but the films formed at high c.d. are too porous to prevent excessive surface corrosion. InP exhibits severe inhibition to anodic dissolution even in 4M HCl solution by the formation of a coherent film that can be removed only by extensive cathodic reduction.

Also, we reported previously on p-InP/ $V^{2+}-V^{3+}$, 4M HCl/C solar cells (2) that represent efficient EIS junctions (3). The function of this device is thus intimately linked to the passivation behavior of p-InP (1). A similar condition has been observed for p-InP-indium-tin oxide (ITO) solar cells that represent efficient SIS junctions (4) where the dielectric is a phosphorus oxide film of tunneling thickness (5). Investigations in InP_yAs_{1-y}/ITO solar cells show that the dielectric becomes porous at $y \geq 0.85$. At higher P concentration, the solar power conversion efficiency peaks presumably because of a reduction in the dielectric film thickness, but at lower P concentrations, the solar cell characteristic degrades steeply (6). In this paper, we report on the passivation and electrodisolution behavior of alloys at the InAs-InP pseudobinary that show complete solid solubility over the entire range of compositions InP_yAs_{1-y} , $0 \leq y \leq 1$. Also, we include information

on p-InP_yAs_{1-y}/ $V^{2+}-V^{3+}$, HCl/C and InP_yAs_{1-y}/ I_3^- , I^- , HCl/C junctions.

Experimental Results and Discussion

Both InP_yAs_{1-y} bulk single crystals and epitaxial layers were used for the fabrication of the electrodes. The bulk crystals were grown by zone leveling, as described elsewhere (7). The epitaxial layers were grown by liquid phase epitaxy on nominally undoped and semi-insulating InAs and InP substrates, respectively. The composition of the samples was checked by x-ray diffraction and x-ray fluorescence analyses. The n-type crystals and epilayers were nominally undoped with carrier concentrations $1 \times 10^{16} \leq N_D - N_A \leq 3 \times 10^{16} \text{ cm}^{-3}$. The p-type material was Zn doped to $N_A - N_D = 5 \times 10^{16} \text{ cm}^{-3}$. Au:Zn and In were used to make an ohmic contact to the p- and n-type material, respectively.

The contacts and substrates were embedded into epoxy so that only the InP_yAs_{1-y} was exposed to the electrolyte. The usual three-electrode potentiostatic arrangement was used, employing carbon counter and saturated calomel reference electrodes.

Figure 1 show cyclic voltammograms in 1M HCl solution for (a) bulk p-InP_{0.47}As_{0.53}, (b) bulk n-InP_{0.45}As_{0.55}, (c) n-InP_{0.57}As_{0.43} epitaxially grown on InP, and (d) n-InP_{0.37}As_{0.63} epitaxially grown on InAs. The solid and dashed lines correspond to measurement under simulated AM1 illumination and in the dark, respectively. Note that up to 55% InAs in the pseudobinary alloy the passivation characteristics of pure InP electrodes, i.e., passivity in potential range B, transpassive current flow in region C, and cathodic activation in region A, are retained. However, the passive region B extends over a nar-

Fig. 1. Current-voltage curves at illuminated (-) and dark (---) in 1M HCl solution in (a) bulk $p\text{-InP}_{0.47}\text{As}_{0.53}$, (b) bulk $n\text{-InP}_{0.45}\text{As}_{0.55}$, (c) $n\text{-InP}_{0.57}\text{As}_{0.43}$ epitaxially grown on InP, and (d) $n\text{-InP}_{0.37}\text{As}_{0.63}$ epitaxially grown on InAs.

rower potential range and the transpassive anodic c.d.'s are larger than for pure InP. Also, on repeated cycling the oxidation wave (labeled E) decreases. For pure InP, this peak has been identified by ring-disk electrode measurements (1) to be partially related to the oxidation of In metal formed on the surface during the preceding reduction period in potential region A. The phenomenon in Fig. 1c may be either a reduction in the formation of In metal due either to the presence of other oxidation products formed in the transpassive cycle or to changes in surface composition related to the graded nature of the epitaxial film. Although the latter is indicated by the absence of a similar behavior for the n-type bulk material, the phenomenon is difficult to understand on the basis of a graded epitaxial structure alone, because under the conditions of LPE of $\text{InP}_y\text{As}_{1-y}$ the distribution coefficient of P is larger than unity. Therefore, corrosion of the epilayer should expose in successive cycles compositions that are richer in InP leading to a widening of passive region B that is not observed. For the largest As concentration (Fig. 1d), the epilayer shows InAs-like behavior.

Solar cells were measured using essentially the same $\text{V}^{2+} - \text{V}^{3+}$, HCl electrolyte as described in Ref. (2) and 0.05M I_2 , 1M CaI_2 , 1M HCl solution for the p-type photocathodes and n-type photoanodes, respectively. Figure 2 shows the spectral response of a $p\text{-InP}_{0.47}\text{As}_{0.53}$ photocathode in the spectral region between 800 nm and 1.5 μm . In accord with the decrease in the energy gap of the alloy as compared to pure InP, the long wavelength cutoff is shifted to larger wavelength. Also, the open-circuit voltage of the device is smaller than for pure InP, as expected from the decrease in the built-in voltage with decreasing energy gap. However, in contrast to expectations based on a consideration of the bandgap, the short-circuit c.d. of the alloy cell is, also, substantially smaller than for pure InP.

The latter observation is consistent with the behavior observed for the n-type $\text{InP}_y\text{As}_{1-y}$ photoanodes in I_3^-/I^- , HCl solution. Figure 3 shows a plot of the short-circuit current density (I_{sc}) relative to the value observed in the same solution for pure n-InP electrodes vs. the mole fraction of InAs in the pseudobinary alloy. For small additions of As to the anion sublattice, the short-circuit c.d. increases in accord with the extension of the spectral response to larger wavelength with decreasing energy

Fig. 2. Long wavelength edge of the spectral response of a $p\text{-InP}_{0.47}\text{As}_{0.53}/\text{V}^{2+}, \text{V}^{3+}, \text{HCl}/\text{C}$ junction.

Fig. 3. Plot of $I_{sc}(y)$ vs. y of $\text{InP}_y\text{As}_{1-y}/\text{I}_3^-, \text{I}^-, \text{HCl}/\text{C}$ cells in units of the value of I_{sc} observed for pure n-InP electrodes in the same solution.

gap. However, at $\sim 16\%$ InAs, the short-circuit c.d. decreases, and no photoeffect is observed for $\text{InP}_y\text{As}_{1-y}$ epilayers for $y \leq 0.4$. This limit agrees with the observed threshold in the As concentration at which the passivation/electrodissolution behavior shifts from InP to InAs-like characteristic. Also, it is consistent with the earlier results on solid-state devices (6) where the gain in I_{sc} overcompensates the decrease in V_{oc} to $\sim 15\%$ InAs and photovoltaic activity vanishes at $0.4 \leq y \leq 0.5$. However, in the case of our liquid junctions, V_{oc} deteriorates more rapidly so that the efficiency of the alloy cells at the present stage of development is smaller than the efficiency of the pure InP cells. Whether this pattern may be affected by cyclic optimization or other manipulations of the interfacial chemistry is currently unknown. In view of the limited stability of n-InP photoanodes in I_3^-/I^- solutions a search for better redox partners for n-InP $_y$ As $_{1-y}$ photoanodes appears to be preferable to more extensive exploration of the $\text{InP}_y\text{As}_{1-y}/\text{I}_3^-, \text{I}^-, \text{HCl}$ system.

Summary and Conclusions

The electrodisolution and passivation behavior of $\text{InP}_y\text{As}_{1-y}$ alloys in acid solutions has been studied for both n- and p-type bulk single crystals and epitaxial alloy layers on InP and InAs substrates. InP-like passivation behavior is observed to $y \geq 0.45$, while larger As concentrations lead to electrodisolution behavior that is charac-

teristic of pure In As. The threshold in the passivation behavior coincides with the As concentration at which photovoltaic activity vanished in $\text{InP}_y\text{As}_{1-y}$ liquid junction solar cells, and similar characteristics in the short-circuit current density vs. alloy composition relation are observed, as previously reported for indium-tin oxide/ $\text{InP}_y\text{As}_{1-y}$ solar cells. This result strengthens the argument that the efficiency of InP-based liquid junction solar cells is closely linked to their passivation characteristics and points to close similarities between SIS and EIS solar cell device structures.

Thermoelectricity

VIII. The Thermal Conductivity Quality Factor, Q_k , A Semiconductor Characterization Tool

Donald Tuomi*¹

Roy C. Ingersoll Research Center, Borg-Warner Corporation, Des Plaines, Illinois 60018

ABSTRACT

Through surveys of the relationships between thermal conductivity and electrical conductivity in bismuth antimony telluroselenide alloys a pragmatic approach is used to define a thermal conductivity quality factor, Q_k , relating doping level to thermal conductivity. This empirical variable permits the evaluation of thermoelectric alloys in terms of materials parameters rather than the engineering design variables of the figure of merit, Z . Imperfection structure variables contribute to the optimization of both electron- and phonon-transport phenomena defined by the combined Seebeck and thermal conductivity quality factors, Q_s and Q_k .

Thermoelectric energy conversion for generating electric power or supplying refrigeration and air conditioning depends upon using heavily doped semiconductors (1). The engineering performance of the n- and p-type semiconductors must be optimized to the absolute solid-state limits in order to realize fully the business opportunities present. The materials are characterized by properties of both dielectrics and metals in a complex way (2, 3).

The engineering optimization depends upon doping proper structure and composition alloys to the largest figure of merit, Z . This is $Z = S^2\sigma/k$ where S is the Seebeck coefficient, σ electrical conductivity, and k the thermal conductivity. A challenge exists to optimize the materials processing and composition variables (4) in combination with device engineering (5) to the limits of the promised long life and reliability.

Simplifications are needed in the isolation and identification of the electronic and thermal energy transport variables. The identification of the power coefficient S_σ^2 with characteristics of the mobility-effective mass product, $\mu_0(m^*/m_0)^{3/2}$, for electrons led to introducing the Seebeck quality factor as a materials variable (5-9).

General device theory identifies the mobility-effective mass product divided by the lattice thermal conductivity, $\mu_0(m^*/m_0)^{3/2}/k_L$, as the critical material parameter to be maximized in order to attain high figures of merit (1, 10). With the introduction of the Seebeck quality factor, Q_s , the goal is maximizing Q_s/k_L .

The lattice thermal conductivity proves on closer examination to involve as many materials variables, as does the Seebeck quality factor. The challenge thus arose to devise a thermal conductivity quality factor Q_k for phonon transport equivalent Q_s for electron transport. This required an empirical evolution from the interaction of theory with experiment, much as did the Q_s .

The Thermal Conductivity of Materials

A brief scan through two volumes of thermal conductivity data compiled by the Thermophysical Properties Research Center (11) quickly emphasizes ranges and bounds on thermal conductivity variations in materials ranging from dielectrics to metals, and from perfect crys-

tals to amorphous structures. The total range extends from a low limit of 0.001 to a high range of 100 W/cm K.

The perfect crystals of diamond serve to define in combination with sapphire and silver the upper limits to heat flow at successively lower temperatures, as shown in Fig. 1. The lattice thermal conductivity of the dielectric materials maximizes at temperatures below 100 K, while metallic well-crystallized alloys maximize only at the temperature of liquid hydrogen and less.

Metallic alloys are characterized by thermal conductivities which are in the 0.3-8 W/cm K ranges for temperatures above 100 K. The temperature dependency is not very marked, as contrasted to the data for dielectric materials.

The relatively pure, intrinsic-class silicon and germanium semiconductors are characterized by temperature thermal conductivity curves similar to ordinary crystalline dielectrics. The heavily doped alloys show a dramatically decreased temperature dependence of thermal conductivity. This approaches a metallic characteristic above 100 K (12). The $1/T$ proportionality of the dielectrics is replaced by near T^0 behavior at ambient temperatures, or even an inversion to a positive temperature coefficient.

Classical theory describes the thermal conductivity as involving an electronic component described by the Wiedemann-Franz law, $k_e = L\sigma T$, where L is the Lorenz number, σ the electrical conductivity, and T the absolute temperature. Classical statistics assign the Lorenz number a value of $2(k/e)^2$ for nondegenerate electrons, and $(2\pi/3)(k/e)^2$ for the degenerate case, where k/e is the ratio of the Boltzmann constant, k , to the electronic charge, e . As noted by Drabble and Goldsmid (12), the electronic component dominates the thermal conductivity of metallic materials; but in semiconductors difficulties are encountered in identifying precisely the magnitudes of the electronic and lattice contributions to the thermal conductivities.

Thermal Conductivity Theory

The development of semiconductors as the route to useful thermoelectric alloys stimulated both experimental and theoretical investigations of the ways to alter the lattice thermal conductivity contribution to the figure of merit, Z . The existence of controllable contributions of electrons and phonons, k_e and k_L , to the thermal conduc-

Fig. 1. Thermal conductivity ranges for: (a) diamond, (b) sapphire, (c) BeO, (d) Al₂O₃, (e) vitreous SiO₂, (f) Ag, (g) Pb, (h) Si, (i) Ge, (j) Bi, and (k) Bi₂Te₃ alloys. After Touloukian *et al.* (11).

tivity was recognized very early in the research and development effort (1). Since the mean free path of electrons was expected to be greater than that for phonons, performance enhancements were expected through use of high atomic weight alloys in combination with solid solution alloying as in PbTe-PbSe, Bi₂Te₃-Bi₂Se₃, or Bi₂Te₃-Sb₂Te₃.

The extensive review of thermal conductivity and lattice vibrational modes published by Klemens in 1958 (13) brought attention to the complex combinations of solid-state structural imperfections which were expected to influence the thermal conductivity of the lattice. The fundamental origin of thermal resistance is the increasing anharmonicity of the lattice vibrations with increasing temperature. Thus, in Fig. 1, the development of the low temperature maximum in thermal conductivity with increasing temperature of the crystalline insulators arises from increasing phonon scattering by anharmonicity of the lattice vibrations. The high temperature region beyond the maximum is dominated increasingly by "Umklapp" process scattering of the phonons. This lattice component of thermal conductivity exhibits a reciprocal of the absolute temperatures, $1/T$, dependence, with increasing temperature. However, at temperatures below the thermal conductivity maximum, the "normal" processes of phonon scattering dominate along with boundary scattering in the case of perfect crystals. The thermal conductivity no longer is an intensive property of the crystal, but is now a function of the dimensions since "normal" processes do not contribute to thermal resistivity, the lattice vibrations are simple harmonic oscillations.

Klemens' review brings attention to the diversity of imperfection phenomena in materials structures which alter the vibrational behaviors of the atoms. These range from the familiar isotope effect of changing the nuclear mass, to impurity substitutional alloying, to lattice vacancies, to lattice interstitials, to dislocations, to grain boundaries, and to more complex associated imperfection structures. The alteration of the crystal lattice from an ordered re-

peating perfect structure to the disordered amorphous state shifts the thermal conductivity into an imperfection-structure-dominated form. This is made evident in Fig. 1 by the vitreous silica curve defining a lower bound region for the thermal conductivity of dielectric solids.

Klemens' survey of the phenomena in metals, alloys, and semiconductors further emphasized the situation complexity in attempting to identify uniquely the electronic and lattice components of thermal conduction. The electron scattering arises from interactions with lattice vibrations as well as the imperfection structures. A parallel exists to the phonon scattering processes noted for dielectric materials. The semiconductors of the heavily doped class of interest in thermoelectrics present an extremely difficult situation for using theory to direct experiment except in a qualitative-semiquantitative context.

The later review by Drabble and Goldsmid (12) focused upon the characterization and theory evaluations of thermal conduction processes as applied to semiconductors. Emphasis is again given to the overall difficulties in utilizing theory to direct experiment. The doping process for altering the electrical conductivity introduces static point defects which themselves alter the thermal conductivity of the lattice as in iodine doping of Bi₂Te₃ (14).

Further complications are evident in attempts to analyze the thermal conduction processes in heavily doped lead telluride using classical statistics (15). The ambipolar electron contributions to thermal conductivity at ambient temperatures are evident at electrical conductivities below 500 mho/cm for both n- and p-type Bi₂Te₃. These data emphasize the difficulties in experimentally defining the lattice components of thermal conductivity for the two different alloys at ambient temperature (16).

A later review of thermal conduction in semiconducting materials by Steigmeier (17) focused upon studies of lattice thermal resistivity in elements, compounds, and alloys with particular attention to higher temperature behaviors, *i.e.* above the Debye temperature. The results, particularly for Ge-Si alloys, indicated progress in formulating theory to account for limited experimental observations. The discussions of Kudman (18) emphasize the importance of both mass fluctuation and lattice strain contributions to phonon scattering in III-V and IV-VI compounds, with strain effects possibly the dominant factor according to theory evolutions by Abeles.

More recently, Spitzer (19) described a chemical bond approach to the lattice thermal conductivity characteristics of crystals. This investigation identifies the crystalline structures of compounds as the critical variable determining the range of thermal conductivity. Surprisingly, all tetrahedrally bonded compounds had higher thermal conductivities than octahedrally bonded materials. Increasing the coordination number of the atoms in the unit cell decreases the thermal conductivity. The low thermal conductivity Bi₂Te₃ and PbTe alloys are octahedrally coordinated, as contrasted to the high thermal conductivity Ge-Si materials in the tetrahedral coordination class.

More recently still, Slack (20) reviewed the thermal conduction characteristics of pure nonmetallic crystals at high temperature. The discussion brings attention to the acoustic vibrational mode phonon dominance in rare gas crystals with one atom per unit cell. The more complex crystal structures will simultaneously involve both acoustic and optic modes in their vibrational energy spectrum with the acoustic modes transporting the thermal energy. Complex crystalline structures are needed with a multiplicity of optic modes to reduce the phonon transport in acoustic modes, thus reducing the lattice thermal conductivity.

Slack, in concluding, suggests that, as the number of atoms per unit cell is increased to very large values, the thermal conductivity of the lattice approaches the minimum limit of a room temperature glass. The challenge is identifying phonon scattering mechanism which will produce an equivalent result within a semiconducting alloy.

Clearly, theory and experiment suggest that many different imperfection structures may be used to modify both phonon and electron scattering behavior in alloys. The complexity requires recourse to experiments for identifying the presence of physically real effects which are directly related to the input variables.

Defining of the Thermal Conductivity Quality Factor

From the literature to 1962, varied graphs were prepared of the Seebeck coefficient vs. electrical conductivity and the thermal conductivity vs. electrical conductivity. For the 200-50 $\mu\text{V/K}$ Seebeck coefficient range, significant degeneracy effects were expected to be influencing the Lorenz number so that classical values should not be applicable. As noted by Drabble and Goldsmid (14), the Bi_2Te_3 class alloys showed consistently smaller values than expected for an alloy fitting acoustic-alloy scattering vibrational mode characteristics in the S - σ relationship (6-9). A need clearly existed to be able to define a thermal conductivity quality number which would be useful for comparing samples as better than or worse than others.

Theory did not readily provide a selection through, for example, the estimation of the lattice component by subtracting the electronic component. As shown in Fig. 2, the Lorenz number depends upon the relaxation time characteristics of the electron energy as well as the Fermi level as defined by the Seebeck coefficient. The observed fit of acoustic mode-alloy scattering of electrons to the Seebeck coefficient-electrical conductivity relationship defined through the Seebeck quality factor, Q_s , (9) did not provide an invariant lattice thermal conductivity component when the corresponding Lorenz numbers were used to estimate the electronic term to be subtracted from the measured thermal conductivity.

The graphical analysis of all available k - σ data for the better quality bismuth telluride n- and p-type alloys showed a greater internal consistency of the p-type results. This led to constructing the empirical curve of Fig. 3 utilizing the p-type Bi_2Te_3 alloy data as shown. This curve defined by the equation

$$k = 10 + 0.000372 \sigma$$

led to defining the thermal conductivity quality factor (21)

$$k = Q_k + 0.00372 \sigma$$

where the thermal conductivity is in units of (mW/cm K) and the electrical conductivity in (mho/cm).

The Q_k number has many of the characteristics classically identified with subtracting an electronic component from the thermal conductivity of a set of samples. Thus the curves a through f in Fig. 3 reflect varied options for the classical Lorenz number subtraction of the electron term k_e . In light of the Q_s characterization of the Seebeck coefficient-electrical conductivity relationship of, S to σ in terms of acoustic mode-alloy scattering and the relaxa-

Fig. 2. The Lorenz number, L , in the Wiedemann-Franz law relationship of thermal conductivity to electrical conductivity, $k = L_o T$, dependence upon the Seebeck coefficient for variations in the energy dependence of the electron relaxation time (20).

Fig. 3. The definition of the thermal conductivity quality factor reference line $Q_k = 10.0$ by experimental data on p-type better quality bismuth telluride-class alloys of similar chemical compositions. Reference electronic thermal conductivity curves are for (a) degenerate classical statistics, (b) nondegenerate classical statistics, (c) $\epsilon^{-3/2}$ electronic energy, ϵ , relaxation dependence, (d) $\epsilon^{-1/2}$, (e) $\epsilon^{1/2}$, and (f) $\epsilon^{3/2}$ case.

tion time relationship for L , the Lorenz numbers in Fig. 2, none of the theoretical identifications of a to f are justifiable as an experimental reference base defining a quality factor for the thermal conductivity.

A further insight into the relationship is provided by plotting the experimental points for the Ag_2Se thermal conductivity-electrical conductivity relationship (23). This alloy has a Seebeck quality factor of 100 Q_s and thermal conductivity quality factor of 7 Q_k , as defined by graphically constructing a family of parallel lines to the defined reference curve of 10.0 Q_k .

A summary of the better class alloy thermal conductivity data is given in Fig. 4. The distributions of quality among both Q_s and Q_k are as follows

- p-type: $360 \pm 37 Q_s$ and $10.0 \pm 0.77 Q_k$
- n-type: $337 \pm 68 Q_s$ and $11.69 \pm 1.77 Q_k$

with the $Q_s/Q_k = M$ ratios being 36.0 and 28.0, respectively, consistent with the higher reported figures of merit for the p-type. The variabilities noted among the different samples were interpreted as showing that either signifi-

Fig. 4. Better quality n- and p-type Bi_2Te_3 -class alloy thermal conductivity-electrical conductivity data utilized in thermal conductivity quality factor, Q_k , evolution.

cant measurement errors existed or unique optimum alloy performances had not been attained experimentally.

The Seebeck quality factor, Q_s , had been found to be independent of temperature for the bismuth telluride alloys. Consequently, the available temperature-dependent thermal conductivity data were plotted on the reference curve figure defining Q_k . The results in Fig. 5 indicate that under some limited conditions the Q_k may be independent of temperature, or a second-order effect for 300-240 K, the temperature range for refrigeration alloys.

The complex interactions of point defects and alloying additions with the lattice and electron components of thermal conductivity produce surprising effects on the total thermal conductivity characteristics as well as the Seebeck coefficient-electrical conductivity relationship. The empirical definition of the thermal conductivity quality factor accepts this complex reality as an experimental fact. The assumption was made that as data accumulated a refinement of the modeling could be done in two ways. First, effects identified with process and composition variables could be related to the thermal conductivity quality number in an empirical way. Subsequent characterization of alloys in a structural chemical sense would provide at least conceptual views of the interacting factors. Second, as inadequacies of the Q_k concept became apparent, a revision of the graphical representation would be feasible.

The composite Q_s and Q_k curves used in data analysis are shown in Fig. 6. The characteristics commonly encountered for Bi_2Te_3 alloys maximize the figure of merit in the 700-1200 mho/cm range, but the power coefficient $S^2\sigma$ frequently maximizes at the higher ranges of electrical conductivity. Technology development goals involve an initial optimization of $Q_s/Q_k = M$ followed by controlled doping to maximize the figure of merit.

Extensive illustrations are not feasible on the use of Q_k to analyze published data. This reflects the historic difficulties in conveniently and accurately measuring all three parameters S , σ , and k on the same sample. The emphasis on the Z meter and power coefficient measurements frequently results in virtually no thermal conductivity data being available.

One example from the literature arises from the study of Cosgrove *et al.* (24) of thermoelectric effects of crystal growth conditions for $BiSbTe_3$ composition with 0.56 w/o selenium addition, or $BiSb(Te_{0.983}Se_{0.016})_{3.05}$. This nonstoichiometric composition is in the two-phase field region of the Bi-Sb-Te-Se tetrahedron between the $(Bi,Sb)_2(Te,Se)_3$ composition plane and the (Te,Se) eutectic solid solution. The anion-rich phase is n-type, while the cation-rich phase of the $BiSbTe_3$ solid solution is p-type.

The research identified the changes in thermoelectric properties on varying the crystal growth temperature gradient, G , from 25°, to 50°, to 250°C/cm while changing the crystal growth rate, R from 0.08 to 15.2 cm/h. The G/R ratio varied from 5 to 670. Measurements of S , σ , k , and Z

Fig. 5. Temperature-dependent thermal conductivity-electrical conductivity data for varied samples of n- and p-type Bi_2Te_3 alloys compared to the $Q_k = 10$ reference curve.

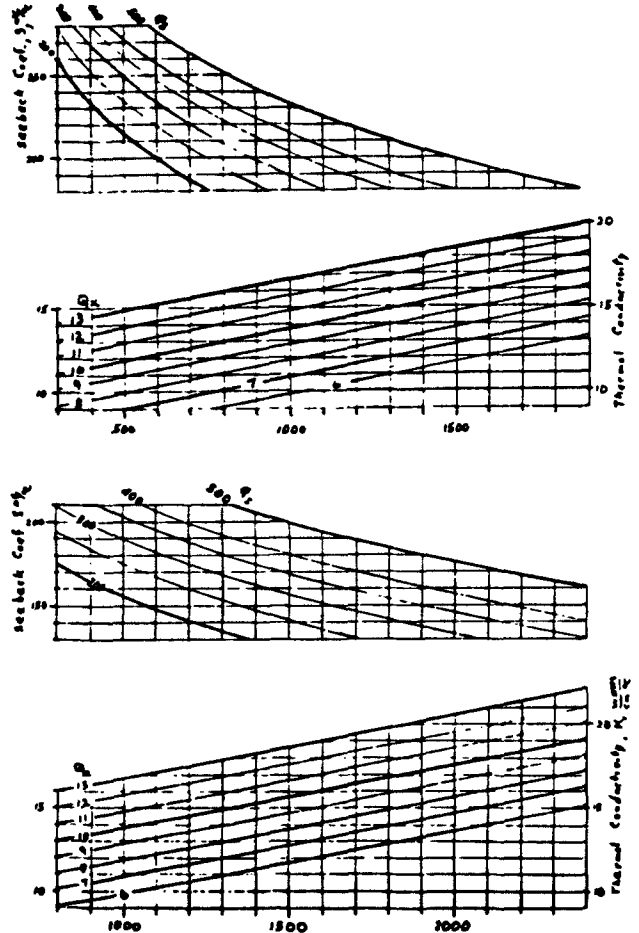

Fig. 6. Alloy optimization: S - σ - k , Q_s , Q_k interrelationships for laboratory data analysis.

permitted identifying the dependence of the variables on $G/R^{1/2}$.

The experimental results are presented in an unconventional way in Fig. 7 through 10 to illustrate phenomenologically the use of Q_s and Q_k descriptors. The relationship of the Seebeck coefficient to electrical conductivity in Fig. 7 shows how decreasing the crystal growth rate and increasing the temperature gradient to 250°C/cm with the growth rate at 0.435 cm/h improved alloy quality simultaneously with an apparent shift in the Fermi level as shown by increasing S and σ . The 50°C/cm gradient

Fig. 7. The Q_s , Seebeck quality, characteristics of varying growth rate, R , and temperature gradient, G , samples of n-type $BiSbTe_3$ plus 0.56 w/o Se (24).

Fig. 8. The Q_{kT} thermal conductivity quality, characteristics of varying growth rate, R , and temperature gradient, G , samples of n-type BiSbTe_3 plus 0.56 w/o Se (24).

samples show anomalous characteristics compared to 25° and 250°C/cm.

The corresponding thermal conductivity curves shown in Fig. 8 illustrate the decrease in thermal conductivity paralleling the increase in Seebeck coefficient in Fig. 7. A minimum in Q_k near 8.7 is evident for the 50° and 250°C/cm temperature gradients, while a 10.0 Q_k range is reached at 25°C/cm.

The correlations of Q_s , Q_k , and $Q_s/Q_k = M$ with varying preparative conditions are in Fig. 9, and the correlation of Q_s to Q_k in Fig. 10. The outlier specimen at the steepest temperature gradient and slowest crystal growth rate is unusual as a 350 Q_s , 8.8 Q_k , and 39.8 M . The high figure of merit of $3.15 \times 10^{-3}/\text{K}$ represents an extreme in performance for an alloy at the BiSbTe_3 composition. The overall

Fig. 9. The correlation of Q_s , Q_k , and $Q_s/Q_k = M$ with the variation of growth rate, R , and temperature gradient, G , in samples of n-type BiSbTe_3 plus 0.56 w/o Se (24).

Fig. 10. The correlation of Q_s to Q_k for the sample series with variations of growth rate, R , and temperature gradient, G , in samples of n-type BiSbTe_3 plus 0.56 w/o Se (24).

internal consistency of the data would suggest this Q_s outlier more probably is in the 300 range and the figure of merit corresponds to $Q_s/Q_k = M$ of 30 or less rather than the higher value of Fig. 9.

Clearly, the samples of BiSbTe_3 doped with 0.56 w/o selenium incorporated a structural-chemical heterogeneity in the distribution of n- and p-type regions in the cross section. This gives rise to circulating current degradation of Q_s and Q_k .

Implications of Q_s and Q_k

Rather profound implications are present through the applicability of the Seebeck and thermal conductivity quality factors to the description of the thermoelectric properties of heavily doped semiconducting materials. This empirical, seemingly pragmatic approach provides a basis for value judgments critical to technology advancement. Furthermore, as experimental results are acquired in an organized framework, modifications of the quality factor concepts may be introduced in an evolutionary defined manner useful to advancing the technology as well as the science and engineering aspects.

An immediate consequence of using materials parameters to characterize alloys is the recognition and acceptance of the need for precise, accurate thermoelectric property measurements. The experimental designs must identify and distinguish between errors of thermoelectric parameter measurements and deviations introduced by materials variables. Careful planning of experimental designs is important, but failure to introduce the key variables is catastrophic. The objective is to develop commercial production technologies for the highest possible figure of merit n- and p-type alloys using compositions and procedures making commodity production of alloys feasible. Thus, a major program focus has been on developing adequate thermoelectric property measurements technology (25-26) to be used in adequately sophisticated statistical design approaches to experimentation.

A second consequence of the Q_s and Q_k parameter evaluation of materials is a recognition of the challenge complexity. A single or pair of samples preparative technology approach has limited justification for identifying likely candidate alloys. In general, the alloy performance must be optimized simultaneously for superior electron and phonon transport structural-chemical features. When the task is preparing a single-phase solid solution alloy with superior, reproducible properties, the phase rule defined bounds on the alloy are replaced by kinetic considerations. Sophisticated conceptual views to experimental design are important if the desired results are to come into reach of the experimentalist.

A third consequence is that the experimentation has a focus upon creating response surface relationships for the variables Q_s , Q_k , M , and Z connecting to the composition

and process variable space as well as to the structural-chemical descriptions for the solid state. This becomes crucial when technology transfer to production areas is undertaken. The new problems of scale-up must be identified and optimizable as a logical progression rather than becoming a mess of confounded variables. Too many variables exist for ease of sorting by simple experiments.

A fourth consequence of the application of Q_s and Q_k to experimental materials evaluation is a recognition of the difficulties in planning definitive studies. The literature contains thousands of publications relating to semiconductors for use in thermoelectrics. This accumulation of three decades is difficult to place into a rational perspective. The detailed analysis of one general case in depth and breadth is important for identifying the true character of both materials processing and materials characterization problems within a single relevant complex alloy system such as the $(\text{Bi,Sb})_2(\text{Te,Se})_3$, rhombohedral crystal system alloys. Many of the generally accepted paradigms prove to have limited validity.

A fifth consequence of defining the $Q_k = 10$ reference line is the introduction of an experimentalist view towards future options. The bismuth telluride alloys are in the thermal conductivity class for amorphous silica, a 13.7 mW/cm K thermal conductivity at room temperature. The lower value for Ag_2Se shown in Fig. 3 shows that an electrically conductive, 1000 mho/cm solid may be produced with significantly smaller lattice components. Thus, a critical aspect of progress towards higher figure of merit refrigeration alloys with improved efficiencies lies in the discovery and optimization of alloys giving access to high Q_s , which may be alloyed to minimum Q_k without degrading the thermoelectric performance. The existence of 500-600 Q_s Bi_2Te_3 samples as outlier materials with a 1500 Q_s approached by Bi-Sb alloys implies that the proposal has more than speculative merit.

The sixth implication emerging from the Q_s - Q_k approach to thermoelectric property characterization is that at elevated temperatures a greater promise exists for attaining improved alloy performance. The thermal conductivity of the crystal lattice is characterized by a $1/T$, reciprocal dependence upon temperature. Thus, a lower lattice component should be accessible at, say, 900K as compared to 300 K if the radiation terms remain small enough. The $ZT = 2$ gadolinium selenide alloy, Gd_2Se_3 , is characterized by a less than 100 Q_s electron transport feature, so the superior figure of merit from a low lattice thermal conductivity would be further benefited by improvements in the Seebeck quality (7). The existing Bi_2Te_3 , PbTe , Si-Ge , etc., alloys represent the beginning to a technology rather than the end to new options.

The discussion emphasized that progress depends upon the escalation of the breadth and depth of understanding on how the crystalline imperfection structures do control electron and phonon transport in solids. The three-dimensional structural chemistry of the space lattice interaction with the unit cell becomes critical to the optimization process. Achieving ultimate performance limits means the elimination of gross degrading phenomena on macro, micro, and submicro scales. This makes possible the recognition of optimizations in the atomic scale properties of the n- and p-type solid solution phases.

Summary

An empirical, pragmatic basis has been utilized to develop an approach to identifying the comparative qualities of experimental samples of thermoelectric materials. The approach emphasizes the need to learn how to manipulate imperfection structures in real solids so as to optimize the material performance, particularly for use in thermoelectric energy conversion. A route is created which permits a systematic approach to organizing experimental data in comparative ways. As data accumulate, the opportunity for undertaking more fundamental

studies emerges while efforts are continued to develop materials suitable for commercial developments.

The approach acknowledges the complexity of heavily doped semiconductors with regard to all aspects of materials science. Progress is dependent upon learning ways for coping constructively with this complexity. Subsequent papers will address various aspects in the study of bismuth telluride, $(\text{BiSb})_2(\text{Te,Se})_3$ -class materials relevant to the general challenges.

Acknowledgments

The continued support of Borg-Warner Corporation and the Roy C. Ingersoll Research Center management and staff is gratefully acknowledged. Without this, advances in the technology would not have been possible. Particular acknowledgments are given to Dr. D. W. Collier and Dr. L. V. Sloma's contributions along the way, and to Dr. D. F. Hoeg and W. H. Weltyk for the support making possible the documentation. Specific acknowledgment needs to be given to Dr. A. Reich, Stanley Cook, Bharat Kalsa, and John Horwath for varied contributions to the conceptual evolutions. Dr. Jack Madigan (deceased) was responsive to the original concept evolutions by teaching physics to a chemist. Throughout the support of many friends and colleagues near and far has been deeply appreciated.

Manuscript received Dec. 30, 1983.

Donald Tuomi, Ph.D. and Associates, Limited, assisted in meeting the publication costs of this article.

ABSTRACT

The present status of plasma etching of refractory gates is reviewed in the context of high resolution patterning. Etching of various refractory metals (*cf.* Mo, W) and metal silicides (*cf.* MoSi₂, WSi₂, TaSi₂) is particularly emphasized and discussed in terms of etch rate, anisotropy, etch selectivity over SiO₂, resist, and other thin film materials. Key issues addressed include choice of etchant (*cf.* CF₄, NF₃, CCl₄), additive gas (O₂, Ar, He), and reactor configuration (planar plasma, RIE, flexible diode, triode). Factors influencing the control of edge profiles in single-level and composite gate structures are described. End-point detection of these plasma processes is reviewed and compared with that developed for silicon etching. Also, basic mechanisms in these processes, such as desorption of reaction products, are discussed with respect to their effect on the etching characteristics of these refractory materials.

Refractory metals, metal silicides, and other metal compounds are under active development as gate and interconnecting materials in VLSI circuits because of their low resistivity (as compared to doped poly-Si) and, in the case of the silicides, good oxidation properties. This rapid development is demonstrated by the large body of work reported in the last few years, as reviewed by several recent articles (1-6).

Fine line patterning for the small dimensional (~1 μm) features required by VLSI necessitates the use of plasma etching techniques, such as planar plasma etching and reactive ion etching. The salient feature of these plasma processes is the use of reactive gases *vs.* inert gases commonly used in conventional sputter etching. Dry etching of poly- and monocrystalline silicon has been studied extensively (7-10), both in terms of basic plasma chemistry and microelectronic applications. In contrast, relatively little work has been reported for refractory metals and metal silicides. In this paper, the present status of plasma etching of refractory metal silicides for VLSI is reviewed. To begin with, in the "General Considerations" section, the general considerations of plasma etching processes and the pertinent aspects of metal and silicide etching are discussed. The specific processes, as applied to various gate structures (single-level metal or silicide, polycide, and others), are described, respectively, in the three following sections, in terms of advantages and trade-offs. Then, the basic mechanisms that take place during the etching of these materials are discussed, with respect to the effect they exert on the etching behavior (etch rate, selectivity, etc.). Finally the results are summarized.

General Considerations

In Table I, a summary of refractory metals on which plasma etching has been reported in the literature (11-35) is presented along with the etching gases used for each. Both fluorinated and chlorinated gases as well as their mixtures have been studied. A similar table for silicides is shown in Table II (36-53). As is well known in silicon etching, one of the fundamental differences between

fluorine- and chlorine-based plasma is the higher volatility of the reaction products (*i.e.*, silicon fluorides) in the former. To facilitate the desorption of the silicon chlorides so that further etching can proceed, ion-assisted reactions are necessary in chlorine-based plasma. However, this enhances the etching anisotropy, since the sidewall of the etched film or substrate is not subjected to energetic ion bombardment. Also, oxygen is often added, particularly for the halocarbons (like CF₄ and CCl₄), to enhance the etch rate of many of these gases. Its effect is believed to be the more efficient generation of fluorine atoms or radicals (8). Also indicated in the two tables are the reactor configurations which have been used. As the plasma technology evolved, cylindrical (barrel-type) reactors have been replaced by planar (parallel-plate) reactors. This latter group can be categorized into planar plasma etching (PPE), reactive ion (or sputter) etching (RIE), and, most recently, flexible diode (FDE) and triode-type (TE) etching modes (54-56). Generally, PPE systems are operated at higher pressures (~100 mtorr to 1-5 torr) than RIE, FDE, and TE systems (10 to 100 mtorr). For comparison, conventional sputter etching uses inert gases at 1 to ~10 mtorr. The main configuration difference between the PPE and RIE modes is in the RF power coupling, with the power supply connected to the top electrode for PPE and to the bottom electrode (on which the wafers are situated) for RIE. The FDE and TE modes are further refinements of the first two. In FDE, the RF power can be switched between the two electrodes during the process, while, in TE, both of the electrodes are simultaneously powered (with the chamber wall grounded). For a more detailed discussion of plasma etcher design and etching modes, see Ref. (54-56). Since each type of reactor may be optimized for the specific application, any direct comparison among these etching modes is difficult and must take into account the system and operating parameters (such as pressure and electrode spacing).

Gate structures incorporating refractory metals and/or metal silicides are shown in Fig. 1 (4) and discussed in the following sections. Since the patterning of these refractory materials is intricately related to the MOS gate structures' being implemented, it is useful to first point out

various gate structures that have been suggested and their related etching requirements (Table III). The simplest gate structure is a direct replacement of the poly-Si with a refractory metal or metal compound-like silicide. The patterning process, in this case, should etch the gate conductor anisotropically and selectively over the gate dielectric (SiO₂, Si₃N₄) and the masking material (photoresist). Despite the simplicity of the single-level gate approach, the reliability of the poly-Si gate has led to the implementation of various composite gates in which the poly-Si/SiO₂ interface is maintained while the conductivity is enhanced with a silicide overlayer. The most widely accepted approach is the silicide/doped poly-Si ("polycide") structure. However, because of the bilayer nature of the polycide, its etching is more demanding. The requirements include: anisotropic and selective etching of both the silicide and poly-Si over the masking layer

and selective removal of poly-Si over the gate dielectric. In the next three sections, the etching of single-level metal and silicide gates is discussed first, and then the patterning of the polycide and other gate structures are described.

Pattern Definition of Single-Level Gates

Metals.—Among the refractory metals, molybdenum and tungsten are most widely used as MOS gates and interconnections. One of the major conditions for a metal to be considered as a gate material is its stability with the gate dielectric, which is usually SiO₂ or Si₃N₄. The group consisting of molybdenum, tungsten, and rhenium is the most stable over both oxide and nitride (4, 58) and hence most appropriate for microelectronic applications. Other metals, such as titanium and tantalum, can react with the oxide or nitride at relatively low temperatures (~600°C)

Fig. 1. Various gate structures incorporating refractory metals and metal silicides (4).

and thus may not be directly placed over the gate dielectric. However, these other refractory metals have been used in other applications, such as interconnections in hybrid circuits and superconductors in Josephson junctions. Therefore, the etching gases and modes used for their patterning have been included, for the sake of completeness, in Table I along with those for molybdenum and tungsten.

Fluorinated plasmas.—It has been known for some time now that fluorocarbon plasma can etch many refractory metals. Similar to silicon etching, addition of a small amount of oxygen to CF_4 substantially increase the etch rate of these metals. For example, adding 4% oxygen to CF_4 enhances the etch rate of molybdenum by about a factor of 4 (4). For high resolution patterning, planar-type reactors are usually utilized in either the planar plasma etching (PPE) (1) or reactive ion etching (RIE) mode (14). Recently, other fluorinated gases, most notably NF_3 and SF_6 , which can generate more fluorine atoms or radicals, have also been investigated (15-19), resulting in much higher etch rates. In Fig. 2, the etch rate of Mo and SiO_2 is

shown as a function of pressure for a planar reactor operating in the PPE mode. While the silicon and oxide etch rates increase with pressure, the metal etch rate remains fairly constant within the pressure range studied. Such a dependence is believed to be due to the lower volatility of molybdenum fluorides than the silicon fluorides. Diluting NF_3 or SF_6 with inert or oxidizing gases generally results in a decreased concentration of reactant species. Examples of this have been shown for NF_3/Ar or N_2 (57) and SF_6/O_2 (18). Therefore, addition of conventional dilutants (Ar , O_2 , He) only leads to a reduced metal etch rate. This trend is illustrated in Fig. 3 and 4 for the PPE of molybdenum in NF_3/Ar (15) and RIE of tungsten in SF_6/O_2 (18), respectively. Furthermore, while both molybdenum and tungsten can be selectively etched over SiO_2 , the etch rate of Si_3N_4 is usually faster than those of the metals in fluorine-based plasma (4).

Edge profiles of these metals have only been studied in a few of these plasmas. A vertical-to-horizontal etch ratio of 3 was measured for NF_3 etching of Mo at 100 mtorr in PPE (15), while very anisotropic profiles were obtained for both Mo and W in SF_6/O_2 using RIE at relatively low pressures (10-20 mtorr) and high power (18, 19).

Chlorinated plasmas.— CCl_4 has been most thoroughly studied among the chlorine-based compounds. Pure CCl_4 plasmas not only generate undesirable polymers in the etching chamber, but also etch Mo and W very slowly, and hence cannot be used. Addition of large amounts of oxygen (more than 50% by volume) greatly enhances the etch rate and selectivity over SiO_2 (60-100) (20-22). The reason for the large increase in etching is believed to be the formation of molybdenum oxychlorides, which have a much higher volatility than the chlorides. Obviously, because of the large amounts of oxygen added, the resist etch rate is also increased, but this is considered an acceptable tradeoff. For example, when the oxygen percent-

Fig. 3. Etch rates of Mo, MoSi₂, doped poly-Si, and SiO₂ as a function of argon percentage in NF₃/Ar mixtures (16).

age is varied from 20% to 80%, the photoresist (AZ1350J) etch rate is only tripled while the Mo etch rate is five times higher (21). Similar variations in etch rate with oxygen content were measured for oxygen percentage between 60% and 80% (Fig. 5) (22). Similar dependence on oxygen content was observed for negative electron beam resist (20). In addition, the silicon etch rate was sharply suppressed at over 70% oxygen, making selective etching of Mo over silicon feasible (21). As will be discussed in the "Mechanisms" section, similar characteristics are expected for tungsten, rhenium, and chromium, but only the case of chromium etching has been verified in the context of photomask fabrication (34, 35). Actually, in one case, carbon dioxide, instead of oxygen, was used as the oxidant so as to retard photoresist degradation (35).

The edge profiles obtained in CCl₄/O₂ plasmas were almost totally vertical. This may be due to molybdenum oxychlorides, which can only be formed or desorbed under energetic ion bombardment. In fact, traces of oxychlorides can be found on the electrode surfaces and the chamber walls after etching. Thus, precautions must be taken to prevent contamination of the exposed wafer surfaces. To clean up the chamber walls after etching, a fluorinated plasma (like CF₄) can be used (22).

Halide mixtures.—To improve the etching characteristics, combinations of fluorine- and chlorine-based gases can

Fig. 4. Etch rate of tungsten as a function of oxygen content in SF₆/O₂ mixtures for a reactive ion etcher (18).

Fig. 5. Etch rate of molybdenum films deposited in two different sputtering systems as a function of oxygen percentage in CCl₄/O₂ mixtures (22).

be used. Basically, there are two ways of introducing two or more halide components into the etching reactions. The first is direct mixing of the gases at the inlet of the reaction chamber. Since the ratio of each component is controlled by the gas flow, it can be adjusted at will. The second is to use a molecule containing all of the halide components, such as fluorochloromethane.

As far as halide mixtures are concerned, the refractory metals have been mostly patterned using chlorofluorocarbons. For example, reactive sputter etching of Mo with CCl₂F₂ and C₂Cl₃F₃ has been reported in an early study (26). Using these reactive halide compounds, an etch rate four to five times higher than using argon was observed for molybdenum.

Metal silicides.—The stability trends mentioned earlier for refractory metals on SiO₂ and Si₃N₄ also apply to the metal silicides (2, 4). The situation is less critical for the silicides because, among the silicide compounds, only the disilicides which have a large percentage of silicon (66.7%) are commonly used. Nevertheless, the disilicides most often implemented in single-level structures are still those of molybdenum and tungsten. Etching gases and modes are listed in Table IV.

Fluorinated plasmas.—For silicide etching in fluorinated plasmas, the basic mechanisms involve the reaction of the silicide with the generated fluorine radicals to form metal and silicon fluorides. Similar to refractory metal etching, the initial plasma etching of silicides involved fluorocarbons (such as CF₄/O₂) in barrel reactors. This reactor/etchant combination resulted in acceptable silicide etch rate and selectivity (over SiO₂ and photoresist), but also in isotropic edge profiles. For example, etch rates of 800-1000 Å/min have been reported for MoSi₂ (37) and NbSi₂ (44) at 100W of RF power and a pressure of 0.2-0.3 torr with an etch rate selectivity over thermal oxide of ~15 to 1. To improve the linewidth control while increasing the etch rate, more advanced techniques using parallel-plate-type reactors in conjunction with other fluorinated compounds (such as NF₃ and SF₆) have been employed. An example of this is PPE of MoSi₂ over SiO₂ in NF₃-based plasmas. Diluting NF₃ with inert gases (argon, in this case) leads to a monotonic decrease in silicide etch rate (Fig. 3). For argon concentration as high as 50%

in NF₃/Ar, the selectivity over oxide did not significantly deteriorate.

Chlorinated plasmas.—Compared to fluorinated plasmas, fewer works have been reported on chlorinated plasmas. In one study (22), RIE of MoSi₂ using CCl₄/O₂ was reported. Generally, lower etch rates of both silicide and oxide were measured than in the NF₃ case. The relationship between etch rates (of MoSi₂, SiO₂, and photoresist) and pressure for 50% O₂ in CCl₄ is shown in Fig. 6. The silicide etch rate increases with pressure (as in NF₃ plasmas), whereas the oxide etch rate is constant (while it increases with pressure NF₃). For the same RIE system, CCl₄ diluted with oxygen (40%–70%) resulted (22) in a lowered etch rate for both MoSi₂ and SiO₂ (Fig. 7).

Fluorinated/chlorinated mixtures.—Recently, several combinations of fluorine/chlorine compounds have been investigated for a few silicides. However, most of the studies addressed the problem of polycide etching and hence concentrated on optimizing silicide/poly-Si etch rate ratio and edge profiles. These results will be discussed in the third part of the section below. In one recent study, RIE of MoSi₂ and NbSi₂ over oxide was investigated with SF₆ or NF₃/CCl₄ or HCl mixtures. The details will be published elsewhere (53). In general, the silicide and poly-Si etch rate increases with increasing fluorine content, RF power, and pressure. For example, at 100W in a 50/50 NF₃/HCl mixture, the etch rates of MoSi₂ and SiO₂ were 370 and 60 Å/min but were increased to 540 and 300 Å/min, respectively, when the RF power was raised to 300W. Also, HCl and NF₃ plasmas tend to have a higher

substrate dc bias (by about an order of magnitude) than CCl₄ or SF₆ plasmas under identical conditions.

Patterning of Polycide Gates

To preserve the reliable nature of poly-Si gate structures while enhancing the conductivity with silicides, a

composite silicide/doped poly-Si (polycide) structure is widely used. The pattern definition of this bilayer structure is complicated by the possible undercut of either material. As discussed in the "General Considerations" section, the requirements for etching this structure are more stringent. In the ideal case, equal etch rates and perfect anisotropy under all conditions for both materials would yield the vertical profile shown in Fig. 8a. If the anisotropy for the two materials is not but equal, the dashed edge profile would result. To achieve a realistic optimal solution, one has to understand the interdependent relationships involving the loading dependence of etch rate and anisotropy of the materials exposed during etching. For example, severe silicide "pull-back" (Fig. 8b) can result from either (i) high silicide/poly-Si etch rate ratio ($\gg 1$) or (ii) increased lateral silicide etching upon the near completion of vertical silicide etching. If the second case is operative, separate vertical etch rate data for silicide and poly-Si would not predict the correct profile. However a silicide "roof" (Fig. 8c) can be formed only when the silicide/poly-Si etch rate ratio $\ll 1$. This discussion assumes that the etching cycle is terminated precisely at the point where the underlying oxide is exposed, and, therefore, there is no overetching. To obtain vertical edge profiles for this composite gate structure, two basic approaches have been taken. One is to optimize the choice of etchants and operating conditions, and the other is to design novel reactor configurations. In the following, both of these approaches will be described for the specific silicide/etchant combination reported.

Fluorinated plasmas.—Coevaporated tungsten silicide polycide edge profiles have been studied as a function of oxygen percentage in CF_4 for a planar reactor in the PPE mode (48). Figure 9 shows the etch rates of both WSi_2 and poly-Si and their etch rate ratio as a function of oxygen percentage in CF_4 . At low oxygen concentration ($<3\%$), the silicide is etched faster than the n^+ poly-Si, leading to a pull-back of the silicide layer. At higher O_2 contents, the doped poly-Si is removed faster, resulting in a silicide overhang. A similar trend was reported (41) for RIE of WSi_2 in a flexible diode reactor with CF_4/O_2 mixtures, but the oxygen percentage at which equal silicide/poly-Si etch rates were measured was $\sim 35\%$ (Fig.

Fig. 8. Schematic drawings of three types of possible edge profiles for the polycide structure.

Fig. 9. Etch rates of WSi_2 and doped poly-Si and their etch rate ratios as a function of O_2 percentage in CF_4/O_2 mixtures for a PPE reactor (39).

10). In either study, micron-size WSi_2 polycide gates with acceptable profiles were realized. This cross-over point in tungsten silicide *vs.* poly-Si etch rates apparently cannot be found (48) when adding oxygen (up to 50%) to SF_6 (see Fig. 11).

For $MoSi_2$ polycide etching, both CCl_4/O_2 and NF_3 plasmas are usable. For example, in Fig. 2, the etch rate dependence on pressure is shown for poly-Si, $MoSi_2$, Mo, and SiO_2 in NF_3 . It is seen that the poly-Si-to-silicide etch rate ratio is about 3-4, leading to silicide roof formation. A similar overhang was reported (43) for the PPE in CF_4/O_2 of cosputtered $TaSi_2$ on doped poly-Si.

Fluorinated/chlorinated mixtures.—To improve or tailor the etching characteristics, combinations of gases can be used. The objective is to provide the optimum reactant gas for each layer of the polycide. Etching of refractory metal silicides in pure chlorinated plasmas usually yields a very low etch rate due to the limited volatility of the resulting metal chlorides. To enhance the silicide etch rate, either oxidants or fluorine components may be added. Oxidant additives are used when they can convert the metal chlorides to more volatile oxychlorides. Similarly, higher volatility can be achieved in many cases with metal fluorides obtained from the introduction of fluorine components. This latter approach is exemplified in Fig. 12 and 13 for RIE of

Fig. 10. Etch rates of WSi_2 as a function of oxygen in CF_4 for a planar reactor in the RIE mode (41).

Fig. 11. Etch rates of WSi₂ and n⁺ poly-Si as a function of oxygen percentage in SF₆/O₂ mixtures for a PPE reactor (48).

Fig. 12. Etch rates of TaSi₂ and n⁺ poly-Si as a function of gas composition for SF₆/Cl₂ mixtures (51).

TaSi₂ polycide (51). It is interesting to note that, in SF₆/Cl₂ mixtures (Fig. 12), while the poly-Si and TaSi₂ etch rates do not change uniformly with increasing SF₆ content, their ratio decreases monotonically but is always larger than unity (i.e., no crossover point). However, the addition of CF₄ to chlorine plasmas results in two apparent crossover points (Fig. 13).

An alternative method to introduce chlorine and fluorine species is the use of a molecule consisting of both components, such as fluorochlorocarbons. Only very limited data have been reported on this approach (49) using CCl₂F₂ in the triode-type etching mode on WSi₂ polycide. A third alternative employs a sequence of etching gases and modes for the silicide, interfacial region, and poly-Si (47).

Fig. 13. Etch rates of TaSi₂ and n⁺ poly-Si as a function of gas composition for CF₄/Cl₂ mixtures (51).

Etching of Other Gate Structures

While the single-level metal or metal compound and composite polycide gate structures have been most extensively investigated, there are other novel structures which have also attracted considerable attention lately.

Self-aligned gate structures.—Realizing that the pattern definition of a composite silicide gate like the polycide requires stringent optimization and extensive development efforts, self-aligned silicide/poly-Si gate processes have been proposed recently (59-62). A variety of silicides (PtSi, TiSi₂, TaSi₂, CoSi₂, and others) have been incorporated into gates and contacts in this type of self-aligned processing. This approach involves patterning of the poly-Si gate and opening of the silicon substrate contacts, deposition of a metal layer, heat-treatment to form silicide only over the exposed silicon areas, and the selective removal of the unreacted metal. While no high resolution silicide patterning is needed in this process, plasmas may be used in the last step to selectively remove the unreacted metal.

Edge-defined structures.—To achieve submicron device structures without resorting to the use of advanced lithographic equipment, edge-defined patterning has been investigated. Many device features—oxide spacers and gates, just to mention two—have been realized with this maskless approach. The edge-defined approach usually involves the following steps: (i) definition of a vertical edge, (ii) conformal deposition of either a gate material (direct technique) or a material to be used as a transfer mask (indirect technique), (iii) anisotropic etching of the conformal film, resulting in a residue along the initial edge, (iv) selective removal of the initial step material, leaving only the residue, and (v) transfer of the pattern into the underlying gate material layer (indirect technique only). The direct technique has been applied to the realization of submicron MoSi₂ structures shown in Fig. 14 (45). The anisotropic etching was performed in a PPE reactor at relatively high power and low pressure with NF₃ plasma. The step material used was aluminum, which was patterned in a CCl₄ plasma. The molybdenum silicide layer was conformally deposited by dc magnetron sputtering and then anisotropically etched in a PPE reactor with NF₃.

Metal/metal nitride structures.—Recently, molybdenum gates overcoated with a layer of its own nitride have been studied to avoid dopant ion channeling. Unless the nitride layer is formed through self-aligned nitridation after the Mo patterning, patterning of the composite molybdenum nitride/Mo stack is needed. Only limited data have been reported in RIE with CCl₄/O₂ (22). The nitride etch

Fig. 14. SEM micrograph of a submicron MoSi_2 line fabricated with an edge-defined technique (45).

rate is generally about 40% higher than the Mo etch rate. For example, etch rates of 1460 and 1070 $\text{\AA}/\text{min}$ was obtained for Mo_2N and Mo, respectively, in 75/25 CCl_4/O_2 at 250 mtorr. Furthermore, lateral undercut of only 0.1 μm on each side was measured for a $\text{Mo}_2\text{N}/\text{Mo}$ composite.

Endpoint Detection

To selectively etch a single layer or multiple layers of thin films over underlying layers or substrates, the ability to detect the endpoint of the plasma etching process is essential. A variety of techniques have been developed to meet this need. Among them are optical emission spectroscopy, mass spectrometry, optical reflection, impedance monitoring, Langmuir probe, and pressure change (72). Mass spectrometry and optical emission spectroscopy are apparently the most popular. Both of these techniques involve the monitoring of reactive species and/or etch products. However, the product species are preferred because they originate solely from the etching reactions. For example, in plasma etching of silicon, silicon dioxide, and silicon nitride, the peak most often mon-

Fig. 15. Endpoint detection of PPE of sputtered MoSi_2 over oxide using a photodiode sensitive in the 300-700 nm region (peak sensitivity at 500 nm) (73). Etching conditions: $\text{CF}_4/4\% \text{O}_2$, 70W, 1.2 torr.

itored in mass spectrometry is SiF_3^+ ($M/e = 85$ amu) even though other species such as O^+ , Si^+ , and CO^+ have also been used (72). During the etching of these refractory materials, the product species generally have large M/e ratios (>200 amu) and hence harder to detect in quadrupole-type spectrometers (where transmission varies as $1/M$). Consequently, the reactant species are preferred, but very little

Fig. 16. Vapor pressures of some refractory metal fluorides (63-65).

Fig. 17. Vapor pressures of some refractory metal chlorides (68-71).

work in this area has been reported. Unlike mass spectrometry, optical emission spectroscopy is nonintrusive and generally easier to set up, but the identification of the peak signals is more difficult. For fluorinated plasmas, atomic fluorine and CO (if fluorocarbons are used) are generally monitored for all silicon compounds because of their great sensitivity. Atomic silicon or SiCl_3 are usually measured for chlorine-based plasmas (72). Since the emission lines from either the metals or metal compounds within 200 and 700 nm are not strong enough for endpoint detection, the reactant species are usually used instead. For the metals, atomic fluorine line at 704 nm was monitored for CF_4/O_2 etching of LPCVD tungsten on oxide (70) and atomic chlorine line at 256 nm for RIE of sputtered Mo on oxide with CCl_4/O_2 (22). In the latter case, a loading effect on the 256 nm line intensity was observed (22). During the etching of refractory metal silicides, the peaks used for silicon (F, CO, etc.) can also be used, owing to the large percentage of silicon present. For example, a photodiode sensitive in the 300-700 nm region (which includes the CO peaks) and a maximum sensitivity at 500 nm has been found to be effective for endpoint detection during PPE of MoSi_2 and other silicides over oxide in an automated single-wafer etcher Fig. 15 (73). Because of the high reflectivity of the metals, the optical reflection method which measures the reflectivity changes as the etched layer gets thinner can also yield satisfactory results. In fact, this method was used in conjunction with optical spectroscopy during the plasma etching of tungsten on oxide mentioned earlier as well as etching molybdenum on oxide (72).

Mechanisms

To control the etching process, one must understand the fundamental mechanisms that occur. In the case of the silicides, this is complicated by the fact that they are binary compounds. In turn, polycide is an even more complex bilayer structure. Surface reactions during etching require the breaking of metal-silicon and metal-metal bonds as well as silicon-silicon bonds. Also, for binary compounds, there is a greater variety of possible reaction products, the desorption of which can affect the etch rate. The metal halides that are formed in this process are less volatile than the silicon halides. Therefore, only the former can be a rate-limiting step in the etching process. In Fig. 16, the vapor pressures of some of the pertinent metal fluorides are shown as a function of temperature (63-65). For comparison, silicon tetrafluoride, which is not included in the figure, has a vapor pressure of over 20

* At 25 atm.

atm at room temperature. WF_6 is the most volatile fluoride in this group; TiF_4 is the least. Among the metal fluorides, the hexafluorides are more volatile than the pentafluorides and other lower fluorides. For example, MoF_6 vaporizes at $35^\circ C$, but MoF_5 boils at $214^\circ C$, while MoF_4 and MoF_3 are estimated to have higher boiling points. Thus, any lower fluorides formed will remain at the surface until further reactions convert them to the higher fluorides and eventually desorb from the surface. Consequently, the higher metal fluorides are the reaction products expected in the effluent.

The situation is slightly more complicated with the addition of oxygen. In Table V, the melting and boiling points and applicable sublimation temperatures (some of them estimated when experimental data not available) of the metal and silicon oxyfluorides are shown along with those of the fluorides (66, 67). It can be noted that the oxyfluorides are less volatile than the fluoride compounds. Thus, while, on one hand, adding oxygen can enhance the generation of fluorine atoms, on the other, it can also retard the etching with the formation of a surface layer of metal oxyfluoride.

For chlorinated plasmas, the addition of oxygen can enhance the etching when the metal oxychlorides are more volatile than the corresponding chlorides. The vapor pressures of several metal chlorides are shown in Fig. 17 as a function of temperature (68-71). In contrast to the fluorides, $TiCl_4$ is the most volatile and WCl_6 is the least. The melting and boiling points, and the sublimation temperatures (measured or estimated), whenever applicable, are shown in Table V (66, 67). It can be seen that the oxychlorides of Group VIA metals have higher vapor pressure than the corresponding chlorides, whereas the opposite is true for the Group IVA and VA metals. The importance of volatility of oxychlorides has been clearly demonstrated in the molybdenum and chromium etching in CCl_4/O_2 plasmas (20-22, 34, 35). Increasing oxygen from 30% to 70% in CCl_4/O_2 mixtures, the Mo etch rate is four times higher, while the underlying SiO_2 etch rate is halved, leading to an exceptionally high etch rate ratio (~ 60) (21).

Summary and Concluding Remarks

We have reviewed the plasma etching of refractory metal silicides, summarizing the etching gases used for the various gate structures implemented. The factors influencing the patterning of high resolution silicide gates and interconnects have been pointed out. Since both plasma etching and refractory metal silicides are key parts of VLSI technology, we expect the development in this area to continue to advance rapidly.

An XPS and TEM Study of Intrinsic Adhesion Between Polyimide and Cr Films

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

An examination of the interface between Cr and cured polyimide (PI) was carried out using x-ray photoelectron spectroscopy and transmission electron microscopy. The results indicate that, after curing, the interface remains sharp and planar, at least on a submicron scale, with no discernible material mixing or mechanical interlocking. During Cr metallization of cured polyimide (PI) at room temperature, the first few monolayers of Cr appear to react with the pendant oxygen in the PI substrate. This layer of oxidized Cr atoms forms chemical bonds with PI on the one side, and metallic bonds with the subsequent Cr deposit on the other. It is estimated that the interfacial reaction may give rise to an eightfold increase in intrinsic adhesion strength of the Cr/PI system as compared to Cu/PI couples for which no interfacial reaction have been observed.

In the active development of an advanced VLSI packaging technology, polyimides have recently emerged as a strong contender for use as insulating and pattern delineating materials. Adhesion between the cured polyimide (PI) and wiring metallurgy thus becomes a topic of both theoretical and practical interest. It is well known that when two solids join to form a couple an intermediate region of mixing or mechanical interlocking may be produced between the bulk of the two solids depending on the nature of the solids and the joining process which is used. The adhesion properties of a couple depends therefore on the morphological and chemical physical nature of the interface.

To explore the intrinsic attributes of adhesion between cured PI and Cr metallurgy, we have used x-ray photoelectron spectroscopy (XPS) to monitor the interfacial reaction during metallization, and transmission electron microscopy (TEM) to examine the morphology of the interface. The former technique had been previously employed in a number of investigations involving metallization of polymer film (2).

Experimental

In order to obtain planar interfaces prior to processing, oxidized silicon wafers were used as substrates. 120 nm SiO₂ layers were obtained by thermal oxidation in dry ox-

ygen at 1000°C. Cr (200 nm), Cu (400 nm), and Cr (200 nm) layers were deposited sequentially in that order on the oxide layers from E-beam, heated evaporation sources. Polyamic acid (du Pont 5878) in a N-methylpyrrolidone (NMP) solvent was then spread on the Cr layers by spinning. Planar PI (200 nm) films were obtained by a standard curing procedure (350°C, 30 min). The thickness uniformity of the cured PI films was checked by ellipsometry (3) and was believed to be within ± 2.5 nm. The TEM study was carried out on a Philips 400-T electron microscope. The specimens for TEM examination were prepared by cementing together two cured PI samples face to face with epoxy. The epoxied samples were then sliced into strips of appropriate size, and the strips thinned down to a thickness of 5-7 μ m by polishing both sides of the strips. The Cr/PI interface was finally exposed by ion milling in a direction normal to the strips.

The XPS investigation was conducted in a UHV spectrometer system (PHI-1000), which consisted of a double-pass cylindrical mirror analyzer and a MgK _{α} x-ray source. Measurements were made *in situ* at a pass energy of $E_{\text{pass}} = 25$ eV when thin Cr films (one monolayer or less) were successively deposited at room temperature on a freshly cured PI film, prepared on a planar metal substrate as described above. The evaporation source was fabricated from tungsten filaments which were electroplated with a 2 μ m thick Cr layer in a chromic acid solution, followed by cleaning in H₂ at 1000°C for 30 min. The base pressure of the vacuum system was routinely maintained at 6 \times

*Electrochemical Society Active Member.

10^{-10} torr. During the deposition runs, however, it rose to 1×10^{-9} torr. The oxygen partial pressure in these instances was estimated to be less than 5% or $<5 \times 10^{-11}$ torr from the mass-spectroscopic data obtained from our UHV system. The deposition pressure varied from 5×10^{-9} to 5×10^{-8} torr, depending on the rate of deposition used. The rate of deposition was calibrated with an Inficon 2000 thickness monitor for various regulated power inputs applied to the film source. It ranged from 0.1 to 0.5 \AA per second in our deposition runs. The exposure of the evaporated films to the UHV ambient at the deposition pressure was less than 5s in all cases. To minimize the possibility of carbon contamination, the electron flood gun was not used during measurement. In view of specimen charging, no attempt was made to determine accurately the absolute binding energies. The core level spectra associated with C, O, N, and Cr were measured in an expanded energy scale following a spectral survey scan after each deposition to locate the kinetic energies of core electrons under the conditions of surface charging. In analyzing our experimental data, we relied primarily on the C1s and Cr2p core electron spectra, although other core level spectra (N1s and O1s) were also used for monitoring the interfacial reactions (4). This is because the Cr2p spectra for the overlayer and the C1s spectra for the cured PI are better documented in the literature (5).² A Gaussian decomposition program (6) was used to resolve overlapping peaks in the C1s spectra. In addition, the spectra difference technique (4) was used to help remove the arbitrariness of the curve fitting procedure. The technique proves to be particularly advantageous in this investigation since it is not sensitive to energy shifts due to specimen charging.

Results

TEM examination revealed that the interface between the cured PI and Cr overlayer was sharp and planar at least on a submicron scale (Fig. 1A, 1B, and 1C). Note that the procedure for TEM specimen preparation is different from that for ESCA investigation. At higher magnification, the interface exhibited scaled irregularities which

²Supplied by R. H. Lacombe, IBM East Fishkill Facility, Hopewell Junction, New York.

Fig. 1. TEM micrographs of the interface between Cr metal and cured PI at various magnifications. Note that the interfaces are marked with arrows.

were comparable in dimension to the crystallites in the Cr layer (Fig. 1D). There was no evidence of mixing or interpenetration at the interface as a result of PI curing. The observation lends support to the ellipsometric result regarding thickness uniformity of cured PI layers. It is thus reasonable to surmise that the interface of the Cr-metalized PI will be planar if the initial surface of the cured PI is planar.

The "full scan" XPS spectra of the freshly cured PI surface and those metallized with Cr films of varying thickness are shown in Fig. 2. It is evident that the signals associated with C, O, and N from the PI substrate attenuate with increased Cr overlayer thickness. At the same time, the Cr signal appears and grows in magnitude.

The C1s core level spectra of cured PI film consisted of three resolvable peaks prior to deposition. With successive deposition of Cr overlayers, the C1s spectra not only decreased in integrated intensity, but also exhibited changes in shape. Shown in the central column of Fig. 3 are the C1s spectra for a PI film with 0, 1.5, and 2.5 monolayer Cr coverage (spectra a, b, and c). It should be noted that the spectrum with 0.5 monolayer coverage was not included for analysis because of the uncertainties associated with extra-atomic relaxation processes attributable to submonolayer coverage. In Fig. 3d, 3e and 3f, spectra are shown to have been resolved into individual Gaussian peaks using the constraints obtained with the aid of the spectra difference technique and the previously published data (5). For example, the difference spectrum between 1.5L and zero coverage (Fig. 4a) indicates that there are at least two peaks present in the C1s spectra. The published XPS data on cured PI derived from polyamic acid resins (5) gave three C1s peaks at lower binding energy values with energy separations of 3.9 and 1.3 eV. These parameters were then used as the constraints in our Gaussian curve fitting for spectra a and b. At thicker Cr coverage (> 2.5 monolayers) the difference spectra (Fig. 4b) exhibited the presence of no more than two peaks. In such cases, 1.3 eV separation was used as a curve fitting constraint.

Fig. 2. X-ray photoelectron spectra of a bare PI surface with successively increased amount of Cr overlayer: 1-freshly cured PI; 2-1 monolayer(L) coverage; 3-1.5L; 4-2.5L; 5-3.5L; 6-4.5L; and, 7-same, but at a different spot of the surface. The deposition pressure is given for each deposition in the plot.

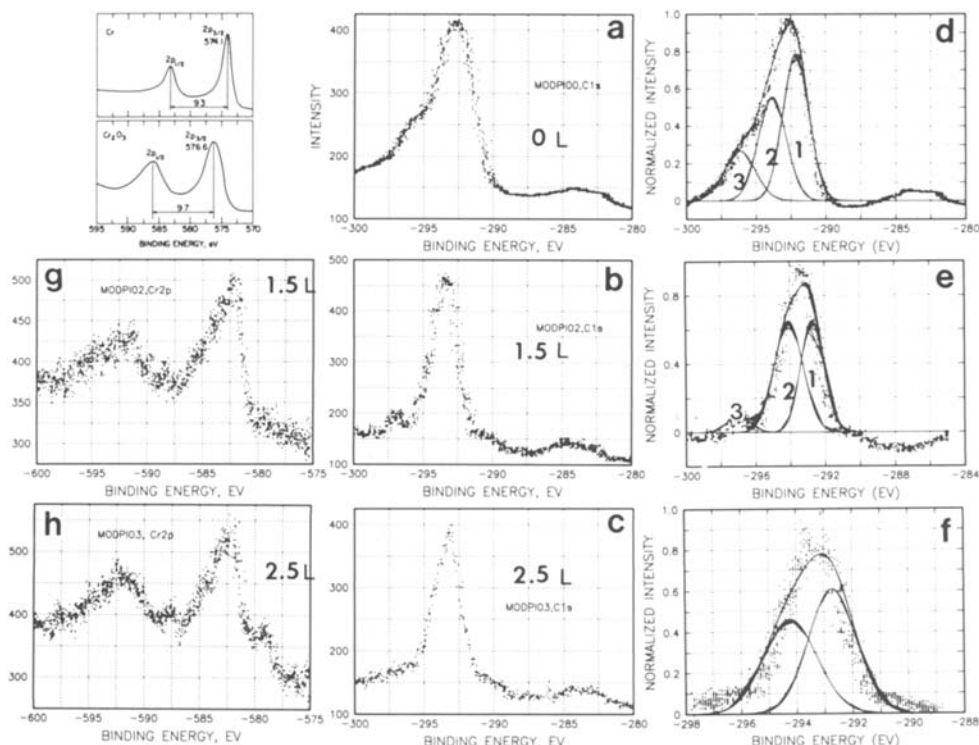

Fig. 3. C1s and Cr2p core level spectra of PI with 0L, 1.5L, and 2.5L Cr coverage. Note that peak 3, attributable to C atoms with carbonyl bonds, disappears in the background noise after 2.5 monolayers of Cr deposition while metallic Cr2p doublet emerges (Fig. 3h). See text.

As the C1s spectra indicate, the peak with the largest binding energy (labeled as peak 3) disappeared into the background after 2.5 monolayers of Cr deposit. At the same time, inspection of the corresponding Cr2p spectra (Fig. 3g and 3h) for these surfaces reveals that after 2.5 monolayers' deposition, additional peak attributable to the metallic doublet emerged against the background of those of the oxidized chromium. This is obvious when reference is made to the standard 2p spectra (6) for Cr and Cr₂O₃ reproduced in the upper left corner of Fig. 3. As a matter of fact, the metallic Cr peaks, though barely discernible, already exist in the spectrum with 1.5 monolayer coverage.

The O1s and N1s spectra of the freshly cured and metalized PI surfaces cannot be resolved with confidence by

Fig. 4. C1s difference spectra: (a) between a PI surface with 1.5L Cr overlayer and o bare PI surface and (b) between PI surfaces with 3.5L and 2.5L Cr overlayer, respectively.

Gaussian fitting. The binding energies of O1s electrons have been reported to be 530.0 eV for Cr₂O₃ (6, 8) and 532.2 and 533.5 eV for cured PI (5). As shown in Fig. 5a, 5b, and 5c, the O1s peaks appear to have broadened with successive deposition of Cr overlayer. When the C1s peak is used as the internal reference for the energy scale, it is found that a steady-state surface charging was not achieved during our XPS measurement since the amount of charging fluctuated between 7.5 and 8.5 eV from one spectrum to another. Thus, the apparent broadening of the O1s spectra cannot be resolved with some physically meaningful constraints. Similar situation prevails for the N1s spectra in Fig. 5d, 5e, and 5f.

The O1s difference spectra (Fig. 6a, 6b, and 6c) also show that the O1s signal associated with the oxidized Cr cannot be readily distinguished from that originating from the PI substrate, as one would expect from the reported binding energy values (5, 6, 8). This is evident from the fact that the decrease and increase in O1s intensity occur practically at the same binding energy when the surface charging is taken into account (Fig. 6).

Fig. 5. O1s and N1s spectra for a PI surface with 0L, 1.5L, and 2.5L Cr overlayer. No useful information can be extracted because (i) the spectra are noisy, and (ii) surface charging effect makes it difficult to determine the absolute chemical shifts. See text.

Fig. 6. O1s difference spectra (a) between a PI surface with 1.5L Cr overlayer and a bare PI surface, (b) between PI surfaces with 2.5L and 1.5L overlayers, and (c) between PI surfaces with 3.5 and 2.5L overlayers.

Discussion

When the total area of the C1s spectra and the areas of individual resolved peaks are plotted against the thickness of the Cr overlayer, it becomes clear that while the attenuation of the total peak area follows closely to the calculated escape length effect, those of the individual peaks do not (Fig. 7). In calculating the attenuation through Cr overlayer, we used 1.2 nm and 0.227 nm for the inelastic mean free path (IMFP) of C1s electrons and the effective monolayer thickness of Cr, respectively. Both of these parameters were determined according to Seah and Dench (8). Particularly noteworthy is the fact that during the first 1.5 monolayer deposit peak 3 decreased at a higher rate than the calculated whereas the neighboring peak 2 increased in magnitude.

Based on the published data (5) we can assign the three resolved C1s peaks as follows. A fully cured PI has 22 carbon atoms in its molecular unit (Fig. 8), of which 4 with carbonyl bonds ($=O$) (relative concentration: 18.2%) will be designated as peak 3. This particular peak assignment was established in a PI curing study reported in Ref. (5). The ten carbon atoms with H-bonds (45.5%) and the eight with $-N$, $-O$, or $-C$ bonds (36.3%) in the benzene rings will be assigned peaks 1 and 2, respectively. It will be noted that in addition to dissimilar atomic species, the difference in charge distribution about C atoms of groups 2 and 3 consists in the absence of a resonating carbon bond in the latter group. These peak assignments are substantiated by the agreement between the calculated relative concentrations and measured peak area ratios, and by the agreement with the reported spectra of cured PI (5) when specimen charging (approximately 7.5 eV) is taken into account. Thus, regrouping of C1s peaks and appearance of oxidized and metallic Cr2p peaks during metallization indicate that in the first few monolayers of deposition Cr was oxidized, resulting in a charge redistribution about the carbon atoms with carbonyl bonds ($=O$). This strongly suggests that the pendent oxygen in PI is involved in the reaction since no significant change in N1s spectra has been detected.

Fig. 7. Change in total and resolved C1s peak areas with Cr overlayer thickness.

Oxidation of Cr involving the pendent oxygen in PI can occur in one of the two likely ways: (i) formation of Cr oxygen complexes followed by the scission of C-N bonds depicted by the equation

(in this case, the binding energies of C1s, O1s, and possibly N1s electrons are expected to change after the first monolayer of Cr deposit) and (ii) formation of CrO , CrO_2 , or Cr_2O_3 with breakage of carbonyl ($\text{C}=\text{O}$) bonds, in which case only C1s and O1s electrons are expected to exhibit appreciable chemical shifts. Furthermore, we should anticipate the integrated O1s intensity to deviate from the expected attenuation behavior since formation of oxide alters the atomic density of oxygen, and growth of oxide may not be limited to one monolayer of deposit.

Shown in Fig. 9 is the change in integrated O1s signal intensity with successive Cr deposition. The attenuation calculated for O1s electrons in Cr (with IMFP=1.2 nm) is shown as a straight line for comparison (curve 1). In contrast to the behavior of C1s electrons, we note that after 1.5 monolayers' deposit, the integrated O1s intensity is

Fig. 8. Molecular unit of a fully cured PI and assignment of resolved C1s peaks.

Fig. 9. Experimental and calculated variation of O1s integrated intensity with Cr overlayer thickness. Curve 1 gives the calculated attenuation for overlayers consisting of Cr metal. Curve 2 gives the calculated intensity variation for the case where the first monolayer of deposit is partially oxidized. Curve 3 shows where the first monolayer is completely oxidized. Curve 4 shows where each layer of deposit is oxidized. See Appendix.

consistently higher than the calculated, indicative of extraneous oxygen uptake. The uptake could arise either from oxygen incorporation from the UHV ambient or atomic rearrangement whereby oxygen from PI moved across the interface during oxide growth. Elementary calculation using available thermodynamic data (10) indicates that oxidation of Cr is possible at an oxygen partial pressure of 10^{-11} torr, corresponding to a base pressure of 1×10^{-10} torr in our system. The driving force for the Cr_2O_3 formation at an oxygen partial pressure of 10^{-13} atm, at 300 K, (8) is given by $\Delta G \approx -110$ kcal/g-at. Cr, where ΔG is the free energy of formation. This is consistent with the observation by Allen *et al.* (8) that it is not possible to produce and maintain Cr surfaces completely free of oxygen even at a base pressure of 10^{-10} torr. The amount of oxygen uptake from the UHV ambient can be readily estimated if a sticking coefficient of unity is assumed. Since the exposure of deposited film to deposition ambient ranged from 4 to 10s, the oxygen uptake will be no greater than 1% of a monolayer.

To inquire into the origin of the oxygen uptake, we have calculated the variation of O1s integrated intensity with increased overlayer for three hypothetical cases (see Appendix): (i) in which each successively deposited Cr film was completely oxidized to form Cr_2O_3 (curve 4, Fig. 9), (ii) in which only the first Cr overlayer was completely oxidized (curve 3), and (iii) in which the first overlayer was partially oxidized or oxidized to form suboxides (curve 2). Comparison of the experimental data with the calculated intensities indicates that consistent with the Cr2p data, oxidation is indeed limited to the first few monolayers of deposit. It also suggests that the supply of oxygen from the PI substrate was insufficient to fully oxidize the overlayer and that outdiffusion of oxygen from substrate to overlayer is confined to a rather localized scale. The O1s intensity data thus appear to favor the view that oxidation of Cr by the pendent oxygen occurs with breakage of carbonyl bonds. It should be pointed out, however, that our TEM electron diffraction study failed to identify any Cr_2O_3 phase at the interface. Furthermore, although the duration of exposure to deposition pressure was only of the order of a few seconds, one cannot completely rule out the possibility of larger than estimated oxygen uptake from the UHV ambient because there might be transient upsurge of oxygen partial pressure when the filament power is turned on. Nor can our O1s and N1s data provide sufficient collaborative information for us to determine unequivocally the consequence and products of the interfacial oxidation. In short, our investigation indicates that during metallization of PI at room temperature, the first few monolayers of Cr are

oxidized by the pendent oxygen in the substrate. Pending further investigation, the product of this interfacial oxidation cannot be exactly ascertained: it may result in the formation of either Cr-O-C complexes or a separate oxide phase at the interface. However, the extent of oxidation and subsequent charge transfer and, possibly, a slight atomic rearrangement to accommodate the structural mismatch must be limited to a few monolayers of material.

Adhesion between the two phases of a couple arises from molecular forces acting across surfaces differing in nature. In the case of flawless and stress-free intimate contact, a condition which is most likely fulfilled in the process of metallization, van der Waals' interaction must be always operative because of its universal nature (10). If interfacial reactions occur during the process of joining, then added to van der Waals' contribution to the adhesion strength are the contributions from either chemical bonds formed across the interface or the electrostatic forces associated with the formation of double charge layer as a result of charge transfer.

As our study suggests barring excessive oxygen contamination during metallization, the Cr/PI interface formed at room temperature shall consist of a few partially oxidized monolayers of Cr atoms sandwiched between the PI and Cr metal. The oxidized Cr atoms form chemical bonds with the pendent oxygen in the PI, on the one side, and metallic bonds with the Cr overlayer, on the other. Furthermore, dangling bonds produced the interfacial reaction may give rise to secondary reactions accompanied by the formation of additional bonds between the substrate and the overlayer.

When the interface is sharp and planar, as in the case of our Cr/PI system, van der Waals' forces are inversely proportional to the third power of the separation between the two parallel plates (11) and amounts to *ca.* 10^6 dyne-cm⁻² or 1.02×10^8 kg/m².

Various theoretical and experimental studies of bond fracture in polymers (12) indicate that the breaking stress of chemical bonds in polymers varies from 7×10^3 to 10^5 kg/cm². The formation of chemical bonds across the PI/Cr interface is therefore expected, by a conservative estimate, to increase the intrinsic adhesion strength at least by eightfold.

Conclusions

Our study has shown that Cr metallization of cured PI at room temperature results in a couple with a sharp and planar interface if the initial PI surfaces are planar and clean. Barring excessive oxygen contamination from the deposition ambient, the first few monolayers of Cr will react with the pendent oxygen atoms in the PI, forming either Cr oxygen complexes or Cr oxides at the interface. Consideration of the chemical bond contribution to the adhesion strength of the Cr/PI system suggests that the interfacial reaction between Cr and PI increases the intrinsic adhesion strength significantly. Other things being equal, metallization of PI with Cr will have at least an eight-fold increase in adhesion strength as compared to other metals such as Cu (13), which do not react interfacially with PI.

Appendix

The intensity of photoelectrons of a given energy ejected by monochromatic x-ray from a homogenous bulk film is expressible by

$$I = \int_0^{\infty} F \alpha D k \exp(-x/\lambda) dx = F \alpha D k \lambda$$

where F is the x-ray flux, α the photoionization cross-section, D the density of the atoms from which the photoelectrons are produced, k the transmission coefficient of the spectrometer, and λ the IMFP of the photoelectrons in the film. In our *in situ* measurement, where the photon flux and other instrumental parameters are equal for the substrate and overlayer, the O1s integrated intensity of the overlayer (say, Cr_2O_3), I_{ox} , can be expressed in terms of the O1s integrated intensity of the substrate, I_{PI} (8)

$$\frac{I_{\text{ox}}}{I_{\text{PI}}} = \frac{D_{\text{ox}} \lambda_{\text{ox}}}{D_{\text{PI}} \lambda_{\text{PI}}}$$

The atomic densities of oxygen in Cr_2O_3 and fully cured PI, D_{ox} and D_{PI} , can be determined from their densities and molecular weights, and are found to be $6.22 \times 10^{22}/\text{cm}^{-3}$ and $8.05 \times 10^{21}/\text{cm}^{-3}$, respectively. For O1s electrons the IMFP's are nearly equal in Cr and Cr_2O_3 (8). The IMFP of O1s electrons in cured PI is not accurately known, but is estimated to be 1.6 times that in Cr or Cr_2O_3 based on the IMFP data on organic compounds (9). Thus

$$I_{\text{ox}} = 4.8 \times I_{\text{PI}}$$

which compares favorably with the experimental intensity ratio (4.0) for the bulk Cr_2O_3 and PI films. Given the O1s integrated intensity of the bare PI surface, we can therefore calculate the intensity variation with increasing overlayer thickness for various hypothetical cases (1). If the growing overlayer consists of Cr only, we have simply

$$I = I_{\text{PI}} \exp\left(-\frac{n d_{\text{Cr}}}{\lambda_{\text{Cr}}}\right)$$

where n is the number of monolayers deposited and d_{Cr} is the effective monolayer thickness of Cr.

If, during deposition, the overlayer has been completely oxidized to form Cr_2O_3 , we then have

$$I(n) = I_{\text{PI}} \exp\left(-\frac{n d_{\text{ox}}}{\lambda_{\text{ox}}}\right) + 4.8 \times I_{\text{PI}} \left[1 - \exp\left(-\frac{n d_{\text{ox}}}{\lambda_{\text{ox}}}\right)\right]$$

If only the first monolayer has been completely or partially oxidized and the subsequent deposit consists of Cr, then we have

$$I(n) = \left\{ I_{\text{PI}} \exp\left(-\frac{d_{\text{ox}}}{\lambda_{\text{ox}}}\right) + 4.8r \times I_{\text{PI}} \left[1 - \exp\left(-\frac{d_{\text{ox}}}{\lambda_{\text{ox}}}\right)\right] \right\} \exp\left(-\frac{(n-1)d_{\text{Cr}}}{\lambda_{\text{Cr}}}\right)$$

where $0 < r < 1$ is the extent of oxidation and $n \geq 1$.

For the calculated intensity variations shown as curves 1-4, Fig. 9, we have used the following physical parameters: $\lambda_{\text{Cr}} = \lambda_{\text{ox}} = 12\text{\AA}$, $d_{\text{ox}} = 0.307 \text{ nm}$, $I_{\text{PI}} = 796 \text{ eV counts}$, and $r \sim 0.3$, which is obtained from $(D_{\text{PI}}/D_{\text{ox}})^{2/3}$.

A Comparison of Reactive Ion Beam Milling and Reactive Ion Etching for Multilevel Resist Patterning

R. N. Castellano¹

Stanford University, Stanford, California 94305

ABSTRACT

Several multilevel resist processes have been designed to overcome the problem of nonplanar surfaces during high resolution patterning. Reactive ion etching and plasma etching are the most commonly used methods for pattern delineation. In this study, reactive ion beam milling with an oxygen beam has been shown to generate highly anisotropic resist profiles at high (100 nm/min) etch rates.

As the size of the minimum features on integrated circuits decreases toward submicron geometries, there will not necessarily be a concomitant decrease in the height of these features. For example, as the width of Al(Si, Cu) interconnections decreases from 3 to 1 μm , the metal thickness must remain close to 1 μm in order to avoid excess electrical resistance and to minimize electromigration caused by high current densities. Thus, an increasingly difficult problem is the generation of resist patterns over a nonplanar surface because of highly stepped topographies. For most resists, high resolution can only be achieved with a thin resist on a featureless surface; x-ray

¹ Present address: Strategic, Incorporated, Cupertino, California 95015-2150.

and electron-beam resist thicknesses greater than approximately 0.5 μm lead to seriously degraded resolution during exposure. In response to this problem, a number of multilevel resist processes have been reported (1-5) in order to improve pattern fidelity by reducing proximity effects (6) and eliminate development time variations due to wafer topography (2). In general, a thick (1 μm) layer of an organic resist is spun onto the substrate to be etched and baked at high temperature ($T > 120^\circ\text{C}$) to flow the resist which tends to planarize the surface by presenting a relatively flat top surface. A thin (0.1 μm) intermediate layer such as Si or SiO_2 is deposited on this resist and serves as a pattern transfer mask. The uppermost layer is a thin (0.4 μm) resist material used for high resolution lithographic

patterning because of its planarity. The pattern is transferred into intermediate layer by a reactive plasma process. This layer, in turn, acts as an inert mask for the patterning of the thick resist layer by a second reactive plasma process.

Reactive ion etching (RIE) is the reactive plasma process most commonly employed for patterning the intermediate and bottom layers. Essentially, the lower pressure (larger mean free path) and physical-chemical etching mechanisms of the RIE method allow for more anisotropic patterning compared to plasma etching (PE) in which a chemical removal predominates and undercutting (isotropic etch) can result. Because of the high degree of anisotropic etching, along with acceptable etch rates and selectivities that have been demonstrated with fluoro- or chloro-carbon reactive gases in RIE during integrated circuit fabrication, it has been a natural course that this method should be utilized for multilevel resist processes. The ultimate resolution of RIE has not been ascertained, but Oro and Wolfe (7) have reactive ion etched 0.6 μm thick crosslinked poly(methylmethacrylate) with 50 nm resolution.

Ion beam milling (IBM) is a common method for the generation of high resolution patterns. The low mean free path of the sputtered species (250 cm at 8×10^{-5} torr) suggests that IBM is a viable method for high aspect ratio pattern delineation. Etch rates of photoresist as high as 200 nm/min using a beam of oxygen ions (8) are comparable to those obtained by RIE (9). Flanders *et al.* (10) have shown that reactive ion beam milling (RIBM) with an oxygen beam can produce 40 nm linewidths in 0.2 μm thick polyimide. A comparison of the properties of PE and RIE with RIBM is shown in Table I.

In this study, RIBM has been utilized to generate multilevel resist patterns in optical resist with 0.75 μm linewidth resolution. These results are compared to multilevel patterns generated by PE and RIE.

Experimental

The tri-level resist system used in this RIBM study consisted of 1 μm AZ1350J (Shipley) - 0.08 μm polysilicon - 1 μm AZ1350J layers. The substrates were thermally oxidized <100> Si wafers. After exposure (Canon optical projector) and development of the top resist layer, the polysilicon was patterned in a low frequency planar PE system (PlanarEtch IIA, Technics, Incorporated, San Jose, California) using CF_4 . Etching was carried out at 75W RF power at a pressure of 0.1 torr for 1 min. Subsequently, the planarizing resist was patterned with a RIBM system (MIM-TLA 20, Technics, Incorporated) which utilized a 20 cm Kaufman source. Argon was injected into the ion gun and oxygen introduced into the vacuum chamber. The percentage of O_2 was varied between 25% and 100% at a total operating pressure of 8×10^{-5} torr. The accelerating voltage was varied between 500-1000V at a current density of 0.5 mA/cm². The samples were rotated and the angle of incidence of the beam trajectory maintained at 90°. The etch rates of a polysilicon thin film and a bare thermally oxidized wafer were also measured after milling at the above parameters to determine the selectivity of the resist to the Si mask and SiO_2 underlayer.

Results and Discussion

tion are shown for a channel edge and a mesa structure in Fig. 1a and 1b, respectively. The bottom planarizing resist layer is characterized by vertical wall profiles. No undercutting, trenching, or redeposition is observed; problems sometimes observed in IBM using argon gas (11). The width of the channel is 0.75 μm . The top layer of resist has been faceted, resulting in changes in linewidth dimensions. Faceting is a result of the angular dependence of removal rate associated with physical sputtering due to the fact that, after a collision of an incident ion with a surface atom, the probability that the ejected atom acquires a momentum vector away from the sample surface increases as the angle of incidence decreases from 90° to 0°. At normal incidence, more than one collision is necessary for the atom to be ejected because the momentum vector must be changed by 90°. A maximum angle, θ_{max} , is associated with each material and is typically 40°-50° from normal incidence. Since the top resist layer tends to have a slightly rounded edge close to θ_{max} from baking, lateral etching occurs with loss of dimensional control. In this tri-level system, this faceting does not influence the profile of linewidth of the bottom resist layer, which will act as a mask for subsequent patterning of the substrate. The interlevel polysilicon layer also tends to isolate the bottom resist layer from the faceting effect of the top resist film.

Fig. 2. Resist etch rate vs. oxygen concentration

Shown in Fig. 2 are the etch rates of resist, the polysilicon intermediate layer, and SiO₂ underlayer as a function of the percentage of oxygen at an accelerating voltage of 500V at a pressure of 8×10^{-5} torr. The observed increase in the etch rate for resist is straightforward; increasing the percentage of oxygen results in a greater number of activated oxygen species for chemical oxidation of the organic resist. It is not clear why the etch rates of polysilicon and SiO₂ increase with increasing O₂ concentration. It is possible that during the milling of the resist, a carbonaceous material was deposited on the polysilicon and SiO₂ test wafers as a result of decomposition of the resist. An increase in the O₂ concentration would facilitate removal of carbon by formation of CO and CO₂. The etch rates of resist, as high as 100 nm/min, are comparable to those obtained by RIE (9). Also of importance is the selectivity in etch rates between polysilicon and the resist. At 75% O₂, this ratio is 0.14, indicating that a minimum polysilicon thickness of 0.14 μm is necessary to prevent erosion of the bottom resist.

The etch rates of the resist, polysilicon, and SiO₂ also increase linearly with increasing accelerating voltage at constant (75%) O₂ concentration, as illustrated in Fig. 3. The slopes of these curves are 9, 7, and 16×10^{-6} μm/min/eV for polysilicon, SiO₂, and resist, respectively. The small changes in etch rates are consistent with physical sputtering under argon ion bombardment in which sputter yield increases at a slow rate above 300 eV and ac-

Fig. 3. Resist etch rate vs. accelerating voltage

Fig. 4. Resist profile after reactive ion etching

tually decreases above 10⁴ eV (12, 13). At 1000V, the polysilicon/resist selectivity is 0.18.

The slopes of the curves in Fig. 2 are 9, 2, and 76×10^{-5} μm/min for each percentage point increase in O₂ for polysilicon, SiO₂, and resist, respectively. This order of magnitude enhancement in resist etching over polysilicon and SiO₂ is compared to only a factor of 2 increase vs. voltage in Fig. 3.

The experimental observations in this study are a result of combined chemical etching and physical sputtering of the resist material. Chemical etching predominates. It is apparent that resist etch rates increase linearly with increasing O₂, even though no Ar was injected into the gun while O₂ was injected into the chamber. This indicates significant backstreaming of the O₂ into the ion gun where it is ionized and accelerated as a beam of oxygen ions.

The physical sputtering component of the 1350J resist etch rate is minimal under these conditions. Indeed, extrapolation of the resist etch rate curve to 0% O₂ in Fig. 2 yields a sputter rate of only 14 nm/min, compared to etch rates of 100 nm/min with 100% O₂.

Another possible mechanism is ion-enhanced, gas-surface chemistry (14). Although neutral oxygen molecules do not spontaneously react with the resist, they may react with ion beam-activated sites. The number of these sites generally increases with energy. Because of the two-dimensional structures of resist, however, the collision cascade from an incident ion is terminated in this neighboring chain and the generation of activated sites may not be large. It is not possible to determine the contribution of this process to the total resist etch rate from these experimental conditions, but this mechanism had been confirmed by Geis *et al.* (15) for Cl₂ etching of GaAs.

Several planar diode PE and RIE systems were evaluated with respect to tri-level patterning under a variety of pressures, gas flows, and power levels using O₂ as the reactive species. In most cases, a grass-like residue at the bottom of the channel, several hundred nanometers thick, remained after etching. This is illustrated in Fig. 4. All the systems utilized Al electrodes, and it was determined by electron microprobe analysis that Al was present in the residue. It is probable that eroded electrode particulates are deposited on the resist and mask further removal. Attempts to cover the Al electrode with a Teflon layer were only partially successful. A comparison of Fig. 1 and 4 shows that no residue remains after RIBM. Previous studies have shown that no material from the ion gun was detected after ion beam milling with argon (16).

Conclusion

It has been demonstrated that RIBM is a viable technique for high resolution multilevel resist patterning.

Highly anisotropic edge profiles result with no undercutting and no residual deposited materials.

The Solubility of Chromium in Gallium Arsenide

M. D. Deal*¹ and D. A. Stevenson**

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

The solubility of Cr in GaAs was investigated using well-defined Cr sources selected from specific regions of the Cr-Ga-As system and SIMS analysis. Using these sources, maximum solubilities and solid-liquid distribution coefficients were obtained. These results and the ternary information were used as a point of reference for correlating previous literature values of Cr solubility. The study of the dependence of Cr solubility upon donor concentration and concurrent capacitance voltage measurements were used to establish the electrical activity of Cr in GaAs.

Chromium is intentionally introduced in the growth of gallium arsenide (GaAs), both during bulk growth and epitaxial layer growth. The purpose of this addition is to compensate the electrically active residual defects and impurities in order to provide semi-insulating substrates for the growth of active layers. As a consequence, there is interest in the solubility of chromium (Cr) in GaAs for a wide variety of growth and processing conditions. However, the failure to recognize that the Cr solubility depends in a fundamental way on the temperature, Cr source, and extent of equilibrium in the system or process has led to considerable confusion. A major source of this confusion arises from a failure to consider fundamental ternary-phase equilibria principles in the design and interpretation of solubility experiments.

There is good agreement that the maximum solubility of Cr in otherwise undoped GaAs at or just below the melting point (1238°C) is about $2 \times 10^{17} \text{ cm}^{-3}$, as obtained from melt doping in bulk crystal growth (1-3). Values obtained from liquid-phase epitaxial (LPE) growth by Woodard (4) are often quoted as maximum solubilities for a specific temperature, without recognizing that these LPE solubility values correspond to equilibrium with a specific liquid composition and are not expected to be either a unique solubility for that temperature or the maximum value. Furthermore, solubilities from these LPE experiments have been compared to those obtained from indiffusion experiments using a pure Cr source in a closed ampul (5). However, there are three problems with such a comparison: the indiffusions were not performed long enough to establish equilibrium; the pure Cr source for the diffusion source and the liquid source in the LPE are clearly different; and, as noted in Ref.(5), the pure Cr diffusion source was changing significantly during the indiffusion.

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

¹Present address: American Microsystems, Incorporated, Santa Clara, California 95051.

Further confusion arises from the frequent use of non-equilibrium systems in relation to solubility levels. Morokoc *et al.* (6) propose a solubility of Cr in GaAs of $1 \times 10^{16} \text{ cm}^{-3}$ at 580°C from molecular beam epitaxy (MBE) experiments. This value is orders of magnitude higher than any others reported for that temperature. Bonnet *et al.* (7) state that the solubility limit of Cr in GaAs is around $5 \times 10^{16} \text{ cm}^{-3}$ (temperature not known) from their metal-organic chemical vapor deposition (MOCVD) results. Linh *et al.* (8) point out that their own MBE and MOCVD results for Cr solubility differ from each other as well as from other reported results. Both these methods of layer growth, however, are nonequilibrium techniques, and are not suitable for equilibrium solubility studies. These examples show the lack of concern for equilibrium considerations, and especially the ternary-phase relations, when measuring and interpreting the Cr solubility in GaAs. A major reason for this has been the complete lack of information on the ternary Ga-As-Cr system and, in fact, misleading information on the Cr-As binary system. With recent ternary information on this system (9), however, it has been possible to interpret previous solubility information and to design new solubility studies. We present an experimental study of Cr solubility in GaAs using this phase-equilibria information as a guide.

Experimental

General considerations.—The key consideration in designing the present solubility studies was the recently determined ternary Cr-Ga-As system (9). A representative isothermal section for 800°C is shown in Fig. 1 for $X_{As} < 0.5$. The most significant features of this diagram are: a Cr phase is never in equilibrium with GaAs, there is a broad liquid + GaAs_(s) region, and there is a ternary tie triangle including a GaAs_(s) phase. The latter two regions are suitable for Cr sources for solubility; however, it should be noted that when temperature is fixed, the remaining degrees of freedom are one and zero, respectively, in accord with the Gibbs phase rule. Thus, the solubility should be

Fig. 1. Compositions of sources D, H, I, J, and W

identical for any points in the tie triangle, such as points D, H, and I in Fig. 1, whereas point J in Fig. 1 is in the $\text{Ga}_{(1)} + \text{GaAs}_{(s)}$ region and will correspond to a specific tie line, and the solubility will differ from that of the tie triangle source.

Experimental techniques.—For most of the experiments, the GaAs used was Cominco LEC high resistivity, undoped GaAs. According to Cominco, the resistivity was $\geq 10^7 \Omega \text{ cm}$ and the dislocation density was $\leq 10^4 \text{ cm}^{-2}$. This material was used in most cases, rather than Bridgman GaAs, because of its very low impurity level, which is the reason why it is semi-insulating without Cr additions. Other GaAs material used included: Crystal Specialties undoped GaAs (Bridgman); Hewlett-Packard Te-doped and undoped GaAs (LEC); and Morgan Semiconductor Si-doped GaAs. The GaAs wafers, 350–400 μm thick, were cut into approximately $1 \times 1.5 \text{ cm}$ squares. Before annealing, the squares were cleaned according to a 14-step schedule which was designed to remove particles, organic impurities, native oxides, and inorganic chemicals.

The Cr sources used were appropriate Ga-As-Cr phases which were made prior to the solubility anneals by mixing appropriate amounts of Cr, Ga, GaAs, and CrAs, and annealing these mixtures to establish an equilibrium Cr source. The source material was then crushed, and small samples of it were examined with x-rays to establish that the appropriate phases were present. The ampuls used were made from high purity quartz with a constriction in the ampul to separate the powder-source material and the GaAs substrate. The total interior volume of the ampul was $\approx 2 \text{ ml}$. A diagram is shown in Fig. 2.

Immediately after cleaning the GaAs wafer, the wafer and source were placed in the ampul, which was evacuated to $\approx 10^{-6}$ torr, and sealed. The vacuum inside the ampul was checked by a Tesla coil before and after each anneal. After annealing the samples for the appropriate time and temperature, the ampuls were quenched in water. The GaAs wafers were then ultrasonically cleaned in methanol, boiled in HCl to remove any loose particles and/or dissolve any precipitates from the surface, and then rinsed in isopropyl alcohol. The GaAs wafers were then analyzed by SIMS.

Composition analyses.—For this work, a Cameca "IMS 3F" SIMS system, at Charles A. Evans and Associates (San Mateo, California), was used. For Cr in GaAs, an O_2^+ primary beam was used, with an energy of 12.5 keV. The beam size was either 75 or 150 μm in diameter (which rastered out respective areas of 250×250 or $500 \times 500 \mu\text{m}^2$) and the sampling area, controlled by an aperture in front of the detector, was 75 μm^2 (or 150 μm^2). The usual pri-

Fig. 2. Schematic diagram of the annealing system used for the solubility and diffusion experiments.

mary beam current, which determined the sputtering rate, was $\approx 6 \mu\text{A}$, resulting in a sputtering rate of $\approx 50 \text{ \AA/s}$.

The conversion of ion intensity to Cr concentration was established with a calibration using ion implantation of Cr and by use of the As matrix ion intensity as a reference. At the start of each set of analyses, a "low chromium" sample was analyzed by SIMS to determine the background level for that day. This was usually $\approx 1 \times 10^{15} \text{ cm}^{-3}$ and sometimes less.

The time-to-depth conversion was determined by measuring the depth of the SIMS crater after each analysis with a Dektak, which uses a very sensitive stylus to measure step distances, and then assuming that the sputter rate is constant throughout the profile (confirmed by periodically profiling of Ga and/or As to establish that they give constant concentration-depth profiles). There is an uncertainty factor in the absolute depth measurement of 15%. A depth measurement taken across the entire SIMS crater showed the crater to be very uniform. Micrographs were also taken which confirm that the SIMS sputtering of GaAs was uniform, in contrast to some matrix materials, which do not sputter uniformly.

Results and Discussion

Anneals of GaAs with a "D source," as shown in Fig. 1 were performed at 800°C for 6, 12, and 24h in order to determine the length of time needed to reach the Cr solubility level in the bulk of the GaAs (*i.e.*, $> 4 \mu\text{m}$ from the surface); SIMS Cr profiles indicated that 12h was sufficient time to establish equilibrium at 800°C. The Cr solubility was thus determined to be $3 \times 10^{16} \text{ cm}^{-3}$ ($\pm 1.5 \times 10^{16} \text{ cm}^{-3}$) at 800°C. Eight anneals were then done at that temperature using sources D, H, I, and J (Fig. 1) for 6, 12, or 24h as indicated in Fig. 3. As mentioned earlier, according to the phase rule and the Ga-As-Cr ternary-phase diagram, GaAs samples in equilibrium with sources D, H, and I should have the same Cr solubility, while a sample in equilibrium with source J should be different, and probably less. The SIMS Cr profiles, shown in Fig. 3, verify this. The bulk Cr levels for the D, H, and I samples are all around $3 \times 10^{16} \text{ cm}^{-3}$, while that for J is $\approx 4 \times 10^{15} \text{ cm}^{-3}$. (The unusual surface buildup of Cr is a result of surface effects and does not relate to equilibrium bulk solubility.) These results confirm the proposed ternary-phase diagram (9) and also confirm the applicability of the phase diagram and the phase rule for this type of study.

These results explain why Woodard's solubility values (4) are lower than those obtained for sources D, H, and I; his results are for GaAs in equilibrium with $\text{Ga}_{(1)}$, whose Cr content is 0.86 atom percent (a/o), which corresponds approximately to point W in Fig. 1. This is to the right of J in the $\text{GaAs}_{(s)}-\text{Ga}_{(1)}$ region and hence one would expect a lower Cr solubility in $\text{GaAs}_{(s)}$.

Solubility anneals were then performed with the H source at 700°, 750°, 900°, and 1000°C in order to obtain the temperature dependence of the Cr solubility for the

Fig. 3. Cr in GaAs concentration profiles from 800°C solubility experiments for various times and with various sources, as indicated in the profile designations.

GaAs_(s)-CrAs_(s)-Ga_(l) tie triangle Cr source. These were performed for 18, 18, 8, and 7h respectively—long enough to reach the maximum level in the bulk. The resulting SIMS Cr profiles, including that for 800°C, are shown in Fig. 4. The Cr solubility vs. 1/T is plotted in Fig. 5. As expected, the Cr solubility extrapolates to the maximum Cr solubility of $2 \times 10^{17} \text{ cm}^{-3}$ just below the melting point of GaAs.

Fig. 4. Cr in GaAs concentration profiles from solubility experiments for times and temperatures indicated.

Fig. 5. Cr solubility in GaAs (for GaAs_(s)-CrAs_(s)-Ga_(l) region), with maximum solubility of Cr in GaAs as indicated.

As is the case with most impurities in semiconductors, Cr exhibits retrograde solubility in GaAs; the solubility increases with temperature above the 670°C eutectic point, between CrGa₃ and GaAs.

To confirm that the bulk levels reached in the solubility experiments correspond to equilibrium conditions, an experiment was done in which a GaAs wafer was annealed at 900°C (with the H source) for a long time (12h) and then annealed at 800°C (again with the H source). SIMS analysis was done after each anneal with the resulting Cr profiles shown in Fig. 6. As one can see, the bulk

Fig. 6. Cr in GaAs concentration profiles, from solubility experiments. A: 900°C, 12h indiffusion with H source. B: subsequent 800°C, 12h anneal with H source. C: 800°C, 12h indiffusion into undoped GaAs, with H source.

Cr level after the 900°C anneal (curve A) was at $\approx 8 \times 10^{16}$ cm^{-3} , the determined solubility level for that temperature. The bulk Cr level after the subsequent 800°C anneal (curve C) is lower, $\approx 4 \times 10^{16}$ cm^{-3} . Also shown (curve B) is the profile of the original 800°C solubility determination, with a bulk level of 3.5×10^{16} cm^{-3} . This shows that the same Cr concentration (within experimental error) was reached both from above and from below, confirming that it is the equilibrium solubility.

From the solid solubility results, and from the Ga-As-Cr phase diagram (specifically, the Cr concentration in the Ga-rich liquid in equilibrium with $\text{CrAs}_{(s)}$ and $\text{GaAs}_{(s)}$), the distribution coefficient, k , of Cr in GaAs was determined for various temperatures; the distribution coefficient equals $[\text{Cr}]_s/[\text{Cr}]_l$, the solid being $\text{GaAs}_{(s)}$ and the liquid being $\text{Ga}_{(l)}$. These numbers, as well as the liquid and solid solubility values from which they were calculated, are tabulated in Table I. The distribution coefficients vs. $1/T$ are plotted in Fig. 7. The distribution coefficient at 800°C was also determined from sample J (GaAs in equilibrium with J source), and is the lower point at 800°C. The results show that k does not vary much with Cr concentration; even with a variation in solubility of an order of magnitude between J and D, k differed by only a factor of two. Also plotted in Fig. 7 are the results of Woodard (4), from his LPE studies (which are for $\text{GaAs}_{(s)}$ in equilibrium with a Ga-rich liquid of 0.86 a/o Cr concentration). These are consistent with the results for higher Cr concentrations. Therefore, while the solubilities vary as the total composition moves across the phase diagram, the ratio of solid solubility to liquid solubility remains approximately constant, as one would expect for dilute solutions. In addition, the distribution coefficients determined from Cr-doped GaAs crystal growth, which are for temperatures just below the melting point of GaAs, are shown [from Ref. (1, 10-13)]. As one can see, the results of the present work fill the gap nicely between the lower temperature results of Woodard for LPE conditions and the higher temperature results from bulk crystal growth. (Note: upon further examination of the "crystal growth" values, one observes the following trend: the more Cr in the melt, the smaller the k value. This is a logical trend since the melting point of GaAs decreases as the content in the melt increases. Therefore, the temperatures and the corresponding k values for those six cases would be different. Taking this into account, the six points should not be plotted at the same temperature, but for decreasing temperatures, and would follow the trend of k decreasing with decreasing temperature.)

To see if there is a difference in Cr solubility between one type of undoped GaAs and another, solubility anneals were done using GaAs substrates from different suppliers (Cominco, Hewlett-Packard, and Crystal Specialties). The differences between the resulting solubilities were within the expected error of the experiments. Therefore, the way the GaAs is produced apparently has no appreciable effect on the final equilibrium solubility.

To see the effect of doping on the solubility of Cr in GaAs, solubility anneals were performed at 800°C using the H source in Te-doped (n-type) GaAs. After an 18h anneal, 10 μm of the GaAs was etched off each surface (using a 16:1:1 $\text{H}_2\text{O}:\text{H}_2\text{O}_2:\text{H}_2\text{SO}_4$ solution) to ensure that any

Fig. 7. Distribution coefficient, k , vs. $1/T$ for Cr in GaAs. Circled data are from this work; data with triangles are from others: A, C: Ref. (11); B: Ref. (10); D: Ref. (1) and (12); E: Ref. (13), and F, G, H: Ref. (4).

surface artifacts are removed and to remove any Te-depletion region caused by Te outdiffusion. (However, since the diffusivity of Te at 800°C is very small, this was not a problem.) SIMS analysis indicated a Cr solubility of 8×10^{16} cm^{-3} , almost three times that for undoped GaAs at that temperature. This is consistent with the model of Cr as a deep acceptor in GaAs (on a Ga site) (14-17), since the presence of a donor usually increases the solubility of an acceptor (18, 19), based on charge equilibrium considerations. (Likewise, the presence of another acceptor usually decreases the solubility of an acceptor.) These results are consistent with those of Brozel *et al.* (3), who found in their crystal growth experiments that the Cr solubility increases with increasing Si concentration, the Si acting as a donor. C-V carrier concentration measurements, using gold contacts to the GaAs surface and a Hewlett-Packard automated C-V measuring system, were made on the Te-doped sample both before and after the Cr indiffusion. Before Cr diffusion, the n-type carrier concentration was 3.8×10^{17} cm^{-3} , (consistent with the reported Te doping of $\approx 3 \times 10^{17}$ cm^{-3}), whereas after Cr diffusion, it was 2.4×10^{17} cm^{-3} . This means that 1.8×10^{17} cm^{-3} carriers were compensated by the chromium. If, as proposed by Brozel *et al.* (3), the Cr acts as a double acceptor in n-type GaAs with the donor concentration greater than twice the Cr concentration, then $1/2 \times (1.8 \times 10^{17})$ cm^{-3} , or 9×10^{16} cm^{-3} Cr atoms should be electrically active. This compares very well with the measured 8×10^{16} cm^{-3} chromium (the difference is well within the experimental error). This means that the bulk chromium seen in the SIMS profiles is in solution, and are not precipitates or clusters. It is also good evidence of the accuracy of the SIMS analysis in this work.

In heavily doped GaAs (n-type), all the Cr is probably ionized (3), and acts like a normal acceptor, and its solubility should increase with an increase in the n-type doping level. The increase in the Cr solubility should then be given by the model for the influence of the donor concentration on the acceptor solubility (18-20).

$$C_s'' \approx C_s' (1 + gn/n_i)(1 + g) \quad [1]$$

Table I. Distribution coefficient, k , of Cr in GaAs (Ga-rich side)

T	$[\text{Cr}]_l$	$[\text{Cr}]_s$	k
700°C	0.17	7×10^{15}	9×10^{-7}
800°C	0.16	3×10^{16}	4.5×10^{-6}
800°C	0.05	4×10^{15}	2.5×10^{-6}
900°C	0.15	9×10^{16}	1.2×10^{-5}
1000°C	0.12	1.3×10^{17}	2.5×10^{-5}

$[\text{Cr}]_l$: Concentration (mole fraction) in Ga-rich liquid.
 $[\text{Cr}]_s$: Cr concentration (cm^{-3}) in GaAs.
 k : $[\text{Cr}]_s/[\text{Cr}]_l/4.4 \times 10^{22}$.

where C_s'' is the new solubility level, C_s' is the solubility in the intrinsic, or undoped case, n is the electron concentration (due to the doping), n_i is the intrinsic carrier concentration, and g is the degeneracy factor, which according to Sze (21), is equal to 1/4 for acceptors in Ge, Si, and GaAs. Testing this for the case discussed above, at 800°C [$n_i = 7 \times 10^{16} \text{ cm}^{-3}$ (22)], a Te doping of 3.8×10^{17} , and an intrinsic Cr solubility of $3 \times 10^{16} \text{ cm}^{-3}$, one would predict from this equation a new solubility of $6 \times 10^{16} \text{ cm}^{-3}$. The actual solubility, from SIMS, is $8 \times 10^{16} \text{ cm}^{-3}$. A similar calculation at 850°C (with the same Te doping), would predict a solubility of $8 \times 10^{16} \text{ cm}^{-3}$. A solubility experiment was done at 850°C in the same way as in the previous case, and the SIMS Cr profile indicated a new solubility of $9 \times 10^{16} \text{ cm}^{-3}$. As predicted, at high temperatures, the relative increase is less because n_i increases. As a first-order approximation, Eq. [1] is adequate.

A similar experiment was done in n-type Si-doped GaAs at 800°C for 48h. The exact Si concentration was estimated to be in the low-to-mid 10^{17} cm^{-3} , as with the Te case, and the results were qualitatively similar. The Cr solubility was higher than in the undoped case: $7 \times 10^{16} \text{ cm}^{-3}$ vs. $3 \times 10^{16} \text{ cm}^{-3}$. Even though the donor was on a different site (on a Ga site, rather than an As site as is the case of Te), the effect was the same, indicating that it is an electrical effect, rather than a steric and/or lattice stress effect.

Summary

The solubility of Cr in GaAs was studied using Cr sources that were taken from two types of regions from isothermal sections of the Cr-Ga-As system: a ternary tie triangle region including $\text{Ga}_{(1)}$, $\text{GaAs}_{(s)}$, and a $\text{CrAs}_{(s)}$; and a $\text{GaAs}_{(s)}$ - $\text{Ga}_{(1)}$ region. The former values correspond to maximum solubilities, whereas the latter correspond to tie lines and corresponding distribution coefficient. The experimental values of the maximum Cr solubility determined for temperatures from 700° to 900°C extrapolated nicely to previously reported values of the maximum solubility of Cr near the melting point of GaAs. Distribution coefficients were also determined over the same temperature range and connect nicely with distribution coefficients obtained from liquid-phase epitaxy at lower temperatures and solubilities obtained from bulk crystal growth at higher temperatures. Enhanced solubility in Te- and Si-doped GaAs in combination with the deep double acceptor (electron trap) model for Cr in GaAs.

Acknowledgments

We thank Lisa Michael for assistance in the experiments and Dr. Richard A. Reynolds for his suggestions and guidance through all phases of this investigation. We

thank Charles A. Evans and Craig Hopkins for their skill in the SIMS analysis. We acknowledge financial support from the Advanced Research and Application Corporation (ARACOR) and the Defense Advanced Research Projects Agency.

The Variation of Physical Properties of Plasma-Deposited Silicon Nitride and Oxynitride with Their Compositions

V. S. Nguyen,* S. Burton, and P. Pan*

IBM General Technology Division, Essex Junction, Vermont 05452

ABSTRACT

Silicon nitride and silicon oxynitride films with refractive indices varying from 1.60 to 1.95 were deposited on silicon substrates using plasma-enhanced chemical vapor deposition (PECVD) processing. Variation of the film's physical properties with composition is examined. Refractive indices, infrared, Auger analysis, and plasma etching of plasma-deposited films are studied before and after an annealing cycle. A direct correlation between etch rates and etch profiles of the deposited films with their composition was observed. Plasma etching, using a 92% CF_4 + 8% O_2 gas mixture, showed that the etch rate of oxynitride film increases with hydrogen concentration and decreases as the oxygen content increases. The length of the undercut, i.e., etch profile, depends on the amount of oxygen and hydrogen content in the films. Infrared data suggests that silicon oxynitride film with a refractive index of 1.75 is more stable under thermal annealing cycles, as compared to other silicon oxynitride films. Ellipsometric measurements showed that film thickness and refractive index uniformity are comparable with those of CVD processing. However, Auger depth profile analysis revealed poor compositional uniformity in all deposited films, especially at the silicon or silicon dioxide substrate interfaces.

Due to the demand for improvement in integrated circuit reliability, increased attention has recently been paid to the development of the final passivation layer which protects integrated circuits from contamination (e.g., alkaline ions and moisture). Silicon nitride films prepared by plasma-enhanced chemical vapor deposition (PECVD) processing were found to be a suitable material for final passivation. A recent study (1) indicated that converting a plasma-deposited silicon nitride to silicon oxynitride by introducing oxygen improves thermal stability, cracking resistance, and decreases film stress. In addition, low temperature plasma-deposited films also have many applications in multilayer resist lithography (2), interlevel dielectrics for multilevel metallization structures (3), and as a diffusion mask or photolithographic mask coating. However, the use of plasma-deposited films in electrically active regions of integrated circuits is still very limited (4) because the deposition is difficult to control and there is limited understanding of film properties.

In order to improve this situation, we have studied the deposition, bonding, composition, and plasma etching properties of PECVD silicon nitride and silicon oxynitride films. It has been reported that some physical properties of plasma-deposited silicon nitride are strongly dependent on composition ratio and hydrogen concentration (5-8). In this paper, we report the direct correlation between etching properties and etch profiles of both plasma-deposited (PECVD) silicon nitride and silicon oxynitride films with their composition and bonding. Fourier transformed infrared (FTIR) and Auger (AES) analysis techniques were used to analyze film compositions and bonding before and after the thermal annealing cycle.

Experimental Procedure

Films were deposited in a high frequency (13.56 MHz), parallel-plate plasma reactor with a ring-type gas injection system. The process parameters for the best uniformity ($\sigma = +3\%$) silicon nitride deposition are given in Table I. Silane and ammonia were used as reactants for this deposition process; ammonia instead of nitrogen was chosen as a reactant gas because it provides better thickness and refractive index uniformity. This is due to the comparable dissociation energy between N-H and Si-H. Helium was used as an inert carrier gas; its effect on plasma deposition has been discussed previously (9). Silicon oxynitride films were formed by reacting silane, ammonia, and nitrous oxide under the same process conditions as silicon nitride deposition. Nitrous oxide flow rate was varied from 8 to 18 standard cubic centimeters per minute (sccm) to change the oxygen concentration. The films

were deposited on both bare silicon and thermally grown silicon dioxide substrate surfaces.

Film thickness and refractive index were measured using a He-Ne laser ellipsometer (wavelength = 632.8 nm) together with Talystep techniques. FTIR studies were performed with 500 nm silicon nitride and silicon oxynitride films deposited on bare silicon substrates. Background absorption of the substrate was subtracted from the spectra to obtain the bulk film spectra. The maximum resolution of the spectrometer was 0.5 cm^{-1} wavenumber. Auger analyses for compositional depth profiles were performed with 100 nm films on both silicon and silicon dioxide substrate surfaces. The films were sputtered by 1 keV Ar^+ ion to determine the depth composition. The detection limit of this tool is 0.5 atomic percent (a/o). The films were examined as deposited and after annealing in an argon atmosphere for 20 min at 1000°C .

The plasma etching experiments were carried out in another parallel-plate radial flow etching reactor. The upper electrode is driven with a frequency of 13.56 MHz. The ground electrode, 56 cm diam, is temperature controlled. The conditions for etching were 0.16 W/cm^2 RF power, 250 mtorr, and 160 sccm total flow using 8% O_2 in CF_4 . The grounded substrate electrode was temperature controlled at 40°C during the process. Etch rates were determined as a function of oxynitride composition and annealing conditions. Etch rates were calculated using a laser interferometry end-point trace, dividing the cycle thickness by the time required to etch one cycle. The formula used to calculate cycle thickness is $\lambda/2n$, where λ is the wavelength of the laser and n is the film's refractive index.

Scanning electron microscopy (SEM) was used to study the etch profiles of photoresist/plasma films/silicon substrate structure. The etch profiles of plasma-deposited

Table I. Plasma deposition conditions of silicon nitride

films before and after annealing in argon for 20 min at 1000°C were examined.

Results and Discussion

Film deposition.—The results of silicon nitride deposition (Fig. 1) show that the film thickness and refractive index uniformity are good. The refractive index varied from 1.95 to 2.00 within a batch with a deposition rate of 7 nm/min.

Figure 2 shows the results of silicon oxynitride deposition at various nitrous oxide flow rates ranging from 8 to 18 sccm. At flow rates of 8, 12, and 18 sccm, the refractive indices were 1.85, 1.75, and 1.65, respectively. Silicon oxynitride films had relatively good thickness uniformity ($2\sigma = 5\%$) for each batch. The deposition rates of silicon oxynitride deposition varied only slightly, from 6.5 to 7 nm/min. We also used carbon dioxide and diatomic oxygen gas as oxygen sources for silicon oxynitride deposition under the same conditions. However, these oxygen sources resulted in poor refractive index ($RI = 1.46-2.00$) and thickness uniformity ($2\sigma = 100\%$). Nitrous oxide appeared to be a better oxygen source for silicon oxynitride deposition.

The film uniformity in this PECVD process has been attributed to a large penning effect of the helium inert carrier gas. We have examined and discussed the extent of this effect with various inert carrier gases in PECVD processing previously (9).

Fig. 2. Variation of refractive index vs. position of plasma-deposited silicon oxynitride in the parallel reactor.

Infrared and Auger analysis.—The IR spectrum of silicon nitride films with a refractive index of 1.95 showed the presence of N-H (3350 cm^{-1}), Si-H (2200 cm^{-1}), Si-N ($850-900\text{ cm}^{-1}$), and Si-O (1150 and 450 cm^{-1}) (Fig. 3) (10, 11). No oxygen was detected in this film with AES. This indicates that the amount of oxygen in the film is below the detection limit of our measurements (0.5 a/o). The silicon nitride sample was also found to be silicon rich with about 28 a/o excess silicon from the stoichiometric ratio of Si_3N_4 . Electron spectroscopy for chemical analysis (ESCA) data indicated the presence of a Si-(Si_3) phase in this silicon nitride film. Infrared spectra of silicon nitride films after annealing showed a marked reduction in the intensity of Si-H and N-H bands (Fig. 3a). The data appears to be consistent with both nuclear reaction analysis profiling and quadrupole mass analysis results (12, 13) of the hydrogen content in plasma-deposited silicon nitride films as deposited and after annealing. These results indicate that a significant amount of hydrogen was evaporated from the film during the annealing process. One expected that the density of as-deposited material is lower and the presence of hydrogen (and helium) gas in the film is higher than for standard CVD silicon nitride films. This explains why the refractive index of silicon-rich film is only 1.95. After annealing, a small amount of film would typically peel off, probably a result of trapped gases.

Infrared analysis of plasma-deposited silicon oxynitride films with the refractive index varying from 1.85 to 1.65 also showed the presence of N-H, Si-H, Si-O, and Si-N bonds at various intensities (Fig. 3b). However, no O-H bond was observed in either plasma-deposited silicon nitride or oxynitride films. Substantial overlap between Si-O and Si-N bands prevented an exact normalized intensity measurement. The intensity of the Si-O bands, *i.e.*, the number of Si-O bonds, increased as the film's refractive index decreased. This result corresponds well with our Auger analysis data which indicated the average oxy-

Fig. 3. Infrared absorption plasma-deposited silicon nitride (a, top) and silicon oxynitride (b, bottom) (refractive index = 1.75).

gen concentration increased from 2.1 to 35.8 a/o as the film's refractive index decreased from 1.85 to 1.65 (Table II). The compositional analysis data appear to be consistent with the reported results of PECVD films with a refractive index of 1.55 (14). Although positive identification of Si-N-O bonds cannot be confirmed due to band overlap, one may expect that these types of bonds must also exist. The IR spectral intensity analysis of Si-H and N-H bands indicated that significantly less hydrogen was evaporated from the silicon oxynitride with a refractive index of 1.75 during annealing (as compared to other plasma-deposited films).

Auger analyses of all films showed no significant change in silicon, nitrogen, or oxygen composition after the samples were annealed. Furthermore, Auger depth profiles showed poor compositional uniformity during the first 10-30 nm of deposition for all experimental films examined, *i.e.*, the result indicated the presence of a two-layer structure. The bottom 10-20 nm layer near the substrate interface was more silicon rich than the top layer (Fig. 4a-4d). For our typical plasma-deposited silicon nitride films, the ratio of the silicon content in the bottom layer to the top was 1.17. These two-layer structures are probably a result of the changes in electron temperature and density of silane reactive species concentration during the first few minutes of deposition processing. It appeared that more silane was dissociated to reactive species and deposited during the first few minutes of operation. The silicon-rich interface appeared to be an intrinsic property of plasma-deposited films and a direct result of initial transient phenomena observed in our PECVD processes.

Table II. Auger analysis data of silicon nitride and oxynitride films

Refractive Index	Average Atomic Percent Composition		
	Silicon	Nitrogen	Oxygen
1.95	71.4	28.6	0
1.85	43.7	54.2	2.1
1.75	31.2	52.3	16.5
1.65	38.5	25.7	35.8
1.45 (Silicon Dioxide)	32.9	0	67.1

Note: No Significant Change in Si, N, and O Composition Before and After Annealing

There are several factors that interrelated and enhanced each other to prolong the initial transient period in PECVD processing, such as the initial variation of RF power gas impedance. The RF power required a short period of time to reach its steady state. During this transient period, changes in electron temperature and density distribution will occur, thus varying the reactive species concentrations and the composition of deposited films. The reactant and inert carrier gases used in PECVD processes have different gas impedance which directly affect the electron density and temperature of the plasma. During the initial stages of the deposition process, some of the reactant gases are broken down to by-products of silane, for example, Si_2H_6 , SiH_2 , SiH_3 , SiH , and Si , and thereby change the total gas impedance. A

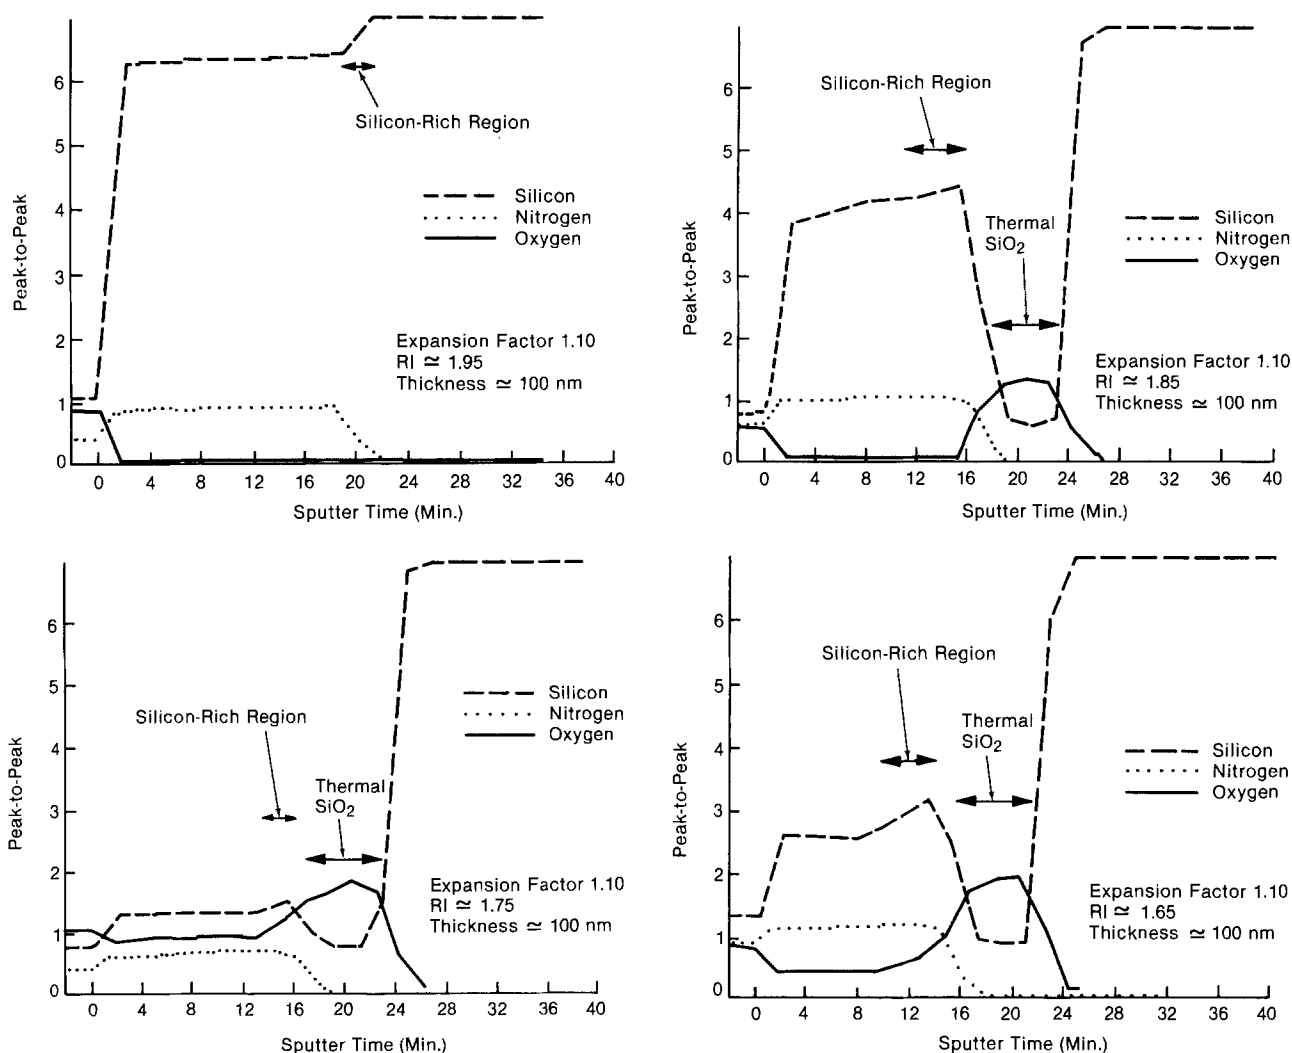

Fig. 4. Auger depth profiles for a (top left): silicon nitride (refractive index = 1.95), b (top right): silicon oxynitride (refractive index = 1.85), c (bottom left): silicon oxynitride (refractive index = 1.75), and d (bottom right): silicon oxynitride (refractive index = 1.65).

transient period is required to stabilize the plasma to steady state.

Due to the weaker Si-H bonds of silane as compared to N-H bonds of ammonia and N-O bonds of nitrous oxide, more silane is broken into reactive species during initial transient periods. This will substantially increase the concentration ratio of Si/N reactive species during initial transient periods compared to those of steady-state plasma. Therefore, more silicon will be deposited on the substrate during this period, thus creating the silicon-rich interface phenomena in all plasma-deposited silicon nitride and oxynitride films. In a previous presentation (15), we showed a direct correlation between Si-rich interfaces in plasma-deposited films and initial transient phenomena in PECVD processes.

Plasma etching.—In pure CF₄ plasma under low pressure and high frequency conditions, reactive fluorine atoms (F) and fluorocarbon radicals are produced by electron-impact dissociation reaction as follows (16)

Other unsaturated species, such as C₂F₄, are formed in secondary reactions between fluorocarbon radicals, especially those involved with CF₂. In CF₄ plasma, both F and F₂ react with unsaturated species by the following reactions

With the addition of oxygen to the plasma, oxygen atoms will be generated in the plasma. Both O and O₂ will compete with free fluorine atoms for CF₂ by the following reactions

The addition of oxygen gas in CF₄ plasma will then increase the concentration of reactive fluorine atoms (17). In the absence of ion bombardment, fluorine atoms react slowly with SiO₂ (18). As we have shown, IR and AES data indicate all increased number of Si-O bonds and oxygen concentration as the silicon oxynitride film's refractive index decreases. In terms of bond energy, the relative strength of Si-O bonds is greater than that of Si-H, Si-Si, and Si-N bonds (11). Films with lower refractive indices will etch more like SiO₂, which requires ion bombardment of the surface for etching at reasonable rates (19-22). Under fixed etching conditions, *i.e.*, the same ion bombardment and reactive species concentrations, films with higher oxygen concentration will etch slower. This is consistent with the film etch rate results shown in Table III. A decrease in film refractive index from 1.95 to 1.65 corresponds to a decrease in etch rate for both as-deposited and after-annealed films.

Another factor strongly influencing the etch rate of plasma-deposited films is the amount of hydrogen incorporated in the film. Again, in terms of bonding, the Si-H is the weakest of the four types of silicon bonds present, and therefore has the highest probability of being broken by electron and ion bombardment, leaving the reactive Si sites available for fluorine atoms to attack during the plasma-etch process. Thus, in films with a large number of Si-H bonds, one would expect a greater number of reactive Si sites and faster etch rates. Films with more hydrogen content are also less dense and more easily penetrated by fluorine atoms. This phenomena is observed in the annealed *vs.* as-deposited films. The IR data indicate a large reduction in the number of Si-H bonds present after anneal, while Auger analysis showed

Table III. Plasma etching of silicon nitride and oxynitride films

*Etching Conditions:

- O ₂	= 13 sccm	

* Etch Rates (Average):		
Film Refractive Index	As Deposited (Å / Minute)	Annealed (Å / Minute)
1.95	1950	830
1.85	2100	520
1.75	930	400
1.65	510	370
LPCVD Si ₃ N ₄	200	

no significant change in Si, N, or O composition after annealing. The dramatic decrease in the film's etch rate observed after annealing is apparently due to loss of hydrogen during the anneal cycle. The loss of hydrogen translates to a decrease in the easily activated Si-H sites, a denser structure, and possibly more Si-N, Si-O, and Si-Si bonds. Low pressure chemical vapor deposition (LPCVD) silicon nitride films which contain much less hydrogen etched at slower rates of 20 nm/min.

Etch profiles of the plasma films also vary due to a different film composition. Figure 5 shows the photoresist-plasma film-silicon substrate structure under examination. The pictures in Fig. 6a and 7a show the difference in etch profile between the unannealed and annealed samples with refractive indices of 1.95. A large undercut is clearly observed for the unannealed sample. Since reactive species such as fluorine (F) and unsaturated CF_n radicals can etch Si-H sites readily without any ion bombardment, isotropic etching will occur (23). This isotropic mechanism will result in a larger undercut in unannealed films where substantial amounts of Si-H and N-H exist. As we have previously discussed, the number of Si-O bonds is significantly higher in the lower refractive index film, and films with these types of bonds require ion bombardment to achieve reasonable etch rates. Since ion bombardment is a directional process, higher etch rates will be observed in the vertical direction. Films with high oxygen concentration, therefore, have more anisotropic etching properties and less undercut. This is consistent with the observation that the undercut for silicon oxynitride samples with refractive indices of 1.65 (Fig. 6b and 7b) are slightly less than that for the silicon nitride samples (Fig. 6a and 7a). While substantial improvement in the undercut length was observed for silicon nitride (*n* = 1.95) samples after annealing (Fig. 6a and 7a), no significant difference in undercut profiles was found between annealed silicon oxynitride (RI = 1.65) samples (Fig. 7b). This indicates a larger influence of oxygen over hydrogen in relatively stoichiometric silicon oxynitride film. It is therefore possible to obtain a range of desirable

Fig. 5. Photoresist-plasma film-silicon substrate profiles

etch profiles in plasma-deposited films not only by varying the etching conditions (plasma *vs.* reactive ion etching), but also by varying the film's oxygen and hydrogen compositions.

Conclusion

Good uniformity silicon nitride and silicon oxynitride films with refractive indices varying between 1.60 and 1.95 were deposited on silicon and silicon dioxide substrate surfaces using plasma-enhanced chemical vapor deposition (PECVD) processing. In terms of uniformity, nitrous oxide was found to be a better oxygen source for plasma silicon oxynitride deposition. In our previous study (9), He was found to be a very efficient carrier gas in the plasma compared to other inert gases at low silane concentration.

Infrared and Auger analyses show the films deposited under the described conditions contain significant amounts of hydrogen. Substantial loss of hydrogen was observed after annealing. The concentration of other species, such as Si, N, and O, however, remains unchanged. Infrared analysis of hydrogen band intensities suggests that silicon oxynitride films with a refractive index of 1.75 are probably more stable during thermal annealing. Although ellipsometer measurements showed that film thickness and refractive index uniformity are good, Auger depth profiles revealed poor compositional uniformity during the first 10-30 nm of deposition for all experimental films examined. This nonuniformity is due to the variation of electron temperature and silane reactive-species concentration during the first few minutes of

deposition processing, *i.e.*, the initial transient instability in RF power and gas impedances.

Direct correlation between etching properties of plasma-deposited films and their oxygen and hydrogen compositions was observed. Under identical etching conditions, plasma etch rates of plasma-deposited films decreased with decreased hydrogen concentration (upon annealing) and with increased oxygen concentration in film composition. Variations of etch profiles are also found to be directly correlated to hydrogen and oxygen concentration. Oxygen concentration appears to have a larger influence than hydrogen on etching properties of silicon oxynitride. The changes in etch rate and etch profiles corresponds well to the variation of hydrogen and oxygen concentration. These changes can be explained by the variation of bond energies and the etch-rate enhancement by ion bombardment.

ABSTRACT

Silicon nitride local oxidation masking layers fabricated by low energy nitrogen ion implantation into silicon have been employed in the fabrication of n-channel silicon-gate MOSFET's. Processing considerations which are unique to the application of these very thin (10 nm) silicon nitride films are detailed. The effects of oxygen contamination during implantation are described, as are those of subsequent wafer processing steps such as RCA cleaning and oxygen plasma photoresist stripping. It is also shown that resputtered material from the wafer holder can result in iron contamination of the resulting silicon nitride films. Finally, we show that careful attention to these possible problems can produce transistors with reasonable current-voltage characteristics, as compared to conventionally processed devices.

The implantation of low energy nitrogen ions into silicon has been shown to result in the formation of a thin film of silicon nitride in intimate contact with the underlying silicon. This silicon nitride layer forms a suitable mask to prevent oxidation of the underlying silicon during the local oxidation process which is typically employed in silicon integrated circuit processing to isolate adjacent devices.

Because no silicon dioxide is present between the silicon and silicon nitride layers, the lateral encroachment of silicon dioxide into active device regions (the "bird's beak" effect) is minimized (Fig. 1), allowing increased device packing densities. In this paper, we characterize the aspects of the implantation process which affect the properties of the resulting silicon nitride film when it is employed in integrated circuit fabrication processes.

Experimental

All samples described in this study were cleaned by the RCA procedure (1) prior to nitrogen implantation. Oxidations were performed either in steam or in burnt hydrogen. Both 5 and 7.5 cm diam silicon wafers of varying resistivity were used. Nitrogen implantations were performed in a commercial 15 cm diam beam ion mill (2, 3), with the ion beam incident perpendicular to the wafer surface, unless otherwise noted. The ion beam was neutralized with a hot wire (thoriated tungsten) filament in order to avoid surface charging and consequent nonuni-

formities in the implanted layer. The samples were mounted on a water-cooled stage and rotated within the ion beam in order to increase process uniformity. The presence or absence of sample cooling did not affect either the film thickness or its oxidation resistance. Silicon dioxide film thicknesses were measured using a surface profiler, while studies of the composition of the implanted silicon nitride film were performed using Auger electron spectroscopy. The fabrication of active transistors was achieved using a conventional n-channel MOS process, except for the local oxidation step. Details of the electrical characterization of these devices and process parameters will be covered in a subsequent publication.

Ion Beam Nitridation

In order to minimize the problems associated with lateral oxidation, it is necessary to eliminate any silicon dioxide which may be present between the silicon nitride layer and the silicon surface. This is achieved by forming the silicon nitride layer by nitrogen ion implantation into the silicon substrate (4-8). The nitride layer thus formed is beneath the silicon surface, its exact position and thickness being dependent upon the implantation parameters. With a Kaufman-type ion source (9, 10), it is possible to achieve nitrogen ion fluences of $8.01 \text{ E}17 \text{ cm}^{-2}$ in 2 min. (For the commercial ion mill used in this study, the actual typical cycle time, including vacuum pump-down and venting, is 15 to 20 min.)

Fig. 1. Comparison of lateral oxidation during field oxide growth for (a, top) conventional deposited silicon nitride mask and (b, bottom) low energy ion-implanted silicon nitride mask. Samples were oxidized simultaneously at 1180 K for 320 min. The significant reduction of the bird's beak in (b) results from the absence of a silicon dioxide layer beneath the silicon nitride mask.

Because nitrogen can chemically bond to silicon, a significant portion of the incident nitrogen remains in the sample after implantation. Typical Auger spectroscopy concentration profiles of the resulting films are shown in Fig. 2. Essentially no change is observed in these profiles after the films have been subjected to nitrogen ambient anneals at 750° and 1050°C. Although the sputtering rate for nitrogen ions is less than that for argon, erosion of the substrate wafer will still occur, as will be demonstrated in the following discussion. Thus, the result of the nitrogen implantation process at these low energies involves a balance between the implantation and erosion processes.

The variation of silicon nitride film thickness with implantation energy is shown in Fig. 2. Film thickness is found to be relatively insensitive to implantation energy. For implantation energies of 1.9-2.1 keV, the resulting silicon nitride film thickness may be estimated at approximately 12 nm. This value is comparable to values reported by Chiu *et al.* (11). Ellipsometric measurements of as-implanted films yielded parameter values of $\Psi = 15.4$ and $\Delta = 151$. Following a nitrogen anneal at 750° or 1050°C, values of $\Psi = 13.9$ and $\Delta = 172$ were observed. Reduction of these values to yield nitride film thicknesses was hindered by the lack of an independently measured value for the index of refraction of the nitride film and by the presence of a silicon dioxide film at the surface. Similar difficulties have been reported by Chiu *et al.* (11), and for nitride films implanted at higher energies, by Tsujide and Nojiri (12). The effect of ion beam induced sputter erosion upon the silicon is shown in Fig. 3. Here, erosion rate data are presented for the case of a 2.1 keV, 1 mA cm^{-2} nitrogen ion beam. The ion beam-induced erosion

Fig. 2. Dependence of silicon nitride film thickness upon implantation energy. All implants were performed for 2 min with a 1.0 mA cm^{-2} beam. Auger spectroscopy sputtering rate was approximately 4 nm/min.

rate for silicon is found to be about 25 nm/min, while that for silicon dioxide is about 58 nm/min. These values may be compared to the erosion rate observed when 2.1 keV argon ions are employed, which is about 76 nm/min for both silicon and silicon dioxide. The dependence of implanted layer profile upon incident nitrogen ion dose is shown in Fig. 4. Reducing the implantation time (and therefore the dose) by a factor of 10 to $8.0 \text{ E}16 \text{ cm}^{-2}$ does not change the nitrogen concentration profile. Upon further reducing the implanted ion dose by a factor of ten (in this case, by reducing the ion beam current density to 0.1 mA cm^{-2}), a reduction in the implanted nitrogen profile is observed.

The resistance of these thin silicon nitride layers to thermal oxidation in steam is shown in Fig. 5. Although the silicon nitride films successfully mask the growth of 780 nm of silicon dioxide at 970°C, they are completely consumed prior to the growth of 420 nm of silicon dioxide at 1070°C. Using the oxidation model of Deal and Grove (13, 14), one can estimate the time required to grow the amounts of silicon dioxide shown in the three cases in which the silicon nitride layer was totally consumed. In turn, this provides an estimate of the amount of time required to break down the silicon nitride layers them-

Fig. 3. Material erosion during low energy nitrogen implantation. Data taken for 2.1 keV, 1.0 mA cm^{-2} , 2 min implantations.

Fig. 4. Dependence of silicon nitride film profile upon nitrogen implant dose. Implants were performed at an energy of 2.1 keV and beam current density of 1.0 mA cm^{-2} (except 0.1 mA cm^{-2} for the total dose of 8.0 E15 cm^{-2}). Auger spectroscopy sputtering rate was approximately 2.5 nm/min.

selves. By then assuming a linear oxidation rate (5) for the silicon nitride layer, this data can be compared with the data of Hui *et al.* (5) and the linear oxidation rates of silicon in both wet and dry ambients (11, 12), as shown in Fig. 6.

The oxidation resistance of these silicon nitride films is also dependent upon their initial impurity content, the most obvious contaminant being oxygen. Oxygen contamination can arise from trace oxygen content in the nitrogen gas source or from air leaks in the vacuum system. The presence of oxygen during implantation results in a thinner silicon nitride layer being produced, with a resulting reduction in oxidation resistance. For example, when a partial pressure of 18% oxygen was maintained in the ion mill vacuum system during implantation, the silicon nitride layer was consumed after 1.6h of wet oxidation at 1210 K. This contrasts with a time of 3.2h, which is observed when no oxygen is intentionally introduced into the system. Conversely, a 40% partial pressure of oxygen during implantation reduced this time to 1.1h.

Fig. 5. Oxidation resistance of implanted silicon nitride films as a function of wet oxidation temperature for two sets of samples with nominal 450 and 750 nm field oxides, respectively. The crosshatched regions represent the resulting amount of silicon dioxide grown in the implanted regions following nitride breakdown, while the open regions represent the corresponding field oxide thickness.

Fig. 6. Variation of oxidation rates with temperature for implanted silicon nitride films assuming an initial film thickness of 10 nm. Also shown is the oxidation rate data measured by Hui *et al.* (5), for both ion-implanted (— — —) and plasma-deposited (----) silicon nitride and the linear oxidation rates for $\langle 111 \rangle$ silicon (—), in both wet and dry ambients (13, 14). (More recent work by Deal (28) reports slightly different oxidation rates for $\langle 111 \rangle$ silicon, and notes that the oxidation rate for $\langle 100 \rangle$ silicon is a factor of 1.7 slower for both oxygen and water vapor ambients.)

Additional oxygen contamination in these thin silicon nitride films can result from the wafer cleaning procedures employed just prior to high temperature oxidation. Typically, an RCA-type cleaning procedure (1) is employed prior to inserting the wafers into the diffusion tube. This subjects the thin silicon nitride film to an oxidizing agent, hydrogen peroxide. In addition, in many cases, the silicon nitride film will have been exposed to the oxygen plasmas which are generally used to remove photoresist. In either case, atomic oxygen is available to attack the silicon-nitrogen bonds.

In the case of RCA cleaning, we have found that properly prepared basic and acidic cleaning solutions oxidize only the surface layers of the nitride films, and thus do not normally constitute a major problem. Figure 7 displays the atomic concentration profiles of three samples which were simultaneously implanted with nitrogen. Figure 7a represents a control sample which was not subjected to any subsequent processing, while each sample in Fig. 7b was exposed to one of the RCA solutions for 10 min. The samples characterized in Fig. 7c were not exposed to either of the RCA cleaning solutions, but had been exposed to an oxygen plasma for either 15 or 30 min. The oxygen plasma is more effective in attacking silicon nitride, but still leaves a significant portion of the silicon nitride film intact.

In addition to oxygen, carbon is typically detected in ion beam-nitrided silicon films. The carbon is detected primarily near the exposed surface of the silicon nitride, with its concentration dropping off farther into the film. The observed carbon profile is similar to that detected following argon ion bombardment of silicon, suggesting that it may, in part, result from material adsorbed onto the sample surface following nitrogen implantation. The carbon profiles do not change as the silicon nitride is oxidized, which suggests that it is not being driven into the silicon substrate, and thus may be removed when the silicon nitride layer is removed.

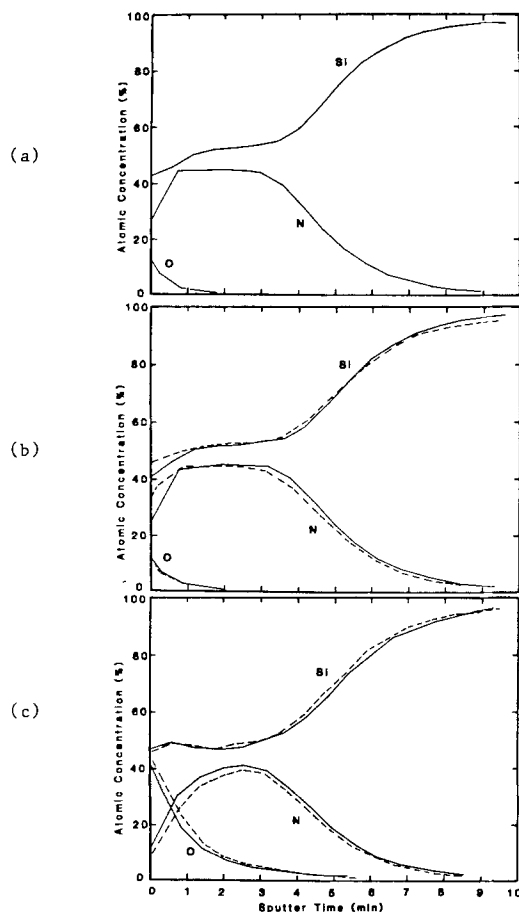

Fig. 7. Auger spectroscopy concentration profiles of ion-implanted silicon nitride films simultaneously prepared and subjected to various wafer cleaning procedures. (a): Control, as-implanted sample. (b): Samples cleaned for 10 min in basic (ammonium hydroxide, —) and acidic (hydrochloric acid, ---) RCA cleaning solutions at 360 K. (c): Samples exposed for 15 (—) or 30 min (---) to a photoresist stripping oxygen plasma (350W at 0.133 kPa oxygen pressure). Auger spectroscopy sputtering rate was approximately 2.5 nm/min.

A final source of contamination involves the platen on which the sample wafers are mounted. Because the ion beam-nitridation process is essentially a low energy sputtering process in which the incident ions "stick" to the substrate being bombarded, there is a potential problem associated with resputtering of the substrate holder material. In the present case, the wafer supporting platen was made of aluminum, while the hold-down clamp which is used to improve heat transfer from the wafers to the water-cooled substrate is fabricated in stainless steel. Thus, when the hold-down clamp is used, iron, chromium, and nickel traces are detected in the 10 nm thick silicon nitride film. Alternatively, when the hold-down clamp is not used, and the support platen is not completely covered with silicon wafers, aluminum is detected. In either case, peak concentrations of the contaminant metals can reach several atomic percent. The contaminant distributions shown in Fig. 8 are typical of those observed when the sample holder is not coated with silicon nitride. The fact that the iron concentration reaches a maximum near the silicon-silicon nitride interface is not understood, although it may result from a buildup of a relatively inert iron nitride film on the surface of the sample holder as the nitridation process continues. This could reduce the amount of iron which is resputtered, and serve to lower the contaminant concentration near the surface of the silicon nitride film.

Typical leakage-current measurements for $250 \times 250 \mu\text{m}$ junction diodes fabricated using both local oxidation processes are shown in Fig. 9. The enhanced leakage in the case of the ion beam-nitrided devices is not completely understood at present, since Wright etching of ion

Fig. 8. Auger spectroscopy profile detailing presence of typical contaminants, oxygen (---), carbon (-.-.), and, when an untreated sample holder is used, iron (—), which was resputtered from the stainless steel platen. Sample was implanted with nitrogen (---) at 2.1 keV, 1.0 mA cm^{-2} , for 2 min. Auger spectroscopy sputtering rate was 4.0 nm/min .

beam-nitrided regions following local oxidation does not reveal an increased density of etch pits, as compared to similarly etched samples fabricated using the conventional local oxidation process. In addition, n-channel silicon gate MOSFET's were fabricated. Ion beam nitridation parameters for the local oxidation step included a beam

Fig. 9. Comparison of junction diode leakage currents for devices fabricated using either ion beam nitridation (—) or a conventional local oxidation process (---) during the growth of a 510 nm thick isolation oxide film. Diode junction area = 4.4 E4 cm^2 .

energy of 2.1 keV and a beam current density of 1.0 mA cm^{-2} . Some wafers were simultaneously processed using a conventional local oxidation process employing 80 nm of plasma-deposited silicon nitride on top of a thermally grown 60 nm thick silicon dioxide layer. All of the wafers were then etched in hot phosphoric acid to delineate the transistor mesa regions, and thermally oxidized at 900°C for 280 min in burnt hydrogen, yielding a field oxide layer 690 nm thick. All subsequent processing was identical for both the ion beam-nitrided and conventionally processed samples. The goal in this work was to evaluate the reduction of device channel width (from W to W' , see Fig. 10) resulting from the conventionally local oxidation process and any changes in effective device width (W') which result from the use of ion beam nitridation.

Discussion

As shown in Fig. 2, silicon nitride film thickness is relatively insensitive to the energy of the implanted nitrogen ions. For comparison, the mean range of nitrogen ions implanted into silicon with an energy of 2.1 keV is approximately 6.0 nm (15). Essentially doubling the incident ion energy is found to increase film thickness by less than 40%. This relative insensitivity to ion beam energy is primarily a result of the simultaneous physical erosion of the silicon surface due to sputtering. Samples implanted at an angle of 45° [the angle for which the sputter erosion rate approaches a maximum (16, 17)] show a significant reduction in nitride film thickness when compared to the results shown in Fig. 2. To be sure, implantation at a 45° angle will reduce the effective perpendicular range of the incident ions by about 30%, but this is not sufficient to explain the magnitude of the observed reduction in film thickness. Also, we obtain essentially identical Auger concentration profiles for samples implanted at angles of 0.0°, 7.0°, and 10.0° with respect to normal incidence.

These observations are confirmed by the data presented in Fig. 3, which show an erosion rate of about 25 nm/min for nitrogen implantation of silicon, as compared to a typical erosion rate of about 76 nm/min for argon ion bombardment under the same conditions. Part of this reduction in sputtering rate is a result of the reduced sputtering yield of nitrogen ions as compared to that of argon

ions (2), but a substantial amount of this difference is due to the bonding of the incident nitrogen ions into the silicon lattice when they come to rest. By comparison, the sputtering rate of silicon dioxide under 2.1 keV argon ion bombardment is also 76 nm/min (for a beam current density of 1.0 mA cm^{-2}), while the rate for nitrogen ion bombardment is about 58 nm/min. In this case, where there is less opportunity for the nitrogen atoms to find available bonding sites to silicon atoms, the sputtering rate is 2.3 times higher than that for a silicon substrate. This differential etching behavior has been used to develop a novel contact window opening process (18), which requires only a single photolithography step. Similar reductions in erosion rate have been documented for argon ion milling of metallic layers in an oxygen ambient (19-21), wherein the oxygen bonds to the metal atoms, forming a metallic oxide surface layer. Effectively, this results in an increase in the number of atoms which must be sputtered from the surface in order to remove a given number of metal atoms, and thus the sputtering rate is effectively reduced.

In addition to being relatively insensitive to implantation energy, the nitrogen concentration profile is also independent of the number of implanted ions, or implantation dose, as shown in Fig. 4. Implantation doses as low as 8.0 E16 cm^{-2} result in nitrogen profiles which are essentially identical to those for implantation doses a factor of ten larger. Further reductions in implantation dose below 8.0 E16 cm^{-2} , however, result in a reduction of the maximum nitrogen concentration within the films, leaving a silicon-rich silicon nitride film.

The oxidation resistance of these ion beam-nitrided silicon films (Fig. 5, 6) agrees well with the data of Hui *et al.* (5), having an oxidation activation energy of about 2.0 eV. The absence of any change in either nitrogen concentration profile or oxidation resistance following a nitrogen ambient anneal is consistent with results in the literature. Hezel and Lieske (7) find no change in Auger spectra following a nitrogen anneal, although they do observe a slight increase in silicon-nitrogen bonding, as measured by low energy electron spectroscopy. Similarly, Ramin *et al.* (22) find no change in infrared absorption with annealing, although they do observe "slightly improved" oxidation resistance. The reduction in this oxidation resistance as a result of oxygen contamination during implantation can be significant, and demonstrates the need for a leak-free vacuum system and a low oxygen content nitrogen source. A similar concern must be shown for any wafer cleaning processes employed while the silicon nitride layer is present. Although a properly performed RCA cleaning procedure does not seriously affect the silicon nitride layer, we have observed that, if the basic solution (hydrogen peroxide and ammonium hydroxide) becomes depleted of hydrogen peroxide, the silicon nitride layer will be rapidly etched, as will the underlying silicon, by the ammonium hydroxide. This is consistent with the observations of Kern and Puotinen (1), who point out the problem of hydrogen peroxide depletion, and suggest limiting the use of the basic solution to less than 40 min. Finally, it should be noted that although the proper application of typical cleaning processes may not seriously reduce the oxidation resistance of the silicon nitride films, the repeated application of these cleaning steps (for example, two exposures to the oxygen plasma as a result of poor photolithography results) can consume a major portion of the 10 nm thick silicon nitride film.

The problem of heavy metal contamination, as evidenced by the Auger data in Fig. 8, is potentially fatal to any semiconductor processing technique. However, the existing evidence suggests that the most likely source of this contamination is the wafer holder assembly. Thus, a relatively simple solution to this problem, then, is to coat both the hold-down clamp and the platen with a relatively inert material, such as plasma-deposited silicon or silicon nitride. Although this coating must be periodically renewed, this has essentially eliminated the metal contamination problem within the detection limits of Auger spectroscopy (less than 1 atomic percent). In addition,

Fig. 10. Plan and cross-sectional views of a typical MOSFET transistor. Of importance for the present discussion are the channel length, L , and width, W , and the change in the latter (to W') which results from a change in the size of the device well (from — to) due to lateral oxidation.

transient capacitance measurements (23) of junction diodes fabricated in ion beam-nitrided device wells show no evidence of the relatively well-characterized iron-related defect levels (24, 25) in the underlying silicon. Thus, although it is necessary to exercise some caution in this regard, it appears that the metal contamination problem is controllable.

The effects of local oxidation-induced stress and/or contamination upon the performance of devices fabricated using ion beam nitridation is not well understood. Hui *et al.* (26) have reported enhanced leakage current in diodes fabricated using the SILO process with a plasma nitridation step, even though (4) they generally detect no increase in stress-induced defects associated with the use of these very thin nitrided-silicon films. Our results, measured on $250 \times 250 \mu\text{m}$ junction diodes (Fig. 10) show even larger leakage currents in ion beam nitrided samples. At present, we can offer no explanation as to the exact origin of the enhanced leakage current, although deeply penetrating nitrogen ions which were not removed along with the silicon nitride film and/or residual unannealed implantation damage could produce such effects.

The photomask set used to fabricate the devices for which current-voltage curves appear in Fig. 11, contains device patterns with mask dimension channel widths and lengths which vary from 4.0 to 10.0 μm . As shown in Fig. 10, the conventional local oxidation process results in a reduction in the dimensions of the active device well or mesa region. Only the channel width of the transistor is directly affected by this shrinkage, however, since the transistor channel length is determined by the dimension of the polysilicon gate. Having a mask set with both variable channel lengths (L) and widths (W), then, allows one to evaluate the effects of a change in channel width due to the local oxidation process used, while allowing for the possibility of other variations in photoresist processing or polysilicon etching between samples. Such an approach is necessary since the device drain current is proportional to the ratio of the effective channel width (W') to the effective channel length (L). A detailed analysis of the electrical properties of the devices fabricated in this study, using the analysis technique described by Chern *et al.* (27), will appear in a subsequent publication. These results are qualitatively described, however, by the current voltage characteristics shown in Fig. 11. For devices of similar (W/L) mask dimensions, the electrical characteristics of the ion beam-nitrided devices are generally similar to those which were fabricated using the conventional local oxidation process. Thus the fabrication of active de-

vices using the ion beam-nitridation process does result in devices with reasonable electrical characteristics.

Summary

Ion beam nitridation of silicon using a conventional ion milling machine is a quick, efficient way to form a thin silicon nitride layer on silicon, which may be employed to fabricate active devices with reasonable current-voltage characteristics. For typical nitrogen ion beam parameters of 2.1 keV acceleration potential and 1.0 mA cm^{-2} beam current density, incident ion doses of $8.0 \text{E}17 \text{ cm}^{-2}$ can be achieved in 2 min, resulting in the formation of a silicon nitride film approximately 10 nm thick. As a result of the simultaneous occurrence of implantation and sputter erosion, this process is very insensitive to variations in the implantation process, resulting in uniform, reproducible silicon nitride films. In addition, this coincidence of implantation and sputter erosion can be used to advantage in a novel contact opening process. Subsequent wafer processing steps such as RCA cleaning or oxygen plasma photoresist stripping can attack the resulting thin film, but their effects can be minimized with proper attention to the process parameters. Finally, the fabrication of active devices using the ion beam-nitridation process to mask the growth of a 690 nm thick field oxide results in transistors with reasonable current-voltage characteristics, being qualitatively comparable to those of devices fabricated simultaneously, but using a conventional local oxidation process.

Germanium Doping of InP Films Grown by Liquid Phase Epitaxy

B. H. Chin and R. E. Frahm

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We have investigated Ge doping at high concentrations in InP films grown at 648°-640°C on <100> InP by liquid phase epitaxy. Hall measurements show that the carrier concentration saturates at $\sim 9 \times 10^{18} \text{ cm}^{-3}$ for a mole fraction of Ge in the liquid (χ_{Ge}^l) greater than 0.10. In the carrier-saturation regime, the Ge concentration in the solid, as measured by secondary ion mass spectroscopy, increases superlinearly with χ_{Ge}^l . Transmission electron microscopy reveals no precipitate formation.

In the liquid phase epitaxy (LPE) of InP, tin is the usual n-type dopant. For strongly doped <100> layers, however, we have recently shown that tin is not suitable (1) because the carrier concentration ($N_D - N_A$) saturates at $\sim 6 \times 10^{18} \text{ cm}^{-3}$. As an alternative n-type dopant, germanium is particularly attractive on account of its high purity and low vapor pressure. Ge doping at high concentrations has received considerable attention in bulk InP crystals grown by liquid-encapsulated Czochralski (LEC) (2-4), highly doped LPE films, however, have not been well characterized. Rosztochy *et al.* (5) grew Ge-doped layers on <111> B substrates at a growth temperature of 650°-600°C. A linear relationship between ($N_D - N_A$) and χ_{Ge}^l , the mole fraction of Ge in liquid indium solution, was observed up to $\chi_{\text{Ge}}^l = 0.17$, corresponding to ($N_D - N_A$) = $2.6 \times 10^{19} \text{ cm}^{-3}$; the distribution coefficient was determined to be $k = 0.011$. Similar results were obtained by Astles *et al.* (6), who grew layers on <111> A, <111> B, and <100> substrates at $\sim 650^\circ\text{C}$. The doping behavior was essentially the same for all faces: ($N_D - N_A$) vs. χ_{Ge}^l was linear up to $\chi_{\text{Ge}}^l = 0.10$, corresponding to ($N_D - N_A$) = $8 \times 10^{18} \text{ cm}^{-3}$; the derived distribution coefficient was $k = 0.005$. Last, Kuphal (7) found a value of $k = 0.005$ for <100> layers grown at $\sim 700^\circ\text{C}$; the ranges of χ_{Ge}^l and ($N_D - N_A$) were not stated.

In this paper, we present a detailed study of <100> layers doped up to $\chi_{\text{Ge}}^l = 0.18$. The layers have been characterized by the following techniques: (i) Hall measurements to determine the carrier concentration ($N_D - N_A$), (ii) secondary ion mass spectroscopy (SIMS) to monitor the Ge concentration in the solid, c_{Ge}^s (atoms/cm³), and (iii) transmission electron microscopy (TEM) to probe for the presence of precipitates.

Experimental

Since we have previously described our experimental procedures in detail (1), we shall recap only the salient features here. The epitaxial layers were grown from two-phase, indium-rich, solutions onto <100>-oriented, Fe-doped, semi-insulating InP substrates. To minimize the variation of distribution coefficient with temperature, the layers were deliberately grown over a narrow temperature interval, 648°-640°C, at a cooling rate of 0.7°C/min. The carrier concentrations in the epitaxial layers were subsequently determined by Hall measurements in the van der Pauw configuration; for rapid, accurate data acquisition, a fully computer-controlled apparatus was utilized (8). To monitor actual Ge concentrations, SIMS depth profiles¹

were performed on the samples; a Cs⁺ ion source was used for sputtering, and the mass 72 Ge peak was monitored. Conversion of the SIMS signal levels to atomic concentrations was achieved by comparison with signals from an ion-implanted standard. For TEM analysis, a 3 mm diam disk was ultrasonically cut from a wafer. After the substrate had been polished down to $\sim 25 \mu\text{m}$ with bromine-methanol, a number of small holes were opened up near the center of the disk with a jet polish of bromine-methanol.

Results

In Fig. 1, we have plotted the room temperature values of ($N_D - N_A$) as a function of χ_{Ge}^l . [Note that χ_{Ge}^l has been calculated from $\chi_{\text{Ge}}^l \approx M_{\text{Ge}}/(M_{\text{In}}^0 + M_{\text{Ge}})$, where M_{Ge} and M_{In}^0 are, respectively, the number of moles of pure Ge and pure In in solution. A direct measurement of the solubility of InP verified that the dissolved InP may be neglected over the range of χ_{Ge}^l considered here.] The background level in nominally undoped layers was $< 1 \times 10^{17} \text{ cm}^{-3}$, an order of magnitude less than the lowest intentional doping level. For $\chi_{\text{Ge}}^l < 0.10$, ($N_D - N_A$) increases lin-

Fig. 1. Plot of room temperature carrier concentration and germanium concentration as a function of mole fraction germanium in liquid.

¹SIMS analysis performed by C. A. Evans and Associates, San Mateo, California.

early with χ_{Ge}^1 ; the extracted value of the distribution coefficient is $k = 0.003$. [Here, we use the definition of k found in Ref. (6) and (7).] For $\chi_{\text{Ge}}^1 > 0.10$, $(N_D - N_A)$ saturates at $\sim 9 \times 10^{18}/\text{cm}^3$.

Carrier saturation may be induced by a number of causes. The principal ones are: (i) a solubility limit of Ge in the liquid is attained, (ii) a solubility limit of Ge in the solid is attained, (iii) Ge is incorporated into neutral or acceptor sites as well as donor sites, and (iv) the background acceptor level from impurities increases with χ_{Ge}^1 . (More involved mechanisms, such as defect complexes, may, of course, also be invoked.) The trivial case, (i), may be dismissed because direct measurement of the Ge solubility in an InP solution indicated that, over the whole range of χ_{Ge}^1 considered here, the solutions were undersaturated with respect to Ge.

To distinguish among the remaining cases, the samples were analyzed by SIMS and TEM. First, wide-field SIMS scans of three samples, with $\chi_{\text{Ge}}^1 = 0, 0.020$, and 0.18 , respectively, showed no significant increase of background impurities with increasing χ_{Ge}^1 . Second, the values of c_{Ge}^s were measured by SIMS; they are plotted as a function of χ_{Ge}^1 in Fig. 1. For $\chi_{\text{Ge}}^1 < 0.10$, we see that c_{Ge}^s varies linearly with χ_{Ge}^1 . Within the accuracy of the SIMS calibration (\sim a factor of two), there is general agreement between the values of c_{Ge}^s measured by SIMS and those expected from the Hall measurements. The value of the distribution coefficient derived from the SIMS data is $k = 0.007$. In the carrier saturation regime, $\chi_{\text{Ge}}^1 > 0.10$, the SIMS results reveal a curious behavior: c_{Ge}^s does not saturate but, rather, increases superlinearly with χ_{Ge}^1 .

Since the SIMS data suggests the possibility of precipitate formation, the most highly doped samples, with $0.06 \leq \chi_{\text{Ge}}^1 \leq 0.18$, were examined by TEM. To a resolution of $\sim 20\text{\AA}$, however, the TEM analysis failed to reveal any precipitates. Our result is in accord with the analysis of highly Ge-doped InP grown by LEC. Although Brown *et al.* (2) first reported precipitates in bulk crystals doped to $\sim 10^{19}/\text{cm}^3$, they later attributed the features in their TEM images to etching artifacts (9).

Summary

We have investigated Ge doping in InP films grown on $\langle 100 \rangle$ InP by LPE over the temperature range $648^\circ\text{--}640^\circ\text{C}$. The net carrier concentration $(N_D - N_A)$ determined from Hall measurements varies linearly with χ_{Ge}^1 up to $\chi_{\text{Ge}}^1 = 0.10$; the extracted distribution coefficient is $k = 0.003$. For $\chi_{\text{Ge}}^1 \geq 0.10$, $(N_D - N_A)$ saturates at $\sim 9 \times 10^{18}/\text{cm}^3$. Measurements by SIMS show that the atomic concentration of Ge in the solid, c_{Ge}^s , also varies linearly with χ_{Ge}^1 up to $\chi_{\text{Ge}}^1 = 0.10$; the value of k determined from the SIMS data is 0.007 . For $\chi_{\text{Ge}}^1 \geq 0.10$, c_{Ge}^s varies superlinearly with χ_{Ge}^1 . At low doping levels, our measurements are in reasonable agreement with previous work (5-7). Our results for high doping levels, however, do not agree with those of Rosztochy *et al.* (5), who found no evidence of carrier saturation up to $\chi_{\text{Ge}}^1 = 0.17$, corresponding to $(N_D - N_A) = 2.6 \times 10^{19}/\text{cm}^3$. This discrepancy is probably due to the differences in the following growth conditions

which may affect dopant incorporation (10-12): (i) substrate orientation, (ii) growth temperature, (iii) cooling rate, and (iv) growth rate. In our work, films were grown on $\langle 100 \rangle$ substrates at a temperature of $648^\circ\text{--}640^\circ\text{C}$ and a cooling rate of $0.7^\circ\text{C}/\text{min}$; the resulting growth rate was typically $\sim 0.5 \mu\text{m}/\text{min}$. In the work of Rosztochy *et al.* (5), however, films were grown on $\langle 111 \rangle$ B substrates at a temperature of $650^\circ\text{--}600^\circ\text{C}$ and a cooling rate of $5^\circ\text{C}/\text{min}$ (growth rates were not given).

In conclusion, then, our data show that, under our particular growth conditions, Ge probably behaves as a simple donor at low doping levels ($\chi_{\text{Ge}}^1 \leq 0.10$). The Hall and SIMS measurements, however, may also indicate dopant incorporation at a fixed compensation ratio. At high doping levels ($\chi_{\text{Ge}}^1 > 0.10$), the mechanism of dopant incorporation is more complex and not determined. Although the superlinear variation of c_{Ge}^s vs. χ_{Ge}^1 , as measured by SIMS, is consistent with the nucleation and growth of precipitates (13), TEM failed to reveal precipitates. The possibility of precipitates not detected by TEM must, of course, be further explored.

Acknowledgments

Phosphorus-Doped Polycrystalline Silicon via LPCVD

I. Process Characterization

B. S. Meyerson*

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

W. Olbricht

Cornell University, Ithaca, New York

ABSTRACT

We have studied the low pressure chemical vapor deposition (LPCVD) process as applied to the preparation of *in situ* phosphorus-doped polycrystalline silicon films. Thickness profiling, electron microprobe, and mass spectrometry have been utilized in the characterization of this process. The addition of phosphine (PH_3) as the dopant bearing precursor molecule was found to result in a factor of 25 decay in film growth rates relative to the intrinsic LPCVD process. The physical and chemical characteristics of samples prepared in this manner are shown to be a strong function of local reactor geometry, with growth-rate variations of a factor of two within a wafer commonly observed. Mass spectrometry data is presented supporting the proposal that phosphine passivates the silicon surface, and the implications of this phenomenon for altering silicon growth kinetics are discussed. A model is presented accounting for the growth-rate variations observed within individual wafers, as well as for the sensitivity of the phosphine-doped process to system geometry.

In recent years, as technology has made increasingly severe demands on the physical uniformity, conformality, and chemical homogeneity of materials for use in LSI and VLSI devices, significant advances have been made in the area of thin film deposition, particularly in the field of low pressure chemical vapor deposition (LPCVD) (1-4). LPCVD is especially attractive in that one may deposit large numbers (~200) of highly conformal, uniform films ($\pm 2\%$) in a single run. A chemical system where this technique works particularly well is the pyrolysis of silane (SiH_4) to yield intrinsic polycrystalline silicon films (1). A logical extension of the LPCVD technique would be to the preparation of *in situ* doped polycrystalline silicon by the introduction of the phosphorus bearing precursor phosphine (PH_3) into the intrinsic polysilicon LPCVD process. This technique offers a great reduction in complexity over more conventional doping technologies, which in general rely on the post-deposition implantation (5) of dopant, or the indiffusion of dopant from a dopant-rich layer applied to the sample surface (6). Although *in situ* doping is straightforward in concept, the introduction of silicon/phosphorus chemistry into this previously well-characterized technique causes a rapid degradation of the LPCVD process, with severe growth-rate suppression and film inhomogeneity two primary difficulties encountered. In this paper, the first in a set of two, macroscopic phenomena observed during the LPCVD preparation of *in situ* phosphorus-doped polycrystalline silicon are discussed. In the second paper of this set, a variety of surface science techniques are applied to study the microscopic interactions of silane and phosphine with silicon surfaces, and thus better understand the underlying mechanisms responsible for the problems observed in this paper.

Experimental

Samples were prepared in an LPCVD system configured as shown in Fig. 1. The LPCVD system consists of a 4 in. bore quartz furnace tube, pumped by a Leybold Haereus WS150 roots blower backed by a D30AC mechanical pump. An Inficon IQ200 mass spectrometer was used to analyze furnace effluent as well as initial process gas quality. Source gases supplied to the system were silane (SiH_4), phosphine (PH_3), and argon as an inert purge gas. Films were deposited on 2.25 in. diam Si substrates which had been thermally oxidized to a depth of 900Å, allowing thickness profiling of deposited films using interferometry (IBM Film Thickness Analyzer). Samples were placed in the twentieth slot of a 35 wafer

carrier, wafers mounted coaxially on 0.16 in. centers. Remaining slots were filled with blanks (wafers not removed run to run) to maintain carrier symmetry. Silane input was 30.0 sccm, with pressure maintained at 100 μm via a pressure feedback loop to a servo-controlled butterfly valve in series with the roots blower. Depositions were carried out at 623°C, for both the case of pure silane and a range of silane/phosphine mixtures. Subsequent to deposition, films were profiled for both thickness (using the FTA) and phosphorus content (by electron microprobe).

Results

We display in Fig. 2 the sharp contrast between films obtained from pure silane (A) vs. those obtained upon the addition of 2.5% phosphine (0.75 sccm) to the source gas (B). The addition of phosphine to the silane LPCVD process results in the suppression of film deposition rates by over an order of magnitude, and is accompanied by the onset of severe nonuniformity in thickness of the films deposited. The degree of growth rate inhibition as well as the uniformity of both film thickness and phosphorus content are strong functions of the interwafer spacing, and this is displayed, respectively, in Fig. 3 and 4. As the spacing upstream of the test wafer is increased, by the sequential removal of blanks immediately upstream, one observes a reduction in film thickness variation as well as an increase in deposition rate, but both remain at great variance to the intrinsic case. In addition, the bulk phosphorus content of the films drops from 3.0% to 1.8% with increasing interwafer spacing. Although inferior in uniformity, the phosphorus-doped films were of good quality otherwise, with pinhole densities and surface textures comparable with their intrinsic counterparts.

Figure 5 displays mass spectrometry data obtained while monitoring furnace effluent during film depositions from increasing ratios of phosphine to silane input gas at 623°C and 100 μm pressure. The partial pressure of unreacted silane in the reactor exhaust increased discontinuously by approximately 20% upon the addition of less

Fig. 1. Schematic of the LPCVD system

Fig. 2. Deposition rate profile across a wafer diameter for (A) $T_s = 623^\circ\text{C}$, $P = 0.1$ torr, $\text{SiH}_4 = 30.0$ sccm, and (B) as A with $\text{PH}_3 = 0.75$.

than two parts per thousand phosphine to the source gas. Above this phosphine level, the concentration of unreacted silane was found to be relatively insensitive to increased phosphine levels in the source gas. Apart from silane, peaks corresponding to a $1.0 \mu\text{m}$ partial pressure of disilane were also observed in the furnace effluent, although none was present in the source gas itself.

Discussion

During the attempt to produce phosphorus-doped polysilicon films by LPCVD, two serious process failures occurred. The reduction in film deposition rates by a factor of 20 results in unacceptably long time requirements for film deposition, and the lack of physical and chemical homogeneity in films so produced renders them unfit for use in VLSI technology. We consider first the mechanism resulting in the severe growth rate suppression.

To proceed with any form of analysis, it is necessary to establish a model framework for the LPCVD of silicon from silane. We propose, as others (7, 8) have, the reaction sequence

adsorption, decomposition to an intermediate state [the silylene (9) radical is a reasonable candidate], followed by the evolution of remaining hydrogen, Si incorporation, and the structural ordering of the lattice (10). It is unnecessary for the purpose of the following argument to establish the rate limiting step in silane LPCVD. However, examining the mechanism, we find that reaction [1] is the sole point where phosphine could trivially interdict silicon film growth, by preferential adsorption at surface sites. Gas-phase chemistry that one might propose wherein phosphine consumes silane by some mechanism,

Fig. 3. Deposition rate profile vs. interwafer spacing (D)

Fig. 4. Phosphorus distribution vs. interwafer spacing

Fig. 5. Residual silane partial pressure vs. phosphine input

thus excluding it from the deposition process, could only produce effects of magnitude $[\text{PH}_3]/[\text{SiH}_4] = 2.5\%$, insufficient to explain the order of magnitude effects we observe. The formation of a stable layer of adsorbed phosphine is plausible as the presence of a lone pair of valence electrons on the phosphine molecule should enable phosphine to compete successfully with silane (a fully coordinated molecule) for available surface sites. One could then postulate the nondissociative adsorption of a stable layer of pentavalent phosphorus bridging adjoining silicon atoms, while one would have to propose a dissociative adsorption scheme for the silane molecule (*i.e.*, hydrogen loss occurs to allow the bonding of silane to the surface). In the second paper of this set, we will seek to demonstrate the validity of this argument by a detailed examination of the interactions of silane and phosphine with the silicon surface.

The second problem encountered upon phosphorus doping was the onset of significant inhomogeneities in films so deposited (Fig. 2 and 3). If we assume this deposition process is first order in reactant flux to the silicon surface, typical for LPCVD, observed growth-rate profiles (Fig. 3) mirror a steep concentration gradient in the active deposition species, having its minimum along the furnace axis in the interwafer region. To understand the origin of the aforementioned reactant concentration gradient, it is necessary to determine the role played in this process by reactant surface kinetics *vs.* reactant transport.

If a reaction is purely surface kinetic controlled, it should result in uniform film deposition, as kinetic control is defined to be the case where reactant flux to the growth surface greatly exceeds the reaction rates of the relevant heterogeneous (surface) chemistry. Thus, reactant transport is far more rapid than depletion, and reactant concentration is only slowly varying with position in the reactor. Conversely, when heterogeneous reaction rates are sufficiently rapid such that reactant transport is the rate limiting step, reactant concentration is a strong function of position within the reactor, as rapid depletion of the film forming species occurs. Hitchman (8)

calculates that kinetic control dominates the LPCVD process when using a pure silane source, and states the criteria for uniform deposition (kinetic control) as

$$K \ll D/L, \text{ where } K = (Q/A)Ln(C_{(\text{initial})}/C_{(\text{final})})$$

K is an effective heterogeneous rate constant, where D is the diffusion constant of the reactive species, L is the relevant system dimension (the wafer diameter is a good choice if one desires uniform deposition across this dimension), Q is the volume flow per unit time through the reactor, A is defined as the total surface area for the reaction, and C is the reactant concentration. The inequality above has been shown (8) valid for the case of silane LPCVD, so rather than compute anew the values of all terms, it is equally instructive to estimate the effect that the introduction of phosphine has on the terms of the inequality. Upon switching from the undoped to the phosphine-doped process, the quantity D/L remains unchanged, as pressure, temperature, and system geometry are unchanged. Taking C as the silane concentration, our mass spectrometry data show $C_{(\text{initial})}/C_{(\text{final})}$ to decrease by 20%, as silane consumption declines that amount upon the introduction of phosphine. Upon the addition of phosphine, Q/A is unchanged, as silane flow and system geometry are fixed. As defined above, we see K is thus reduced in magnitude as silane consumption falls off with the addition of phosphine. With the inequality above satisfied for the case of undoped silane LPCVD, using the assumptions just stated, it remains satisfied for the case of phosphorus-doped LPCVD as well. This implies that the deposition reaction should remain under kinetic control, with good film uniformity, contrary to experimental evidence.

The aforementioned inconsistency would not have come about had the effective heterogeneous reaction rate increased greatly upon the addition of phosphine. A method for resolving this impasse is to propose that the active species participating in film deposition is no longer predominantly silane. We have already discussed the suppression of silane's heterogeneous decomposition chemistry due to phosphine adsorption. Consequently, we should now consider the possibility that nominally less rapid homogeneous (gas-phase) reactions operating in parallel with the surface chemistry may play a more prominent role in the film forming process.

Utilizing a technique referred to as homogeneous chemical vapor deposition (HOMOCVD), Scott *et al.* (11) have demonstrated that when one quenches silane's rapid heterogeneous decomposition reactions by depositing on a cold ($T < 250^\circ\text{C}$) substrate from a heated silane source ($T_{\text{gas}} > 650^\circ\text{C}$), a film may be grown directly from silylene (SiH_2) produced by the homogeneous decomposition of silane

Silylene resulting from the pyrolysis of silane is believed to then insert into Si-H bonds on the silicon surface, resulting in silicon deposition. Both homo- and heterogeneous chemistries were shown to operate in parallel, but the more rapid heterogeneous silane decomposition processes dominate film growth unless they are quenched. In the instance of phosphorus-doped LPCVD, heterogeneous silane chemistry is also greatly suppressed, though in this case by the preferential adsorption of phosphine rather than by cooling the substrate. This effectively increases the fractional contribution of homogeneous chemistry (*i.e.*, deposition from homogeneously generated silylene) to the phosphorus-doped LPCVD process. Although the presence of adsorbed phosphine would quench silane surface chemistry, it would not be expected to interdict film growth due to silylene. Blazejowski and Lampe (12) investigated the insertion of silylene into phosphine's P-H bonds to form monosilylphosphine

and obtained reaction rate constants roughly equal those

found for the insertion of silylene into Si-H bonds. Thus, the substitution of P-H bonds for Si-H at the growth interface in the case of phosphorus-doped LPCVD would not be expected to interfere with film growth by silylene insertion at that surface. Also, in work by Meyerson *et al.* (13), phosphine was used to prepare phosphorus-doped films by HOMOCVD, and films were seen to deposit somewhat more rapidly in the presence of phosphine, leading us to conclude again that phosphine will not degrade the contribution of homogeneous chemistry to the silicon growth process.

In addition to contributing directly to film growth, silylene may also reinsert into silane, producing disilane via reaction [6]

Thus, a series of homogeneous reactions proceed, producing intermediate species such as silylene, disilane, and monosilylphosphine. These species are known to be highly reactive relative to silane. Silylene insertion reactions proceed at near gas kinetic rates (9, 14) (insertion rates equal to collisional frequencies), while disilane's instability relative to silane is well documented (9). Monosilylphosphine was shown (15) to be stable in the gas phase at up to 550°C , yet it is highly unstable in the presence of surfaces, and will decompose to film at ambient temperature. Therefore, the homogeneous generation of these highly reactive species in the reactor environment, in concert with the suppression of silane's heterogeneous contribution to the growth process, serves to enhance the effective reaction rate constant K . Hitchman, using an LPCVD system very similar to ours, obtained values for K and D/L of 1.5 and 3.0×10^3 , respectively, for silane LPCVD, thus satisfying the criteria for uniform deposition with $K \ll D/L$. If we now view the phosphorus-doped LPCVD process as controlled by homogeneously generated precursors such as silylene, we must use the appropriate K value, $K_{(\text{silylene})}$, in the inequality. We may obtain an order of magnitude estimate of the relationship between $K_{(\text{silylene})}$ and $K_{(\text{silane})}$ by noting that Farrow (7) and Janai (16) found values of 10^{-4} and 10^{-6} , respectively, for the decomposition probability of silane when impinged upon a 600°C silicon surface, while silylene reacts with near unity probability. Thus, we may estimate $K_{(\text{silylene})} \approx 10^4 K_{(\text{silane})}$. Consequently, $K_{(\text{silylene})} \sim 1.5 \times 10^4$, *i.e.*, $K_{(\text{silylene})} > D/L$, and one would expect the rapid depletion of this reactant to occur. Reactant transport, therefore, plays a major role in controlling the rate of phosphorus-doped film deposition, and the concentration of active film precursors is a strong function of position within the reactor. A similar argument is possible for disilane, or monosilylphosphine, in that they are all highly reactive relative to silane, but silylene is by far the most reactive and thus the best example.

Viewed as a transport-limited deposition process, phosphorus-doped silicon LPCVD behaves as expected. Depletion of the active species in the interwafer region results in film growth rate profiles as shown in Fig. 3. By symmetry alone it is apparent that film thickness minima will occur along the furnace axis. A variety of methods may be employed to qualitatively model (17) the functional form of the growth rate profiles obtained when deposition is carried out under transport control. In the Appendix, we have conducted a worst case calculation of the expected growth profiles for an LPCVD process operating in this regime. As expected, our model (see Fig. 6 and 7) predicts variations in excess of those observed, though the results are correct in their qualitative dependence of both uniformity and growth rate on the interwafer spacing. Our calculation allows only for the contribution to growth of reactive species generated in the annulus external to the interwafer region, as the transport properties of these species will determine the uniformity of resulting films. The complete process, however, is the sum of several mechanisms operating parallel. A residual contribution to deposition by heterogeneous silane decomposition is present, as well as the contribution by gas-phase reac-

Fig. 6. Geometry of system considered in Appendix (see text)

tions in the interwafer region itself, and both add uniform background deposition rates to the total process. For the case of 0.15 in. wafer separation, taking 4 Å/min as the background, fitting the model curve (Fig. 8) at center and edge to our data results in reasonable agreement across the entire wafer. However, owing to the simplicity of the model, its extension beyond this demonstration cannot be made without an independent measure of the parameters utilized in fitting the curve to the data. This requires that one obtain spatially resolved data on the various gaseous components of the deposition source, and this technology is currently in its infancy.

We have seen in Fig. 4 that both the phosphorus content and its distribution across a given wafer are strong functions of wafer spacing. Workers in the field of gas-phase kinetics have demonstrated (12) the rapid conversion of phosphine to the unstable intermediate monosilylphosphine in the presence of the products of silane pyrolysis. Whether the rate of this conversion leads to the depletion of phosphine in the interwafer region (see Fig. 4), or, alternatively, the spatially varying flux of silicon bearing species to the growth interface interacts with ad-

Fig. 7. Growth rate profiles expected for the case of a transport-limited LPCVD process.

Fig. 8. Data for the case of 0.15 in. interwafer spacing vs. the predicted profile.

sorbed phosphine to produce the phosphorus distributions observed, we are not at present in possession of sufficient data to make a reasonable estimate of the relative importance of these potential mechanisms.

Conclusions

The intrinsic silicon LPCVD technique is not trivially transferable to the preparation of *in situ* doped polycrystalline silicon. The addition of phosphine to the well-characterized pure silane LPCVD process results in both the suppression of film deposition rates by a factor of 20, coupled with a severe degradation of film uniformity. Our results are consistent with the preferential adsorption of phosphine at the growth interface, thus inhibiting heterogeneous silane decomposition chemistry, accounting for the reduction in deposition rates. In the second paper we will examine the manner in which silane and phosphine compete for available surface sites, and therefore further test the conclusion above.

We observe the onset of severe uniformity problems upon the addition of phosphine as a dopant in the silane LPCVD process. This difficulty is attributed to the suppression of heterogeneous silane decomposition chemistry, which allows normally secondary homogeneous chemical processes to play a role of increased importance. The growth rate profiles observed indicate the LPCVD process has been shifted into a transport-controlled regime by the presence of these homogeneously generated film precursors. Mass spectrometry provides evidence for a 1.0 μm partial pressure disilane (Si_2H_6), a highly reactive by-product of the homogeneous decomposition of silane, and thus also supports the presence of its precursor, silylene (SiH_2). We have presented a straightforward model for the limiting case of an LPCVD process operating under transport control, and have demonstrated how this leads to growth rate profiles such as those observed here.

APPENDIX

We will demonstrate the consequences of the presence of highly reactive species within the LPCVD reactor environment by considering the limiting case where the following conditions are met.

1. The molecular mean free path exceeds the interwafer dimension, *i.e.* molecular flow dominates in the interwafer region.

Table I. Predicted vs. observed wafer spacing

Wafer spacing	Variation (observed)	Variation (predicted)
0.15 in.	1.98	30.53
0.31 in.	1.71	8.08
0.47 in.	1.54	4.05
0.63 in.	1.37	2.65
2.0 in.	—	1.10

2. The reactant under consideration has a reaction probability of unity upon impact with the silicon surface.

Condition 2 is actually quite reasonable for a reactant such as silylene, which is known to insert into Si-H bonds at gas kinetics rates (with probability near unity). The conditions above will lead to a worst case prediction of thickness variations within a wafer undergoing LPCVD of an unspecified film, in that deposition is assumed to be due solely to species generated in the gas phase, with that generation process being rate limiting.

The large annular region external to the wafers $R_{\text{furnace tube}} > r > R_{\text{wafers}}$ is taken to be the source of the reactive species (reactant Q), which then enters the interwafer region and is removed by collisions at surfaces. Consider a flux F_0 of reactant Q crossing the differential area dA' on the cylindrical surface defined by the wafer edges (see Fig. 6), and then striking the lower wafer in the region dA . The total flux F_T of Q reaching the lower wafer is

$$\int_A \int_{A'} \frac{F_0}{4\pi s^2} \cos \Omega \cos \Omega' dA dA'$$

Integrating only over source (primed) terms, we calculate the flux of Q as a function of radial position ($r = \sigma$) across the wafer. Referring to Fig. 6

$$\cos \Omega = \frac{x'}{s} \quad \cos \Omega' = \frac{R - \sigma \cos \Theta'}{s}$$

$$F(\sigma) = \frac{F_0}{4\pi} \int_{\Theta'=0}^{\Theta'=2\pi} \int_{r'=0}^{r'=h} \left(\frac{1}{s^2} \right) \left(\frac{x'}{s} \right) \left(\frac{R - \sigma \cos \Theta'}{s} \right) R dx' d\Theta'$$

where

$$s = (\sigma^2 + R^2 + x'^2 - 2\sigma R \cos \Theta')^{1/2}$$

Integration over x yields

$$-\frac{F_0}{8\pi} \int_{\Theta'=0}^{\Theta'=2\pi} \left(\frac{R - \sigma \cos \Theta'}{\sigma^2 + R^2 + h^2 - 2\sigma R \cos \Theta'} \right) R d\Theta' + \frac{F_0}{8\pi} \int_{\Theta'=0}^{\Theta'=2\pi} \left(\frac{R - \sigma \cos \Theta'}{\sigma^2 + R^2 - 2\sigma R \cos \Theta'} \right) R d\Theta'$$

Defining the dimensionless (w.r.t. R) parameters

$$\sigma_d = \frac{\sigma}{R} \quad \text{and} \quad h_d = \frac{h}{R}$$

integration over Θ' yields

$$\text{flux}(\sigma) \propto F_0 \left(1 - \frac{1 - \sigma_d^2 - h_d^2}{((\sigma_d^2 + h_d^2 + 1)^2 - 4\sigma_d^2)^{1/2}} \right)$$

In Fig. 7, we plot flux vs. σ using $R = 1.125$ in., and h as shown. As expected for a worst case calculation, the computed ratios of edge growth rate vs. wafer center growth rates (see Table I) exceed those observed, but the qualitative dependence of both growth rate and deposition uniformity upon wafer spacing is correct. Increased interwafer spacing results in both increased net film growth rates and enhanced uniformity. As this calculation accounts only for those reactant molecules generated external to the interwafer region, a uniform background deposition rate may be summed with the deposition profiles obtained here, reducing the severity of predicted inhomogeneity (see Fig. 8 and main text). However, upon reaching 2.0 in. interwafer dimension, films are expected to vary within $\pm 10\%$ at worst, setting a general upper bound on the system dimensions required to produce films of adequate uniformity for electronic device purposes. To obtain other than a limiting case model for the LPCVD system is complex, and beyond the scope of this paper. As such, we will defer such a calculation to a paper to follow.

Phosphorus-Doped Polycrystalline Silicon via LPCVD

II. Surface Interactions of the Silane/Phosphine/Silicon System

B. S. Meyerson* and M. L. Yu

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Secondary ion mass spectrometry (SIMS), low energy electron diffraction (LEED), and Auger electron spectroscopy (AES) have been employed to study the interactions of silane (SiH_4) and phosphine (PH_3) with the Si(100) surface. Phosphine adsorption and desorption were investigated at surface temperatures in the range $25^\circ \leq T \leq 700^\circ\text{C}$. At ambient temperature, phosphine saturated the bare Si(100) surface after 3-5L exposure, and fitting adsorption data to a Langmuir model yields the value $s = 1.0$ for the sticking coefficient. Phosphine adsorption was found to follow the 2×1 pattern of the underlying silicon. Competitive adsorption experiments set an upper bound of $s \leq 0.025$ for silane adsorption under like conditions. The silicon surface was observed to be passivated with respect to silane adsorption by prior exposure to phosphine, with a layer of preferentially adsorbed phosphine formed which served to preclude subsequent silane adsorption. The results obtained here are discussed in the context of their bearing upon the phosphorus-doped low pressure chemical vapor deposition process.

In this paper, we will study the interactions of silane, phosphine, and the silicon surface, in an effort to understand in detail the microscopic phenomena leading to the order of magnitude suppression of film growth rates during the LPCVD preparation of phosphorus-doped polycrystalline silicon. This phenomena, discussed in the first paper of this set, has been observed by others (1, 2). Detailed kinetic equations were devised (1) to test the consistency of the models proposed, after which novel inert gas diluents and/or alternative furnace and wafer carrier geometries were studied in an effort to ameliorate the difficulties associated with this particular chemistry. In modeling such a process kinetically, a limitation is that one may demonstrate the model to be consistent with observation, but not necessarily unique. For this reason, we pursue an alternative approach, that being the direct observation via surface probe techniques, of the interactions relevant to the phosphorus-doped LPCVD process.

Experimental

We have studied the interaction of silane and phosphine with the Si(100) surface using low energy electron diffraction (LEED), Auger electron spectroscopy (AES), photo emission spectroscopy (PES), and secondary ion mass spectrometry (SIMS). The detailed interaction of each adsorbate with the surface will be reported separately (3, 4), with the emphasis here placed on data relevant to the mutual interaction of these two adsorbates with the silicon surface.

The experiments were conducted in an ultrahigh vacuum (UHV) apparatus, baked, and then pumped to below 2×10^{-10} torr base pressure. A silicon (100) sample was cut from a 10 Ω -cm n-type silicon wafer, etched lightly in HF, then suspended in the sample chamber by Ta clamps of low thermal mass such that the sample could be heated resistively (using a dc current). Sample temperature was determined by a Chromel-Alumel thermocouple spot-welded to the clamps adjacent to the sample. Thermocouple readings were calibrated from 750° to 1100°C using optical pyrometry. Overlapping data from pyrometry and thermocouple measurements were found to be in good agreement. Once at base pressure, the sample was flashed to 1100°C for 15s thermal etching cycles. Surface contaminant levels were monitored by *in situ* AES until only negligible residual C or O was detected and LEED showed a clear $p(2 \times 1)$ pattern, consistent with the bare (100) surface. Between sequential adsorption studies, 600° - 900°C anneals sufficed to return the surface to its initial bare state as determined again via AES. Avoidance of repeated 1100°C cleaning is desirable to eliminate excessive thermal etching and accompanying changes in surface morphology. Controlled exposure of the silicon surface to PH_3 and SiH_4 was achieved using calibrated leak

valves to bring the system up to preset partial pressures. Mass spectrometry was utilized at various stages in the experiments to ensure source purity. All filaments (ion gauges and titanium sublimation pumps) as well as ion pumping equipment were turned off during these exposures to avoid introducing unwanted by-products of gas-phase chemistry (such as atomic hydrogen formation at the hot filaments) caused by the aforementioned equipment. We therefore employed a 170 liter/s turbomolecular pump to maintain the system at the desired exposure pressure.

Phosphine adsorption on Si at substrate temperatures in the range $25^\circ \leq T_s \leq 625^\circ\text{C}$ was monitored via observation of the 120 eV phosphorus LMM Auger line. Phosphine which had been adsorbed at $T = 25^\circ$ and 550°C was removed from the surface by subsequent annealing (1 min anneals at each temperature step), observing the evolution of phosphine using AES. Though suitable for monitoring phosphine, AES is unable to distinguish silicon atoms in adsorbed silane from the bulk silicon. Thus, to track silane adsorption we employed static mode SIMS, utilizing a 500 eV, 2 mm diam, 1 nA, Ne^+ primary beam generated by a differentially pumped ion gun to monitor both SiH_x^+ fragments and H^+ from adsorbed silane, thus quantifying the degree of silane surface coverage. The competitive adsorption of silane with phosphine required a modified detection scheme, as interference from the H^+ signal of phosphine as well as overlap of several SiH_x^+ and PH_y^+ peaks made silane detection unsure. Consequently, we substituted fully deuterated silane SiD_4 during competitive adsorption experiments, and found only negligible interference with the D^+ signal due to H_2^+ ($\text{H}_2^+/\text{H}^+ \sim 0.5\%$), allowing the straightforward detection of adsorbed silane in the presence of phosphine.

Competitive adsorption of silane and phosphine was examined in two distinct modes. Initially, the sample was exposed to sufficient phosphine concentration (20L) to ensure the presence of a phosphine-saturated silicon surface, subsequent to which SiD_4 was introduced into the chamber, tracking the displacement of phosphine by the SiD_4 via the SIMS D^+ signal. In the second mode, the sample was exposed to a 1:10 mixture of PH_3/SiD_4 , at 10^{-7} and 10^{-6} torr partial pressures respectively for 100s, observing the Si (LMM) Auger line in ratio to the phosphorus (LMM) Auger line. We report our findings in the following section.

Results

Figure 1 displays adsorbate surface coverage as a function of exposure for both silane and phosphine when the two gases are adsorbed independently on a clean silicon surface. It is apparent from the data that the saturation of surface sites proceeds to completion far more rapidly for phosphine, with the Auger signal saturating after expo-

*Electrochemical Society Active Member.

Fig. 1. Phosphine and silane adsorption on the bare Si(100) surface

sure to 3-4L ($1\text{L} \cong 10^{-6}$ torr/l/s) of gas. One may calculate¹ a value of $s = 1.0$ for phosphine's sticking coefficient on the bare silicon surface from this result. LEED patterns taken during phosphine adsorption remained typical of the underlying 2×1 silicon surface, indicating that an ordered adsorption of phosphine had occurred. In contrast to phosphine, silane adsorption reaches equilibrium on a far longer time scale, beyond 40L exposure, indicating a greatly reduced value of s relative that for phosphine. Calculation of an exact value of $s_{(\text{silane})}$ directly from a simple Langmuir adsorption scheme as was done for phosphine was not possible as silane adsorption is dissociative, yielding more than one site coverage per molecule adsorbed. Instead, bounds on $s_{(\text{silane})}$ are set using the method elaborated further on in this paper.

Saturation values for phosphine surface coverage were obtained over a range of adsorption temperatures as displayed in Fig. 2, and a broad maximum is seen at 550°C . Silane adsorption at elevated temperatures was avoided as its decomposition to form film on the silicon surface might result in sample morphology changes making run comparisons invalid.

In Fig. 3, AES data are given for the evolution of phosphine (adsorbed at $T_s = 25^\circ$ and 550°C .) from the silicon surface as a function of annealing temperature, along with accompanying hydrogen loss from the adsorbed (at $T_s = 25^\circ\text{C}$) phosphine. An interesting feature here was the disappearance of the hydrogen signal from the adsorbed phosphine at approximately 500°C , while the phosphorus signal remained unchanged. It is evident that phosphine dissociates at the surface, evolving hydrogen, and leaving bound phosphorus atoms on the surface.

Data taken at room temperature for the case of deuterated silane adsorption onto a phosphine-saturated silicon surface demonstrated that silane does not readily displace adsorbed phosphine. The D^+ signal from newly adsorbed SiD_4 failed to exceed 1.0% of the saturation value found for SiD_4 adsorption on a bare silicon surface, even after the phosphine-covered surface was exposed to the equivalent of 100 monolayers silane flux to the surface. Hence, in all cases, the presence of a phosphine saturated surface served to virtually exclude the subsequent adsorption of SiD_4 .

Three AES spectra are shown in Fig. 4; trace A for a bare silicon surface, trace B for phosphine adsorption on

¹Taking the normalized surface coverage as N , $dN/dt = F_s(1 - N)$, $N = 1 - e^{-Fst}$, $F = \text{flux in L/s}$, $s = \text{sticking coefficient}$, and $t = \text{time (s)}$. A semilog plot of $(1 - N)$ vs. Fst yields s for a known flux F .

Fig. 2. Phosphine adsorption at elevated substrate temperature

Fig. 3. Data from phosphine and hydrogen desorption experiments, curve A for PH_3 adsorbed at 25°C , B for phosphine adsorbed at 550°C , and C the hydrogen signal for phosphine adsorbed at 25°C .

bare silicon, and trace C the signal obtained from the competitive adsorption of the 1:10 phosphine/silane ratio gas source. Despite the presence of ten times the atomic flux of silane vs. phosphine to the Si surface, the phosphorus Auger peak reaches 80% of the value obtained in the instance of phosphine adsorption on the bare silicon surface. Assuming all other species on the surface are deuterated silane, using a straightforward Langmuir adsorption scheme we compute $s_{(\text{silane})} < 0.025s_{(\text{phosphine})}$. As it is probable that silane adsorption is a dissociative phenomenon, the value $s = 0.025$ must serve as an upper bound on silane's sticking coefficient, as deuterium freed by silane's dissociation may occupy surface sites directly, leading to a higher value of $s_{(\text{silane})}$ than is in fact the case.

Fig. 4. AES spectra for (A) bare Si(100) surface, (B) PH_3 -saturated Si surface, and (C) competitively adsorbed PH_3 and SiH_3 (see text).

Discussion

We have determined the sticking coefficient of phosphine to be greater than 40 times that of silane. We find that once phosphine forms an adsorbed layer, its displacement by subsequent exposure to silane is extremely slow. Additionally, the adsorbed phosphorus is stable on the surface at temperatures typical of those at which LPCVD operates, although our data indicate the onset of hydrogen loss from the adsorbed phosphine above 400°C. Thus, we have direct evidence for the "poisoning" of the phosphorus-doped LPCVD process due to the preferential adsorption of phosphine *vs.* silane, resulting in the suppression of heterogeneous silane chemistry that is believed (5, 6) dominant in the silane LPCVD process. Although our measurements were conducted on the (100) silicon crystal face, others (7, 8) have examined the adsorption of phosphine on Si(111), and the adsorption of atomic phosphorus on Si(111) (9). In all cases, a sticking coefficient of near unity was deduced, and the rapid saturation of the silicon surface was observed. As our results are consistent with those for the (111) orientation, we feel it probable that our findings are general for the phosphine/silicon system, rather than specific to a particular silicon surface morphology.

In our earlier work (10), it was noted that one must invoke the presence of reactive intermediates to account for the observed film thickness variations. We have found here that phosphine, once adsorbed, virtually excludes silane from the silicon surface, yet we observed (10) film growth rates as high as 18 Å/min at the edges of test wafers. With silane's access to the surface sites reduced to the extent our Auger data indicate, growth rates approaching 20% of those for undoped silane LPCVD cannot be adequately accounted for in terms of heterogeneous silane chemistry. Thus, we must again invoke the presence of species, other than silane, which compete successfully with phosphine for the silicon surface. Though we have a strong existence theorem for the presence of such species, and have identified at least one such reactant (disilane) via mass spectrometry (10), *in situ* reactant detection and profiling in the LPCVD environment is essential to the further understanding of these processes, and will be undertaken shortly.

The maximum in phosphorus surface coverage observed at 550°C is attributable to two phenomena. During annealing experiments performed on phosphine saturated silicon surfaces, hydrogen loss from the surface was seen to occur above 400°C (Fig. 3). The hydrogen evolved during anneals could originate from two sources. One source is adsorbed phosphine, stripped of its hydrogen above 400°C, leaving behind bare adsorbed phosphorus atoms in the range $500^\circ < T_s < 650^\circ\text{C}$. Additional surface thus becomes available as phosphine molecules dissociate, allowing higher concentrations of adsorbed phosphorus at temperatures above 400°C. Alternatively, hydrogen bound directly to the silicon surface due to hydrogen transfer from adsorbed phosphine may also evolve, opening additional sites for phosphine adsorption. Photoemission studies failed to detect a significant signal for Si-H bonding on the phosphine-covered silicon surface, and we therefore believe that little hydrogen (<10% is our detection limit) is transferred to the surface from adsorbed phosphine molecules. Thus, though we cannot exclude the possibility that hydrogen removal directly from the silicon surface contributes to the maximum in phosphine adsorption observed, our failure to observe Si-H bonding implies it contributes less than 10% to the effect. Though the adsorption of in excess of one monolayer (at $T > 400^\circ\text{C}$) of phosphine would also result in an adsorption maximum, the constancy of the bulk silicon Auger peak under varying adsorption temperatures indicates that the adsorbed phosphine layer does not propagate outward from the surface. Above 600°C, the decrease in phosphorus surface coverage is due to evolution of the atomic phosphorus from the surface. We do not believe the disappearance of the phosphorus AES signal is due to diffu-

sion of phosphorus into the bulk, as the diffusivity of phosphorus in silicon at these temperatures is for our purposes negligible (11), and we observed no loss of Si Auger signal as would have occurred had P diffused into the bulk, displacing subsurface silicon atoms.

The outcome of these experiments has implications for the other dopant species one might employ in LPCVD. Alternative n-type dopant species for use in LPCVD will by definition share the basic electronic structure of phosphine (12), with arsine (AsH_3) an example. This similarity in valence electron configuration has the expected result, *i.e.*, arsine is also observed (2) to severely depress silicon growth rates, presumably owing to its preferential adsorption over silane. All the above assumes the arrival of the dopant molecules intact at the growth surface, as gas-phase pyrolysis clearly changes the nature of the species reaching the surface and thus alters the deposition chemistry. Phosphine (13) is known to be quite stable on the temperature/residence time scales in use during LPCVD, and we have verified this via mass spectrometry, finding no significant decomposition of pure phosphine at 625°C. Arsine stability has been investigated (14) as it relates to gallium arsenide CVD, and it too undergoes negligible decomposition on the LPCVD temperature/residence time scale.

Conclusions

By direct observation of the competition between silane and phosphine for adsorption sites on the silicon surface, we have verified the formation of a stable layer of adsorbed phosphorus during the phosphorus-doped LPCVD process. It has been demonstrated that phosphine, the phosphorus dopant source, has a sticking coefficient $s = 1.0$ when adsorbed on the bare silicon (100) surface, while the value for silane under identical conditions was found to be $s \leq 0.025$. We find that adsorbed phosphine will dissociate, evolving hydrogen, at temperatures below those necessary to desorb phosphorus itself, leading to a maxima in phosphorus adsorption at 550°C. Once adsorbed, phosphine is stable under a silane flux, and thus effectively passivates the silicon surface with respect to heterogeneous silane chemistry and is responsible for the suppression of growth rates in the phosphorus-doped LPCVD process.

ABSTRACT

The enhancement by Bi adatoms of the anodic peak for oxidation of HCOOH at a Pt electrode in 0.5M H₂SO₄ was studied as a function of temperature. The results are interpreted on the basis of an increased value of the pre-exponential term in the Arrhenius rate equation, which is attributed to an increase in the frequency of the vibrational motion leading to desorption of the strongly adsorbed product of the organic oxidation. This increase is concluded to be the direct effect of the site-to-site surface migration of the freshly deposited Bi adatoms.

It is well known that the electrochemical oxidation of many organic compounds on noble metal electrodes in aqueous solutions is characterized by rapid fouling of the electrode surfaces by the strongly adsorbed intermediate and/or final products of the faradaic reactions. These adsorbed materials, call them "poisons," are desorbed very slowly or not at all, and the electrode current decays very rapidly for a constant applied electrode potential. The instantaneous electrode current and total faradaic charge which can pass before substantial fouling has occurred can be increased significantly by the *in situ* electrodeposition of certain metal adatoms on the electrode surface. Three prominent explanations for the apparent electrocatalytic activity of the ad-atoms are reviewed briefly, and we offer an alternative explanation based on results of a temperature study for oxidation of HCOOH at a Pt electrode in 0.5M H₂SO₄ containing Bi(III).

Explanations for the Apparent Electrocatalytic Activity of Adatoms

The third-body effect.—This model has as its basis the speculation that the strongly adsorbed poisons are formed by dimerization of less strongly adsorbed free radicals, *e.g.*, ·COOH in the case of the oxidation of HCOOH, on adjacent surface sites. Electrodeposited metal adatoms are presumed to be uniformly distributed on the electrode so as to occupy alternate surface sites. With such an arrangement of adatoms, the proximity of adsorbed radicals is not favorable for the dimerization reaction. Hence, a uniform surface coverage by the adatoms of 0.5 monolayer is predicted to yield the maximum catalytic benefit. Angerstein-Kozłowska *et al.* (1), Adzic *et al.* (2, 3), and Motoo and Watanabe (4) have concluded this mechanism is operative for adatoms of Hg, Bi, Pb, Tl, and Cd in the oxidation of HCOOH on Pt electrodes. The metal adatoms are referred to as the "third bodies." This model does not explain satisfactorily the quantitative differences observed in the enhancement effect of various metals. Furthermore, it has yet to be proved that adatoms are uniformly distributed rather than clustered for surface coverages less than the equivalent of one monolayer.

The suppression of hydrogen adsorption.—This model was proposed by Spasojevic *et al.* (5) for oxidation of HCOOH and presumes that the poisons are formed via interaction of adsorbed H atoms with ·COOH radicals. Electrodeposited metal adatoms inhibit the adsorption of H

atoms by site exclusion and thereby decrease the extent of the reaction supposed to produce the strongly adsorbed poisons. Numerous organic oxidations which lead to surface fouling occur in regions of electrode potential for which the equilibrium surface coverage by H atoms is virtually zero, *i.e.*, $E \gg E_{H^+,H_2}^0$, a fact which is counter to the basic presumption of this model.

The bi-functional model.—Motoo and Watanabe (6, 7) proposed this explanation of the enhancement effects of metal adatoms, which has been applied to the electrocatalysis by the adatoms Sn, Ge, As, and Ru of the oxidation of CH₃OH, HCHO, and CO on Pt (6-11). Oxygen atoms or oxygen containing species, *e.g.*, the ·OH radical, adsorbed on the metal adatoms catalyze the oxidation of organic molecules and radicals adsorbed on adjacent surface sites. Kock *et al.* (8) derived a mathematical expression based on this model relating the catalytic currents to the free energy of adsorption of oxygen on the metal adatoms. The theory was found to be in good agreement with experimental results. This model appears to be contradicted by data from alkaline solutions for which the catalytic current ceases on the positive scan of potential when the metal adatoms are oxidized to their insoluble oxides.

An alternate model.—We propose a mechanism which in its simplest form is given by Eq. [1]-[3]. In these equations, S represents a surface site, R a reactant molecule in the diffusion layer, and P the product of the faradaic reaction which functions as a poison when adsorbed at a surface site

Desorption of the reaction product (P) from a reaction site by reaction [3] is necessary for continuation of the faradaic signal. The metal adatoms are concluded to enhance the rate of desorption (k_3) in this mechanism. No bonding interaction is presumed to occur between the adatoms and R or P; consequently, a reaction is not shown which involves the direct chemical participation of adatoms. The faradaic signal is proportional to the molar surface coverage by adsorbed R, $\theta_R \Gamma_{\max}$, as given by

$$i = nFAk_2\theta_R\Gamma_{\max} \quad [4]$$

where Γ_{\max} is the maximum coverage (mol cm⁻²) corresponding to $\theta_R = 1$. It is observed that the voltammetric response is in the form of an anodic peak and, for the

Fig. 1. i-E curves for Pt in 0.5M H_2SO_4 with and without Bi(III). $W = 400 \text{ rev min}^{-1}$, $\phi = 6.0 \text{ V min}^{-1}$. Curves: — 0.00 μM Bi(III), 0.40 μM Bi(III), - - - 0.40 μM Bi(III), - · - · 2.0 μM Bi(III).

peak current ($i = I_p$), a steady-state condition is momentarily satisfied. Hence

$$\frac{di}{dt} = 0 = nFA\Gamma_{\max} \left[k_2 \left(\frac{d\theta_R}{dt} \right) + \theta_R \left(\frac{dk_2}{dE} \cdot \frac{dE}{dt} \right) \right] \quad [5]$$

The symbol ϕ is substituted for the rate of potential scan, (dE/dt) , and we write

$$k_2 \left(\frac{d\theta_R}{dt} \right) = -\theta_R \phi \left(\frac{dk_2}{dE} \right) = \theta_R \phi k_2 \left(\frac{\alpha F}{RT} \right) \quad [6]$$

where α includes the symmetry factor and the number of electrons up to and including the rate-determining step.

We have as yet been unable to obtain a satisfactory rigorous solution to the system of equations, and we proceed instead with the assumption that for a large value of the bulk concentration of R (C_R^b), the concentration of R at the electrode surface equals the bulk concentration ($C_R^s \approx C_R^b$) and $\theta_R + \theta_p \approx 1$. The value of θ_{H_2O} is small but not zero and we apply the steady-state approximation for θ_{H_2O} , i.e., $d\theta_{H_2O}/dt \approx 0$, with the result

$$\theta_{H_2O} = \frac{k_3 - k_3\theta_R + k_{-1}\theta_R}{k_1 C_R^b} \quad [7]$$

The time derivative of θ_R is evaluated which, together with Eq. [7], yields

$$\frac{d\theta_R}{dt} = k_3 - k_3\theta_R - k_2\theta_R \quad [8]$$

Equations [6] and [8] are combined and the result is solved for θ_R to give

$$\theta_R = \frac{k_3}{k_2 + k_3 - \alpha F \phi / RT} \quad [9]$$

Hence, Eq. [4] can be written for the peak current as

$$I_p = -nFA\Gamma_{\max} \frac{k_2 k_3}{k_2 + k_3 - \alpha F \phi / RT} \quad [10]$$

The value of I_p is expected to be independent of C_R^b , on the basis of the assumption leading to Eq. [10], as is observed for large values of C_R^b .

Experimental

Voltammetric data was obtained with a Pt rotating disk electrode (RDE, 0.43 cm^2), Model PIR rotator and Model RDE-3 potentiostat (Pine Instrument Company, Grove City, Pennsylvania). The X-Y recorder was Model 7035B (Hewlett-Packard). The electrolysis cell (ca. 500 ml) had a double wall construction for circulation of thermostated water from a Model 2095 refrigerated and heated circulating bath (Forma Scientific, Incorporated, Marietta, Ohio). Temperatures were controlled in the range 10°-43°C with a precision of $\pm 0.1^\circ\text{C}$. All electrode potentials were measured in V vs. SCE.

Solutions were prepared from reagent-grade chemicals using triply distilled water. Solutions of Bi(III) were prepared from $\text{Bi}(\text{NO}_3)_3$.

Results and Discussion

Current-potential curves.—Typical i-E curves for Pt in 0.5M H_2SO_4 are shown in Fig. 1 with and without added Bi(III). Bismuth adatoms are deposited at $E < \text{ca. } 0.5\text{V}$, i.e., over the entire accessible range of values for which platinum oxide (PtO) is not present on the electrode surface. Bismuth adatoms are oxidized on the positive scan to produce the peak at 0.6V appearing on the wave for PtO production. Cadle and Bruckenstein (12) demonstrated that a significant fraction of the oxidized Bi(III) remains adsorbed on the Pt surface. The adsorbed Bi(III) is reduced simultaneously with reduction of PtO on the negative scan, i.e., $E \approx 0.4\text{V}$. The transport-limited current for the reaction $\text{Bi}(\text{III}) + 3e \rightarrow \text{Bi}^0$ is 0.2 μA in $4 \times 10^{-7}\text{M}$ Bi(III), which is not perceptible for the current sensitivity represented in Fig. 1. Several cyclic scans are necessary to reach the reproducible surface coverage by Bi adatoms for this low concentration, and the i-E curves shown are the reproducible curves obtained after 10-20 repetitive cycles.

The surface coverage by Bi adatoms, θ_{Bi} , is conveniently determined on the basis of the decrease in the cathodic charge for the reaction $\text{H}^+ + e \rightarrow (\cdot\text{H})_{\text{ads}}$ in the potential range 0.10 to -0.25V vs. SCE . Values of θ_{Bi} calculated for a 1:1 substitution of Bi for $(\cdot\text{H})_{\text{ads}}$ are given in Table I for several values of $C_{\text{Bi(III)}^b}$.

The effectiveness of Bi adatoms to enhance the anodic signals for HCOOH at the Pt electrode in 0.5M H_2SO_4 is il-

illustrated in Fig. 2. In the absence of Bi(III), the largest peak signal is obtained on the negative scan of potential (peak D) immediately following reduction of PtO. The products of the reaction for peak D which remain adsorbed on the electrode result in substantial loss of surface activity, and only a very small peak (A) is obtained for oxidation of HCOOH on the subsequent positive scan. The adsorbed organic poisons are oxidatively removed during formation of surface oxide for $E > 1.0\text{V}$. The addition of Bi(III) to the solution with subsequent formation of Bi adatoms results in a very substantial increase in peak A with only a modest effect on peak D. Values of the peak signals, $I_{p,A}$ and $I_{p,D}$, are shown in Fig. 3 as a function of $C_{\text{Bi(III)}}^b$. Again, the i-E curves in Fig. 2 and the peak values in Fig. 3 correspond to the reproducible data achieved after several cyclic scans of potential. Since the adsorbed product for the oxidation of HCOOH obliterates the cathodic peaks for formation of $(\cdot\text{H})_{\text{ads}}$ in the presence or absence of Bi(III), θ_{Bi} cannot be determined in the presence of HCOOH and we can only suppose that HCOOH has a negligible effect on θ_{Bi} for a given value of $C_{\text{Bi(III)}}^b$. On this basis, we conclude for peak A that the maximum enhancement observed for ca. $10 \mu\text{M}$ Bi(III) corresponds to $\theta_{\text{Bi}} \approx 0.25$ (see Table I). For $\theta_{\text{Bi}} \rightarrow 1.0$, the resultant decrease in surface sites available for adsorption of HCOOH is expected to cause a decrease in the peak current. The value of $I_{k,A}$ is observed to decrease for $C_{\text{Bi(III)}}^b > 10 \mu\text{M}$.

The value of $I_{p,D}$ continues to increase for $C_{\text{Bi(III)}}^b$ exceeding $10 \mu\text{M}$. Because only a portion of the Bi(III) produced by oxidation of Bi adatoms remains adsorbed to the surface oxide, the value of θ_{Bi} corresponding to peak D, obtained immediately after reduction of the surface oxide, is concluded to be less than 0.25. Provided Bi(III) is electro-deposited at a transport-limited rate, it is predicted that a period of approximately 15s is required to accumulate a 0.25-monolayer coverage by Bi adatoms under the condi-

Fig. 3. $I_{p,A}$ and $I_{p,D}$ as a function of $C_{\text{Bi(III)}}^b$ for 0.25M HCOOH in 0.5M H_2SO_4 . $W = 400 \text{ rev min}^{-1}$, $\phi = 60 \text{ V min}^{-1}$.

tion $C_{\text{Bi(III)}}^b = 10 \mu\text{M}$ and $W = 400 \text{ rev min}^{-1}$, assuming $D = 1 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, $\nu^{-1/6} = 2.2 \text{ cm}^{1/3} \text{ s}^{-1/6}$ and $\Gamma_{\text{max}} = 2 \times 10^{-9} \text{ mol cm}^{-2}$. The time required for the applied potential to scan across the region from 0.5V , where peak D begins to appear, to 0.4V , the peak potential for peak D, is 1.0s for $\phi = 6.0 \text{ V min}^{-1}$. This is hardly sufficient for θ_{Bi} to increase substantially beyond the value of $\theta_{\text{Bi(III)}}$ characteristic of the oxidized surface for $E > 0.6\text{V}$.

In a separate experiment, Bi adatoms were deposited at 0.0V in the absence of HCOOH. After several minutes, HCOOH was added to the cell and the potential scanned in the positive direction. Very little enhancement of peak A was observed in comparison to the same experiment without Bi(III). In this case, the electrode surface had not become deactivated by the adsorbed products of HCOOH oxidation, and, according to the three models for adatom catalysis mentioned, the Bi-ad atoms should have retained their catalytic activity. Therefore, we conclude that existing models are not adequate and that it is essential, for observation of the enhancement phenomenon, that the equilibrium status of the Bi adatoms be disarranged periodically such as occurs for cyclic voltammetry in the presence of Bi(III).

Fig. 2. i-E curves for Pt in 0.5M H_2SO_4 containing 0.25M HCOOH. $W = 400 \text{ rev min}^{-1}$, $\phi = 6.0 \text{ V min}^{-1}$. Curves: — $0.00 \mu\text{M}$ Bi(III), - - - $3.2 \mu\text{M}$ Bi(III), ···· $8.4 \mu\text{M}$ Bi(III).

Fig. 5. Plot of $\ln \{I_p\}$ vs. $1/T$ for peak A. 0.25M HCOOH in 0.5M H_2SO_4 , $W = 400 \text{ rev min}^{-1}$, $\phi = 6.0 \text{ V min}^{-1}$. Curves: 0-0.0 μM Bi(III), \bullet -10.0 μM Bi(III).

Temperature effects.—The effect of variation in temperature was studied for 0.25M HCOOH in the presence and absence of 10 μM Bi(III). At this high concentration of HCOOH, $I_{p,A}$ and $I_{p,D}$ are nearly independent of C_{HCOOH}^b and Eq. [10] is presumed appropriate for describing I_p . The peak potential for peak A is virtually unchanged by the addition of Bi(III), and the enhancement mechanism is concluded not to involve a change in the rate of the electron-transfer reaction. Such an observation is consistent with Eq. [10], provided $k_2 \gg k_3 - \alpha F\phi/RT$. On that basis, we write

$$I_p = nFA\Gamma_{\text{max}}k_3 \quad [11]$$

The rate of desorption is expressed in the manner

$$k_3 = Z \cdot \exp \{-E_{\text{act},3}/RT\} \quad [12]$$

where $E_{\text{act},3}$ is the apparent activation energy for the reaction in Eq. [3]

$$\ln \{I_p\} = \ln \{nFA\Gamma_{\text{max}}Z\} - E_{\text{act},3}/RT \quad [13]$$

and plots of $\ln \{I_p\}$ vs. $1/T$ (K^{-1}) are expected to yield a slope of value $-E_{\text{act},3}/R$.

Experimental results are shown plotted in Fig. 3 and 4 and the results of linear regression analyses of the data are presented in Table II. Large uncertainties are expected for the intercept, *i.e.*, $\ln \{nFA\Gamma_{\text{max}}Z\}$, because of the rather narrow range of temperatures used and the large extrapolation required for evaluation at $1/T \rightarrow 0$. The differences in slope and intercept for peak D (negative scan) are not statistically significant for the presence and ab-

sence of Bi(III). This observation is consistent with our earlier conclusion that $\theta_{\text{Bi}} < 0.25$ for peak D even when $C_{\text{Bi(III)}}^b = 10 \mu\text{M}$ and the primary mechanism for reactivating the electrode during the negative scan is the reduction of surface oxide immediately prior to the appearance of peak D to produce a reduced Pt surface free of adsorbed organic poisons.

Values of slope and intercept in Fig. 5 are concluded to be statistically different for peak A in the presence and absence of Bi(III). Of great significance is the observation that the presence of Bi adatoms actually increases rather than decreases the apparent activation barrier. The experimental reality that Bi adatoms do, in fact, enhance the value of $I_{p,A}$ is explained by a substantial increase in the pre-exponential part (Z) of Eq. [12], *i.e.*, an increase of a factor of ca. 20,000. We interpret Z in the usual manner as representing the frequency of the vibrational process which leads to the desorption reaction. Correspondingly, the term $\exp \{-E_{\text{act},3}/RT\}$ represents the probability that a single vibrational event will successfully lead to desorption. We conclude that the large increase in the frequency factor for reaction [3] results from the site-to-site surface migration of freshly deposited Bi atoms as they move from the sites of electrodeposition to sites of maximum stability. This is consistent with the observation that the benefit of Bi adatoms to enhance the anodic signal for HCOOH decays rather rapidly with time at a constant potential when the surface arrangement of the Bi adatoms has reached its equilibrium state. For enhanced anodic reactions where the site hopping mechanism is operative, it cannot be expected that steady-state signals will be obtained for hydrodynamic electrodes at constant potential.

Conclusion

The effect of Bi(III) to enhance the rate of anodic oxidation of HCOOH at a Pt electrode in 0.5M H_2SO_4 during the positive scan of electrode potential results from a substantial increase in the frequency of the vibrational event leading to desorption of the adsorbed products of the oxidation of HCOOH rather than a decrease in the activation barrier of the rate controlling step. Hence, the Bi adatoms do not function in the role of a true catalyst in that their presence does not offer an alternate reaction pathway

having a smaller activation energy. Use of the description "electrocatalysis" in this case is inappropriate, and we have carefully avoided its application to the description of the enhancement phenomenon.

Ion-Beam Etching of InP and Its Application to the Fabrication of High Radiance InGaAsP/InP Light Emitting Diodes

Osamu Wada

Fujitsu Laboratories Limited, 1677, Ono, Atsugi 243-01, Japan

ABSTRACT

A novel application of Ar ion-beam etching to the fabrication of microlenses on an InP substrate is described. Baking a positive acting photoresist layer was found to facilitate a very reproducible method of forming a spherical mask suitable for ion-beam etching. Characteristics of Ar ion-beam etching of InP are studied, and etching parameters such as the ion energy, the ion incident angle, and the target supporting technique are optimized for obtaining optically smooth etched surfaces. The generation of cones and other microfeatures previously reported on ion-beam-etched InP was completely eliminated, through this optimization, by choosing the energy of 1000 eV and the incident angle of 60°-70° as well as introducing a target supporter made of Ti. The geometry of a lens thus formed on an InP substrate was confirmed to be a sphere. The present technique was applied to fabricating InGaAsP/InP double heterostructure light emitting diodes at the wavelength of 1.3 μm which have monolithic lenses on the light extraction surfaces. The result showed an improvement in the light power coupled to a standard fiber by a factor as large as 1.8.

Ion-beam etching or ion milling technique, in which the bombardment of energetic ions such as Ar⁺ is utilized to sputter etch the target material, has been applied by now to a variety of semiconductor device as well as integrated circuit-fabrication processes. In comparison to wet chemical etching and other dry etching techniques such as plasma and reactive ion etching, the distinct characteristics of ion-beam etching involve a relatively small material selectivity in the etching rate and an ability of anisotropic etching with no mask undercut (1-3). The former makes it possible to etch any material even with a multilayer structure such as Ti/Pt/Au to which the application of chemical etching would be difficult. The latter characteristic is the dominant reason for the use of ion-beam etching in the fine pattern formation down to submicron dimensions in Si and, more recently, GaAs integrated circuits (4), optical waveguide, and grating devices, including distributed-feedback-type (DFB) injection lasers composed of AlGaAs/GaAs (5, 6) and InGaAsP/InP (7) heterostructures. The large area uniformity and the high etching depth controllability are also advantages of ion-beam etching which realizes the batch processing of semiconductor wafers.

Ion-beam etching can improve the pattern quality and complexity when it is applied within the existing semiconductor processes, as mentioned above. However, the extension of its advantages to a novel process would facilitate a drastic improvement in the device and circuit performance. In particular, there has been an accelerating need in the development of high performance light sources and detectors composed of InP and its related compounds for optical fiber communication systems at the wavelengths near 1.3 and 1.5 μm . We have previously reported a novel fabrication method of InGaAsP/InP double heterostructure (DH) light emitting diodes

(LED's) having monolithic InP lenses (8). This has been achieved by an extensive use of controlled and low material selective etching characteristics of the ion-beam etching, and a remarkable improvement in the LED-fiber optical coupling efficiency has been demonstrated. This method of lens formation consists of only two simple process steps: namely, photoresist mask preparation and ion-beam etching, both of which are suitable for batch processing. In addition, this method can eliminate elaborate assembling process required when a separate microlens made of a dielectric material (9) is attached to the individual LED chip.

The purpose of this paper is to describe the details of the lens formation on an InP substrate using Ar ion-beam etching technique. The process sequence is explained briefly in the next section, and the details of the mask preparation and ion-beam etching processes are described in the following two sections. Particularly, the ion-beam etching has been applied to etch the InP substrate down to 8 μm depth. Previous reports on ion-beam etching of InP have shown occasional degradations in the etched surface morphology, including the generation of a number of "cones" (10, 11). In the present study, a sequence of experiments has been carried out to improve the morphology as well as to precisely control the etch rate by the selection of etching parameters such as the ion energy, ion incident angle, and the target supporting technique. In the final part of this paper, the application of this process to the fabrication of LED's and the performance results are demonstrated.

Lens Formation on InP Substrate

Figure 1 illustrates the sequence of processes for forming spherical lenses on an InP substrate (8). Photoresist masks for ion-beam etching are first prepared on the

Fig. 1. Sequence of processes for InP lens formation. (a): Mask formation by patterning and baking a photoresist layer. (b): Ar ion-beam etching until complete removal of the mask. (c): Completed InP lens.

substrate surface (a). A commercial positive acting photoresist, Shipley AZ-1350J, has been used in our study. The photoresist patterns with the diameter appropriate to the device design in the range of 60-250 μm , in the present case, are delineated by conventional photolithographic technique. They are then baked at a temperature higher than the glass-transition point of photoresist so that spherical contours are generated by the effect of surface tension on the photoresist surface. Then the substrate is subject to Ar ion-beam etching (b) using, in this experiment, Veeco Microetch system in which Ar^+ ions are generated by a Kaufman ion gun, neutralized, and then fed to bombard a rotating target.

During the etching, the spherical mask contour is transferred to the InP substrate surface. The lens shape is dependent on the initial mask thickness and the mask to substrate ion-beam etch rate ratio which is a function of etching parameters, e.g., the ion energy and the ion incident angle θ .

The morphology of the lens surface is of the most importance in device applications, and it has to be optimized by choosing suitable etching conditions, as will be described in the applications section. By terminating the ion-beam etching when the whole photoresist mask is etched off, an InP lens can be obtained (c). If the etched surface exhibited microfeatures, slight etching by a chemical solvent could be introduced to improve the surface smoothness.

Photoresist Mask Preparation

The most important procedure in preparing the photoresist mask is the baking to generate spherical surfaces. Schematic cross sections of the photoresist layer baked at various temperatures are shown in the inset of Fig. 2. At a temperature just above the glass-transition point at which the flow initiates, the layer exhibits a concave with the

thickness at the center, d , smaller than the initial thickness d_0 , as shown in Ref. (2). By increasing the temperature, the photoresist viscosity decreases and the surface tension dominates in determining the surface geometry to generate a convex as shown in Ref. (3). It is theoretically proved that the geometry stabilized by the effect of surface tension is a sphere (12), and, actually, our stylus measurements have confirmed this.

Figure 2a shows a plot of the photoresist thickness at the center as a function of the baking temperature. The initial thickness d_0 was 3.2 μm . The baking was carried out under a nitrogen flow just after the photoresist development procedure, and the duration was fixed to be 2 min; no appreciable difference was found for longer bakings. As shown in the figure, the temperature required for generating a convex becomes lower for smaller diameter D . It is also found from this result that the convex formation can be achieved only for small diameters up to 80 μm . Figure 2b shows a plot similar to that of Fig. 2a, except that the photoresist layer was exposed to ultraviolet light, prior to the baking, for 220s using a conventional mask alignment equipment. By this exposure, the transition from concave to convex with respect to the temperature increase becomes more distinct; therefore, the stability of the process improves, and the maximum diameter for the convex generation increases to 150 μm . Such an effect is considered to be attributed to the decrease of the photoresist viscosity due to the lowering of the polymer molecular weight under the exposure. Figure 3 summarizes the maximum diameter of the photoresist pattern for which a spherical geometry can be generated as a function of the baking temperature for the duration of 2 min. For our application to the LED fabrication, the diameter of about 100 μm is appropriate. This can be achieved by a baking at the temperature above 190°C.

Our experiments showed that a negative acting photoresist OMR-83 (Tokyo Ohka) exhibits similar convex generation, but in only a narrow range of the baking temperature, the upper value of which is restricted due to the photoresist evaporation. The use of positive acting photoresist is therefore more suitable for this process. It is worth noting here that the generation of a spherical surface is an outcome of the effect of the surface tension, which is highly immune from most deviations in process conditions such as the baking temperature and duration.

Ion-Beam Etching of InP

Etch rate.—The etch rates of the photoresist layer and the (100)-oriented InP wafer were measured at a variety of the ion incident angle (θ) for different ion energies E_i . Figure 4 shows the data obtained at $E_i = 500$ and 1000 eV. The ion current density used is 0.57 mA/cm². The maximum etch rate occurs at smaller angle for InP than for photoresist, and this peak shifts to larger angle as the ion energy increases. This is interpreted by the fact that the chance of a primary ion-target atom collision resulting in the momentum being directed away from the substrate surface increases due to the increase in the primary ion penetration depth at larger incident angle. The detail of the incident angle and energy dependences of the sputtering yield will be discussed in a separate paper.

Figure 5 shows the dependence of the ratio at the etch rate of InP over that of photoresist on the ion incident angle for two ion energies. No appreciable difference in the dependence can be found within the experimental error for two ion energies. The etch-rate ratio monotonically decreases as the incident angle increases, particularly at a small gradient above $\theta = 60^\circ$; this is profitable to stabilize the etch-rate ratio and therefore the lens curvature in practical processes. As will be described in the next section, the incident angle more than 60° is used in the practice from the morphology point of view.

Etched surface morphology.—As the morphology of ion-beam-etched InP surface is one of the most important factors in determining the lens characteristics, a detailed experiment was conducted to study the causes for

Fig. 2. Baking characteristics of positive-acting photoresist disk with various values of diameter D (a) without and (b) with exposure prior to baking. The thickness of the photoresist layer at its center d can be maximized when a sphere is generated at an elevated temperature. The exposure widens the diameter limit for sphere generation (b).

degradation of surface morphology. Some of previous works showed the occasional generation of "cones" on InP surfaces (10, 11). The elimination of these was the goal of this series of experiments.

The surface smoothness was compared on samples etched to about $1 \mu\text{m}$ depth using various values of the energy and the incident angle. InP wafers partially masked by photoresist were supported on a substrate holder made of stainless steel. The stylus measurements of smoothness revealed a slight improvement when using larger ion energy (1000 eV, in comparison to 500 eV) and a strong dependence on the incident angle. Figure 6 shows the incident angle dependence of the surface roughness together with scanning electron micrographs of the mask peripheries, gathered at the energy of 500 eV. At the angle of less than 30° , the etched surface exhibits the formation of fine globules and droplets all over the unmasked regions and cones at the mask peripheries. Auger electron spectroscopy measurements performed on some of these etched samples indicated an appreciable deficiency of P near the surface. Taking this into account, the droplets observed as white contrast particles, for example, in the

Fig. 4. Ar ion-beam etch rates of InP and positive acting photoresist as a function of ion incident angle for two different ion energies. The ion current density is 0.57 mA/cm^2 .

middle micrograph of Fig. 6, are considered to be composed of In precipitates. This is consistent with the previous reports (13). The geometries of cones at mask edges show no explicit dependence on the incident angle. The generation of cones is suspected to be related to the redeposition of atoms sputtered from the mask, the unmasked regions of the substrate, and even the substrate holder. More details will be discussed later. The morphology degradation is found to be suppressed at the incident angle at 60° , although the etched riser still has wavy feature as shown in the micrograph. The roughness below a few tens of angstroms can be achieved at the incident angle of greater than 50° . It is understood from this result that the use of a large incident angle at the sacrifice of

Fig. 6. Ion incident angle dependence of surface roughness of InP substrate after etching down to approximately $1.1 \mu\text{m}$. Insets are scanning electron micrographs showing the degradation of morphology at mask peripheries for the incident angles of 0° , 30° , and 60° .

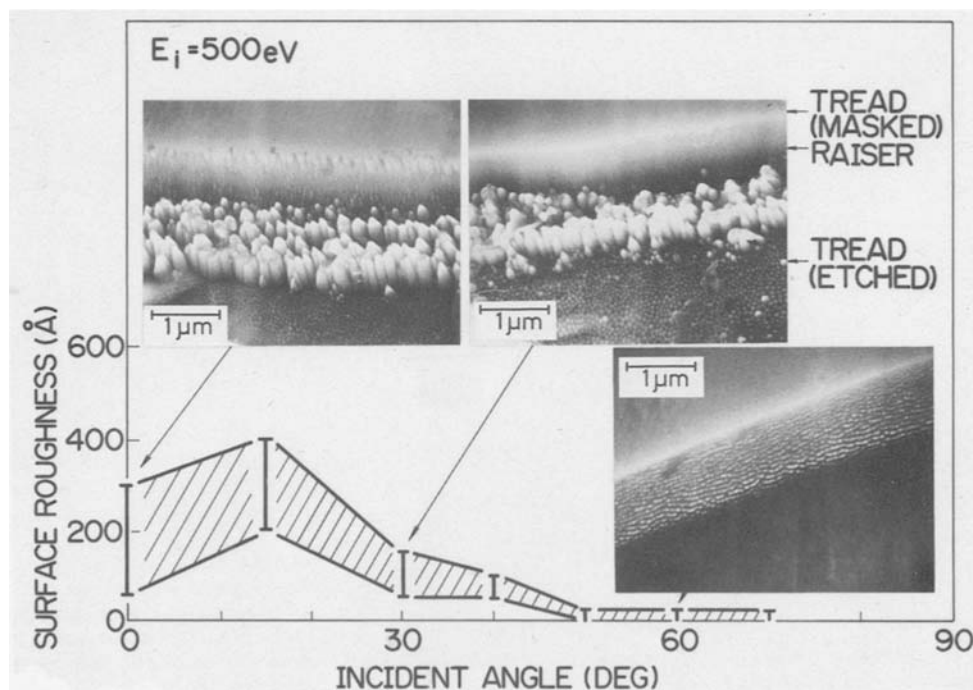

Fig. 5. Ratio of etch rate for InP over that for photoresist as a function of ion incident angle at two ion energies.

long etching time is effective for obtaining smooth etched surfaces.

To look further into the details of etched surface morphology, the effect of the redeposition was studied by varying the substrate supporting methods. The influence of the material supporting the substrate was tested by using photoresist and Ag as small and large sputtering rate (2, 14) materials, respectively. Scanning electron micrographs of both samples taken at tilted angles ($\sim 60^\circ$) are shown in Fig. 7. The ion incidence was normal to the substrate surface, and an ion energy of 500 eV was used. The etching duration was 10 min, which gave the average etching depth of approximately $1.1 \mu\text{m}$. The surface obtained for the photoresist case does not contain any large size cones and hillocks except small globules, but the sample supported on a Ag plate exhibits numerous sharp cones along the ion incident direction. This result may suggest that the redeposition of Ag atoms on the InP substrate during the etching brings about, regardless of its relatively high sputtering yield, the local masking effect to produce cones (15-17). Auger analysis carried out on the InP substrate supported and etched on the Ag plate showed no Ag atom presence on the etched surface. This would be, however, not surprising because it has been shown that extremely small amount of foreign atoms can give rise to the formation of cones on the surface being etched (17). Nevertheless, possibilities of not only the

Fig. 7. Scanning electron micrographs indicating effect of material for substrate supporter. Etching has been carried out at $E_i = 500$ eV for 10 min. A cone observed in (a) is considered to be generated by some imperfection included in the original InP surface. Note that the sputter rate is much larger for Ag than for AZ-1350J.

chemical and/or metallurgical reaction of Ag with InP but also the incorporation of impurity atoms having the low sputtering yield and/or high melting point (20) should be considered in order to fully understand the cone generation. A marked difference in the surface feature observed within the present set of samples at least reveals a strong influence of the choice of the supporting material on the etched surface morphology.

The redeposition effect was examined also by using an InP substrate having a special structure (shown in Fig. 8). A part of the substrate of approximately 2 cm^2 area was surrounded by InP walls with a height of approximately 1.5 cm. This substrate was supported on a stainless steel holder, considering that the surface feature obtained by the stainless steel holder is similar to that observed in the experiment using photoresist (Fig. 7a). The ion-beam etching was performed with $E_i = 500$ eV at the normal incidence. The etching duration was selected to be as long as used in practice, 55 min, which corresponds to an etching depth of about $6 \mu\text{m}$. Scanning electron micrographs at two different positions within the wafer are shown in Fig. 8. The part of the surface surrounded by the walls (A) exhibits only small globules similar to that seen in Fig. 6 and Fig. 7a, whereas the outer part (B) suffers from having numerous cones which are aligned in the ion direction. The density of cones generated was found to increase at the edge of the substrate. The present result is

likely to be again consistent with the model in which the redeposition of atoms sputtered from the InP substrate as well as the substrate supporter on the InP substrate causes the generation of cones. The higher density of cones at the substrate edge is considered to suggest a stronger effect of the redeposition from the substrate supporter material rather than from the InP substrate itself. It is also found reasonable to say that the globules as observed in Fig. 6 grow to become larger size cones in the course of a prolonged etching.

The result described above indicates the importance of preventing the sputtered atoms from depositing on the surface of the substrate being etched. This can be achieved in the case of the normal incidence by the structure of Fig. 8, but a configuration to lift up the substrate, which is useful for any incident angles, was recently suggested by Williams *et al.* (18). We designed a substrate holder as shown in Fig. 9, in which titanium was chosen because of its low sputtering rate. The substrate surface is approximately 2 cm apart from the holder plane in this configuration, and a remarkable effect in eliminating the surface microfeature has been confirmed in etching down to $8 \mu\text{m}$ depth. An example of this will be given later in this paper (Fig. 13).

Spherical lens formation.—We first consider the geometry of a lens formed by ion-beam etching using a spherical photoresist mask. Figure 10 illustrates the substrate cross section before and after the etching. The aperture diameter of the lens is D , and the maximum height of the photoresist mask at its center is h_r . The radius of the mask is given by

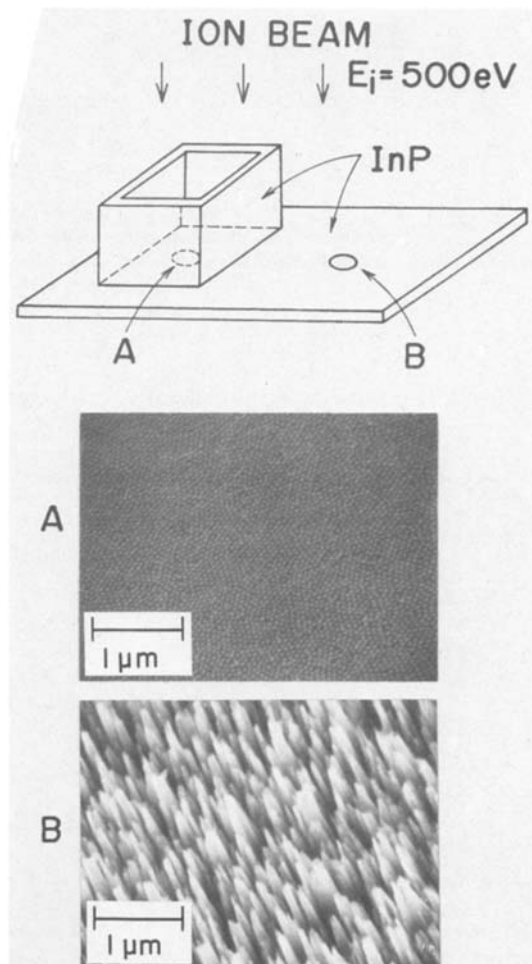

Fig. 8. Structure of target used for examining redeposition effect and scanning electron micrographs showing surface features obtained at different positions on the target. The generation of numerous cones at B indicates that the redepositing atoms enhance the cone generation. The ion incidence is normal to the substrate plane, and the etching time is 55 min.

Fig. 9. Structure of target supporter made of Ti, in which target can be lifted up toward incident beam.

Fig. 10. Schematic cross section of InP substrate with spherical photoresist mask. A lens contour to appear is shown by a dotted line.

$$r_r = [h_r^2 + (D/2)^2]/2h_r \quad [1]$$

After the ion-beam etching, a lens shape as shown by the dotted line in Fig. 10, is generated and this becomes an ellipse expressed as

$$\frac{x^2}{r_r^2} + \frac{[y + (k-1)r_r + h_r]^2}{k^2 r_r^2} = 1 \quad [2]$$

with the radius at x of

$$R(x) = \frac{r_r}{k} \left[1 + (k^2 - 1)^{3/2} \left(\frac{x}{r_r} \right)^3 \right] \quad [3]$$

where k stands for the mask to target etch rate ratio. When the second term in the bracket of Eq. [3] is well smaller than unity, the lens geometry becomes a sphere with a constant radius of

$$R(x) = R = r_r/k \quad [4]$$

This applies at least to the near-axis radius in our practical case where the values of k and $D/2r_r$ are both less than 3 and 0.1, respectively.

The lens geometry was actually measured by stylus and compared with the calculation explained above. Figure 11 shows an example of the results, in which the height of the photoresist mask was $3.0 \mu\text{m}$ and the value of k of 2.3 was selected at the ion incident angle of 65° during the etching. The lens height h_l has been measured to be $7.0 \mu\text{m}$, and the calculation curve has been obtained with the assumption of a sphere with the radius determined from $R = [h_l^2 + (D/2)^2]/2h_l$. The agreement between the measurement and the calculation is considered to be excellent, taking into account the simplicity of the calculation. The present method has been thus confirmed to realize spherical lenses. The optical property of lenses with a variety of the radius has been previously demonstrated through the observation of images of patterns prepared on the substrate surface opposite to the lens, in which a good agreement has been seen between the measured and calculated magnification characteristics (8).

Application to InGaAsP/InP DH LED's

The present method was applied to improve the light coupling efficiency of InGaAs/InP DH LED to optical fiber. The structure of the LED is shown in Fig. 12. The fabrication method will be explained just briefly in the following, since it is essentially same as that already reported (19). The DH structure, which includes a low doped n-type InGaAsP active layer with the composition of a $1.3 \mu\text{m}$ wavelength emission and the thickness of about $1.5 \mu\text{m}$, was grown on a (100)-oriented n-InP substrate by conventional sliding boat system of liquid-phase epitaxy. A $40 \mu\text{m}$ diam p contact composed of a Au/Zn/Au multilayer was formed, and an isolating SiO_2 layer and subsequently a thick-plated Au layer were formed. The substrate was then polished to approximately $100 \mu\text{m}$ thickness, and the present lens formation procedures were applied. After the lens was formed, an n contact of AuGe/Ni film was prepared and a SiO_2 antireflection coating was deposited. The individual LED chip was mounted on a copper heat sink and assembled with a spherical-ended fiber.

An example of scanning electron micrograph of the lensed LED thus fabricated is shown in Fig. 13. The lens aperture and the lens height in this case are 90 and $8 \mu\text{m}$, respectively, giving a magnification of 2. In etching the InP substrate, the higher ion energy, 1000 eV , and the larger incident angle, 65° , were adopted together with the use of the target supporter made of Ti (Fig. 9). It is significant to note that the lens surface is completely free from any inhomogeneities and far improved in comparison with a surface that would be obtained without an optimization of etching conditions as has been performed in our experiment. The remarkable improvement of the surface smoothness, particularly observed outside the lens aperture, can be noticed by comparing Fig. 13 with the previous results, e.g., Fig. 7 of Ref. (8).

Figure 14 shows the characteristic of the light power coupled to a graded-index fiber as a function of the bias

Fig. 11. Comparison of lens geometries obtained by stylus measurement and calculated by assumption of sphere. It is clear that a spherical lens is formed by the present technique.

current for both the lensed and conventional flat-surface LED's prepared from the same epitaxial wafer. An improvement of the coupled power by a factor of 1.8 is estimated at the current of 100 mA, by introducing the lensed LED structure. The ultimate power of $35 \mu\text{W}$ at 100 mA is classified in the highest available power with the surface emitting-type LED at the $1.3 \mu\text{m}$ wavelength. It would be both interesting and important to point out another advantage of the lensed LED structure: the improvement in the frequency response characteristics (19). The lens makes the light generated near the p contact center, where a faster response can be realized than at the contact edge owing to the current crowding effect, to be coupled predominantly. This effect gives rise to more than 50% improvement in the cut-off frequency characteristics, and the maximum value of 120 MHz has been achieved in our experiment.

Summary

A technique for preparing spherical lenses on an InP substrate by means of Ar ion-beam etching using a thermally deformed photoresist layer as an etching mask was investigated and applied to the fabrication of high radiance InGaAsP/InP DH LED's. The mask, having a geometry of perfect sphere, was found to be formed easily and reproducibly by introducing the exposure prior to baking and choosing a suitable baking temperature. The conditions of Ar ion-beam etching were optimized in terms of the controllability of the etch depth into InP and the morphology of the etched surface. It was found that a very

Fig. 13. Scanning electron micrographs showing lensed surface of completed LED chip. Note that the lens surface is free from any imperfections.

Fig. 14. Bias current dependences of light power coupled to fiber for both lensed and conventional flat-surface LED's. The lensed LED gives 1.8 times greater power than the conventional device.

smooth surface can be generated by using (i) a relatively high ion energy (1000 eV), (ii) a large ion incident angle (60° - 70°), and (iii) a titanium-made supporter which lifts up the InP substrate. The present substrate supporter was significantly effective in eliminating the redeposition effect and in producing microfeature-free lens surfaces. Experiments also confirmed the reproducible generation of InP lenses with smooth spherical surfaces. This technique was applied to fabricate surface emitting InGaAsP/InP DH LED's at $1.3 \mu\text{m}$. The device performance was measured, and a remarkable improvement in the coupling efficiency, namely, by a factor of 1.8, was demonstrated.

It is worth pointing out that the present technique exhibits a high reproducibility and a high controllability of lens geometry. Moreover, this technique is favorable to the batch processing. In view of further applications, the present technique can be suitable for preparing non-spherical lenses too, since the geometry of the lens can be varied by the selection of the mask to substrate ion-beam etch-rate ratio. This can be carried out by changing, for example, the ion incident angle during the etching. Such applications are considered to be interesting in fabricating various devices for fiber as well as waveguide optics.

Oxidation-Induced Defects at the Poly/Mono Silicon Interface

W. J. M. J. Josquin and M. J. E. Ulenaers

Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

ABSTRACT

The application of polycrystalline silicon in intimate contact with monocrystalline silicon can give rise to the growth of oxidation-induced stacking faults. When Si_3N_4 is employed on top of the polysilicon, the oxidation can also generate dislocations along Si_3N_4 edges. It appears that the key parameters in the defect generation mechanisms are the oxygen concentration at the poly/mono interface and, related to that, the epitaxial realignment of the polysilicon on the substrate. The experiments indicate which conditions are beneficial for the application of polysilicon on the back of silicon wafers for enhanced gettering purposes. They also indicate how oxidation-induced defects can be avoided when polysilicon is applied on the front side of silicon wafers as a gate material and/or as a diffusion source.

Polycrystalline silicon in intimate contact with monocrystalline silicon is extensively used in silicon IC technology for quite diverse purposes. On the one hand, polycrystalline silicon is applied to the back of silicon wafers to obtain an enhanced gettering effect. In this case, the presence of crystal defects at the back of the wafer is the key to an effective gettering action. It has been shown that the employment of patterned Si_3N_4 on top of the polysilicon further improves the gettering efficiency (1). On the other hand, polysilicon is applied to the front side of silicon wafers as a gate material and/or as a diffusion source. In this case, Si_3N_4 is often employed on top of the polysilicon so that local oxidation techniques can be used to pattern the polysilicon (2, 3). For these applications, the occurrence of any defect in the device area can be fatal for the device performance.

In both cases, two types of defects can be expected: oxidation-induced defects originating from the poly/mono interface (8) and stress-induced dislocations along Si_3N_4 edges. The present study deals with the defect-generation mechanisms and the elimination of defects in devices with polysilicon diffusion sources, but many of the results are also significant for the understanding of enhanced gettering mechanisms.

Experimental

The substrates used throughout the study were p-type, 15-25 Ω cm, <100> CZ silicon wafers, unless otherwise specified. The wafers were cleaned in fuming nitric acid and hot concentrated nitric acid, causing the wafers to be covered with a native oxide layer, which will be referred to as cleaning oxide. Subsequently, one set of wafers was dipped in a 1% HF solution to remove the cleaning oxide, a second set received no further treatment, and a third set was heat-treated at 850°C in dry nitrogen for 30 min to densify the cleaning oxide. RBS analysis has revealed that this results in oxygen concentrations at the poly/mono interface which are equivalent to 0.5, 1.4, and 2.0 nm SiO_2 , respectively (4). The various sets of wafers will be referred to as wafers with dipped, cleaning oxide, and densified cleaning oxide interfaces.

The wafers were covered with 0.1 μm of polycrystalline silicon deposited from SiH_4 at 625°C and a pressure of 140 mtorr. On top of the polysilicon, a Si_3N_4 layer 0.1 μm thick was deposited from SiH_2Cl_2 and NH_3 at 820°C and a pressure of 200 mtorr. Then a preoxidation annealing treatment was applied of either 20h at 850°C or 5h at 1000°C in dry nitrogen to simulate extensive low or high temperature processing. Next, a photomask was used to pattern the Si_3N_4 layer. On half of the wafers the polysilicon was also etched using anisotropic plasma etching. Then the wafers were oxidized in wet oxygen ($p_{\text{H}_2\text{O}} \sim 0.80$) to an oxide thickness of about 0.55 μm .

In this way, all the polysilicon was converted into SiO_2 . Oxidation was carried out at temperatures of 1000°, 950°, 900°, and 850°C. Finally, the oxide and nitride layers were stripped and Wright etch was applied to reveal oxidation-induced defects. The etched surfaces were examined in an SEM using a magnification of 5000 \times , unless otherwise specified.

From some of the wafers, TEM specimens were prepared by thinning stripped wafers from the back in an etchant composed of HNO_3 , HF, and CH_3COOH (4:1:1). Observations were made with a Philips EM400T microscope operated at 120 kV.

On some wafers, no Si_3N_4 was deposited, and the final oxide of 0.55 μm was etched back to 0.15 μm , which then served as the gate oxide of gate-controlled diodes fabricated on those wafers.

Results

Field defects.—The first results concern wafers with a dipped poly/mono interface which received a preoxidation anneal at 850°C. Figure 1 shows SEM micrographs of the samples after oxidation at four different temperatures (A: 850°C, B: 900°C, C: 950°C, and D: 1000°C) and Wright etching. After oxidation at 1000° and 950°C, very high densities of stacking faults were found ($\sim 10^8$ cm $^{-2}$); at 900°C a small number of small etch pits was observed, and at 850°C no crystal defects could be detected. These results were found to be reproducible both for <100>- and <111>-oriented wafers, with and without phosphorous gettering at the back of the wafers.

Fig. 1. SEM micrographs of Wright-etched samples with a dipped poly/mono interface and a preoxidation anneal at 850°C for different oxidation temperatures: A: 850°C, B: 900°C, C: 950°C, and D: 1000°C (5000x).

Figure 2 shows the corresponding TEM micrographs of the samples oxidized at 900° (A), 950° (B), and 1000°C (C). In the 850°C sample, again no defects could be detected. The other three samples show defect densities of about 10^8 cm^{-2} . At 900°C, the only observable defects are stacking faults, whereas at 950° and 1000°C, dislocations as well are observed which may be the result of an unfauling reaction of the stacking faults. The length of the stacking faults is 2.2 μm at 1000°C, 1.4 μm at 950°C, and about 0.75 μm at 900°C. Using weak beam imaging, we found no impurity decoration of the defects. The discrepancy between the defect densities observed in the 900°C

sample by TEM and by preferential etching suggests that the preferential etching technique may have failed to reveal the small stacking faults.

Figure 3 shows the corresponding SEM micrographs of the wafers with a cleaning oxide at the poly/mono interface and a preoxidation anneal at 850°C: there are now no defects to be seen, irrespective of the oxidation temperature.

Wafers with a dipped interface and with a cleaning oxide interface were processed to obtain gate-controlled diodes. About 0.15 μm of the oxide grown at the four different temperatures served as the gate oxide. Table I lists

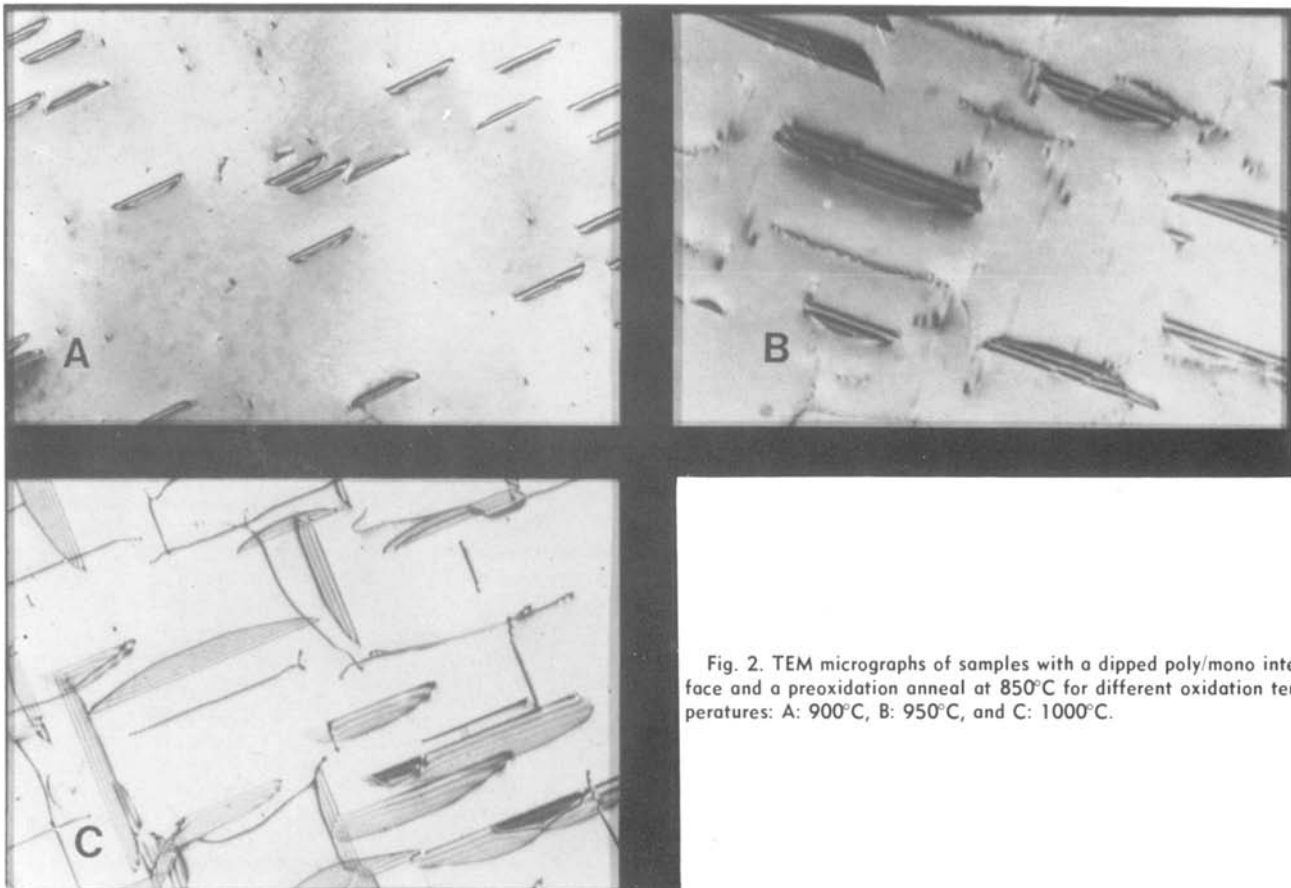

Fig. 2. TEM micrographs of samples with a dipped poly/mono interface and a preoxidation anneal at 850°C for different oxidation temperatures: A: 900°C, B: 950°C, and C: 1000°C.

Fig. 3. SEM micrographs of Wright-etched samples with a cleaning oxide interface and a preoxidation anneal at 850°C for different oxidation temperatures: A: 850°C, B: 900°C, C: 950°C, and D: 1000°C (5000x).

Fig. 4. SEM micrographs of Wright-etched samples with a cleaning oxide interface and a preoxidation anneal at 1000°C for different oxidation temperatures: A: 850°C, B: 900°C, C: 950°C, and D: 1000°C (5000x).

the reverse current densities for the depletion mode: for a dipped interface and an oxidation temperature of 850°C or for a cleaning oxide interface the current density is about 1 nA/cm², which is equal to the current level found on control wafers on which no polysilicon had been deposited. For a dipped interface and an oxidation temperature higher than 850°C, the current density is at least an order of magnitude higher and increases slightly with the oxidation temperature. The current densities were found to be independent of the substrate orientation (<100> or <111>) or the type of material (FZ or CZ). It is clear that there is a strong correlation between the reverse current densities and the observed defect densities.

Figure 4 shows the SEM micrographs for wafers with a cleaning oxide interface which received a preoxidation anneal at 1000°C: the defect densities are seen to be similar to the ones found for wafers with a dipped interface and an 850°C preoxidation anneal (Fig. 1). In fact, for wafers with a dipped interface, the temperature of the preoxidation anneal does not affect the final defect density. The field defect densities after Wright etching are summarized in Table II in a semi-quantitative way.

Wafers with a densified cleaning oxide interface show zero defect densities, independent of the preoxidation annealing temperature or the oxidation temperature.

When the polysilicon was removed prior to the oxidation by anisotropic etching in a Cl₂ plasma, using a 100% overetch to a depth of about 0.1 μm in the substrate, no defects were observed, irrespective of interfacial conditions, preoxidation anneal, or oxidation temperature.

Figure 5 shows SEM micrographs of the polysilicon surface morphology immediately after a preoxidation anneal at 1000°C for the three interface conditions: dipped

(A), cleaning oxide (B), and densified cleaning oxide (C). The sample with a dipped interface shows a relatively smooth surface, the sample with the cleaning oxide interface gives a rougher surface, whereas the densified cleaning oxide interface results in a smoother surface.

Edge defects.—Edge defects can be observed most clearly when no field defects are present. Therefore, we will first discuss the results obtained on wafers where the polysilicon was removed by plasma etching prior to the oxidation to avoid field defects. Figure 6 shows the SEM micrographs of samples that were locally oxidized using $0.1 \mu\text{m Si}_3\text{N}_4$ as an oxidation mask on wafers with a

dipped poly/mono interface which received a preoxidation anneal at 850°C. The defect density along the Si_3N_4 edges is seen to be very high after oxidation at 850° (A), 900° (B), or 950°C (C), and only slightly lower at 1000°C (D).

Figure 7 shows the corresponding micrographs for wafers with a cleaning-oxide interface. At 850° (A), 900° (B), and 950°C (C) no defects are observed; at 1000°C (D), a considerable defect density is found. A comparison of Fig. 1 (field defects) and fig. 6 (edge defects) illustrates that whenever stacking faults occur after oxidation of polysilicon, defects along Si_3N_4 edges are found as well. The opposite is not true, however: when a wafer is free of

Fig. 6. SEM micrographs of Wright-etched samples with a dipped interface, a preoxidation anneal at 850°C, and polysilicon etched prior to oxidation at A: 850°C, B: 900°C, C: 950°C, and D: 1000°C (5000x).

Fig. 7. SEM micrographs of Wright-etched samples with a cleaning oxide interface, a preoxidation anneal at 850°C, and polysilicon etched prior to oxidation at A: 850°C, B: 900°C, C: 950°C, and D: 1000°C (5000x).

stacking faults, it may still contain edge defects. After an oxidation at 850°C, stacking faults are never observed; nevertheless, Fig. 6a shows a large number of edge defects.

Similarly, a wafer with a cleaning oxide interface does not show stacking faults after oxidation at 1000°C, but does show a considerable number of edge defects (cf. Fig. 3d and 7d).

When wafers with a cleaning oxide interface are preannealed at 1000°C, the same trend is observed as for wafers with a dipped interface: very high defect densities after oxidation at 850° (A), 900° (B), or 950°C (C) and only a slightly lower defect density at 1000°C (D). The edge defect densities observed after Wright etching are summarized in Table III in a semi-quantitative way.

Wafers with a densified cleaning-oxide at the poly/mono interface never show edge defects.

For the wafers where the polysilicon is not removed in a plasma prior to the local oxidation, one might expect

the final defect density to be the sum of the field defects [Fig. 1 (dipped) and 3 (cleaning oxide)] and the edge defects [Fig. 6 (dipped) and 7 (cleaning oxide)]. Figures 8 and 9 show the actual results for wafers with a dipped and a cleaning oxide poly/mono interface. It appears that there is a one-to-one correlation in the occurrence of edge defects between wafers with and without plasma etching of polysilicon. The edge defect density, however, can be very different from the case where the polysilicon was removed prior to the oxidation. The sample with the dipped interface oxidized at 850°C is the most striking example: the edge defect density in Fig. 8a (without poly-etching) is orders of magnitude smaller than the one observed in Fig. 6a (with poly-etching).

Discussion

Field defects.—RBS analysis has shown that a dipped poly/mono interface contains about 2.5×10^{15} O atoms/cm², which is equivalent to 0.5 nm SiO₂ (4). It was also found that such an interface is clean enough to allow an almost complete epitaxial realignment of the polysilicon at 1000°C. The minimum yield obtained in the 100 channeling direction is about 6%-7%, compared to 3% for an ideal crystal and to 100% for unrecrystallized polysilicon (4). Hence, the polysilicon layer in real intimate contact with the substrate and subjected to a heat-treatment at 1000°C, should be considered as imperfect monocrystalline material rather than as polycrystalline material. This may explain the observations on surface roughness (Fig. 5): the relatively smooth surface of the sample with the dipped interface is attributed to the high degree of crystallinity of the layer. The same heat-treatment of polysilicon on a cleaning oxide results in local nucleation on the substrate through pinholes in the interfacial oxide, followed by dendritic growth into a layer with a rough surface, similar to the results reported by Tsaur and Hung (5). The densified cleaning oxide is obviously dense enough to prevent nucleation of the polysilicon on the substrate: the layer recrystallizes only in itself with only a small increase in surface roughness.

From the fact that a densified cleaning-oxide at the poly/mono interface prevents the defect generation, we conclude that it is the partial or complete epitaxial realignment of the polysilicon on the substrate which creates the nucleation sites from which the stacking faults can grow during a subsequent oxidation. Stacy *et al.* (6) concluded from TEM observations that the stacking faults and microtwins in the polysilicon do not simply grow into stacking faults in the substrate, but that the

Fig. 8. SEM micrographs of Wright-etched samples with a dipped poly/mono interface and a preoxidation anneal at 850°C for different oxidation temperatures: A: 850°C, B: 900°C, C: 950°C, and D: 1000°C (5000x).

stacking faults in the substrate start to grow at the moment that the oxidation front reaches the poly/mono interface, from nucleation sites which are probably generated by the microtwins and stacking faults within the polysilicon. This is supported by the fact that the stacking faults in polysilicon which are bounded by $1/6 \langle 112 \rangle$ partials cannot simply develop into oxidation-induced stacking faults bounded by $1/3 \langle 111 \rangle$ Frank partials. The lengths of the stacking faults in our experiments seem to be in agreement with these observations. The stacking fault lengths, as determined from TEM, are 2.2, 1.4, and 0.75 μm for oxidations at 1000°, 950°, and 900°C, respectively. Theoretically, the oxidation time needed to obtain a certain stacking fault length can be estimated from

$$L_{\text{SF}} = K'' t^{0.66} \exp(-2.37 \text{ eV}/kT)$$

where L_{SF} is the stacking fault length, K'' is a constant, and t is the oxidation time (7). For the oxidation temperatures of 900°, 950°, and 1000°C, the calculated oxidation times are 132, 80, and 42 min, respectively, which does not

agree with the experimental times of 270, 150, and 90 min, but agrees rather with the time which elapses after the oxidation front has passed the poly/mono interface: 172, 96, and 58 min, respectively.

The calculation also explains the absence of defects after oxidation at 850°C even in cases where the defect nuclei must be present. The estimated stacking fault length is so small (0.3 μm) that the corresponding depth of the stacking fault is much less than the oxide thickness, so that an actual stacking fault cannot be expected.

We suggest that as long as the oxidation front has not reached the poly/mono interface, the excess concentration of silicon interstitials at the interface is negligible, because the remaining part of the polysilicon layer acts as an effective sink for interstitials. The stacking fault nuclei at the poly/mono interface can only start to grow when this polysilicon sink has been consumed by the oxidation.

Finally, if the epitaxial realignment of the polysilicon is avoided by having a sufficient amount of oxide at the poly/mono interface and by limited high-temperature treatments, the defect nuclei are absent and no stacking faults are observed in the oxidized area.

Fig. 9. SEM micrographs of Wright-etched samples with a cleaning oxide interface and a preoxidation anneal at 850°C for different oxidation temperatures: A: 850°C, B: 900°C, C: 950°C, and D: 1000°C (5000x).

Edge defects.—It is well known that excessive stresses during local oxidation can give rise to generation of dislocations along Si_3N_4 edges, extending along {111} planes in the silicon crystal. Generally the key factors in the generation of these oxidation-induced dislocations are the intrinsic stress in the Si_3N_4 layer, the viscoelastic behavior of the expanding SiO_2 (9, 10) and the occurrence of nonplanarities in the silicon surface (11). However, when dealing with polysilicon on top of monocrystalline silicon, the dominant parameters in the defect generation mechanism appear to be the oxygen concentration at the poly/mono interface and, closely related to that, the crystalline structure of the polysilicon layer, whereas the above-mentioned factors are only of secondary importance.

For those conditions where oxidation-induced stacking faults are observed in the field, the polysilicon has partly or completely realigned epitaxially on the substrate. As a consequence of this realignment, the Si_3N_4 is effectively in direct contact with monocrystalline silicon and dislocations along Si_3N_4 edges will be generated in the same way as for conventional local oxidation with Si_3N_4 in direct contact with silicon (9). For an oxidation at 1000°C, the dislocation density is somewhat lower than at 850°, 900°, 950°C because the viscoelastic flow of the SiO_2 at 1000°C relieves some of the stress.

From the fact that dislocations along Si_3N_4 edges are never observed on wafers with a densified cleaning oxide at the poly/mono interface, we conclude that these dislocations can only be transferred to the substrate when there is at least an onset of epitaxial realignment of the polysilicon on the substrate. The sample with the cleaning oxide interface oxidized at 1000°C (Fig. 9d) shows no stacking faults but a considerable number of dislocations. This suggests that some nucleation of the polysilicon on the substrate must have occurred, but that the amount of epitaxially realigned material is not sufficient to create oxidation-induced stacking faults.

The only phenomenon left to explain is the fact that the dislocation densities tend to be higher after plasma etching of polysilicon. The reason for this is that the oxidation of a shaped silicon surface gives an additional stress component because of the volume expansion of the SiO_2 at the foot of a step in the surface (11). However, it is clear that the stress induced by the Si_3N_4 is the dominant factor for the dislocation generation. If the epitaxial realignment of the polysilicon is completely avoided, the stress from the Si_3N_4 cannot act upon the substrate, and, in that case, even an oxidation of a shaped surface at a temperature of 850°C does not generate dislocations (Fig. 7a).

Finally, it should be noted that the use of a densified cleaning oxide at the poly/mono interface is a possible method of avoiding all kinds of defects, but such an inter-

facial oxide presents a significant barrier to dopant atoms which have to diffuse from the polysilicon into the substrate (4). It has been shown that an undensified cleaning oxide at the poly/mono interface is not a significant barrier to the diffusion of dopant atoms and is therefore a more realistic approach in eliminating defects (4).

Conclusion

From these observations the following conclusions can be drawn: if it is desired to have a high defect density at the interface between polycrystalline and monocrystalline silicon for enhanced gettering purposes, the amount of oxygen at the poly/mono interface should be as low as possible and prolonged processing steps at high temperatures are beneficial. The application of a Si_3N_4 pattern on top of the polysilicon will further increase the defect density.

However, when dealing with polysilicon diffusion sources, a small amount of oxygen at the poly/mono interface is beneficial and extensive high temperature processing should be avoided. In such a case, the best advice is: let poly be poly.

Modeling Rapid Thermal Diffusion of Arsenic and Boron in Silicon

ABSTRACT

Rapid thermal annealing (RTA) of high dose B and As implants is believed to produce large transients of point defects that may exist for the duration of the anneal (2-30s). Enhanced diffusion during RTA of boron implants $>10^{15}$ cm $^{-2}$ is related to damage clusters at the peak of the range which can grow into cross-grid dislocation networks. This process can create point defects through dislocation-dislocation reactions and by nonconservative climb processes. Enhanced diffusion during RTA of high dose As implants $>2 \times 10^{14}$ cm $^{-2}$ is related to the amorphous Si surface layer formed during implantation. Regrowth of this layer into a defect-free, crystalline layer is assumed to produce point defects which remain behind until they diffuse away. In the meantime, they contribute to enhanced As diffusion during the first 5-10s of the RTA cycle. Preamorphization at low temperature eliminates this enhanced diffusion of As by eliminating the source of point defects presumed to be vacancies because of the associated defect removal in the implanted layer. Enhanced dopant diffusion has been modeled by overlaying an empirical transient point defect model on thermally assisted diffusion models associated with steady-state furnace environments. A weighted exponential function was used to describe the transient process with a decay time of 4.4s.

Pulse and short-time annealing of ion-implanted Si have been receiving attention as potentially useful techniques for achieving shallow junctions free of extended defects. However, several observations have been made of significant dopant diffusion occurring as a result of rapid thermal annealing (RTA) using incoherent light sources (1-4). And, it has been observed that this enhanced diffusion occurs during the initial stage of the RTA cycle (4, 5). Hence, enhanced diffusion during RTA is observed to be a transient process, and therefore requires computer modeling in order to understand the important mechanisms that are operating. The purpose of this paper is to discuss RTA diffusion models for B and As in Si, and to describe the computer modeling effort required to simulate RTA diffusion profiles.

Experimental

Czochralski-grown (100) Si wafers, 8-15 Ω -cm p-type were implanted with As at liquid nitrogen temperature, room temperature, and 200°C at 1×10^{15} cm $^{-2}$, 50 keV. Room temperature As implants were also performed at 50 keV for doses of 2×10^{14} cm $^{-2}$ and 1×10^{16} cm $^{-2}$. n-Type As-doped wafers were implanted with 35 keV B $^{+}$ at a dose of 2×10^{15} cm $^{-2}$ (6). Samples were RTA processed in either air or N $_2$ in an AG Associates Heatpulse System Model 210M. Measurements of the temperature vs. time profiles obtained in the Heatpulse system are shown in Fig. 1. For a furnace set point temperature of 1100°C, the RTA cycle begins at 850°C. For a 2s RTA cycle, it can be seen that the temperature may only reach 1000°C. These profiles were approximated for computer modeling by 200 ms incremental time steps during which a constant average temperature is assumed. This allows the program to solve the finite difference equations for diffusion during constant temperature intervals.

Arsenic and B profile measurements were made on the North Carolina State University Cameca MS-3F ion probe. Reproducible wafer temperature measurements were performed by supporting wafers on a Chromel-Alumel thermocouple during RTA. No independent temperature measurements were made to verify the curves in Fig. 1. However, they agree generally with curves supplied by the manufacturer.

Diffusion Models

The approach taken in modeling RTA diffusion of dopants was to overlay a transient point defect calculation onto the steady-state, thermally assisted diffusion

models that existed in the program PREDICT. A detailed description of the models in PREDICT is beyond the scope of this paper, and will be presented elsewhere (7). Briefly, the PREDICT modeling program is based upon the multiple charge-state vacancy model of diffusion which assumes that under steady-state furnace conditions vacancies exist in Si in several ionization states. The total diffusion coefficient of a dopant in Si is the sum of the contributions to diffusion made by each type of vacancy (8). Overlaid on the vacancy model is the supplementary effect of self-interstitials on diffusion of dopants. In principle, both vacancies and self-interstitials may occur simultaneously, and somewhat independently. Thus, if both types of point defects are important, diffusion processes may involve both types (9, 10)

$$D_i = D_i^I + D_i^V \quad [1]$$

where D_i^I is the interstitial contribution and D_i^V is the vacancy contribution to the total measured intrinsic diffusivity, D_i . Recent analyses of diffusion data taken while the silicon surface was being oxidized correctly show that generated self-interstitials assist dopant diffusion, i.e., P, As, and B (11). However, simplified calculations are unable to correctly predict the fraction of diffusion flux due to the interstitial or vacancy mechanisms, since they ignore the many different kinds of point defect-impurity association and recombination processes that

Fig. 1. Measured temperature vs. time data (O) for an undoped wafer with a thermocouple attached to the back side in the RTA furnace. The furnace set-point temperature was 1100°C. The straight line approximations were used in computer calculations of dopant diffusion with time steps of 0.2s.

can occur. This problem was recently solved by Mathiot and Pfister (12), who numerically solved all of the necessary continuity equations involving vacancies, self-interstitials, and dopant-defect complexes. Their results show that for P, As, and B diffusion below 1100°C, the interstitialcy components are less than 25%. Thus, we have assumed that D_1^v dominates in Eq. [1] under nonoxidizing conditions.

As-implanted profiles were assumed to be Gaussian, based on measured range statistics. However, exponential tails were included in the initial profiles as determined by direct profile measurements. The steady-state, thermally assisted diffusion effects that are included in PREDICT are listed in Table I. Effects that increase diffusion beyond the expected intrinsic diffusivity include time-dependent oxidation-enhanced diffusion (OED), concentration-dependent diffusion, and any other process that creates the supersaturation of point defects (vacancies or silicon self-interstitials). The retarded diffusion effects listed in Table I are associated with reduced point defect levels.

Boron diffusion during RTA.—Thermally assisted diffusion of B in Si is assumed to occur primarily by the monatomic species via neutral and donor point defects. During oxidation of the Si surface, vacancy-assisted diffusion is dominated by a partial interstitial process. Concentration-dependent diffusion is modeled as the increase in donor point defects as B concentration exceeds n_i . Concentration-dependent OED is treated as a reduction in Si self-interstitials due to increased vacancy concentration with doping above n_i (13).

A comparison of steady-state, thermally assisted diffusion calculations with RTA data of a 2×10^{15} cm⁻², 35 keV B implant is shown in Fig. 2. It can be seen that during the 1050°C, 5s RTA, a significant tail on the B profile is created. However, the model calculations are unable to predict the occurrence of this tail. In fact, this modeling predicts that little or no movement of the profile occurs.

In order to understand the origin of the enhanced diffusion of B during RTA, consider the TEM plan-view micrographs shown in Fig. 3. Sadana *et al.* (3) implanted B at a dose of 5×10^{15} cm⁻², 35 keV in (100) Si. Figure 3a shows the as-implanted sample which exhibits a single-crystal diffraction pattern, indicating that no amorphous layer is produced by the implanted B even at this high dose. A 1000°C, 30 min furnace-annealed sample in N₂ shows a high density of irregularly shaped loops in addition to a dislocation network. The RTA sample in Fig. 3c shows that after 10s at 1100°C in air, a dislocation network is forming. After a 30s 1100°C RTA, a well-defined cross-grid dislocation network was observed in the implanted region, as shown in Fig. 3d. The significance of these micrographs is that during the RTA cycle, a cross-grid dislocation network is being created and stabilized. As a result, point defects are being generated through dislocation reactions and cross-slip processes.

Sadana *et al.* (3) have shown through TEM cross

Fig. 2. As-implanted B data and 1050°C, 5s RTA in air data. The solid curve is the calculated implant distribution and the dashed curve is calculated on the basis of steady-state, thermally assisted diffusion of B during RTA.

sections that the dislocation network is formed at the peak of the implanted B profile. In general, it is found that if the implant dose exceeds 1×10^{15} cm⁻², the high B concentration in the peak will likely generate damage clusters (3). A TEM cross-sectional micrograph is shown in Fig. 4 along with the corresponding 5×10^{13} cm⁻², 35 keV B profile following a 1100°C 10s RTA. It can be seen that the B in the peak of the profile has diffused more slowly than the B external to the dislocation network. This network was sufficiently stable that even after a 1000°C 30 min N₂ furnace anneal, the dislocation network was still in place. In addition, the B outside of the dislocated region diffused quite rapidly compared to normal, thermally assisted diffusion.

The preceding results and the model assumptions can be summarized as follows.

1. The B⁺ implant is not sufficient to drive the Si surface amorphous. Thus, no solid-phase epitaxial regrowth occurs.

2. For doses greater than 10^{15} B/cm², networks of dislocations occur at the peak of the profile following annealing due to the high B concentration.

3. Point defects are generated during dislocation network stabilization which occurs within the first 30s of RTA.

4. The lifetime of generated point defects is very low within the network of dislocations. This dislocation region is an efficient generator and recombination area for point defects, and, as such, the crystal can easily maintain point defect equilibrium.

5. The lifetime of point defects is relatively high outside of the dislocated network. Thus, generated point defects can diffuse significant distances away from the network before they recombine.

6. Enhanced B diffusion occurs outside of the dislocation network where generated point defects can reach supersaturated levels.

A schematic diagram of the situation during RTA of implanted B is shown in Fig. 5. The dislocation network is indicated by the cross-hatched area in the figure. It is assumed that within this area diffusion can proceed almost normally (14) with no point defect supersaturation. However, during the first 30s of the creation of this network, a significant population of point defects is generated which diffuses out into the nondislocated crystal. These point defects contribute to enhanced diffusion outside of

Fig. 3. TEM plan-view micrographs of 35 keV B implanted (100) Si, $5 \times 10^{15} \text{ cm}^{-2}$; (a, top left) as-implanted, (b, top right) furnace-annealed 1000°C/10s in air, (c, bottom right) RTA for 1100°C/10s in air, (d, bottom right) RTA for 1100°C/30s in air. After Sadana *et al.* (3).

the cross-hatched area. The time dependence of the density, C_{pd} , of this point defect supersaturation is represented by an equation of the form

$$C_{pd} = K(T) \exp(-t/\tau) \quad [2]$$

Inside the dislocated band, it is assumed that

$$C_{pd} = C_{equil} \quad [3]$$

where C_{equil} is the equilibrium concentration of point defects. The establishment of the dislocation network involves nonconservative processes such as climb which can be efficient vacancy generators (15). The intrinsic diffusion coefficient is multiplied by an enhancement factor of the form

$$D_B = D_i (1 + K'(T) \exp(-t/\tau)) \quad [4]$$

Over the RTA furnace setpoint range of 1000°-1100°C, it was found that

$$K'(T) = 5 \times 10^{-6} \exp\left(\frac{2.0 \text{ eV}}{kT}\right)$$

$$\tau = 4.4\text{s}$$

giving B diffusion coefficient enhancements of 100-400 at $t = 0$ outside of the dislocated region shown in Fig. 5.

Computer simulations of RTA of B implants are shown in Fig. 4, 6, and 7. Notice that in Fig. 6 little diffusion occurs within the first 0.22 μm of the B profile following a 5s RTA at 1050°C. It appears, in fact, that some negative diffusion has occurred back towards the surface. The model presented here cannot account for this. However, enhanced diffusion outside of the dislocated region can be accounted for by assuming the model in Fig. 5.

After 10s, the temperature in the RTA furnace has increased sufficiently to cause some diffusion to occur at the peak of the B profile. This level of diffusion is completely accounted for by steady-state thermally assisted diffusion processes. However, the bulk of the diffusion in the tail region of the profile is dominated by the assumed transient vacancy production associated with the formation of the dislocation network. The time dependence of this process is evident in Fig. 6 and 7, where movement of B in the tail region is greatest during the initial period of RTA when the temperature is lowest.

The rapid thermal anneals associated with Fig. 4, 6, and 7, were all performed in an air ambient. Calculations show that the OED associated with this air ambient is sufficient to cause some additional enhanced diffusion beyond that which occurs during the dislocation network formation. However, insufficient data were available to model this effect adequately. Other models, such as B precipitation and B clustering, were investigated to explain the profile shapes obtained. However, these attempts were not successful.

Arsenic diffusion during RTA.—The defect morphology introduced by high dose As implants is significantly different from the high dose B case. It is known that at room temperature, a $2 \times 10^{14} \text{ As/cm}^2$ implant is sufficient to create an amorphous surface layer in Si (16). In addition, such an amorphous layer can epitaxially regrow to a single-crystalline layer in milliseconds at 1000°C (17). Solid-phase epitaxy (SPE) of this amorphous layer produces defect-free material, although secondary defects below the amorphous/crystalline interface may still be present (3). However, it has been shown that these secondary defects also anneal out during RTA at 1100°C for

Fig. 4. Comparison of TEM cross-sectional micrographs corresponding to a measured B profile following RTA at 1100°C/10s in air. The simulated B profile is based upon the model depicted in Fig. 5. After Sadana et al. (3).

10s (3, 6). This suggests that a supersaturation of vacancies exists for a period of time to facilitate defect shrinkage following SPE.

The application of steady-state, thermally assisted diffusion calculations to RTA of implanted As in (100) Si is shown in Fig. 8. Arsenic was implanted at 100 keV, $1 \times 10^{16} \text{ cm}^{-2}$, and a 1150°C 5s anneal was performed in air. The solid circles and curves that pass through them are respectively the measured (6) and calculated as-implanted distribution of As. After the RTA anneal, the As has diffused more than predicted by calculations performed under the assumption of a constant 1150°C exposure at 5s. By using a time-dependent temperature ramp as actually measured in the RTA furnace, the calculated diffusion length at 10^{20} cm^{-3} is only 180Å. Thus, the steady-state calculations are insufficient to explain the enhanced diffusion that occurs during RTA of As (2).

Attempts were made to try to understand the origin of the enhanced diffusion of As during RTA. Shown in Fig. 9 are As diffusion profiles obtained by putting wafers in compressive or tensile stress during the RTA process. It can be seen that no significant difference exists in the As profiles measured in the stressed and the unstressed wafers.

In order to understand the role of the amorphous layer created during implantation on enhanced diffusion dur-

Fig. 5. Schematic diagram of the transient point defect model for B diffusion during RTA. The cross-hatched region corresponds to the implant-induced dislocation network where normal diffusion occurs.

Fig. 6. Comparison of RTA B profile data with transient model diffusion calculations at 1050°C.

ing RTA, a $1 \times 10^{15} \text{ As/cm}^2$ 50 keV implant was performed at 200°C. This implant temperature is sufficient to insure that the implant would not create an amorphous layer (16). The wafer then underwent RTA at 1100°C for 10s in N_2 . The results are shown in Fig. 10. The effect of the 200°C anneal was to form an as-implanted profile with a long tail. During RTA, little or no diffusion occurs in the tail portion of the profile. However, some thermally assisted diffusion occurs in the higher concentration portion of the profile. This diffusion can be accounted for through steady-state modeling calculations as shown. By comparison, the same implants carried out at LN_2 temperature and room temperature produced amorphous layers. Following RTA, some enhanced diffusion is observed as shown in Fig. 11. No measurable difference is

seen between the profiles for the LN₂ and RT implants, even though the amorphous layer created by the LN₂ implant was deeper by $\sim 300\text{\AA}$ (18).

The following is known about As implantation in silicon: (i) arsenic doses greater than 2×10^{14} cm⁻² at room temperature drive the Si surface region amorphous (16);

Fig. 11. Comparisons of RTA results for wafers arsenic-implanted at LN₂ temperature, room temperature, and 200°C. The LN₂ and RT implants leave the Si surface amorphous, and the dashed curve is calculated assuming transient point defects occur after SPE. The tail on the 200°C implant resulted from the hot implant, as shown in Fig. 10.

(ii) solid-phase epitaxial regrowth (SPE) occurs during RTA in milliseconds at high temperatures (17). Point defect generation during RTA may be caused by: (i) solid-phase regrowth where vacancies or self-interstitials are generated and diffuse from the regrown region. A typical diffusion length of vacancies would be $2 \mu\text{m}$ after 5s at 1050°C . (ii) Annealing of secondary implant damage also occurs in the 5-10s time frame at T greater than 1050°C (3, 5). This suggests that vacancies are the dominant, remnant point defect after SPE.

To study the effect of SPE on RTA, a 550°C anneal for 30 min was performed on as-implanted samples. Such an anneal is sufficient to regrow approximately 90% of the amorphous layer associated with a high dose As implant (19). The effect of a low temperature, recrystallization anneal on enhanced diffusion of As is demonstrated in Fig. 12. A $1 \times 10^{16} \text{ As/cm}^2$, 50 keV implant was performed in two Si wafers. One wafer was preannealed at 550°C for 30 min in N_2 . RTA was then performed on both wafers at 1100°C for 10s in N_2 . It can be seen in Fig. 12 and 13 that the preannealed wafer exhibited very little enhanced diffusion. The calculated curve shown in Fig. 12 is based on steady-state, thermally assisted diffusion calculations. In Fig. 13, a comparison is made between the results obtained on the two wafers. It can be seen that without the 550°C preanneal, significant enhanced diffusion of As has occurred.

Modeling of enhanced diffusion of As during RTA was achieved by overlaying a transient vacancy model onto the steady-state diffusion models in PREDICT II. These models assume As diffusion occurs primarily by V^- and V^+ vacancies. Thus diffusion coefficients were made to be directly proportional to the vacancy transient. At high concentrations, diffusion of electrically active As is reduced by clustering (20, 21), and clustering was assumed to occur instantaneously and independently of the vacancy transient. Diffusion coefficients of the form of Eq. [4] were used with

$$K'(T) = 1.3 \times 10^{-6} (E/200) \exp\left(\frac{2.0 \text{ eV}}{kT}\right)$$

$$\tau = 4.4\text{s}$$

for As doses $> 2 \times 10^{14} \text{ cm}^{-2}$ and temperatures in the 1000°C - 1150°C range. The parameter E is the As implant en-

Fig. 12. Rapid thermal annealing of arsenic-implanted silicon that was preannealed at 550°C for 30 min to regrow 90% of the amorphous layer.

ergy and is included to account for the increased width of the amorphous region with implant energy for $50 \leq E \leq 200 \text{ keV}$. It is assumed, unlike the case of B, that enhanced diffusion occurs over the entire profile since no dislocation network is created. Examples of calculated profiles using the transient model are shown in Fig. 8, 11, and 13.

It should be pointed out that the "activation" energy associated with $K'(T)$ is somewhat fictitious, since we are dealing with temperature transients as shown in Fig. 1. For As the product $D_{\text{As}} \cdot K'(T)$ has an activation energy of 2.1 eV, where $D_{\text{As}} = 23 \exp(-4.1 \text{ eV}/kT)$ (8). Recently, Kalish *et al.* (4) found that the activation energy for enhanced As diffusion during RTA was $\sim 1.8 \text{ eV}$, in reasonable agreement.

Another comparison of RTA As data with transient model calculations is shown in Fig. 14. Here, $2 \times 10^{14} \text{ As/cm}^2$ 50 keV implants were performed at room temperature. Thus, the Si surface was driven amorphous. RTA was performed at 1100°C for 5 and 15s in N_2 . Enhanced diffusion is observed beyond that which is attributable to normal thermally assisted diffusion. The amount of this enhanced diffusion agrees with the transient model calculation.

The time evolution of the redistribution of a 50 keV, $1 \times 10^{16} \text{ As/cm}^2$ implant in Si during 1100°C RTA is shown in Fig. 15. The transient nature of enhanced diffusion is evident in this figure. Significant motion of the profile is observed after 2, 5, and 10s. However, much less diffusion occurs after 10s. Computer simulations are shown for comparison with $K'(1100^\circ\text{C}) = 7$ and $\tau = 4.4\text{s}$. The exponential time decay assumed for the vacancy supersaturation models the enhanced diffusion reasonably well. However, it is not possible to extract τ directly by plotting x_i vs. RTA time due to the fact that temperature is constantly changing as shown in Fig. 1. Extensive computer simulations were the only alternative. At concentrations above 10^{21} cm^{-3} agreement between theory and data is poor as a result of As precipitation which has not been modeled.

Arsenic and Boron Codiffusion during RTA

The application of RTA to the annealing of double-implanted As and B in Si is shown in Fig. 16. RTA was

Fig. 14. Comparison of RTA As data with transient model calculations for $2 \times 10^{14} \text{ cm}^{-2}$, 50 keV implants.

performed at 1000°C for 10s in air (2). For comparison, model calculations assuming thermally assisted diffusion only are shown. The experimental profiles show that substantial movement of As has occurred beyond what would be expected at 1000°C for 10s. In addition, tails have formed on both the As and B profiles. The double implant using $1.2 \times 10^{16} \text{ cm}^{-2}$, 200 keV As and $2 \times 10^{15} \text{ cm}^{-2}$, 42 keV BF_2 into (100) Si present a substantially dif-

Fig. 16. The application of RTA to the annealing of a double-implanted layer (As into B implanted Si). Comparison of the SIMS data with steady-state model calculations shows significant As diffusion has occurred. Transient model calculations were made with K' (1000°C) = 105 and $\tau = 4.4s$.

ferent modeling environment for B diffusion during RTA. SPE of the amorphous layer created by the As implant is considered to be the dominant source of transient point defects.

The result of overlaying the transient point defect model on the thermally assisted diffusion calculations for the conditions described in Fig. 16 are also shown. In these calculations, K' (1000°C) = 105 for both As and B and $\tau = 4.4s$. Reasonably good agreement is obtained with the measured data except in the low concentration tail regions. It is not clear at this point whether these tails are measurement errors. It is interesting to note that the point-defect transient assumed to be created by SPE causes significant As diffusion, but the B profile essentially does not move from its as-implanted position. Thus, the presence of the heavily doped As layer is believed to control the charge state of the generated point defects (vacancies) such that few of these point defects are of the type that B needs to diffuse (8).

Summary and Conclusions

Modeling the diffusion of As and B during RTA presents a unique challenge, since point-defect generation mechanisms are believed to be operating during the short annealing intervals. In the case of high dose B implants, damage clusters created by the high concentration of B in the peak of the implant distribution grow into well-defined cross-grid dislocation networks during the first 10-30s of the anneal. Quantifying the concentration of point defects generated during this process requires knowledge of the types of dislocation reactions, climb processes, and cross-slip processes that may occur simultaneously. For the case of As implantation, it was assumed that the process of SPE leaves behind vacancies that participate in the shrinkage of secondary defects at the original amorphous/crystalline interface. Since the re-growth of amorphous layers leaves a crystalline layer that is practically defect free, the vacancies probably diffuse out of the recrystallized region rather than recombine within the region. The time required to do this is on the order of 5-10s at 1050°C, which corresponds to the period over which enhanced As diffusion is observed. Pre-

amorphization at low temperature eliminates this enhanced diffusion.

Calculations of diffusion during RTA were performed by overlaying a transient point defect model on thermally assisted diffusion models associated with steady-state furnace processes. A weighted exponential function was assumed to describe the transient process, and diffusion coefficients were directly multiplied by this function. Numerical integrations were performed over 200 ms constant temperature intervals to approximate the RTA environment.

The results of this study are at best semi-quantitative. The experimental data represent measurements of time-averaged phenomena with varying temperatures. More detailed modeling requires knowledge of wafer temperature vs. time, point defect generation mechanisms, and quantification of the transient processes involved.

ABSTRACT

A new growth technique of the low dislocation density GaAs crystals is described. The ambient As vapor pressure was controlled through precise control of temperature in a quartz chamber in which a crystal was grown by the Czochralski method. The dislocation density in the undoped crystals ($2^\circ\phi$, $\langle 111 \rangle$) was as low as $2 \times 10^8 \text{ cm}^{-2}$, which was lower than the case of the commercial LEC method by a factor of ten. The origin of such a pronounced reduction of the dislocation density is discussed by taking into account the effects of the melt stoichiometry and the thermal stress exerted on the grown crystal.

Dislocations in GaAs crystals are known to exert a very considerable influence on the performance of devices such as microwave devices, IC's, and laser diodes. It is already clear that dislocations in substrates reduce the lifetime of the laser diodes (1), and it has been shown that the dislocation distribution affects the uniformity of the FET threshold voltage in the IC (2). Therefore, numerous at-

tempts have been made to develop the growth technique of dislocation-free GaAs crystals.

Nishizawa *et al.* (3) have revealed that the ambient As vapor pressure greatly affects the stoichiometry and therefore the defect density in GaAs crystals. On the basis of an extensive investigation of the liquid-phase epitaxy and annealing of GaAs, they reported the optimum As vapor pressure (P_{opt}) for growth of the stoichiometric GaAs crystal as follows

*Electrochemical Society Active Member.

$$P_{\text{opt}} = 2.6 \times 10^6 \exp\left(-\frac{1.05}{kT_g}\right) \quad [1]$$

where T_g is the growth temperature. In the case of crystal growth from the melt, putting the melting temperature of GaAs, 1238°C, into T_g in Eq. [1], one obtains the value of P_{opt} as 813 torr. The As pressure is determined by the lowest temperature, T_{As} , in the chamber in which the crystal is grown. By using the relationship between T_{As} and the vapor pressure (4), the temperature corresponding to the As pressure of 813 torr is obtained as 612°C.

Recently, Parsey *et al.* (5) grew GaAs crystals by the horizontal Bridgman (HB) method under a controlled As vapor pressure and succeeded in reducing the dislocation density in 1 cm diam crystals to 500 cm⁻².

In the case of the liquid-encapsulated Czochralski (LEC) method, it is much more difficult to obtain dislocation-free crystals than with the HB method because the excessive thermal stress caused by the high temperature gradient just above the encapsulant assists dislocation generation (6). For this reason, it has been proposed to grow crystals by the LEC method by elevating the ambient temperature (6). However, it has also been shown that higher ambient temperatures tend to generate Ga droplets on the surface of the crystal due to As escape (7).

Thus, growth of GaAs crystals by the Czochralski method (without the liquid encapsulant) under a controlled As vapor pressure will lead to a significant reduction of the defect density through the combined effects of improvement of the melt stoichiometry and reduction of the thermal stress without formation of Ga droplets. Steinemann *et al.* (8) and Leung *et al.* (9) have shown that low dislocation density crystals can be grown by the Czochralski method under an As atmosphere. However, because of the complexity and limitation of repeated use of their apparatus, their techniques have not been applied for industrial use.

In this study, a new apparatus for the Czochralski method (without the liquid encapsulant) is proposed for growth of large crystals under a controlled As vapor pressure. It is also shown that the crystals (2"φ, undoped) grown by this apparatus are characterized by a low dislocation density of 2 × 10³ cm⁻².

Apparatus

A schematic diagram of the crystal puller is shown in Fig. 1. Crystal growth is carried out under a controlled As vapor pressure in a quartz chamber. The quartz chamber is 60 cm high and 10.8 cm in inner diameter (id), and the quartz crucible is 8.4 cm id.

In order to grow crystals under a controlled As pressure, the following requirements should be fulfilled. First, the temperature within the quartz chamber must be precisely controlled. The As pressure is controlled by the temperature at the top portion of the quartz chamber and the temperature of the other parts must be maintained above this temperature to avoid As deposition onto the chamber wall. Furthermore, the portion indicated by the arrow in Fig. 1 must be kept transparent during growth in order to observe the growing crystal; the temperature at this portion must be such as to avoid GaAs deposition. These requirements are met by controlling temperatures of three separate carbon heaters shown in Fig. 1.

Second, an effective seal is required between the chamber and the pull rod as well as the crucible supporting rod. As a sealing material, molten B₂O₃ (9) in Mo lids is used. The third requirement is as follows. After the growth of the crystal, the crystal and the crucible must be taken out of the quartz chamber without fracture of the chamber and the crucible. To meet this, taper joints between the quartz chamber and Mo lids are used.

The growth operation is made as follows. First, after the metal chamber is evacuated, the heaters A and C are heated to melt the B₂O₃ and the upper and lower lids are sealed by the taper joints. Then, the heater B is heated to melt GaAs. During the melting process, N₂ gas is intro-

Fig. 1. Schematic diagram of the crystal puller. 1: Upper lid. 2: Heater A. 3: B₂O₃. 4: Quartz chamber. 5: Seed. 6: Heater B. 7: GaAs melt. 8: Metal chamber. 9: Heater C. 10: Lower lid.

duced into the metal chamber in order to balance the pressure outside of the quartz chamber against the As pressure within the quartz chamber. After melting the GaAs, the temperature of the heater A is so controlled that the desired As pressure within the quartz chamber is realized. After these processes, a seed is lowered, and a crystal is pulled by the ordinary Czochralski method.

Experimental Procedures

For the growth of each crystal, presynthesized GaAs (600g) and sufficient arsenic to give a required As vapor pressure over the GaAs melt were charged in a quartz crucible and a <111> seed was used. Two crystals, no. 1 and 2, were pulled under the As pressure controlling temperatures of 616° and 620°C, respectively. Pulling conditions such as the temperatures of the heaters B and C, and the position of the crucible with respect to the heater B were similar for the two crystals. In both cases, the temperature gradient just above the melt surface, which is mainly affected by the position of the crucible with respect to the heater, was about 10°C/cm. This value was much lower than the case of the commercial LEC method (~100°C/cm). Similar values of the carrier concentration and the Hall mobility at room temperature were obtained at the front portion of the two crystals and were 5 × 10¹⁶ cm⁻³ and 3.3 × 10³ cm²/V s, respectively.

From crystal 1, (111) slices were cut perpendicularly to the growth axis. After polishing, the dislocation density distribution was determined by EPD measurements on an etched surface and by x-ray topography. (110) slices

Fig. 2. Radial dislocation density profiles across wafers cut from the shoulder. Crystals 1 and 2 were pulled under the As pressure controlling temperatures of 616° and 620°C, respectively.

were cut longitudinally from crystal 2. The dislocation distribution in these slices were examined by x-ray topography. A (111) slice perpendicular to the growth axis was also cut to examine the EPD distribution for comparison with the case of crystal 1.

Results and Discussion

Radial etch-pit density distribution.—The radial etch-pit density distributions across wafers cut from the shoulder are shown in Fig. 2. The EPD distributions are U shaped, and the EPD's around the center of wafers cut from the two crystals are about $2 \times 10^8 \text{ cm}^{-2}$, which is lower than the case of the commercial undoped LEC crystals by a factor of ten. Another important result is that the EPD in crystal 1 is lower than that in crystal 2. This fact appears to show the dependence of the EPD on the As vapor pressure during the crystal growth.

Possible explanations for the pronounced reduction of the dislocation density achieved by this study are as follows. First, improvement of the stoichiometry of GaAs melt due to the As vapor pressure led to suppression of point defect formation and in turn dislocation formation. It is possible that dislocation loops are formed by aggre-

Fig. 3. X-ray topograph of a (111) wafer cut from the shoulder of a crystal which was pulled under an As pressure controlling temperature of 616°C.

gation of point defects (10). In addition, climb motion of dislocations, which is assisted by point defects (10), will reduce the back-stress acting on dislocation sources and lead to generation of new dislocations. The As pressure dependence of the EPD mentioned above appears to suggest the importance of the stoichiometry. Second, since As vaporization from the crystal surface was reduced by the As atmosphere, the growth of crystals under a low temperature gradient along the pulling axis was possible without formation of Ga droplets. As a result, generation of dislocations due to thermal stress was suppressed.

Results of x-ray topography.—Figure 3 shows an x-ray topograph of a (111) wafer cut from the shoulder of crystal 1 which was pulled under an As pressure controlling temperature of 616°C. Around the center of the wafer, isolated dislocations are observed. Dislocations form the cell structures only loosely, whereas toward the edge of the wafer dislocations begin to form distinct cell structures elongated along the $\langle 110 \rangle$ direction. These cell structures appear to be formed by the climb motion of dislocations glided in (111) planes.

A dislocation distribution in a longitudinal slice of crystal 2 is shown in Fig. 4. The temperature of the As source was kept constant during growth. Although the dislocation density is high around the seed end, it rapidly decreases toward the shoulder. It is to be noted that the dislocation distribution in the portion where the crystal diameter is increasing is different from that in another portion where the diameter is decreasing. In the former portion, dislocations around the center do not form distinct cell structures and the dislocation density decreases with pulling time. However, in the latter portion, dislocations form cell structures even in the center region; the dislocation density increases with pulling time. Such a variation in the dislocation distribution with the crystal diameter was observed over the whole length of this crystal. Since the pulling rate was kept constant during growth of the body, variation in the crystal diameter appeared to be caused by some variation in the temperature of the GaAs melt. It is possible that the temperature of the GaAs melt, as well as the temperature of the As source, affects the dislocation density. If this is the case, precise control of the temperature of the melt is necessary to reduce the dislocation density.

Summary

A new apparatus was developed to grow GaAs crystals by the Czochralski method under a controlled As pressure. The dislocation density in undoped, 2" ϕ crystals grown by this apparatus was as low as $2 \times 10^8 \text{ cm}^{-2}$. Such a pronounced reduction of the dislocation density seemed to be associated with both the improved melt stoichiometry resulting from the As vapor pressure control and the reduced thermal stress due to the low temperature gradient just above the melt. Further investigation based on the precise control of the As pressure is needed to evaluate the net effect of the stoichiometry on the defect density.

The apparatus described in this paper is applicable for industrial use to grow large GaAs crystals with low dislocation densities.

ABSTRACT

Highly sensitive SIMS measurements of chlorine content in 1000-3000Å of silicon dioxide show that only very small amounts of chlorine (less than $6 \times 10^{11} \text{ cm}^{-2}$) can be found in steam-grown oxides in which gaseous or liquid HCl or TCA has been added during the oxide growth. Oxides grown in dry oxygen with gaseous HCl or TCA addition show a large range in chlorine content depending on the growth conditions. Chlorine can be incorporated into steam-grown oxides at temperatures as low as 750°C when the last 5%-10% of the desired oxide thickness is grown in dry O₂ and TCA atmosphere. The activation energy for this process is 2.3 eV. The increase in chlorine content is less than linear with TCA concentration and independent of oxide thickness.

In MOS processing, hydrogen chloride treatments are often performed by passing an excess of HCl over the silicon wafers during critical steps or piping HCl into the furnace during tube cleaning. The use of hydrogen chloride during the growth of the gate oxide of a MOS device is a well established technique (1-3). The chlorine reduces the sensitivity of the oxide to sodium-induced shifts of the threshold voltage; a total sodium content as low as $1 \times 10^{11} \text{ cm}^{-2}$ causes a shift of several tenths of one volt.

The analytical techniques for measurement of chlorine in silicon dioxide, i.e., secondary ion mass spectroscopy (SIMS) and nuclear backscattering, have not been sensitive enough for more detailed quantitative work at the 10^{11} - 10^{14} cm^{-2} level. This paper discusses a technique that has the required sensitivity and its application to various growth conditions for MOS gate oxides.

Conversion of Volume Concentration to Areal Density

For an investigation of oxide layers with chlorine content in the region of interest for MOS applications, the chlorine detection system should be able to detect levels of the order of 10^{10} at./cm^2 . This areal density is of the same order as the MOS interface charge density usually found in well-controlled oxide layers. It is more useful to express the values in terms of an areal density similar to the dose used in ion implantation of impurities into MOS devices.

Most of the measurement techniques, however, give the volume concentration of the species. Therefore, conversions between the two quantities are needed.

For uniformly distributed chlorine in 1000Å of SiO₂ with a volume concentration of $N = 1 \times 10^{15} \text{ cm}^{-3}$, the areal density or content C is $C = 10^{15} \text{ cm}^{-3} \times 10^{-5} \text{ cm} = 10^{10} \text{ cm}^{-2}$. For nonuniformly distributed layers, which is the normal case with most of the chlorine being found near the Si/SiO₂ interface, the integral over the oxide thickness

t_{ox} has to be taken

$$C = \int_0^{t_{\text{ox}}} N(x) dx \quad [1]$$

For actual MOS transistors, the areal density must be related to a shift in threshold voltage. For oxide layers which are 1000Å thick, an areal density of $1 \times 10^{11} \text{ ion/cm}^2$ corresponds to a threshold voltage shift of 0.5V. This value scales roughly with the areal density. VLSI circuits have up to factor five thinner oxides and are less sensitive to voltage shifts by the same factor.

Instrumentation

Auger sputtering.—Auger sputter analysis, which is based on a layer-by-layer removal technique combined with characteristic Auger electron energy analysis, is a useful technique for analyzing impurities in thin layers (4). The practical detection limit for this technique, however, is about $1 \times 10^{19} \text{ at./cm}^3$, and hence Auger analysis has a lower limit problem when analyzing practical chlorine-doped oxides.

Secondary ion mass spectrometry.—The technique of SIMS utilizes a beam of energetic ions to sputter away a solid surface producing ionized sputtered particles which can be mass spectrometrically detected. This analytical method can provide in-depth information on atomic constituents if one or more mass peaks are recorded as the sputtering process erodes the sample, thus producing the detected signal from continuously greater depths beneath the original sample surface.

The strength of the SIMS technique is its very high sensitivity for most elements. Previous SIMS analyses of chlorinated oxides (5, 6) have reported detection limits of $1 \times 10^{19} \text{ at./cm}^3$ or 170 ppm atomic. Previous SIMS instrumentation, however, was limited by the design that only

the positive ion Cl^+ could be monitored. It is obvious from the electron population of the Cl 3p orbital that this atom is much more likely to be sputtered as Cl^- than Cl^+ . If this species could be detected, then considerably higher sensitivity should be achievable than previously reported.

The primary ion beam used in these experiments was $^{40}\text{Ar}^+$. It is now well known (7) that negative ion yields (and thus sensitivities) can be greatly increased if Cs^+ ions are used as the primary bombarding species. While our SIMS instrument is equipped with a cesium ion source (8), we chose not to use it because the Cs which becomes implanted into the sample can create artifacts in the data as the profile approached the SiO_2/Si interface, just where most of the chlorine is located.

The unique design of the secondary ion optics of the SIMS instrumentation used for our studies (8-12) allows these negatively charged chlorine ions to be detected with high efficiency and low background. Volume detection limits of $1-3 \times 10^{17}$ at./ cm^3 are routinely achievable, with areal density sensitivities of $1-2 \times 10^{14}$ / cm^2 .

Calibration of SIMS

The large range in elemental sensitivities and the matrix or chemical effects encountered in SIMS require the use of a standard sample of chlorine in SiO_2 to calibrate the instrument for this particular analysis. The standard chosen was 180 keV $^{35}\text{Cl}^+$ implanted into thermally grown SiO_2 film of approximately 1 μm thickness (SIMS profile shown in Fig. 1). Such samples make ideal standards for SIMS due to the high accuracy ($\pm 1\%$) with which the dose (3×10^{14} cm^{-2}) can be controlled, and the localization of the implanted atoms in depth. No prior knowledge of the implant distribution is needed. The depth scale is determined by measuring the depth of the sputtered crater subsequent to the analysis by profilometry. Knowledge of the depth scale and the area under the measured profile (implanted dose) allows one to establish the concentration scale and thus to convert the counts/s into volume concentration. Previous calibrations have been done using Cl implants with doses of 1×10^{14} , 3×10^{14} , and 1×10^{15} cm^{-2} . The calibrations were so accurate that only one dose is needed.

The chlorine can move under the influence of an electric field. Since it is in a matrix of insulating SiO_2 , the

Fig. 1. Chlorine depth profile of an ion-implanted standard used for calibrating SIMS sensitivity for Cl in SiO_2 . The sample is a 10,000 Å thick thermally grown SiO_2 layer which has been implanted with $^{35}\text{Cl}^+$ ions at 180 keV to dose of 3×10^{14} at./cm^2 . Shown is the actual profile as measured by SIMS. Also shown is the $^{18}\text{O}^-$ concentration indicating constant sensitivity during the SIMS analysis.

charge built up during argon sputtering must be minimized by the use of a compensating electron beam (10).

Also critically important to quantitative SIMS depth profiling of SiO_2 films is the ability to maintain constant instrument transmission (sensitivity) while sputtering through the layers. Previous efforts at SIMS analysis of SiO_2 films (13) have suffered from changes in sensitivity of two orders of magnitude during the analysis due to surface charging effects from the sputtering beam. Constant sensitivity throughout the analyses in this report can be inferred from the steady signal of the $^{18}\text{O}^-$ ion detected along with the $^{35}\text{Cl}^-$ signal (see Fig. 1).

Chlorine Sources

The handling of liquified chlorine and liquified hydrogen chloride from steel tanks is more troublesome than handling of other substances. A small amount of water vapor in the gas stream will cause metal corrosion of the connecting plumbing and transfer heavy metal impurities into the silicon dioxide. Azeotropic mixtures of hydrogen chloride and water have been in long use as HCl-steam boilers. The boiler is made of clean quartz glass, and Teflon tubing is used for connecting the boiler to the furnace tube. However, it is not always desirable to pass wet HCl through the oxidation tube.

More recently, HCl or Cl_2 have been generated from chlorinated hydrocarbons. This concept is not new. Most of the early literature shows data on trichloroethylene (TCE), then the most often used dry cleaning and degreasing fluid (14-19).

Trichloroethylene (TCE).—The formula is as follows

Decomposition in an oxygen atmosphere at elevated temperatures occurs according to the following two equations

(1,1,1) Trichloroethane (TCA).—The chemical formula is

The decomposition in an oxygen atmosphere is

(1,1,2) TCA decomposes in the same fashion as (1,1,1) TCA, but is more toxic and since it has a lower vapor pressure tends to enrich in the evaporator when mixtures of (1,1,1) and (1,1,2) TCA are used. Some traces of (1,1,2) TCA can always be found in MOS-grade (1,1,1) TCA.

At high temperatures and in an excess of oxygen, the following reaction occurs

The beneficial component is Cl_2 . In the presence of steam, the equilibrium moves toward the left and less Cl is incorporated into the gate oxide.

TCE inherently would be better for the chlorination of gate oxides. However, in the USA the EPA restrictions on its use are severe and can only be overcome with difficulty. Therefore, all our work is presently performed using (1,1,1) TCA.

Fig. 2. Chlorine, oxygen, and hydrogen SIMS concentration profile for 900Å SiO₂ sample. The layer was grown for 55 min at 875°C in an azeotropic mixture of boiling hydrochloric acid and water (about 50% each by volume). Only a small amount of chlorine can be seen at the interface. The chlorine content is $3 \times 10^{11} \text{ cm}^{-2}$.

Early Results as a Function of Sample Preparation

Oxides grown with an azeotropic mixture of water and hydrochloric acid, a mixture that has been shown to be beneficial for MOS devices (20-21), show only traces of chlorine at the detection limit (see Fig. 2). The same is true for silicon dioxide grown in steam with additions of gaseous HCl (see Fig. 3) or with chlorine generated by the oxidation of (1,1,1) trichloroethane (TCA). From Eq. [4], it can be seen that the addition of H₂O will shift the equilibrium toward the left. Since Cl₂ is the active species, less gets into the oxide.

However, oxides grown in dry oxygen with the addition of gaseous HCl show appreciable chlorine content (see

Fig. 3. Chlorine, oxygen, and hydrogen SIMS concentration profile for 950Å SiO₂ sample. The layer was grown for 30 min at 900°C in steam with the addition of 1% of gaseous HCl. Only a small amount of chlorine can be seen at the interface. The chlorine content is $3 \times 10^{11} \text{ cm}^{-2}$.

Fig. 4. Chlorine, oxygen, and hydrogen SIMS concentration profile for 1050Å SiO₂ sample. The layer was grown at 1100°C in oxygen with 3% gaseous HCl. The chlorine content is $2.8 \times 10^{15} \text{ cm}^{-2}$.

Fig. 4). A peak always occurs at the Si/SiO₂ interface, and, often, a second lower peak occurs at the SiO₂/air or metal interface. Under an electric field at elevated temperatures, the chlorine distribution will shift, but the areal density will remain constant. An anneal in forming gas (10% hydrogen, 90% nitrogen) at 1100°C will reduce the areal density by a factor of 2.

Lower Temperature Oxides with Chlorine

The dry oxidation method with O₂ and gaseous HCl is slow and requires, for a sufficient thickness, high temperature and/or a long time cycle. Unfortunately, a long oxidation cycle makes the boron and phosphorus junction depths deeper than desired.

We have investigated a process in which the first part of the oxide is grown in steam followed by a dry oxida-

Fig. 5. Chlorine SIMS profile in 827Å of SiO₂ after 10 cm³ TCA had passed over the sample at 750°C for 60 min. The chlorine content is $7.5 \times 10^{12} \text{ cm}^{-2}$.

Fig. 6. Chlorine SIMS profile in 963 Å of SiO₂ after 10 cm³ TCA had passed over the sample at 950°C for 60 min. The chlorine content is 3.0×10^{14} cm⁻².

Fig. 7. Chlorine SIMS profile in 2097 Å of SiO₂ after 10 cm³ TCA had passed over the sample at 1150°C for 60 min. The chlorine content is 6.5×10^{14} cm⁻².

tion with a chlorine ambient. The dry oxidation can then be done at much lower temperatures, leaving the diffusion cycle almost unaffected.

The steam oxides were grown for 100 min (by combustion of hydrogen and oxygen) at a temperature of 875°C on (100) n-type silicon wafers of 5-10 Ω-cm resistivity. The ellipsometrically measured oxide thickness averaged 812 ± 12 Å.

The dry oxidations were done at 100°C intervals, from 750° to 1150°C. The first group of samples were subjected to a gas stream injection of 1 cm³ of TCA. This was done linearly over a period of 30 min. The second group of samples was subjected to the injection of 10 cm³ TCA over a 60 min period. An injection time of 30 min would have required a larger oxygen-gas flow than the 4 liter/min used. Table I shows the increase in oxide thickness with the TCA injections. It is appreciable at temperatures over 950°C.

The SIMS profiles show that the transport of chlorine to the silicon/silicon dioxide interface is slow at temperatures below 850°C. At higher temperatures, most of the chlorine will accumulate at this interface (see Fig. 4-7).

Table I. Oxide thicknesses t_{ox1} after 875°C 30 min pyrolytic steam oxidation, oxide thickness t_{ox2} after TCA treatment at temperatures between 750° and 1150°C. Two volumes of TCA were used 1 cm³ in 30 min and 10 cm³ in 60 min. The oxide thickness increases appreciably at the higher temperatures. The total chlorine increases with temperature and TCA volume

Temp. (°C)	1 cm ³ TCA, 30 min			10 cm ³ TCA, 60 min		
	t_{ox1} (Å)	t_{ox2} (Å)	Total Cl (cm ⁻²)	t_{ox1} (Å)	t_{ox2} (Å)	Total Cl (cm ⁻²)
750	766	785	1.0×10^{12}	812	827	7.5×10^{12}
850	804	829	8.4×10^{12}	815	853	5.9×10^{13}
950	811	881	6.6×10^{13}	813	963	3.0×10^{14}
1050	811	1059	5.2×10^{14}	813	1336	1.8×10^{15}
1150	824	1510	1.3×10^{15}	813	2097	6.5×10^{15}

Table II. Constants C_0 and E for an Arrhenius-type plot $C = C_0 \cdot \exp(\Delta E/kT)$ of Fig. 8 with R as the correlation coefficient of the linear regression

Curve	Conditions	C_0 (cm ⁻²)	ΔE (eV)	R
1	1 cm ³ TCA/30 min	2.750×10^{23}	-2.328	0.99743
2	10 cm ³ TCA/60 min	2.145×10^{23}	-2.129	0.99915

The oxide thicknesses and the total chlorine content for the ten samples are listed in Table I. The chlorine content vs. $1/T$ is shown as an Arrhenius plot in Fig. 8, with the numerical values given in Table II. An activation energy of 2.3 eV has been calculated from these measurements. The ratio of measured chlorine content of the two samples to TCA liquid volumes is less than predicted by linearity, and decreases with temperature.

A second set of samples was prepared to study how much chlorine is incorporated with increasing TCA volume and oxide thickness. The initial steam oxide was grown at 875°C of two thicknesses of 1000 and 2700 Å on

Fig. 8. Chlorine content C as a function of $1/T$. Least squares fit lines to the equation $C = C_0 \cdot \exp(E/kT)$ give a reasonable description. Curve 1 is for 1 cm³ TCA in 30 min, curve 2 is for 10 cm³ TCA in 60 min. The values C_0 and E are listed in Table II.

Fig. 9. Chlorine content C as a function of TCA volume. The TCA injection is for 120 min at 950°C . The data for 1200\AA SiO_2 are marked by +; the data for 2800\AA by x. The least squares fit line is representing data from both oxide thicknesses. The numerical values are given in Table IV.

5-10 $\Omega\text{-cm}$ n-type bulk silicon wafers. Precise amounts of TCA were injected into the oxidation tube from a motor-driven syringe system over a period of approximately 120 min at a temperature of 950°C . After this treatment, the oxide thicknesses increased to 1250 and 2800\AA .

Table III lists the total chlorine content in the samples. Figure 9 indicates a linear relationship when both the chlorine content and the TCA volume (and indirectly the Cl concentration) are plotted on a log-log scale. Table IV lists the constants and correlation coefficients of least squares fits.

Capacitance/Voltage Stability

Chlorinated oxides are extremely stable. Figure 10 shows the capacitance/voltage characteristics under $\pm 10\text{V}$ bias at 300°C . The total chlorine content is $1.0 \times 10^{14} \text{ cm}^{-2}$ after a 20 min 1150°C forming gas anneal. The total shift is less than 20 mV. The theoretical curve for $N_{ss} = 0$ coincides with these curves.

Discussion

SIMS analysis of chlorine in silicon dioxide has allowed a quantitative study of how chlorine is incorporated into SiO_2 . The sensitivity has been increased so as to permit quantitative measurement of low levels, thus the analysis can be applied to actual MOS gate oxides.

Oxides grown with an azeotropic mixture of hydrochloric acid and water are beneficial for reducing the sodium sensitivity, but chlorine cannot be detected in sufficient quantity in these oxides. The same is true for silicon dioxide grown in steam with additions of gaseous HCl or chloro-

Table III. SIMS chlorine constant (cm^{-2}) in silicon dioxide of various thicknesses as a function of TCA volume injected during a 120 min oxygen heat cycle at 1050°C

TCA volume (cm^3)	1200 \AA oxide	Repeat 1200 \AA	2800 \AA oxide
0.3	1.5×10^{13}		
1	2.9×10^{13}	2.83×10^{13}	3.24×10^{13}
3	6.7×10^{13}		8.25×10^{13}
10	1.2×10^{14}		1.43×10^{14}
30	2.1×10^{14}	2.08×10^{14}	2.07×10^{14}

Table IV. A least squares fit for the SIMS chlorine content C (cm^{-2}) as a function of the TCA volume V (cm^3) can be represented by the following equation: $\log(C) = A + B \cdot \log(V)$ and the following constants A and B

Oxide thickness (\AA)	A	B	R
1200	13.4904	0.5816	0.9940
2800	13.5358	0.6204	0.9209
both	13.5082	0.5747	0.9787

Fig. 10. Capacitance-voltage characteristics under bias-temperature stress of MOS capacitor with 1000\AA thick SiO_2 layer with $1 \times 10^{14} \text{ cm}^{-2}$ chlorine in it. All experimental curves with zero, $+1 \times 10^6$ and $-1 \times 10^6 \text{ V/cm}$ field fall within 20 mV of each other and the theoretical curve. This represents an extraordinary degree of stability.

rine generated by the oxidation of (1,1,1) trichloroethane. The beneficial results can only be explained by the chlorine cleaning action of the oxidation tube and/or by preventing the sodium from entering the SiO_2 .

At temperatures of 1200°C , the addition of HCl to the steam will substantially increase the minority carrier lifetime (22).

Oxides grown in dry oxygen with the addition of gaseous HCl show appreciable chlorine content. This method of oxide growth is slow and requires, for a sufficient thickness high temperature and/or a long time cycle. Unfortunately, such an oxidation cycle makes the boron and phosphorus junction depths deeper than desired.

We have developed a process in which the first part of the oxide is grown in steam, followed by a dry oxidation with a chlorine containing ambient. The dry oxidation can be done at much lower temperatures, leaving the diffusion cycle almost unaffected. The activation energy for the chlorine incorporation was found to be 2.3 eV. This allows practical chlorine incorporation at a temperature as low as 800°C .

Chlorinated oxides are electrically very stable. Capacitance voltage temperature bias stressing indicates total shifts of less than 20 mV. No negative instability that has been linked to chlorine in the oxide (23) has been found especially for polysilicon MOS capacitors that are shielded from deep UV irradiation common in sputtered-metal deposition systems. In our favor is the use of the (100) direction of the silicon substrate material and the low chlorine concentration in the oxide. In our opinion, chlorine is not harmful to MOS gate oxides. Very clean steam oxides without chlorine ambient have also shown similar stability. The addition of chlorine into the gas stream creates an extra margin useful in a production environment.

Experiments which were designed to show the sodium interaction with chlorine in the oxide did not show appreciable sodium passivation. In these experiments, well-quantitized levels of sodium have been implanted into chlorinated SiO_2 . SIMS measurements with sodium are very difficult to perform. Electrical measurements that rely on the sodium mobility in SiO_2 at temperatures of 300°C do not show reduced threshold voltage shifts for the chlorine levels and low chlorine incorporation temperatures used here. At high temperatures and very high chlorine levels that will form a liquid phase of $\text{Si}_x\text{Cl}_y\text{O}_z\text{H}_2$, sodium passivation occurs (24-26).

A New Silicone-Based Negative Resist (SNR) for Two-Layer Resist System

Masao Morita, Saburo Imamura, Akinobu Tanaka, and Toshiaki Tamamura

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Polymers Section, Tokai, Ibaraki 319-11 Japan

ABSTRACT

A new silicone-based negative resist (SNR) for a two-layer resist system was synthesized by the chloromethylation of oligomeric diphenyl siloxane (ODPS), in which the polymerization of ODPS occurred simultaneously. The molecular weight of SNR could be controlled by the reaction conditions. SNR showed excellent dry etching resistance to O₂ RIE owing to the siloxane main chain structure and high sensitivity and high resolution to electron beam, x-ray, and deep UV radiation due to chloromethyl groups as the crosslinking units. The high glass transition temperature of SNR (150°C) due to diphenyl structure contributes to improving resolution and eliminates lithographic problems involved in low T_g conventional silicone resins. Submicron patterns with a high aspect ratio were fabricated in a two-layer system comprised of SNR on AZ1350 photoresist bottom layer.

As the minimum pattern size in VLSI reaches submicron dimensions, single-layer resist systems cannot satisfy all requirements in electron beam lithography or photolithography. A demand to establish practical multi-layer resist (MLR) systems has been growing, because the MLR has various advantages over single-layer resist systems, such as the planarization of surface topography, higher resolution and higher aspect ratio, proximity effect reduction in electron beam lithography, and so on (1-5). A decision to introduce a MLR system depends on the trade-off between these advantages and the substantial increase in the number of processing steps, which is a vital drawback for MLR systems.

With respect to resist materials for MLR systems, polymers containing certain amounts of inorganic elements are one of the most important class of resists, because they can possess a very high resistance against oxygen reactive ion-etching (O₂ RIE) (1, 5, 6). Two-layer resist (2LR) systems composed of this type of resist as a thin top layer and an organic polymer film as a thick bottom layer are now regarded as among the most promising for realizing a practical MLR system with a relatively small increase in the number of processing steps.

Several organometallic polymers or inorganic resists have been already proposed (7-10). Among them, silicone resins are particularly interesting, because of very high O₂ RIE resistance, and a wide variety of available raw materials to synthesize new resists. Hatzakis *et al.* (7) reported that commercially available, high molecular weight poly(vinyl methyl siloxane) and poly(dimethyl siloxane) act as high sensitivity (2 μC/cm²) and high resolution (contrast

of 2.0) inorganic polymer resists. The good wettability of silicone resins onto organic polymer layers, which prevents the formation of pinholes even in a thin layer of top resist, is also pointed out as another advantage of silicone resins. However, because of the extremely low glass transition temperature (T_g), aliphatic polysiloxanes are normally viscous liquid or gum at room temperature so that several problems arise such as adhesion of dust and control of resist thickness (11). Besides these problems, high T_g is an important factor for negative resist polymers from various aspects. We have pointed out that the degree of resist swelling during development can be substantially depressed in a high T_g polymer, forming resist patterns with a fine edge definition and a steep pattern profile (12). When synthesizing new resists, high T_g will make the chemical modification and purification of polymers much easier.

It is known that the substitution of the methyl groups of poly(dimethyl siloxane) by phenyl groups can improve the thermal stability of silicone resin. However, T_g of a silicone resin in which 75% of the methyl groups are substituted with phenyl groups is still about -30°C. When all methyl groups are completely replaced by phenyl groups, the resulting polymer is expected to have very high T_g, because commercially available oligomeric diphenylsiloxane has a T_g of about 150°C. However, poly(diphenylsiloxane) (PDPS) has not been produced in a high molecular weight form.

We have succeeded in synthesizing high molecular weight PDPS containing chloromethyl groups as a cross-linking functional group (13). The resist called silicone-

based negative resist (SNR), shown in Fig. 1, can provide very high resolution two-layer resist systems (14, 15). This paper deals with the synthesis and the resist performance of SNR.

Experimental

To synthesize high molecular weight PDPS, oligomeric diphenylsiloxane (ODPS) available from Petrarch Systems was used as a starting material. The ODPS with a molecular weight of 1400 (polymerization degree of about 7) had Si-OH groups at both ends. The chloromethylation of ODPS was carried out in chloromethylmethyl ether using SnCl_4 as a catalyst. The temperature and reaction times must be rigorously controlled so that polymers with various molecular weights are produced without forming gel. The typical reaction conditions are as follows: ODPS (30g) was dissolved in chloromethylmethyl ether (500 ml). Then, SnCl_4 (25 ml) was added to the solution. The reaction mixture was stirred for 17h at 0°C , and a white polymer was isolated by reprecipitation in methanol. The molecular parameters of polymers obtained were determined compared with polystyrene standards by gel permeation chromatography (GPC) using a Model HLC-802UR (Toyo Soda).

For the sensitivity measurements, the resist was spin-coated on a silicon wafer from a nominal 5% solution in methylisobutyl ketone. The initial thickness at 1000 rpm was about $0.2\ \mu\text{m}$. The resolution of SNR was evaluated in a two-layer resist system where a photoresist AZ-1350J (Shipley) was used as a bottom layer. $1.25\ \mu\text{m}$ thick AZ resist was spin-coated on Si wafers. $0.2\ \mu\text{m}$ thick SNR layer was coated on a hard-baked AZ layer. Monochlorobenzene was used as a spinning solvent for SNR when AZ is soft-baked at a temperature lower than 90°C . The resist film was so thin that no prebaking was carried out before exposure.

A computer-controlled electron beam exposure machine ELS-5000 (Elionix) operating at 20 kV was used for lithographic evaluation. After exposure, samples were developed by dipping in a suitable developer. Normally, methylethyl ketone:isopropanol mixed solvent and isopropanol were used as a developer and rinse solvent, respectively. The development of SNR on soft-baked AZ layer was carried out by the combination of xylene and cyclohexane. As electron beam sensitivity, $D_{n^{0.5}}$ and D_n^i were used, which are defined as a dose to leave half of the initial thickness and a minimum dose required to form insoluble gel on substrate. The contrast (γ) was defined as $\gamma = (1/2) [\log (D_{n^{0.5}}/D_n^i)]^{-1}$. Sensitivity curves for x-ray and deep UV exposure were determined with a step-and-repeat-type x-ray exposure machine SR-1 developed at NTT (16) using an Mo target and a 200W deuterium lamp (Ushio Electric Company), respectively.

Dry etching resistance of SNR was evaluated by reactive ion etching (RIE) with a parallel-plate etching ma-

chine DEM-451 (ANELVA) using O_2 and CF_4 gases. In two-layer resist systems, the developed SNR patterns were transferred to the AZ layer by O_2 RIE. Typical O_2 RIE conditions were a gas pressure of 10 mtorr and a power of $0.1\ \text{W/cm}^2$. Patterns obtained were evaluated by scanning electron microscope (SEM) observation with JSM-35 (JEOL).

Results and Discussion

SNR syntheses.—Figure 2 shows the GPC curves of several polymers produced by the chloromethylation of ODPS. Table I summarizes the molecular parameters of SNR samples as well as their resist properties for electron beam exposure. So far, SNR's with a molecular weight range of 6,400-113,000 were produced, without forming gel. An average polymer yield was 60% after two reprecipitations with the tetrahydrofuran-methanol system. The chloromethyl group content is about 20%, which is enough for sensitizing SNR to high energy beams as was observed in chloromethylated polystyrene (CMS) (12).

A key point for SNR development is the finding that the polymerization reaction of ODPS occurs at the same time as the chloromethylation in the Friedel-Craft-catalyzed chloromethylation reaction of ODPS (13). The mechanism of the polymerization reaction is now under investigation. However, terminal OH bonds in ODPS and chloromethylmethyl ether seem to be deeply involved with the polymerization reaction, because methyl-terminated siloxane oligomer could not be polymerized under the same reaction conditions. Polymerization did not occur without chloromethylmethyl ether. The condensation of the OH group is also confirmed by NMR studies, where a small peak assigned to the OH group at 1.5 ppm observed in ODPS disappears in the resultant polymers (13).

Normally terminal OH groups in di- or mono-methyl substituted oligomeric siloxanes are very reactive, producing high molecular weight polysiloxanes by condensation, whereas the OH groups in ODPS seem to be stabilized by the diphenyl groups. When chloromethyl

groups are introduced into phenyl rings, the electronic states of ODPS are changed, making the terminal OH groups reactive. Another consideration is that the combination of chloromethylmethyl ether and SnCl_4 generates an active catalyst which can initiate condensation as well as chloromethylation. Consequently, SNR can be synthesized by only one reaction step from relatively cheap ODPS, suggesting a low resist cost when SNR is commercialized.

Resist performance of SNR.—Figure 1 shows a chemical structure of SNR. SNR consists of three important functional groups. First, a siloxane main chain makes SNR strongly resistant to O_2 RIE. Second, phenyl groups realize a high T_r (150°C). Third, the chloromethyl groups attached to the phenyl groups give SNR high sensitivity to high energy radiation such as electron beam, x-ray, and deep UV light. The obtained resist performances are as follows.

Sensitivity.—SNR has an almost equivalent structure to CMS except for its main chain structure. CMS is one of the representative negative electron resists with high sensitivity and high resolution, particularly applicable to dry-etching processes because of high dry-etching resistance. SNR also has a high sensitivity, as shown in Fig. 3, where several SNR sensitivity curves to electron beam are plotted. The starting material ODPS also exhibits negative-type behavior, but the chloromethylation clearly realizes a large sensitization. The sensitivities are in a range of $0.68\text{--}35 \mu\text{C}/\text{cm}^2$ for \overline{M}_w between 1.13×10^5 and 6.4×10^8 , as listed in Table I, and the relationship is almost linear as observed in another negative electron resist (15).

In comparing the cross-linking reactivity of negative electron resists, the product of molecular weight \overline{M}_w and the minimum dose D_n^1 has been used to eliminate the factor of molecular weight. The average $D_n^1 \overline{M}_w$ of SNR's is $0.12 \text{ C}/\text{cm}^2$ whereas that of a starting material, ODPS is $2.4 \text{ C}/\text{cm}^2$, indicating distinctively high cross-linking reactivity of the chloromethyl group. SNR reactivity is even higher than that of CMS with the same chloromethylation ratio ($0.2 \text{ C}/\text{cm}^2$). Though many reasons may be offered, such as the effect of residual OH groups and higher efficiency in energy transfer to reactive sites in SNR, it may be erroneous to compare \overline{M}_w of quite different types of polymers by using GPC with polystyrene standards. Absolute values of \overline{M}_w must be exactly determined before detailed arguments can be made. However, it cannot be denied that SNR shows high electron beam sensitivity compared with that of CMS.

Figure 4 plots the sensitivity curves of SNR-4 ($\overline{M}_w = 4.4 \times 10^4$) and CMS ($\overline{M}_w = 1.8 \times 10^5$) to x-ray from Mo target (5.4\AA). The $D_n^1 \overline{M}_w$ of SNR is $1500 \text{ J}/\text{cm}^2$, whereas that of CMS is $3600 \text{ J}/\text{cm}^2$, indicating high sensitivity of SNR to

Fig. 4. X-ray sensitivity curves of SNR and CMS. (a): SNR, $\overline{M}_w = 4.4 \times 10^4$. (b): CMS, $\overline{M}_w = 1.8 \times 10^5$. Target: Mo.

x-rays as well as electrons. The $D_n^1 \overline{M}_w$ of SNR to x-ray showed a better value than expected from the comparison of SNR and CMS in electron beam sensitivity. This is because Si and O atoms contained in SNR absorb x-rays, particularly in the $5\text{--}6.7\text{\AA}$ wavelength region, as shown in Fig. 5, where the absorption coefficient of SNR is compared with those of CMS and PMMA. When Mo target is used, SNR has about three times larger absorption than CMS and two times greater than PMMA.

SNR is also useful in deep-UV lithography. In Fig. 6, the sensitivity curve of SNR-3 to a deuterium lamp is

Fig. 5. X-ray wavelength dependence of absorption coefficients for (a) SNR, (b) PMMA, and (c) CMS.

compared with those of CMS ($\overline{M}_w = 6 \times 10^4$) and PMMA. Figure 7 shows UV absorption spectra of SNR and CMS. The strong absorption of phenyl groups around 260 nm gives SNR higher sensitivity than CMS. The self-filtering effect due to very strong absorption will be no problem because SNR used in lithography is usually very thin.

Contrast.—A contrast of SNR to electron beam exposure, listed in Table I as γ , is a function of \overline{M}_w and $\overline{M}_w/\overline{M}_n$, as is observed in many negative electron resists (12, 15). The contrast of SNR is lower than that of CMS because the molecular weight distribution of SNR is much greater than that of CMS. It would be improved by the fractionation of SNR polymers or the use of monodisperse poly(diphenyl siloxane) as a starting material, if a ring opening living polymerization of cyclic diphenylsiloxanes were possible. However, as SNR can be uniformly coated in a very thin film of about 0.1 μm , sufficiently high resolution is obtained without any modification of the polymers, as shown later.

Dry etching resistance.—SNR has high resistance against dry etching, especially against O_2 RIE. The etching rate of SNR is less than 5 nm/min for the RIE condition used (10 mtorr, 50 sccm, 0.1 W/cm^2 , bias of 500V), whereas that of AZ-1350 is more than 80 nm/min, as shown in Fig. 8.

Fig. 8. Etching characteristics of (a) SNR and (b) AZ for O_2 RIE. Conditions: 10 mtorr, 50 sccm, 0.1 W/cm^2 , bias of 500V.

Fig. 9. Auger electron spectroscopy depth profiles of etched SNR. ●: Carbon. □: Oxygen. ○: Silicon. Etching time: (a) 0 min, (b) 1 min, (c) 5 min, and (d) 10 min. O_2 RIE condition: 10 mtorr, 0.1 W/cm^2 .

When relatively high O_2 gas pressure such as 100 mtorr is adopted, the etching rate of SNR is almost negligible.

The high O_2 RIE resistance of SNR is needed to accomplish high resolution lithography. Since SNR is hardly etched, the thickness can be as thin as possible, and a limit in thinning resist would depend on another factor, that is, the formation of pinholes. We confirmed that 0.1 μm is enough thickness to perform practical fabrications without increasing pinhole density. This could be due to the good wettability of silicone polymers.

We examined the oxidation of SNR to SiO_2 during O_2 RIE by means of Auger electron spectroscopy (AES). Auger electron intensities from silicon, oxygen, and carbon were measured in depth direction for SNR samples etched by O_2 RIE for various times. The samples were etched under the above conditions for 1, 5, and 10 min, respectively. Figure 9 shows AES depth profiles of SNR. In the unetched sample (Fig. 9a), a constant elemental composition which is equivalent to that of SNR was observed from the surface to bottom; whereas, the surface of etched samples (Fig. 9b to 9d) show a drastic decrease of carbon content and an increase of oxygen content, indicating the oxidation of SNR to SiO_2 . It should be noted that the oxidized regions were at most 10 nm from the surface and were independent of etching time. This means that the surface of SNR is immediately converted to SiO_2 by O_2 RIE. The SiO_2 layer formed on SNR is slightly etched by a sputtering effect, but SNR just under the SiO_2 layer is immediately oxidized to SiO_2 , so that the thickness of the surface SiO_2 is constant vs. etching time.

SNR is expected to show a high resistance against conventional RIE using halogenated carbon gases as judged by its aromatic structure and high T_g . The SNR etching rate against CF_4 RIE is compared with other resists, summarized in Table II. SNR shows much higher resistance to CF_4 RIE than poly(aliphatic methacrylates), but slightly lower resistance compared to CMS and AZ. This means that the SNR layer in two-layer resist systems is relatively easily removed when the substrate layer is etched by RIE using a two-layer mask. However, this property is an advantage for SNR, because after the etching, O_2 plasma ashing can be used for resist removal,

which is one of the few problems with multiple-layer resist systems.

SNR/AZ two-layer system.—A submicron pattern with high aspect ratio is demonstrated by the SNR/AZ two-layer resist system. It takes only six steps to accomplish the resist process by using SNR. These are AZ-1350J coating, baking at 200°C for 60 min, SNR coating, electron beam exposure and development, and O_2 RIE. This is only a two-step increase compared with a single-layer resist system. Figures 10 and 11 show SEM photographs of fabricated patterns using SNR-4. A $0.3 \mu\text{m}$ line and $0.7 \mu\text{m}$ space pattern and a $3 \mu\text{m}$ line and $0.2 \mu\text{m}$ space pattern are clearly formed. The proximity effect is efficiently reduced, indicating the high resolution capability of this resist system.

Furthermore, SNR shows good solubility in many solvents, including most ketones, esters, ethers, aromatic hydrocarbons, and many halogenated hydrocarbons. Plain hydrocarbons and alcohols are nonsolvents. As compared with CMS, SNR shows better solubility, perhaps due to the siloxane main chain structure. This provides a very wide variety of developers and spinning solvents. As a bottom layer in a two-layer resist system, various poly-

mers can be used even if that polymer is soluble in many solvents. For instance, the hard baking of AZ photoresist is not necessary with a suitable combination of spinning solvent and developers. Monochlorobenzene can be used as the spinning solvent, and xylene is one of the most excellent developers for SNR; both hardly dissolve soft-baked AZ resist. The use of a soluble bottom layer has another merit in stripping the resist. As the hard-baked AZ is normally stripped by O_2 plasma ashing, scums are sometime observed on the substrate when SNR layer is not completely removed. When soft-baked AZ resist was used as a bottom layer, SNR could be easily lifted off and no scum was observed.

Summary

New silicone-based negative resists (SNR's) for a two-layer resist system were synthesized by the chloromethylation of oligomeric diphenylsiloxane. SNR showed excellent dry etching resistance against O_2 RIE, and could be applied to an imaging resist of two-layer resist systems. Practical high sensitivities to electron beam, x-ray, and deep UV radiation were obtained. An excellent resolution was realized in a two-layer resist system using SNR.

Mixed Conduction and Defect Structure of $\text{ZrO}_2\text{-CeO}_2\text{-Y}_2\text{O}_3$ Solid Solutions

B. Calès and J. F. Baumard

Centre de Recherche sur la Physique des Hautes Températures, CNRS, 45045 Orléans Cédex, France

ABSTRACT

The electrical properties of the solid solutions between stabilized zirconia and ceria, $(0.9-y)\text{ZrO}_2\text{-}y\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ with $0 < y < 0.9$, have been investigated, between 1273 and 1673 K, in a large range of oxygen partial pressures. The total electrical conductivity and the concentrations of the various charge carriers, determined through thermogravimetry and measurement of magnetic susceptibility at high temperature as a function of oxygen partial pressure, makes it possible to develop a model accounting for the transport properties as a function of temperature and oxygen partial pressure. On the basis of the present results, the materials in question appear to be suitable as membranes semipermeable to oxygen.

Refractory oxides with a fluorite-type structure, such as stabilized zirconia and pure or doped ceria, have been extensively studied in recent years (1, 2). Most of them are characterized by a predominant ionic-type conductivity, which proceeds through the motion of oxygen ions via vacancies (2). Owing to the electrolytic character of these materials, they can be potentially used at intermediate temperatures (of the order of 1273 K) in applications such as oxygen gauges (3, 4) or fuel cells and electrolyzers (5).

However, at temperatures higher than ≈ 1673 K, these oxide electrolytes may exhibit a partial electronic conductivity (6). The resulting oxygen flux through the electrolyte (7), although believed to have a detrimental effect on the property of the material as an oxygen gauge at temperatures higher than 1473 K, may be judiciously applied to the problem of selective oxygen pumping at high temperature. Thus stabilized zirconia walls have been recently used as oxygen semipermeable membranes for the extraction of the oxygen arising from steam decomposition (8). Such a membrane must be characterized by a mixed, ionic, and electronic, conductivity. Indeed, in a gradient of oxygen chemical potential, the ionic component of the conductivity allows the oxygen to diffuse as O^{2-} ions through the membrane, while the electronic component ensures a transfer, between the two electrolyte-gaseous phase interfaces, of the electrons required for the exchange of oxygen between the electrolyte and the gaseous phases. Furthermore, it has been shown (8) that the oxygen transfer is maximum when the ionic component of the conductivity is equal to the electronic component. This is not precisely the case for stabilized zirconia (9), the oxygen semipermeability of which is limited by the value of its electronic conductivity which is very low.

However, the electronic conductivity of stabilized zirconias may be enhanced by doping these materials with an oxide the cation of which may present different valence states. This is the case for cerium oxide, CeO_2 , which is characterized, at high temperature, by a redox equilibrium between the tetravalent Ce^{4+} and the trivalent Ce^{3+} states of cerium ions (10), accountable for an n-type electronic conductivity. Cubic solid solutions with a fluorite-type structure may be obtained between stabilized zirconias and ceria in large ranges of composition (11).

The aim of the present work was to investigate the electrical transport properties of solid solutions between stabilized zirconia $0.9\text{ZrO}_2\text{-}0.1\text{Y}_2\text{O}_3$ and CeO_2 in order to define the ability of such compounds to be used as oxygen semipermeable membranes. This has been achieved by the study of the electrical conductivity and the investigation of the high temperature defect structure of the solid solutions $(0.9-y)\text{ZrO}_2\text{-}y\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$, $0 < y < 0.9$. The properties of the two compositions corresponding to $y = 0$ and $y = 0.9$ have been reported elsewhere (9, 12) and will not be considered further here.

Experimental

Sample preparation.—The solid solutions were prepared by solid-state reaction between the oxide pow-

ders: monoclinic zirconia (Ugine-Kuhlman), ceria (Rhône-Poulenc), and yttria (Pechiney), with a level of purity above 99.9%. Appropriate proportions of ZrO_2 , CeO_2 , and Y_2O_3 powders were mechanically mixed in acetone and dried for 12h at 500°C. The calcined materials were then isostatically pressed into rods and fired for 5h at 2073 K in air, in a laboratory-built furnace (6).

X-ray diffraction shows that the solid solutions $(0.9-y)\text{ZrO}_2\text{-}y\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$, with $0 \leq y \leq 0.9$, are characterized by a cubic fluorite-type structure, the lattice parameter of which increases linearly with the ceria content y (Fig. 1)

$$a = (5.145 + 0.243 = y)\text{Å}$$

The first term corresponds to the lattice parameter of stabilized zirconia as reported in Ref. (1). The lattice expansion occurs as a consequence of the substitution of zirconium ions by cerium ions, the ionic radius of which is greater ($\text{Zr}_{\text{VI}}^{4+} = 0.79\text{Å}$, $\text{Ce}_{\text{VI}}^{4+} = 0.9\text{Å}$) (13). The value of a obtained for $y = 0.9$ is in good agreement with the lattice parameter previously reported for the solid solution $0.9\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ (14).

Conductivity measurements.—The specimens used for total conductivity measurements were cut into cylinders.

Fig. 1. Dependence of the lattice parameter of the solid solutions $(0.9-y)\text{ZrO}_2\text{-}y\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ on composition.

Small grooves were then cut in the cylindrical sample to define the position of the electrodes. Platinum wires are tightly wrapped in the grooves around the sample and coated with platinum paste. The whole assembly is fired to improve the contacts and provide a good adhesion. The conductivity measurements were carried out in a platinum furnace between 1273 and 1673 K, over a large range of oxygen partial pressures, using a standard four-probe dc method. High oxygen partial pressures (10^{-1} - 10^{-5} MPa) were achieved by using Ar-O₂ mixtures, while lower oxygen chemical potentials were obtained with CO-CO₂ mixtures.

Measurements of defect concentrations.—As previously reported (12), the specific electrical properties of solid solutions containing cerium dioxide arise from the formation, at low oxygen activities, of oxygen vacancies and the simultaneous reduction of cerium ions from the tetravalent Ce⁴⁺ to the trivalent state Ce³⁺. Such a behavior must give rise to a weight loss of the samples, which can be measured by thermogravimetric techniques, and to a noticeable variation of their magnetic susceptibility: Ce³⁺ ions are paramagnetic, while all the other anions and cations present only a diamagnetic contribution. In order to get the various defect concentrations involved in the transport properties of these compounds, a thermogravimetry and magnetic susceptibility equipment for use at high temperatures was built. Since this apparatus has been previously described in detail (12), only the principle of operation is summarized below.

The composition of the solid solutions in the (T , $p_{O_2} = 10^{-1}$ MPa) states is taken as a stoichiometric reference and may be explicitly written $Zr_{0.818-y}Ce_yY_{0.182}O_{1.91}$. Under these conditions, the solid solutions are characterized by a weight p_1 and a molar susceptibility $\chi_M(1)$. Assuming that the additivity law of magnetic susceptibilities is satisfied (15), the latter quantity is equal to the sum of the molar diamagnetic contributions $\chi_M^d(k)$ of the various species k

$$\chi_M(1) = (0.818-y)\chi_M^d(Zr^{4+}) + y\chi_M^d(Ce^{4+}) + 0.182\chi_M^d(Y^{3+}) + 1.19\chi_M^d(O^{2-}) \quad [1]$$

The oxygen partial pressure is then gradually lowered below 10^{-1} MPa, under isothermal conditions; when equilibrium has been reached, the composition of the solid solutions departs from the "stoichiometric" composition by a value x , according to

The deviation from stoichiometry follows from the relationship

$$x = \frac{2(p_1 - p_2)M}{p_1 M(O_2)} \quad [2]$$

where M and $M(O_2)$ denote the mean molar weight of the solid solution and the molar weight of oxygen molecules, respectively, and p_2 the sample weight for $p_{O_2} \ll 10^{-1}$ MPa.

Owing to the formation of paramagnetic Ce³⁺ centers, the molar susceptibility of the nonstoichiometric sample, $\chi_M(2)$, differs from $\chi_M(1)$, and the difference, $\chi_M(2) - \chi_M(1)$, allows one to define a molar susceptibility $\chi_M(3)$. Assuming that the variation of the sample molar weight can be neglected in a first approximation, $\chi_M(3)$ is found from

$$\chi_M(3) = x[2\chi_M^p(Ce^{3+}) + 2\chi_M^d(Ce^{3+}) - 2\chi_M^d(Ce^{4+}) - \chi_M^d(O^{2-})]$$

or

$$\chi_M(3) = x[2\chi_M^p(Ce^{3+}) + C] \quad [3]$$

where $\chi_M^p(Ce^{3+})$ denotes the paramagnetic susceptibility

of the Ce³⁺ ion and C a correction for the diamagnetic contributions.

Results and Discussion

Electrical conductivity.—The general nature of the variations of the electrical conductivity with the oxygen partial pressure is similar for all compositions (Fig. 2-4), and three domains can be distinguished in the $\log \sigma - \log p_{O_2}$ plots. In the first one, for the highest oxygen partial pressures, the conductivity is constant or very slightly dependent on p_{O_2} . It has also been observed for the compositions $0.9ZrO_2-0.1Y_2O_3$ ($y = 0$) and $0.9CeO_2-0.1Y_2O_3$ ($y = 0.9$) (16). This domain shrinks as the ceria content y and/or the temperature increases. At lower oxygen partial pressures, the conductivity increases rapidly up to a maximum value and the rise of conductivity is the more important as the ceria content is higher. At low CeO₂ contents, for instance $y = 0.09$ (Fig. 2), the maximum is barely noticeable and disappears completely above 1573 K. Finally, for the lowest oxygen partial pressures, the conductivity strongly decreases down to a value lower than the conductivity level observed under oxidizing atmospheres.

At high oxygen activities, the conductivity is mostly ionic in nature, as found earlier for the compositions $y = 0$ and $y = 0.9$ (16). The conductivity takes place by motion of oxygen ions via vacancies and, for a given temperature, its value is fixed by the concentration of oxygen vacancies ($V_{O^{\cdot\cdot}}$)*, formed in the material as charge compensating defects when Y³⁺ ions substitute M⁴⁺ cations ($M = Zr^{4+}, Ce^{4+}$). According to the formalism of Kröger and Vink (17), this reaction is written as

The concentration of oxygen vacancies [$(V_{O^{\cdot\cdot}})^*$] is then only dependent on the yttria content.

Under reducing conditions, the increase of conductivity may be explained as in the case of doped ceria $0.9CeO_2-0.1Y_2O_3$ (12). In this domain, excess carriers, resulting from the displacement of the redox equilibrium between the two valence states of cerium ions

give rise to an electronic-type conductivity. The additional oxygen vacancies involved in this equilibrium are marked with a double asterisk, while those resulting from reaction [4] are marked with a single asterisk.

Fig. 2. Variation of the total electrical conductivity of $0.81ZrO_2-0.09CeO_2-0.1Y_2O_3$ vs. oxygen partial pressure.

Fig. 3. Variation of the total electrical conductivity of 0.63ZrO₂-0.27CeO₂-0.1Y₂O₃ vs. oxygen partial pressure.

On assuming that, as for nonstoichiometric pure or doped ceria (10), the electrons are localized on cerium sites and move in the lattice between cerium ions through a hopping process, the electronic part of the conductivity should be roughly proportional to the product of charge carriers concentration $[Ce_M']$ and the concentration of available sites $[Ce_M^X]$. According to this assumption, a decrease of p_{O_2} should displace Eq. [5] towards the right-hand side and should lead to an increase of the product $[Ce_M'] [Ce_M^X]$ and thus should enhance the conductivity. When the oxygen partial pressure is low enough to reduce a large fraction of the cerium ions to the trivalent state, the product $[Ce_M'] [Ce_M^X]$ and therewith the partial electronic conductivity should go through a maximum. This occurs when the concentrations of cerium ions in the two valence states are equal, each being half of the total concentration of cerium ions which is constant.

Fig. 4. Variation of the total electrical conductivity of 0.45ZrO₂-0.45CeO₂-0.1Y₂O₃ vs. oxygen partial pressure.

A maximum value is indeed observed in the $\log \sigma - \log p_{O_2}$ plots (Fig. 3 and 4). Similar results have been also reported for the binary solid solutions $(1-y)ZrO_2-yCeO_2$. For instance, in the case of 0.3ZrO₂-0.7CeO₂, a conductivity maximum has been observed by Gouet (18) and attributed to a $[Ce^{3+}]/[Ce^{4+}]$ ratio close to unity. According to Fehrenbacher and Tallan (19), the conductivity maximum of 0.8ZrO₂-0.2CeO₂ is once more related to the reduction of half the cerium ions to the trivalent state.

For the lowest oxygen partial pressures investigated here, it has been noticed that the conductivity level is lower than the value found for the ionic plateau in the vicinity of oxygen pressures of 10⁻¹ MPa. Nevertheless, under strongly reducing conditions, a major fraction of the cerium ions is reduced to the trivalent state and the value of the product $[Ce_M'] [Ce_M^X]$ should be very low. Then the conductivity should again present a predominant ionic character. This indicates that the ionic component of the conductivity is depressed by the presence of additional oxygen vacancies resulting from the reduction of the Ce⁴⁺ ions (Eq. [5]). Indeed, it has been clearly shown that, from a given content of dopant oxide [of the order of 10 mole percent (m/o) in the case of Y₂O₃ (20)], the ionic conductivity of stabilized zirconias decreases when additional heterovalent cations are added. In the present case, beyond the concentration of oxygen vacancies initially fixed by the yttria content (10 m/o), the ionic conductivity should gradually decrease during the reduction of the Ce⁴⁺ ions.

As a consequence, the observed maximum of the $\log \sigma - \log p_{O_2}$ plots does not necessarily correspond to a quantitative equipartition of cerium ions between the Ce⁴⁺ and Ce³⁺ states, since a decrease of the total conductivity may be partly induced by a lowering of the ionic component. Therefore, the knowledge of the reduction rate of cerium ions seems to be of prime importance in explaining the transport properties of the $(0.9-y)ZrO_2-yCeO_2-0.1Y_2O_3$ solid solutions. This will be treated below.

Structural considerations.—It is generally admitted that the decrease of the ionic conductivity of fluorite-type solid solutions for high contents of oxygen vacancies is related to the formation of associated defects or defect ordering (21). In the case of the cubic solid solutions between zirconia and trivalent lanthanide oxides Ln₂O₃, order-disorder transitions have been observed in a range of composition which depends, to a first approximation, on the ratio of the cationic radii of Zr⁴⁺ and Ln³⁺ ions (22). Moreover, the results obtained by Negas *et al.* (23) have shown that the reduction of Ce⁴⁺ ions at low oxygen activities may induce the ZrO₂-CeO₂ cubic solid solutions to form ordered compounds with a pyrochlore-type structure. Concerning the $(0.9-y)ZrO_2-yCeO_2-0.1Y_2O_3$ solid solutions, under low p_{O_2} , the reduction of cerium ions to the trivalent state generates, within the cationic and anionic sublattices, large amounts of atomic and electronic defects which may induce such order-disorder phenomena. The structure of these materials, quenched after an anneal under reducing conditions, therefore, has been analyzed by x-ray techniques.

For low ceria contents, for instance 0.81ZrO₂-0.09CeO₂-0.1Y₂O₃, after annealing under $p_{O_2} = 10^{-15}$ MPa at 1373 K, the x-ray diffraction patterns exhibit any characteristic line of a pyrochlore-type ordered phase. A similar result has been obtained for the composition 0.72ZrO₂-0.18CeO₂-0.1Y₂O₃ which consists of a single phase having a fluorite-type structure. However, its lattice parameter increases with the rate of reduction, owing to the fact that the cationic radius of Ce³⁺ is higher than that of Ce⁴⁺ (13); it rises from $a_F = 5.194\text{\AA}$ for $p_{O_2} = 10^{-1}$ MPa to $a_F = 5.197\text{\AA}$ for $p_{O_2} = 10^{-11}$ MPa and $a_F = 5.207\text{\AA}$ for $p_{O_2} = 10^{-17}$ MPa.

For higher concentrations of ceria, an ordered phase has been observed only after long time annealings (~100h). A second phase having a pyrochlore-type structure seems to gradually precipitate in the disordered fluorite-type matrix, the size of the pyrochlore domains increasing very slowly owing to the low kinetics of cation

diffusion (24). The lattice parameter of the pyrochlore-type phase $a_p = 10.530\text{\AA}$ is about twice the lattice parameter of the fluorite-type phase $a_f = 5.320\text{\AA}$, the defect ordering in the anionic and cationic sublattices inducing a double cell for the crystal structure.

The effect of such a second phase on the electrical transport properties should be taken into account. In the case of binary $\text{ZrO}_2\text{-Ln}_2\text{O}_3$ systems, the formation of a pyrochlore-type structure is generally related to a decrease of the ionic conductivity (25). Thus, in the present case, even if, for low CeO_2 content, there is a small decrease of the conductivity under low oxygen activities which may probably be explained on the basis of interactions between oppositely charged defects, for higher ceria contents, the very low kinetics for the solid-gas phase equilibria and the rapid decrease of the conductivity under reducing conditions must be partly related to the formation of pyrochlore-type domains. This result has been confirmed by the analysis of the high temperature defect structure.

Correlations between defect structure and transport properties.—As a result of the previous considerations, two distinct compositions have been investigated between 1273 and 1473 K, using the techniques of thermogravimetry and measurement of magnetic susceptibilities.

Solid solution with low ceria content: $0.81\text{ZrO}_2\text{-}0.09\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$.—The various defect concentrations have been measured as presented in the experimental section.

The departure from stoichiometry x of the $0.81\text{ZrO}_2\text{-}0.09\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ solid solution has been deduced from the thermogravimetric measurements, using Eq. [2], and is plotted in Fig. 5 vs. the oxygen partial pressure. For a given temperature, in the whole range of oxygen partial pressure investigated here x varies closely as $p_{\text{O}_2}^{-1/4}$. Moreover, the deviation from stoichiometry is relatively small, and the charge balance relationship between the defect concentrations is

$$[\text{V}_{\text{O}^{\cdot\cdot}}] = [(\text{V}_{\text{O}^{\cdot\cdot}})^*] = 1/2 [\text{Y}_{\text{M}}'] \gg [(\text{V}_{\text{O}^{\cdot\cdot}})^{**}] = 1/2 [\text{Ce}_{\text{M}}'] \quad [6]$$

where $[\text{V}_{\text{O}^{\cdot\cdot}}]$ denotes the total oxygen vacancy concentration.

On assuming that the concentration of Ce^{3+} ions is low enough to obey the dilute solution laws, the equilibrium constant K relative to Eq. [5] may be written using the concentration of Ce_{M}' species instead of its activity

$$K = \frac{a_{\text{V}_{\text{O}^{\cdot\cdot}}} [\text{Ce}_{\text{M}}']^2}{a_{\text{O}_2} a_{\text{Ce}_{\text{M}}^x}} p_{\text{O}_2}^{1/2} \quad [7]$$

In the domain defined by the electroneutrality relation [6], the activities $a_{\text{V}_{\text{O}^{\cdot\cdot}}}$, a_{O_2} , and $a_{\text{Ce}_{\text{M}}^x}$ may be considered as essentially constant, and it follows from Eq. [7]

$$[\text{Ce}_{\text{M}}'] = 2 [(\text{V}_{\text{O}^{\cdot\cdot}})^{**}] \propto p_{\text{O}_2}^{-1/4} \quad [8]$$

The same $p_{\text{O}_2}^{-1/4}$ dependence is then expected for x , since

$$x = [(\text{V}_{\text{O}^{\cdot\cdot}})^{**}] = 1/2 [\text{Ce}_{\text{M}}'] \quad [9]$$

The susceptibility $\chi_{\text{M}}(3)$, deduced from magnetic measurements, should follow the same p_{O_2} dependence as x , and, according to Eq. [3], a direct proportionality should be observed between $\chi_{\text{M}}(3)$ and x . Indeed, the $\log \chi_{\text{M}}(3)$ vs. $\log x$ plots are straight lines with slopes close to unity (Fig. 6).

The concentration of the different defects, $\text{V}_{\text{O}^{\cdot\cdot}}$ and Ce_{M}' , involved in the transport properties have been deduced from the values of x and $\chi_{\text{M}}(3)$, using Eq. [9] and [3]. However, it is not allowed to relate the partial, ionic or electronic conductivity σ_k of these materials to their respective charge carrier concentration C_k , i.e., $[\text{V}_{\text{O}^{\cdot\cdot}}]$ or $[\text{Ce}_{\text{M}}']$, by the classical relationship

$$\sigma_k = Z_k q C_k v_k$$

where Z_k and v_k denote the valence and the mobility of species k and q the electronic charge.

Fig. 5. Variation of the departure from stoichiometry of $0.81\text{ZrO}_2\text{-}0.09\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ vs. oxygen partial pressure.

Indeed, it is now accepted (26) that the ionic conductivity σ_i of fluorite-type solid solutions does not depend linearly on the concentration of oxygen vacancies. Furthermore, in the present case, we have considered a decrease of σ_i when additional oxygen vacancies are created under reducing conditions. Nevertheless, it has been shown in a previous paper (12) that the decrease of the ionic conductivity in such fluorite-type solid solutions is analogous to that observed for stabilized zirconias when additional oxygen vacancies are generated by additions of trivalent Y^{3+} ions (20) and may be accurately approximated by the same empirical laws. Using the same treatment, the variations of σ_i vs. p_{O_2} have been deduced from the values of $[\text{V}_{\text{O}^{\cdot\cdot}}]$ given by the thermogravimetric measurements; the electronic part of the conductivity is then obtained by difference between the total conductivity σ_t and σ_i

Fig. 6. Dependence of the magnetic susceptibility $\chi_{\text{M}}(3)$ on the departure from stoichiometry of $0.81\text{ZrO}_2\text{-}0.09\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$.

Fig. 7. Plots of the defect concentrations $[V_{O}^{\cdot-}]$ and $[Ce_M']$ and of the conductivities σ_t and σ_i vs. oxygen partial pressure, at 1373 K.

$$\sigma_e(p_{O_2}) = \sigma_t(p_{O_2}) - \sigma_i(p_{O_2})$$

Figures 7 and 8 show the p_{O_2} dependence of the concentrations of charge carrier $[V_{O}^{\cdot-}]$ and $[Ce_M']$ and the partial conductivities obtained according to this procedure at two temperatures, 1373 and 1473 K, for $0.81ZrO_2-0.09CeO_2-0.1Y_2O_3$.

For the highest oxygen partial pressures ($p_{O_2} > 10^{-6}$ MPa), the conductivity is mostly ionic and constant. In-

Fig. 8. Plots of the defect concentrations $[V_{O}^{\cdot-}]$ and $[Ce_M']$ and of the conductivities σ_t , σ_i , and σ_e vs. oxygen partial pressure, at 1473 K.

deed, in this domain, $[V_{O}^{\cdot-}]$ does not depend on p_{O_2} since the content of oxygen vacancies resulting from the reduction of Ce_M^x ions is negligible compared to that fixed by the Y_2O_3 content. Under reducing conditions, according to the relationship [8], deduced on the basis of a model of randomly distributed and noninteracting electronic defects, the concentration $[Ce_M^x]$ varies approximately as $p_{O_2}^{-1/4}$. The observed decrease of the total conductivity is here directly related to the decrease of its ionic component and, at 1373 K (Fig. 7), the values of σ_i calculated for the lowest oxygen partial pressures are in good agreement with the measured values of σ .

At higher temperatures, for instance, at 1473 K (Fig. 8), the effect of the electronic component σ_e on the variation of σ_t is no longer negligible. Furthermore, it will be noticed that, for the lowest oxygen partial pressures, the major part of cerium ions are reduced to the trivalent state and the ratio $[Ce_M^x]/[Ce_M^{\cdot}]$ is larger than unity. The electronic conductivity σ_e , which is proportional to $[Ce_M^x]/[Ce_M^{\cdot}]$, would then decrease for more reducing conditions. However, σ_e is of the same order of magnitude as σ_i for an oxygen partial pressure $p\theta$ of about 10^{-12} - 10^{-13} MPa. For $0.9CeO_2-0.1Y_2O_3$ ($y = 0.9$), the partial pressure $p\theta$ corresponding to the condition $\sigma_i = \sigma_e$ is equal to $\approx 10^{-8}$ MPa at the same temperature (12). Such a lowering of the parameter $p\theta$ results from a decrease of the electronic conductivity due to a lower electronic mobility. Indeed, for a deviation from stoichiometry $x = 1.7 \cdot 10^{-2}$, the electronic mobility in $0.81ZrO_2-0.09CeO_2-0.1Y_2O_3$ is equal to $v_e = 3.1 \cdot 10^{-8} m^2V^{-1}s^{-1}$, while under the same conditions the electronic mobility of $0.9CeO_2-0.1Y_2O_3$ is at least a factor of ten higher (12). Owing to the order of magnitude of v_e , one may reasonably attribute the electronic conductivity of the solid solutions $(0.9-y)ZrO_2-yCeO_2-0.1Y_2O_3$ to a small polaron mechanism with electrons localized on cerium sites, as in the case of pure or doped nonstoichiometric ceria (10). As a consequence, the variation of the electronic mobility with respect to the composition should be related to a change of the probability for an electron to jump from a localized site to another, which is expected to be a decreasing function of the jump distance (27).

Solid solution with high CeO₂ content: $0.45ZrO_2-0.45CeO_2-0.1Y_2O_3$.—The properties of the solid solution $0.45ZrO_2-0.45CeO_2-0.1Y_2O_3$ are in part similar to those of $0.81ZrO_2-0.09CeO_2-0.1Y_2O_3$. Indeed, in a limited range of oxygen partial pressure, the size of which shrinks when the temperature increases, the departure from stoichiometry x follows the same $p_{O_2}^{-1/4}$ dependence (Fig. 9), and the proportionality relationship between the susceptibility $\chi_M(3)$ and x is also observed. Beyond this domain, the deviation from stoichiometry increases rapidly and any solid-gas phase equilibrium has not been reached even after 100h. For this reason, the values of x reported in Fig. 9 for the lowest oxygen partial pressures, at 1373 and 1473 K, do not correspond to equilibrium conditions.

The lower limit of the domain with a $p_{O_2}^{-1/4}$ dependence is observed for an oxygen partial pressure of 10^{-12} MPa about at 1373 K and 10^{-10} MPa at about 1473 K. This is approximately equal to the oxygen partial pressure corresponding to the conductivity maximum of the $\log \sigma - \log p_{O_2}$ plots (Fig. 4). Owing to the results of x-ray analysis, which show an ordered phase with a pyrochlore-type structure for lower oxygen activities, the rapid increase of x can be reasonably attributed to the formation of a two-phase system which consists of a disordered fluorite-type matrix into which pyrochlore-type ordered domains gradually precipitate.

The defect concentrations $[V_{O}^{\cdot-}]$ and $[Ce_M^x]$ and the partial conductivities σ_i and σ_e were deduced or calculated using the same steps as in the case of $0.81ZrO_2-0.09CeO_2-0.1Y_2O_3$. Typical results obtained at 1373 K are plotted in Fig. 10. It should be observed that, in opposition with the previous case, the electrical conductivity of $0.45ZrO_2-0.45CeO_2-0.1Y_2O_3$ is mostly electronic in na-

Fig. 9. Dependence of the departure from stoichiometry of $0.45\text{ZrO}_2\text{-}0.45\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ on oxygen partial pressure.

ture, since the electronic component is equal to the ionic one for a higher oxygen partial pressure $p\Theta \approx 10^{-6}$ MPa. For oxygen partial pressures lower than about 10^{-12} MPa, the total conductivity rapidly decreases, although the concentrations of oxygen vacancies and Ce^{3+} ions strongly increase. This will be due to the formation of pyrochlore-type ordered domains, the conductivity of which would be lower. Indeed, the relation between the conductivity maximum and an equipartition of cerium ions between the two valence states Ce^{3+} and Ce^{4+} (the hypothesis proposed by various authors to explain the electrical properties of ceria-based solid solutions) is no longer accurate in the present case, since for the oxygen

Fig. 10. Plots of the defect concentration $[\text{V}_{\text{O}}^{\cdot\cdot}]$ and $[\text{Ce}_{\text{M}}^{\cdot}]$ and of the conductivities σ_{iv} , σ_{iv} , and σ_{e} vs. oxygen partial pressure, at 1373 K.

partial pressure corresponding to a maximum of conductivity, $p_{\text{O}_2} \sim 10^{-11}$ MPa at 1373 K, only about 6% of cerium ions are reduced in the trivalent state. Furthermore, the decrease of σ_{e} cannot be simply explained on the basis of a decrease of the ionic component σ_{i} , since, close to the maximum, the total conductivity is practically equal to its electronic component σ_{e} . It must be then assumed that the formation of the ordered domains induces an important decrease of the electronic conductivity, and, more precisely, owing to the rapid increase of the charge carrier concentration $[\text{Ce}_{\text{M}}^{\cdot}]$ in this domain, a decrease of the electronic mobility.

Conclusion

The study of mixed ionic and electronic conductors belonging to the $\text{ZrO}_2\text{-CeO}_2\text{-Y}_2\text{O}_3$ system has been motivated by the potential applications of these materials as oxygen semipermeable membranes in various processes involving an oxygen extraction at high temperature. This is particularly the case for the production of gaseous fuels, such as H_2 or CO , by direct thermal splitting of H_2O or CO_2 and extraction of the oxygen arising from the dissociation reaction (25). At the temperatures of 1873-2273 K required for the decomposition reaction (25), it has been previously shown that the material used as semipermeable membrane should present, in a given range of oxygen partial pressure $[p_{\text{O}_2}(\text{I}), p_{\text{O}_2}(\text{II})] = (10^{-3}, 10^{-7}$ MPa) (25), a mixed electrical conductivity with equivalent ionic and electronic components. It is therefore interesting to compare the transport properties of the $(0.9-y)\text{ZrO}_2\text{-}y\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ solid solutions to the requirements of such processes. The oxygen partial pressure $p\Theta$, for which these materials exhibit equal ionic and electronic partial conductivities, should be thus of the same order of magnitude as the partial pressures $p_{\text{O}_2}(\text{I})$ and $p_{\text{O}_2}(\text{II})$.

The conditions of temperature and oxygen partial pressure required for these techniques correspond to the hatched domain of Fig. 11. The different values of the parameter $p\Theta$, obtained for the $(0.9-y)\text{ZrO}_2\text{-}y\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$

Fig. 11. Temperature dependence of the oxygen partial pressure $p\Theta$ in the case of stabilized zirconia (●) (9), $0.45\text{ZrO}_2\text{-}0.45\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ (▲), and $0.81\text{ZrO}_2\text{-}0.09\text{CeO}_2\text{-}0.1\text{Y}_2\text{O}_3$ (□). The hatched domain corresponds to the temperature and oxygen partial pressure working conditions of oxygen semipermeable membranes.

solid solutions from the thermogravimetric and magnetic susceptibility measurements, are reported in the same figure. As a reference, the temperature dependence of $p\theta$ of the stabilized zirconia, primarily used as oxygen semipermeable membrane (9), is also plotted in Fig. 11.

As previously stated (9), stabilized zirconia is not an attractive material for applications as oxygen semipermeable membranes, since the corresponding values of $p\theta$ are much lower than the oxygen partial pressures $p_{O_2}(I)$ and $p_{O_2}(II)$. The solid solutions (0.9- y)ZrO₂- y CeO₂-0.1Y₂O₃ appear to be more appropriate. For the composition $y = 0.45$, the values of the partial pressures $p\theta$ extrapolated at high temperature are of the same order of magnitude as the pressures $p_{O_2}(I)$ and $p_{O_2}(II)$. However, the solid solution 0.45ZrO₂-0.45CeO₂-0.1Y₂O₃ gives rise, under reducing conditions, to large departures from stoichiometry and to pyrochlore-type ordered domains which have a detrimental effect on the electrical properties. The oxygen partial pressure for which this second phase has been observed increases rapidly with the temperature, and, consequently, this composition is not suitable for such applications.

The formation of an ordered phase has been observed also for solid solutions with higher concentrations of ceria, for instance, $y = 0.63$ (25), so that it seems more advisable to use solid solutions with a ceria content low enough to keep the structure disordered, in ranges of temperature and oxygen partial pressure of interest for such processes.

The use of a composition with about 20 m/o of cerium oxide appears to be a good solution, since the values of the parameter $p\theta$ will be appreciably higher than in the case of $y = 0.09$, about $10^{-11.5}$ MPa at 1473 K, owing to the increase of the electronic conductivity level arising from a higher ceria content. Moreover, such a solid solution does not correspond to the composition range for which the pyrochlore-type phase is observed (25). Indeed, the x-ray analysis of the solid solution 0.72ZrO₂-0.18CeO₂-0.1Y₂O₃, annealed under various reducing atmospheres ($p_{O_2} = 10^{-11}$ - 10^{-17} MPa), clearly shows that this material is a single, fluorite-type, phase.

For these reasons, the composition 0.72ZrO₂-0.18CeO₂-0.1Y₂O₃ has been used to prepare oxygen semipermeable membranes, which are presently under investigation. Preliminary results show that the oxygen semipermeability of such membranes is higher by about a factor of 50 than the oxygen semipermeability of membranes made of "classical" stabilized zirconia (28).

Reactions of NaCl with Gaseous SO₃, SO₂, and O₂

W. L. Fielder, C. A. Stearns, and F. J. Kohl

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

Hot corrosion of gas turbine engine components involves deposits of Na₂SO₄ which are produced by reactions between NaCl and oxides of sulfur. For the present investigation, NaCl single crystals were exposed at 100°–850°C to gaseous mixtures of SO₃, SO₂, and O₂. The products formed during this exposure depend, primarily, on the temperatures. The four product films were NaCl · SO₃, Na₂S₂O₇, Na₂SO₄, and NaCl-Na₂SO₄. The kinetics of the reactions were measured.

Hot corrosion degradation of components of gas turbine engines burning relatively clean fuels usually involves deposits of only Na₂SO₄. Two processes have been proposed to account for the deposits: (i) deposition by impaction of NaCl particles on the turbine surfaces and subsequent reaction of the condensed NaCl with oxides of sulfur, and (ii) reaction in the hot combustion stream to form Na₂SO₄ with subsequent deposition. Some previous investigators have observed the conversion of NaCl to Na₂SO₄ under real or simulated combustion atmospheres in the presence of oxide scales on turbine-type substrates (1-3). Such experiments, while verifying that conversion of NaCl to Na₂SO₄ does occur, did not clearly differentiate between processes (i) and (ii). Furthermore, the influence of the substrates, used in these experiments, upon the rates of conversion was still unclear.

The present study was concerned primarily with observing the surface reactions occurring when solid NaCl is exposed to oxides of sulfur (*i.e.*, the reaction in process (i) that might occur after NaCl impaction) over a broad temperature range without the influence of oxide scales or turbine-type substrates. Therefore, NaCl, either as single crystal or as a 1:1 powder mixture with Na₂SO₄, was exposed to gaseous mixtures of SO₃ in SO₂-O₂ between 100° and 850°C. The products and kinetics of the reactions were determined.

Experimental

Samples of single-crystal NaCl were obtained by cleaving from a high purity boule grown from the melt. For a few runs, samples of anhydrous powder mixtures of 1:1 molar NaCl and Na₂SO₄ were prepared by melting high purity NaCl and Na₂SO₄ at 700°C. Anhydrous, high purity mixtures of SO₂ in O₂ were obtained commercially or were prepared in-house by pressure dilutions from commercial SO₂ and O₂.

The sample was suspended (inside a quartz tube) from a sensitive electrobalance. The sample was maintained at the desired temperature, exposed to the SO₂-O₂ mixture, and the weight change was followed with time. For most of the runs, the flow rates of the mixtures were about 17 cm³ s⁻¹ (3.4 cm s⁻¹). A Pt catalyst was used to produce the desired concentration of SO₃ in the SO₂-O₂ mixture.

For the anhydrous runs, the H₂O contents in the gaseous atmospheres were less than 20–40 ppm as indicated by hydrometric analyses. For a few runs, the influence of H₂O was observed by introducing it into the system by dilution by passing a parallel O₂ flow through an H₂O bubbler. For these runs, the H₂O content was determined with sufficient accuracy using vapor pressure data and measured flow rates.

High pressure mass spectrometric sampling techniques were used to analyze the gaseous reactant compositions and to identify the gaseous products. The apparatus and techniques have been discussed previously (4). This technique facilitates determination of the concentrations of the gaseous reactants and/or products being produced under the actual experimental conditions because it effectively "freezes" the chemical composition of the gas flow. For the mass spectrometer SO₂ calibration curves, mixtures of SO₂ and O₂ of known compositions were used. A commercial SO₃ analyzer was used initially to determine

the absolute SO₃ concentration produced in a mixture of SO₂-O₂ flowing over the Pt catalyst. At the same time, the mass spectrometer calibration curve was obtained using these SO₃ results and recorded mass peak intensities for SO₃, SO₂, SO, and O₂.

Results and Discussion

The product films formed on the NaCl surface, when it is exposed to oxides of sulfur, depend primarily upon the temperature of exposure. The four films observed were solid NaCl · SO₃, molten Na₂S₂O₇, solid Na₂SO₄, and molten Na₂SO₄-NaCl.

Solid NaCl · SO₃.—A solid film of NaCl · SO₃ forms when NaCl at 100°–150°C is exposed to SO₃

This reaction has been previously used as an analytical method for determining SO₃ concentrations in the presence of SO₂ and O₂ (5).

The rate of formation of the solid product film of NaCl · SO₃ at 150°C was obtained by exposing a NaCl sample to a SO₂-O₂ mixture containing 0.1 mole percent (m/o) SO₃. The weight of the sample initially increased linearly with time (at about 2.7 × 10⁻⁴ mg cm⁻² s⁻¹) for about 1 h. Then, the sample weight increased parabolically (as shown in Fig. 1) with a rate constant, *k*, of about 2.4 × 10⁻¹⁰ g² cm⁻⁴ s⁻¹ suggestive of a mass-transfer control process.

The rate-limiting process for the formation of the NaCl · SO₃ film is still uncertain. A solid-state diffusion process does not seem likely because it should be characterized by smaller parabolic rate constants. And, even though a reasonable value of about 2 × 10⁻⁵ cm² s⁻¹ can be calculated for a diffusion coefficient, *D*, mass transfer of SO₃ through a liquid film (as the rate-limiting process) also does not seem likely since no evidence of a liquid film was observed at 150°C. This value of 2 × 10⁻⁵ was calculated by assuming the approximate relation of *k* = 2*DCd* where the concentration of SO₃ in the gas, *C*, was

Fig. 1. Plot of (weight gain)² with time for the exposure of single-crystal NaCl to 0.1 m/o anhydrous SO₃ at 150°C (flow rate of 17 cm³ s⁻¹).

$3.6 \times 10^{-6} \text{ g cm}^{-3}$ and a value of 2 g cm^{-3} was estimated for the density of the film, d .

Molten $\text{Na}_2\text{S}_2\text{O}_7$.—Between 400° and 450°C , molten $\text{Na}_2\text{S}_2\text{O}_7$ is the principal film product formed when NaCl is exposed to oxides of sulfur

Based on weight gain measurements, a mass-balance calculation showed that the film produced at 420°C , after about 10 min, was molten $\text{Na}_2\text{S}_2\text{O}_7$, with only a slight excess of SO_3 . The sample was exposed for 1.5h at 420°C (i.e., to build up a film for analysis) and then quenched to minimize any further change in the film composition. Examination of the sample after quenching indicated that the film had been molten. X-ray analysis of a small portion of the film showed only $\text{Na}_2\text{S}_2\text{O}_7$, Na_2SO_4 , and the NaCl substrate. After reheating this film to about 500°C in flowing O_2 for about 12h, the $\text{Na}_2\text{S}_2\text{O}_7$ was converted to a porous nonadhering film of Na_2SO_4 as indicated by x-ray analysis. Therefore, for the temperature range of 400° to about 450°C , molten $\text{Na}_2\text{S}_2\text{O}_7$ is the principal film product that is formed.

The rate of formation of the $\text{Na}_2\text{S}_2\text{O}_7$ (and Na_2SO_4) film was determined at 415°C by exposing a NaCl single crystal to an anhydrous mixture of 0.1 m/o SO_3 in SO_2 - O_2 . As shown in Fig. 2, the rate of weight change was parabolic with a rate constant of $5.8 \times 10^{-9} \text{ g}^2 \text{ cm}^{-4} \text{ s}^{-1}$ from which a diffusion coefficient of about $4 \times 10^{-4} \text{ cm}^2 \text{ s}^{-1}$ was calculated. This value is in reasonable agreement with those values usually obtained for diffusion processes in liquids and in particular with the value of about $2 \times 10^{-4} \text{ cm}^2 \text{ s}^{-1}$ reported for the diffusion of $\text{S}_2\text{O}_7^{2-}$ ions in molten Na_2SO_4 (6), and for SO_3 in a chloride melt (7).

The exact mechanism for the $\text{Na}_2\text{S}_2\text{O}_7$ film formation is still unclear. However, it seems reasonable to propose that, initially, a very thin film of Na_2SO_4 may form at the NaCl surface. Subsequently, as suggested by the thermodynamic data (8) for the equilibrium between SO_4^{2-} and $\text{S}_2\text{O}_7^{2-}$, the ratio of $\text{Na}_2\text{S}_2\text{O}_7$ to Na_2SO_4 at equilibrium should be of the order of 10:1 for a SO_3 concentration of 0.1 m/o. Consequently, Na_2SO_4 formed at the NaCl surface at 415°C should convert, essentially, to molten $\text{Na}_2\text{S}_2\text{O}_7$.

Solid Na_2SO_4 .—The reactions that occur when NaCl is exposed at 450° to 625°C to SO_2 and O_2 mixtures containing SO_3 are

High pressure mass spectrometry showed that Cl_2 is the principal gaseous product produced during the reaction under anhydrous conditions while HCl is evolved when

Fig. 2. Plot of (weight gain)² with time for the exposure of single-crystal NaCl to 0.1 m/o anhydrous SO_3 at 415°C (flow rate of $17 \text{ cm}^3 \text{ s}^{-1}$).

reasonable quantities of H_2O are present. Chemical and x-ray analyses revealed that solid Na_2SO_4 is the principal film product that forms on the NaCl surface in this temperature range. These films, unlike the $\text{Na}_2\text{S}_2\text{O}_7$ films at 420°C , are porous and are removed easily from the NaCl crystal upon cooling. This predominance of Na_2SO_4 over $\text{Na}_2\text{S}_2\text{O}_7$ for this temperature range is in agreement with the Na_2SO_4 - $\text{Na}_2\text{S}_2\text{O}_7$ concentrations as calculated from the thermodynamic data. For example, for a SO_3 concentration of 0.1 m/o, the calculated Na_2SO_4 concentration exceeds that of $\text{Na}_2\text{S}_2\text{O}_7$ at about 450°C and becomes increasingly larger with increasing temperature.

Experiments showed that SO_3 was the key reactant rather than SO_2 . For example, the rate of formation of Na_2SO_4 at 500°C was almost three orders of magnitude faster for the anhydrous system when a Pt catalyst was present. For both of these systems, the SO_2 levels were comparable, but the SO_3 concentration was negligible for the system without the catalyst.

Weight gain rates were obtained at varying flow rates. A typical curve is shown in Fig. 3. Both the anhydrous and the H_2O containing systems gave similar types of curves except that the rates of weight gain were larger when H_2O was present. For the system shown in Fig. 3, the rates of weight gain became independent of flow rate above $5 \text{ cm}^3 \text{ s}^{-1}$. Therefore, for this system shown in Fig. 3, mass transfer in the gas phase above the sample should not be rate limiting for flow rates greater than about $5 \text{ cm}^3 \text{ s}^{-1}$.

The weight gains were measured with time (at flow rates where the rates of weight gains are independent of flow rates). A typical curve for an anhydrous system is shown in Fig. 4 (at a flow rate of $10 \text{ cm}^3 \text{ s}^{-1}$) for the exposure at 465°C . Similar types of curves were obtained for the system containing 0.1 m/o H_2O , for comparable quantities of SO_3 , except that the weight gains were almost an order of magnitude larger than for the anhydrous system. As seen in Fig. 4, the weights for the anhydrous systems increased linearly with time (i.e., the rate was essentially constant with time). Also, mass spectrometry results showed that the rates of formation of Cl_2 and HCl were essentially constant with time.

The rates of weight gain were first order with SO_3 pressure for the anhydrous systems and first order with H_2O content for those systems containing varying concentrations of H_2O . Typical curves are shown in Fig. 5. Likewise, the rates of formation of HCl were shown by mass spectrometry to be first order with H_2O concentrations.

Arrhenius-type plots are shown for both systems in Fig. 6 where the data has been normalized to 0.1 m/o SO_3 . For the anhydrous systems, the rate K , expressed in units of $\text{mg cm}^{-2} \text{ s}^{-1}$, is

$$K = 0.6 P_{\text{SO}_3} \exp(-22,000/RT) \quad [4]$$

Fig. 3. Plot of rates of specific weight gain with flow rates for the exposure of single-crystal NaCl to 0.3 m/o H_2O and 0.01 m/o SO_3 at 550°C .

Fig. 4. Plot of total weight gain with time for the exposure of single-crystal NaCl to 0.1 m/o anhydrous SO_3 at 465°C (flow rate of $10 \text{ cm}^3 \text{ s}^{-1}$).

where pressure is in units of atmospheres. The values for the activation energy and pre-exponential factor are quite small, being about $22 \text{ kJ mol}^{-1} \text{ K}^{-1}$ and $0.6 \text{ mg cm}^{-2} \text{ s}^{-1} \text{ atm}^{-1}$, respectively. For the systems containing 0.09 m/o H_2O , the rates of weight gain were almost an order of magnitude faster than for the anhydrous systems, but the slope was essentially zero.

It is proposed that the limiting process for the formation of a solid Na_2SO_4 film between 450° and 625°C , under anhydrous conditions, is the kinetics of the reaction of SO_3 at the NaCl surface since the rate of formation of the product film was constant with time (e.g., Fig. 4). This is in agreement with a chemical control process where the rate of reaction should be independent of the product layer thickness. A mass-transfer control process (in pores or solid state) seems unlikely since this process is characterized by diminishing reaction rates with time as the product layer becomes thicker. Furthermore, a boundary-layer diffusion process in the gas phase does not seem likely because the measurements were made at flow rates where the rates of weight gain were independent of flow rate. Furthermore, boundary layer diffusion rates should not change radically as the temperature was increased from 620° to 640°C , but the rates of weight gain of a NaCl single crystal were found to increase rather sharply at about 630°C (to be discussed later).

Because the observed activation energy value is small, it is believed that no strong bonds are being broken, and, indeed, a low energy process has been proposed for the formation of Na_2SO_4 (9). For this process a planar SO_4 species (produced from SO_2 and O_2) and SO_3 are absorbed

Fig. 5. Plot of rates of specific weight gain with concentration for the exposure of single-crystal NaCl to SO_3 and H_2O (flow rate of $17 \text{ cm}^3 \text{ s}^{-1}$).

Fig. 6. Plot of rates of the specific weight gain with t^{-1} for the exposure of single-crystal NaCl to 0.1 m/o SO_3 under anhydrous and moisture conditions (flow rate of $17 \text{ cm}^3 \text{ s}^{-1}$).

upon the NaCl surface to form a S_2O_7 transition species where the SO_3 and SO_4 are connected by an O—O bond. Rearrangement and Cl_2 oxidation (i.e., electron transfer) leads to a trigonal pyramidal $\text{S}_2\text{O}_7^{-2}$. It was suggested that the rate-limiting step, which requires only a relatively small energy, may involve the transformation of this species to the tetrahedral $\text{Na}_2\text{S}_2\text{O}_7$. Any $\text{Na}_2\text{S}_2\text{O}_7$ so produced is in equilibrium with Na_2SO_4 . Because Na_2SO_4 is the more stable species at these temperatures, the $\text{Na}_2\text{S}_2\text{O}_7$ will then decompose to give solid Na_2SO_4 at the NaCl surface.

As indicated previously (Fig. 6), the rates of weight gain with temperature for the systems containing 0.09 m/o H_2O could be fitted to one straight line with a slope of essentially zero (at about $1.5 \times 10^{-4} \text{ mg cm}^{-2} \text{ s}^{-1}$). No postulate can be put forward at this time to explain the observed lack of an activation energy for this process.

Molten Na_2SO_4 -NaCl.—Initial experiments showed that the rates of weight gain increased sharply (by at least an order of magnitude) when the single-crystal NaCl temperature was raised above 625°C during exposure to SO_3 - SO_2 - O_2 atmospheres. Samples held at temperatures above 640°C for short intervals and then quenched showed a molten film mixture of Na_2SO_4 and NaCl on the surface, as determined by sulfate and chloride analyses. This is in agreement with the phase diagram which shows that a eutectic is formed at about 625°C (10).

Similar results were obtained when solid mixtures of 1:1 Na_2SO_4 and NaCl were exposed to SO_3 . For example, upon exposing this sample mixture to 0.1 m/o SO_3 between 620° and 630°C , the sample melted and the rate of weight gain above 625°C increased rather sharply by almost an order of magnitude. For data taken after relatively short times, the rate of weight gain remained essentially constant at about $10^{-3} \text{ mg cm}^{-2} \text{ s}^{-1}$ over the range of 650° - 850°C .

The reaction of SO_3 with the NaCl in the molten 1:1 mixture of NaCl and Na_2SO_4 (contained in a crucible) was studied by exposing it between 700° and 750°C to SO_2 - O_2 mixtures, containing 0.1 m/o SO_3 , at flow rates of about $17 \text{ cm}^3 \text{ s}^{-1}$. The data, normalized to 0.1 m/o SO_3 , is shown in Fig. 7. A rate constant of $7.0 \times 10^{-10} \text{ g}^2 \text{ cm}^4 \text{ s}^{-1}$ was obtained from the parabolic curve suggestive of a mass-transfer control process. It is proposed, that for temperatures above 625°C , SO_3 reacts with NaCl at its surface to produce Na_2SO_4 , which can then form a molten phase with the NaCl. Presumably, mass transfer of one of the reacting species (i.e., SO_3) becomes rate limiting as SO_3 continues to react with NaCl in the melt to produce additional Na_2SO_4 .

An order of magnitude estimate can be made for the time required to consume NaCl particles under simulated gas turbine conditions operating at 800°C . A rate of about $10^{-4} \text{ mg cm}^{-2} \text{ s}^{-1}$, is assumed for a combustion atmosphere, containing about 0.01 m/o SO_3 (a rate of about 10^{-3} was obtained for this molten phase region for 0.1 m/o SO_3). If we assume compressor shedding, it is not unreasonable to assume that NaCl cubes of $10 \mu\text{m}$ on a side might transit to the hot turbine blade. This particle, when

Fig. 7. Plot of (weight gain)² with time for the exposure of a molten mixture of 1:1 Na₂SO₄ and NaCl to 0.1 m/o SO₃ (flow rate of 17 cm³ s⁻¹).

exposed to the simulated gas turbine conditions, would require of the order of an hour to be converted to Na₂SO₄. This rather lengthy time interval suggests that the deposits formed on the component parts should show some NaCl. This is contrary to what is actually observed on scrapings from turbine blades. As a consequence, processes involving impaction of NaCl particles upon the component parts with subsequent reaction to form Na₂SO₄ appear to be of less significance than processes involving a conversion to Na₂SO₄ in the hot combustion stream with subsequent deposition (11).

Summary

1. A series of product films were obtained upon exposure of NaCl to SO₃ in SO₂-O₂ gas mixtures: (i) solid NaCl SO₃; (ii) molten Na₂S₂O₇; (iii) solid Na₂SO₄; and (iv) a molten mixture of Na₂SO₄ and NaCl.

2. Experimentally measured rates indicated that processes (i), (ii), and (iv) of the above are mass-transfer controlled. The formation of solid Na₂SO₄ (iii), however, is a reaction kinetic process with a small activation en-

ergy of about 22 kJ mol⁻¹ K⁻¹. Mechanisms for this process, involving the transformation of a S₂O₇ transition structure to a tetrahedral SO₄⁻² ion, are proposed.

3. The relatively slow rates at 800°C suggest that the process where Na₂SO₄ forms in the hot combustion atmosphere and then deposits on the turbine component parts may be of greater significance than the process where NaCl impacts on the component surfaces and reacts there to form Na₂SO₄.

The Homogeneous Nucleation of Condensed Silicon in the Gaseous Si-H-Cl System

Carlyle S. Herrick* and David W. Woodruff*

General Electric Company, Corporate Research and Development, Schenectady, New York 12345

ABSTRACT

The chemical vapor deposition of semiconductor silicon by pyrolysis of SiH₄ and SiH₂Cl₂ often produces undesirable silicon powder in the reactor, owing to homogeneous nucleation in the gas phase. Experiments reported herein show the temperature-composition dependence of powdered silicon formation from SiH₂Cl₂-H₂ mixtures. Classical nucleation theory has been applied to the Si-H-Cl system to calculate nucleation rates for liquid or solid silicon from each silicon containing homolog. In general, these rates are dual valued, there being both a higher and a lower temperature associated with each. The lower temperature values compared favorably with literature values reported by Eversteijn and with experimental measurements reported here.

The high purity silicon required for transistors, most integrated circuits, and allied electronic circuitry is obtained at the present time from the pyrolysis of a silicon containing homolog selected from the Si-H-Cl system. By the term homolog, we mean any compound in the series SiH₄, SiH₃Cl, SiH₂Cl₂, SiHCl₃, and SiCl₄.

Those homologs containing the most chlorine usually produce desirable deposits of void-free solid silicon, while homologs containing the most hydrogen often produce some fine powder of particulate silicon. Powder generally has significant deleterious effects on product

*Electrochemical Society Active Member.

quality. It may cause undesirable surface roughness, or may limit yield or reduce the deposition rate. In bulk quantities, silicon powder may suffer due to the large surface area and the impurities which adsorb on it.

The same high hydrogen content homologs which produce undesirable silicon powder also produce higher conversions and yields than do the high chlorine content homologs at the same operating conditions (1). In bulk silicon production as well as in silicon epitaxy, this translates into higher deposition rates and faster production. There is, therefore, considerable interest attached to the problem of understanding silicon powder formation.

Powder formation is generally acknowledged to result from homogeneous nucleation in silicon vapor to produce fine particles of solid silicon. Homogeneous nucleation is described by a classical theory which was developed mainly by Volmer, Weber, Becker, and Doring (2) and modified by Katz and Wiedersich (3) as well as by a statistical mechanical theory of Lothe and Pound (4) and Binder and Stauffer (5). At the present time, the latter theory does not agree well with experimental measurements. However, the classical theory has recently enjoyed considerable success in describing closely the experimental results for a number of systems near room temperature (6). In no published study has the classical theory been applied at the high temperatures required for the chemical vapor deposition of solid silicon nor has it been applied to a system in which chemical reaction takes place.

This paper describes the homogeneous nucleation of solid silicon as measured experimentally in mixtures of SiH_2Cl_2 with hydrogen and as calculated for all of the Si-H-Cl system homologs using the classical theory. Calculated results are compared with experimental values reported here as well as with values from the several sources reported in the literature.

Experimental Measurements

Gas-phase nucleation experiments were conducted in a tube furnace using a gaseous mixture of dichlorosilane (DCS) and hydrogen as the feed. After mixing in a bed of glass beads, the feed was introduced into a 1.27 cm (0.5 in.) od, 1.02 cm (0.4 in.) id quartz tube having a hot zone 30.5 cm (1 foot) long. The outlet end was connected to a small Ehrlemeyer flask with a loose glass wool plug placed in the side port. This side port was connected to a scrubber to remove residual chlorosilane.

During the course of an experiment the individual gas flow rates were set to produce the predetermined compositions and total flows indicated in Table I. The initial furnace temperature was set low enough not to cause gas-phase nucleation of silicon. Temperature was increased stepwise 10° every 10 min until brown silicon powder was observed either at the tube outlet or on the glass wool plug. The experiments were repeated at a variety of concentrations between 0.02 and 0.20 mole fraction DCS in H_2 . The temperature uncertainty was about ± 5 K.

Table I is a list of the results for the various concentrations and flow rates of DCS tested. The correlation between inlet composition and the onset temperature for

visible homogeneous nucleation of solid silicon is shown in Fig. 1. The four points with the greatest scatter were all measured at the higher total gas flow rate, which appeared to be less sensitive to the experimental conditions than the lower rate. Also contributing to data scatter at the lower compositions was the difficulty in detecting smaller amounts of silicon. These data are the first attempt to establish the onset of homogeneous nucleation for DCS- H_2 mixtures.

Nucleation Rate Calculations

Nucleation rates are calculated here by the straightforward application of classical nucleation theory without invoking adjustable parameters of any kind. For nucleation in the gas phase, the theory proceeds from the assumed existence in the gas phase of a distribution of "clusters" of associated gas molecules, each of which will in time dissociate to gas-phase monomers. Gas-phase clusters containing the maximum number of molecules are of "critical size" because the addition of a single gas-phase monomer molecule creates a new entity, a stable

Fig. 1. Experimental temperatures for the onset of homogeneous nucleation of solid silicon from mixtures of SiH_2Cl_2 and H_2 . Larger dots indicate two coincident points.

nucleus, having a monomer evaporation rate lower than the monomer condensation rate. Its continuing future existence in associated form is assured either as a liquid or as a solid. Equation [1] expressed these ideas in mathematical notation (see list of symbols).

$$I = awn \exp \left(\frac{\Delta G_{cs}}{kT} \right) \quad [1]$$

where the quantity $n \exp \Delta G_{cs}/kT$ represents the concentration of critical-size clusters in the gas, and the quantity (aw) represents the condensation rate of monomer on a cluster. Approximately

$$\Delta G_{cs} = \frac{16\pi}{3} \frac{\sigma^3}{\Delta G_v^2} \quad [2]$$

and

$$\Delta G_v = -\frac{kT}{V_c} \ln \frac{P}{P_0} \quad [3]$$

also

$$r_{cs} = -\frac{2\sigma}{\Delta G_v} \quad [4]$$

Then for an ideal gas, the kinetic theory of gases gives

$$w = 4\pi r_{cs}^2 P (2\pi mkT)^{-1/2} \quad [5]$$

The accommodation coefficient α is taken to be unity, an appropriate assumption in view of Langmuir's extensive measurements on similar systems at similar temperatures. The ratio P/P_0 is the supersaturation which, because α is assumed independent of the partial pressure, is equal to the condensation ratio, the driving force promoting nucleation (3). Values for the vapor pressure of silicon, P_0 , are subject to disagreement. The values used in this work are those published by the American Institute of Physics (7). They can be correlated by different straight lines above and below the melting point.

$$\log_{10} P_0 = 5.8225 - 2.0483 \times 10^4/T \quad T > 1685 \text{ K} \quad [6]$$

$$\log_{10} P_0 = 7.5341 - 2.3399 \times 10^4/T \quad T < 1685 \text{ K} \quad [7]$$

These data suggest a boiling point of 3518 K for silicon, higher than other sources, and consequently somewhat lower vapor pressures at the operating temperatures.

The partial pressures of silicon, P in Eq. [3] and [5] and n in Eq. [1] are obtained from equilibrium calculations for the gaseous single-phase Si-H-Cl system. The algorithm employed in Ref. (1) was used here with the output constrained to the vapor phase. The surface energies of condensed-phase silicon nuclei are taken to be equal to the surface tensions, which are estimated by the method suggested in Ref. (8).

Nucleation rates were calculated for all of the silane homologs using Eq. [1]-[7] over a range of temperatures and composition. Table II and Fig. 2 are typical of the re-

Fig. 2. Homogeneous nucleation rates for silicon from the silane homologs at various temperatures. Inlet composition is 0.01 mole fraction homolog and 0.99 mole fraction hydrogen. Total pressure is 1 atm.

sults. The rates cover a range greater than 53 decades, more at higher homolog concentrations. Each homolog exhibits a maximum in the nucleation rate vs. temperature curve. Therefore, there are usually two temperatures at which one can obtain a given nucleation rate. At the lower temperature, the nucleation rate is determined by a very large supersaturation and a very small concentration of silicon vapor. The reverse condition occurs at the higher temperature, where the supersaturation is small and the concentration of silicon vapor is large (see Table II).

Instead of concentration of silicon atoms in the vapor, Table II lists the mean free path between Si-Si collisions, a quantity directly proportional to the reciprocal of concentration, for the additional insight which that quantity provides. In addition, Table II lists fractional numbers of atoms in a critical size cluster. Of course, the use of fractional atoms is an entirely artificial device. It results from

Fig. 3. The locus of all points at which the homogeneous nucleation rate is one nucleus/cm³/s for each silane homolog. In the enclosed regions nucleation rates are greater; elsewhere they are lower. Below the silicon melting point (~1685 K), nuclei are solid; above that temperature, nuclei are liquid. Solid lines are calculated from classical nucleation theory, symbols are experimental. ■: This work, SiH₂Cl₂. ●: SiH₄, Ref. (9). ▲: SiH₄, Ref. (10).

treating Eq. [4] as a continuous function rather than as a function limited to those discrete values corresponding to whole numbers of atoms per cluster. So doing greatly reduces the amount of effort required to solve Eq. [1]-[7] simultaneously. The solutions (Fig. 2 and 3) become continuous functions which consist of a number of real values periodically interspersed in a monotonic continuum of imaginary ones.

It is apparent from Fig. 2 that there is no unique value for the onset of homogeneous nucleation. It is common practice to select a rate of one nucleus per cubic centimeter per second to mark the onset, and that value will be used here. It is indicated by the horizontal dashed line in Fig. 2. In that neighborhood, a factor of 10 change in nucleation rate is created by approximately a 17 K temperature change in the lower temperature level and by a 2 K change in the upper level. Uncertainties in determining nucleation onset temperatures experimentally are likely to be near these magnitudes. At the conditions chosen for Fig. 2 and Table II, the low temperature nucleation onset for SiH₄ occurs at a temperature of about 1046 K, a supersaturation of about 33,000, a Si-Si mean free path of about 6.2 km, and 3.5 atoms in a critical-size cluster. Some values for other conditions are given later in this paper.

Repeating the calculations (Eq. [1]-[7]) a large number of times permits one to construct Fig. 3, which traces the loci of all points in the system at which the nucleation rate is 1 nucleus/cm³/s. Selected values of temperature and composition from Fig. 3 are given in Table III for convenience including the upper and lower limiting compositions. The loci for SiCl₄ and SiHCl₃ form closed paths, while the other homologs bound closed areas in combination with a mole fraction of 1.0, an impenetrable boundary even though it is not part of the loci. Nucleation rates inside the closed areas are greater than one while rates outside are lower. Figure 2, a cross section of Fig. 3 at 0.01 mole fraction, illustrates nucleation rate behavior inside and outside of the closed areas.

At high initial concentrations, between 0.1 and 1.0 mole fraction, only SiH₄, SiH₃Cl and SiH₂Cl₂ are able to generate supersaturations large enough to nucleate 1 nucleus/cm³/s. As initial concentration decreases below 0.1 and 0.01 mole fraction, SiHCl₃ and SiCl₄ become able to generate the necessary supersaturations, but, at first, only at high temperatures. Convergent behavior becomes evident with further decreases in actual composition as differences in constitution between homologs diminish in importance and concentration becomes the dominant fac-

tor. The lower functional values of concentration differ very slightly among the homologs. This difference is not visible in Fig. 3, but is detailed in Table III. Although the precision of Table III is not quite good enough to demonstrate the fact, it appears that there are no points of coincidence between the loci for the various homologs. Instead, they constitute a set of nested curves which never quite coincide with one another.

There is no previous work of comparable scope with which to compare the Fig. 3 result. Calculations by others have been confined to narrow temperature ranges; hence, they never explored the geometry of the nucleation onset locus. Figure 3 is characterized by two principal shapes; a left pointing V shape with a high temperature leg and a low temperature leg, which describes the behavior of materials with only nominal thermal stability, and an inverted air-foil shape, which describes the behavior of materials with greater thermal stability. These shapes are nested and nearly coincident at the lowest

functional concentration. There is reason to expect that this general behavior may be exhibited by many other materials when the full range of nucleation behavior is explored.

Table IV lists calculated values for the supersaturations corresponding to Fig. 3 and Table III. It is noteworthy that the maximum and minimum values of supersaturation differ by nine orders of magnitude. Broadly speaking, one finds from Table IV that along the high temperature leg of the V-shaped characteristic curve that supersaturations are always less than 10. Along the low temperature leg of the V, supersaturations are always greater than 100. By this criterion, all work reported in the literature for other materials appears to fall along the high temperature leg of the respective systems. For silane homolog pyrolysis, on the other hand, temperatures along the high temperature leg (2300-2400 K for the more reactive homologs at a 0.01 initial mole fraction) are clearly much higher than those employed in silicon processing practices, so the region of interest appears to fall along

the low temperature leg. This is confirmed by the comparison with experimental data shown in Fig. 3.

In Fig. 3, the data of Eversteijn (9) is in excellent agreement with the calculated values for the onset of nucleation in SiH₃-H₂ mixtures. The onset data for SiH₄Cl₂-H₂ mixtures reported earlier in this paper is also in excellent agreement with the calculated values. On the other hand, the data of Murthy *et al.* (10) shows a substantial deviation. Had Murthy *et al.* corrected their data to find effective concentrations (as did Eversteijn), satisfactory agreement might well have been obtained.

Table V lists values for the critical nucleus size to demonstrate that the classical calculation involves size values that are in a reasonable range. Tables III, IV, and V all follow the same order, with values for the low temperature leg being listed first.

Nucleation calculations must fulfill several difficult conditions if they are to be significant in a high temperature system such as Si-H-Cl. The first requires that the amount of "jitter" in the calculated results be limited, otherwise much of what might be revealed by the method could instead be obscured. Jitter refers to seemingly random changes in calculated result arising from small changes in an input variable and the uncertainties introduced by using calculational techniques involving convergence in some form. The criteria for satisfying convergence must permit calculating the smallest necessary converged result with reasonable reproducibility. In this case, the partial pressures of silicon involve a convergence calculation and values as low as 1.4×10^{-12} atm occur. The Table III nucleation onset temperatures are reported using four significant figures as an indicator of the absence of calculational "jitter" at that level. As a result, one can make the necessary comparisons between homologs that clearly indicate nested curves rather than some less definite conclusion.

The second condition for significance is some form of demonstrated accuracy, preferably the form arising from comparison with experimental data. Enough criticism has been raised against the classical nucleation theory (2-5) to create substantial doubt about every application to a new system. A comparison is therefore necessary if the doubt is to be eliminated.

Growth of InSb and InAs_{1-x}Sb_x by OM-CVD

P. K. Chiang and S. M. Bedair

Department of Electrical and Computer Engineering, North Carolina State University, Raleigh, North Carolina 27695-7911

ABSTRACT

Organometallic chemical vapor deposition (OM-CVD) growth of InSb and InAs_{1-x}Sb_x has been obtained using triethylindium (TEI), trimethylantimony (TMS), and arsine (AsH₃) on (100) GaAs, (100) InSb, and (111)-B InSb substrates. InSb with excellent morphology was achieved on both (100) InSb and (111)-B InSb substrates. The measured electron mobility at 300 K of undoped InSb grown on (100) GaAs semi-insulating substrates was 40,000 cm²/V-s at a carrier concentration of $N_D - N_A = 2.0 \times 10^{16}$ cm⁻³. Carrier concentration of $N_D - N_A = 1.2 \times 10^{15}$ cm⁻³ has been measured at 77 K. InAs_{1-x}Sb_x (0.07 $\leq x \leq$ 0.75) with mirror-like surfaces have been grown on (100) InSb and InAs substrates. This composition range of 0.55 $< x <$ 0.75 ($E_g \approx$ 0.1 eV) has been successfully achieved for the first time. Solid composition variations as a function of growth temperature and InSb substrate orientations are also discussed.

There are two wavelength ranges, 3-5 and 8-12 μ m, which cover the atmosphere window where minimum absorption is present. The InSb infrared detector has significant application for the detection of 3-5 μ m radiation. This material has received increasing attention over the past few years. Epitaxial growth of InSb has been reported by LPE (1); however, there are several problems associated with the surface morphology. MBE growth of InSb (2) has been also recently reported; however, the electrical properties of the epitaxial layers have not been reported. Organometallic chemical vapor deposition (OM-CVD) is a potential technique for the epitaxial growth of InSb on large area substrates with surface morphology and electrical properties suitable for infrared focal plane arrays. Relatively little work has been reported on the growth of InSb and its alloys by OM-CVD. Manasevit (3) reported the growth of InSb on Al₂O₃ by OM-CVD with a room temperature mobility of 15,000 cm²/V-s and a carrier concentration of $(2-3) \times 10^{16}$ cm⁻³; however, no discussion of optimized growth parameters and the growth of epitaxial layers on InSb substrates has yet been reported.

InAs_{1-x}Sb_x with $x = 0.6$ has the lowest bandgap (\approx 0.1 eV) of the III-V compounds. This bandgap can be suitable for detectors in the 8-12 μ m wavelength region. InAs_{1-x}Sb_x epilayer growth by LPE is difficult because of the very wide separation of liquidus and solidus curves in the phase diagram (4). There have been several reports of OM-CVD growth of InAs_{1-x}Sb_x on InAs and insulating substrates (5, 6); however, poor surface morphology of the epitaxial layers has always been a problem especially for high value of x . We are not aware of any reported epitaxial growth of InAs_{1-x}Sb_x, with 0.5 $< x <$ 0.7, where the bandgap is about 0.1 eV.

In this paper, we report for the first time the epitaxial growth of InSb on InSb substrate by OM-CVD. Optimum growth conditions for mirror-like surfaces and the electrical properties of the epitaxial layers will be presented. Also, we report here the growth of InAs_{1-x}Sb_x on InSb and InAs substrates with mirror-like surfaces over the composition range 0 $< x \leq$ 0.75.

Experimental

Epitaxial layers were grown in a vertical quartz reactor (9.5 cm id and 30 cm long) using 300 kHz RF induction for heating the graphite susceptor. Triethylindium (TEI) (Alfa), trimethylantimony (TMS) (Alfa), and arsine (AsH₃) (5% in H₂, Matheson or Phoenix Research) were used as indium, antimony, and arsenic sources, respectively. Palladium-diffused H₂ was used as the carrier gas at a nominal flow rate of 3.6 l/min. Substrates included (100), (111)-B InSb, and (100) 2° toward [110] InAs and Cr-doped semi-insulating GaAs.

Both InSb and GaAs substrates were prepared by cleaning with TCE, acetone, and methanol. Final treatments included an 8:1 (lactic acid:HNO₃) etching for InSb, and a 7:1:1 (H₂SO₄:H₂O₂:H₂O) etching for GaAs substrates.

The deposition temperature for InSb was varied from 375° to 480°C. Both TEI and TMS flows were started when the substrate temperature reached the growth temperature for InSb deposition. No group V overpressure was maintained during the preheat.

InAs_{1-x}Sb_x growth on (100) InSb substrates showed mirror-like surface morphology with different III/V ratios. However, it had not shown satisfactory surface morphology on (111)-B InSb substrates; therefore, we concentrated our experiments on (100) InSb substrates.

Conventional van der Pauw method on clover leaf samples cut from the epitaxial layers grown on Cr-doped GaAs substrates was used with alloyed In contacts for the electrical characterization. X-ray diffraction was used for determining the solid composition of InSb in InAs_{1-x}Sb_x.

Results and Discussion

InSb.—The optimum growth conditions which produced the best surface morphology on both (100) and (111)-B InSb substrates are 460°C growth temperature with flow rates of 1.45×10^{-5} mol/min and 1.13×10^{-5} mol/min for TEI and TMS, respectively. Figure 1 shows the surface morphologies of InSb epi-layers grown on (100)- and (111)-B InSb substrates under optimum growth conditions. The best results were obtained with a slightly In-rich gas phase (TMS/TEI = 0.78 partial pressure ratio) similar to the OM-CVD growth of GaSb under Ga-rich gas phase done by Cooper *et al.* (7). This is different from most arsenic containing growth, such as GaAs, which are grown with a group V-rich gas phase. It is more difficult to grow GaAs because excess As is very volatile at the growth temperature for GaAs; therefore, it is easily separated from the binary during growth (8). However, In and Sb have a relatively low vapor pressure at growth temperatures less than 480°C. Excess In or Sb will deposit on the substrate and incorporate into the layer as In or Sb droplets.

Figure 2 shows that the growth rate is proportional to the TMS flow rate with a constant TEI flow rate and growth temperature. Growth rate varies from 0.01 to 0.043 $\mu\text{m}/\text{min}$ while maintaining good surface morphology.

Fig. 1. Surface morphologies of InSb epilayers grown on two InSb substrate orientations. a (top): (100) InSb substrate (300 \times). b (bottom): (111)-B InSb substrate (300 \times).

Fig. 2. Growth rate of InSb as a function of partial pressure ratio of TMS/TEI with TEI = 2.90×10^{-5} mol/min and growth temperature 450°C.

This growth rate of 2.5 $\mu\text{m}/\text{h}$ makes OM-CVD a very practical method for the epitaxial growth of InSb.

The dependence of growth rate on growth temperature with constant TMS/TEI partial pressure ratio is shown in Fig. 3. Both higher growth rate and better surface morphology have been obtained at a high growth temperature. At growth temperatures above 480°C, local melting of the InSb substrate was observed (InSb mp = 525°C). In addition, there was no growth when temperature was decreased to 375°C, probably owing to the insufficient dissociation of the OM sources. Because of the lack of available InSb semi-insulating substrates, we used GaAs (100) 2° toward [110] Cr-doped semi-insulating substrates to study the electrical properties of the InSb epilayer. It could be estimated (9) that there exists 10^{14} cm^{-2} dislocation density at the interface between the InSb epilayer and the (100) GaAs substrate due to their 14% lattice mismatch. The InSb epilayers grown on GaAs were shown to be single crystal by x-ray diffraction, however, with poor surface morphology. Figure 4 shows the room temperature electron mobility *vs.* the partial pressure ratio of TMS/TEI with constant TEI flow rate at two different growth temperatures. All samples show n-type conductivity at partial pressure ratios of TMS/TEI from 0.4 to 1.5. At room temperature, carrier concentrations in the range 2×10^{16} to $8 \times 10^{16} \text{ cm}^{-3}$ have been obtained. This range is close to what can be achieved since at room temperature the intrinsic carrier concentrations for InSb, n_i , is about $2 \times 10^{16} \text{ cm}^{-3}$. At liquid nitrogen temperature, the lowest measured carrier concentration is about $1 \times 10^{15} \text{ cm}^{-3}$. This indicates the presence of N_D-N_A background impurity of the order of magnitude 10^{15} cm^{-3} since n_i for InSb at liquid nitrogen temperature is in the 10^9 cm^{-3} range. We have not yet identified the nature and sources of these impurities.

Our best room temperature electron mobility is 40,000 $\text{cm}^2/\text{V}\cdot\text{s}$ at a carrier concentration of $N_D-N_A = 2.0 \times 10^{16} \text{ cm}^{-3}$ (thickness = 1 μm) grown at 400°C with a 2.9×10^{-5} and 2.47×10^{-5} mol/min flow rate of TEI and TMS, respectively. This result is comparable with what has been

Fig. 3. Growth rate of InSb as a function of temperature with flow rate of TEI:TMS = 2.9×10^{-5} : 2.47×10^{-5} mol/min.

obtained using infinite solution liquid-phase epitaxy by Holmes and Kamath (1). They reported electron carrier

Fig. 4. Room temperature electron mobility of InSb as a function of TMS/TEI partial pressure ratio (flow rate of TEI fixed at 2.9×10^{-5} mol/min) at growth temperatures 400°C (O) and 450°C (Δ). The thickness of all the samples are 1-2 μm except sample A ($\approx 4 \mu\text{m}$). Substrates are (100) GaAs Cr-doped semi-insulators.

concentrations and mobilities for 20 μm thick InSb epilayers ranging from 2 to $4 \times 10^{16} \text{ cm}^{-3}$ and from 5 to $6 \times 10^4 \text{ cm}^2/\text{V-s}$, respectively. In Fig. 4, we also find that the electron mobilities increase from 25,000 $\text{cm}^2/\text{V-s}$ for a 2 μm thick epilayer to 35,000 $\text{cm}^2/\text{V-s}$ for a 4 μm thick epilayer, which were grown at the same growth conditions. This indicated that mobility is dependent on the thickness of the epilayer as has been previously observed in the OM-CVD growth of GaAs (10). Figure 5 shows the temperature dependence of the electron mobility. The electron mobility tends towards a maximum value in the vicinity of 300 K and decreases monotonically with increasing temperature. This result is similar to that reported by Wieder's study of dendritic films of InSb (11). Such mobility temperature dependence can be partially explained to be a result of the presence of high dislocation density in the InSb epilayer on GaAs substrates. Ehrenreich (12) has shown that lattice scattering dominates above 200 K and has a temperature dependence of the electron mobility $\mu \propto T^{-1.7}$. In addition, Dexter and Seitz (13) have indicated that the density of dislocations, N , necessary to give dislocation scattering at temperature T equal to the lattice scattering is $N = 6 \times 10^4 T^{5/2} \text{ cm}^{-2}$ which is $\approx 10^{11} \text{ cm}^{-2}$ at 300 K. Since there exists 10^{14} cm^{-2} dislocation density at the interface between InSb epilayer and (100) GaAs substrate, dislocation scattering has to be considered as well as impurity and lattice scattering effects. Dexter and Seitz also indicated that dislocation scattering effect increases with decreasing temperature. The reciprocal mobility can be described as

$$\frac{1}{\mu} = \frac{1}{\mu_i} + \frac{1}{\mu_l} + \frac{1}{\mu_d} \quad [1]$$

where μ , μ_i , μ_l , and μ_d represent the experimentally measured mobility, impurity scattering mobility, lattice scattering mobility, and dislocation scattering mobility, respectively. From Putley's paper (14), we estimated that the impurity scattering mobility, at carrier concentration,

Fig. 5. Temperature dependence of the InSb electron mobility. The measured values of μ were used in conjunction with lattice scattering mobility μ_l and impurity scattering mobility μ_i to determine the dislocation scattering mobility μ_d .

$n = 10^{16} \text{ cm}^{-3}$, $\mu_i \approx 1.1 \times 10^4 T^{0.73}$. For the two curves shown in Fig. 5, the measured values of μ were used in conjunction with $\mu_i = 1.1 \times 10^4 T^{0.73}$ and $\mu_i = 1.09 \times 10^9 T^{-1.68}$ (11) to determine μ_d as a function of temperature by means of Eq. [1]. The results indicate that μ_d increases linearly with temperature. Thus, Eq. [1] can be expressed as

$$\frac{1}{\mu} = \frac{T^{-0.73}}{1.1 \times 10^4} + \frac{T^{1.68}}{1.09 \times 10^9} + \frac{1}{\mu_d}$$

letting $\mu_d = \beta T$ where β is constant ($\approx 330 \text{ cm}^2/\text{V}\cdot\text{s/K}$).

This result shows that the Dexter-Seitz's dislocation scattering mechanism represents the mobility limiting process. Finally, we believe that much higher mobility can be achieved both at 77 and 300 K if InSb is grown on a lattice matched semi-insulator such as CdTe.

InAs_{1-x}Sb_x-InAs_{1-x}Sb_x ternary layers have been grown in the composition range of $0 < x \leq 0.75$ on (100) InSb substrates, with mirror-like surface morphologies. The variations of the solid composition at growth temperature of 460°C with constant TEI and AsH₃ flow rates is shown in Fig. 6. As shown in this figure, the mole percent of InSb in the solid phase cannot be increased substantially upon further increase in TMS flow rates. Values of x higher than 0.6 can be achieved by decreasing the mole fraction of AsH₃ in the gas phase. This has also been observed in the case of OM-CVD growth of GaAs_{1-x}Sb_x, where reducing the AsH₃ partial pressure was found to be more effective in obtaining higher GaSb in the solid phase than increasing the TMS partial pressure as being reported by Bedair *et al.* (15). Data shown in Fig. 6, however, are obtained for the minimum AsH₃ partial pressure that can be obtained from our OM-CVD system. Another way to increase the value of x is to decrease the growth temperature and to increase the TEI flow rate. Figure 7 shows the dependence of the InSb percent in the solid phase on the TEI flow rate at two different growth temperatures. As shown in this figure, growth at 440°C resulted in higher values of x than that at 460°C for

Fig. 6. Mole percent of InSb in the InAsSb epilayer as a function of the flow rate of TMS with the flow rate of TEI:AsH₃ = 2.03×10^{-5} : 1.22×10^{-5} mol/min at growth temperature 460°C using (100) InSb substrates.

Fig. 7. Mole percent of InSb in the InAsSb epilayer as a function of the flow rate of TEI with the flow rate of TMS:AsH₃ = 2.96×10^{-5} : 1.22×10^{-5} mol/min at growth temperature 460°C using (100) InSb (-o-o-) and (111)-B InSb (-•-•-) substrates. This figure also shows the mole percent of InSb in the InAsSb epilayer as a function of the flow rate of TEI with the flow rate of TMS:AsH₃ = 2.96×10^{-5} : 1.22×10^{-5} mol/min grown on (100) InSb substrates at two different growth temperatures, 460°C (-o-o-) and 440°C (-Δ-Δ-).

the same flow rate of reacting gases. A possible explanation is that AsH₃ dissociates more efficiently at higher temperatures and As is preferentially incorporated into the crystal over Sb (7). Under this circumstance, lower InSb percent in the solid phase was obtained at higher temperatures. In this figure, we also show the dependence of the solid composition on the substrate orientations. With each substrate orientation, the InSb percent in solid phase is proportional to the flow rate of TEI. The growth on (111)-B InSb substrates has a higher percent of InSb in the solid composition as compared to the growth on (100) InSb substrates. This result may indicate that the growth is controlled by surface reaction kinetics rather than by mass transport.

Finally, we had grown InAs_{1-x}Sb_x with $x = 0.63$ on (100) 2° toward [110] InAs substrates at growth temperature 460°C with very good surface morphology. This InSb percentage in the solid is higher than what had been previously achieved on InAs substrates by OM-CVD (5, 6). However, further study of the growth on InAs substrates has not been done yet.

Conclusion

OM-CVD epitaxial growth of high quality InSb has been demonstrated. This was achieved by careful control of growth temperature and the TMS/TEI partial pressure ratio. A room temperature mobility of 40,000 cm²/V·s has been measured even with 14% lattice mismatch between the InSb epilayer and GaAs substrate. Dislocation scattering mechanism has been used to explain the variations of mobility with temperature.

InAs_{1-x}Sb_x growth on (100) InSb substrates has been obtained from 7% to 75% InSb in the solid phase with good surface morphologies. The dependence of the InSb percent in the solid phase on growth temperature and gas

partial pressures can be explained by preferential incorporation of As over Sb. In addition, the variation of the InSb percent in the solid phase as a function of substrate orientation was studied. Thus OM-CVD technique can be a potential technique of the epitaxial growth of InSb and $\text{InAs}_{1-x}\text{Sb}_x$ for infrared focal plane arrays covering the 3-5 and 8-12 μm ranges.

Low Resistivity Thin Film Refractory Silicides Grown in Ultrahigh Vacuum at Low Temperature

R. Pantel, Y. Campidelli, and F. Arnaud d'Avitaya

Centre National d'Etudes des Télécommunications, 38243 Meylan Cedex, France

ABSTRACT

Refractory metal silicides, MoSi_2 and WSi_2 , have been grown successfully on (100) silicon wafers in ultrahigh vacuum. It is demonstrated that an MBE-like growth technique, *i.e.*, metal evaporation on a clean heated monocrystal, yields device-worthy thin film silicides of excellent electrical conductivity. For silicide films from 50 to 150 nm thick and substrate temperatures ranging from 750° to 900°C, resistivities as low as 65 $\mu\Omega$ cm for MoSi_2 and 30 $\mu\Omega$ cm for WSi_2 are obtained. Similar resistivities for cosputtered silicides would require films 200–500 nm thick annealed at 1100°C for 30 min.

Refractory silicides have long been considered the most likely candidates for interconnections and electrical contacts in VLSI (1, 2). Molybdenum and tungsten silicides have attracted special attention because their metallurgical, chemical, and electrical properties are good and compatible with the usual fabrication processes. However, all the studies on molybdenum and tungsten have pointed out the difficulties inherent in obtaining silicides from them. The presence of impurities such as carbon and oxygen can hinder and even block the reaction between these metals and silicon (3-5). In addition, their mechanical properties seem to be responsible for the very rough surface of the silicides obtained via metal deposition and subsequent sintering with silicon. As a consequence, the only fabrication method used at present is codeposition of both metal and silicon. This technique leaves two major problems unsolved, however: poor resistivity when the silicides film is less than 150 nm thick and cracking when the thickness of the film exceeds 350 nm for tungsten and 500 nm for molybdenum (6). Moreover, such films require annealing at high temperatures (1000°–1100°C for 0.5-1h) to improve their resistivity.

In this paper, we present a process for the fabrication of thin film molybdenum and tungsten silicides which overcomes the above-mentioned drawbacks. The process consists in metal evaporation on a hot silicon substrate in ultrahigh vacuum. Films 30-150 nm thick were grown at temperatures between 600° and 800°C. The films, whether as grown or post-annealed at 900°C, are smooth, adhere well to the silicon substrate, and have low resistivities.

Experimental

The experiment was carried out in a Riber MBE 2300 ultrahigh vacuum (UHV) system. Silicon wafers are intro-

duced via a loading chamber at 2×10^{-10} torr base pressure. In the evaporation vessel after bakeout, the ultimate pressure of 5×10^{-11} torr is obtained by means of an ionic pump. The refractory metals are evaporated using a 2 kW electron gun. This gun is outgassed for several hours prior to metal deposition. During evaporation, pumping is speeded up by titanium sublimation and liquid nitrogen cooling of the condensation panels. The deposition rate is monitored by a quartz balance previously calibrated by other thickness measurement techniques (RBS and mechanical stylus).

The system is equipped with a low energy electron diffractometer (LEED) to check surface crystallinity and an Auger electron spectrometer for analysis of chemical composition. Oven and sample holder have been designed to heat 2 in. silicon wafers uniformly up to 1200°C without warpage. The temperature is measured by an optical pyrometer, and a thermocouple located at the back side of the wafer. Reproducible temperatures are obtained by using a stabilized power supply.

The substrates used in this experiment were 2 in. (100)-oriented p-type silicon wafers having a resistivity $> 10^8 \Omega$ cm. Before loading in the UHV system, the samples were chemically cleaned according to Shiraki's method (7) for preparing silicon wafers in molecular beam epitaxy (MBE). The most critical steps in such sample preparation are (i) removal of residual carbon by repetitive oxidation in boiling nitric acid followed by a HF dip, and (ii) growth of a very thin monoxide film which protects the surface of the wafer until its introduction into the vacuum chamber. Once the wafer has been loaded in the UHV system, this oxide layer is removed via a gradual temperature increase up to 750°C followed by a flash anneal at 950°C for 90s. When it has cooled down to room tempera-

ture, the surface is observed by LEED. The diffraction patterns show the sharp over structure (2×1) typical of a clean (100) Si surface. The absence of any contaminants, such as carbon or oxygen, is further checked by AES. The samples are now ready to receive the evaporated metal. The refractory source metals are 99.999% pure (Marz, MRC) molybdenum and tungsten ingots, which are outgassed at a temperature higher than their evaporation temperatures. Molybdenum and tungsten layers 15 nm to 60 nm thick were evaporated at 0.1 nm/s onto silicon substrates heated to a temperature of 650°–750°C in the case of molybdenum and 600°–800°C in the case of tungsten. The temperature elevation due to metal evaporation is calculated from the radiation power intercepted by the wafer and found to be approximately 50°C for molybdenum and 100°C for tungsten. Once the desired silicide thickness is attained, evaporation is stopped and the samples are allowed to cool.

The silicide films were subsequently observed *in situ* by AES. RBS measurements, SEM observations, and electrical measurements were also carried out. Finally, the films were annealed in forming gas at 900°C for one hour in a classical furnace (previously evacuated to 10^{-6} torr) to observe the evolution of their resistivities.

For comparison purpose, some evaporations were also made onto silicon substrates at room temperature and the silicides were formed by post-annealing *in situ* for 10 min at 650°C for molybdenum and 750°C for tungsten.

Results

Figure 1a shows the Auger spectrum of the cleaned silicon surface before metal deposition. Neither carbon nor oxygen was detected.

Figures 1b and 1c show typical Auger spectra of the surface obtained after deposition of molybdenum and

tungsten on hot silicon substrates (650° and 750°C, respectively). These spectra likewise exhibit an absence of contaminants and provide clear evidence of reaction of the metals with silicon. The Si/Mo and Si/W ratios of both silicides, however, suggest a surface composition rich in silicon. Previous studies have shown that silicides annealed in UHV are generally coated with a monolayer of silicon (8-9). Whatever that may be, all the molybdenum and tungsten silicides presented in this paper were found (by x-ray diffraction) to be pure disilicides.

Figures 2a and 2b show the corresponding typical RBS spectra. A simple calculation shows that the silicides are slightly silicon enriched ($\text{MoSi}_{2.1}$ and $\text{WSi}_{2.15}$). These profiles also suggest that the films are continuous and of uniform thickness: 70 nm for MoSi_2 and 150 nm for WSi_2 . This uniformity is confirmed by SEM observations. Figures 3a and 3c show the surfaces of MoSi_2 and WSi_2 films grown on hot substrate at 650° and 750°C, respectively. For comparison, we also present the SEM images of the above-mentioned silicides obtained by metal deposition on substrates at room temperature and subsequently annealed at 650° and 750°C for molybdenum and tungsten, respectively (Fig. 3b and 3d). This comparison gives evidence of the higher quality of the films obtained by the MBE-like method.

Figures 4a and 4b show the electrical resistivities of as-grown MoSi_2 and WSi_2 films for various temperatures in the 600°–800°C range. The evolution of resistivity after annealing at 900°C for 1h in forming gas is also reported. We note that the gain in resistivity is not significant for samples reacted at 750° and 800°C for MoSi_2 and WSi_2 films, respectively. The best result is around $65 \mu\Omega \text{ cm}$ for 58 nm thick MoSi_2 films and $30 \mu\Omega \text{ cm}$ for 150 nm thick WSi_2 films. The curve shown as a continuous line is from Denison (6), who has published the best resistivity

obtained to date on cosputtered films of MoSi_2 ($50 \mu\Omega$ cm) and WSi_2 ($26 \mu\Omega$ cm).

Discussion

The cleaning of silicon wafers under ultrahigh vacuum conditions has eliminated impurities both at the interface and in the silicide, as Auger analysis has shown. This absence of impurities explains the low temperature reaction

between silicon and the refractory metals. However, elimination of impurities is not the only determining factor for obtaining good, *i.e.*, smooth and continuous, thin silicide films. Actually, we reported earlier (4) that MoSi_2 thin films obtained by evaporation in ultrahigh vacuum on substrates at room temperature followed by a 950°C annealing leads to nodular discontinuous films. Since, in the present study, the substrate is kept at the actual tem-

perature of silicide formation, one might almost say that the silicide grows as if one were depositing not only the refractory metal but the silicide compound. This process is not very far from equilibrium, and stresses are minimized. As shown by SEM, the result is a smooth surface. On the contrary, when metal is deposited on room temperature substrates and the silicide is formed by post thermal annealing, stresses due to temperature elevation and silicide formation are created. The result is quite rough surface.

The RBS profiles of the MBE-like-grown silicides show a continuous film with a silicon stoichiometry slightly greater than two, and Auger spectra indicate a silicon enrichment of the surface. These two characteristics ensure the stability of the silicide during thermal processing (oxidation and thermal annealing), especially if the silicides are to come in contact with silicon (polycide, self-aligned silicide). This is not the case for some metal-rich refractory thin films such as W_4Si or Mo_3Si , which have been found to be highly conductive (10-11) but incompatible with VLSI processing (11).

The stability of our silicides is also observed in the evolution of resistivity with thermal annealing. The films, with the exception of MoSi_2 grown at 650°C , are only slightly improved by 900°C treatment. In this particular case, it is known that a hexagonal-to-quadratic crystalline transition occurs around 700°C , and this may explain the improvement in resistivity we observed.

So far, the best resistivities for molybdenum and tungsten silicides have been obtained by Denison on cosputtered films. However, his films were treated at 1100°C for 30 min, and only the thick films (200–500 nm) exhibited good resistivities. Denison observed a drastic increase in resistivity when film thicknesses went below 150 nm. In fact, it has already been shown that the resistivity limitation of cosputtered WSi_2 films is due to grain boundary scattering (12), which may be caused by segregation of impurities. Thus, the only way to improve the resistivity of cosputtered films is via an increase in grain size, and for that purpose a 1100°C anneal is necessary. However, where very thin films are concerned, grain size cannot be increased beyond that of the film thickness; otherwise, the film will become discontinuous resulting in poor conductivity.

In the case of our UHV-grown films, one does not observe a drastic limitation of resistivity for slight thick-

nesses. TEM observation shows grains of uniform dimensions (around 50 nm) arranged in a mosaic which minimizes the total surface of boundaries. The layers are free of impurities. This explains the good resistivities as well as the thermal stability since grain size is not significantly modified by annealing at 900°C .

It has been reported in the literature that impurities induce surface topography effects (3, 13) when thin film silicides are grown by reaction of metal with a silicon substrate. This explains the quite smooth surfaces we have obtained, the best silicides being those grown on hot substrates. This would indicate that stress is also a factor which creates rough surfaces.

UHV silicides also exhibit good adhesion. This is due to the reaction of metal with the silicon substrate which ensures effective silicide-silicon interface bonding. On the contrary, cracking of thick cosputtered films during thermal annealing has been reported (6). Indeed, those films grown without reaction with the substrate are insufficiently bound.

Conclusion

The first important result of working in UHV and following a special procedure for cleaning wafers has been the elimination of impurities. This is, of course, conducive to low temperature reactions of metal with silicon and leads to pure silicides. By contrast, we have shown that if the silicides are formed via metal evaporation and post annealing, the films present serious limitations (surface roughness, among others). A significant improvement has been made by choosing a MBE-like growth technique involving a thermally assisted reaction during a slow rate evaporation of the refractory metal. The good quality of the films obtained in this way confirms that impurities and stresses were the causes of problems previously encountered when reacting a metallic film with silicon.

The method is versatile and still further improvements in such silicide films can be expected by adjustment of growth conditions. Experiments are now in progress to explain the high conductivities, which are in all likelihood due to the particular crystallographic properties of the films.

We feel that the results presented here make these silicides very attractive for the technological process involved in VLSI and particularly for the purpose of self-aligned silicide devices. This technique consists in

selective deposition of the silicides on sources, drains, and gates of MOS transistors (14) and involves very thin layers of silicides, low temperature annealing, and the lowest possible resistivities. The thin film silicides we have presented in this paper quite satisfy these criteria.

Plasma-Enhanced Chemical Vapor Deposition of Silicon Epitaxial Layers

R. Reif*

Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Silicon epitaxial layers are conventionally deposited by atmospheric or reduced pressure chemical vapor deposition (CVD) at temperatures of 1050°-1200°C. This relatively high processing temperature limits the minimum thickness and conductivity of epitaxial films deposited on substrates containing heavily doped regions near the surface because of solid-state outdiffusion and autodoping. In order to minimize outdiffusion and autodoping, the epitaxial process step needs to be carried out at lower temperatures. Plasma-enhanced CVD (PECVD) is a technique capable of depositing silicon epitaxial layers at relatively low temperatures (700°-800°C) and with reasonable deposition rates (200-2000 Å/min). This article discusses the PECVD process and its application to the low temperature deposition of silicon epitaxial films.

Silicon epitaxy is an important processing step in the implementation of several integrated circuit technologies such as bipolar, CMOS, and VMOS (1), as well as many memory (2), microwave, and photonic devices (3). The preferred technique for the fabrication of silicon epitaxial layers is chemical vapor deposition (CVD), which is conventionally carried out at atmospheric or reduced (40-100 torr) pressure, and at temperatures of 1050°-1200°C.

An important drawback of the conventional CVD technique is the relatively high processing temperature (1050°-1200°C) required for silicon epitaxial growth. This high temperature causes significant dopant redistribution near the film-substrate interface (4). This dopant redistribution limits the minimum thickness and conductivity of lightly doped films deposited on substrates containing heavily doped regions near the surface. Consequently, it imposes restrictions on the level of on-chip integration that can be achieved by active down scaling, *i.e.*, by scaling down lateral and vertical device dimensions. It is for this reason that alternative epitaxial deposition techniques which minimize this undesired dopant movement during the epitaxial process are desirable.

The CVD of silicon epitaxial layers requires two high-temperature processing steps: (i) a predeposition *in situ* cleaning of the wafer surface, which is usually carried out at a temperature of 1150°-1200°C in a H₂ or HCl/H₂ ambient. This step is needed to remove the native silicon dioxide film and any other undesired film or contaminants from the wafer surface, and (ii) the actual deposition step,

which is normally carried out at a temperature of 1050°-1200°C, depending on the silicon source used.

The high predeposition temperature releases dopant atoms from the wafer surface by evaporation, and these dopant atoms are later incorporated in the epitaxial layer during growth. Such unintentional doping of the epitaxial film is usually referred to as autodoping (5). In addition, the high deposition temperature causes further dopant movement because of solid-state outdiffusion. Both autodoping and outdiffusion are responsible for the undesired redistribution of impurities commonly associated with silicon epitaxy by CVD.

In order to minimize autodoping, the predeposition cleaning step must be carried out at lower temperatures to limit impurity evaporation, and/or lower pressures to quickly remove from the system any evaporated impurities. In order to minimize solid-state outdiffusion, the epitaxial deposition step must be carried out at lower temperatures. Several techniques have been proposed as possible low temperature, low pressure alternatives for the silicon epitaxial process: molecular beam epitaxy (MBE) (6), ion cluster beam deposition (7), ion beam epitaxy (8), and plasma-enhanced CVD (PECVD) (9-14). One potential advantage of PECVD is that it requires low (0.01-1 torr) pressures for operation, while all the other beam-related techniques need high vacuums. Consequently, PECVD appears more compatible with manufacturing requirements, *i.e.*, easy operation and maintenance and high wafer throughput.

This article reviews the PECVD of epitaxial silicon. The physics and chemistry of the PECVD process are briefly

*Electrochemical Society Active Member.

discussed in the next section. Following this, the most important advances in the PECVD of silicon epitaxy are reviewed.

Plasma-Enhanced Chemical Vapor Deposition

Glow discharge.—A simple model of a glow discharge consists of a partially ionized gas containing equal volume densities of positive and negative charged species (mostly ions and electrons, respectively) and different volume densities of ground-state and excited species (15, 16). Most of the glow discharges used in microelectronics are generated by the application of a radio frequency (RF) electric field to a gas. The energy from the field accelerates free electrons in the gas, while the ions are relatively unaffected because of their much heavier mass. The accelerated electrons lose little energy in elastic collisions with atoms or molecules because of the large difference in mass, and initially lose little energy in inelastic collisions (*e.g.*, excitation and ionization). Once these electrons acquire sufficiently high energies, their collisions with gas species lead to excitations and ionizations, the latter generating additional electrons which are, in turn, accelerated by the RF field. In steady state, the glow gains electrons from ionizations and other mechanisms (*e.g.*, electron emission from positive ion bombardment on the electrodes and other surfaces within the chamber), and loses a numerically equal number of electrons and ions to the electrodes and walls.

The inelastic collisions between high energy electrons (which obtained their energy from the applied electric field) and gas molecules produce highly reactive species such as excited neutrals and free radicals, besides more electrons and ions. In this manner, the applied electric field supplies the energy used to create highly reactive species without significantly raising the gas temperature. PECVD uses these reactive species to deposit thin films (16) (*e.g.*, silicon nitride, silicon dioxide, amorphous silicon, and polycrystalline silicon) at temperatures lower than those possible by thermally activated CVD. In addition, the energy from the RF field might also be used to modify the structure, stoichiometry, and other properties of the deposited films. This can be done by controlling the bombardment of ions into the substrate surface; the importance of ion bombardment is discussed below.

The glow discharges currently used in microelectronics are relatively low pressure (0.1-1 torr) plasmas. The plasma density (*i.e.*, density of free electrons and ions) is typically about $10^{19}/\text{cm}^3$. The degree of ionization is typically $\leq 10^{-4}$, *i.e.*, the gas consists mostly of neutrals. The Maxwell-Boltzmann distribution is usually used to approximate the energy distribution of free electrons in the glow, with the fastest electrons having energies as high as 10-30 eV (17). These high energy electrons are responsible for excitation and ionization, since the corresponding threshold energies are typically ≥ 10 eV (*e.g.*, the threshold energies for excitation and ionization are 11.56 and 15.8 eV, respectively, for argon). In a typical room temperature glow discharge environment, the ground-state species in the gas may have energies corresponding to temperatures slightly above 300 K, the excited species and ions may have energies corresponding to 400 K up to thousands of degrees Kelvin, and the free electrons may have energies corresponding to 10^4 - 10^5 K. Consequently, the glow discharge environment is not in thermal equilibrium, and thermodynamics cannot be used to predict the outcome of a plasma deposition experiment.

Potentials in RF glow discharges.—Several potentials are important in the RF glow discharges used in microelectronics: the plasma potential, the floating potential, and the sheath potentials. The plasma potential (V_p) is the potential of the glow region of the plasma, which is normally considered nearly equipotential. It is the most positive potential in the chamber and is the reference potential for the glow discharge. The floating potential (V_f) is the potential at which equal fluxes of negative- and positive-charged species arrive at an electrically floating

surface in contact with the plasma. If the chamber walls are electrically insulated, $q(V_p - V_f)$ is the maximum energy with which positive ions bombard the walls, where q is the unit electron charge (18). Most sputtering threshold energies are 20-40 eV (15). Therefore, $V_p - V_f \leq 20$ -40 eV is normally desired to avoid sputtering walls, which may lead to film contamination.

As mentioned above, the plasma potential is always positive with respect to all surfaces in contact with the plasma. This is because the electron mobility in the plasma is much greater than the ion mobility and, consequently, the initial electron flux to all surfaces is always greater than the ion flux. As a result, the surfaces in contact with the plasma become negatively charged, and a positive space charge layer or sheath forms near these surfaces. Because there are fewer electrons in the sheath, fewer atoms are excited by electron collisions, and fewer atoms relax to give off radiation. Consequently, the sheath region is dark relative to the glow region. The sheath regions extract positive ions from the glow region and accelerate them into the electrodes and other surfaces in contact with the plasma. Similarly, the sheath regions accelerate secondary electrons emitted from surfaces (*e.g.*, due to positive ion bombardment) into the glow region. Therefore, the sheath voltages are very important because they determine the maximum energy with which positive ions bombard the electrodes, and help estimate the maximum energy with which secondary electrons emitted from electrodes enter the glow region. It can be shown that in an asymmetric plasma system with a "blocking" capacitor, the ratio of the sheath voltages is proportional to the reciprocal of the ratio of their corresponding electrode areas (19-21). If the blocking capacitor is absent or the plasma system is symmetric, then the sheath voltages at each electrode are the same.

Qualitative model.—A qualitative model for PECVD now becomes apparent. Inelastic collisions between high energy electrons in the plasma and gas-phase reactants help establish a steady-state population of highly reactive species. The rate of these inelastic collisions is a function of the reactant partial pressure, the collision cross section (which is energy dependent), and the electron energy distribution (15-17). The latter is a function of plasma power and system pressure (17). The glow discharge also acts as a source of positively charged species, mostly ions. The highly reactive species in the glow have a relatively high sticking coefficient and adsorb readily on the substrate surface (16). These reactants, once adsorbed, and because of their relatively weak internal binding, are easily broken down by the thermal energy provided by the substrate into their constituent atoms yielding a solid film. This surface decomposition reaction is enhanced by positive ion bombardment on the substrate surface.

Ion bombardment not only affects deposition rates, but also the structure, composition, and other properties of the film (22). Furthermore, ion bombardment is particularly important when the glow discharge is used to enhance the deposition of crystalline films. On one hand, it can be used to clean substrate surfaces by sputtering contaminants, including native oxides (this feature is important in silicon epitaxy). But, ion bombardment can also be used to create adsorption sites [thereby reducing the distance the average adatoms must travel (23)], and to enhance adatom surface mobility (24).

PECVD of Epitaxial Silicon

Table I summarizes the results obtained by researchers in this field (9-14).

Townsend and Uddin (9) carried out their work in a conventional horizontal water-cooled reactor. An RF generator was used to inductively heat the silicon carbide-coated susceptor, and a 350W, 27 MHz generator was used to create a glow discharge. The 27 MHz generator was connected to a pair of external aluminum ring electrodes. The silicon source used was 1% silane in pure hydrogen.

Table I. Summary of results for the PECVD of silicon epitaxy

Authors	Deposition temp (°C)	Deposition rate (Å/min)	Discharge power (W)	Gas ambient	Operating pressure (torr)
Townsend and Uddin (9)	800-900	200-400	350 (27 MHz)	SiH ₄ /H ₂	0.2-0.6
Pons <i>et al.</i> (11)	760	600	500 (13.56 MHz)	SiH ₄	0.03-0.1
Shanfield and Reif (12)	750-900	200-400	25 (dc)	SiH ₄ /H ₂	0.02
Suzuki and Itoh (13)	600-850	1200-2400	200 (13.56 MHz)	GeH ₄ /SiH ₄	1×10^{-2} - 3×10^{-2}
Donahue <i>et al.</i> (14)	775	450	20 (13.56 MHz)	SiH ₄	1.5×10^{-2}

The operating pressure was 0.2-0.6 torr. A hydrogen glow discharge was established immediately before the start of the plasma enhanced deposition step and maintained for a few minutes to clean the substrate surface. This pre-deposition clean-up was found to give epitaxial layers of very high surface quality. When the deposition was not carried out in the presence of a glow discharge, the pre-deposition clean-up consisted of a 30 min hydrogen treatment at 1100°C. Layers deposited at 850°C without plasma enhancement (*i.e.*, with the 27 MHz generator turned off) were single crystal but contained about 200 stacking faults/cm². The stacking fault density decreased with increasing deposition temperature. The authors reported that all attempts to deposit epitaxial silicon without plasma enhancement at temperatures below 850°C were unsuccessful. When the glow discharge was used, however, the layers deposited at 800°C and above were epitaxial. The deposition rate at 800°C was about 200Å/min. The deposition rates obtained with and without the aid of the glow discharge were similar, *i.e.*, these authors did not find evidence of plasma enhancement in the deposition rate. [As is shown below, Donahue *et al.* (14) did observe plasma enhancement of deposition rates at even much lower RF power, 20W, but also at much lower operating pressures, 1.5×10^{-2} torr.] The layers deposited with the aid of the glow discharge exhibited lower stacking fault densities and better surface quality. This improved quality was attributed to a more effective predeposition clean-up provided by the glow discharge compared to the normal heat-treatment in hydrogen.

Pons *et al.* (11) reported the deposition of silicon epitaxial layers at a substrate temperature of 760°C. They used a 0.5 MHz generator to inductively heat the susceptor and a 13.56 MHz generator to create the glow discharge. Both sapphire and silicon substrate wafers were used. The silicon source was 100% silane, and the operating pressures were in the range of 0.03-0.1 torr. Silicon epitaxial layers were deposited at a rate of 600 Å/min using 500W of RF power supplied to the plasma.

Shanfield and Reif (12) used a direct current (dc), low pressure plasma discharge system (see Fig. 1) to deposit silicon epitaxial layers in the temperature range of

750°-900°C. Deposition rates of 200-400 Å/min were obtained using a silane/hydrogen discharge of 25W at an operating pressure of 0.02 torr.

Suzuki and Itoh (13) used a different plasma CVD geometry to deposit silicon epitaxial layers at 750°C. They used a vertically aligned system with RF (13.56 MHz) excitation to generate a glow discharge. The glow was confined between two horizontal, parallel mesh electrodes, which were perpendicular to the gas flow. The wafer was located downstream, parallel to the mesh electrodes, and 150 mm below the lowest electrode. Pure silane and germane were used as the source of silicon and germanium, respectively, and pure hydrogen chloride was used for surface etching. Experiments were carried out at operating pressures of 1×10^{-2} and 3×10^{-3} torr, which resulted in deposition rates of 1980 and 840 Å/min, respectively. All these deposition experiments were carried out in the presence of a glow discharge, *i.e.*, the results of experiments carried out without plasma enhancement were not reported. The power level supplied to the discharge was 200W. The gas ambient consisted of silane, but germane was added to the plasma at the beginning of the deposition. The addition of germane was found to be essential, and it was proposed that it cleaned the wafer surface by removing the native silicon dioxide layer coating the substrate. This would occur by the reaction of Ge + SiO₂ to form GeO₂, which is reduced at this temperature (750°C) in the presence of hydrogen to Ge, or reduced by Ge to GeO, which is volatile. The oxygen would volatilize

Fig. 1. Schematic diagram of PECVD chamber with dc excitation. [After Shanfield and Reif (12).]

Fig. 2. Schematic diagram of PECVD chamber with RF excitation. [After Donahue *et al.* (14).]

as a gas or would react with H_2 to form H_2O , which would also etch Si and volatilize. The addition of germane, however, resulted in the formation of a Si-Ge alloy in the first 1000Å of the epitaxial film. Predeposition cleaning consisting of hydrogen chloride gas (850°C, 10 min) was found unsuitable because it yielded nonspecular epitaxial surfaces. The films were *in situ* doped by adding phosphine diluted in helium to the plasma, but they had to be annealed (1000°C, 60 min) to electrically activate most of the phosphorus in the film. Hall effect measurements indicated that the film electron mobility was similar to bulk values for carrier concentrations in the range of $(2 \times 10^{16}) - (3 \times 10^{18} \text{ cm}^{-3})$.

Donahue *et al.* (14) have deposited silicon epitaxial layers at 775°C using a low pressure CVD system both with and without plasma enhancement using silane. A schematic diagram of this system is shown in Fig. 2. The system consists of a gas distribution system, the chamber, the heating system, the pumping system, and the RF circuit. "Research purity" gases (less than 0.1 ppm each of O_2 , H_2O , etc.) are delivered to the chamber through stainless steel welded lines, and the flows are controlled using mass flow controllers. The available gases are argon, nitrogen, hydrogen, silane, and arsine. The chamber consists of a quartz tube sealed to stainless steel endplates by silicone gaskets. A single wafer sits on a silicon-carbide-coated graphite susceptor facing a radiant heater (six infrared lamps of 6 kW each). The wafer temperature is monitored by an infrared pyrometer that looks through a window in the top of the chamber, and a feedback loop controls the lamp power. A mesh is needed between the window and the plasma to prevent deposition on the window. The chamber is pumped on by a turbomolecular pump which is backed by a mechanical pump. The RF circuit consists of a 1 kW, 13.56 MHz generator and an automatic matching network, and it is coupled to the gas by an external copper plate wrapped around the top third of the chamber. The RF current return path is through a silicon-coated stainless steel false bottom located above the bottom endplate. Direct current bias can be applied between the false bottom and the graphite susceptor. By

Fig. 3. Transmission electron diffraction micrograph of an epitaxial film deposited at 775°C with plasma enhancement (14).

using pure silane during deposition at an operating pressure of 1.5×10^{-2} torr, deposition rates of 450 and 340 Å/min were obtained with and without plasma enhancement, respectively. The power level supplied to the discharge during the PECVD experiments was only 20W, which probably explains the lower deposition rate observed here compared to that reported by Suzuki and Itoh (13). These results also disagree with those of Townsend and Uddin (9), in that they did not observe any plasma enhancement in the deposition rate; however, they worked at much higher operating pressures.

Donahue *et al.* (14) found that the predeposition *in situ* cleaning of the substrate surface to remove the native silicon dioxide film was essential for achieving epitaxial growth at this low temperature (775°C). Surface cleaning was done by sputtering the wafer in a 50W argon plasma at 775°C for 5 min with a dc bias applied between the false bottom and the susceptor. A polycrystalline deposit resulted when either the argon plasma cleaning or the dc bias during the predeposition argon plasma was not included in the procedure. Hazy epitaxial films resulted when only 100 or 200V of dc bias were used, but only if the plasma was used during the deposition. This suggests that the silane plasma is capable of cleaning away enough of the native silicon dioxide film to allow epitaxial growth. The plasma may also be providing energy to enhance the mobility of adsorbed silicon species. Finally, if a 300V bias was applied during the argon cleaning, smooth, specular epitaxial films of identical quality were obtained with or without plasma enhancement during the deposition (see Table II and Fig. 3 and 4).

The results obtained by Donahue *et al.* (14) clarify two important issues: (i) the presence of a glow discharge enhances the silicon epitaxial deposition rate even at relatively high temperatures (775°C) and low RF discharge power (20W). Similar results were observed by Shanfield and Reif (12) using a dc discharge. (ii) The predeposition *in situ* cleaning of the substrate surface determines the structure, quality, and morphology of these low temperature epitaxial films. Table III compares the different predeposition cleaning treatments used by different researchers.

The low temperature epitaxial films reported in Ref. (14) had an intrinsic resistivity of 40 Ω cm. Cs/SIMS measurements in these films found oxygen and carbon levels of $10^{18}/\text{cm}^3$ and $2 \times 10^{19}/\text{cm}^3$, respectively. An oxygen donor level located 0.147 eV below the conduction band was found by plotting the log of carrier concentration *vs.* temperature obtained from Hall measurements.

Epitaxial layers of GaAs have also been obtained by plasma-enhanced techniques (25, 26). Deposition temperatures of 350°C and deposition rates of 0.2 μm/min have been reported (25). Plasma cleaning of the substrate sur-

face to remove native oxide layers prior to epitaxial deposition is also believed to be essential for GaAs epitaxy at these low temperatures.

Summary and Conclusions

This article briefly discussed the physics and chemistry of the PECVD process, the importance of low temperature silicon epitaxy for the fabrication of VLSI chips, and the most recent advances in the PECVD of silicon epitaxial films. It is shown that the most important step to achieve silicon epitaxy at low (700°-800°C) temperatures is the predeposition *in situ* cleaning of the substrate surface. Although this low temperature process represents an attractive alternative to MBE, much more work is still needed to evaluate the quality of these low temperature films. In particular, issues such as defect density, *in situ* doping, pattern shift, pattern distortion, carrier mobilities, and carrier lifetimes are currently being investigated and will determine the impact of this technology.

Ferromagnetic Iron Oxides from Synthetic β -FeOOH by Vacuum Thermal Decomposition

Katsuya Inouye, Kiyohito Shibata, Sumio Ozeki, and Katsumi Kaneko

Department of Chemistry, Faculty of Science, Chiba University, Chiba 260, Japan

ABSTRACT

The synthetic β -FeOOH (Akaganeite) was dehydrated at 300°-500°C for 1-20h under vacuum of 10^{-3} and 10^{-5} torr. The magnetic properties of the obtained dehydration products have been measured for saturation magnetization (M_s), residual magnetization (M_r), and coercive force (H_c). M_s and M_r were proportional to the chemically analyzed Fe^{2+} content in the samples. With reference to the x-ray diffraction results, it was found that the dehydrated products of β -FeOOH *in vacuo* are the oxides in the Fe_3O_4 series containing different amounts of Fe^{2+} in the range 1-3 mmol g^{-1} , and with a certain amount of α - Fe_2O_3 . The oxidation of the dehydrated β -FeOOH in air at 225°C for 20h gave oxides of the γ - Fe_2O_3 series, which are entirely different in magnetic properties but almost similar in x-ray reflections in comparison with those of the dehydrated β -FeOOH. The variations of H_c and the reduced remanence (M_r/M_s) with the Fe^{2+} content are also discussed.

The decomposition product of synthetic β -FeOOH (Akaganeite), particularly under vacuum or in an inert atmosphere, has recently been the subject of interest in different problems: first for a possibility of producing ferromagnetic acicular powder material suitable for magnetic tapes (1, 2), and, second, for the investigation of pore formation by dehydration which is relevant to the adsorbability of gaseous molecules such as N_2 , CCl_4 (3), H_2O (4), and NO (5).

The present work deals with the first problem, particularly to discussion of whether the dehydration product is γ - Fe_2O_3 (maghemite) as commonly believed by the preceding authors. As is well known, acicular microparticles embracing maghemite are useful material for electronic purposes. It was Mackay (6) who first suggested from electron diffraction evidence that γ - Fe_2O_3 is the decomposition product of β -FeOOH under a vacuum of the electron microscope condition, although he reserved the possibility that it is Fe_3O_4 (magnetite). Watson *et al.* (7) also reported that the dehydration of β -FeOOH in an electron microscope gives γ - Fe_2O_3 on the basis of selected-area electron diffraction measurements. In a similar study on pore formation in β -FeOOH by Galbraith *et al.* (8), the product in the electron microscope was mentioned as γ - Fe_2O_3 . Gonzalez-Calbet *et al.* (4) asserted more recently that the dehydration product of β -FeOOH at 10^{-3} torr and 350°C for 1h is γ - Fe_2O_3 , a conclusion mainly based on the x-ray diffraction patterns which are characteristic of γ - Fe_2O_3 . Naono *et al.* (3) examined the "micropore" formation in dehydrated β -FeOOH at 10^{-5} torr and 25°-500°C for 10-20h, but their dehydration products at higher temperature range appeared to be α - Fe_2O_3 (hematite). In our previous experiment (5), β -FeOOH changed at 10^{-5} torr and 350°-500°C to a black strongly magnetic product. Although this product was distinguished by a high adsorption capacity for NO molecules, its properties and structure remained to be investigated.

It has become practically important that the raw material of magnetic iron oxide power is expected in the future to be iron chloride obtained as an acid-washing waste in the steel industry. It is also widely known that the hydrolysis of iron chloride gives β -FeOOH easily. It is

hence envisaged that the preparation of a magnetic oxide from β -FeOOH is promising. In this report, we will provide the magnetic properties of the dehydration product of β -FeOOH *in vacuo*, and its oxidation product as well, and will also discuss the kinds of products obtained, with reference to the examinations by x-ray diffraction, chemical analysis, and electron micrography.

Experimental

Synthetic β -FeOOH and other materials.— β -FeOOH was prepared by the hydrolysis of 0.1M FeCl_3 at 95°-100°C for 5h (9). The precipitates were filtered, washed with distilled water until no chloride ions were detected, and dried at 110°C for 1h. The BET surface area by nitrogen adsorption was 25 $\text{m}^2 \text{g}^{-1}$. The Fe_3O_4 and γ - Fe_2O_3 used as reference materials are commercial pure-grade reagents ex. Wako Chemical Industries and Toda Chemical Industries, respectively; each showed sharp x-ray diffraction patterns without considerable impurities.

Vacuum dehydration.—Approximately 10 mg sample was situated in a glass cell connected with a vacuum system and temperature controller. The sample was evacuated at 10^{-3} or 10^{-5} torr, and then heated at a rate of 3.3°C min^{-1} up to temperatures in the range 300°-500°C. The temperature deviation at 380°C was +5° and -10°C. The time of heating was 1-20h at each final temperature. The dehydrated sample was cooled to room temperature under the same vacuum. The preliminary experiments revealed that the magnetic values (see next section) elevate during heating to approach constant values with the heating temperature in the range 300°-500°C and with the heating time between 1 and 20h, irrespective of the degree of vacuum. The typical heating conditions for comparison of the magnetic properties of the products were: 380°C, 10^{-3} torr, and 3h.

Magnetic measurement.—A tablet composed of a 10 mg sample and 300-400 mg KBr was used for the measurements to prevent movement of sample powders in the magnetic field. The tablet was formed with a compression pressure of $8 \times 10^3 \text{ kg cm}^{-2}$. The magnetic hysteresis curve was drawn at room temperature by means of a Far-

aday balance with the magnetic field ranging from -720 to $+5740\text{G}$ (10^{-4} T). From the hysteresis curve, the saturation magnetization (M_s), the residual magnetization (M_r), and the coercive force (H_c) were obtained.

Oxidation of dehydrated sample.—The oxides obtained by heating at different temperatures *in vacuo* were further subjected to oxidation in air in an electric furnace regulated at $225^\circ \pm 7^\circ\text{C}$ for 20h. This oxidation condition was selected as appropriate for the oxidation of Fe_3O_4 to $\gamma\text{-Fe}_2\text{O}_3$ in the industrial production of acicular magnetic powder as described in numerous patents.

Chemical analysis and sample characterization.—The content of Fe^{2+} in the samples was determined by the Zimmerman-Reinhardt oxidation-reduction titration by use of a standard $\text{K}_2\text{Cr}_2\text{O}_7$ solution for the sample solution in HCl. The x-ray diffraction patterns were obtained by an automatic diffractometer (Rigakudenki 2028) with Mn-filtered $\text{Fe K}\alpha$ radiation at 35 kV and 10 mA. JEM 50B (Japan Electron Optics) was employed for the electron microscopic examinations of carbon-coated samples at 50 kV. Observation at a low voltage was preferable to avoid sintering between microcrystals.

Results and Discussion

As already reported by Gonzalez-Calbet *et al.* (4), as well as by the present authors (5), a strongly magnetic oxide is formed from $\beta\text{-FeOOH}$ in the limited temperature range between 300° and 500°C under a vacuum of $10^{-3}\text{-}10^{-5}$ torr. Above 500°C , $\alpha\text{-Fe}_2\text{O}_3$ is the sole product, which is known to be antiferromagnetic.

Figure 1 shows the x-ray diffraction patterns of the samples obtained by heating at 380°C and 10^{-3} torr for 3h and by air oxidation at 225°C for 20h, in comparison with the patterns of Fe_3O_4 and $\gamma\text{-Fe}_2\text{O}_3$. It appears that the dehydration product is composed of $\alpha\text{-Fe}_2\text{O}_3$ (marked with h in Fig. 1), $\gamma\text{-Fe}_2\text{O}_3$, and/or Fe_3O_4 . The reflections of $\gamma\text{-Fe}_2\text{O}_3$ and Fe_3O_4 are very similar to each other as compared in Fig. 1. Numerous studies have been published on the distinguishability between $\gamma\text{-Fe}_2\text{O}_3$ and Fe_3O_4 based on the magnetic and crystallographic examinations. The surveys of those reports can be found in Shieber's book (10) and more recently in Datta's review (1). It is apparent that no single technique can characterize unambiguously each oxide. Gonzalez-Calbet *et al.* (4) asserted that lattice parameters at $d_{(102)}$, 0.7085 nm, $d_{(110)}$, 0.5955 nm, and $d_{(104)}$,

0.5094 nm are characteristic of $\gamma\text{-Fe}_2\text{O}_3$, which are marked with small filled circles in Fig. 1. However, it seems doubtful if these weak diffraction patterns can be the basis for the reasoning of $\gamma\text{-Fe}_2\text{O}_3$ formation by dehydration, if one compares the patterns of the dehydrated product with those of $\gamma\text{-Fe}_2\text{O}_3$ and Fe_3O_4 .

It is noticeable that the chemical analysis of the oxides clearly gives evidence of Fe^{2+} in the concentration range $1\text{-}3$ mmol g^{-1} , as is described later. This fact means that the presence of an iron oxide like Fe_3O_4 containing Fe^{2+} cannot be denied. We recall that the presence of Fe^{2+} has been observed in iron oxide hydroxides and iron oxides by heating *in vacuo* (11).

However, the saturation magnetization (M_s) and the residual magnetization (M_r) increase linearly with the Fe^{2+} concentration, as shown in Fig. 2 and 3. The coercive force (H_c) appears to be almost independent of the Fe^{2+} concentration or increases slightly in the middle range of the Fe^{2+} concentration, and it tends to decrease towards the value of Fe_3O_4 (shown by triangle) in a higher concentration range than 3 mmol g^{-1} , as illustrated in Fig. 4. The samples, for which magnetic data are shown in Fig. 2, 3, and 4 by open circles, are the oxides obtained by heating the $\beta\text{-FeOOH}$ at various temperatures ($350^\circ\text{-}500^\circ\text{C}$) and $10^{-3}\text{-}10^{-5}$ torr for various durations (1-20h).

The samples after the oxidation of dehydrated products in air at 225°C still have some amounts of Fe^{2+} and their values of M_s , M_r , and H_c increase linearly with the Fe^{2+} concentration. However, it is apparent that the dependence of magnetic values upon Fe^{2+} concentration is entirely different between the dehydrated oxides and their air-oxidation products. The dependencies of M_s , M_r , H_c , and M_r/M_s on the Fe^{2+} concentration of the oxidation products (see the filled circles in Fig. 2, 3, 4, and 5) are greater than those of the dehydrated oxides. The M_s , M_r , and H_c of the $\gamma\text{-Fe}_2\text{O}_3$ sample as the reference are also shown in each figure by double circles on horizontal dashed lines. From the intersections of the full lines and dashed lines in Fig. 2-5, the Fe^{2+} concentration in the oxidation product having magnetic values of $\gamma\text{-Fe}_2\text{O}_3$ is estimated as 0.17 ± 0.05 mmol g^{-1} . The Fe^{2+} concentration by chemical analysis in this $\gamma\text{-Fe}_2\text{O}_3$ was 0.15 ± 0.01 mmol g^{-1} . The fairly close agreement for the content of Fe^{2+} from the chemical analysis and the magnetic experiments implies that the magnetic properties of oxidation products are characteristic of $\gamma\text{-Fe}_2\text{O}_3$. We call them the $\gamma\text{-Fe}_2\text{O}_3$ series, in con-

Fig. 1. X-ray diffraction patterns of $\gamma\text{-Fe}_2\text{O}_3$, Fe_3O_4 , dehydrated $\beta\text{-FeOOH}$ (380°C , 10^{-3} torr for 3h), and its air-oxidation product (225°C for 20h). As for the symbols in figure, see text.

trast to the dehydration products, denoted as the Fe_3O_4 series.

The x-ray diffraction patterns of an oxidized sample in air at 225°C for 20h are illustrated also in Fig. 1. The spinel-structure reflections observed in the dehydration product remain identifiable. Both the dehydrated product and its oxidation product show the x-ray patterns indicating the coexistence of $\alpha-Fe_2O_3$, marked with h in the figure. The sample after the air oxidation appears therefore to be composed of defective $\gamma-Fe_2O_3$ and $\alpha-Fe_2O_3$. It seems significant that the magnetic properties of the Fe_3O_4 series, *viz.*, the dehydrated $\beta-FeOOH$, are entirely different from those of the $\gamma-Fe_2O_3$ series, *viz.*, the air-oxidation products. It may well be that the dehydrated products of $\beta-FeOOH$ *in vacuo* are of the Fe_3O_4 series with different amounts of "insufficient" Fe^{2+} and that the air oxidation of the dehydration products gives the oxides of the $\gamma-Fe_2O_3$ series still with a small amount of Fe^{2+} . It may

appear strange that the linear relationships between M_s (and M_r) and the Fe^{2+} concentration pass through the zero points of magnetic values (Fig. 2 and 3), but it can be related to the structural transformation of the oxides of the $\gamma-Fe_2O_3$ series into nonferromagnetic $\alpha-Fe_2O_3$ by a rather extensive air oxidation.

Gonzalez-Calbet and Alario-Franco (12) examined recently the decomposition of $\beta-FeOOH$ within several minutes to suggest that the nucleation of $\gamma-Fe_2O_3$ initiates its growth, during which a single macropore, as observed by the electron microscope, is formed. According to the theoretical treatment by Knowles (13), the acicular particles of partially oxidized Fe_3O_4 , showing higher H_c and reduced remanence (M_r/M_s) relative to typical Fe_3O_4 or $\gamma-Fe_2O_3$, is considered to comprise an inner core of Fe_3O_4 with an outer layer of $\gamma-Fe_2O_3$. The volume change with oxidation results in a stress field interacting with the magnetization. Our results for H_c and M_r/M_s for "partially oxidized" Fe_3O_4 samples containing less Fe^{2+} than Fe_3O_4 (Fig. 4 and 5) seem to support, though vaguely, the view by Knowles. It should be mentioned that the values of H_c and M_r are highly structure sensitive, influenced by morphological properties of the particles, so that the meaning of comparison of these values between samples is complex and limited.

The particle images by electron microscope have been abundantly provided in various papers, especially those discussing pore structure in $\beta-FeOOH$ microcrystals and their dehydration products *in vacuo* (3, 4, 6, 8, 9, 11). Our electron microscopic observations are by no means different from those so far published. The average particle size of 300 nm length and 50 nm width did not considerably alter with the vacuum dehydration (250 × 40 nm) and the air oxidation (280 × 40 nm). No sintering between particles has been observed throughout the heat-treatments.

The direct use of dehydrated $\beta-FeOOH$ or its oxidation products as an acicular powder for magnetic tapes still seems to be unfavorable as far as the H_c values in the range of 200-350 ($10^3/4\pi$) $A m^{-1}$ of the products described in the present paper are concerned. Suitable means to improve the magnetic properties should be found up to a commercially attractive level for H_c of at least 500 ($10^3/4\pi$) $A m^{-1}$. Furthermore, the length to width ratio should be increased up to 10-15 for the original $\beta-FeOOH$ crystals by a better procedure of synthesis. Further investigations may yet find a useful magnetic material from $\beta-FeOOH$ by means of a more direct path than the complicated routine procedure using $\alpha-FeOOH$.

Conclusion

By the measurement of saturation magnetization, residual magnetization, and coercive force of the dehydration products of a synthetic $\beta-FeOOH$ at 300°-500°C under a vacuum of 10^{-3} - 10^{-5} torr for 1-20h and of their oxidation products in air at 225°C for 20h, and with reference to the x-ray diffraction patterns and chemical analysis of Fe^{2+} concentration in each product, the following conclusions have been reached.

1. The dehydrated $\beta-FeOOH$ is a mixture of oxides in the Fe_3O_4 series containing different amounts of Fe^{2+} and $\alpha-Fe_2O_3$. It is unlikely that the dehydration of $\beta-FeOOH$ *in vacuo* gives, as believed by the authors of most of the preceding reports, $\gamma-Fe_2O_3$.

2. The oxidation of the above dehydration products in air at 225°C for 20h produces a mixture of oxides in the $\gamma-Fe_2O_3$ series, which show entirely different magnetic properties from those of the Fe_3O_4 series, and $\alpha-Fe_2O_3$.

3. The saturation magnetization and residual magnetization of both the dehydration products and the oxidation products are proportional to the Fe^{2+} concentration in the oxides. The dependence of the magnetic values on the Fe^{2+} content is steeper for the $\gamma-Fe_2O_3$ series than that for the Fe_3O_4 series.

ABSTRACT

Conventional gaseous BBr_3 and CVD SiO_2 are presently used in the Westinghouse baseline process for the production of high efficiency (13%-15%) dendritic web solar cells. The objective of this study was to replace the CVD SiO_2 mask and the subsequent BBr_3 diffusion step with a liquid SiO_2 /liquid boron dopant diffusion process. The number of process steps are reduced significantly with the use of the liquid process. Data on time-temperature relationship on sheet resistance, junction depth, etc., were obtained and are presented. Various application techniques for the liquid process were investigated. As a first step, a manually applied sponge-squeegee applicator was used, which was later replaced with a meniscus coating machine. This equipment permitted the application of uniform layers of liquid dopants of controlled thickness on the dendritic web. Various runs were made to make direct comparison of the liquid and baseline processes. The results of cell efficiencies achieved using the liquid process indicate that high efficiencies (13%-15%) can be achieved with this process. Results of V_{oc} , I_{sc} , fill factor, etc., are presented in detail and compared with the baseline process. Dark IV measurements made on liquid-processed cells indicate excellent quality junctions and high lifetime values. The series and shunt resistance measurements on typical cells show no difference as compared with the baseline process. Junction profiles are presented for both a gaseous diffused cell and a liquid processed cell. The profiles show no dissimilarities.

The purpose of this paper is to present results on the doping of dendritic web silicon with liquid metallo-organics to produce an n^+pp^+ solar cell structure.

Dendritic web silicon is crystalline silicon grown in long strips. In the as-grown condition, it is thin, generally 120-150 μm thick, and requires no sawing or lapping prior to the cell fabrication process.

Figure 1 shows the Westinghouse baseline process sequence in block form. The original Westinghouse baseline process sequence required gaseous diffused back and front junctions, each junction formation step being preceded by a chemical vapor deposition (CVD) applied oxide masking step. The development work being conducted at Westinghouse and reported herein involves the substitution of liquid-applied oxide masks for the CVD-applied masks and substitution of liquid-applied dopants for gaseous diffused dopants.

Figure 2 shows a length of dendritic web silicon and a solar cell fabricated from this material. The edges (dendrites) and the center section (web) are one single crystal with a re-entrant twin plane. The dendrites are generally left on the strip until the final processing steps. The material is normally processed in 33 cm long strips.

Figure 2 also shows a typical solar cell fabricated on dendritic web silicon. Its natural rectangular shape permits a high packing factor of active cell area in the solar modules.

In the experiments reported here, we used a p-type web with a resistivity of 4-8 $\Omega\text{-cm}$. The cell sizes are a nominal 2×10 cm, with ten contact pads per cell. The double doping process sequence uses a boron containing liquid for the back surface field diffusion and a phosphorus containing liquid for the n^+p front junction producing an n^+pp^+ junction structure.

Because of the different diffusion constants of B and P in silicon and the requirements for shallow front junctions, the process sequence requires two diffusions. The first is a boron diffusion to form the p^+p back surface field, followed by a phosphorus diffusion at lower temperature to form the front n^+p junction.

Baseline Process Comparisons

In the work reported here, the liquid dopant experiments were carried out in conjunction with a baseline gaseous diffusion process using BBr_3 and POCl_3 . In this way, the efficacy of the liquid dopant process could be determined.

*Electrochemical Society Active Member.

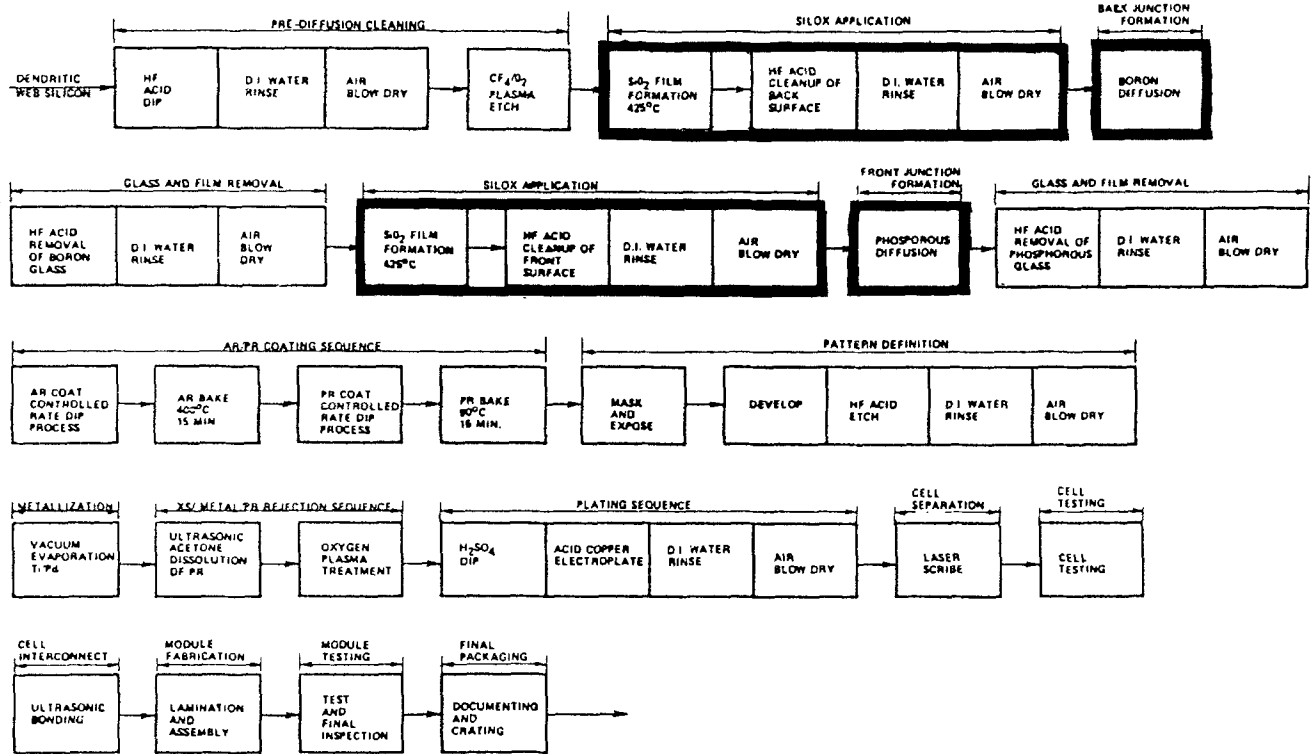

Fig. 1. Westinghouse baseline process sequence flow chart

Since two diffusions were required to form the n^+pp^+ structure, an SiO_2 layer was used as a diffusion mask. In the baseline process, the mask was a CVD SiO_2 layer, while in the liquid process, we used a solution containing SiO_2 .

Table I shows the process steps required for three different junction formation techniques used. The first column is the baseline gaseous BBr_3-POCl_3 process. The second column is a liquid mask/liquid boron + liquid mask/ $POCl_3$ process, while the third column is the liquid mask/liquid boron + liquid mask/liquid phosphorus process. The work reported herein describes the results of column 2, back junction, p^+ . The work of column 3, front junction, n^+ , is not completed.

Due to the long lengths of dendritic web processed in the Westinghouse facility (33 cm), the liquids were manu-

ally applied using a sponge-squeegee rather than the normal spin-on method used for wafers.

This method of application was generally satisfactory. After the coated strip was baked (before diffusion), the surface showed the normal oxide colors. The thickness of the layers was 0.25 to 0.5 μm .

Table II shows the results of a diffusion time-temperature study to determine conditions for the desired $40 \Omega/\square$ sheet resistivity for the back junction, p^+ . The underlined $980^\circ C$ temperature for 30 min was chosen for all further work.

Figure 3 shows junction profiles of the liquid produced p^+p junction as compared to a gaseous BBr_3 -produced p^+p junction. There is no essential difference.

Lighted and dark IV measurements made on the two types of cells, liquid applied p^+ vs. gaseous p^+ , are shown

Fig. 2. A length of dendritic web silicon and a solar cell fabricated from it.

980	45	45
980	60	30

Baseline BBr₃ gaseous diffusion carried out at 960°C for 20 min. 80% N₂, 20% O₂ ambient diffusion environment.

Baseline process specification for boron-doped p⁺p junction = 40 Ω/□ ± 10 Ω/□.

* Liquid dopant diffusion carried out at 980°C for 30 min. 80% N₂, 20% O₂ ambient diffusion environment. Actual run data produces 40 Ω/□ nominal instead of 55 Ω/□ indicated by research data.

in Table III. Again, there is no essential difference between the two types of cells, with both cells having excellent lifetimes and junction depletion regions having very few recombination centers.

The efficiency of these cells (liquid mask/liquid boron and liquid mask/POCl₃) is comparable to the baseline-processed cells.

To demonstrate the feasibility of using belt furnaces (which are highly automatable) for liquid dopant drive-in diffusion, a series of experiments were conducted at Radiant Technologies Incorporated, Cerritos, California, using one of their belt furnaces. Using web material from the same run, one-half of the liquid boron dopant cells were diffused using a belt furnace, and the second half were diffused using a standard diffusion tube furnace. The data presented in Table IV indicate that the performance of cells processed with the belt furnace was equal to those processed with a diffusion tube furnace. These fur-

Fig. 3. Liquid vs. gaseous p⁺p junction profiles

nance experiments were significant in that they demonstrated that liquid dopant cells are amenable to being processed with automatable equipment, which, in turn, can be reflected in lower processing costs.

Table V shows the average efficiency of baseline processed cells vs. the liquid boron p⁺p junction cells fabricated over a 3 month period. These data indicate that the liquid process is indeed a suitable replacement for gaseous diffusion.

The next series of experiments, which is continuing, is to verify that a n⁺p junction can be produced using a liquid phosphorus dopant and can be used to replace the gaseous POCl₃ diffusion.

The same procedure has been used to determine the proper diffusion time, diffusion temperature, and ambient gas for the liquid phosphorus study as was done for the liquid boron reported herein. To obtain the required 60 Ω/□ sheet resistivity, a diffusion temperature of 890°C for 20 min in an ambient of 100% O₂ is being used for the phosphorus dopant studies.

Our present plans are to develop a statistically significant data base with the liquid phosphorus dopants the same as was done with the liquid boron dopants. From our study, we conclude that an n⁺pp⁺ junction structure can be formed on p-type dendritic web silicon using liquid-applied dopants and liquid-applied diffusion masks. The cells produced with liquid dopants perform at least equal to or better than the baseline gaseous process. Cost analyses conducted on the gaseous process using the Solar Array Manufacturing Industry Costing Standards (SAMICS) developed at the Jet Propulsion Laboratory indicate front and back junction formation costs at 37.3 and 5.7 ¢/W, respectively, for a 1 and a 25 MW/yr production volume. Although costing studies have not been completed for liquids, it is expected that the junction forma-

Effect of Photoirradiation of GaAs Surface during HF Treatment

Masayoshi Ohno

Much interest has been centered on the surface of compound semiconductors such as GaAs (1). Controlling the chemical, crystallographic, and electrical properties of the surface has become indispensable for realizing GaAs integrated circuits (2). One of the problems in GaAs IC fabrication, however, is to obtain uniformity of the electric properties for each device as well as a reproducibility from wafer to wafer. It is thus necessary to find primary factors affecting surface change, so as to be able to achieve homogeneity and reproducibility for the surface.

Recently, the effects of various etchants on the GaAs surface have been reported (3-6). Chang *et al.* reported that the etching with HCl or NH₄OH results in As-rich surface (3). In the case of etching with HCl, exposure of the etched surface to a small amount of air allows not formation of oxide nor hydrated oxide, but oxygen chemisorption. After prolonged exposure to air, however, the etched surface is oxidized (5). The mechanism of oxidation needs further clarification.

The oxidation process for a cleaved surface has been also studied (7-8). Room temperature oxidation of the cleaved surface can be induced through exciting the oxygen molecules (7). It seems important that the oxidation of the cleaved surface needs exciting energy provided by discharge.

Photoetching phenomena have themselves been studied for the last several decades (9-11). Etching can be accomplished in very dilute electrolytes assisted by photoirradiation (9). These reports suggest that photoirradiation has considerable effect on the chemical properties of semiconductor surfaces.

This paper reports some preliminary results of investigations into photoirradiation effect, during and after acid treatment, on GaAs surface chemical composition and morphology.

Horizontal Bridgman (HB) grown and liquid encapsulation Czochralski (LEC) grown Cr-doped semi-insulating GaAs (100) wafers were washed in boiling trichloroethylene, then chemically etched of about a 0.2 μm in a solution of 1(1N)NaOH:1(1N)H₂O₂, rinsed in deionized water ($\rho > 18 \text{ M}\Omega \text{ cm}$), and dried by blowing dry N₂. Samples were immersed in several kind of acids, mainly HF, for 3 ~ 600 min, were rinsed in deionized water, and were dried by dry N₂ (acid treatment). After exposure of the samples to air, the GaAs surface was observed under an optical microscope and a scanning electron microscope (SEM), and was examined by Auger electron spectroscopy (AES). In particular, effects of photoirradiation during acid treatment and exposure to ambient air were investigated.

Figure 1 shows a typical HF-treated GaAs (100) surface. The acid treatment was carried out in a solution of 1 (50%) HF + 1H₂O:(1:1)HF, for 20 min in bright light. After it was rinsed in deionized water for 3 min and dried in dry N₂, the surface was partially irradiated using the illuminator of a microscope for 60 min during exposure to air. The micrograph indicates the difference in surface features (morphology) between the irradiated and nonirradiated regions. The appearance of fine particles on the irradiated region could clearly be observed. Consequently, photoirradiation after HF treatment has a particular influence on the appearance of fine particles. The appear-

Fig. 1. Micrograph showing HF-treated GaAs surface in bright room light. Right-hand side (bright) area was photoirradiated in air for 60 min using the illuminator of an optical microscope.

ance of fine particles could be observed in the case of HF treatment in (1:1) HF for 3 min and photoirradiation using room light during exposure to air.

Observation using SEM (Fig. 2) made it clear that the fine particles were crystalline material. As the HF-treatment time increased to several hours, the number of the fine crystalline particles increased.

This phenomenon could be observed after acid treatments with sulfuric acid or phosphoric acid, when the acid treatment was carried out for 24h in bright room light using each concentrated acid, respectively. But in the case of hydrochloric acid, this phenomenon could not be observed when GaAs surface was photoetched in bright room light for 24h using concentrated acid. These results agreed well with a study using ellipsometry (12).

Etched in bright light	In bright light	Appeared
	Exposed to air	None
Etched in dark	In dark	None
	Exposed to air	None
Etched in dark	In bright light	None
	Exposed to air	None

The effect of photoirradiation and atmosphere on the appearance of fine crystalline particles is summarized in Table I. It can be noted that the appearance of fine crystalline particles on the surface might be assisted by a photoirradiation, during both acid treatment and following exposure to oxygen in ambient air.

The composition of the fine crystalline particles was studied. The particles were found to be sublimated at about 100°C in air and also dissolved in room temperature water in about 15 min. On the basis of these observations, it was speculated that the fine crystalline particles are diarsenic trioxide arsenorite, which is composed of As_2O_3 units (13). From Ref. (13), the rate of vaporization of a crystalline arsenorite As_2O_3 at about 100°C is about 10^0 mg/cm² min. Using this value, the time for the disappearance of 1 μm diam crystals was estimated to be about 10^{-1} min. This estimate agreed well with the observation.

If the particle is diarsenic trioxide claudetite, the time for the disappearance of 1 μm diam crystals was similarly estimated at about $10^6 \sim 10^7$ min. So, the particles do not seem to be claudetite. Furthermore, the particles do not seem to be diarsenic pentoxide; As_2O_5 is deliquescent and easily dissolved in water. A sublimation of gallium oxide is difficult, so the particles do not seem to be gallium oxide.

The results analyzed by AES for surface under various exposure conditions are shown in Fig. 3. The HF treatment was carried out in (1:1)HF for 270 min in bright light. The HF-treated wafers were then stored about 1 day in dark and bright light. One sample was heated up to about 100°C for 30 min after the storage under bright light. In the case of HF treatment in bright light and followed by storage in the dark, the surface was covered with almost arsenic only, and no fine crystalline particles appeared. This indicated that acid treatment in bright light made the surface rich in As (3). However, with storage under photoirradiation, oxygen and gallium increased, while arsenic decreased, and fine crystalline particles appeared. After the sample was heated up to about 100°C for 30 min, arsenic and oxygen decreased, while gallium did not vary and the fine crystalline particles vaporized. This change indicates that the photoirradiation under air exposure brought about oxidation of the

Table II. Dependence of irradiated light wavelength upon appearance of fine crystalline particles

Wavelength (nm)	Fine particles
350 < λ < 600	Appeared
690 < λ	Appeared
900 < λ	None

As-rich surface, resulting in a production of As₄O₆ fine crystalline particles. The density (in number) of the fine particles increased with HF treatment time; this may be due to the increment of the As layer. The oxidation of the arsenic layer brought about the appearance of the GaAs layer under the initial As layer, and thus the gallium content was increased.

The mechanism of the fine particles' formation is related to the dependence of irradiated light wavelength on the phenomenon. Then, the dependence was investigated as follows in order to identify the mechanism. HF treatment was done in (1:1)HF for 15 min in bright light. The photoirradiation under air exposure was carried out under filtered illumination for 60 min using an optical microscope. The dependence of irradiated light wavelength on this phenomenon is shown in Table II. It seems that electron-hole pairs creation by the photoirradiation play an important role in the phenomenon (14). This is because the threshold of photoirradiation effect exists between 690 and 900 nm regions. It was speculated that the threshold wavelength may be around the bandgap energy of GaAs.

In conclusion, HF etching treatment under photoirradiation resulted in an As-rich surface for GaAs crystal. The As-rich surface could be oxidized in air by means of photoirradiation, and fine crystalline particles were formed on the surface. The particles were thought to be As₄O₆ (arsenorite). Based on the above results, much attention has to be paid to the photoirradiation in both etching process and air exposure of the GaAs surface in the GaAs IC process.

Acknowledgments

The authors would like to express their thanks to Y. Watanabe for the AES experiments. They are also indebted to M. Ohmori, Y. Nanisi, H. Yamazaki, and T. Honda for their support and valuable comments during this experiment. One of the authors (M.O.) in particular would like to thank Y. Katayama, T. Kurokawa, T. Okada, H. Hiratsuka, and T. Yamada for their helpful discussions and much administrative support.

Stress Effects in Boron-Implanted Polysilicon Films

Min S. Choi* and Eric W. Hearn*

IBM Corporation, General Technology Division, East Fishkill Facility, Hopewell Junction, New York 12533

Polycrystalline silicon films are used throughout the semiconductor industry in the fabrication of both metal-oxide-semiconductor (MOS) and bipolar products. For example, in MOS products, doped polysilicon is used for gate and interconnection materials. In bipolar products, polysilicon is used for device isolation, passive resistors, or active base elements.

While these films are usually used with different ranges of doping, stress measurement of doped polysilicon is not well reported.

Earlier reports of thick (up to 500 μm) intrinsic polysilicon films gave tensile stress properties (1). Later reports using thinner films (4000-6000 \AA) showed compressive stress properties (2). The thinner films were deposited under different conditions than the thick films, and were both intrinsic and boron diffused.

The purpose of conducting this study was to determine quantitative stress measurements made on boron-implanted and annealed polycrystalline films to assess the possible effect of stress on device fabrication, such as pattern distortion and change in the electrical property of a substrate. Comparative warpage measurements were made treating various film structures as substrates.

The effect of doping concentrations and annealing temperatures on the film stress was also studied.

*Electrochemical Society Active Member.

Film stress was determined using comparative warpage measurements on oxide, polysilicon, and nitride films.

Experimental Procedures

Sample preparation.—The substrates used were p-type (10-20 Ω cm), 82.5 mm diam and 0.4 mm thick. After 2000 \AA thermal oxide was grown, polysilicon was deposited to a thickness of 2000-5000 \AA by low pressure chemical vapor deposition (LPCVD) at 625°C by the decomposition of silane. A 500 \AA LPCVD oxide cap was deposited at 430°C, and two-thirds of the samples were ion implanted with boron (1×10^{14} - $5 \times 10^{15}/\text{cm}^2$, 45-100 keV) and annealed. All films except nitride were simultaneously deposited on both sides of wafer. Dose and energy of the implantation were adjusted so that the doping concentration after annealing was 5×10^{18} or $1 \times 10^{20}/\text{cm}^3$. The peak dopant concentration is located near the middle of the films as determined by published data (3). This approach assumes that boron spreads quickly at annealing temperatures greater than 925°C. This was verified by SIMS analysis in a separate experiment.

After annealing (925°-1100°C, 60 min), back-side reactive ion etching (RIE) of oxide or of oxide and polysilicon was done on some wafers. Subsequently, 2000 \AA nitride was deposited on some of these wafers at 1000°C using SiH₄, NH₃, and H₂ carrier gas. This series of procedures resulted

Fig. 1. Sequence of oxide, polysilicon, and nitride film depositions used in this experiment.

in the film configurations shown in Fig. 1. Table I gives the details of the respective wafer splits for doping, film thicknesses, and annealing temperatures.

Warpage measurements.—The warpage of wafers was measured on a Mikrokator thickness gauge (see Fig. 2). This measurement resulted in the warpage values used in the modified stress equation (4) for small bending due to film stress (σ_f)

$$\sigma_f = \pm \alpha \frac{1}{3} \frac{t_s^2 \Delta h}{t_f r^2} \frac{E_s}{1 - \nu} \quad [1]$$

where t_s is the substrate thickness, t_f the film thickness, r the radius of wafer, Δh the deviation of wafer from optical flat (warpage), E_s Young's modulus of the silicon substrate (1.805×10^{12} dyne/cm²), ν Poisson's ratio for the substrate, α a correction factor (1.5) for deflection measurement,¹ + the tensile or concave warpage, and - the compressive or convex warpage.

Results

Warpage measurements.—From the experimental data represented in Fig. 1 and 2 and Table I, stress was calculated using the following hypothesis.

Warpage values may be compared interchangeably between any composite structure by defining the substrate to be that portion of the wafer cross section containing the greatest number of symmetric top and bottom layers.

This assumption is valid under the condition that the film thickness is negligible compared to the wafer thickness, so the elasticity of the wafer is not affected. After

widely-accepted experimental x-ray warpage data (5) were compared to the present "disk" warpage measurement and resulted in a correction factor of 1.5.

Table I. Experimental parameters for each wafer

Wafer #	Doping	Thickness	Temp. (60 Min. Anneal)

20			5000Å Polysi			

Fig. 2. Warpage measurement

the warpage for a particular film or film composite was measured, the stress was calculated using Eq. [1].

For example (from Fig. 1), the substrate warpage caused by the polysilicon film is calculated from the warpage difference between two cross sections: $D_{(\text{warpage})} - B_{(\text{warpage})} = \text{Polysilicon}_{(\text{warpage})}$ by using B as the substrate. Equivalent results were obtained using levels D and C . For the stress values of silicon nitride, good correlation was found between direct and indirect level comparisons, i.e., $F_{\text{warpage}} - E_{\text{warpage}}$ (direct) as compared to $(F-A) - \{(E-C)\}$ (indirect).

To show the effectiveness of the hypothesis, Fig. 3 illustrates the correlation of polysilicon stress calculated using two different structures.

Figure 4 shows similar results for polysilicon + oxide, and Fig. 5 shows the results for Si₃N₄.

Standard linear regression (6) method was used to get the correlation coefficients. As seen in Fig. 3-5, the correlations are good and give assurance that the warpage

Fig. 3. Correlation of comparative warpage measurements on polysilicon films.

Fig. 4. Correlation of comparative warpage measurements on polysilicon + oxide films.

Fig. 5. Correlation of comparative warpage measurements on Si₃N₄ films.

values are true indicators of stress changes associated with processing.

These data indicate that the stress of the polysilicon on top of the oxide is compressive and varies between approximately -1×10^9 and -6×10^9 dyne/cm² over the entire range of doping and heat-treatments used in this experiment.

Polysilicon + oxide stress (Fig. 4) was also compressive, and varied between -1×10^9 and -5×10^9 dyne/cm². This is comparable to either SiO₂ or polysilicon.

The nitride stress in Fig. 5 is tensile and ranges between 4.0 and 8.0×10^9 dyne/cm². This value is slightly lower than unannealed nitride films on bare substrates reported in Ref. (5). The difference could be a result of the nitride films' being deposited under different conditions.

Undoped polysilicon and nitride films were deposited on bare substrates; their respective stress values were 4.0×10^9 and 7×10^9 dyne/cm². This compares favorably with the undoped polysilicon and nitride values on top of oxide films. This lends credence to the relative film comparative technique.

Effect of annealing temperature on stress.—Figure 6 is a plot of stress calculated for samples with 3000Å polysilicon films that were exposed to various doping levels and heat-treatments.

The results show that there is a temperature threshold near 1000°C, where the stress decreases. Unfortunately, one of the samples (no. 16) broke, and the second data point for the 10^{20} /cm³ curve is missing. However, stress and grain size (and morphology) do not change appreciably for the different concentrations and annealing tem-

Fig. 6. Annealing temperature vs. polysilicon film stress (3000Å) for different doping levels.

peratures up to 1000°C [see Fig. 6 and Ref. (11)]. Based on these findings, we feel justified in assuming the graphed qualities for the missing data point. The entire data base is sparse. However, the trend is clear, and the correlation of the earlier data (Fig. 3-5) is encouraging.

It is also noted that for unannealed samples, the stress is higher in the implanted case than in those samples without implantation.

This trend seems to continue up to where the stress obviously changes (relaxation temperature). This is a reasonable trend, considering that the implantation damage may not be annealed thoroughly at temperatures lower than the relaxation temperature.

The relaxation of the 5×10^{18} /cm³ sample occurs at a higher temperature than does the intrinsic polysilicon. This is probably due to a concentration effect, and will be explained in the discussion section.

Discussion

It has been reported that the compressive stress of thermal oxide can be explained by a thermal mismatch between the oxide and the silicon substrate (2). The observed tensile stress for the CVD nitride films is largely caused by the intrinsic film stress (7). For the 60-500 μm thick polysilicon films grown on oxidized wafers using different reaction gases and temperatures above 1100°C, some authors report tensile stresses (1, 8). However, for the thin film case (4000-6000Å) (2) compressive stress is in agreement with the observations reported here.

The nature of the observed compressive stress of the polysilicon film is believed to be due to the intrinsic properties of the film because the difference in the coefficients of expansion between polysilicon and single-crystal silicon is small (1, 2).

The stress relaxation near 1000°C, observed for different ranges of doping (Fig. 6), is assumed to be due to the annealing effect. The grain-size measurement of a transmission electron microscope (TEM) showed that substantial grain growth occurs above 1000°C.

The relaxation temperature of the higher doped (5×10^{18} /cm³) sample is higher than that of the undoped sample. This could be attributed to the ion-implantation damage rather than the doping effect. TEM results show that film morphology and grain size look about the same in the three samples at 1000°C. However, for the highest doped samples (1×10^{20} /cm³), the stress near the relaxation temperature appears lower than the undoped or the 5×10^{18} /cm³ samples. This may be explained as follows.

Brotherton *et al.* (9) report a relationship exists between the substrate lattice constant and the stress in the lattice (σ_s).

Also, the lattice constant of silicon is shown to decrease (resulting in a tensile stress) as a function of boron concentration (10) (see Fig. 7). Assuming a lattice constant corresponding to the 1×10^{20} /cm³ doping concentration used in this experiment, Fig. 8 shows the resultant change in stress due to boron concentration using Brotherton's equation in Ref. (9).

Fig. 7. Silicon lattice constant vs. boron concentration

Fig. 8. Stress induced by change in silicon lattice constant as a result of boron in the lattice. From Ref. (9).

This calculation shows that at $1 \times 10^{20}/\text{cm}^3$ boron concentration, the stress can change 2×10^9 dyne/cm² in the tensile direction. If we assume a similar behavior for the polycrystalline films, the magnitude of the induced tensile stress is comparable to the measured compressive stress in these polysilicon films and can, therefore, partially compensate for the film stress.

Summary

Comparative warpage measurements were used to measure the film stress of polysilicon and nitride. The film stress of polysilicon (2000-5000Å) on top of oxide was found to be approximately $-(1-5) \times 10^9$ dyne/cm² (compressive) over the range of doping from intrinsic to $10^{20}/\text{cm}^3$, and of annealing temperature from 25° to 1100°C. Temperature effects on polysilicon film stress were

larger than the doping effects. The film stress of nitride deposited on oxide plus polysilicon was found to be $+(4-8) \times 10^9$ dyne/cm² (tensile). Stress relaxation was observed near 1000°C annealing temperature for the polysilicon films.

Short Time Annealing of Coevaporated Tungsten Silicide Films

T. O. Sedgwick,* F. M. d'Heurle,* and S. A. Cohen

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

Short time annealing (STA) which is thermal processing for times short compared to standard furnace annealing is being explored as a means of reducing the time-temperature exposure of device structures in silicon technology (1). Early efforts in STA employed pulsed or CW laser or electron beams to heat samples for times of milliseconds down to nanoseconds. These energy sources, however, usually require scanning of a small area spot over a large sample with the disadvantages of nonuniform exposure, high localized thermal stresses, and low sample throughput. Many recent STA studies employ incoherent light sources to anneal large-area samples (~10 cm) which are spatially uniform in temperature for time intervals of 1-100s. The technique is best referred to as isothermal STA. These heat sources include arrays of tungsten halogen lamps, high intensity argon or xenon discharge lamps, and resistance-heated graphite blackbody radiation sources. This technique is meant to acquire the additional advantage of a full wafer isothermal process while retaining the known advantage of a reduced thermal cycle.

As device dimensions shrink and the degree of integration increases in VLSI technology, refractory metal silicides have found important application as device interconnections because of their metallic-like conductivity,

ability to be oxidized, and thermal stability (2, 3). For many applications, a silicide/polycrystalline Si (poly-Si) double layer called a polycide structure is used (4) as a gate electrode and interconnection.

The silicides of Ta, Mo, and W, all of which are being investigated as potential high conductivity interconnects can, in principle, be formed by direct reaction. However, the reaction of the metal with Si occurs at high temperatures and with poor reproducibility. Thus, direct reaction has not been the preferred fabrication method for device applications. We note, however, that Wakita *et al.* and others (5) have formed Mo and W silicide by CW argon laser annealing of the metal/silicon structure.

Reproducible formation of refractory silicide may be obtained by coevaporation or cosputtering of the elements or sputtering of the compound, or CVD of suitable precursors. All these techniques are finding application in practical device fabrication. Even with this initial degree of premixing, an additional thermal cycle in the range of 1000°-1200°C is required to crystallize the compounds and produce highly conducting films. Tsai *et al.* (6) reported the dependence of film resistance on annealing time and temperature, but did not investigate annealing times less than 3 min because of standard furnace process limitations. Recently, Sedgwick *et al.* (7) and McPherson *et al.* (8) have reported on the STA of WSi₂ and MoSi₂, respectively.

*Electrochemical Society Active Member.

In the fabrication of small devices in VLSI, there are four important requirements on this thermal anneal process: (i) the silicide should become homogeneous and well adherent, (ii) the silicide should become as conductive as possible, (iii) the time-temperature cycle should not perturb the dopant distribution in any underlying partly fabricated device, and (iv) the dopant in the polycrystalline Si (poly-Si) of a polycide structure should not be grossly depleted.

In the present study, we present results of the STA of WSi_2 with reference to the above items. With regard to item (ii), we have studied annealing down into the few second time range. With regard to (iii), we compare the properties of the silicide after a STA at $1200^\circ C$, 6s with those after a standard furnace anneal at $950^\circ C$, 30 min. With respect to diffusion in Si, these two thermal treatments are equivalent; from a standard diffusion calculation, they lead to minimal dopant motion of B in a submicron FET technology where the B implant is already present in the channel region of the device. The results for item (iv) are as yet only qualitative and preliminary.

Experimental

Figure 1 shows a schematic of the graphite resistance heater used for the STA experiments. The horizontally arranged resistance heater has a free standing area of 4×5 in. and is 0.050 in. thick. It is made of graphite from POCO. Rapid heating is achieved by passing up to 600A alternating current at 14V through the graphite using the water-cooled clamps. The polycide samples about 1 cm^2 , were placed on small quartz chips 0.020 in. thick in the center of the graphite plate. The temperature of the sample was monitored *in situ* using a Irtroic Model 3100 IR pyrometer focused to a $1/2$ mm diam spot. It was positioned to look vertically down, through a quartz window and small holes in horizontal Ta shields (not shown in Fig. 1), at the sample top surface. The ambient was dry N_2 and the heating apparatus was carefully purged at room temperature and at $450^\circ C$ before high temperature annealing.

Typical time temperature curves are shown for nominal $1200^\circ C$, 3s exposures in Fig. 2, and a $1200^\circ C$, 60s exposure in Fig. 3. The IR pyrometer was calibrated by focusing it close to a Pt-PtRd thermocouple bonded to the chip surface and allowed to equilibrate for at least 15s. Figure 4 shows that the thermocouple and the pyrometer read the source temperature within $12^\circ C$ over the range 900° - $1200^\circ C$. STA experiments in the time range of a few seconds still resulted in overall agreement within $12^\circ C$. The furnace anneal at $950^\circ C$, 30 min was carried out in a standard furnace with argon or N_2 ambient.

GRAPHITE STRIP HEATER

Fig. 1. Schematic of graphite resistance STA apparatus

Fig. 2. Pyrometer trace of time-temperature nominal 3s anneal at $1200^\circ C$ in graphite resistance apparatus.

Fig. 3. Pyrometer trace of time-temperature for a 60s anneal at $1200^\circ C$.

The polycide structures I, II, and/or III in Fig. 5 were used in the experiments. The silicide was deposited by coevaporation with a stoichiometry of $WSi_{2.1-2.3}$. Structure I was 1300\AA silicide on a Si (100) wafer. Structure II was 1300\AA coevaporated WSi_2 on 1500\AA of heavily doped P-, As-, or B-doped LPCVD or CVD poly-Si on 1000\AA dry wet thermal SiO_2 . Structure III was an RIE patterned film with submicron dimensions. This structure was 300\AA evaporated silicon on 1500\AA coevaporated WSi_2 on 1000\AA of $POCl_3$ -doped polysilicon on 100\AA thermal SiO_2 .

Sample resistance was measured with a four-point probe. B, P, and As profiles were measured by secondary ion mass spectrometry (SIMS) and W profiles were measured with Rutherford backscattering spectroscopy (RBS).

Results and Discussions

Figure 6 shows an RBS profile of the W in a structure II sample with B-doped polycide as deposited, both after a $950^\circ C$, 30 min furnace anneal and after a $1200^\circ C$, 6s STA exposure. The unintentional (but useful for the present experiment) W concentration minimum (corresponding to a Si concentration maximum) just below 2.07 MeV in the as-deposited film is not removed by the furnace anneal, but good homogenization is apparent after the STA process. [This is in agreement with the previous observations (6, 9) that while excess W can be annealed out at tempera-

tures as low as 800°C, the elimination of excess Si requires temperatures of the order of 1000°C.]

Figures 7a and 7b show samples of structure III after STA at 1200°C, 6s. The perfectly intact lines exhibit no adverse effect of STA.

The variations of resistance with annealing time and temperature for polycide samples of structures I and II are displayed, respectively, in Fig. 8 and in Fig. 9, 10, and 11. Within a small variation, all the results are very similar even though the poly-Si in Fig. 9, 10, and 11 is heavily doped with P, As, and B, respectively. The major result is that the resistance is a fairly strong function of the temperature. The resistance decreases only weakly as a function of increasing time in the range 3s to 5 min at both 1000° and 1100°C. At 1200°C, the resistance is independent of time. Apparently, at 1200°C, the silicide annealing process is fast compared to 3s.

Table I compares the minimum resistance observed in samples of structure II for both STA at 1200°C, 6s and fur-

Fig. 11. Sheet resistance of 1360Å WSi_2 and B-doped poly-Si after annealing at various times and temperatures.

Fig. 9. Sheet resistance of 1360Å WSi_2 on P-doped poly-Si after annealing at various times and temperatures.

Fig. 10. Sheet resistance of 1360Å WSi_2 on As-doped poly-Si after annealing at various times and temperatures.

nance anneal at 950°C, 30 min. The principal result is that the STA process yields resistances of two to three times less than for the furnace anneal. We will touch on this fact again at a later point. The small differences between samples with differently doped poly-Si underlayers are judged not significant without further supporting data.

At this time, we offer some qualitative comments but do not present a quantitative explanation for the silicide resistivity as a function of time and temperature, a phenomena which we believe is quite complex. The grain size of the silicide films has not been measured in this work, although it no doubt increases as a function of annealing time and temperature. In general, there exists a positive correlation between grain size and conductivity in silicide films. However, this is not enough to justify the often-encountered statement that the decrease in resistivity is due solely to grain growth. The attempt to relate quantitatively grain sizes and resistivities in silicide films leads to material parameters which appear too extreme to be physically valid (2, 10). The lowest resistivity achieved, about 35 $\mu\Omega$ cm (Fig. 8, 11), appears to be in good concordance with the minimum published value for WSi_2 .

The data of Table I clearly show the factor of 2 to 3 advantage in lowered resistance when using a 1200°C, 6s *vs.* a 950°C, 30 min anneal. As pointed out above, these two widely different thermal treatments were chosen to lead to a minimal and equivalent B diffusion in any underlying device. Figure 12 shows an Arrhenius-like plot of B diffusion in Si where the area with vertically hatched lines corresponds to the acceptable process region. For the limiting B-diffusion line, we have used a SUPREME calculation, where the shallow-channel B is required not to move significantly. The actual device requirement is that the substrate sensitivity not be degraded significantly in a submicron FET technology (11). In terms of the dopant motion, this corresponds to a B diffusion less than 700Å at a C/C_0 value of 3.3×10^{-2} . On the same Fig. 12, one also finds the apparent temperature *vs.* time region (hatched with horizontal lines) required to obtain a silicide sample resistance less than 4 Ω/\square . Only the data at 1100° and 1200°C were used. The very high apparent thermal activation of the silicide annealing process defines a new processing region, at high temperatures

Table I. Resistance of WSi_2 polycide structure II

	STA anneal	Furnace anneal
Structure	1200°C, 6s	950°C, 30 min
WSi_2 /B-doped poly-Si	2.8 Ω/\square	10.5 Ω/\square
WSi_2 /P	3.7	8
WSi_2 /As	3.7	8.8
Resistivity of silicide	38-50 $\mu\Omega$ cm	109-143 $\mu\Omega$ cm

Fig. 12. Arrhenius-type plot showing overlap regions (cross-hatched) where minimal B diffusion occurs (line-hotched) and where sufficient silicide annealing (lines hatched) to achieve a resistance less than $4 \Omega/\square$.

and short times, where both sufficient silicide conductivity is obtained and minimal diffusion is expected.

The definition of such a satisfactory new region for thermal treatment in the present case is possible because of the wide range of temperatures and times available currently in thermal annealing, and because the thermal activations for the two processes are widely different.

Figure 13 shows SIMS profiles of the B concentration in a polycide sample structure II as deposited, after STA, and after furnace annealing. The depth scale is not calibrated because of the differing sputtering rates but the step-like B concentration in the as-deposited trace corresponds to the doped poly-Si layer and the region to the left corresponds to the WSi_2 layer. Upon STA or furnace annealing, the B redistributes throughout both the silicide and poly-Si layers. Unfortunately, because of the matrix effect on the SIMS sensitivity in the different layers, the actual concentration of B in each layer may not be equal, even though the B levels have the same relative height. Samples of WSi_2 on both P- and As-doped poly-Si were measured, but are not shown here. In these cases, there was a significant decrease in dopant in the poly-Si layer after the 950°C , 30 min furnace anneal and an even greater decrease after the 1200°C , 6s STA cycle. There was clearly a net loss of dopant in the P and As cases, presumably by evaporation from the WSi_2 surface.

Overall, the present furnace annealing results are consistent with those previously reported (12, 13). The

Fig. 13. SIMS plot of B concentration in a structure II sample as a function of annealing. Depth and vertical scales vary in each material (WSi_2 on the left, poly-Si on the right, see text).

motion of B from poly-Si into WSi_2 has been observed as low as 800°C , and the accumulation of B in WSi_2 up to 1000°C has also been reported (9, 14). Similarly, the rapid diffusion of P and As through poly-Si and WSi_2 and evaporation have been observed (9, 14). [During furnace annealing, the evaporation of As (9), and probably also of P, can be avoided by the deposition of a CVD silicon oxide cap.] More recently, the motion of P through cosputtered TaSi_2 has been investigated by Pelleg and Murarka (15), and the rapid diffusion of As through doped poly-Si has been studied by Arienzo *et al.* (16). Rough estimates of diffusion in our samples annealed at 1200°C , 6s using the published data (15, 16) indicate that significant out diffusion of As and P is at least plausible during STA. Yet, we note with interest that McPherson *et al.* report essentially no loss of P in a polycide structure of sputtered MoSi_2 annealed at 1250°C , 16s (8). Because of the very marked similarity between MoSi_2 and WSi_2 [see, for example, Ref. (2)], the reported different behaviors of P in the two compounds during STA is quite surprising. Could it be that a residual layer of SiO_2 (or other impurity) at the interface between MoSi_2 and poly-Si hindered the out diffusion of P?

Summary

Short time annealing (STA) of coevaporated WSi_2 on single-crystal and polycrystalline Si (poly-Si) doped with B, P, and As has been carried out with a graphite resistance heater up to 1200°C for times as short as 3s.

STA at 1200°C for 6s resulted in good film homogenization and fine line patterns down to submicron dimensions, which remained intact and well adherent. STA at 1200°C for 6s yielded a silicide resistivity 2 to 3 times lower than furnace annealing at 950°C , 30 min. These two anneals would produce a calculated minimal and equivalent B diffusion in an underlying partially fabricated device. Dopants in the poly-Si of the polycide structure move rapidly through both the poly-Si and the WSi_2 for both STA and furnace annealing. The B redistributes throughout the polycide, but the As and P are lost from the WSi_2 surface by evaporation.

COMMENTS

Each issue of the **Journal** will have a section of "Comments." In this section, we provide a means via short pieces, *i.e.*, one column or less, to applaud, dispute, or otherwise discuss the papers published in the **Journal**. Space will be provided for one response by the paper's author(s) to each comment.

Since space available in each issue for the "Comments" section is limited, it is important to be concise.

Comments should be sent to the Editor, Dr. Norman Hackerman, President's Office, Rice University, P.O. Box 1892, Houston, TX 77251.

This is the first appearance of the "Comments" section.

Effects of the Helmholtz Layer Capacitance on the Potential Distribution at Semiconductor/Electrolyte Interface and the Linearity of the Mott-Schottky Plot

K. Uosaki and H. Kita
pp. 895-897, Vol. 130, No. 4

H. Gerischer:¹ The paper of the above authors contains some serious errors in the equations quoted. The last term in the numerator of Eq. [4] must read $n_0 \cdot e^{y_s}$, not n_0 . Equations [8] and [9] represent the approximation for the case of a depletion layer in an n-type semiconductor and should read correctly

$$Q_{sc} = \left(2e\epsilon\epsilon_0 N_D \right)^{1/2} \left(\Delta\psi_{sc} - \frac{kT}{e} \right)^{1/2} \quad [8]$$

$$C_{sc} = \left(\frac{e\epsilon\epsilon_0 N_D}{2} \right)^{1/2} \left(\Delta\psi_{sc} - \frac{kT}{e} \right)^{-1/2} \quad [9]$$

Besides this, the paper gives a misleading impression of the relation between the space-charge layer capacitance and the Helmholtz double-layer capacitance of normal semiconductor electrodes since the calculations are made with an unusually high carrier concentration in the bulk ($n_0 = N_D = 10^{19} \text{ cm}^{-3}$) and an exceptionally large dielectric constant ($\epsilon = 173$). Most semiconductors such as ZnO, CdS, CdSe, GaP, GaAs, Si, MoS₂, MoSe₂, WS₂, and WSe₂, have static dielectric constants in the order of 6-12. Usual carrier concentrations are in the order of 10^{16} - 10^{18} . With such values, the space-charge capacity is by far smaller than for the example given in this paper. Consequently, the relation between the variation of the voltage drop in the Helmholtz double layer and the voltage applied to the whole interface (referred to the flatband potential) is drastically reduced in comparison to the data given in Fig. 1 of this paper.

More realistic data are shown in Fig. 1a and b, which was derived for depletion layers in the absence of surface states from the following relations, being valid for $y_{sc} > 4$

$$Q_{sc} = (2e\epsilon_0 k T N_D)^{1/2} (y_{sc} - 1)^{1/2} \quad [1]$$

$$C_{sc} = e \left(\frac{\epsilon_0 N_D}{2kT} \right)^{1/2} (y_{sc} - 1)^{-1/2} \quad [2]$$

$$y_{sc} = \frac{e\Delta\psi_{sc}}{kT} \text{ with } \Delta\psi_{sc} = \psi_b - \psi_s \quad [3]$$

$$y_H = \frac{e\Delta\psi_H}{kT} = 2 \frac{C_{sc}}{C_H} (y_{sc} - 1) \quad [4]$$

The voltage drop in the space-charge layer $\Delta\psi_{sc}$ and in the Helmholtz layer $\Delta\psi_H$ is represented in Eq. [3] and [4] in terms of kT/e units (25 mV at $T = 298 \text{ K}$). With $\epsilon_0 = 8.854 \cdot 10^{-14} \text{ As/V} \cdot \text{cm}$ and $C_H = 10 \mu\text{F}$, the relation $[y_H/(y_H + y_{sc})]$ has been calculated and is plotted against $y_H + y_{sc}$ in Fig. 1a for $N_D = 10^{19}$ and 10^{17} with $\epsilon = 173$, and in Fig. 1b for the same donor concentrations with $\epsilon = 10$. One sees that the relative contribution of y_H to the whole potential drop $y_H + y_{sc}$ is very small for $N_D = 10^{17}$ and $\epsilon = 10$, representing the usual situation in semiconductor electrochemistry.

The necessary correction for the variation of $\Delta\psi_H$ in the extrapolation to the flatband potential in a Mott-Schottky plot has been correctly derived in the paper of DeGryse *et al.*² and quoted as Eq. [10] in the above paper. It is, however, also drastically reduced, if the dielectric constant has a normal value and the donor density is

²R. De Gryse, W. P. Gomes, F. Cordon, and J. Vennik, *This Journal*, 123, 711 (1975).

Fig. 1. Relative contribution of the voltage drop variation in the Helmholtz double layer, y_H , to the whole voltage variation over the semiconductor/electrolyte interface, $y_H + y_{sc}$, for two different donor concentrations and two different dielectric constants of the semiconductor. Helmholtz double-layer capacity: $10 \mu\text{F}$.

¹Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin 33, Germany.

smaller than 10^{19} . DeGryse *et al.* have found with $C_H = 10 \mu\text{F}$ as correction for the extrapolated value of V_{FB} at an n-type semiconductor with $\epsilon = 173$ and $N_D = 10^{19}$ the large value of -0.12V . From the correction formula, $\Delta V_H = -[\epsilon\epsilon_0 e N_D / 2C_H^2]$, one obtains with $\epsilon = 10$, instead of 173, only -7 mV , and with $N_D = 10^{17}$ instead of 10^{19} , this correction is fully negligible.

It is certainly important to be aware of the possibility that the potential drop in the Helmholtz double layer can vary with the applied voltage. However, one should also see that the importance of this effect depends very critically on the doping level and the magnitude of the dielectric constant. A variation in $\Delta\psi_H$ will much more often be due to the presence of surface states with a density in the order of 10^{13} cm^{-2} within a narrow range of energies.

K. Uosaki and H. Kita:³ We must admit that Eq. [4], [8], and [9] of our paper contain misprints, as Professor Gerischer has pointed out. But note all the calculations have been carried out by using proper equations.

Although Gerischer commented that our calculations were made only with an unusually high carrier concentration in the bulk ($n_0 = N_D = 10^{19} \text{ cm}^{-3}$), we calculated the potential distribution with a wide range of carrier concentrations ($10^{16} \text{ cm}^{-3} \sim 10^{20} \text{ cm}^{-3}$) as shown in Fig. 1 of our paper.

Gerischer said this paper gives a misleading impression of the relation between the space-charge layer capacitance and the Helmholtz double-layer capacitance of normal semiconductors. However, we think it is important to stress the effects of the Helmholtz double-layer capacitance on the potential distribution and linearity of the Mott-Schottky plot because many semiconductor electrochemists simply ignore the Helmholtz layer capacitance without considering its physical significance.

As far as the effect of the Helmholtz layer capacitance on the linearity of the Mott-Schottky plot is concerned, we supported the general conclusion of De Gryse *et al.*⁴ but pointed out that the real Mott-Schottky plot deviates from the linear line calculated by using Eq. [10] of our paper, which was derived by De Gryse *et al.* with the Mott-Schottky approximation,⁴ near the flatband potential.

Galvanostaircase Polarization

S. T. Hirozawa

pp. 1718-1721, Vol. 130, No. 8

F. Mansfeld:⁵ Hirozawa's paper gives an interesting application of a very simple experimental technique. However, some discussion of the conclusions by the author concerning pitting of aluminum is necessary to avoid even more confusion in the general topic of "critical potentials" than there exists now. There is no theoretical justification in the paper for the claim that extrapolation of the E-I curves to $I = 0$ leads to the breakdown potential E_b for increasing I and to the protection potential E_{prot} for decreasing I . The statement " E appears to have no direct relevance to localized corrosion; however, it seems to have indirect relevance" is quite puzzling in the light of the previous claim concerning E_b and E_{prot} .

In analyzing Hirozawa's experiment, one could conclude that the application of the first constant-current step produces pitting. The corresponding potential maximum is probably the pitting potential. While the current is increased stepwise, the kinetics in the growing pits are measured, since there is not much contribution from the passive surface. The observed small hysteresis in uninhibited solutions is due to changes in the pit growth kinetics, pit size, conductivity in the pits, etc. In the inhibited solutions, the electrochemical kinetics in the growing pit are altered, owing to the presence of the inhibitor. As the pits grow (which they do even when the current is de-

creased), hysteresis occurs because the inhibitor concentration in the pit decreases and for other, presently unknown reasons. As can be seen from Hirozawa's data (his Fig. 3 and 4), the electrochemical kinetics in this case tend to return to those for the uninhibited case.

In summary, the galvanostaircase method applied to Al shows some promise for the study of electrode kinetics in growing pits. However, the claim that the breakdown and protection potentials can be determined from Hirozawa's data cannot be accepted unless it is substantiated by further theoretical and experimental work.

S. T. Hirozawa:⁶ Mansfeld claims that extrapolation for E_b and E_{prot} from GSCP curves has not been theoretically justified and would only increase the confusion presently existing concerning the critical potentials. Others (7-9) using galvanokinetic or galvanostatic polarization techniques have used terms that are analogous to E_b and E_{prot} (paragraph 1 of my paper).

It is true that we have no theoretical justification for the use of the E_b and E_{prot} , but we do have experimental justification using long term constant potential corrosion tests (second paragraph of my paper). The two main causes for the confusion concerning the critical potentials are nomenclature and the use of potential-controlled polarization techniques under highly passivating conditions which lead to induction time effects and current hysteresis.

For Al under highly passivating conditions, *e.g.*, in anti-freeze coolants, E_b (which is often considered to be the pitting potential) appears to have no direct relevance to localized corrosion because E does not have to be raised above E_b , to initiate pitting: one only needs to raise E above E_{prot} to initiate pitting. Hence, E_b is not a critical potential, but it does have indirect relevance because the greater the difference between E_{prot} and E_b , the greater is the tendency for crevice corrosion.

Mansfeld's statement that "in analyzing Hirozawa's experiment, one could conclude that the application of the first current step produces pitting" is true for Fig. 3 and 4, where the evidence for pitting is quite apparent. Pitting occurs on metals that are passivated, preferably by a layer of insoluble salts. In Fig. 1 and 2, pitting is not evident. Chloride is nonpassivating; therefore, the corrosion is general and not localized. The passivation of Al by nitrate is unique. The first current step does not break down the passive layer, but rather it builds it up further. Hence, the use of the term, E_b , is not appropriate; it is used here for the want of a better name. The gradual change of potential during the first two steps probably indicates changes in the resistance of the inner oxide layer as well as the distribution of nitrate within the passive layer under the influence of the electric field.

In conclusion, the GSCP method should dispel some of the confusion related to the critical potentials, induction effects, and the scan rate, hysteresis, and charge effects on the value of E_{prot} .

The Effect of Stress on the Redistribution of Implanted Impurities in GaAs

J. Kasahara, Y. Kato, M. Arai, and N. Watanabe

pp. 2275-2279, Vol. 130, No. 11

C. Blaauw:¹⁰ The authors analyze the effect of stress, induced by a plasma silicon nitride capping film, on the diffusion constants for Si and Se implants in GaAs. Several incorrect assumptions are made, which affect analysis of the results. For example, Eq. [1] implies that the intrinsic stress of the capping film is taken to be zero, whereas it is well known that plasma silicon nitride films

are deposited in a state of tensile stress (11, 12). More seriously, the analysis of the diffusion coefficients in terms of jump frequency and vacancy concentration rests on the assumption that the substrate-induced stress at 850°C is proportional to the thickness of the capping film. This assumption is not justified, as the properties of plasma silicon nitride are not necessarily uniform throughout the film. We have carried out stress measurements as a function of film thickness, for plasma silicon nitride on GaAs, which show that both the intrinsic stress and the temperature dependence of the stress depend on film thickness (2). Extrapolating stress *vs.* temperature curves to 850°C, we find that the substrate-induced stress for a 0.4 μm film is only approximately 40% larger than that of a 0.1 μm film deposited under the same conditions. If a similar relationship were to apply for the work under discussion, this would move the data points at $\approx 0.3 \mu\text{m}$ in Fig. 7, of the paper in question well to the left on the corresponding stress scale, in good agreement with the linear solid line of this figure. This would imply that there is no need

¹¹A. K. Sinha, H. J. Levinstein, and T. E. Smith, *J. Appl. Phys.*, **49**, 2423 (1978).

¹²C. Blaauw, *J. Appl. Phys.*, **54**, 5064 (1983).

to assume a stress-dependent vacancy concentration within the region of investigation.

J. Kasahara:¹³ I appreciate the interest and useful reading of our paper.

Basically, I agree with the comments, which pertain mainly to our Fig. 7. Although further quantitative study is necessary, if the intrinsic stress and thickness-dependent temperature dependence of the stress have some influence, the scale of the lower axis for the stress might be modified. Dr. Blaauw discussed this subject in his Ref. (2), which was not available when our manuscript was being prepared. Also, it is difficult to apply his data directly to our data, because the deposition system for SiN is different. Further, considering the behavior of the stress dependence of the diffusion of Zn, known to be by an interstitial-substitutional mechanism, and the result of Se with about 0.6 μm of thicker SiN, I think it is too important to ignore the effect of the vacancy concentration. Further discussion probably requires measuring the stress *in situ* at the annealing temperature investigated.

Further Evidence for Monoatomic Hydrogen as a Darkening Agent in Chemography

I. A. Blech and J. Kruger

Department of Materials Engineering, Technion, Haifa 32000, Israel

INTRODUCTION

It has been demonstrated recently that freshly etched or abraded silicon surfaces in contact with photographic plates in the dark will produce visible images⁽¹⁾. The process to obtain such images was named chemography. It was suggested that the images were produced by a gas, probably atomic hydrogen, emitted from the silicon surface. Hydrogen evolution was thought to occur as a result of the reaction of water vapor present in the air with the fresh silicon surface forming silicon hydride and atomic hydrogen. The sensitivity of photographic plates to atomic hydrogen was demonstrated previously by placing such plates in a stream of atomic deuterium which caused a considerable darkening⁽¹⁾. It was also shown that molecular hydrogen does not darken the photographic plates.

The present paper provides further evidence that atomic hydrogen is responsible for the darkening of photographic plates in chemography by producing atomic hydrogen through the electrolysis of water.

EXPERIMENTAL

The experimental apparatus is shown schematically in Fig.1. Two stainless steel electrodes were immersed in an electrolyte. Each electrode was 1.1 cm wide, 0.4 cm thick and 7.5 cm long. The photographic plates (Ilford nuclear plates type L4, 50 μ m) were masked off from the electrodes by an adhesive tape and were mounted with their emulsion facing the electrodes leaving a gap of

0.5–1.0 mm between the emulsion and the surface of the electrodes. Sufficient electrical current was supplied to produce copious evolution of hydrogen at the cathode. After a selected time the current was stopped and the photographic plates were removed and rinsed. Dark images were already clearly visible on the plates that were facing the cathode even without development. The plates were developed in D19 Kodak developer for 2 minutes at room temperature. Prints with the same contrast as the original plates were made using an intermediate negative.

RESULTS AND DISCUSSION

The electrolytes used were the following: (1) 0.1N H₂SO₄, (2) 0.1N H₂SO₄ containing 0.05 g/l NaAsO₂ (3) 0.1N H₂SO₄ containing 0.1 g/l NaAsO₂. The rationale behind using solutions (1),(2) and (3) was to produce varying amounts of atomic hydrogen by electrolyzing water in solutions containing different amounts of an arsenic compound, NaAsO₂. It is known⁽²⁾ that arsenic compounds poison the hydrogen recombination reaction,

Therefore, if monoatomic hydrogen is responsible for the darkening of photographic plates, solutions with varying degrees of efficiency in the production of stable atomic hydrogen should exhibit varying degrees of darkening. This is exactly what is demonstrated in Fig.2. It can readily be seen that, when no NaAsO₂ is present in the sulfuric acid solution (Fig.2a), darkening was observed at the bottom of the plate near the edge of the masking tape where the plate was nearest to the electrode surface. There is apparently some atomic hydrogen in bubbles rising along the cathode and the spray above the solution surface as indicated by the darkened areas observed in Fig.2a.

* Electrochemical Society Active Member

¹ Lady Davis Fellow - Technion.
Present address: Dept. of Materials Sci. and Engr., Johns Hopkins Univ. Baltimore MD.

Key words: hydrogen, chemography, photographic emulsion

Fig.2b shows the considerable enhancement in darkening that occurs when a recombination reaction poison is added. When the concentration of the poison is increased, Fig.2c shows increased darkening over that shown in Fig.2b.

Apparently, after the atomic hydrogen has left the cathode surface, it has a sufficiently long lifetime to migrate over to the anode. There it darkens the photographic plate on its edges which are less shielded by the oxygen evolving at the anode. This can be seen in Fig.2d.

In order to be certain that the NaAsO_2 in the 0.1N H_2SO_4 was not responsible for the darkening effects, we exposed photographic plates to solutions (2) and (3) in absence of an electrolyzing current. Virtually no darkening was observed for periods of exposure longer than those used during electrolysis.

The possibility of AsH_3 , formed by the reduction of AsO_2^- at the cathode, being responsible for the darkening was ruled out by producing such darkening at potentials where hydrogen is evolved but where the production of significant amounts of AsH_3 is precluded by thermodynamics. Also, three different solutions containing no arsenic compounds produced darkening.

The foregoing experiments clearly support the conclusion that monoatomic hydrogen causes darkening of photographic plates. This strongly suggests that it is the agent responsible for the darkening observed in chemography.

ACKNOWLEDGEMENT

This research was supported by the fund for the promotion of research at the Technion.

Crystallographic Orientation Dependence of Transition Layer at Magnetron-Sputtered Ta₂O₅/Si Interface

S. Seki, T. Unagami, and O. Kogure

*Nippon Telegraph and Telephone Public Corporation,
Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki 319-11, Japan*

In recent years, tantalum pentoxide (Ta₂O₅) films have received particular interest for use in electronic devices. The higher dielectric constant of Ta₂O₅ films, compared with that of SiO₂, makes them attractive as gate insulators for MOS devices. For these applications, Ta₂O₅ films were prepared by chemical vapor deposition (1) and thermal oxidation of a deposited Ta film (2,3). More recently, it has been indicated that a Ta₂O₅ gate insulator with relatively good interface properties can be obtained by RF-magnetron sputtering (4). Based upon this result, Si-TFT's with this magnetron-sputtered Ta₂O₅ film as a gate insulator have been fabricated on quartz (5). These investigations have clarified that the dielectric constant of deposited Ta₂O₅ becomes lower than that of the bulk of Ta₂O₅, due to the existence of the low dielectric constant transition layer at the Ta₂O₅/Si interface.

In device applications, it has become important to obtain Ta₂O₅ with higher dielectric constant on Si. The present work explores roles of Si substrate in determining dielectric constant of Ta₂O₅ deposited on Si, and indicates that crystallographic orientation has an influence on the dielectric constant of Ta₂O₅.

The transition layer at the interface was studied by dielectric constant variation with deposited Ta₂O₅ thickness. Dielectric constant was calculated from the capacitance of an Al/Ta₂O₅/Si capacitor in accumulation. Single-crystalline silicon wafers with different specifications ((a) p-type, <100>-oriented and 9 to 11 ohm-cm, (b) p-type, <100>-oriented and 0.07 to 0.13 ohm-cm, (c) p-type, <111>-oriented and 1.2 to 1.8 ohm-cm, and (d) p-type, <110>-oriented and 0.07 to 0.13 ohm-cm) were used as substrates. These substrates were cleaned by a mixture of H₂SO₄ and H₂O₂, and then rinsed

in deionized water. Immediately before being installed into the sputtering chamber, wafers were dipped into dilute HF to remove the oxide formed during the previous processing steps. Ta₂O₅ films were fabricated using an RF-magnetron sputtering system. The Ta₂O₅ target was 10 cm in diameter and 5 mm thick. The target to substrate distance was 5 cm. The sputtering chamber was evacuated to less than 1x10⁻⁷ Torr prior to sputtering, and then backfilled with sputtering gas, which consisted of a mixture of argon and oxygen (partial pressure ratio of Ar/O₂ = 90/10). The sputtering pressure was 5x10⁻³ Torr. Electron-beam evaporated aluminum was used as electrodes. Prior to capacitance measurement, these MOS capacitors were annealed at 450°C for 30 minutes in a hydrogen ambient. Capacitance measurements were performed at 1 MHz in the dark, shielded box.

Figure 1 shows variations in deposited Ta₂O₅ dielectric constant with changes in thickness. Variations for three Si substrates with different crystallographic orientation are compared. For each substrate, the dielectric constant of deposited Ta₂O₅ increases monotonically with Ta₂O₅ thickness. At the same time, the dielectric constant depends on the crystallographic orientation of the silicon substrate. At every thickness, the dielectric constant follows the sequence ε(110) > ε(111) > ε(100). On the other hand, dielectric constant plots of Ta₂O₅ deposited on <100>-oriented silicon substrates with the resistivity of 0.07 to 0.13 ohm-cm and 9 to 11 ohm-cm were found to be on the same curve. Hence, the results shown in Fig. 1 are due to the crystallographic orientation of the substrate.

To clarify the reason for this variation depending on the crystallographic orientation, the dielectric constant profile within the Ta₂O₅ film was calculated from the results shown in Fig. 1. Figure 2 (a) and (b) indicate the dielectric constant profiles of Ta₂O₅ deposited on <100>-oriented Si and on <110>-oriented Si, respectively.

Key words: transition layer, crystallographic orientation, Ta₂O₅, interface.

The bars represent the average value of the dielectric constant for each layer. The lowest average value was taken as the dielectric constant for the sample with the minimum thickness. The dielectric constant for the second layer was then obtained by reevaluating the dielectric data, using a multilayer model consisting of the first and second layer (4). This calculation was repeated for each successive layer. The results shown in Fig. 2 indicate that both Ta_2O_5 layers consist of two regions: a low dielectric constant transition layer at the interface and the higher dielectric constant homogeneous layer. The dielectric constant of the homogeneous layer on $\langle 100 \rangle$ -oriented Si is the same as that on $\langle 110 \rangle$ -oriented Si. The values are about 24.5, close to that of the bulk of Ta_2O_5 . The dielectric constant of the homogeneous layer on $\langle 111 \rangle$ -oriented Si was also calculated to be about 24.5. This indicates that the crystallographic orientation has no influence on the homogeneous layer formation. This has been confirmed by etch rate experiments, performed by reactive ion etching using CF_4 as a reactive gas (6). A typical etch rate was measured to be 150 Å/min for each homogeneous layer, independent of the crystallographic orientation. These results indicate that dielectric constant variation shown in Fig. 1 is attributed to the transition layer at the interface.

Figure 1 Relative dielectric constant versus Ta_2O_5 thickness for Si substrates with different crystallographic orientation.

Though the Si was etched with HF just before sputtering in these experiments, oxide would reform very quickly during subsequent exposure to air before installing into the sputtering chamber. If we assume that the transition layers are ascribed to air-oxidized SiO_2 grown on Si, and that total

(a)

(b)

Figure 2 Variations in relative dielectric constant with changes in distance from the Ta_2O_5/Si interface. (a) on $\langle 100 \rangle$ -oriented Si, (b) on $\langle 110 \rangle$ -oriented Si.

insulator on Si consists of this SiO₂ ($\epsilon=3.4$) and homogeneous Ta₂O₅ layer ($\epsilon=24.5$), the SiO₂ thickness can be calculated from the results shown in Fig. 2 to be 26.5 Å for <110>-oriented silicon and 39.2 Å for <100>-oriented silicon. These values are much larger than the air-oxidized film thickness grown on Si substrate by exposure to air before sputtering, which is estimated to be less than 10 Å (7). This indicates that the transition layer is not solely attributed to the air-oxidized film on Si, and that this transition layer is the result of the interaction of silicon and sputtered particles in the early stage of Ta₂O₅ formation on Si. Based upon the results described above, it can be concluded that the crystallographic orientation has a great influence on the transition layer formation at the Ta₂O₅/Si interface.

In summary, influences of the resistivity and crystallographic orientation of Si substrate on dielectric constant of Ta₂O₅ deposited on Si have been investigated. The present study has indicated dielectric constant of Ta₂O₅ deposited on <110>-oriented Si becomes higher than that of Ta₂O₅ deposited on <111>-oriented and on <100>-oriented Si, independent of substrate resistivity. This variation is due to the transition layer at the interface, and the crystallographic orientation has an influence on the transition layer formation.

Thin Thermal Oxide on Silicon

E. A. Taff*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

INTRODUCTION

The growth kinetics of thermal oxide on silicon were detailed by Deal and Grove (1) with a resulting development of a linear-parabolic relationship. The silicon-oxygen surface reaction constitutes a linear part and the diffusing oxidant gives the parabolic part of the defining equation. Thin dry oxides (<250A) were not discussed. A sampling of the literature (2-7) shows that experimental data and physical modeling continues to appear. Hauffe (8) gives a discussion of a model of very thin (<100A) film growth proposed by Mott and Cabrera. In this treatment space charge effects are ignored, electrons are transferred by electron tunneling and charged ions are transported by high fields in the very thin dielectric layer. This model also has been applied to silicon (9-10). Fehlner (9,11) dealt with low temperature films of not more than 30A thickness to fit the Mott-Cabrera model. Van der Meulen, Irene and Hopper et. al (2-4) present data which is generally for higher temperature oxides. Their analyses did not readily fit any simple model. Apparently, as yet, there is no consensus on the major factors governing the growth of thin oxides on silicon. The purpose of this note is to present data for support of a model of oxide growth while detailed studies continue.

EXPERIMENTAL

Silicon wafers of 1-10 ohm-cm resistivity of <111> and <100> orientation were cleaned, HF acid dipped, and

fired at 1200C in hydrogen. The initial measured thicknesses of film on the silicon were 3-4 Angstroms. Further oxidations were done in a temperature controlled furnace in dry oxygen. The oxidized wafers were cooled and removed from the furnace from time to time. A Rudolf Research Auto-El ellipsometer was used for the thickness measurements.

RESULTS AND DISCUSSION

Film growth results are shown in Fig. 1 for temperatures of 450C, 612C and 821C. These curves, for <111> and <100> silicon orientations, have been selected to illustrate the premise that the usual linear-parabolic model holds for the lower temperatures as well as for higher temperatures. The additional factor is a Mott-Cabrera mechanism as is discussed by Hauffe (8). The 450C points of Fig. 1a were obtained over the course of several months though they extend to only 40A. The solid line is the exponential equation $t = \exp(14.1 - 101/x)$ where x is the thickness in Angstroms and the time is in minutes. This is a simplified form of reciprocal logarithmic film growth from Hauffe (8). Extrapolation of data from activation energies for the linear-parabolic model given by Deal and Grove or derived from my own curves indicates that there should be no oxide growth at this temperature. All the growth must be due to the Mott-Cabrera mechanism and the excellent curve fit to the data should be expected. The 612C points of Fig. 1b fit well, up to 40A, a reciprocal logarithmic equation $t = \exp(8.3 - 75/x)$. As in Fig. 1a there is no orientation effect observed thus far. However, at 612C the two orientations are different for oxide growth above 50A, and the linear-parabolic mechanism becomes a

*Electrochemical Society Active Member
Keywords: films, ellipsometry,
transport

larger factor.

Extrapolated activation energy data again lends credence as the expected growth rates from the linear parabolic model are of the correct amplitude for 612C. At 821C in Fig. 1c, the orientation difference is readily apparent; the growth curves can be approximately analyzed as before (1-4). However, the rapid orientation independent growth for 25A taking only about five minutes seems to be quite normal when considered with Fig. 1a and Fig. 1b. At higher temperatures, this initial growth will be more difficult to detect as the linear-parabolic model coefficients becomes larger.

It is postulated that only two basic oxygen transport mechanisms control silicon oxidation. Up to 25A at 821C, and observably beyond at lower temperatures, the Mott-Cabrera scheme prevails. The charged oxygen species involved in quickly forming the initial film diminish very rapidly with film thickness, although a 40A oxide has been shown where competing processes have not been active. At longer times or a higher temperatures where the rate constants become larger, the linear-parabolic oxidation scheme becomes dominant. Also, these linear-parabolic rate constants as in the low pressure study or Kamigaki and Itoh (9) could be so greatly reduced that at the lowest pressures only the reciprocal logarithmic growth remains.

Fig. 1. Growth curves of dry oxide on two orientations of silicon for three temperatures. For 450C the data for both orientations fits $t = \exp(14.1 - 101/x)$. For 612C the linear-parabolic growth is apparent at $>40\text{A}$. At $<40\text{A}$ $t = \exp(8.3 - 75/x)$ is a good fit to the data. For 821C larger linear-parabolic coefficients affect the growth at $>25\text{A}$.

Heterojunction by Photoelectrochemical Surface Transformation: n:CuInSe₂/p - CuISe₃Se^o

*Hahn-Meitner-Institut für Kernforschung Berlin,
Bereich Strahlenchemie, D-1000 Berlin 39, Germany*

Heterojunction formation by photoelectrochemical alteration of semiconductor surfaces is reported. Growth of a new semiconducting phase at the n-CuInSe₂/I⁻-I₂-Cu⁺ interface is achieved by controlling electrochemical parameters. The interfacial layer is identified as CuISe₃Se^o and exhibits p-type conductivity. Under illumination the interphase mediates efficient charge transfer between CuInSe₂ and the I⁻/I₂ redox couple while inhibiting semiconductor dissolution.

Current interest in CuInSe₂ systems from its exceptional optoelectronic properties, resulting in the development of efficient solid state (1) and photoelectrochemical (2) solar cells. Performance of the latter pivots on the growth of an interfacial layer induced by specific electrolyte composition, resulting in a substrate-film-electrolyte structure. In this note we explore the location of the photoactive junction and the circumstances leading to the CuInSe₂ surface transformation.

Interfacial films were grown on back ohmic contacted, epoxy insulated and etched (112) faces of n-CuInSe₂ by operation as photoanodes in an electrolyte consisting of 1 M I⁻, 0.05 M I₂, 0.02 M CuI and 2 M HI. This involved, cyclic polarization of the electrode between the potential limits of short circuit and open circuit or leaving it at the maximum power point. Film quality was monitored by the photocurrent-voltage output. Generally 3 - 4 intermediary etches were required to optimize the film performance.

Scanning electron micrographs of the electrochemically treated CuInSe₂ electrodes show that a polycrystalline film consisting of randomly oriented, flat, hexagonal crystallites is grown on the CuInSe₂ substrate (3). Crystallite sizes range between 2 - 5 microns. A cross-section of a cleaved electrode evidences that the film does not penetrate deeper than 2 microns into the substrate even after pro-

key words: Semiconductor Interfaces, Solar Energy, Photoelectrochemistry

longed operation (5 weeks) in a solar cell, but appears to completely cover the substrate growing into microscopic cavities.

The distinct crystallite geometry suggests that a chemically well defined compound is grown at the CuInSe₂/electrolyte interface. X-ray diffraction analysis of the crystallites identifies the new phase as consisting of mainly CuISe₃ and up to 30 % elemental Se. No evidence for formation of polycrystalline CuI was found.

Chemical reactions of illuminated CuInSe₂ with the electrolyte constituents obviously transform the semiconductor surface to generate the CuISe₃-Se^o phase. In the absence of Cu⁺ in the electrolyte, elemental Se^o and triangular crystallites of CuI have been detected on photocorroded CuInSe₂ surfaces (3). CuI is partly soluble in iodide solution forming CuI₂⁻. Addition of Cu⁺ to the solution probably raises the surface concentration of CuI₂⁻ to a critical value required to initiate CuISe₃ film growth. CuISe₃ crystals have been previously prepared by reacting stoichiometric mixtures of CuI and Se in HI medium under hydrothermal conditions (4). The reactants employed in the hydrothermal synthesis of CuISe₃ are thus provided by the electrolyte and the semiconductor components in our cell while the reaction enthalpy is probably supplied by the photopotential.

Fig. 1 compares UPS energy distribution curves, N(E) of the untreated CuInSe₂ single crystal and the CuInSe₂/CuISe₃-Se^o structure, with the Fermi levels E_Fⁿ aligned to the edges of the valence band. E_Vⁿ and E_V^p for the two samples differ by 0.65 eV. |E_Vⁿ-E_Fⁿ| is 0.85 eV for CuInSe₂ and 0.2 eV for the film. With a bandgap, E_g^p of 2 eV for CuISe₃ (5) and for Se (6), the film is thus a p-type semiconductor. Measurement of the relative work functions, φ, of the two samples with the vacuum levels aligned also indicate that the E_Fⁿ's differ by 0.65 V. Hence E_Vⁿ(CuInSe₂)=E_V^p(film). Adding the electron affinity, χⁿ of 4.58 eV (7) to the E_gⁿ of 1 eV for CuInSe₂ the absolute value of E_Vⁿ is estimated to be 5.58 eV.

The energetics of the structure are given in Fig. 2. Experimental and literature values for various electronic parameters indicated with superscripts n and p refer to n-CuInSe₂ and p-CuISe₃-Se⁰, respectively. An estimate for the work function of the I⁻-I₂-Cu⁺-HI electrolyte of $\phi^e=5.1$ eV is obtained by adding the measured redox potential of +0.2 V (SCE) to the more recent value of (NHE)=4.7 eV (8). Comparison of E_F^n , E_F^p and ϕ^e yields a potential of at least 0.65 eV at the substrate/film junction and of 0.2 eV ($\Delta\phi$) at the film/electrolyte interface. This implies a p-n junction between the solids and a rectifying junction at the electrolyte contact. The spectral response and the anodic photocurrent, however, attest the light absorption and photogeneration of h^+ in the n-CuInSe₂ (2,3). A barrier at the film/electrolyte interface would impede h^+ transfer to I⁻. The high quantum efficiency and the photovoltage of 0.42 V (2) argue against such a barrier and suggest that the principal potential drop occurs in the p-n junction with the electrolyte providing an ohmic contact. Interactions between the semiconductor and electrolyte upon immersion may account for the energetic difference, $\Delta\phi$, as the scheme in Fig. 2 disregards the effects of pH and specific adsorption.

Adsorption of Trifluoromethane Sulfonic Acid on Pt by FTIR and Radiotracer Methods

P. Zelenay,* M. A. Habib,† and J. O'M. Bockris†

Department of Chemistry, Texas A&M University, College Station, Texas 77843

The oxygen reduction rate on Pt was found to increase two orders of magnitude in trifluoromethane sulfonic acid (TFMSA) than in H_3PO_4 electrolyte (1,2). Petrii et al. (3) found adsorption of the $CF_3SO_3^-$ ion on platinum to be small and to have no effect (compared with H_2SO_4) on the catalytic activity of Pt in methanol electrooxidation. Recently, Habib and Bockris (4,5) reported the adsorption of H_3PO_4 on Pt as measured by in-situ FTIR and radiotracer techniques. Hyde et al. (6) concluded that phosphoric ion is physisorbed on Pt but the TFMSA is not. However, the latter compound was found to be unstable on Pt after 72 hours and some kind of degradation product seemed to be present (6). We report here the adsorption of $CF_3SO_3^-$ ion on Pt and compare with that of H_3PO_4 .

The IR Spectra for the adsorbed layer, as reported here, were obtained by subtracting from spectra obtained at a series of potentials at which adsorption was expected, the spectrum taken in a region of more cathodic potential, where adsorption was judged to be absent. The detailed experimental set up and the procedure are described elsewhere (5). The electrode was polarized potentiostatically in the range of $-0.2V$ and $1.6V$ (NHE).

TFMSA, one of the strongest of all known acids (7), is completely dissociated to $CF_3SO_3^-$ and H_3O^+ ions in aqueous solutions. The IR adsorption band at 1250 to 940 cm^{-1} consists of several peaks due to the resonance vibration of the $S=O$ bond (8) (Fig. 1). The peak observed at 1155 cm^{-1} is caused by asymmetric stretching vibration of the $S=O$ bond and the peaks at 1080 , 1045 and 1005 cm^{-1} are ascribed to the symmetric stretching vibration of the $S=O$ bond. Another adsorption band occurs at ca 1380 to 1290 cm^{-1} and is due to the vibration of the C-F bond (see e.g., peak at 1345 and 1295 cm^{-1}). All these peaks observed at $0.0V$ are found to increase with anodic potential (Fig. 1).

*On leave of absence from the Department of Chemistry, Warsaw University, Warsaw, Poland.
Key Words: Adsorption, Trifluoromethane-sulfonic acid, Platinum.

Fig. 1: Differential spectra of adsorbed $CF_3SO_3^-$ ion on platinum at various potentials; $C_{CF_3SO_3} = 2 \times 10^{-2}\text{ mole}\cdot\text{dm}^{-3}$

The adsorption bands originated in TFMSA were confirmed by the fact that no bands were observed in the absence of the acid. That the bands were due to the adsorbed $CF_3SO_3^-$ ion was confirmed by the disappearance of the bands at 1250 to 940 cm^{-1} and 1380 to 1390 cm^{-1} when the incident light was perpendicularly polarized.

The area under the adsorption bands which corresponds to the amount of $CF_3SO_3^-$ ions on the surface is normalized to the surface excess at $0.8V$ as measured by radiotracer method. The results obtained both by FTIR and the radiotracer technique are shown in Fig. 2. The agreement is good up to $1.2V$. At anodic potentials higher than $1.2V$ a slight decrease

Fig. 2: Γ and θ of CF_3SO_3^- ion as a function of potential; $C_{\text{CF}_3\text{SO}_3^-} = 2 \times 10^{-2} \text{ mole} \cdot \text{dm}^{-3}$

Fig. 3: Comparison of the fractional coverages of H_3PO_4 (4) and CF_3SO_3^- ion on Pt

in the intensity of the IR bands was observed, presumably due to oxidation of the sulfonate ions. One of the possible reaction paths is:

If the adsorbed CF_3SO_3^- ions are oxidized then the bands due to the $\text{S}=\text{O}$ and C-F bonds vibration in sulfonate ions will not appear in the spectrum and hence a decrease in the area of the corresponding IR bands will result as found in the present work. But in the radiotracer experiment, since carbon in the CF_3 group is tagged (^{14}C radionuclide), the increase in the radiotracer signal is expected as confirmed in Fig. 2.

The increase of the radiotracer signal

being observed at high anodic potentials may also be attributed to the "trapping" of CF_3SO_3^- ions in the growing oxide layer on Pt. Such an effect would be detectable in the radiotracer experiment only since the FTIR technique is limited to the outer layer of the adsorbed species.

The fractional surface coverage, θ , in Fig. 2 has been calculated on the basis of a molecular model of CF_3SO_3^- , in which the ions are assumed to adsorb with their SO_3^- ends towards the surface occupying 30.4 \AA^2 area per ion. The surface coverage around 0.8V is thus 0.43. The solution used in this case was $2 \times 10^{-2} \text{ mole} \cdot \text{dm}^{-3} \text{ CF}_3\text{SO}_3\text{H (aq)}$.

A comparable maximum coverage for H_3PO_4 on Pt was reported from a solution of $10^{-2} \text{ mole} \cdot \text{dm}^{-3} \text{ H}_3\text{PO}_4$ in $1 \text{ mole} \cdot \text{dm}^{-3} \text{ HClO}_4 \text{ (aq)}$ (5). For the sake of comparison of CF_3SO_3^- adsorption with that of H_3PO_4 , the adsorption of CF_3SO_3^- ion was measured by the radiotracer method using a solution of $2 \times 10^{-2} \text{ mole} \cdot \text{dm}^{-3} \text{ CF}_3\text{SO}_3^-$ in $1 \text{ mole} \cdot \text{dm}^{-3} \text{ HClO}_4 \text{ (aq)}$. The surface coverages for the CF_3SO_3^- ion and H_3PO_4 on Pt as a function of potential are shown in Fig. 3.

The measurements under the same experimental conditions suggest greater adsorption of H_3PO_4 compared to that of CF_3SO_3^- .

Development and Commercialization of the Monsanto Electrochemical Adiponitrile Process¹

D. E. Danly*

Monsanto Fibers and Intermediates Company, Pensacola, Florida 32575

Mr. President, I would like to begin this Vittorio de Nora-Diamond Shamrock Award address by expressing my sincere appreciation to the members of the Board of Directors of The Electrochemical Society for naming me the award recipient. When I learned several months ago that I had been selected for this honor, I was immensely pleased, but also surprised; I really consider myself more a conventional chemical engineer than an electrochemical technologist. My assignment with Monsanto over the past 26 years has been to seek cost-effective processes for synthetic fiber intermediates, employing whatever type of technology best gets the job done. Fortunately, as a result of Manual Baizer's 1960 discovery of an efficient electrochemical method for reductively coupling acrylonitrile to form adiponitrile (which is an important nylon intermediate), I have been able to spend much of the past 20-plus years in the area of technology of primary interest to this Society.

Before I get into the description of the development and commercialization of the Monsanto electrochemical adiponitrile process, I must say that I could not possibly accept this award without making it very clear that I had a tremendous amount of able help in this successful venture. The team responsible for the laboratory and pilot plant development of our electrohydrodimerization process (or, as we called it, EHD) consisted of about 20 chemists and engineers working in our technical center at Pensacola, Florida. Many others in our Engineering and Manufacturing organization also made significant contributions as we moved from laboratory to pilot plant to an operating commercial facility. So as I stand before you this afternoon, please consider that, in a very real sense, I am acting rather as the captain of a ball club representing his team.

The story of the Monsanto EHD process begins in our St. Louis research labs, where Dr. Baizer had been asked to investigate the possibility of converting acrylonitrile (AN) to adiponitrile (ADN). The impetus for this work stemmed from Monsanto's projections at that time of high growth rates for nylon and acrylic fibers, which translated into a need for additional ADN and AN production capability. If adiponitrile could be made from acrylonitrile, the size of the new AN plant could be increased, improving plant economics, and adipic acid capacity formerly required to provide feed for the existing ADN process would be freed up for use in producing additional nylon 66 salt.

The reductive coupling of AN had been examined by a number of prior investigators, but only with modest success. The highest selectivity to ADN was about 60% for a reaction system using potassium amalgam, as reported by Knunyants and Vyazankin in the USSR. While falling far short of acceptable yields, this work did lead Baizer to

think in terms of an electrochemical approach, and he began to experiment with various electrolyte/electrode systems. I do not plan to relate the details of this research effort, although it is a fascinating story in itself. Let me simply summarize the very significant discovery stemming from Baizer's study — namely, that electrolysis of AN in relatively concentrated aqueous solutions of certain quaternary ammonium salts gave nearly quantitative yields of ADN. Cathodes of mercury or lead gave the best results.

Once the feasibility of the EHD chemistry had been demonstrated in Baizer's 500 ml lab cell, the question was addressed of how to best proceed with the process development. After much discussion and debate at headquarters in St. Louis, it was decided (and I firmly believe correctly so) that the operating division expected to commercialize the process should carry out the scale-up studies. Thus, the task fell to the Chemstrand Division (now Monsanto Fibers and Intermediates Company), which had in-place at Pensacola, Florida, a chemical process development group under Dr. Frank Riordan. I had joined this organization three years previously, following completion of my graduate work in chemical engineering at the University of Florida. None of the group had any real experience in electrochemistry. I was probably the only one who had ever been to a national Electrochemical Society meeting, that a single event as a result of a part-time job at the University in battery research. Being perfectly frank, my background in electrochemistry went little beyond familiarity with the Nernst equation, and I actually found little opportunity to use it in the following days. Since I was eager to be involved in development of this unique process, I may have been guilty of overselling my expertise, but for whatever reason, I found myself appointed project leader for the pilot plant EHD studies.

This was late 1961, and since our forecasts indicated we needed additional ADN capacity by early 1965, we determined that we only had a little over a year to prove out the process. Thus, I need not have worried about getting on the project, since before long the entire research and development group was working on one aspect or another of the process. The chemists began screening electrode materials, diaphragms, alternate electrolytes, and operating conditions, while the mechanical engineers began to consider the cell design. Baizer's lab cell was a glass resin flask containing a platinum wire anode and a mercury pool as cathode, with an aluminum cup serving to separate the anolyte and catholyte. Having calculated that it would take 350,000 of these cells to give the targeted plant capacity of 15,000 metric tons per year, we began to appreciate the magnitude of the scale-up challenge facing us.

Electrode Selection

The selection of a cathode material was relatively easy. Baizer had shown that either lead or mercury was suitable, and we were so horrified by the anticipated envi-

Old Process

Fig. 1. Routes to adiponitrile

ronmental and cell design problems with mercury that we quickly settled on lead. We tested a long list of other materials reported to give high hydrogen overvoltages, but none was found superior to lead.

Anode selection proved to be considerably more difficult. We began our studies using platinized titanium, but the platinum loss was clearly intolerable. With a switch from Baizer's anolyte of toluene sulfonic acid to dilute sulfuric acid, the use of lead alloys was made possible. Tainton's alloy of 1% Ag in lead had been used successfully in aqueous H_2SO_4 for the manufacture of electrolytic zinc, and this was our early choice, although we tested a number of other lead alloys reported in the literature to have greater stability.

The real surprise in anode development came during the first attempts to operate a pilot-scale cell. While anode corrosion rates as low as 3 mm/yr were measured in short lab tests, we found that in extended pilot-plant runs the corrosion rate would increase by 20-fold over a 24h operating period. Our analytical folks were able to place the blame on a buildup of nitrates and various chlorine containing anions in the anolyte. The nitrate anions were evidently being formed by oxidation of AN diffusing through the membrane into the anolyte compartment, while the chlorine was entering the system in small amounts in the sulfuric acid and quaternary ammonium salt. The problem was solved by putting tight chloride specifications on the raw materials and instituting a continuous purge and makeup of anolyte to hold the nitrate concentration below a critical level.

Selection of Supporting Electrolyte

Baizer's recommended catholyte was a 40% aqueous solution of tetraethylammonium p-toluenesulfonate. This electrolyte possessed two properties which at that time were believed to be necessary for high ADN selectivity: (i) the cation was not reduced at the cathode, and (ii) the salt greatly enhanced the solubility of AN in the solution. Other factors considered important for a commercial process were the electrolyte cost, electrical conductivity, and ease of removal of ADN from the electrolyte. More than 30 quaternary ammonium salts were prepared for measurement of these properties. Four of these were selected for extensive benchscale and pilot plant testing, from which it was determined that the yield of electrolysis by-products (propionitrile and high-boiling AN oligomers) decreased with increasing size of the quaternary ammonium cation. Salts with cations larger than tetraethylammonium were not felt to be practical because their aqueous solutions exhibited poor electrical conductivities and very high AN and ADN solubilities, making extraction of product difficult. Tetraethylammonium ethylsulfate was a clear choice, since it not only gave the best ADN selectivity, but also could be simply prepared by combination

of two low-cost intermediates, triethylamine and diethylsulfate.

In attempting briefly to outline our research and development studies, I am greatly oversimplifying the story. I have made it sound as though we tested cathodes, ... picked one, ... tested anodes, ... picked one, ... tested electrolytes, ... picked one, and so forth. It really was not that straightforward. For example, we solved the problem of poor stability of pure lead as an anode by adding a small amount of silver, only to discover the Ag cation introduced into the anolyte by corrosion of the anode passed through the membrane, deposited on the cathode, and sharply depressed the ADN selectivity. This particular problem was ultimately resolved by electrodeposition of the silver ions contained in the recycled quaternary ammonium salt on a lead-shot cathode of a packed-bed electrolyzer. We also found that the best anode alloy when using a p-toluene sulfonate anion in the catholyte was not the best one when we switched to ethylsulfate anion. Small amounts of these anions migrating from the catholyte into the anolyte had a significant impact on anode stability.

Membrane Development

The selection of a diaphragm for separation of anolyte and catholyte required something more than the cut-and-try approach used with electrodes and supporting electrolyte. We did begin our search by testing samples of all of the commercial cation-permselective membranes, but the majority of these failed in less than a day. Unfortunately, the perfluorinated membranes now proving so successful in chloralkali cells were not around in 1962. Of the materials available, the most encouraging results were with a membrane made by Ionics, Incorporated, composed of sulfonated polystyrene/divinylbenzene polymer and a glass fiber reinforcing cloth. With these, benchscale runs of a week or so were possible. Since considerable improvement in durability was needed to achieve the targeted 1000h service life, we entered into a joint membrane development program with Ionics. They provided numerous test samples, varying such parameters as degree of

polymer cross-linkage, type of reinforcing fabric, and membrane thickness. We geared up for performance testing, setting up six 1 dm² flow cells, which we operated around the clock at typical EHD operating conditions.

When we began pilot plant operation with an 80-fold scale-up in membrane area, we found, to our dismay, that the formulation that had given several hundred hours service life in the 1 dm² benchscale cells did not even last for a day. In pilot operation, the ion-exchange resin was randomly spalling off, forming small windows for movement of anolyte into the catholyte. As an expedient solution, we simply installed dual membranes, banking on the odds against the windows' lining up, and this allowed run lengths of a week or two.

This rather brute-force solution was not very elegant, but at least allowed us to stay on line with our pilot plant cell to try to answer other unresolved process and cell design questions. Some months later, our friends at Ionics developed a membrane incorporating two layers of glass cloth in the same resin matrix. These exhibited operating lives of up to 2000h in lab cells and were adopted as the standard.

Cell Design

Since the process as we knew it at that time required separation of anolyte and catholyte, we thought in terms

of a plate-and-frame design for the commercial cell from the outset. This decision was reinforced when, in the early days of process development, we called in the renowned consultant, Dr. Robert B. MacMullin. Bob, as many of you know, was the second recipient of the Society's Electrochemical Engineering and Technology Award. He was asked to provide a design for a 250A lab cell and then to make a preliminary design and cost estimate for the electrolysis portion of a commercial EHD plant. Although we never constructed the MacMullin cell, his detailed design calculations were extremely valuable in educating us in the techniques of voltage balances, electrolysis system heat balances, cellhouse layout, and a multitude of other electrochemical engineering considerations.

The other distinguished advisor we enlisted was Dr. Vittorio de Nora. Following discussions with us in Pensacola during one of his frequent trips to the U.S., it was agreed that the de Nora firm in Milan would design and build us a prototype cell. I was immediately dispatched to Italy to provide the de Nora engineers with what little process information we had.

At the time of Dr. de Nora's visit, the development team at Pensacola had already moved well into the design of the first pilot-plant cell. We decided early-on that this cell should be the same size as visualized for the full-scale facility. Surely if we could make a bank of 3-5 cells work in the pilot plant, operation of a plant using several hundred identical units *should* pose no problem. The size of the cell was set by the dimensions of the largest membrane then offered by Ionics: roughly 90 × 100 cm. Since we were trying to develop all the required plant design data in the space of 12 months, we pushed forward simultaneously with both the Monsanto and de Nora cell designs.

The first Monsanto design was a single cell unit with the electrodes mounted on polyethylene plates, into which were machined cavities for electrolyte distribution (Fig. 2). Anolyte flow was vertically upward, while catholyte was introduced through a central vertical plenum, where it split and flowed horizontally to the two sides. Dividing of the catholyte flow was aimed at reducing the length of the catholyte flow path in order to minimize the pressure differential across the membrane. This cell was used briefly in the initial pilot-plant operation, but problems in sealing of the membrane gaskets and evidence of uneven distribution of electrolyte across the cathode led us to install the de Nora cell unit as soon as it arrived by air from Italy.

Fig. 2. Monsanto Mark I EHD cell.

Fig. 3. de Nora cell

The de Nora unit (Fig. 3) contained five bipolar cells. The electrolyte streams were introduced through tapered, external distribution boxes, then passed through a series of small holes into internal plenum chambers in the cell plates. This design provided greatly improved uniformity of electrolyte flow compared to the first Monsanto design. This cell was operated for several months to conduct studies of spacer design and the effects of catholyte velocity, composition, and temperature. The chief problems with the cell were the integrity of the hydraulic seals and recurring failures of the external distribution boxes, which were made by welding together sections of polypropylene sheeting.

These problems were overcome in the third-generation design (Fig. 4), which employed tapered electrolyte distribution cavities machined into polypropylene plates behind the electrodes. The membranes were held between two mated polypropylene frames for convenience in handling. The fluid leakage problem was solved by the use of a beaded gasket, which markedly lowered the required sealing force. This proved to be a reliable assembly, and with minor modifications it was ultimately adopted for use in the commercial plant.

Probably one of the most important electrochemical engineering concerns we faced was that of achieving high mass-transfer rates at the cathode surface. The transfer of AN across the diffusion layer from bulk catholyte to the cathode turned out to be less critical than neutralization of the hydroxyl ions produced at the cathode (Fig. 5). Acrylonitrile reacts very rapidly with water under alkaline conditions to form the cyanoethylation by-products hydroxypropionitrile and bis-cyanoethylether. These side reactions represented a very significant AN-yield loss in early experiments at low catholyte flow velocities. Our first approach was to employ turbulence promoters, such as plastic webbing or baffles, similar to the types proven effective in electro dialysis devices. While several of these significantly lowered losses of AN due to cyanoethylation, buildup of AN polymer on the plastic spacers in time gave rise to an intolerable pressure drop along the catholyte flow path. Various means of in-place cleaning were tested, but we finally concluded that only fully open channels offered any chance for reasonable on-stream time. After many aborted efforts, we found the most dependable way to form the open channels was to attach narrow plastic ribs directly to the Pb cathode in

Fig. 4. Mork II Monsanto cell

Fig. 5. Cyanoethylation reactions

much the same way the chrome strip is fastened to one's automobile fender. We tested different gauges, widths, and thicknesses of the parallel strips, and most importantly, the catholyte velocity needed to control the cyanoethylation side reaction (Fig. 6). A velocity of 2 m/s was selected as giving the optimum balance between AN-yield loss and catholyte pumping cost.

While definition of the cell design and optimization of the electrolysis conditions were paramount to the success of the process development, a substantial effort was also needed to define the product recovery and purification systems. Processing downstream of the cells (Fig. 7) consisted of extraction of ADN from catholyte with AN, stripping of the AN to produce a crude ADN, and final clean up in a four-column distillation train. We felt it was imperative to demonstrate the process in the pilot plant with all the recycle loops closed. Had we not done this, the serious consequences of silver ion buildup in the recycle QAS might never have been recognized. We also felt obliged to show that our refined ADN could be satisfactorily hydrogenated to hexamethylene diamine and converted into standard-quality nylon polymer. All of these steps were demonstrated in the pilot plant.

In scaling up a new process, one generally prefers to complete laboratory demonstration and then prepare the plant-design documents. Our tight timetable for commercialization of the process did not allow us this luxury. A very preliminary design of the full-scale facility was developed even before the first pilot-plant run by a member of the Engineering Department assigned to work with the

Fig. 6. Effect of catholyte velocity on cyanoethylation by-products

Development team. Our first pass through the projected process economics was based on operation at a cathode current density of 20 A/dm², and we discovered the investment in cells would be enormous. We examined higher current densities on paper and found the optimum balance between electrolysis operating costs and capital burden occurred in the current density range 40-60 A/dm² (Fig. 8). Fortunately, lab studies showed no measurable decline in electrolysis performance below 100 A/dm², provided the catholyte flow was 2 m/s. This early conceptualization and evaluation of the proposed commercial process thus proved to be most valuable in guiding our development efforts.

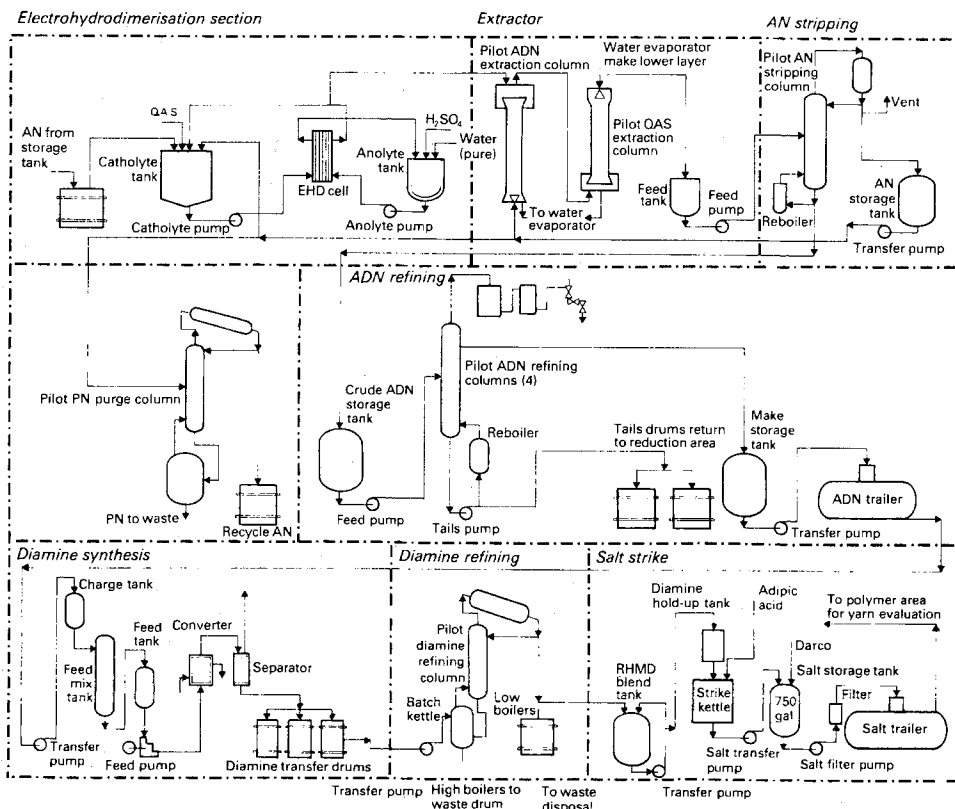

Fig. 7. Complete pilot plant system.

Fig. 8. Current density optimization

The preliminary plant design was modified repeatedly as we learned more about the process and cell requirements, and a final document was approved almost exactly one year from the initial pilot plant run. The first EHD facility (Fig. 9) was constructed at our Decatur, Alabama, plantsite and had a design capacity of 14,500 MT/Y ADN. The electrolysis system consisted of 16 cell presses, each housing 24 bipolar cells and operating at about 3000A. Four independent catholyte circulating systems were employed to minimize the impact of a major membrane failure on total plant operations.

I wish I could tell you the plant was built, started up, and ran like a Swiss watch from the outset. However, I must confess that initial plant operation was plagued by short membrane lives, deterioration in ADN selectivity due to a buildup of previously unidentified impurities in the recycle QAS, and several small fires stemming from ruptured catholyte hoses supplying feed to the cells. These problems were largely resolved during the first

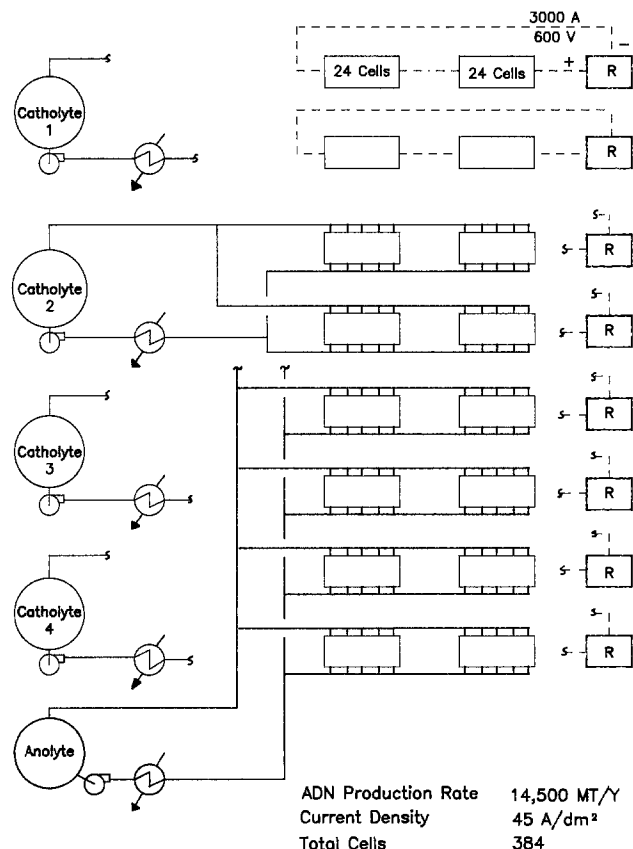

Fig. 9. Original EHD plant layout

year of operation by use of improved membranes from Ionics, installation of a supplemental QAS cleanup system, and a change-over to steel-reinforced hoses.

Meanwhile, back at the labs in Pensacola, we were busy seeking ways to make a step-change improvement in the process. The divided-cell technology we had commercialized had three serious drawbacks: the electrical power usage was high (7-8 kWh/kg), the cells were complicated and expensive, and membrane replacement still remained a significant operating cost. Clearly, if we could devise a workable undivided cell system, we would avoid or reduce all of these penalties. In 1965, the same year as our plant startup, some Russian investigators (Tomilov, Varshavskii, and Knunyants) reported ADN selectivities as high as 90% in an undivided cell using an emulsion of AN in an aqueous electrolyte of 1N sodium hydrogen phosphate containing about 1 weight percent tetraethylammonium phosphate. Their cell employed a graphite cathode and a magnetite anode, and was operated at 18°C to minimize cyanoethylation side reactions. While the fragile nonmetallic electrodes used in this work seemed ill-suited to a commercial cell, the high electrical conductivity of the aqueous alkali phosphate electrolyte seemed most appealing. We initiated studies of alternate cathode and anode materials, targeting an all-metal electrode system capable of operation at higher temperatures, in order to avoid refrigeration.

I will not go through the long laundry list of electrode and electrolyte systems we examined, but will summarize several years of testing by saying that carbon steel proved to be a very satisfactory anode, provided small amounts of Na₄EDTA and Na₂B₄O₇ were added to the phosphate electrolyte as corrosion inhibitors. These additives reduced the anode corrosion rates from about 10 mm/yr in uninhibited electrolyte to a quite acceptable level of 0.5 mm/yr.

Of all the solid metals tested as cathodes, cadmium was found to give the best performance with respect to ADN selectivity and electrode stability. Aided some by serendipity, we discovered that the Na₄EDTA added to enhance anode stability led to mild corrosion at the cadmium cathode, thus serving to keep it free from accumulation of anode corrosion products (Fig. 10). In the absence of EDTA, hydrogen evolution at the cathode increased over a day's operation to the point where it represented greater than 10% loss in cathodic current efficiency. We ultimately found it desirable to introduce sufficient EDTA to chelate all the Cd and Fe cations entering the electrolyte via electrode corrosion.

The other absolutely essential electrolyte component is the quaternary ammonium salt. We screened a number of candidates and found the higher molecular weight analogs to give better results than the tetraethylammonium compounds used in our divided-cell process. Hexamethylene bis(ethyldibutylammonium) phosphate

performed best in terms of ADN selectivity and ease of extraction from the organic products.

Elimination of the membrane vastly simplifies cell design (Fig. 11). Bipolar electrodes are prepared from 1.5 mm thick sheets of carbon steel by electroplating 50-100 μm of Cd on one side. These are stacked together using plastic spacers to set the electrode distance. The total thickness of an individual cell is only about 3 mm; thus, a 100-cell bipolar stack has a thickness of only 30 cm. The electrode stack is fitted with a polypropylene housing and is contained in a cylindrical vessel, which provides a leak-free means of circulating electrolyte through the stack. Plastic electrode extensions at the inlet and outlet ends of the cell serve to limit current bypassing through the electrolyte in the vessel heads. The cost per square meter of cathode area for the undivided stack assembly is less than one-tenth that of the earlier plate-and-frame cell. Our Mechanical Engineering group at Pensacola deserves most of the credit for this accomplishment.

Another major advantage of the undivided cell is the markedly reduced cell voltage and power usage (Table IV). The voltage reduction is due to the use of a significantly more conductive catholyte and elimination of the membrane- and anolyte-IR drops. In addition, the low cell cost shifts the economic optimum current density to lower values, further reducing the total voltage. Cell power usage is cut by almost two-thirds.

However, we were not yet "home free," even though we had a workable electrolyte system and cell design. In the

undivided-cell EHD process, the offgas from the cells is an oxygen stream saturated with acrylonitrile vapor and may also contain 5%-10% H₂. This represented a serious explosion hazard. We felt we were safe within the cell itself, since the gas was present as small, discreet bubbles. But somewhere in the circulating system we had to face up to handling large volumes of this explosive gas mixture.

The proposed solution (Fig. 12) involves the use of a cone-capped electrolyte surge vessel, fitted with a scrubbing column at the apex. The liquid level is maintained several meters up into the column, and the gas bubbles rising through the cone and into the column create an aerated zone, which acts as a shock-absorber in the event of an explosion in the gas phase above. This small-diameter column is designed to withstand a H₂-O₂ explosion, while the rest of the system is not. AN is scrubbed from the offgas with ADN in the upper section of the column, which is packed with plastic Pall rings. The concept of protecting a large, thin-walled vessel from an explosion by a column of aerated liquid was proven out in a small-scale system, and it works.

The improved EHD process is capable of producing ADN at a significantly lower cost than the adipic-acid-based route practiced by many nylon manufacturers, and we believe it is fully competitive with the newer technology involving direct hydrocyanation of butadiene. Monsanto currently has installed EHD capacity of about 180,000 MT/Y ADN, divided roughly equally between the plant at Decatur, Alabama, and a newer facility at Seal Sands, England, brought on-stream in 1978. This is clearly the world's largest example of electro-organic processing.

In conclusion, I would like to try to summarize what I believe to be the key to the success of the EHD process development. Certainly, dedication and innovation were

Fig. 12. EHD offgas system

required on the part of the entire technical team, but the resources surely would have been cut off at an early stage had we not committed capital to that first commercial installation. It really was a gamble on unproven technology, and there were times in those early years when even *I* had some doubts. But with the plant sitting there, we had to

make it work and, as electricity and capital costs rose, we had to make the process better. One seldom can see all the potential improvements at the outset, but as the experience-curve philosophy tells us, with work they will come.

Thank you.

The Mechanisms of Thionyl Chloride Reduction at Solid Electrodes

W. K. Istone^{*1} and R. J. Brodd^{*2}

Ray O Vac Corporation, Madison, Wisconsin 53711

ABSTRACT

An experimental technique has been devised which allows *in situ* sampling of electrolyte from a functioning Li-SOCl₂ cell, followed by rapid FTIR analysis for soluble reaction products. Disulfur monoxide (S₂O) is observed as an intermediate discharge product. The half-life of S₂O is estimated to be about 20 min. The presence of S₂O is consistent with sulfur chemistry, as well as the accepted stoichiometry of the Li-SOCl₂ battery system. A possible safety hazard for low temperature discharges of Li-SOCl₂ cells is identified.

There has been great interest in the thionyl chloride-lithium battery system because of its high energy density and good high rate capability. There is general agreement that the overall discharge reaction for the system is

The details of the reaction are not yet known with certainty. Previous studies of the reaction mechanism have proposed various reaction pathways. Intermediates such as SO, S₂Cl₂, etc., have been postulated (1-4). It is important to know all aspects of the reaction characteristics in order to properly design the electrode structures (e.g., porosity) to accommodate reaction products, and to select materials of construction that are stable in SO, S₂Cl₂, SOCl₂, etc. It is also likely that the safety questions concerning thionyl chloride battery systems are related to the identity and stability of the reaction intermediates. Safety aspects include constructional features of the anode, the cathode, and the complete cell; they also prevent conditions such as internal shorts and the direct reaction of lithium and the sulfur reaction product.

In order to better understand the detailed steps and intermediates of the reaction mechanism, a technique described below has been devised to allow *in situ* sampling of electrolyte at the electrolyte surface. The materials present in the electrolyte are analyzed immediately utilizing Fourier transform infrared spectroscopy (FTIR). It is believed that the technique and relatively short analysis time (30s) have allowed us to confirm the existence of some reaction intermediates not previously observed.

Experimental

Thionyl chloride from Aldrich Chemical Company was redistilled in a glass and in Teflon still at ambient pressure under dry argon by the method of Wetter (5), with 160 ml additions of triphenyl phosphite to 1 liter of thionyl chloride. Care was taken to keep the pot below 82°C and column temperature below 78°C to prevent thermal decomposition of thionyl chloride. Fluka "puriss."-grade aluminum chloride was used as received. LiCl from Alpha Chemical Company was dried at 150°C *in vacuo* for 48h. The 1.6M LiAlCl₄ solutions were prepared in the argon dry box by slowly adding AlCl₃ to thionyl chloride to avoid heating and then slowly adding LiCl in slight excess. The resulting solutions were a very pale straw color.

* Electrochemical Society Active Member.

¹ Present address: St. Regis Technical Center, West Nyak, New York 10994.

² Present address: Standard Oil Company, Amoco Research Center, Naperville, Illinois 60566.

All pure chemicals and solutions were stored in glass inside an argon dry box.

Linear-sweep voltammetry experiments utilized a PAR Model 173 potentiostat and Model 175 waveform generator. Cell discharges were at constant current using a Keithley Model 227 constant current source.

The molar extinction coefficients are not known with certainty for the various reaction-product compounds in thionyl chloride. As a result, the absolute concentrations of the compounds cannot be determined. The amounts of materials were estimated on a relative basis. Since thionyl chloride is present in excess in all solutions, the peak for thionyl chloride at 2400 cm⁻¹ was used as a reference. The height of the peak for a particular compound, relative to the height of the 2400 cm⁻¹ peak, was used to follow changes in concentrations. This normalization procedure was used to eliminate errors due to changes in cell path length or instrumental conditions.

The experimental cell and sampling techniques were described previously (1). The FTIR cell was a Barnes micro flow-through cell having a path length of 0.1 mm. The cell material was KBr, with a total cell volume of 0.4 μl. The cell was connected by Teflon tubing to a syringe, which was used to draw samples of electrolyte into the FTIR cell. A valve prevented siphoning. A second piece of Teflon tubing connected the FTIR cell to the electrochemical cell, utilizing a stainless steel needle as a probe. The SOCl₂ slowly attacked the KBr cell, slightly changing its optical path. Therefore, the results reported here are semiquantitative in nature.

The electrochemical cell was contained in a glass vial containing 5 ml of 1.6M LiAlCl₄ in SOCl₂. A glass fiber mat separated the negative electrode (Foote Chemical Company pure lithium foil of 1 cm² area pressed into expanded stainless steel mesh) from the positive electrode (90% Shawinigan black, 10% PTFE, hot pressed at 275°C into expanded stainless steel grid to form a 1 cm² area electrode). The positive electrode made in this fashion had a porosity of about 60%. The stainless steel sampling probe was placed with its opening pressed against the face of the positive electrode. Experiments were also carried out with PTFE-bonded positive electrodes, using copper powder mixed with the Shawinigan black, as well as other solid planar materials, including glassy carbon, platinum, gold, nickel, and Type 316 stainless steel. The cell was assembled, filled, and sealed under argon atmosphere in a glove box, then transferred to the FTIR for discharge experiments.

The test cell was discharged at 5 mA/cm² constant current, with electrolyte samples of about 1 μl drawn for

analysis before discharge began to establish base line and at 15 min intervals during discharge. The FTIR is a Nicolet MX-1. The 27 scans between 4400 and 225 cm⁻¹, taken to establish each spectrum, required 30s. Most experiments were carried out at a room temperature of 298 K (25°C). Some experiments were carried out at low temperatures of 273 K (0°C) and 260 K (-13°C) to establish the effect of temperature on the reaction rate and, if possible, to stabilize fast reacting species.

Results and Discussion

The infrared correlation chart (Table I) of species pertinent to sulfur oxyhalide chemistry was used to interpret the experimental results. The spectra obtained from the cell electrolyte were analyzed to determine which compounds are observed in analyzed electrolyte, whether these compounds are present as impurities or as the result of electrochemical discharge, and how the compounds' relative concentrations change as a function of experimental stand time and depth of discharge. The electrolytes are spiked with compounds of interest to confirm their presence, with the exception of SO₃ and S₂O.

Figure 1 shows a typical IR spectra taken during discharge of a Shawinigan-black, PTFE carbon cathode. The location of the significant peaks is noted during the experiments. An analysis of the spectra shows that small amounts of SO₂Cl₂, SO₂, S₂Cl₂, SCl₂, and HCl are present in the electrolyte as impurities at the beginning of the experiment. The HCl and SO₂ concentrations increase

Fig. 1. Typical IR spectra showing S₂O, SO₂, and thionyl chloride reference peaks.

slightly with stand time, presumably as a result of moisture pickup from the cell walls. SO₃ is not observed initially and does not appear during stand time or during discharge. The SO and (SO)_x species are difficult to detect because the proximity of the large SOCl₂ bands tend to mask them. The peak heights for S₂Cl₂ and SCl₂ remain constant throughout the experiments. Only the intensities of peaks assigned to SO₂ and S₂O are observed to change as a function of cell discharge. Matrix effects can result in wavelength shifts from the values reported for pure compounds, as opposed to the compound dissolved in 1.6M LiAlCl₄ in SOCl₂. For instance, the SO₂ peak reported at 1332 cm⁻¹ appears at 1335 cm⁻¹, and the S₂O peak of 679 cm⁻¹ appears at 689 cm⁻¹ in SOCl₂ media. The other peaks for these compounds are also detected with similar matrix shifts, though the 1332 and 679 cm⁻¹ are the easiest to monitor.

Figure 2 shows the change in relative concentration of SO₂ and S₂O as a function of cell discharge. It may be noted that the S₂O concentration increases to a maximum and then begins to decrease with time (mAh), whereas the SO₂ concentration increases and then appears to level off. We believe that the plateau in Fig. 2 is related to the steady-state concentration of SO₂ at the electrode surface under the experimental discharge conditions. Companion experiments run at a significantly higher discharge rate (50 mA/cm²) show that the amount of SO₂ increases as a function of discharge time. Hence, the plateau of Fig. 2 may simply be related to the SO₂ diffusion away from the electrode surface in a steady-state situation. No new compounds were found at the higher current density. The results are similar to the results reported at lower current density, but with slightly higher concentrations of the S₂O intermediate. When an electrolyte sample from a discharged electrode is allowed to stand in the FTIR cell for a prolonged period (*e.g.*, 30 min), analyses show that the SO₂ concentration increases and the S₂O is deposited on the FTIR cell walls. Sulfur is a reaction product, and the S₈ species could be found as a reaction product. However, though S₈ has a weak absorption band at 686 cm⁻¹, it has a medium absorption band at 841 cm⁻¹ which would not be interfered with in the observed spectra. Experimentally, no change around 841 cm⁻¹ occurred, as would be expected. Also, on stand, no change should occur if S₈ is responsible for the 690 cm⁻¹ band. This is consistent with the reported decomposition reaction for S₂O (7)

Copper powder added to the positive electrode has been reported to improve the high rate capability of the Li-SOCl₂ cell (11). The copper reacts with SOCl₂ to produce insoluble CuCl. No new soluble materials were observed in thionyl chloride of cells containing copper. Only peaks for SO₂ and S₂O were observed. Figure 3 shows the change in relative concentrations of SO₂ and S₂O, using

Fig. 2. Changes in the concentrations of SO₂ and S₂O as a function of thionyl chloride discharge (Shawinigan black cathode in 1.6M LiAlCl₄ (SOCl₂) at 25°C; discharge rate: 5 mA cm⁻²).

Fig. 3. Change in relative concentrations of SO₂ and S₂O using copper containing cathodes at 25°C (discharge rate: 5 mA cm⁻²).

copper containing cathodes. The results are similar to those with only Shawinigan black.

Figures 4 and 5 show the effect of discharge at low temperature on the relative amounts of SO₂ and S₂O produced. The S₂O material is stabilized at the lower temperatures, and its concentration builds up to higher concentration levels at the lower temperature. It decomposes much more slowly at 273 and 260 K than at room temperature. From our results, we estimate that the half-life of S₂O at room temperature is of the order of 20 min.

Figure 6 shows a linear sweep for a glassy carbon cathode. The results are very similar to those reported for py-

Fig. 4. Relative amounts of SO₂ and S₂O produced at 0°C (Shawinigan black cathode discharge rate: 5 mA cm⁻²).

Fig. 5. Relative amounts of SO₂ and S₂O produced at -13°C (Shawinigan black cathode discharge rate: 5 mA cm⁻²).

Fig. 6. Linear sweep voltammetry of a glassy carbon electrode in 1.6M LiAlCl₄ (SOCl₂).

rolytic carbon (4). The main peak for SOCl₂ reduction is at 2.54V vs. Li, with some reaction at 1.1V vs. Li, presumably due to SO₂ reduction. On the second and third sweeps after the excursion into Cl₂ evolution, peaks at 3.61 and 3.32V were also observed. The peak at 3.61V is usually associated with Cl₂, but could be due in part to SO₃. The peak at 3.32V is thought to be due to SO₂Cl₂ formed during the excursion to higher voltages.

The results reported here are not consistent with previous reports of reaction mechanism. Blomgren *et al.* (4) reported SCl and S₂Cl₂ as intermediates in SOCl₂ reduction. Both of these materials are active in the IR region under observation, but no changes in peak heights were observed in these compounds in the present study. None of the cells took on the blood red color usually associated with sulfur chlorides. Since their time frame for analysis was long, previous studies would not have observed the S₂O reported above. Blomgren *et al.* (4) proposed the following mechanism

The results here do not support the presence of sulfur chlorides as reaction intermediates. The reason for this difference is not obvious. Pure materials were used in both experiments. The only obvious difference is the different carbon electrode materials used in each study. Blomgren *et al.* did not use Shawinigan black, but a black produced by Union Carbide Corporation. They also used pressure-annealed pyrolytic graphite electrodes for linear sweep experiments. It is not clear why this difference should influence the reaction mechanism, if indeed it does.

Schlaikjer *et al.* (4) propose the following mechanism, which uses Teflon-bonded Shawinigan black electrode structures.

They also report the possible formation of solid Li₂SO₃ in small amounts at low temperature discharge.

Dey *et al.* (3) proposed a mechanism somewhat similar to that of Blomgren *et al.*, involving the SO radical, but

with formation of SOCl as the first step of the reduction. They did not report S₂Cl₂ and SCl₂ as intermediates

The SO radical could follow the proposed reaction. However, according to Nickless, the usual path for SO reaction involves S₂O formation.

The identification of S₂O formation reported here would suggest the following mechanism

The observation that S₂O is produced can be taken as proof that SO is formed in the thionyl reduction process. The formation of solid products such as Li₂SO₃ would not be expected unless there were excessive impurities in the SOCl₂ or there was a potential excursion of 4.0V vs. Li. If such an excursion occurred, SO₃ and SO₂Cl₂ could form, giving Li₂SO₃ and Li₂S₂O₃ on discharge. In the discharge of large cells, the IR spectra of discharged electrolyte indicates the presence of SO₃ when cells are held at 4.0V for a short period of time.

The formation of S₂O intermediate could explain some previous observations concerning the rate of SO₂ formation during discharge. It would be expected that smaller-than-stoichiometric quantities of SO₂ would be generated during the initial stages of cell discharge, owing to the stability of S₂O. Only toward the end of discharge, when S₂O production corresponds to the discharge rate, would the SO₂ production be directly proportional to discharge rate. As the stability of S₂O varies with temperature, low temperature discharges (especially at high rates) could lead to buildup of large S₂O concentrations. Warming these cells to room temperature could quickly lead to rapid decomposition of S₂O with rapid heat release and SO₂ pressure buildup.

Conclusions

1. It is possible to detect short-lived intermediates in thionyl chloride reduction using an *in situ* sampling technique, coupled with FTIR apparatus.
2. S₂O specie was identified and, therefore, by implication, the SO specie was identified as intermediates in electrochemical reduction of thionyl chloride.
3. The half-life of S₂O in thionyl chloride is about 20 min.
4. S₂O was identified as an intermediate with carbon, carbon-copper mixture, platinum, gold, nickel, and stainless steel electrodes.

Investigation of SOCl_2 Reduction by Cyclic Voltammetry and AC Impedance Measurements

M. J. Madou*

S. Szpak*

Naval Ocean Systems Center, San Diego, California 92152

ABSTRACT

Cyclic voltammetry and ac impedance measurements, covering the range 10^{-3} - 10^4 Hz, were employed to investigate the reduction of thionyl chloride on glassy carbon surfaces and to determine the associated elementary processes. The quasi-exchange current density of the electroreduction of SOCl_2 is 6.4×10^{-7} A cm^{-2} and becomes larger in the presence of dissolved chlorine. Also, in the presence of Cl_2 , the rest potential shifts to more positive values. At low overpotentials, the reduction of SOCl_2 is kinetically controlled. However, as the overpotentials are increased, a transition to mass-transport control occurs, even before the onset of passivation at +2.7V. The rate of mass transport is governed by the thickness and quality of the LiCl film.

The lithium thionyl chloride battery is one of the most energetic systems reduced to practice thus far and is well developed for lower power density requirements (1). However, to achieve high discharge rates, a new set of problems must be resolved, which requires a more detailed knowledge of the elementary processes that take place within the battery. In particular, reference is made to those processes that occur within the porous structure of the positive electrode.

The reduction of SOCl_2 was studied quite extensively (2-7). The reported results, however, are incomplete inasmuch as they do not provide useful data for electrode modeling which is essential for the rational design of high power output batteries (8, 9). In an attempt to provide this information, we will emphasize the description of the elementary processes rather than concentrate on the identification of reactive species (10, 11).

Experimental

Solutions.—Stock solutions having a composition of 1M AlCl_3 , 1M LiAlCl_4 , 1.6M LiAlCl_4 , 2.2M AlCl_3 , plus 1.9M LiAlCl_4 in SOCl_2 were used as supplied (source: Altus Corporation, San Jose, California 95112). Typical impurity levels, certified by the supplier, were Fe 1.8 ppm, SCl_2 0.1%, and OH 84 ppm in neutral solutions. The acidic solutions usually contained more OH (up to 251 ppm for the 1M AlCl_3 in SOCl_2).

Electrochemical cell and apparatus.—The electrochemical cell used in this investigation is shown in Fig. 1. A porous vitreous carbon and a flat glassy rod, press-fitted into a Teflon screw, were employed as the counter and working electrodes, respectively. Metallic Li and Mo were used interchangeably as reference electrodes. The cell volume was ca. 2 cm^3 .

A Princeton Applied Research potentiostat/galvanostat, Model 173/176, and Universal Programmer, Model 175, were used to perform cyclic voltammetry. Measurements of the electrochemical transfer function were carried out using a Solartron Frequency Response Analyzer (FRA) Model 1172/1183/1185 in an experimental configuration described elsewhere (12).

Procedure.—All measurements were carried out in a dry box under a positive argon pressure. Before each measurement, the working electrode was polished with an Al_2O_3 aqueous slurry (particle size 1 μm) on a polishing cloth, followed by methanol wash, and then wiped dry with a lense paper. A fresh Li reference electrode was used for each set of impedance measurements and between sets of cyclic voltammograms. The porous vitreous

carbon counterelectrode was replaced before each set of experiments.

Results and Discussion

The results and discussion section covers five topics: the choice of reference electrode, the concept of mixed potential and the quasi-exchange current density, the cyclic voltammetry data, the results of impedance measurements, and their relevance to battery modeling.

Choice of reference electrode.—Metallic Li is the reference electrode of choice in neutral solutions. It is not suitable in acidic electrolytes because of the dissolution of the protective LiCl film, which, for small cells, would substantially change the composition of the electrolyte phase. To avoid these difficulties, we have selected Mo as the reference electrode for most of the work in acidic solutions (13). These two reference systems were compared by measuring open-circuit potentials between a Mo electrode and a Li electrode in a U-type cell provided with a fritted glass disk between the cell compartments (e.g., 1.6M LiAlCl_4 in SOCl_2), a V_{oc} of approximately 3.60V was measured. Upon the addition of an aliquot of 1M AlCl_3 solution in SOCl_2 to the Mo compartment, the V_{oc} increased to about 3.95V. Interestingly, these potentials are close to those reported for the carbon/lithium couple in neutral and acidic solutions (14). Such a relationship suggests that the Mo electrode acts as an electrode of the first kind and not as one of second kind, as concluded by Spandau and Brunneck (13), i.e., it responds to the electron transfer associated with the fastest reaction, just as does the carbon electrode (15).

Table I. Summary of postulated overall cell reactions in neutral Li/SOCl₂ system (24)

Overall reaction	(F/mol)	E _o , (V) (calc.)
4Li + 2SOCl ₂ → 4LiCl + S + SO ₂	2.00	3.72
8Li + 3SOCl ₂ → 6LiCl + 2S + Li ₂ SO ₃	2.67	3.60
8Li + 4SOCl ₂ → 6LiCl + S ₂ Cl ₂ + Li ₂ S ₂ O ₄	2.00	3.50
14Li + 6SOCl ₂ → 12LiCl + 4S + Li ₂ S ₂ O ₆	2.33	3.70
10Li + 4SOCl ₂ → 8LiCl + 2S + Li ₂ S ₂ O ₄	2.50	3.57
10Li + 4SOCl ₂ → 8LiCl + 3S + Li ₂ SO ₄	2.50	3.73
8Li + 3SOCl ₂ → 6LiCl + S + Li ₂ S ₂ O ₃	2.67	3.56
6Li + 4SOCl ₂ → 6LiCl + S ₂ Cl ₂ + 2SO ₂	1.50	3.68
10Li + 6SOCl ₂ → 8LiCl + 2S ₂ Cl ₂ + Li ₂ S ₂ O ₆	1.67	3.64
7Li + 4SOCl ₂ → 5LiCl + 3/2S ₂ Cl ₂ + Li ₂ SO ₄	1.75	3.68
6Li + 3SOCl ₂ → 4LiCl + S ₂ Cl ₂ + Li ₂ SO ₃	2.00	3.52
7Li + 3SOCl ₂ → 5LiCl + 1/2S ₂ + Li ₂ S ₂ O ₃	2.33	3.52

Open-circuit potential and quasi-exchange current density.—The calculated values of open-circuit potential, listed in Table I, range from 3.52 to 3.73V for cells employing neutral electrolytes, with higher values in acidic electrolytes, e.g., ca. 4.0V (14), i.e., the same values that were recorded for the C/Li and Mo/Li couples. The gain in the open-circuit potential of ca. 0.4V in acidic electrolytes was attributed by Klinedinst and Domeniconi (14) to the difference in the Gibbs' free energy associated with the respective reactions. Using the available data for the equilibrium constant for the complexation reaction (i.e., formation of LiAlCl₄), they estimated this gain to be between 0.53 and 0.63V. Experimentally, however, the gain is somewhat less, viz., 0.35-0.4V.

A possible explanation for the discrepancy between the theoretical and experimental data is that, in adding the AlCl₃, not only the reaction product has changed (i.e., LiAlCl₄ rather than LiCl) but also the reactant (i.e., AlCl₃·SOCl₂ adduct rather than SOCl₂). There is, indeed, substantial evidence for the existence of the AlCl₃·SOCl₂ and 2AlCl₃·SOCl₂ adducts by Raman spectroscopy (16), and for AlCl₃·SOCl₂ adduct by infrared spectroscopy (17). By taking the reaction of adduct formation, i.e., starting with a more stable reactant, ΔG, and thus also ΔE, will be lowered, in contrast to the situation where no complexation has been taken into account.

In what follows, we will show that the experimentally determined cell potential is not the reversible potential, but is a mixed one, with a cathodic current involving the reduction of SOCl₂ or Cl₂ and the anodic current involving evolution of Cl₂ from either SOCl₂, AlCl₄⁻, or LiCl.

An Evans-type representation of log *i* vs. *V* curves for the reduction and oxidation in neutral electrolyte is shown in Fig. 2. The cathodic and anodic branches were constructed with the aid of potential sweeps commencing at potentials slightly negative to the V_{oc} for the cathodic branch (curve a) and at 4.00V for the anodic branch (curve b). The development of a curvature and hysteresis indicates that the activation-controlled region is relatively narrow (between +3.55 and +3.00V), with a region for the reduction of both Cl₂ and SOCl₂ being between +3.55 and +3.25V only.

The anodic branch arises because of Cl₂ evolution generated by oxidation of SOCl₂, AlCl₄⁻, or LiCl. The Cl₂ generated by the anodic excursion is subsequently reduced during the returned sweep with the amount of cathodic current depending on the anodic charge consumed.

Processes determining the V_{oc} and the quasi-exchange current density, *i*₀^a, are complex. Assuming that the amount of Cl₂ present (or generated) in the solution is small, it follows that the intersection of curves a and b determines both the V_{oc} and *i*₀^a. Extrapolation of data in Fig. 2 yields V_{oc} = +3.55V and *i*₀^a = 6.4 × 10⁻⁷ A cm⁻². Extrapolation of curves c and a yields higher values for the *i*₀^a and a more positive open-circuit potential. The sensitivity of both these quantities to the dissolved chlorine is an expected behavior, provided that the reduction of SOCl₂ is a rapid reaction.

Fig. 2. Evans plot (log *i* vs. *V*). Electrolyte: 1.6M LiAlCl₄ in SOCl₂. Temperature: room. Electrode area: 0.314 cm². Reference Electrode: Li. Sweep rate: 10 mV s⁻¹.

Additional information concerning the magnitude of the electrode transfer resistance associated with the reduction of thionyl chloride can be extracted from data in Fig. 2. Using *i*₀^a = 6.4 × 10⁻⁷ A cm⁻² and substituting into the Stern-Geary relationship, Eq. [1]

$$R_p = \bar{\beta} = \bar{\beta}/2.303 \times i_0^a \times A \times (\bar{\beta} - \bar{\beta}) \quad [1]$$

a value of $R_p = 7 \times 10^4 \Omega \text{cm}$ is calculated. Here $\bar{\beta}$ and $\bar{\beta}$ are the anodic and cathodic Tafel coefficients, respectively, and *A* is the electrode area.

Cyclic voltammetry.—A typical voltammogram in a neutral electrolyte exhibits a large reduction peak (peak I), a rather broad peak located between +2.0 and +1.0V (peak II), followed by a rapid increase in current at ca. +1.0V (peak III). Upon reversal of the sweep, two anodic peaks appear at potentials of ca. +1.1 and +2.9V (peaks IV and V).

There is no disagreement in the identification of peak I and current onset III. However, the origin and structure of peaks II and V have not been resolved as yet. In fact, Behl (2) reported two barely perceptible peaks at +1.7 and +1.3V rather than one broad peak. The existence of these peaks has not been confirmed in this work or in work by others (4, 10, 19). The broad peak II is most likely due to the reduction of SO₂ (10, 19). However, even in SO₂-saturated neutral electrolytes, the peak height remains about the same because, to be reduced, SO₂ must diffuse through the passive film (2). As expected, the effect of SO₂ bubbling on the peak height is more evident in acid solutions since the excess of AlCl₃ partially dissolves the precipitated LiCl, thus making the surface accessible to the electroreduction of SO₂.

Commencing a cyclic voltammogram at a potential positive to the V_{oc} (e.g., at +4.50V) and terminating the sweep at a potential positive to the appearance of peak II, two additional cathodic current peaks, peaks A and B, appear before the SOCl₂ reduction peak (Fig. 3, curve a). The first peak, peak A, at +3.60V, was attributed to the reduction of SCl₂ (8), and peak B, at +3.25V, to the reduction of Cl₂. To confirm this assignment, we have used a Cl₂-saturated electrolyte and commenced the sweep at potentials slightly cathodic to the V_{oc}. As illustrated in Fig. 3, curve b, peak B is substantially increased, i.e., attributable to the reduction of Cl₂. Peak A, although present, was not affected by the presence of dissolved chlorine.

Figure 4 shows the dependence of reduction peak I on the scan rate. The substantial shift of the peak potential with the scan rate is indicative of the highly irreversible character of the SOCl₂ reduction. A plot of peak height *i*

Fig. 3. Cyclic voltammograms on glassy carbon. Scan rate: 100 mV s^{-1} . Electrode area: 0.314 cm^2 . Temperature: room. Reference electrode: Li. Electrolyte: 1M LiAlCl_4 in SOCl_2 (curve a) and $1\text{M LiAlCl}_4 + \text{Cl}_2$ in SOCl_2 (curve b). Scan initiation: (curve a) $+4.5\text{V}$, (curve b) $+4.0\text{V}$.

vs. \sqrt{v} results in a straight line passing through the origin indicating a diffusion-controlled process, in agreement with results of Behl (20) and Doddapaneni (22). Since we did not find the usual effect of stirring of the electrolyte, the diffusion limitation suggested by the *i vs. \sqrt{v}* plot cannot be due to the concentration polarization in the liquid phase. We conclude, therefore, that the diffusion limitation has its origin in the transport of species through the film produced on the electrode surface. The limiting diffusion current density in the electrolyte phase would have been much larger, on the order of Acm^{-2} (23).

Impedance measurements.—Impedance measurements were employed by Meitav and Peled (6) to study the behavior at the open circuit of stainless steel immersed in 1M LiAlCl_4 in SOCl_2 electrolyte. They concluded that the charge transfer reaction resistance is very high. Phillips *et al.* (7) found that also the reduction of SOCl_2 on vitreous carbon surfaces is slow. Qualitatively, these results are in agreement with the i_0 and R_p values determined with the aid of the Evans plot (Fig. 2).

In an attempt to provide additional information, two sets of impedance measurements were made. In the first

Fig. 4. Cyclic voltammograms as function of scan rate. Electrode: glassy carbon, area 0.314 cm^2 . Electrolyte: 1M LiAlCl_4 in SOCl_2 . Temperature: room. Scan rates indicated. Reference electrode: Li.

set, repetitive impedance data (with a 2 min delay time) were obtained at the V_{oc} and at very low cathodic overpotentials in neutral and acidic solutions. In the second set, impedance data were collected at higher cathodic overpotentials, also in neutral and acidic solutions.

A typical Nyquist plot (*i.e.*, a plot of the real *vs.* imaginary part of the electrode impedance) in acid solutions is shown in Fig. 5a, while the corresponding Bode plot (*i.e.*, a plot of the logarithm of the total electrode impedance *vs.* the ac frequency) is shown in Fig. 5b. A straightforward mathematical treatment shows that a semicircle intersecting the real axis at 90° in the Nyquist plot is indicative of a kinetically controlled reaction and can be represented by a simple RC parallel equivalent circuit. However, when a diffusional process is controlling the impedance factor, the Nyquist plot yields a straight line intersecting the real axis at 45° . The corresponding Bode plots are straight lines with slopes -1 and $-1/2$.

The separation and identification of contributing processes is clear in acid solutions (Fig. 5a and 5b). The Nyquist and Bode plots in neutral solutions are similar

Fig. 5. Nyquist (a, left) and Bode (b, above) plots. Electrode: glassy carbon, area 0.314 cm^2 . Electrolyte: $2.2\text{M LiAlCl}_4 - 1.9\text{M AlCl}_3$ in SOCl_2 . Temperature: room.

except that the kinetic and transport controlled processes are less clearly resolved. Here, the Nyquist plot in Fig. 6 is a large "depressed" semicircle, with its center below the real axis. The Bode plot (not shown) is a straight line with slopes approaching -1 and $-1/2$ at the highest and lowest frequencies, respectively. The diffusional process, we believe is associated with switch-on of Cl_2 in the solution.

Consecutive measurements at the V_{oc} or at low overpotentials were reproducible in the acidic electrolytes, while in neutral electrolytes, the impedance increased with each successive measurement. Such a behavior indicates that, in acid solutions, the electrode surface remains free from deposited LiCl , whereas in neutral solutions, the deposited LiCl changes the electrode impedance even at the open circuit. The presence of the deposited LiCl accounts for the difficulty in clearly separating and identifying participating processes.

Fitting the high frequency points in the Nyquist plot (Fig. 5a) to a semicircle yields a R_p of ca. $9.4 \times 10^3 \Omega \text{cm}^{-2}$ and a value of C_p from the imaginary component of the impedance between 60 and $70 \mu\text{Fcm}^{-2}$, the latter being about twice that measured by Meitav and Peled on stainless steel (6).

Results of impedance measurements at different cathodic overpotentials are presented in Fig. 7, with the Nyquist plots on the left-hand side and the Bode plots on the right-hand side. These measurements were taken in steps at 200 mV starting at +3.3V (Fig. 7a) and terminating at +2.5V (Fig. 7e). In contrast to the electrode behavior of the open-circuit potential, no clear evidence for the dominance of transport properties can be presented at low cathodic overpotentials. This is an expected behavior because the diffusional process at low frequencies is associated with the reduction of Cl_2 , which must disappear at potentials negative to the V_{oc} .

Results of the ac impedance measurements, summarized in Fig. 7a-7d, indicate that the electroreduction of SOCl_2 on glassy carbon is complex. The diameter of the single semicircle in Fig. 7a, *i.e.*, at 3.3V is almost the same as at the V_{oc} . If there were only one reduction process involved at V_{oc} , *e.g.*, the SOCl_2 reduction, we would expect the R_p to decrease exponentially with increasing overpotential. This clearly is not the case here and indicates that R_p at the V_{oc} is relatively small because of the contribution due to the reduction of Cl_2 at the V_{oc} . The diameter of the single semicircle in Fig. 7a and 7b decreases as the potential decreases from +3.3 to +3.1V. The approach to the real axis of the semicircles at high frequency is close to 90° , but the centers of the semicircles are found some-

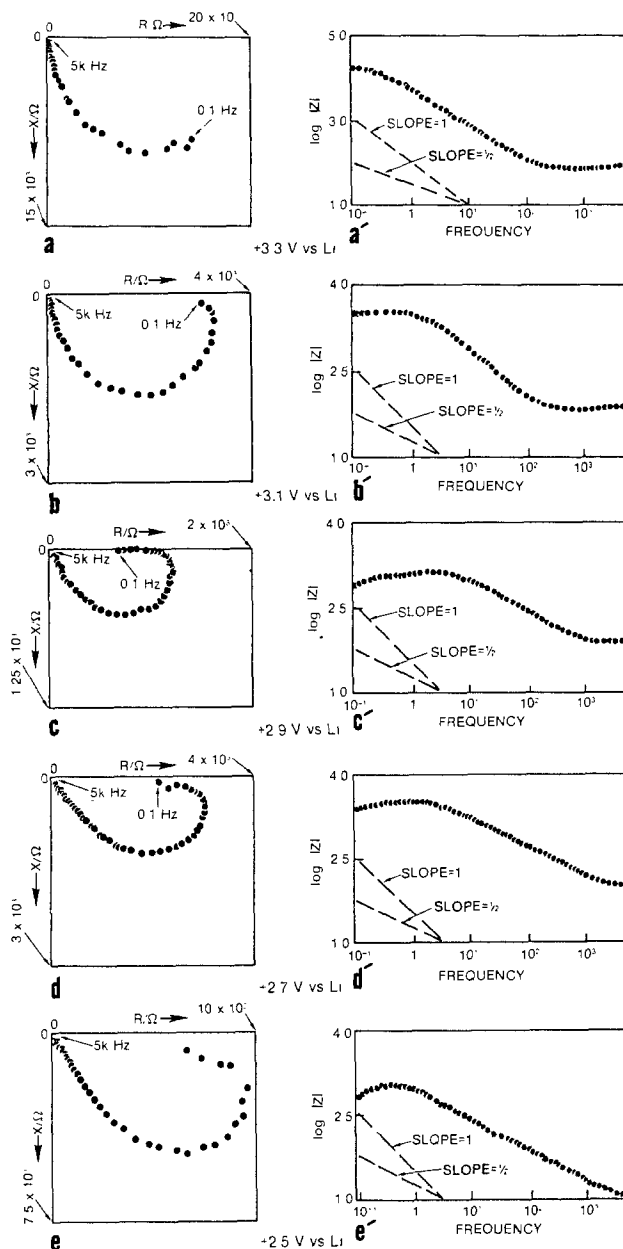

Fig. 7. Nyquist and Bode plots as function of overpotential. Electrode: glassy carbon, area 0.314 cm^2 . Electrolyte: 1M LiAlCl_4 in SOCl_2 . Temperature: room. Reference electrode: Li. Curve a: at +3.3V. Curve b: at +3.1V. Curve c: at 2.9V. Curve d: at +2.7V. Curve e: at +2.5V.

what below the real axis. The Bode plots, Fig. 7a' and 7b', exhibit a slope approaching -1 over a wide frequency range. Taking the point at 0.1 Hz in these figures as representative for the R_p of a relatively LiCl -free surface, we can see that R_p has decreased over almost one order of magnitude with a change of 200 mV in electrode potential.

At electrode potentials close to the reduction peak of SOCl_2 , the impedance spectra indicate diffusional behavior. The Nyquist plots, shown in Fig. 7c and 7d at +2.9 and +2.7V, respectively, exhibit an approach to the real axis at high frequencies of approximately 45° , and the corresponding Bode plots show lines with a slope approaching $-1/2$. The high frequency range, in which the diffusional character of the impedance becomes apparent, sets it apart from the diffusional process in solution, which has been discussed in connection with Fig. 5a and 5b. We note that within the low frequency range of the Nyquist plot in Fig. 7c, 7d, and 7e some points are lying along the real axis, indicating that R_p is increasing during the measurement. This change in R_p is due to the reduction of available area on the electrode surface because of deposition of LiCl .

Relevance to battery modeling.—In the “Cyclic voltammetry” section, we propose that a quasi-diffusional process arises during the SOCl₂ reduction, with its origin being the transport of species to or from the surface of the carbon electrode through voids in the LiCl film. The impedance spectra in Fig. 7a-7e support this picture. The approach of the intercept of the low frequency points toward the real axis in a Nyquist plot, for diffusion-controlled systems, is equal to the sum of series resistance R_s , here equal to the electrolyte resistance, R_p , the electron transfer resistance, and R_d diffusion layer resistance. The magnitude of the diffusion layer resistance is proportional to the thickness of a layer through which diffusion takes place. Here, the thickness of the diffusion layer is that of a LiCl film deposited on a glassy carbon surface. Evidently, the cathodic polarization of carbon electrode reduces R_p but increases R_d owing to an increase in thickness of a LiCl film. The dominance of the R_d with the increase in cathodic polarization is clearly shown in Fig. 7d, where the diameter of the Nyquist plot begins to increase. As cathodic overpotentials are increased, to +2.5V (Fig. 7e), the electrode surface is completely covered, as evidenced by a sudden expansion of the Nyquist plot.

Upon starting the ac impedance measurements at +2.9V and stepping the dc bias towards more anodic potentials (again with 2 min delay) it was found that the quasi-diffusional behavior dominated the impedance even at +3.3V (vs. Li). Obviously, the thicker film formed at +2.9V was permanent and was not removed by reducing the cathodic polarization.

The quasi-diffusional behavior, *i.e.*, transport through solid LiCl film, similar to that in neutral solution, was never observed in acidic solutions, not even at potentials in the passive region. Despite this, the Nyquist plots showed points at low frequency lying along the real axis, indicating, again, the reduction in active area during the measurement. Evidently, in contrast to neutral solutions, in acidic electrolyte, the LiCl film remains sufficiently thin and does not result in quasi-diffusional behavior. The passivation of the electrode surface is likely to occur if the rate of LiCl complexation is slower than LiCl formation.

Conclusions

1. Metallic Li is a suitable reference electrode for measurements in neutral solutions, while Mo is preferable in acidic electrolytes.
2. The rest potential of a carbon electrode, immersed in SOCl₂, is a mixed potential, with the cathodic partial reaction being the reduction of SOCl₂ and the anodic branch arising from the oxidation of SOCl₂, AlCl₄⁻, and Cl⁻.
3. Reduction of SOCl₂ on a glassy electrode is a slow process with the quasi-exchange current density of 6.4×10^{-7} A cm⁻².
4. The reduction of SOCl₂ is kinetically controlled at low overpotentials. However, as these overpotentials are increased, a transition to diffusion control occurs, even before the onset of passivation at +2.7V.
5. All reactions, including SO₂ reduction, that take place at potentials more negative than +2.7V, are controlled by mass transport. The controlling factor is the thickness and porosity of the LiCl film rather than the conditions in the bulk electrolyte.
6. Once formed, the LiCl film cannot be removed by holding the electrode negative to the V_{oc} . Removal of this film requires potentials more positive than the V_{oc} .

7. In acidic solutions, the electrode surface remains free from deposited LiCl. Diffusional control through a LiCl film is possible only if the dissolution of the LiCl film is slower than its formation.

Pore Development during Selective Leaching

A. D. Tomsett, D. J. Young,* and M. S. Wainwright

School of Chemical Engineering and Industrial Chemistry, University of New South Wales, Kensington, New South Wales 2033, Australia

ABSTRACT

The leaching kinetics of a Cu-50 weight percent Al alloy in aqueous NaOH have been studied. The product of the reaction, known as Raney copper, an important industrial catalyst, consists almost entirely of highly porous copper. In forming this material, the Al is selectively dissolved from the alloy, the rate of the leaching reaction being controlled by liquid-phase diffusion within the pores of the leach residue. At constant temperature, the spacing of these pores increases as the leaching rate decreases. As the temperature decreases, so does the pore spacing. The conversion of the original alloy phase, CuAl₂, to porous copper is considered as an example of a phase transformation, and the pore spacing is taken as a measure of the distance over which Cu-Al segregation must occur within the alloy. Models based on volume diffusion adjacent to the reaction front and on boundary diffusion at the front are used to describe the relationship between pore spacing and reaction rate. Application of these models to the experimental data, for a temperature of 20°C, yields estimates of $D = 6 \times 10^{-12} \text{ cm}^2\text{s}^{-1}$ with an activation energy of $53 \pm 2 \text{ kJ}$ for volume diffusion and $D_b = 5 \times 10^{-10} \text{ cm}^2\text{s}^{-1}$ with an activation energy of $62 \pm 4 \text{ kJ}$ for boundary diffusion. It is concluded that alloy segregation takes place at the leach reaction front by a mechanism of boundary diffusion.

The selective leaching in alkaline solution of aluminum from alloys to leave a porous, spongy residue is a well-known, but incompletely understood, phenomenon. Reactions of this type have been exploited since the days of Raney (1, 2) in the manufacture of high surface-area metal catalysts. The widespread use of Raney catalysts in a variety of chemical processes adds practical interest to fundamental questions about the nature of the leaching mechanism. Since the leach reaction determines the product morphology, it is possible that an understanding of the leaching mechanism will lead to the ability to control the morphology and, hence, the catalyst properties. The purpose of this study is to examine the relationships between leaching kinetics and product morphology.

A series of studies (3-6) has shown that caustic leaching of aluminum and zinc from alloys based on copper, nickel, and cobalt proceeds according to parabolic kinetics

$$X^2 = k_p t \quad [1]$$

where X is the thickness of the reaction-product rim formed in time, t . The magnitude of k_p is found to be independent of the orientation of the parent alloy with respect to reaction direction. From these observations, it is concluded that the leach reaction rate is controlled by diffusion through the liquid occupying the pores of the reaction product. This conclusion is consistent with the magnitude of k_p and its activation energy.

During these reactions, the microstructure of the precursor alloy is reproduced in the reaction product. An example is shown in Fig. 1, where a Cu-Al alloy consisting of CuAl₂ grains separated by frozen Al-CuAl₂ eutectic is seen to produce grains of porous copper separated by void space. This observation, together with the fact that copper solubility in strong alkali is negligible, leads to the conclusion that the mechanism is one of selective dissolution and not dissolution reprecipitation. Similar findings apply to Ni-Al and Co-Al alloys.

In all cases, the product material is almost entirely composed of noble metal and is highly porous. The question therefore arises as to how rearrangement occurs within the solid to accommodate the loss of a large fraction of its constituent atoms in a reaction of the type

The reaction is presented schematically in Fig. 2. The highly ordered product morphology depicted is based on the observation (7) that pore sizes are very similar.

Theory

The transformation of a homogeneous parent phase into a highly ordered two-phase structure in which the re-

*Electrochemical Society Active Member.

action products appear in lamellar or rodlike form is a phenomenon familiar to metallurgists. Reaction morphologies of this sort are observed in eutectic and eutectoid transformations (8, 9)

and in discontinuous precipitation (10)

where α , β , and γ denote different phases and α' denotes a distinctly different composition of a solid-solution phase α . In addition, reactions leading to the production of these cellular morphologies have been observed (11-13) in cases of reaction of the parent phase with an externally supplied gaseous reactant, R. Reactions of this type may be written

Although selective dissolution reactions have not hitherto been described in these terms, they appear to fall within this latter class. A brief review of the theory of cellular phase-transformation kinetics is therefore pertinent.

A simple description of transformation kinetics was first provided by Zener (14) on the supposition that segregation of the parent-phase constituent elements toward the tips of the advancing α and β lamellae occurs by diffusion within the parent phase itself. Assuming further that α - β - γ triple-phase junctions are at mechanical equilibrium, then the velocity, v , at which the reaction front advances into the parent phase, is given by

$$v = \frac{D}{S} \frac{A}{a} \left(1 - \frac{S_c}{S} \right) \quad [6]$$

where D is the chemical diffusion coefficient in γ , S is

Fig. 1. Micrograph of section through partially leached Al-50Cu alloy

Fig. 2. Schematic representation of a CuAl_2 -Cu grain and the alloy-reaction product interface.

the combined width of α and β lamellae, A is the relative supersaturation within the parent phase, and α is a geometric constant of order unity. The quantity S_c is a critical lamellar spacing at which the free energy per unit volume of two-phase product equals that of the parent phase and at which reaction ceases. This term arises through the surface free energy associated with the α - β interfaces which are created in the reaction. A complete local-equilibrium solution for eutectoids was provided by Hillert (15) by incorporating the Gibbs-Thompson effect for the pressure-composition variation in the parent phase along the curved interfaces, thereby evaluating the compositional differences driving the diffusion. Hillert in this way shows that

$$A = \frac{1}{f^\alpha f^\beta} \frac{C^{\gamma\alpha} - C^{\gamma\beta}}{C^\beta - C^\alpha} \quad [7]$$

where $(C^{\gamma\alpha} - C^{\gamma\beta})/(C^\beta - C^\alpha)$ is the ratio of the lateral concentration difference in front of limiting flat interfaces to that between the product phases. The constants f^α and f^β are, respectively, the ratios S^α/S and S^β/S ; they are determined by the parent-phase composition.

Because the relationship between ν , S , and relative supersaturation permits an infinite number of solutions, a further condition must be imposed. Zener (14) and Hillert (15) suggest that the system stabilizes at a value of S for which ν is a maximum. If so, then

$$S = 2S_c = \frac{2\sigma^{\alpha\beta}}{RT(C^{\gamma\alpha} - C^{\gamma\beta})} \quad [8]$$

where R is the gas constant and $\sigma^{\alpha\beta}$ is surface energy of the α - β phase boundary.

Alternatively, it has been proposed (16-18) that the rate of entropy production is a maximum, whence

$$S = 3S_c = 3\sigma^{\alpha\beta}/RT(C^{\gamma\alpha} - C^{\gamma\beta}) \quad [9]$$

The consequences of the two optimizations are seen to be similar. Substitution from Eq. [7] and [9] to Eq. [6] leads to the result

$$\nu = \frac{2D}{\alpha f^\alpha f^\beta RT} \frac{\sigma^{\alpha\beta}}{C^\alpha - C^\beta} \frac{1}{S^2} \quad [10]$$

A preferred mechanism of alloy segregation may be diffusion along the interface between the parent and product phases. In the present case, where CuAl_2 of tetragonal symmetry is converted to Cu of cubic symmetry, a discontinuous boundary between the two phases will certainly be formed. Boundary-diffusion theories were developed for discontinuous-precipitation reactions by Turnbull (10) and Cahn (16) and have been adapted to the eutectoid transformation by others (19-21). The resulting

kinetic expression is

$$\nu = \frac{24D_B \delta K}{\alpha RT} \frac{f^\alpha f^\beta \sigma^{\alpha\beta}}{C^\alpha - C^\beta} \frac{1}{S^3} \quad [11]$$

where maximum entropy production has been adopted as the reaction constraint. In Eq. [11], D_B is the boundary diffusion coefficient, δ is the boundary width, and K is the coefficient representing partition of solute between bulk and boundary.

In the selective dissolution process represented by Eq. [2], the product phases are the liquid solution which fills the newly created pores and the copper which separates the pores. In terms of the foregoing theory, the spacing, S , which characterizes the product morphology, is given by the sum of the pore diameter and the width of the intervening copper region. Both size parameters are measurable, as is the reaction velocity, ν .

This paper reports measurements of pore spacings as a function of the selective-dissolution reaction rate. The relationship between pore spacing and reaction velocity is used to test the applicability of phase-transformation theory to the leaching process.

Experimental

An alloy of composition Cu-50.3 weight percent (w/o) Al was prepared by induction melting aluminum (99.9% pure) and copper (99.5% pure) using the method of Marsden *et al.* (22). For the leaching kinetic experiments, the homogeneous melt was cast onto a chilled copper mold to form a plate from which rectangular prisms were cut. The cast alloy consisted of CuAl_2 , plus frozen Al-CuAl₂ eutectic. The prisms were reacted with thrice the amount of 20% w/w aqueous NaOH required to completely react with the aluminum in the alloy. This reaction was carried out isothermally at various temperatures. Partially extracted alloy pieces were removed after various reaction times of up to 24h and thoroughly washed with distilled water until the pH of the wash water was seven. The samples were then mounted in cold setting resin, cross sectioned at right angles to an original face of the specimen, and polished to a 1 μm finish. The depth of chemical attack was measured under an optical microscope using a graduated eyepiece.

Since the leaching reaction kinetics were parabolic, the average reaction rate over the complete course of leaching was lower for a large alloy particle than for a small one. It was therefore possible to investigate reaction morphology as a function of average leaching rate by using alloy samples having discrete particle size ranges. Samples consisting of a large number of particles were prepared by crushing and screening the alloy to yield approximately spherical particles in the size ranges

2000-2360	21.35	382	366	0.195	79,85	218	

specified in Table I. These samples were leached to completion at 20°C.

The extraction method used was similar to that reported by Friedrich *et al.* (4). A 40% w/w NaOH solution was added to the alloy pieces over a period of 0.75h so that the reaction temperature was kept to $20^\circ \pm 2.5^\circ\text{C}$. After extraction was complete, as determined by hydrogen evolution, the catalyst was thoroughly washed with distilled water until the pH of the wash water was seven.

The temperature dependence of the diffusion coefficient was also studied by leaching 1-1.18 mm particles at the temperatures given in Table II.

The composition of the alloy and leach residues was determined by atomic-absorption spectroscopy of acid-digested samples. The BET surface areas of the extracted materials were determined by a single-point chromatographic method (23).

Pore size distributions were calculated from nitrogen isotherms measured at -195°C , using a Micromeritics 2100E ORR surface area and pore-volume analyzer. Samples were transferred to the adsorption flask under water and evacuated at 130°C overnight. The degassed samples were weighed after completion of each experiment.

The crystallite size of the leach residues was estimated from x-ray line broadening of the Cu(200) diffraction line using the Scherrer equation, with corrections for instrumental broadening obtained from the silicon (220) diffraction line. The powdered catalysts were pyrophoric, and it was necessary to coat them with collodian prior to examination. CuK_α radiation was used, and the diffraction patterns were compared with those in the ASTM files to identify the compounds present.

Results

The interface between the unaffected alloy and the leach residue of the alloy (reacted at 50°C for 12h) is shown in Fig. 1. A clearly defined boundary which is parallel to the original alloy surface is discovered. As noted earlier, the CuAl_2 grains have leached to yield porous copper, and the eutectic material has been completely removed.

The thickness of the reaction-affected rim around the partially extracted alloy pieces, as a function of leaching time, is shown at various temperatures in Fig. 3. After an

initial period of chemical-reaction control, the shapes of the curves indicate parabolic leaching kinetics. Therefore, the data have been replotted in Fig. 4, where the straight lines are the results of regression on Eq. [1]. An activation energy is determined from an Arrhenius plot for k_p , and found to be $29 \pm 2 \text{ kJmol}^{-1}$.

Table I gives the BET surface areas, pore radii, pore volumes, and crystallite sizes of the reaction product obtained from samples of various particle sizes. The pore volumes and mean pore radii are calculated from the nitrogen isotherm. The pore volume, V_p , is estimated from the amount of nitrogen adsorbed at a relative pressure of 0.99 and calculated as a normal liquid. The values of r_p correspond to the maxima in plots of $\Delta V_p/\Delta r_p$ vs. r_p . The pore size-distribution consists of a single, narrow peak. The average pore radius, r_a , is calculated by the equation for nonintersecting cylindrical pores, $r_a = 2V_p/S_{\text{BET}}$ (24).

The effect of extraction temperature on these properties is shown in Table II. Pore volumes are not measured in these experiments, and the average pore radius is calculated assuming $V_p = 0.2 \text{ cm}^3/\text{g}$. The surface areas of

Fig. 4. Parabolic plots from Fig. 3

the copper are reported for samples with 40 w/o NaOH after washing with distilled water. The lower areas obtained after washing with NaOH are assumed to be due to removal of alumina produced in the reaction procedure. The atomic-absorption spectroscopy results show that in all leach residues, there is less than 3% aluminum, assumed to be present as alumina and evenly distributed over the reaction-product surface (15).

Discussion

The selective dissolution in alkali of aluminum from a Cu-50 w/o Al alloy proceeds according to parabolic kinetics, the reaction being controlled by liquid-phase diffusion within the reaction-product layer. Increasing the particle size of the alloy, which corresponds to decreasing the average reaction rate, results in a decrease in the surface area and an increase in the pore radius. However, the pore volume is approximately constant. Thus, the decrease in the average reaction rate results in an increase in the average diffusion distance, \bar{S} , at a fixed temperature. We now examine this correlation.

From Eq. [10] and [11], it is seen that the instantaneous reaction rate is related to $1/S^2$ for volume diffusion and $1/S^3$ for boundary diffusion. Because this rate varies with extent of reaction, the value of S also is predicted to vary. Because the measurements of pore size and copper crystallite size are obtained from the entire sample, they represent volume averages. It is therefore necessary to relate these averages to the instantaneous qualities. By definition

$$\bar{S}^2 = \frac{\int S^2 dV}{\int dV}$$

where V represents volume. For spherical particles of radius B

$$\bar{S}^2 = 3 \int_0^B S^2 r^2 dr / B^3 \quad [12]$$

where r is the radial coordinate within the sphere.

From Eq. [10], the diffusion distance is related to the diffusion coefficient and the velocity of the reaction front by

$$S^2 = \frac{\mathcal{H}D}{\nu} \quad [13]$$

where

$$\mathcal{H} = 2\sigma^{\text{CuP}}/f^{\text{Cu}}f^{\text{P}}aRT(C^{\text{Cu}} - C^{\text{P}})$$

From Eq. [1] it follows that

$$\nu = \frac{dX}{dt} = \frac{k_p}{2X} \quad [14]$$

Combining Eq. [13] and [14] yields

$$S^2 = \frac{2\mathcal{H}D}{k_p} X$$

which for a spherical particle becomes

$$S^2 = \frac{2\mathcal{H}D}{k_p} (B - r) \quad [15]$$

Combination of Eq. [12] and [15], followed by integration, yields

$$\bar{S}^2 = \frac{\mathcal{H}D}{2k_p} B \quad [16]$$

The corresponding expression for boundary diffusion is found to be

$$\bar{S}^3 = \frac{\mathcal{H}'D_B\delta K}{2k_p} B \quad [17]$$

where

$$\mathcal{H}' = 24 f^{\text{Cu}}f^{\text{P}}\sigma^{\text{CuP}}/aRT(C^{\text{Cu}} - C^{\text{P}})$$

Equations [16] and [17] predict rather simple dependencies of \bar{S} on B .

In order to calculate \bar{S} , both the pore diameter, \bar{S}^{P} , and the copper width, \bar{S}^{Cu} are required. Knowing the pore volume and S^{P} , S^{Cu} is calculated on the presumption that the pores are uniform, cylindrical, and parallel. These presumptions are borne out by the shape of the N_2 desorption isotherms and by the agreement between r_p and r_a . Proceeding, then, on the basis that the pores' axes are arrayed on a square grid and that the intervening regions of solid are composed of pure, theoretically dense copper, the average interpore distances shown in Tables I and II are calculated. Similar values for \bar{S}^{Cu} are calculated for hexagonally arrayed pores. Comparison of these numbers with the measured average crystallite sizes indicates poor agreement, although the trends with temperature are the same. Since average crystallite size is measured by x-ray line broadening, the average may be biased toward the smaller crystals in the total population. Because no analysis of the diffraction line shape has been performed, the values of \bar{S}^{Cu} calculated from pore data are preferred.

Plots of \bar{S}^2 and \bar{S}^3 vs. B are shown in Fig. 5 and 6. In these plots, the first point, corresponding to a radius of 71 μm , is disregarded because the leaching kinetics (Fig. 4) show that the leaching reaction is under chemical-reaction control at this time. In both plots, the remaining data conform reasonably well with the predicted straight-line relationship. The good fit achieved by the two models does not differ at a statistically significant level. It is therefore concluded that pore spacing is indeed related to leaching rate through the alloy-segregation process. The two possible mechanisms of segregation, however, cannot be distinguished on this basis.

The volume diffusion coefficient is calculated from the slope of the \bar{S}^2 vs. B plot using Eq. [16] and the following values: $a = 1$; $f^{\text{Cu}} = 0.36$; $f^{\text{P}} = 0.64$; $\sigma^{\text{CuP}} = 300 \text{ erg cm}^{-2}$; $C^{\text{Cu}} = 0.13 \text{ mol cm}^{-3}$; $C^{\text{P}} = 0$; and $k_p = 3.97 \times 10^{-8} \text{ cm}^2\text{s}^{-1}$. The value obtained is $D = 6 \times 10^{-12} \text{ cm}^2\text{s}^{-1}$. Values for the diffusion coefficient in CuAl_2 are given by Smithells (26). Extrapolation of this high temperature data to 20°C yields a calculated value of $1 \times 10^{-23} \text{ cm}^2\text{s}^{-1}$. In comparison, the value suggested by the application of the volume diffusion mechanism to the present results is seen to be rather high. A value of $1 \times 10^{-12} \text{ cm}^2\text{s}^{-1}$ has been deduced by Pickering and Wagner (27) for the diffusion of copper in a copper-gold alloy at 25°C and has been attributed to a divacancy mechanism. Such a mechanism might be oper-

Fig. 5. Average diffusion distance squared as a function of particle radius.

Fig. 6. Average diffusion distance cubed as a function of particle radius.

ative in the present case, but no independent evidence for it exists.

If alloy segregation occurs via boundary diffusion, then Eq. [17] applies. In this case, the slope of the \bar{S}^3 vs. B plot leads to the estimate

$$D_B \delta K = 1 \times 10^{-16} \text{ cm}^3 \text{ s}^{-1}$$

Using the values $\delta = 10 \text{ \AA}$ and $K = 2$, it is found that $D_B = 5 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$. Because of the absence of information on the CuAl_2/Cu boundary diffusion properties, it is difficult to comment on this value.

The temperature dependence of \bar{S} can be deduced from Eq. [16] and [17] for the two modes of alloy segregation. Logarithmic differentiation for particles of fixed size leads to

$$\frac{\partial \ln \bar{S}^2}{\partial (1/T)} = -(Q_V - E_A)/R \quad [18]$$

$$\frac{\partial \ln \bar{S}^3}{\partial (1/T)} = -(Q_B - E_A)/R \quad [19]$$

where the linear term in T has been neglected. Here, Q_V is the activation energy for volume diffusion, Q_B the activation energy for boundary diffusion, and E_A the activation energy for the leaching reaction. The results in Table II for alloy particles of the same size, leached to completion at different temperatures, yield \bar{S} as a function of T . These data are used to construct the Arrhenius plot shown in Fig. 7. From the slope of this plot and the measured value $E_A = 29 \text{ kJ}$, it is calculated that if volume diffusion is operative, then $Q_V = 53 \pm 2 \text{ kJ}$; whereas, if boundary diffusion is in effect, then $Q_B = 62 \pm 4 \text{ kJ}$.

Activation energies for volume diffusion in CuAl_2 and Cu have been reported (26) as 127 and 211 kJ, respectively. The value estimated from the application of the volume diffusion model to the present results is seen to be quite inconsistent with these values. On the other hand, the value of Q_B estimated from the boundary diffusion model is about half the value expected for volume diffusion in CuAl_2 , and is therefore quite reasonable.

The volume diffusion model has been found to lead to an inordinately low estimate of the activation energy. It also yields a remarkably high diffusion coefficient, for which no independent supporting evidence exists. For these reasons, the hypothesis that alloy segregation occurs via volume diffusion is rejected. Conversely, the boundary diffusion model has been found to yield an acti-

Fig. 7. Arrhenius plot according to Eq. [18] and [19]

vation energy of the expected magnitude and a diffusion coefficient for which there is no reason to reject. In addition, the model correctly predicts the relationship between spacing and reaction rate. It is therefore concluded that alloy segregation at the leach reaction front occurs by a mechanism of boundary diffusion.

The qualitative consequences are clear. At a given temperature, the alloy diffusion coefficient is fixed, and the pore spacing is controlled by the leach reaction rate. An increase in reaction rate leads to a decrease in pore spacing. Because the pore volume is fixed by the leachable content of the alloy, a decrease in pore spacing leads to an increase in the number of pores and, hence, an increase in surface area. These effects have been demonstrated in the present work by varying the average leaching rate through particle size control. Other methods of controlling the reaction rate would presumably achieve the same purpose.

Changing the reaction temperature affects the leaching rate and the alloy diffusion coefficient. Because the activation energy for alloy diffusion is significantly greater than for leach reaction, the effect on solid diffusion outweighs the other. Thus, an increase in temperature increases the alloy segregation distance more than it does the leaching rate. Consequently, a decrease in pore spacing and an increase in surface area is achieved for alloy particles of fixed size by lowering the temperature. These effects have also been demonstrated in the present work.

Surface Dislocation Pinning by Adsorbed Ions and Water Molecules

C. J. van der Wekken

Laboratory of Metallurgy, Delft University of Technology, 2628 AL Delft, The Netherlands

ABSTRACT

Gold wire specimens were subjected to creep tests under constant load in various salt solutions. The effect of cathodic or anodic polarization on the creep behavior in deaerated acid solutions was found to depend on the nature of the ions present in the solution. Specific adsorption is a necessary but not sufficient condition for the pinning of surface dislocations by ions. A simple model for the observed rebinder effects is proposed.

It has been shown previously (1, 2) that the effects of cathodic polarization on the creep rate of gold wire specimens cannot be explained in terms of changes in the surface stress. Instead, it was concluded from the experimental observations that in deaerated alkaline solutions specifically adsorbed hydroxyl ions have a strong pinning effect on surface dislocations in the metal. As the OH⁻ ions are desorbed during cathodic polarization near and beyond the point of zero charge (pzc), unpinning occurs which results in extra strain. Similar extra strain effects confirming the role of adsorbed OH⁻ ions were observed to occur when the pH was decreased by adding acid to the test solutions (2).

Measurements in acid NaClO₄ solutions (2) suggested that perchlorate ions are also able to pin dislocations. The effects were much smaller, however, than the effects caused by hydroxyl ions. In contrast Cl⁻ ions were concluded not to pin dislocations (1) since no extra strain was measured at potentials near the pzc in acid chloride solutions.

Extra strain effects ascribed to dislocation pinning by adsorbed water molecules (2) have been measured at potentials below -1000 mV vs. SCE. However, in the present study of effects due to adsorbed ions, the attention is focused on potentials above -1000 mV. The specimen is loaded at a potential E_{def} and subsequently polarized in the direction of the pzc. Dislocation pinning by anions is detected during cathodic pulsing after loading at $E_{def} > pzc$. Pinning by cations may occur at $E_{def} < pzc$ and gives rise to extra strain during subsequent anodic pulsing. A variety of test solutions was employed in order to gain more insight into the nature of the dislocation pinning processes at the metal surface.

Experimental Procedure

The test apparatus has been described previously (1). The experimental procedure was essentially similar to that followed earlier (2). The annealed 99.999% pure gold wires of 0.15 μm diam and an average grain size of 15 μm

were loaded in deaerated solutions to a stress of 85 MPa. The test solutions employed, prepared from reagent grade chemicals and high purity deionized (Milli-Q) water, are listed in Table I. The pH values of the solutions were measured at room temperature. The concentrations employed were 1M except for a 0.2M TlAc solution. The reasons for this lower concentration were the high cost of the chemical and its toxicity. Since earlier measurements (2) showed that larger effects could be expected at ~50°C than at room temperature, the present tests were performed at 50°C. After deaerating the test solutions and before applying the load, the specimen surface was pre-reduced for 1 min at -1300 mV, followed by a 1 min pulse at -800 mV vs. SCE.

Possible anion pinning was investigated by loading at either +400 or 0 mV and subsequently subjecting the specimen to a series of 1 min pulses of increasing magnitude in the cathodic direction, similar to the procedure employed earlier (1, 2).

In order to measure dislocation pinning by cations, the specimens were loaded at -800 mV vs. SCE and subjected to 1 min potential intervals following the sequence

Table I. Experimental test conditions and conclusions regarding dislocation pinning by various ions

Test solution	pH	E_{def} vs. SCE	Direction of potential pulses	Conclusion: extra strain due to dislocation pinning by
1M NaClO ₄	0.6	0 mV	cathodic	ClO ₄ ⁻
1M Na ₂ SO ₄	0.6	0 mV	cathodic	SO ₄ ²⁻ (HSO ₄ ⁻)

0.2M Tl Ac	4.2	-400 mV	anodic	—

-800, -600, -800, -400, -800, -200, -800, 0, -800, +200, -800, +400 mV. In the TlAc solution the specimen wire was loaded at $E_{\text{def}} = -400$ mV.

Results and Discussion

The extra strain effects resulting from the applied potential changes were measured in accordance with the definition given earlier (1) and plotted in extra strain-potential pulse (ES-PP) diagrams as shown in Fig. 1. A comparison between the extra strains measured previously in alkaline solutions (2) and the results presented in Fig. 1 shows that the effects measured in all the acid test solutions presently investigated are much smaller. If the present effects are also associated with surface dislocation pinning by adsorbed anions or cations, the pinning species can be identified. A list of pinning and non-pinning ions based on Fig. 1 can be derived. The result is shown in Table I. Considering the magnitude of the observed peaks in the ES-PP diagrams of Fig. 1 and taking into account the large effects caused by OH^- ions in previous studies, the dislocation pinning strength of adsorbed anions can be concluded to decrease as follows

Literature data (3, 4) suggest that hydroxyl ions and Cl^- ions are adsorbed on gold with similar strength.

Taking the change in the pzc in 0.1M solutions (5) as a measure for the strength of specific adsorption on polycrystalline gold, then, yields the following sequence for the anions

Comparing the pinning strength [1] and the strength of specific adsorption [2], it is observed that the sequences are reversed except for the position of OH^- . The observations for the CsCl solution constitute the first example of a rehbinder effect occurring during anodic polarization. Cs^+ cations, which are known to adsorb specifically on Hg, can be concluded from the present observations to adsorb

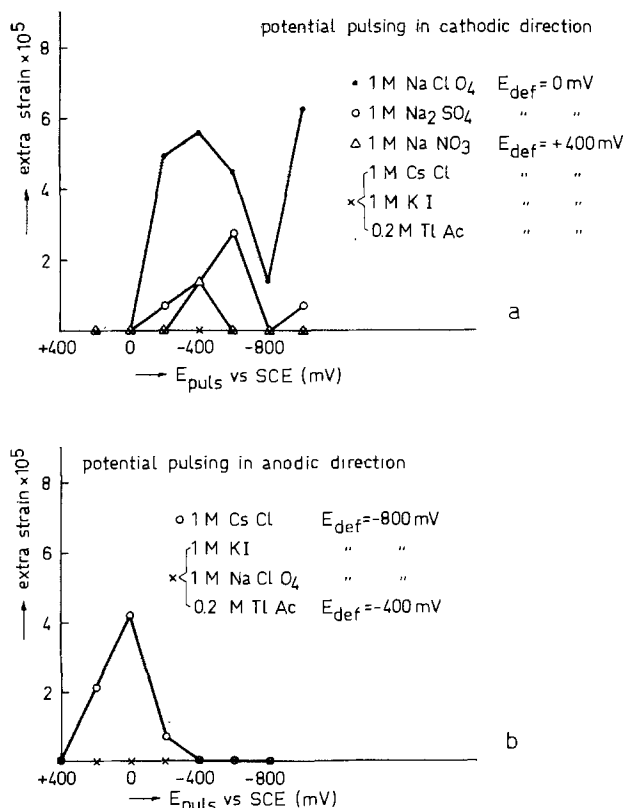

Fig. 1. Extra strain effects measured in deaerated acid salt solutions. a: Loading at a potential E_{def} above pzc and potential pulsing in cathodic direction. b: Loading at a potential E_{def} below pzc and potential pulsing in anodic direction.

specifically on gold as well. The large Tl^+ ions are probably adsorbed stronger than Cs^+ . The fact that no extra strain effect was observed in the (less concentrated) TlAc solution suggests that, probably, the sequences of pinning strength and specific adsorption strength for cations are also reversed. Earlier observations (1) indicated that not specifically adsorbed ions, e.g., the cations in KCl and NaCl solutions, have some influence on the observed rehbinder effects. However, a necessary condition for any extra strain effect in the potential region around the pzc is the occurrence of specific adsorption. If cathodic polarization is applied beyond -1000 mV SCE, a second peak is measured in the ES-PP diagram. This peak has been attributed to pinning by adsorbed water molecules (2).

It can be concluded from the available information that the observed rehbinder effects are primarily determined by contact adsorbed species in the first layer next to the metal surface.

A simple model for surface dislocation pinning in electrolyte solutions.—Figure 2 represents an example of a dislocation with Burgers vector b emerging at the metal surface. As the dislocation moves under the influence of a stress, a slip step is formed. Adsorbed ions I and water molecules W are present in the first adsorbed layer on the metal surface. As the area of the slip step is extended, the dislocation will disrupt the structure of the adsorbed layer. This implies that various interactions between metal atoms, ions, and water molecules will be broken (see Fig. 2). Previous explanations (6, 7) of rehbinder effects were based on the assumption that the energy necessary for the creation of a new surface area would determine the formation rate of new slip steps. The surface stress was considered to be a rate-determining parameter for the deformation process in the surface layer of the specimen. It is clear, however, that the surface stress is a macroscopic quantity which is related to some average value of the interactions mentioned above. It is to be expected that a surface dislocation moving under a certain stress will be stopped (pinned) by the strongest obstacles on its path. Let us consider a situation as represented in Fig. 2 and let the interactions I-Me and W-Me be strong. In that case, in addition to Me-Me bonds, I-W and W-W bonds across the slip plane must be broken if the dislocation is to move. The strongest of the latter two interactions will be likely to function as a barrier (pinning point) for further movement. Suppose that I-W bonds are pinning certain dislocations at a certain electrode potential. The pinning will be released as the ions I are desorbed by a change in electrode potential. The dislocation will then continue its movement in the slip plane and further on experience a weaker pinning by W-W interactions across

Fig. 2. Screw dislocation with Burgers vector b emerging at the surface of a metal electrode covered with contact adsorbed ions and water molecules.

its path. This type of pinning will be released as the adsorbed water is decomposed at potentials below -1000 mV. If the I-W interactions at the surface are weaker than the W-W bonds, pinning will only occur by the W-W interactions and no first peak will be measured in the ES-PP diagram. This is observed in the case of chloride solutions after loading at potentials anodic to the pzc and subsequent pulsing in the cathodic direction. Stronger I-W interactions can be expected for ions, which are known to be more strongly hydrated in the bulk of the solution. It is known that the strength of specific adsorption of ions and the strength of their interaction with hydration water molecules tends to be complementary (8). At the specimen surface, the I-W interaction may similarly increase as the strength of specific adsorption decreases. This could explain the reversed sequences [1] and [2] noted above. OH^- ions constitute an exception. These ions fit very well in the water structure. They are known as order producing ions (8, 9) in solutions, as is the case with F^- . However, the nature of their interactions with water molecules is different. Busing and Hornig (10) concluded that OH^- ions in aqueous solutions form a strong hydrogen bond with at least one water molecule. Not all surrounding water molecules are bonded with equal strength. Strong hydrogen bonds are expected to be retained in the case of specific adsorption. OH^- ions are thus strongly adsorbed, and simultaneously they have strong interactions with surrounding adsorbed water molecules. The strong I-W interactions in this case are probably the explanation for the large extra strain effects found in alkaline solutions.

Figure 2 represents only one possible example of the configuration of the lattice at the specimen surface around an emerging dislocation. Other situations are possible: for example, with the Burgers vector parallel to the specimen surface. What will happen in detail at the surface during slip depends on the relative strength of the various interactions between metal, adsorbed ions, and adsorbed water molecules, as well as on the local geometry of the slip process. It seems reasonable and in accordance with the experimental observations to conclude that the I-W and W-W interactions largely control the extra strain effects. The strength of the W-Me interactions is potential dependent. This has consequences for the magnitude of the second peak in the ES-PP diagram, as shown earlier (2). We may expect, for example, in the case of very weak Me-W interactions during loading—for gold at potentials near the pzc (2)—that during loading Me-W interactions will be broken before W-W interactions. Dislocation pinning will consequently be less, and a smaller second peak will be the result. This was indeed observed (2).

In the above discussion, the use of the term dislocation pinning is not necessarily meant to imply that dislocation movement is permanently blocked. It may well be that the stressed dislocations jump from one barrier to the next one of a similar type. Instead of "pinning," we could

speak of "drag" in that case. From the present tests, it is not clear which term is more appropriate. Both more or less permanent pinning of dislocations as well as drag may play a role. While during loading the stress on the specimen is continually increased, the effective stress on dislocations during the primary creep stage after loading will decrease due to continuing work hardening of the specimen. The decreasing effective stress will lead to conditions where the dislocations become really pinned during longer periods at certain barriers. The removal of these barriers at the metal surface by means of variations in the potential is at the origin of the observed extra strain effects.

Conclusions

1. Specific adsorption is a necessary, but not a sufficient condition for dislocation pinning by ions.
2. The dislocation pinning strength of anions on gold has been observed to decrease according to the sequence

3. Cs^+ cations have been found to pin dislocations.
4. The pinning strength of adsorbed ions has been attributed to the strength of the interactions between the adsorbed ions and adsorbed water molecules. No extra strain effects due to the ions are observed when these interactions are weaker than the water-water interactions in the contact adsorbed layer.
5. The second peak in the ES-PP diagrams is due to interactions between adsorbed water molecules.
6. Dislocations are mechanical microprobes which can be used for the study of the structure of the compact double layer.

AES/XPS Study of Transpassive Films on Iron in Nitrate Solution

M. Datta,* H. J. Mathieu, and D. Landolt*

Department of Materials, Swiss Federal Institute of Technology, CH-1007 Lausanne, Switzerland

ABSTRACT

Anodic films on iron formed in a forced convection system in the transpassive potential region in nitrate electrolytes at current densities up to 40 A/cm² have been studied by *in situ* coulometry and *ex situ* Auger electron spectroscopy (AES) and angle-resolved x-ray photoelectron spectroscopy (XPS). Qualitatively similar results on the variation of film thickness with applied current density are obtained by different methods. The transition from transpassive oxygen evolution to transpassive metal dissolution coincides with a marked decrease in film thickness and with the appearance of nitrogen in a reduced state at the metal-film interface.

Transpassive dissolution of iron and nickel in passivating electrolytes takes place at high current densities in the potential region beyond oxygen evolution and involves breakdown of passive films (1-3). Anodic films formed on iron and nickel in nitrate and chlorate electrolytes were investigated by Hoare and co-workers using potentiostatic polarization and coulometry in a stationary system (4-8). Their results showed that the film thickness increased in the passive potential region then decreased at the onset of the transpassive potential region. The behavior was attributed to an ion exchange mechanism (9), according to which electrolyte anions are incorporated into the film lattice by exchanging positions with oxygen ions leading to film dissolution. However, most of the data showing film thinning refer to a low current density region of exclusive oxygen evolution, and, therefore, their relation to transpassive dissolution, which occurs at much higher current densities, is not evident.

In a recent study, the present authors employed AES (Auger electron spectroscopy) and coulometry to investigate anodic films formed on nickel in the transpassive potential region in nitrate electrolytes under controlled hydrodynamic conditions in a flow channel cell (10). Results indicated that the passive film thickness reached its maximum as a function of current density in the oxygen evolution region. At higher current densities, nitrate ions were observed at the metal-oxide interface (10). In the present study, anodic films formed on iron in a concentrated nitrate electrolyte over a wide current density range in the transpassive potential region were investigated using XPS, AES, and coulometry. In particular, the study obtained information on the relationship among thickness, chemical nature of the films, and transpassive metal dissolution behavior. In addition to depth profiling, angle-resolved XPS was used for characterizing the films.

Experimental

Galvanostatic experiments were performed in a flow channel cell (11), through which the electrolyte was pumped at a constant linear velocity of 2.5 m/s. Cylindrical iron anodes (99.99%, single crystal, [111] orientation), 8 mm diam were mechanically polished to 0.25 μ m finish using diamond spray and ethanol as coolant. Only a part of the anode corresponding to the width of the channel (3 mm) was exposed to the electrolyte, while the remaining part was insulated by a Teflon spacer constituting the flow channel.

The applied anodic current density ranged from 1 mA/cm² to 40 A/cm². Anode potentials were recorded against a mercury sulfate electrode connected to the channel by a back-side capillary. The electrolyte solution (6M NaNO₃ + 0.1M NaOH) was prepared from analytical-grade chemicals and double-distilled water. An alkaline solution was employed to avoid self-activation of the anode after current interruption.

* Electrochemical Society Active Member.

¹ Supplier: Johnson Matthey Chemicals Limited, London, England.

In coulometric studies, anodic oxide films formed at different current densities were reduced by a constant cathodic current (20 mA/cm²), and the quantity of charge for oxide reduction was evaluated from the measured potential-time traces. A switching system with mercury relays was employed for presetting anodic polarization time and for switching between anodic and cathodic currents. The anodic charge passed was kept small (0.5 C/cm²) to minimize possible changes in surface roughness due to dissolution. A digital oscilloscope (Explorer III, Nicolet Instruments) recorded anodic and cathodic potential transients.

For AES and XPS studies, anodically polarized electrodes were quickly removed from the cell, washed with distilled water, rinsed in ethanol, and dried in a cold air stream. They were kept in a desiccator until introduced into the UHV chamber of a combined XPS/AES system with double pass cylindrical mirror analyzer, differentially pumped raster ion gun, and x-ray source (Perkin-Elmer, Physical Electronics Division, Model 590/550 A). All samples were analyzed in the same position, corresponding to an angle of $\alpha = 42^\circ$ between surface normal and CMA axis. In the XPS mode, the Mg x-ray source was operated at 10 keV and 40 mA with a pass energy of 50V. Binding energy calibration of the instrument was based on the measurement of the Au 4f_{7/2} peak at 83.8 eV. Depth profiling was performed by rastering a Kr⁺ beam over an area of 1.5 \times 1.5 mm or 6 \times 7 mm in the AES or XPS mode, respectively. The ion gun, operated at 2 keV, was positioned at an angle of 39° with respect to the surface normal. For calibration purposes, a depth profile of a standard 10 nm Ta₂O₅ film was measured with each series of experiments (12).

Angle-dependent measurements with the CMA were performed using a drum with an angle resolving aperture of 12° (13). The take-off angle of electrons could be varied between 0° and 84° with respect to the surface normal without moving the sample. In these measurements, an Al x-ray source was employed.

Current efficiency for metal dissolution was determined from weight loss measurements using Armco iron (99.9%) anodes. The applied charge corresponded to a maximum dissolution depth of 20 μ m.

Results

The galvanostatic anodic polarization curve for iron in 6M NaNO₃ + 0.1M NaOH at 2.5 m/s is shown in Fig. 1 as is the current efficiency calculated from weight loss measurements assuming divalent iron formation (14). At current densities below 8 A/cm², current efficiency is low because oxygen evolution is the main reaction. The current-potential curve exhibits Tafel behavior, with a slope of ~ 100 mV up to 0.2 A/cm², where the limiting current for OH⁻ discharge is reached (10). Measured potentials at higher current densities are strongly influenced by ohmic drops, which explains the shape of the current voltage curve above ~ 2 A/cm².

Figure 2 shows the charge necessary for reduction of films formed at different current densities. From the measured charge, the apparent film thickness was esti-

Fig. 1. Anodic potential (○) and current efficiency for iron dissolution (■) as a function of current density. Electrolyte: 6M NaNO₃ + 0.1M NaOH.

mated assuming that the film is Fe₂O₃ with a density of 5.24 g/cm³ (15) and that it is reduced at 100% current efficiency. The apparent film thickness as a function of current density exhibits two maxima: one at approximately 0.2 A/cm² corresponding to the limiting current density for the OH⁻ discharge, and the other at approximately 8 A/cm², beyond which the metal dissolution efficiency increases (Fig. 1).

Figure 3 shows Auger depth profiles of films formed at 0.042 A/cm² and 12.5 A/cm². The amplitude of the 703 eV iron, 503 eV oxygen, 272 eV carbon, and 379 eV nitrogen peaks were monitored as a function of time while sputtering the sample with Kr⁺. The important difference between the two films is in their nitrogen profiles. For the films formed at 0.042 A/cm², the nitrogen peak amplitude decreases rapidly with sputtering, in a similar manner as for air-formed films (not shown). The observed surface nitrogen is due to adsorption from air. For the film formed at 12.5 A/cm², however, the nitrogen peak amplitude increases with time reaching a maximum at the oxide-metal interface.

The apparent film thickness was calculated from the sputter time corresponding to a decrease of the oxygen peak amplitude to 50% of its maximum value, assuming that the sputter rate of the film is the same as that of bulk Fe₂O₃. The relative sputter rate of Fe₂O₃ with respect to the Ta₂O₅ standard was determined from a single-crystal sample to be 0.92. The variation of the apparent film thickness as a function of applied current density (Fig. 4a) is qualitatively similar to that obtained by coulometry

Fig. 2. Coulometrically measured charge for film reduction and estimated apparent film thickness as a function of current density.

(Fig. 2), i.e., two maxima are observed. Above 12 A/cm², the film thickness is independent of current density.

Using elemental sensitivity factors (16), the atomic concentration of nitrogen at the metal-oxide interface was estimated from AES depth profiles. The results (Fig. 4b) show that up to a current density of 1 A/cm² the nitrogen concentration is close to the AES detection limit, but beyond 1 A/cm², it increases with increasing current density to a value close to 5 atom percent (a/o) in the high rate metal dissolution region. A similar behavior was previously observed for nickel (10).

Films formed at different current densities were also analyzed by XPS without sputtering. The binding energies of different peaks were determined with respect to C 1s = 284.6 eV. The binding energy of the Fe 2p_{3/2} peak was 710.5 ± 0.2 eV, independent of applied current density, and the N 1s peak was at 398.1 ± 0.4 eV. Comparing the binding energies of the N 1s electrons for different com-

pounds from the literature (17-20), it is concluded that the nitrogen in the transpassive film corresponds to the reduced form, N^{3-} .

Experiments described so far investigated the influence of applied current density on film properties. Further experiments were aimed at the more detailed characterization of transpassive films formed under high rate metal dissolution conditions. Samples polarized at 20 A/cm² were subjected to XPS sputter profiling and angle-resolved XPS measurements. The latter technique, in which the analysis information depth is varied by changing the take-off angle of emitted electrons, permits the characterization of very thin surface layers as a function of depth without the use of ion sputtering (21).

Figure 5 shows XPS sputter depth profiles of transpassive (a) and air-formed (b) films on iron. The data are qualitatively similar to those obtained by AES depth profiling of films formed under similar conditions. The nitrogen at the surface of the air-formed film is due to adsorption from air and disappears rapidly upon sputtering. Transpassive films exhibit nitrogen at the metal-oxide interface. From the XPS depth profiles, the thicknesses of the transpassive and air-formed films were estimated to be 3.7 and 2.4 nm, respectively, and compare well with the AES depth profile data (Table I).

The shapes of the Fe 2p_{3/2} spectra for transpassive and air-formed films depend on the take-off angle (Fig. 6). At

Fig. 5. XPS depth profiles of transpassive and air-formed films on iron. Sputter rate of a standard Ta₂O₅ film is 0.09 nm/min under identical experimental conditions.

$\phi = 0^\circ$, a main peak at 710 eV and a shoulder at 707 eV are observed; these are attributed to oxidized iron and metallic iron, respectively (22-25). The intensity of the metallic iron peak decreases with increasing take-off angle and is almost completely absent at 57°, since at this angle most of the information is derived from the surface film.

The ratio of the signal intensity of oxidized and of metallic iron can be used to estimate the film thickness (12, 20). For a homogeneous oxide film (f) covering a flat substrate (m), the signal intensity ratio, $I_{Fe,f}/I_{Fe,m}$, is related to the film thickness, l , by (20)

$$l = -\lambda_{Fe,f} \cos \phi \ln \left[\frac{K}{K + \frac{I_{Fe,f}}{I_{Fe,m}}} \right] \quad [1]$$

with

$$K = \frac{\lambda_{Fe,f} n_{Fe,f}}{\lambda_{Fe,m} n_{Fe,m}} \quad [1a]$$

Here the iron ionization cross-sectional ratio between film and metal is taken as unity, $I_{Fe,f}$ and $I_{Fe,m}$ are the intensities of iron in the film and in the metal substrate, re-

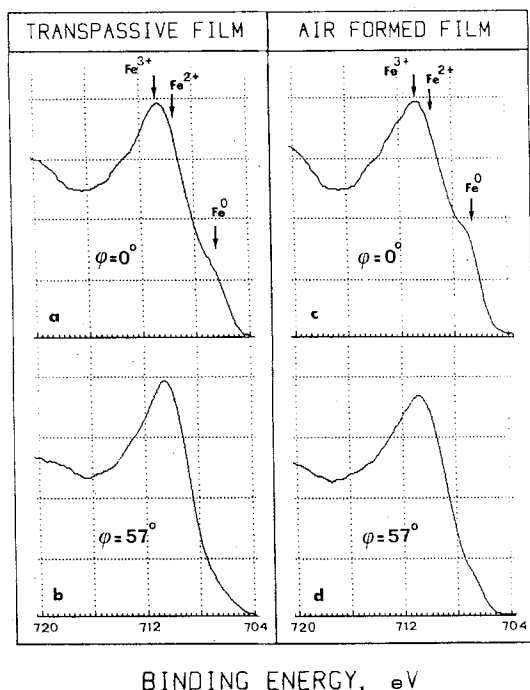

Fig. 6. Fe $2p_{3/2}$ spectra of transpassive (a, b) and air-formed (c, d) films on iron at different take-off angles. (a and c): $\phi = 0^\circ$, (b and d): $\phi = 57^\circ$.

spectively, $\lambda_{Fe,f}$ and $\lambda_{Fe,m}$ are mean free paths, $n_{Fe,f}$ and $n_{Fe,m}$ are atomic concentrations, and ϕ is the take-off angle of photoelectrons with respect to the surface normal. The values of constants used in Eq. [1] to evaluate film thickness are given in Table II.

To evaluate the signal intensity ratio, $I_{Fe,f}/I_{Fe,m}$, the Fe $2p_{3/2}$ spectra from 704 to 718 eV were resolved into four peaks (Fig. 7) at 706.6, 709.5, 710.6, and 714 eV that are attributed to Fe^0 , Fe^{2+} , Fe^{3+} , and a shake-up satellite signal of oxidized iron, respectively (23, 25, 27). The sum of the area intensities of Fe^{2+} and Fe^{3+} peaks was taken as a measure of the intensity of oxidized iron species. The contribution from the relatively small shake-up satellite signal was neglected. The transpassive and the air-formed film thicknesses thus determined from Eq. [1] are 5.1 ± 0.5 and 4.5 ± 0.7 nm, respectively (Table D).

The O 1s spectra of an air-formed and of a transpassive film were measured at different take-off angles. Three different peaks at 529.2, 530.9, and 532.2 eV were attributed to oxide (O^{2-}), hydroxide (OH^-), and water (H_2O), respectively (22-25, 28). Area intensities of these species were determined and are shown in Fig. 8 as a function of take-off angle. Little difference is observed between the two films. This behavior differs from that observed previously with nickel, where transpassive films contained significantly more O^{2-} than air-formed films (20). At the largest take-off angle, the ratio O^{2-}/OH^- decreases (Fig. 8), suggesting that the surface of the film contains more OH^- than the interior.

The energy of the N 1s peak measured at different take-off angles was the same and corresponded to that measured on an air-formed film. This indicates that the

interface and the surface nitrogen are in the same chemically reduced state. The intensity of the N 1s signal on transpassive films showed no appreciable change with the variation of take-off angle, although one would have expected this based on the AES and XPS sputter profiles shown in Fig. 3 and 5. This is attributed to nitrogen adsorbed on the surface of the film; a high take-off angle the loss of intensity from the nitrogen at the film-metal interface is compensated by the increased intensity from adsorbed nitrogen.

Discussion

Characterization of anodic films by coulometry and by surface analytical techniques is subject to several limitations inherent in each method (10, 20). For example, coulometric data may include contributions from side reactions, and their interpretation requires a knowledge of film stoichiometry, density, and true surface area. AES/XPS analysis may be affected by sample transfer and contamination problems. In addition, the sputter rate is known approximately only, and the deconvolution procedures in XPS involve some degree of uncertainty. Therefore, data obtained for air-formed and transpassive

Fig. 8. Relative intensity of O^{2-} , OH^- , and H_2O XPS signals as a function of take-off angle for a transpassive and an air-formed film.

films at different current densities are of interest mostly on a comparative basis.

Film thickness as a function of current density shows two maxima (Fig. 2 and 4a). The first maximum lies close to the limiting current for OH^- discharge (Fig. 1), at which the local pH at the film-solution interface is diminished, favoring dissolution of surface hydroxyl species. This explains the decrease in film thickness in this region. Assuming film growth by high field conduction (29), the film thickness should increase with increasing potential resulting from higher applied current density. This leads to the observed increase in film thickness beyond the first maximum in Fig. 2 and 4a. At sufficiently high current density (anode potential), film breakdown occurs leading to high rate metal dissolution. This is evident in Fig. 9, which shows a scanning electron micrograph of iron dissolved at 10 A/cm^2 for 0.7s. At a current efficiency of 20% (cf. Fig. 1), this corresponds to an average dissolution depth of $0.5 \mu\text{m}$. The photograph confirms that the transpassive dissolution of iron takes place by local breakdown of the passive film at random sites, similar to observations for nickel in nitrate electrolytes (1). The apparent film thickness in the metal dissolution region is independent of current density.

Because of unavoidable transfer effects, the determination of transpassive film composition from XPS measurements is rather uncertain. However, AES and XPS depth profiles do exhibit a distinct nitrogen maximum at the metal-oxide interface at current densities corresponding to transpassive metal dissolution. This nitrogen originates from nitrate ions present in the electrolyte that might have penetrated through faults in the film (10).

The results of the present investigation provide new insight into the high rate transpassive dissolution behavior of iron in nitrate electrolytes. Under conditions of present experiments, transpassive dissolution in $6\text{M NaNO}_3 + 0.1\text{M NaOH}$ sets in at a current density of approximately 8 A/cm^2 , and the metal dissolution efficiency is an increasing function of current density up to 30 A/cm^2 . The apparent film thickness, however, remains constant beyond 12 A/cm^2 (Fig. 2 and 4a). The transpassive dissolution efficiency, therefore, is independent of film thickness, contrary to previous conclusions (4-8). The presence of nitrogen in the interior of the film suggests that passive films under these conditions are highly defective, so that electrolyte anions can penetrate locally up to the metal surface. It is probable that metal dissolution occurs at these sites, while oxygen evolution occurs on the rest of the surface. Micropits formed in this way, may grow until repassivation, e.g., due to ohmic drop, occurs or until different micropits merge together. The current efficiency for transpassive dissolution, thus, would be governed by

the kinetics of depassivation and repassivation phenomena, which determine the average surface fraction available for oxygen evolution and metal dissolution, respectively.

Conclusions

1. For iron polarized in nitrate solution in the transpassive potential region, two states with respect to surface films have to be distinguished: oxygen evolution, where film thickness is a function of applied current density, and metal dissolution, where film thickness is independent of current density. This follows from both *in situ* coulometry and *ex situ* AES/XPS data.

2. In the metal dissolution region, current efficiency for metal dissolution is independent of apparent film thickness, and nitrogen in a reduced state is observed at the film-metal interface.

3. Obtained data suggest that the transition from transpassive oxygen evolution to high rate metal dissolution involves film breakdown initiated by penetration of anions through flaws.

Development of Silver-Palladium Alloy Plating for Electrical Contact Applications

U. Cohen*,¹ K. R. Walton,² and R. Sard*,³

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Silver-palladium alloys were electroplated as high quality coatings from a concentrated chloride bath. Adherent, uniform, and coherent deposits were obtained with thicknesses of up to 20 μm . The alloys were found to be homogeneous, single-phase solid solutions, with palladium content ranging from about 30% to 60%, depending on the operating variables. The microstructure of the plated Ag-Pd alloys consists of very fine grains (100-300 \AA). These alloys have a fcc crystal structure, and the lattice parameter varies continuously with composition. The useful plating rate with moderate agitation was found to be about 0.44 $\mu\text{m}/\text{min}$ at 10 mA/cm^2 , which is almost twice that of conventional cobalt-hardened gold, due to the current efficiency of nearly 100%. Alloys containing about 40% Pd were obtained with these conditions. High speed plating of the Ag-Pd alloy was achieved in a forced flow cell up to rates of about 9 $\mu\text{m}/\text{min}$. To achieve satisfactory deposits, it was generally necessary to use a thin (0.2-0.4 μm) soft gold underplating. Preliminary tests of electrical contact properties revealed that the Ag-Pd coatings possessed low contact resistance (about 1 $\text{m}\Omega$ at 100g load). Other relevant properties include intermediate Knoop microhardness (about 200 kg/mm^2 at 25g load) and an excellent resistance to formation of corrosion films in accelerated tests using flowers of sulfur. The present study indicates that the plated Ag-Pd coatings are superior in contact resistance stability to the bulk wrought alloy R156 (40%Ag-60%Pd). Finally, these coatings show satisfactory wear response in the selected tests provided a hydrocarbon lubricant is present.

The development of a suitable process for electroplating Ag-Pd would provide an attractive alternative to hard gold plating in a variety of electrical contact applications. The material cost per unit volume of a 40%Ag-60%Pd alloy is currently less than 20% that of pure gold.⁴ The properties of metallurgically prepared Ag-Pd alloys are known to be suitable for contact materials (1, 2). In particular, savings in material costs and comparable corrosion behavior in tarnishing environments have led to the conversion of Bell System wire spring relays from pure Pd to this material (1).

The Ag-Pd alloy system consists of a homogenous solid solution phase over its entire composition range. The mechanical and electrical properties, therefore, should be easy to control and to reproduce. Problems associated with precipitation of a second phase in a multiphase alloy, such as erratic, abrupt, or irreproducible changes in the properties, are thus eliminated. Small fluctuations in the alloy composition have only a minor effect on such properties because, in a homogeneous phase, properties vary gradually with the composition.

In his comprehensive treatise (3), Brenner reviewed the unsuccessful attempts up to that time to electroplate the Ag-Pd alloy from various baths. He commented, however, that the concentrated chloride bath, investigated by Graham *et al.* (4) for Ag-Pt alloy plating, should also be feasible for Ag-Pd alloy plating. Although the latter (4) mentioned briefly that they had obtained Ag-Pd alloy from a

similar bath, they gave no details. Andreeva *et al.* (5) then reported Ag-Pd alloys using conditions similar to those specified by Graham *et al.* (4) for plating Ag-Pt alloys. Electrodeposition of the Ag-Pd alloy was also reported from a buffered ammoniacal electrolyte containing EDTA by Kudryavtsev *et al.* (6, 7). The ammoniacal plating system, however, appears to operate under conditions of silver diffusion-limited current, which adversely affects the deposition, composition, morphology, thickness, and rate of growth. We have chosen to work with the concentrated lithium chloride bath, which is simple and contains no additives or hazardous components. This electrolyte relies on the anomalous solubility of AgCl in the presence of chloride ion. At high concentrations of the latter, the solubility increases with the concentration of the chloride ion. The bath, however, is very aggressive towards base metals, causing vigorous displacement reactions with them. An intermediate layer of a more noble metal must thus be applied to protect the base metals against these reactions (8).

This paper describes our preliminary investigation related to: (i) the feasibility of electroplating high quality coatings of Ag-Pd alloy from the concentrated lithium chloride bath and (ii) initial characterization of the plated Ag-Pd coatings and their testings as contact materials. Desirable properties of an electrical contact include a low and stable contact resistance throughout service life and the ability to resist friction and wear. These requirements were discussed by Holm (9), and the contact resistance and wear resistance test methods were described by Antler (10). Comparative studies have been made here of the corrosion resistance, the electrical contact resistance, and the wear performance of the plated Ag-Pd alloys *vs.* the properties of a wrought Ag-Pd alloy (R156) and also *vs.* the properties of hard gold plating. This paper also briefly

summarizes the results of a study of the morphology and microstructure of the plated Ag-Pd coatings (11). In another related study (12), the feasibility of a new method of plating cyclic multilayered alloys (CMA) was demonstrated by plating a wide variety of Ag-Pd structures.

Experimental

In the present work, the electrolyte for Ag-Pd alloy plating consisted of 500g of LiCl, 12g of AgCl, 3g of PdCl₂, 20 ml HCl, and 1000 ml of H₂O. After dissolving the salts, the bath was heated and brought to boiling (~130°C) to ensure complete dissolution of all salts, filtered (when hot), and cooled to the operating temperature (typically, 85°C). Moderate stirring was used during the plating, and the current density range studied initially was 0.5-20 mA/cm². Most samples, however, were plated at 5 ± 0.5 mA/cm².

Figure 1 illustrates the electroplating cell and associated electronics. The cell was a 500 ml reaction flask with an O-ring fitted cover that contained five standard tapered joints. Three electrodes, a thermometer, and a glass-stirrer were inserted through Teflon glands to the plating bath. The flask was immersed in a dark heating oil bath to provide uniform heating and to prevent photodissociation of wet solid AgCl. A stable plating bath temperature (within ± 0.5°C) was maintained with this arrangement.

Chemical analysis of the alloys was usually done with a nondispersive x-ray fluorescence (XRF) analyzer mounted on a scanning electron microscope (SEM). These analyses were corrected by comparison with several standard samples analyzed by wet chemical techniques and by electron microprobe. X-ray diffraction (XRD) was used for phase and texture analyses and for the determination of the lattice parameter. The coating morphology was studied by SEM and metallographic

Fig. 1. Schematic of the experimental setup. The plating cell is immersed in a bath of oil. The oil bath is heated on a hot plate/stirrer equipped with a control thermistor sensor, which is immersed in the oil bath. A Pd wire immersed in the plating solution serves as an internal secondary reference electrode. A large plate (~25 cm²) of Ag metal serves as the anode. Electrical signals are provided to the cell from a potentiostat/galvanostat, PAR 173, combined with a signal programmer, PAR 175. The signals are recorded on an (HP-7004B) X-Y recorder.

cross sections. Transmission electron microscopy (TEM) was used to study the grain size and microstructure (11). Knoop microhardness was tested at 25g force (with a Tukon instrument) on polished cross sections of coatings ≥ 10 μm thick.

Electrical contact resistance was measured using a four-wire technique. In the measuring system (13), a 0.05 cm diam gold wire bent around a 60° Teflon wedge is used as the contact member. With this system, contact closure takes place with virtually no contact wipe. Measurements were performed at 100g load both on samples and standards prior to and after exposure to aggressive environments.

Wear and friction behavior was studied using a rider/flat wear test fixture, which simulates the sliding of separable connectors. The wear behavior with actual connector hardware plated with an Ag-Pd finish was also evaluated. The rider/flat tester is shown schematically in Fig. 2. In this tester, a flat coupon slides back and forth (on the same track) under a 0.25 in. diam spherical rider. The latter is loaded with a known weight. The resulting frictional force is sensed by a transducer through a shaft coupled to the rider assembly and monitored on a chart recorder. The coefficient of friction, μ_f , for a given cycle in the rider/flat experiment, is obtained by dividing half the total swing in the frictional force during each cycle by the load on the rider. The implicit assumption here is that the sliding events in both directions are equivalent. For the accuracy of about 20% sought in this work, this assumption is believed valid. Rider/flat tests were conducted for 200 cycles at a rate of 27 cycles/min (about 1 cm/s). The load on the rider was either 70 or 255g. However, only the results at 255g load are reported here; the results at 70g load are similar and lead to the same interpretations and conclusions. The depth and width of the wear tracks on the flat coupon were determined quantitatively by a Dektak microprofiler equipped with a 5 μm diam diamond-tipped stylus. Qualitative examination of the degree of wear on the coupons was done using optical and scanning electron microscopy.

Results and Discussion

Substrate compatibility.—To determine the compatibility of base metal substrates to the concentrated chloride plating bath, Cu and Ni strips were immersed with no external current in a simulated plating bath (but milder and not including the PdCl₂, for simplicity). The bath contained 50g of LiCl, 0.4g of AgCl, 2 ml of HCl, and 100 ml of H₂O, and was held in the temperature range 70°-80°C. No stirring was used. A vigorous displacement reaction was observed when a Cu strip was immersed in the solution. The strip was soon covered with a very loose and spongy white silver deposit and, at the same time, the Cu strip partially dissolved. After a 60 min immersion, the strip was removed from the solution, the Ag deposit

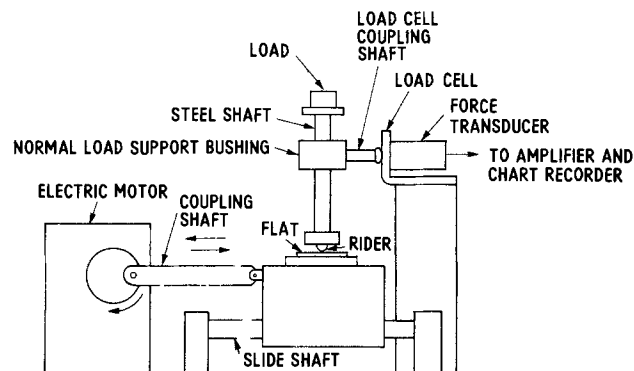

Fig. 2. Schematics of the wear tester. The load support is coupled by a shaft to a load cell (Statham UL4) and a force transducer (Statham UC3). Frictional forces experienced by the rider during sliding are transmitted to this unit. The transducer output is amplified and calibrated to read the frictional force in grams (accuracy to 0.1g) by a bridge amplifier (Statham SC1105).

scraped off, washed, and dried. The Ag deposit weight gain was 107.8 mg, and the Cu strip weight loss was 62.9 mg. These numbers may be compared with the respective atomic weights (107.87 for Ag, 63.54 for Cu), which indicate that the displacement reaction was

A more moderate displacement reaction was observed with a Ni strip. It was slowly covered with white Ag deposit of poor adherence. After an immersion of 17.5h, the strip was removed from the solution (which had become yellow-green in color). SEM examination of the deposit revealed individual Ag crystallites (10-20 μm) over most of the flat substrate surface and large Ag dendrites (400-600 μm on the strip edges). A total weight gain (strip plus deposit) of 110.1 mg was found. It may be noted that the Ag atom is almost twice the weight of the Ni atom, and that, for the displacement reaction

two Ag atoms are deposited for every dissolving Ni atom. Thus, a net weight gain is evidence of a displacement reaction.

Immersion of bare Cu and Ni substrates in the regular Ag-Pd alloy plating bath, under cathodic current, yielded loose powdery and spongy Ag-Pd deposits on Cu, and spontaneous peeling of the deposit from the Ni substrates. Current efficiencies, based on weight gain and Faraday's law, were much greater than 100%, indicating spontaneous displacement reactions had again occurred. These tests clearly demonstrate that the bare Cu and Ni substrates are incompatible with the concentrated chloride bath, containing Ag (or Pd) ions.

Substrates of Cu and Ni, with protective Ag films 1 μm thick (especially if immersed under cathodic current), showed a significant improvement over the bare substrates. However, they still contained some unacceptable rough areas.

Bulk noble metal substrates, such as Pd, Au, and Ag, were generally found compatible and suitable for the plating of the Ag-Pd alloy. However, it was found that prolonged immersion of Ag metal in the plating bath with no external current could have deleterious effects, probably owing to the slow displacement reaction

This reaction could result in poor adhesion and occasional cracking of the Ag-Pd coatings, probably owing to undercutting. The slow displacement reaction of Ag metal with the plating bath was also indicated by the observation that Ag strips, when immersed with no external current in the plating bath, exhibited immediate darkening of the Ag surface in contact with the bath. The metal surface when analyzed by XRF confirmed the presence of Pd metal. Further evidence was provided from SEM analysis of cross sections (12) and electrochemical potential measurements. The electrode potential gradually changed to less negative values *vs.* a Pd metal reference electrode. All these results indicate that Pd is more noble than Ag in this alloy plating system. By starting the plating of the alloy on Ag substrates immediately following immersion, or, preferably, by immersing under cathodic current; it was possible to eliminate the deleterious effects associated with these substrates.

It was found that the application of very thin (0.2-0.4 μm) protective undercoatings of soft gold could provide the most reliable protection to the base metal substrates against the displacement reactions. Soft gold plated from the citrate-buffered bath (14) provided better protection than hard-gold or gold-strike platings. This is believed to be due to the higher density (and lower porosity) of the soft gold. Without adequate substrate preparation, exposed pits or holes to the base metal will, of course, result in extensive displacement. Both unpolished and mechanically polished substrates of Cu, CDA725 alloy (89 w/o Cu-9 w/o Ni-2 w/o Sn), and Ni, when properly prepared

and coated with 0.2-0.4 μm soft gold, proved to be excellent substrates for Ag-Pd alloy plating. The substrate preparation procedure outlined in Table I was developed to give reproducible results for the plating of the Ag-Pd coatings.

The plated Ag-Pd coatings, under favorable conditions, closely reproduced the substrate surface features. Figure 3a depicts the surface of a 2.5 μm thick Ag-Pd coating which was deposited at 5 mA/cm² on an unpolished CDA725 alloy substrate, with a nominal 0.3 μm soft gold undercoating. Another sample, prepared under identical conditions except that the alloy substrate was mechanically polished (0.3 μm alumina was the last abrasive) proved to be so smooth that it was featureless on the scale of 1 μm (*cf.* Fig. 3b). This type of surface finish is similar to that typically found with carefully prepared hard gold deposits.

Effects of current density and waveform.—DC plating.—The effects of current density were studied for the bath composition given above. Ag strips were used as substrates for these experiments. They were chemically etched in a mixture NH₄OH/H₂O₂ (1:1) for 5-10s, rinsed, and dried. They were then masked with adhesive plating tape to prevent nonuniformity stemming from edge effects, and to prevent plating of the strip back side. Coatings ~10 μm thick were deposited to facilitate characterization. Increasing the current density was found, in general, to produce Ag-Pd alloys with increased Ag content, as described more fully below. Table II summarizes the various effects of the current density; and the various surface morphologies are shown in the SEM photographs of Fig. 4. At the lowest current density, 0.5 mA/cm², the deposits were dark gray matte due to the three-dimensional growth features evident in Fig. 4a. At 2 mA/cm², the overall general appearance was similar. However, the microstructure was quite different, as shown in Fig. 4b. This structure gives rise to unfavorable properties, such as high contact resistance. At 5 mA/cm², the surface appeared much lighter, and the morphology was noticeably smoother (*cf.* Fig. 4c). At 10 mA/cm², similar deposits to those obtained with 5 mA/cm² were observed (*cf.* Fig. 4d). Plating with moderate stirring (about 10 cm/s flow rate) and with current density in the range of 5-10 mA/cm² was judged most favorable. A standard condition at 5 mA/cm² was thus adopted to prepare samples for additional measurements, as described below. At a current density of 20 mA/cm², deterioration of the coating was evident close to the edges, where the effective current density was highest. Spontaneous cracking was sometimes observed (*cf.* Fig. 4e and 4f). Thus, under the conditions used (*i.e.* moderate stirring), the useful plating current density is less than 20 mA/cm². It should be noted that, at 10 mA/cm², the plating rate of Ag-Pd was about 0.44 $\mu\text{m}/\text{min}$, which is almost twice that of hard gold plating.

Table I. Substrate preparation for plating

1. Degrease in acetone and trichloroethylene
2. Ultrasonic cleaning in Neutra-Clean 68 solution for about 1 min
3. Rinse in deionized (DI) water
4. Activate in dilute (1:1) HCl for about 30-60s
5. Rinse in DI water
6. Soft gold plate, 0.2-0.4 μm thick*
7. Rinse in DI water and dry**
8. Introduce to the Ag-Pd alloy plating bath under cathodic current†

* Procedure was to immerse (wet) substrates under cathodic current in a bath containing potassium gold cyanide (20 g/l), dibasic ammonium citrate (50 g/l), ammonium sulfate (50 g/l). Conditions were 65° ± 5°C, 8 ± 2 mA/cm², 30-45s, and moderate stirring.

** The substrates must not be introduced wet into the alloy plating bath since precipitation of AgCl due to local chloride dilution may occur on the surface, yielding coatings with poor adhesion (4). The preferred procedure is to dip the substrate, prior to plating, in a concentrated chloride solution.

† This is to insure that the thin gold layer is protective. Substrates with ≥0.4 μm soft gold undercoatings could be immersed in the plating bath with no external current for several minutes without deleterious effects.

Fig. 3. SEM photographs of the surface of 2.5 μm thick Ag-Pd coatings plated at 5 mA/cm^2 using (a, top) unpolished CDA725 alloy substrate and (b, bottom) mechanically polished (with 0.3 μm alumina) CDA725 alloy substrate. Both substrates were plated with 0.3 μm soft gold prior to the Ag-Pd plating.

Much higher current densities were used in preliminary experiments with high speed plating of the Ag-Pd alloy in a forced flow cell (14). The solution velocity in the latter is estimated to be about an order of magnitude higher than in the stirred beaker. A precise value of the cathodic current density could not be determined because of some uncertainty regarding the plated area. Measurements of coating thickness on metallographic cross sections of a series of platings, obtained with a constant current and varying deposition time, revealed a linear thickness increase with plating duration. Assuming 100% current efficiency, an effective surface area of $\sim 9.5 \text{ cm}^2$ was estimated. Smooth coatings could be obtained with total currents up to $\sim 2000 \text{ mA}$. These conditions correspond to a current density of up to $\sim 210 \text{ mA}/\text{cm}^2$ (or $\sim 9 \mu\text{m}/\text{min}$),

which is roughly equivalent to rate attainable with high speed hard gold plating (14). Examination of the cross sections showed that even the very thin ($\sim 0.7 \mu\text{m}$) coatings were continuous over the entire substrate surface. Some thick ($> 7 \mu\text{m}$) coatings showed initiation of nodular growth at locations of relatively higher current densities. The composition of a typical coating obtained at $\sim 105 \text{ mA}/\text{cm}^2$ (or $\sim 4.5 \mu\text{m}/\text{min}$), was found by XRF analysis to be 62%Ag-38%Pd. The surface morphology of the coating, as revealed by SEM examination, was also very similar to the high quality coatings obtained with the much lower current density of 5 $\text{mA}/\text{cm}^2 \sim 0.22 \mu\text{m}/\text{min}$ under moderate stirring. Thus, the deleterious effects of high current densities on the morphology (cf. Fig. 4e and 4f) and excessive Ag content of the deposit, can be overcome by using a high speed flow cell.

Characterization of the plated Ag-Pd coatings.—Composition.—The composition of the coatings varied from about 70%Ag-30%Pd to about 42%Ag-58%Pd, depending on the current density and the rate of stirring. Generally, decreasing the current density or increasing the amount of stirring yielded alloy coatings with higher Pd content. This fact is further evidence that Pd is more noble than Ag in the alloy plating system. Data depicting the effect of dc current density on the alloy composition (for a constant stirring rate) are shown in Fig. 5.

Microstructure.—Transmission electron microscopy (TEM) examination revealed a microstructure of very fine grains (100-300 \AA). Voids of about 20-30 \AA in size were also noted at the grain boundaries. No second phase precipitates were observed. Electron and x-ray diffraction patterns indicated that the alloy coatings were homogeneous, single-phase solid solutions. These measurements also indicated that the fcc lattice parameter varies continuously with the composition in a similar manner to wrought Ag-Pd alloys (15). This dependency is shown in Fig. 6. The Ag-Pd coatings obtained with dc current had a strong fiber texture (preferred orientation) with the [100] direction perpendicular to the surface. As described elsewhere (11), plating of CMA coatings with cyclic current modulation tended to reduce degree of the preferred orientation. In particular, coatings with dense (or thin) multilayers exhibited more random orientation.

Microhardness.—Knoop microhardness was measured with a 25g load on polished cross sections of coatings with at least 10 μm thickness. A nominal value of about 200 kg/mm^2 was observed for optimal conditions. Some results are given in Table II.

Internal stress.—The internal macrostress of the Ag-Pd alloy coatings was continuously monitored using an electronic spiral contractometer (16, 17). The spirals were made of stainless steel 0.020 in. thick. They were plated with 2 μm Ni and with 2 μm soft gold. The gold, applied prior to the measurements, served to protect the spirals from the displacement reactions with the alloy plating bath.

Increasing the current density was found, in general, to decrease the tensile stress or to shift it to a compressive stress. The range of stress values observed for deposits 2.5 μm thick varied from slightly less than 1 kg/mm^2 tensile stress for coatings obtained at 2 mA/cm^2 , to about the same magnitude of compressive stress for coatings obtained at 20 mA/cm^2 . Temperature variations of $\pm 10^\circ\text{C}$ (from the standard 85 $^\circ\text{C}$) had little effect on the macrostress. Thus, the magnitude of the internal macrostress found in the Ag-Pd coatings is rather small and is comparable to pure silver and other widely used electroplatings, such as acid-copper and sulfamate nickel. Moreover, these stress levels are substantially lower than the high values associated with such brittle platings as cobalt-hardened gold (16) and tin-nickel alloy.

Contact resistance.—Effects of tarnishing.—Contact resistance was measured with a four-point probe instrument with a 100g load. The contact resistance of the as-plated Ag-Pd coatings was typically about 1 $\text{m}\Omega$. One

† Four-wire contact resistance measurements at 100g force with soft gold probe (0.020 in. diam wrapped around 60° wedge).

week exposure at 50°C in an environment containing flowers of sulfur and 85% relative humidity (RH) had hardly any effect on this contact resistance with the plated Ag-Pd coatings. Wrought R156 alloy (40Ag-60Pd) exposed to the same environment exhibited a significant increase in its contact resistance. Whereas the mean change in contact resistance, ΔR , of the plated alloy was less than about 0.2-0.3 mΩ, the corresponding value of the R156 alloy was 4-6 mΩ. In these tests, 2.5 μm thick alloy deposits of about 40%Pd were plated on CDA725 substrates with a soft gold undercoat about 0.25 μm thick. Additional results are given in Ref. (12). Indeed, the corrosion resistance of the plated Ag-Pd coatings in this test was found quite similar to that of plated hard gold.

The superior corrosion resistance and contact resistance stability (CRS) of the plated alloys over the wrought alloy, R156, is quite surprising, since the latter contains more palladium. However, the plated alloys differ substantially from the wrought alloy in many respects. For example, the grain size of the wrought alloy is in the neighborhood of several micrometers (about two orders of magnitude larger than the grain size of plated alloys). Also, the plated alloys are more homogeneous in their composition than the wrought material. Wrought alloys may have a composition variation of several weight percent from grain to grain (18), owing to the influence of the anisotropic distribution coefficient during solidification. The finer grain size, as well as the homogeneity of

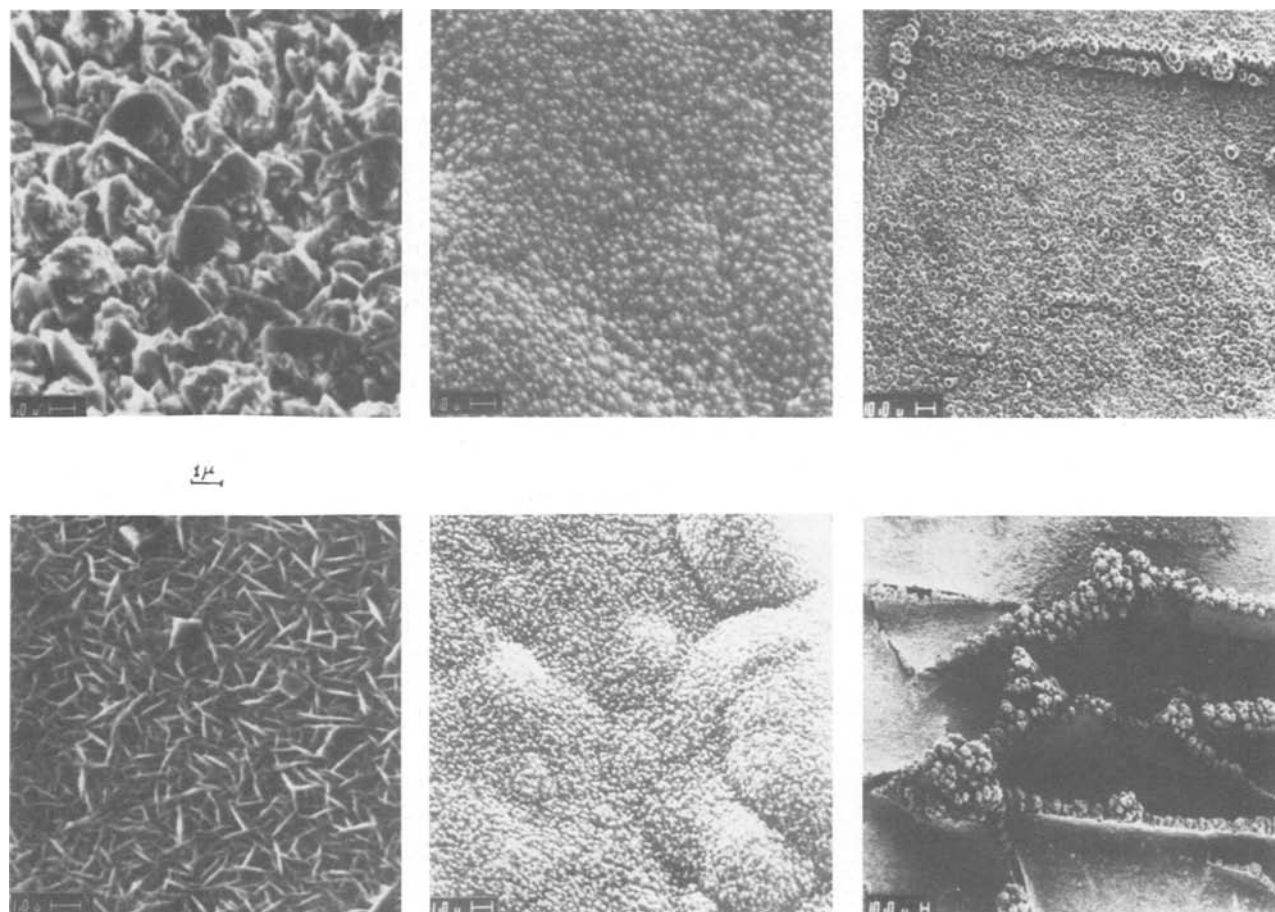

Fig. 4. SEM photographs of Ag-Pd alloy coatings obtained on Ag substrates with (a, top left) 0.5 mA/cm², (b, bottom left) 2 mA/cm², (c, top center) 5 mA/cm², (d, bottom center) 10 mA/cm², and (e, top right, and f, bottom right) 20 mA/cm². Figure 4e shows surface area in the center of the sample; 4f shows cracks closer to the sample edge, where there was higher current density. Note also the smaller magnifications of Fig. 4e and 4f.

Fig. 5. Plated alloy composition vs. dc current density for low speed plating conditions.

the plated alloys, are likely to reduce the mobility of Ag atoms towards the surface, thereby reducing the formation of tarnish films in the sulfiding environment. It is also conceivable that certain impurities which are incorporated in the plated alloys help to reduce the mobility of Ag atoms towards the surface. The presence of incorporated Cl impurity in electroplated Ag-Pd CMA coatings was established by Auger electron spectroscopy (12). Incorporation of Cl in the plated Ag-Pd alloys could also contribute to their superior tarnish resistance over that of the wrought alloy.

Wear and friction.—Polished (rms surface roughness less than $0.5 \mu\text{m}$), and unpolished (rms less than $5 \mu\text{m}$) substrate coupons of CDA725 alloy were used as flats for the rider/flat wear tests. These were plated with either $2.5 \mu\text{m}$ of hard gold or with $2.5 \mu\text{m}$ of Ag-Pd alloy having a composition of $40 \pm 2\%$ Pd (preceded, as usual, by the $0.25 \mu\text{m}$ soft gold undercoating). The riders were hardened steel ball bearings (0.25 in. diam) plated first with $4 \mu\text{m}$ of nickel (Sel Rex 10-03S), then $0.25 \mu\text{m}$ of soft gold undercoating, and finally $5 \mu\text{m}$ of either the hard gold finish, or $5 \mu\text{m}$ of the Ag-Pd finish. Immediately prior to wear tests, both members of the test pair were carefully vapor degreased and then lubricated by dipping into a solution of Bareco wax (KS19416) in trichloroethane or a 2% synthetic hydrocarbon oil (Mobil RM109F).

Fig. 6. Lattice parameter, a_0 , vs. alloy composition. Plated (this study) and thermally prepared Ag-Pd alloys.

Fig. 7. The effect of contact finish variation on the wear and friction of rider/flat systems with microcrystalline wax lubrication, 225g load, 200 cycles, and polished CDA725 alloy substrates. Each data point represents the median value of 4 or 5 wear tests. $\text{AP}^{\text{R}}/\text{AP}$ is alloy-plated rider/alloy-plated flat. $\text{Au}^{\text{R}}/\text{AP}$ is gold-plated rider/alloy-plated flat. $\text{AP}^{\text{R}}/\text{Au}$ is alloy-plated rider/gold-plated flat. $\text{Au}^{\text{R}}/\text{Au}$ is gold-plated rider/gold-plated flat. The median wear depth in micrometers is indicated in parentheses.

The key results are summarized in Fig. 7 and 8 for the microcrystalline wax and hydrocarbon oil lubricants, respectively. It is clear from Fig. 7 that, with the solid lubricant (the microcrystalline wax), the hard gold-plated flats are superior to those with Ag-Pd-plated flats. In particular, the test pair with both rider and flat plated with Ag-Pd behaved very poorly. It is evident, however, that the pair with Ag-Pd-plated rider and hard gold-plated flat shows a wear response equivalent to the hard gold-plated pair. Figure 8 indicates that, with the liquid lubricant, all the test pair combinations are satisfactory and have essentially similar wear response (although there appears to be slightly better performance for the hard gold-plated

Fig. 8. As in Fig. 7, but with the synthetic hydrocarbon oil lubricant

flats). Surface roughness, in the range tested, appears to have little significance on the wear and friction performance. With both lubricants, the smoother substrates revealed a somewhat improved median wear response over the rougher substrates, but essentially identical friction coefficients. Coupons of bulk R156 alloy, when tested as flats with both lubricants under similar conditions, revealed significantly higher friction and wear than the plated Ag-Pd alloys. It should be noted that, without lubrication, both hard gold and the Ag-Pd alloys exhibited high coefficients of friction ($\mu_f \geq 0.6$) and disastrous wear (track depth up to 16 μm).

Some limited wear tests were also done with actual two-piece connector hardware of the type used in electronic switching systems. Standard 946/947 connectors with a mating load of 250g were the test vehicles. The male connector contact finish was 2.5 μm of hard gold plating. It was lubricated with the hydrocarbon oil prior to the testing. The female connectors were first plated with 2.5 μm of the Ag-Pd alloy finish and then tested by 200 mate/unmate cycles at a rate of 27 cycles/min, or about 1 cm/s as with the rider/flat tests. The median force of insertion was 1.8 kg for couples with Ag-Pd plated females (slightly higher than the 1.6 kg value for the reference pairs with soft gold inlay in place of the Ag-Pd alloy). Analysis by SEM and XRF mapping revealed some transfer of Ag-Pd to the male connector surface. However, there was no exposure of the base metal and no indication of unacceptable damage to any of the contacts after the 200 insertion cycles.

Summary

A simple, concentrated chloride electrolyte containing no additives or excessively hazardous components was used to demonstrate the potential benefits of Ag-Pd alloy plating. A very thin soft gold preplate (*i.e.*, 0.20-0.4 μm) was necessary to prevent displacement reactions with base metal substrates. Dense, uniform, single-phase alloys with Ag content of 40%-70% can be obtained at ~100% current efficiency. Decreasing the current density and increasing the amount of agitation increase the Pd content of the plated alloy. The lattice parameters, a_0 , increase continuously with the Ag content of the alloy, in agreement with previous studies of Ag-Pd alloys (15).

Under optimal conditions, the following Ag-Pd alloy properties appear to be favorable for contact applications: (i) microhardness of ~200 (KHN₂₅), (ii) very low internal stresses (<1 kg/mm² compressive), (iii) with a hydrocarbon lubricant, wear and friction characteristics similar to hard gold plating, and (iv) the corrosion resistance in flowers of sulfur is better than R156 alloy and similar to hard gold plating.

The Ag-Pd alloy plating system appears to be an attractive potential substitute for hard gold in certain con-

tact applications. However, more detailed study of the coating properties is required, as is continued development of a fully satisfactory plating process. The bath stability and aging due to photodissociation should be also studied in more detail.

A Quantitative Investigation of the Open-Circuit Photovoltage at the Semiconductor/Liquid Interface

Nathan S. Lewis*

Department of Chemistry, Stanford University, Stanford, California 94305

ABSTRACT

A quantitative analysis of the theoretical value for the open-circuit photovoltage, V_{oc} , of a semiconductor/liquid junction reveals that control of bulk carrier transport properties is crucial to interpreting the observables at the semiconductor/liquid interface. Use of characterized semiconductor samples yields quantitative agreement between the maximum theoretical V_{oc} and experimentally observed values for both n-Si and p-Si surfaces in nonaqueous solvents. This accord between theory and experiment rules out deleterious effects of charged surface states on the V_{oc} of these interfaces. Lower than ideal V_{oc} values in other systems might reflect poor diffusion lengths in the semiconductor, classical tunneling over the barrier, or the effects of surface states. The observation of large photovoltages from n- and p-type-based semiconductor interfaces (n-Si, p-Si, n-GaAs, p-GaAs) in the same solvent is used to rule out a fixed density of charged surface states as the mechanism for obtaining constant photovoltages at these junctions. Direct support for this interpretation is obtained by techniques which verify the presence of mobile surface charge on p-type Si cathode surfaces in the inversion condition. Thus, control and investigation of bulk semiconductor properties that has been eminently significant to the understanding of p-n junction solar cells is also crucial to developing a rational understanding of the observables at the semiconductor/liquid interface.

The aim of this paper is to present a clarified treatment of the energetics at semiconductor/liquid interfaces. Recently, substantial effort has been directed into revision of the model which describes the relevant observables at a semiconductor/liquid junction. Rationales for junction properties include carrier inversion (1-3), pinning of the surface Fermi level by gap states (4-6), and hot carrier injection (7). Each of these models has been proposed to explain the behavior of a particular semiconductor/liquid combination. The specific conditions under which hot carrier injection may be observed have been discussed recently by Nozik (7), and this effect will not be the main focus of our discussion. Surface states have been frequently invoked to explain nonideal junction behavior at a variety of electrode surfaces (4-6). A key difference between carrier inversion and Fermi-level pinning by surface states is that the latter can (in principle) be manipulated by chemical treatment of gap states, while carrier inversion should not be sensitive to such effects.

We have previously demonstrated that modest interface parameters may not be intrinsic to the semiconductor/liquid junction, but can arise from nonideal bulk semiconductor properties (8) or from poor photoelectrochemical cell design (9). In the present work, the open-circuit photovoltage (V_{oc}), an especially important property of a semiconductor/liquid junction, is treated quantitatively. The ideal photovoltage for a semiconductor of bandgap E_g has been claimed to be the value of E_g itself (3, 4a, 10). Thus, constant photovoltages, less than $(1/q)E_g$ in value, have been stated to be diagnostic of surface states which pin the semiconductor Fermi level (3-6, 11). However, a quantitative analysis of the factors involved in the separation of photogenerated carriers indicates that at moderate light intensities (1 Sun), intrinsic bulk recombination kinetics of the semiconductor will prevent attainment of a photovoltage close to the value of $(1/q)E_g$. This maximum restriction on V_{oc} holds even in the absence of any other sources of recombination, and rigorously applies for all surface barrier devices (semiconductor/liquid junctions) and all p-n diodes (12, 13). In addition to presenting a theoretical framework within which to interpret experimental data for semiconductor/liquid interfaces, we describe experiments which rule out a fixed density of surface states as the dominant factor in determination of V_{oc} at p-type Si photocathodes, and present data which establish the presence of mobile surface charge (carrier inversion) at p-type Si surfaces in nonaqueous solvents.

Experimental

The mounting and characterization of semiconductor electrodes has been described previously (8, 9).

*Electrochemical Society Active Member.

Characterization of relevant samples is as follows: n-type Si, (100)-oriented, phosphorus-doped, 4-9 Ω -cm (Wacker Siltronic) ohmic contact with Ga-In eutectic or with phosphorus diffusion (950°C) followed by Al contact; p-type Si, (100)-oriented, boron-doped, 5-10 Ω -cm (Wacker Siltronic) ohmic contact by evaporation of Al and alloying at 650°C for 5 min; n-type GaAs, (100)-oriented, Si-doped, donor density = 8×10^{15} cm^{-3} ohmic contact by evaporation of In and annealing under N_2 at 450°C for 15 min; p-type GaAs, (100)-oriented, Zn-doped, acceptor density = 2×10^{16} cm^{-3} (Laser Diode Company) ohmic contact by evaporation of 98% Au/2% Ge alloy, followed by annealing under H_2 at 450°C for 5 min. Si surfaces were etched before use with 48% HF for 10s, followed by a rinse with H_2O , then by a rinse with solvent, and were air dried. GaAs surfaces were etched with 3:1:1 $H_2SO_4:H_2O_2:H_2O$, 1:1 $H_2O_2:H_2SO_4$, or 12M HCl, rinsed with H_2O , then rinsed with solvent, and air dried before use.

All open-circuit photovoltages were obtained by direct measurement of the voltage between the semiconductor electrode and a large area Pt counterelectrode. Measurements were conducted through a high input impedance voltmeter, and were recorded on a Houston Instruments Model 2000 X-Y chart recorder. The accuracy of these measurements was verified by recording current-voltage curves in a three-electrode configuration *vs.* a Pt wire reference electrode poised at the solution potential. Semiconductor surface conductivity measurements on Si cathodes were performed by monitoring the voltage drop across a calibrated 10 k Ω resistor placed in series with the conductivity cell. Voltage detection was performed with a Princeton Applied Research Model 124A Lock-In Amplifier. The lock-in amplifier supplied the applied voltage, which was a sine wave with a 10 mV amplitude and a frequency of 1 kHz. The output signal was recorded on a Linear Instruments Model 555 Strip Chart Recorder. Negligible changes in conductance were recorded when the semiconductor shunt was omitted from the apparatus.

The CH_3OH solvent was distilled in a nitrogen atmosphere from Mg, and was stored over activated 3Å molecular sieves until use. CH_3CN was distilled from P_2O_5 and stored over 3Å sieves until use. Cobaltocene was purchased from Strem Chemical, Incorporated, and was purified by sublimation. All manipulations with cobaltocene were performed in a Vacuum Atmospheres, Incorporated glove box because of the extreme air sensitivity of this compound. N,N' -dimethyl-4,4'-bipyridinium dichloride dihydrate was used as received from Aldrich Chemical Corporation. N,N' -dibenzyl-4,4'-bipyridinium dibromide was synthesized by addition of benzyl bromide to 4,4'-bipyridine in CH_3CN solvent, and was isolated by addition of diethyl ether. Decamethylferrocene was used as received from Strem Chemical Corporation. N,N,N',N' -

tetramethylphenylenediamine, 1,1'-dimethylferrocene, ferrocene, and acetylferrocene were purchased from Aldrich Chemical Corporation, and were recrystallized before use. Other oxidation states of all redox couples were obtained by constant potential electrolysis in a three-compartment electrochemical cell.

Expectations for the dependence of photovoltage upon solution redox potential.—A model of interface parameters at a p-type semiconductor/liquid junction is represented in Scheme I. Properties of interest include the energies of the semiconductor conduction and valence bandedges, E_{cb} and E_{vb} , the position of the Fermi level of the semiconductor, E_f , the position of the Fermi level of the intrinsic semiconductor when the band bending is zero, E_{fi} , the bandgap of the semiconductor, E_g , and the redox potential of the solution, $E(A^+/A)$. All potentials are defined in accord with the electrochemical scale where more negative potentials are closer to the vacuum level. The energy of the semiconductor Fermi level before equilibration with $E(A^+/A)$ is defined as the "flatband" condition, $E_{FB} \equiv E_{vb} + kT \ln(N_A/N_v)$, where N_A is the bulk equilibrium hole concentration in the doped semiconductor and N_v is the effective density of states in the valence band. We assume that the back contact to the semiconductor is an ohmic or selective (for majority carriers) ohmic contact.

Equation [1] is appropriate to relate the band bending in the semiconductor, V_s , to $E(A^+/A)$, given values of fixed interfacial charge density, Q_{fix} , charge in surface states, Q_{ss} , and charge in the bulk semiconductor, Q_b

$$(qV_s = E_{vb} - q)E(A^+/A) - qV_p + q(d_H/\epsilon_H)(Q_b + Q_{fix} + Q_{ss}) \quad [1]$$

For values of V_s such that $E_f > E_{fi}$, Eq. [1] reduces to the conventional model of the semiconductor/liquid junction. For band bending such that E_f is negative of $2E_{fi} - E_{FB}$, a substantial contribution to the space charge in the semiconductor will come from accumulation of minority carriers. In this regime, the semiconductor is said to be in the strong inversion condition (1, 13), which can lead to V_{oc} values which are insensitive to the actual magnitude of

Scheme I. Representation of the energetic parameters of a semiconductor/liquid interface at charge transfer equilibrium. The energy scale is depicted using the electrochemical potential convention, where increasing negative potentials indicate energies closer to the vacuum level. The diagram is appropriate for a moderately doped, p-type semiconductor, and neglects image force effects or Schottky barrier lowering. The potential drop in the electrolyte is assumed to occur entirely across the Helmholtz layer, which is characterized by a thickness d_H with dielectric constant ϵ_H .

$E_{vb} - qE(A^+/A)$. Under these conditions, the maximum band bending can reach $E_g - qV_p$ ($V_p \equiv (1/q)(E_{vb} - E_f)$ at zero band bending).

The maximum band bending under conditions where Q_{ss} dominates Q_b and Q_{fix} in Eq. [1] will be determined by the energetic distribution of the charged states relative to E_{vb} and E_{cb} . Thus, in the absence of surface chemistry with the electrolyte (a change in Q_{fix}), if the barrier height, ϕ_b , is limited by surface states, the maximum value of ϕ_b for a p-type semiconductor/liquid junction and the maximum value of ϕ_b for the corresponding n-type semiconductor/liquid junction will add up to no greater than $(1/q)E_g$ (3, 12, 13). In the absence of field shaping in an interfacial layer (15), V_{oc} at moderate light intensities will be substantially less than ϕ_b . Within this framework, if the maximum V_{oc} at a photocathode and at the corresponding photoanode should exceed (or even closely approach) $(1/q)E_g$, we can rule out Fermi-level pinning by a fixed surface-state density as the source of constant V_{oc} values with variation in $E(A^+/A)$. We discuss the experimental observation of such conditions below.

Maximum attainable photovoltages at a semiconductor/liquid interface.— V_{oc} values which are significantly less than $(1/q)E_g$ have been interpreted to indicate Fermi level pinning by interface states (3-6, 11, 16). Furthermore, the maximum V_{oc} value is commonly associated with the value of ϕ_b ($\pm 0.1V$) (3, 4, 10c, 17), and nonidealities of V_{oc} are thus taken as indications of lower than theoretical ϕ_b values. In order to develop an explicit relationship between V_{oc} and ϕ_b at the semiconductor/liquid interface, we apply the procedures commonly used by physicists and physical electrochemists to relate E_g and V_{oc} in p-n junction cells and in electrolyte cells (12, 13).

The key notion is that V_{oc} is not an energetic parameter of the interface, but is determined by the generation, recombination, and transport of the minority and majority carriers throughout the semiconductor. Scheme II outlines most of the pertinent mechanisms for recombination of electron-hole pairs at a semiconductor/liquid interface. Depicted are mechanisms for loss of photo-generated carriers: direct and indirect bulk recombination, J_{br} ; recombination at the back contact, J_{bc} ; recombination via surface states, J_{ss} ; thermionic emission of majority carriers over the barrier, J_{ob} ; and tunneling or leakage (perhaps at chemical imperfections) through the barrier, J_{lb} . Most of these current densities are dependent upon the voltage developed in the cell. Additionally, the overall voltage profile of the recombination components yields the dark current-voltage curve for the interface. Also depicted is the current density for capture of photo-generated minority carriers by the electrolyte, J_{ph} , which will lead to useful energy extracted from the system.

The V_{oc} is defined as the potential at which the net collected current is zero; thus, recombination by any of the mechanisms indicated in Scheme II can lower V_{oc} . If no recombination occurred by any of the pathways indicated, then the maximum V_{oc} might approach $(1/q)E_g - V_p$. However, for real solids with finite mobilities of charge carriers and finite diffusion lengths, J_{br} will not approach zero. Collection of any photogenerated current by the electrolyte will necessarily lead to a change in the quasi-Fermi level for electrons from its value in the dark. This change in population will be "resisted" by the finite values of the minority carrier diffusion coefficient, D_n , (for a p-type semiconductor), and the minority carrier diffusion length, L_n . Thus, in the absence of surface recombination or leakage across the barrier, bulk recombination processes will define an upper limit on V_{oc} at a given photocurrent density.

The expression relating J_{br} to these bulk materials parameters is represented in Eq. [2] (12, 13)

$$J_{br}(V) = \frac{qD_n n_0}{L_n} (e^{\frac{qV}{kT}} - 1) = qN_c \frac{D_n}{L_n} e^{-(E_g - qV_p)/kT} (e^{\frac{qV}{kT}} - 1) \quad [2]$$

Scheme II. Representation of the kinetic parameters involved in separation of charge carriers at an illuminated semiconductor/liquid interface. Recombination by any of the mechanisms depicted can contribute to low open-circuit photovoltages in the system. If all other sources of recombination are suppressed, bulk recombination (by both direct and indirect mechanisms) will determine the upper limit on the attainable photovoltage at a given light intensity. Thus, the ultimate limit on the photovoltage represents a bulk property of the semiconductor itself, not a parameter of the semiconductor/liquid junction. Poor bulk properties can thus yield low photovoltages without implying the presence of surface states.

D_n is related to the mobility by $D_n = (kT/q)\mu$, and is thus a function of the semiconductor (the effective density of states in the conduction band), while L_n is a function of the particular crystal under study. N_c is the density of states in the conduction band, n_0 is the electron concentration in the bulk semiconductor before equilibration with the solution, and the other parameters have their usual meanings. Setting $J_{br} = J_{ph}$ will define the maximum possible V_{oc} at photocurrent density J_{ph} for a p-type semiconductor/liquid interface with fixed values of D_n , L_n , N_A , and E_g , and yields the approximate expression in Eq. [3] for V_{oc} . Similar treatments would apply to any semiconductor surface barrier device where photocurrent is to be collected

$$V_{oc} \cong \frac{kT}{q} \ln \frac{J_{ph} L_n}{q N_c D_n} + (1/q) E_g - V_p$$

$$= \frac{kT}{q} \ln \frac{J_{ph} L_n N_A}{q D_n n_i^2} \quad [3]$$

At a semiconductor/liquid junction, under the usual conditions of low level injections, V_{oc} can never exceed the value determined from Eq. [3] (the "diffusion limit") without having an electrochemical corrosion reaction in series with stable photoelectrochemical power production. Table I indicates calculations of typical values of V_{oc} (max) for several common semiconductors under particular experimental conditions. Appropriate modifications can be made for the parameters in Eq. [2] or [3] to predict the theoretical V_{oc} at any photocurrent density given the appropriate materials parameters. It is emphasized that Eq. [2] and [3] refer specifically to p-type semiconductors, but analogous equations apply equally rigorously to n-type materials (replacing D_n with D_p , L_n with L_p , N_A with N_D , etc). The typical experimental variable which must be determined for a p-type crystal is L_n , with larger values of L_n indicating higher quality material. Notably, low L_n or N_A values can yield a low V_{oc} without surface states contributing to recombination. For accurate studies of the

^a Calculated based on Eq. [3]. Relevant semiconductor parameters taken from Ref. (12, 13) and references therein. The theoretical value is calculated for an infinite crystal thickness, and thus ignores any further lowering of V_{oc} owing to the large surface recombination velocity of the back ohmic contact in typical experimental systems. The correction is on the order of 5%, and is not significant to the accuracy of the present values available for semiconductor/liquid junctions.

^b The accuracy of these values are limited both by the dispersion in experimental V_{oc} values (1, 42, 43) and some uncertainty concerning the value of n_i for these crystals. We have used $E_g(\text{MoSe}_2) = 1.06$ eV, $E_g(\text{WSe}_2) = 1.16$ eV and approximate $N_c = N_v = 10^{19}$ for these materials (44).

semiconductor/liquid junction, it has been demonstrated that L_n (or L_p) must be sufficient to insure the collection of photogenerated carriers (8, 19). However, even values of L_n or L_p sufficient to produce unit quantum yields at short circuit with 632.8 nm irradiation might not suffice to obtain the V_{oc} values calculated for the highest quality material in Table I. Thus, although V_{oc} values have been interpreted to represent the chemical nature of the semiconductor/liquid interface (3-6, 10, 11, 17), it is seen that these V_{oc} values might in many cases primarily reflect the bulk properties of the semiconductor.

Although we have not considered any of the other recombination mechanisms depicted in Scheme II, we note that in most surface barrier devices the dominant recombination terms are leakage across the barrier and J_{ob} , the thermionic emission term (13, 20). For a finite barrier height, ϕ_b , classical emission over the barrier will ideally have a dependence on the cell potential as given in Eq. [4] and [5]

$$J_{ob} = J_o (e^{\frac{qV}{kT}} - 1) \quad [4]$$

$$J_o = A^* T^2 e^{-\frac{q\phi_b}{kT}} \quad [5]$$

The effective Richardson's constant, A^* , is related to the free electron value by the ratio of effective electron (hole) mass in the semiconductor to the value in vacuum. If the dark current is dominated by J_{ob} , for a barrier height of $(1/q)E_g$, V_{oc} will be less than $(1/q)E_g$, and can be less than the V_{oc} value obtained from the diffusion limit of Eq. [3]. Use of the A^* appropriate for n-GaAs in Eq. [5] reveals that if V_{oc} for an n-GaAs anode is 0.90V at photocurrent densities of 20 mA/cm², this may be entirely consistent with a V_{oc} controlled by thermionic emission, and does not necessarily imply the presence of surface states. We note that use of expression [5] is predicated on the assumption of rapid carrier capture available in a metal, and liquids might require substantially different descriptions for the over-barrier component than given in Eq. [4] and [5]. The main point is that there are several mechanisms for obtaining low photovoltages at the semiconductor/liquid interface which do not require postulation of charge in surface states. Thus, in cases where V_{oc} is found to be substantially lower than the bulk diffusion limit, a detailed analysis of the junction properties is necessary in order to identify the dominant recombination term at the particular semiconductor/liquid interface.

Results and Discussion

Comparison of theory and experiment: open-circuit photovoltage.—A comparison of the theoretical maximum V_{oc} values calculated from Eq. [3] with accurate experimental data indicates close agreement with ideal behavior in several systems. Listed in Table I are the calculated $V_{oc}(\text{max})$ from Eq. [3] and the experimental values of V_{oc} for semiconductor/liquid junctions where approximate estimates of the photocurrent density and the minority carrier diffusion length are possible. The quantitative comparison in Table I indicates that several of the common semiconductor/liquid junctions previously suggested to have severe limitations of V_{oc} due to Fermi-level pinning (3-5) actually display photovoltages which are close to the maximum possible values. As an example, p-type Si photocathodes have been stated to be Fermi-level pinned because V_{oc} is only 0.35-0.50V with laser excitation of up to 50 mW/cm² (11c, 21). At photocurrent densities of 25 mA/cm² on characterized silicon samples (Table I), we measure a V_{oc} of 0.48-0.52V for p-type Si in the cobaltocene^{+/0}/CH₃CN system. The theoretical value calculated from Eq. [3] (0.55V) is thus within 10% of the observed V_{oc} . Similar agreement between theory and experiment can be observed for n-Si/ferrocene junctions in CH₃OH solvent, where theory and data differ by less than 4% (9). We emphasize that the ideal values as-

sume no losses from any of the other mechanisms depicted in Scheme II, and entirely neglect any contribution from the thermionic emission component or from recombination at the back contact. In view of the fact that we have not searched for conditions to optimize the performance of our liquid junctions, we are highly encouraged by the close accord between ideal expectations and actual experimental results.

It is interesting to compare the V_{oc} values obtained on these Si/liquid systems to the V_{oc} values obtained with Si p-n junctions. It has been suggested that when no surface states are present at a semiconductor/liquid interface, that the value of V_{oc} would approach that of a p-n junction. At 35 mA/cm² photocurrent density, typical p-n junctions (NASA Si secondary standard cells) exhibit a V_{oc} of 0.55-0.57V, and active area efficiencies of 12.5% (22). The n-Si/CH₃OH/ferrocene^{+/0} photoelectrode system ($\rho \approx 5 \Omega\text{-cm}$) yields $V_{oc} = 0.52\text{-}0.56$ at 25 mA/cm², and total area efficiencies of 10.0% (without elimination of residual solution absorption or series resistance losses) (9). Thus, if similar substrates are employed, the photocurrent-voltage parameters attainable at the semiconductor/liquid interface compare favorably in V_{oc} to technologically advanced silicon solid-state systems.

A similar analysis can be applied to p-InP, where V_{oc} values of 0.80V have been obtained and assigned to surface states (3, 23). The bulk diffusion limit on V_{oc} for p-InP with an extremely long diffusion length ($L_n \approx 5 \mu\text{m}$) is approximately 0.9V. In the absence of leakage, and if the thermionic emission limit applies, a barrier height of $E_g - qV_p \approx 1.2$ eV might yield a $V_{oc}(\text{max})$ of only 0.8V. Although there is some discrepancy between the maximum bulk-diffusion-limited V_{oc} and the experimentally reported V_{oc} values, clearly indicating some other dominant recombination pathway at this junction, reference to Eq. [3] indicates that ideal junctions could not yield substantial (> 0.2V) improvements in V_{oc} over the reported data; thus, we conclude that surface-state pinning is not a severe limitation on the value of V_{oc} for p-InP cathodes in aqueous or nonaqueous solvents. This is consistent with the observation by Heller that the oxide on p-type InP will prevent surface states from significantly reducing the attainable V_{oc} value (24). Changes in stoichiometry at n-InP surfaces (owing to chemical reactions with the etchant, atmosphere, etc.) may prevent attainment of the maximum V_{oc} in photoanode-based systems, however, this does not necessarily mandate restrictions on V_{oc} for the p-InP system. The important concept is that Eq. [3] provides a quantitative framework to assess bulk *vs.* surface recombination effects at semiconductor/liquid interfaces.

For the systems listed in Table I (other than the Si-based junctions), it is clear that some improvement in experimental V_{oc} can be attained, and that bulk recombination does not limit the junction properties in all cases. Clearly, when surface etching is found to change junction properties, or when photocorrosion processes dominate the photovoltage, the surface will play an important role in determining the observed V_{oc} . In these cases, Fermi-level pinning may dominate the junction behavior, and this pinning can lead to lower than optimum V_{oc} values. However, Table I demonstrates that in some semiconductor/liquid systems, substantial improvements in V_{oc} could not be attained even if surface-state effects were minimized. We conclude that V_{oc} should be compared to the bulk-diffusion-limited value (and possibly to the ideal thermionic-emission-limited value) and not to the value of E_g , in order to ascertain a potential role for surface recombination at the semiconductor/liquid junction.

We also note that some reported values of V_{oc} significantly exceed the value calculated from the bulk diffusion limit (25, 26). We suggest that these particular interfaces must involve a parallel corrosion reaction which yields artificially high V_{oc} values. It is possible, of course, that the value of ϕ_b might actually exceed E_g if a fixed surface charge of the appropriate sign and density or an

Fig. 1. Open-circuit photovoltage vs. solution redox potential for n-Si and p-Si photoelectrodes in 1.0M KCl/CH₃OH solution. The redox couples used were: (a) cobaltocene^{2+/0}, (b) N,N'-dimethyl-4,4'-bipyridinium dichloride^{2+/+}, (c) N,N'-dibenzyl-4,4'-bipyridinium dibromide^{2+/+}, (d) decamethylferrocene^{2+/0}, (e) N,N,N',N'-tetramethylphenylenediamine^{+/0}, (f) dimethylferrocene^{+/0}, (g) ferrocene^{+/0} and (h) acetylferrocene^{+/0}. A tungsten-halogen bulb was used to provide light intensities which yielded short-circuit photocurrent densities of 25-30 mA/cm².

oxide were present at the interface. This might produce suppression of the J_{ob} component, and other mechanisms might then dominate the dark current. Under no conditions, however, can the dark current be less than the bulk diffusion limit of Eq. [2]; therefore, higher V_{oc} values than those calculated from Eq. [3] must indicate chemical reactions with the electrolyte.

It can also be seen that V_{oc} measurements at any accessible light intensity generally will not provide an accurate estimate of ϕ_b . It has been stated that measurement of V_{oc} by cyclic voltammetry indicates ϕ_b to within 0.1V (3, 4, 21). Furthermore, it has been stated that V_{oc} measurements to determine ϕ_b are analogous to photoresponse measurements in the solid state (17). Photoresponse measurements on Schottky barriers are based upon internal photoemission from the metal into the semiconductor, and are a direct measure of ϕ_b , not V_{oc} (12, 27). We also emphasize the distinctions in Scheme I between ϕ_b , V_s , and V_{oc} .¹ Even in the absence of temperature effects and of recombination kinetics which are nonlinear with light intensity, plots (on linear axes) of the logarithmic dependence of the V_{oc} vs. incident light intensity can appear to exhibit a saturation value which does not reflect ϕ_b . Within the framework described above, V_{oc} should be correlated with V_s or ϕ_b only with a detailed understanding of the interfacial kinetics at the particular semiconductor/liquid junction system.

Comparison of maximum photovoltages for n-type and p-type semiconductors: distinguishing between Fermi-level pinning and carrier inversion.—Having established the theoretical upper limit on V_{oc} , it still remains of interest to determine the mechanism for constant photovoltages over a wide range of solution potentials, $E(A^+/A)$. In this work, two methods have been applied to differentiate between carrier inversion and Fermi-level pinning. One method, discussed below, is based on measurement of the near-surface conductivity of the semiconductor. Additionally, if the sum of the maximum barrier heights for an n-type semiconductor, ϕ_{bn} , and a p-type semiconductor, ϕ_{bp} , in the same solvent should substantially exceed E_g , then Fermi-level pinning by a fixed distribution of surface states inherent to the semiconductor/solvent interface can be ruled out. An even more severe restriction is that the sum of the maximum V_{oc} for the n- and p-type combination should not exceed $(1/q)E_g$. In principle, differential capacitance data can be used to extract the value of E_{FB} ; however, frequency dependences of the measured capacitance generally complicate the analysis (29). The

For an ideal Si/Au Schottky diode (ideal diode quality factor, $n = 1.0$; dark current dominated by thermionic emission), V_{oc} at 30 mA/cm² photocurrent density will underestimate ϕ_b by 0.5V (28). Furthermore, light intensities of over 2000 W/cm² would be needed to obtain a 0.2V agreement between V_{oc} and ϕ_b . Lack of change in V_{oc} with increases in incident light intensity can reflect the onset of recombination processes in the bulk semiconductor or recombination at the interface, and need not imply that the flatband potential has been approached.

onset of photocurrent has also been used in some instances (5a, 30); however, it has not been unambiguously determined how to relate the kinetic parameters measured under these conditions (no well-defined solution redox potential, artificial suppression of dark current due to low concentrations of electroactive species) to the energetic parameter ϕ_b . We have thus carried out direct measurements of V_{oc} as a function of photocurrent density in various solutions (A^+/A) in both CH₃OH and CH₃CN solvent. The values of V_{oc} will determine lower limits of the sum of $\phi_{bn} + \phi_{bp}$ for the pairs of n- and p-type semiconductors.

For the redox couples (A^+/A), in order to insure rapid interfacial kinetics at the semiconductor/liquid interface, we choose outer sphere redox reagents which exhibit reversible electrochemistry at metal electrodes. Typical V_{oc} data for the n-type Si ($N_D = 9 \times 10^{14}$ cm⁻³), and p-type Si ($N_A = 2 \times 10^{15}$ cm⁻³) electrode system are depicted in Fig. 1. The incident light intensity is sufficient to produce photocurrent densities of 25-30 mA/cm² in all cases, and the solutions contain high concentrations of both forms of the redox couple (where possible). We observe V_{oc} values of 0.54 ± 0.02 V for n-Si in the ferrocene^{+/0} system, and 0.45 ± 0.02 V for p-Si in the cobaltocene^{+/0} system. Further changes in redox potential do not yield higher value of V_{oc} at this photocurrent density in methanol solvent.

Similar photovoltage data, obtained by cyclic voltammetry for p-type Si in CH₃CN solvent (6a) and for n-type Si in C₂H₅OH (31) and CH₃CN solvent (6a), have been associated with ϕ_b , and have been used to propose Fermi-level pinning of the Si by surface states. In direct measurement of V_{oc} in a full cell configuration, at higher incident light intensities we observe $V_{oc} > 0.65$ V for n-Si and $V_{oc} > 0.55$ V for p-Si, for a sum of V_{oc} values of > 1.2 V (E_g for Si at 300 K = 1.12 eV). The fact that the sum of the V_{oc} values exceeds $(1/q)E_g$ contradicts the notion that severe restrictions on V_{oc} are present due to a fixed set of charges in surface states.

Data interpreted as evidence for surface states have been obtained previously for n- and p-type GaAs in CH₃CN solvent (5a). p-Type GaAs is reported to yield low V_{oc} values (0.2-0.3V) in both aqueous and nonaqueous solvents (32). In addition, constant (0.55-0.62V) photovoltages have been measured for n-type GaAs in CH₃CN solvent (33, 34). Therefore, it has been stated that n-GaAs and p-GaAs are Fermi-level pinned by surface states (4a, 5a). This is proposed to be consistent with the "1/3 rule" in semiconductor physics which empirically generalizes that surface states tend to reside at $E_{vb} - (1/3)E_g$ (12, 35). At light intensities ≈ 10 Suns, we observe V_{oc} values for n-type GaAs in ferrocene^{+/0} > 0.85 V, and V_{oc} values for p-type GaAs in the cobaltocene^{+/0} system of > 0.75 V. We thus conservatively estimate $\phi_{bn} + \phi_{bp} > 1.6$ eV, which is in excess of E_g for GaAs (1.42 eV). Additionally, the barrier height for n-GaAs in CH₃CN (based on V_{oc} measurements) has been proposed to be in excess of 1.1 eV (34),

implying that surface states should be within 0.3 eV of the valence band, and should thus prevent substantial V_{oc} values at p-GaAs. The observation of $V_{oc} > 0.75V$ in the p-GaAs/cobaltocene^{+/0} system is inconsistent with these predictions. We thus conclude that Fermi level pinning by charge in a fixed density of interface states cannot account for the V_{oc} behavior of GaAs in CH_3CN solvent, and does not necessarily prevent design of efficient semiconductor/liquid junctions with these systems (8a).

We also note that the V_{oc} values for n-Si, p-Si, n-GaAs, and p-GaAs interfaces can substantially exceed those reported for direct Schottky contacts to noble metals such as Pt or Au (12). This cannot be simply due to Fermi-level pinning of ϕ_b , with more favorable interfacial kinetics resulting in higher V_{oc} values at liquid junctions. This possibility is excluded by the observation of V_{oc} values for liquid systems which exceed ϕ_b values for Au Schottky barriers. In contrast to the V_{oc} values of 0.54V for n-Si and 0.46V for p-Si CH_3OH junctions, surface-state pinning in Schottky barriers yields V_{oc} values of only 0.30V for n-Si/Pt interfaces, and yields low barrier height, "ohmic" contacts for p-Si/Pt and p-Si/Au junctions. In addition, we note that analogies (4a, 21) to the commonly quoted Schottky Fermi-level pinning behavior for covalent vs. ionic solids (36) clearly do not apply to the semiconductor/liquid interface, as evidenced by data showing extensive regions of ideal behavior for V_{oc} vs. $E(A^+/A)$ for liquid junctions with n-Si, p-Si (37), p-InP (24), n-CdTe (21a), a-Si:H (8b), and other small E_g semiconductors. Pinning of the Fermi level in solid-state systems can be associated with changes in surface stoichiometry upon formation of the Schottky barrier (38). The recombination induced by surface states which pin the Fermi level can only lower V_{oc} from the theoretical value defined by the diffusion limit of Eq. [3]. Different chemical interactions at liquid interfaces [including formation of surface oxides (9a)] may allow formation of more ideal junctions, and will preclude proposed generalizations of V_{oc} or ϕ_b values observed in Schottky systems to semiconductor/liquid junctions.

Surface conductivity measurements to verify carrier inversion.—An obvious difference between Q_b and Q_{ss} is that increases in Q_b should produce increases in mobile

Scheme III. Diagram of cell arrangement for determination of near-surface conductivity of p-type silicon electrodes. The current response to an oscillating voltage signal applied between the two Pt wires is sensitive to the conductivity of the intermediate Si surface shunt. The method is only sensitive to mobile charge carriers. Thus, it will not detect charge in surface states, and will provide a method to distinguish between carrier inversion and Fermi-level pinning by surface states.

charge, while surface-state charge is essentially fixed. Thus, measurement of the near-surface conductivity should lead to a direct evaluation of the contribution of Q_b to the potential drop across the Helmholtz layer. Our measurement of the near-surface conductivity for p-Si photocathodes in CH_3CN solvent involves detection of the ac conductance between two Pt electrodes which are in close proximity to the semiconductor surface (Scheme III). If the semiconductor develops an inverted, conduct-

Fig. 2. Conductance between two Pt wires arranged as a Scheme III, under various experimental conditions. (a) Injection of 10 mM ferrocene into a 1.0 mM $LiClO_4/CH_3CN$ solution yields no detectable change in measured conductance. (b) Injection of 1.0 mM cobaltocene yields a large, sustained change in measured conductance owing to the shunt formed by injection of mobile surface charge from the cobaltocene into the p-Si surface. Under our circuit conditions, the relationship between the measured change in conductance and the electron concentration in the semiconductor can be approximated by $N_e = (\Delta G)/(Ae\mu)$. Assumption of a 5×10^{-7} cm thick inversion layer in our 0.2×0.3 cm electrode yields $A = 1 \times 10^{-7} \text{ cm}^2$, $l = 0.3$ cm, and thus $N_e \approx 10^{17} \text{ cm}^{-3}$ for a change in conductance of $5 \times 10^{-6} \Omega^{-1} \text{ cm}^{-1}$, as indicated.

ing surface layer, the conductance of the "cell" will change dramatically, and Q_b can thus be estimated directly. In our experiments, the reduced form of the redox couple A^+/A is injected into the solution, and the conductance between the Pt probe electrodes is monitored. This technique is similar to a method recently proposed by Gerischer (1c), which has roots in early field effect experiments on semiconductor surfaces. Because the semiconductor should be in depletion upon injection of the appropriate A, any increase in conductivity can be associated with the presence of mobile minority carriers near the surface, and would therefore imply the presence of carrier inversion.

Figure 2 displays the measured change in conductance between two Pt wires with a p-type Si surface ($N_A = 2 \times 10^{15} \text{ cm}^{-3}$) as the possible shunt. The experiments are performed in dry $\text{CH}_3\text{CN}/1.0 \text{ mM LiClO}_4$. Injection of ferrocene yields little change in the conductance, but injection of cobaltocene produces a pronounced, stable increase in the signal. Because we have injected a neutral molecule into the solution, yet have produced an increase in the measured conductance, we associate this phenomenon with the formation of an inversion layer at the p-type Si cathode. Ferrocene is not a sufficiently strong reductant to effect carrier inversion in p-Si, and no increase in conductivity occurs.

Analysis of the geometry of our cell allows a rough estimate of the carrier concentration in the inversion layer. Assuming a 50\AA inverted region, and a mobility of $480 \text{ cm}^2/\text{V}\cdot\text{s}$, an electron concentration of $10^{17} \text{ carriers}\cdot\text{cm}^{-3}$ is calculated. This is consistent with the presence of strong inversion in the semiconductor, as might be expected for a redox couple with a formal potential as negative as cobaltocene^{+/0}.

Both carrier inversion ($Q_b > Q_{ss}$) and Fermi-level pinning ($Q_b < Q_{ss}$) have been proposed to explain the photoelectrochemistry of p-type Si in CH_3CN solvent (2, 39). The similarity of V_{oc} values for the cobaltocene^{+/0} system in CH_3CN , and CH_3OH , the direct detection of mobile charge carriers at p-Si surfaces in CH_3CN , and the high efficiency of p-Si photocathodes in CH_3CN solvent (40) leads us to propose that carrier inversion is the dominant mechanism of developing charge across the Helmholtz layer for redox couples where $E(A^+/A) < -0.7 \text{ V}\cdot\text{vs. SCE}$ (40).² Carrier inversion can provide a situation where design of efficient photoelectrodes is possible for both carrier types in the same solvent, and is consistent with accurate current-voltage data using high quality Si semiconductor samples.

Conclusions

The ultimate limit on the open-circuit photovoltage at a semiconductor/liquid interface can reflect the bulk recombination kinetics of the semiconductor itself. A quantitative treatment of these kinetics indicates that typical electrode samples may exhibit open-circuit photovoltages substantially below the value of the semi-

² Differential capacitance measurements have been suggested to rule out carrier inversion for p-Si in CH_3CN solvent (39) because the apparent E_{FB} position was found to change before a band bending of $(1/2)E_b$ had been achieved. In this analysis, it is stated that qV_p of the p-Si ($N_A = 2 \times 10^{15} \text{ cm}^{-3}$) is 0.05 eV . However, for this doping level, we calculate $qV_p = 0.24 \text{ eV}$ (12, 13), and can thus use the original data to place E_{vb} at $+0.4 \text{ V}\cdot\text{vs. SCE}$. At this doping level, weak inversion could onset at $-0.15 \text{ V}\cdot\text{vs. SCE}$, strong inversion could then occur at $-0.4 \text{ V}\cdot\text{vs. SCE}$, and the data might be consistent with carrier inversion. Ideal behavior would predict that the reported analysis (39) of a straight line of slope ~ 0.5 for E_{FB} vs. $E(A^+/A)$ might actually be properly described as two distinct regions, each exhibiting a linear dependence of E_{FB} vs. $E(A^+/A)$. Other workers have noted the anomalous behavior of differential capacitance data for p-Si in CH_3CN (6a), and additional data might be warranted to unambiguously describe the dependence of ϕ_s upon potential in this system. We also note that at the highest measured value of V_{ss} , $q(\phi_s)$ is approximately 0.9 eV (if the proper E_{vb} is employed). Thus, if surface states do pin the Fermi level, they must be very close to E_{cb} , and should not appreciably limit V_{oc} . This notion is consistent with the excellent agreement between theory and experiment in Table I, and is strongly supported by other results in our laboratory, which describe the design of efficient p-Si-based photoelectrochemical cells in nonaqueous solvents (40).

conductor bandgap, yet not possess any deleterious effects assignable to Fermi-level pinning. Lower than ideal open-circuit photovoltages may occur because of poor diffusion lengths in the bulk semiconductor, classical carrier emission over the surface barrier, or leakage across low barrier chemical imperfections at the semiconductor/liquid interface. Characterization and control of bulk semiconductor properties is thus crucial to obtaining meaningful data at the semiconductor/liquid interface. Saturation in open-circuit photovoltage with increases in incident light intensity can reflect recombination kinetics of the semiconductor, and may not yield the barrier height. Constant values of the open-circuit photovoltage with changes in solution redox potential can be consistent with carrier inversion at ideal semiconductor/liquid interfaces. The observation of large photovoltages for n- and p-type-based semiconductor interfaces in the same solvent can rule out pinning by a fixed density of charged surface states as the mechanism for obtaining constant photovoltages. Direct evidence for mobile minority charge carriers in the semiconductor can be obtained by ac conductivity techniques, and verifies the presence of an inversion layer for p-type Si cathodes in nonaqueous solvents. Application of the "1/3 bandgap" rule to p-type GaAs/liquid junctions is inappropriate, and in general, behavior of liquid contacts may not correlate with measured properties of Schottky barriers. Fermi-level pinning will prevent design of the most efficient semiconductor/liquid junctions, while carrier inversion may lead to interfaces which operate near the theoretical diffusion-limited photovoltage.

ABSTRACT

Irreversible thermodynamics has been used to describe electrode heat balances of electrochemical cells. The specific example of electrolysis of water in molten sodium hydroxide is chosen for the purpose of illustration. Experimental data are presented for this system. The importance of a distinction between time and charge-dependent changes in entropy is pointed out. Only changes of the last type contribute to cell EMF's. The relation between EMF of thermocells, the temperature coefficient of an isothermal cell, and the electrode heat balances are discussed particularly. Results show a reasonably good agreement between theoretical predictions and experimental observations. With partial pressures of hydrogen and water vapor in the cathodic compartment of 0.8 and 0.2 atm, respectively, 63 kJ is evolved, and with partial pressures of oxygen and water vapor in the anodic compartment of 0.8 and 0.2 atm, respectively, 72 kJ is absorbed during the passage of 1F of current at 623 K.

When it is desired to improve the energy conversion efficiency or the temperature control of an electrochemical reactor, it is important to consider the overall energy flow through the reactor.

For example, if heat is not supplied to electrodes where an endothermic process takes place, a drop in temperature may result. This may lead to an increase in cell voltage, or, in molten salt electrochemical reactors, even freezing of the electrolyte. Conversely, if heat is not conducted from electrodes where exothermic processes take place, a rise in temperature may result. This may lead to a breakdown of the cell or electrolyte boiling. In order to maintain constant temperature at the electrodes, it is helpful to know the magnitude of the reversible heat changes during electrolysis. This includes the Peltier heat for each electrode (1).

It is the purpose of this article to show how reversible heat changes are related to electromotive forces of thermogalvanic cells, and how they can be estimated from EMF measurements. Experiments related to electrolysis of water in NaOH (1) are used to illustrate the theory, since this electrolytic process is promising for the future hydrogen energy system and the accumulation of thermodynamic and electrochemical data are desired for the further engineering development. The results are obtained using nonequilibrium thermodynamics (2). The approach by Førland and Ratkje (2) is chosen, since this describes electrochemical cells directly by local energy conversion processes. This is in contrast to conventional approaches which describe EMF by local electric potential differences due to charge separation (3, 4). The main features of the theory of Førland and Ratkje, in addition to the above, are (i) the use of single ion activities or electrochemical potentials is avoided. This is because energy changes are only defined and measurable with respect to electroneutral processes. (ii) The components of the system are components according to the phase rule. Components involved in electrode reactions are included. This ensures independent mass variables. (iii) The electric current is an independent flux of the system, since this can be controlled externally. (iv) The frame of reference is the wall of the cell container.

For isothermal systems, the superposition of time (diffusion) and charge-(migration) dependent processes has been pointed out (5, 6). In the nonisothermal case, we will

*Electrochemical Society Active Member.

show that a similar superposition is essential when characterizing entropy changes. This superposition separates irreversible (time dependent) and reversible heat changes. Furthermore, the nonisothermal transport processes will be described without using single ion entropies or electronic entropies.

Entropy Production by Heat, Mass and Charge Transfer in a Continuous System

According to Førland and Ratkje (2) and Ratkje (7), the entropy production θ per unit volume and unit time at any point in the electrochemical system can be written

$$\theta = \nabla \left(\frac{1}{T} \right) J_{q'} - \frac{1}{T} \sum_{i=1}^k \nabla \mu_{iT} J_i - \frac{1}{T} \nabla \phi^{\text{obs}} I \quad [1]$$

Current density is assumed to be constant through the system, so no local charge accumulation takes place. $J_{q'}$ is the measurable heat flux. $J_{q'}$ is equal to the heat flow which is required from two heat reservoirs on either side of a volume element to keep constant temperatures. J_i denotes the component fluxes of the k independent components, and I is the electric current density. The chemical potential gradient $\nabla \mu_{iT}$ contains only pressure and composition dependent terms. The symbol $\nabla \phi^{\text{obs}}$ denotes the differential EMF, measured with defined identical electrodes across the volume element. By integration across all volume elements the EMF of the system is obtained. This is illustrated in Fig. 1. T is the absolute temperature.

Fluxes of some components which form parts of the electrodes are completely coupled to the electric current

$$J_i = k_i \cdot I \quad [2]$$

where k_i is an integer or ratio of integers. By inserting this condition into Eq. [1], we obtain

$$\theta = \nabla \left(\frac{1}{T} \right) J_{q'} - \frac{1}{T} \sum_{i=1}^n \nabla \mu_{iT} J_i - \frac{1}{T} \left(\nabla \phi^{\text{obs}} + \sum_{i=n+1}^k \nabla \mu_{iT} k_i \right) I \quad [3]$$

This defines the electric force conjugate to the current as

$$\frac{1}{T} \nabla \phi = \frac{1}{T} \left(\nabla \phi^{\text{obs}} + \sum_{i=n+1}^k \nabla \mu_{iT} k_i \right) \quad [4]$$

Fig. 1. Scheme of the electrochemical system

Fig. 2. Prototype cell for water vapor electrolysis

The quantity $\nabla\phi$ can be regarded as the effective electric potential gradient. The expression [3] for the entropy production can be used to define independent fluxes. This will be done below for our special systems, the water electrolysis system developed by Ito and co-workers (8, 9), and electrochemical systems related to this. The use of equations for specific systems is chosen on purpose to simplify reading. Generalizations to include more components are straightforward and will not give further physical insight.

The System

The electrolysis of water can be efficiently performed in the temperature range 330°-450°C by dissolving water vapor in molten sodium hydroxide (8, 9). The overall reaction is

This cell can be expressed as

The cathodic and anodic reactions are written, respectively, as

and

One possible cell construction is shown in Fig. 2. The cell is made entirely of nickel, and, in order to avoid bipolar effects, the inside of the anodic compartment is covered by an α -alumina wall. A porous α -alumina plate is used as a diaphragm. Water vapor is supplied to the left-

hand side of the cell, and the electrolyte saturated with water circulates by a gas lift of both water vapor bubbles and evolved hydrogen gas in the direction given by the arrows in the figure.

During electrolysis heat will be evolved at the cathode and absorbed at the anode. In order to quantify this, the electrodes have been studied separately in the thermocell shown in Fig. 3: A gas mixture of either H_2O and H_2 or H_2O and O_2 was used for the right-hand side Pt-electrode of this figure. A sodium/ β -alumina electrode at temperature T_1 was used as the constant reference electrode. The temperature T_2 of the gas electrode was varied. Porous α -alumina was used as a bridge between the two half cells. By subtracting the resulting EMF for two values of T_2 , the EMF of the following thermocells are obtained

$$(T) Pt|H_2O(g), H_2(g)|NaOH(l)|H_2(g), H_2O(g)|Pt (T + \Delta T) \quad [8]$$

$$(T) Pt|H_2O(g), O_2(g)|NaOH(l)|O_2(g), H_2O(g)|Pt (T + \Delta T) \quad [9]$$

Fluxes and Forces of the Experimental System of Fig. 2 and 3

Apart from the gas components forming the electrodes ($H_2(g)$, $H_2O(g)$, $O_2(g)$), there is one component present in these systems, *i.e.*, NaOH. Using the general expression [3] for the entropy production, this gives for the fluxes and forces of the system

$$J_{q'} = L_{11}\nabla\left(\frac{1}{T}\right) - L_{12}\frac{1}{T}\nabla\mu_{1T} - \frac{1}{T}L_{13}\nabla\phi \quad [10]$$

$$J_{NaOH} = L_{21}\nabla\left(\frac{1}{T}\right) - L_{22}\frac{1}{T}\nabla\mu_{1T} - \frac{1}{T}L_{23}\nabla\phi \quad [11]$$

Fig. 3. Thermogalvanic cell arrangement.

$$I = L_{31} \nabla \left(\frac{1}{T} \right) - L_{32} \frac{1}{T} \nabla \mu_{1T} - \frac{1}{T} L_{33} \nabla \phi \quad [12]$$

The problem is to find the meaning of the coefficients L_{ij} in each case. Furthermore, $\nabla \phi$ needs clarification when the electrodes are different, e.g., during electrolysis.

One simplification may be introduced: we assume that the solubility of all gas components H_2O , H_2 , and O_2 is so low (9) that the chemical potential, μ_{1T} , of NaOH is not significantly influenced by these components, so that $\nabla \mu_{1T} = 0$.

Superposition of Time and Charge Dependent Processes

For the interpretation of L_{ij} , it is important to acknowledge that the heat transferred consists of one time-dependent term $\Delta q'(t)$ and one charge-dependent term $\Delta q'(Q)$. This superposition can be seen as follows: by elimination of $\nabla \phi$ in Eq. [10] by Eq. [12], and setting $\nabla \mu_{1T} = 0$, we obtain

$$J_{q'} = \left(L_{11} - \frac{L_{13}L_{31}}{L_{33}} \right) \nabla \left(\frac{1}{T} \right) + \frac{L_{13}}{L_{33}} \cdot I \quad [13]$$

The condition $\nabla \mu_{1T} = 0$ corresponds to the situation in which no concentration and/or pressure gradient exists in the system. The total heat transferred ($\Delta q'$) and the charge transferred (ΔQ) during a short time interval, Δt , are $J_{q'} \cdot \Delta t$ and $I \cdot \Delta t$ respectively. Thus

$$\Delta q' = \left(L_{11} - \frac{L_{13}L_{31}}{L_{33}} \right) \nabla \left(\frac{1}{T} \right) \cdot \Delta t + \frac{L_{13}}{L_{33}} \cdot \Delta Q \quad [14]$$

This equation shows that the transferred heat consists of one time-dependent term, which is the first term on the right-hand side, and one charge-dependent term. The latter is time independent, its sign reversed by reversing the sign of ΔQ . This part of the heat transfer is reversible. The heat balance is

$$\Delta q' = \Delta q'(t) + \Delta q'(Q) \quad [15]$$

The presence of gradients in chemical potentials will not change the general form (15), but will merely give an additional contribution to both the time-dependent and charge-dependent parts of $\Delta q'$.

The entropy change per Faraday corresponding to $\Delta q'(Q)$ is

$$S'(Q) = \frac{q'(Q)}{T \cdot \Delta Q} \quad [16]$$

The heat $\Delta q'(Q)$ will contain the heat associated with the electrode reactions, but $\Delta q'(Q)$ will also contain contributions from the reversible transport process through the electrolyte and metal leads. This means that the coefficient ratio L_{13}/L_{33} is also determined by the mechanism of transport

$$L_{13}/L_{33} = TS'(Q) \quad [17]$$

Furthermore, by expressing $\nabla \phi$ by Eq. [12], we obtain

$$(\nabla \phi)_{I=0}, \nabla \mu_{1T=0} = - \frac{L_{31}}{L_{33}} \frac{\nabla T}{T} \quad [18]$$

By application of Onsager relations, we see that the coefficient ratio (17) determines the electric work that can be obtained from the system

$$(\Delta \phi)_{I=0}, \nabla \mu_{1T=0} = -\Delta T S'(Q) \quad [19]$$

For a temperature difference ΔT , it is thus only the heat $\Delta T S'(Q)$ which can be reversibly converted to electric work or vice versa. Equation [19] will next be used to find contributions to EMF or electric work done in the outer circuit.

Reversible Entropy Changes during Electrolysis or EMF Measurements

Consider first the thermocell given by Eq. [8], and a small volume element, as given by Fig. 1. When electrons

pass from left to right in the outer circuit, the following reaction takes place at the left-hand side electrode

The entropy change due to formation of $H_2O(g)$ and removal of $H_2(g)$ and $NaOH(l)$ is equal to

$$\Delta S_1 = S_{H_2O(g)} - \frac{1}{2} S_{H_2(g)} - t_{NaOH} S_{NaOH}^{\circ} \quad [21]$$

where $t_{NaOH} = t_{Na^+}$ (transport number of Na^+) is the number of moles of NaOH transferred from left to right per Faraday. All entropies on the right-hand side of Eq. [21] are state functions. By inserting the experimental values of $P_{H_2O} = 0.2$ atm and $P_{H_2} = 0.8$ atm and using literature data (10), we obtain the entropy change of the left-hand region of the cell per Faraday transferred

$$\Delta S_1 = 150.0 JK^{-1}F^{-1} - t_{NaOH} S_{NaOH(l)}^{\circ} \quad [22]$$

This is the entropy change of the left-hand part of the system due to composition changes caused by charge transfer. Since this is a reversible entropy change, it is equal to the entropy transferred from a heat reservoir at the left-hand side, $S'_{(Q1)}$, minus the transported entropy $\bar{S}_{(Q)}$, due to the charge transport process in the electrolyte. The term corresponding to $\bar{S}_{(Q)}$ due to transport of charge in metallic leads will be neglected here (Peltier heat for metals is small). The terminology is according to Agar (4). The entropy balance is shown in Fig. 4. We have

$$\Delta S_1 = S'_{(Q1)} - \bar{S}_{(Q)} \quad [23]$$

or

$$S'_{(Q1)} = \Delta S_1 + \bar{S}_{(Q)} \quad [24]$$

For the present system, measurements show that $S'_{(Q1)}$ is positive, which means that a negative Peltier heat $TS'_{(Q)}$ is transferred reversibly over a temperature interval of dT . For dT positive, electric work must be supplied, i.e., the EMF is negative. Combining Eq. [18], [24], and [22], one obtains in the one dimensional case

$$\frac{d\phi_1}{dT} = -(\Delta S_1 + \bar{S}_{(Q)}) \quad [25]$$

$$\frac{d\phi_1}{dT} = -150.0 JK^{-1}F^{-1} + t_{NaOH(l)} S_{NaOH(l)}^{\circ} - \bar{S}_{(Q)} \quad [26]$$

The second type of cell investigated, given by Eq. [9],

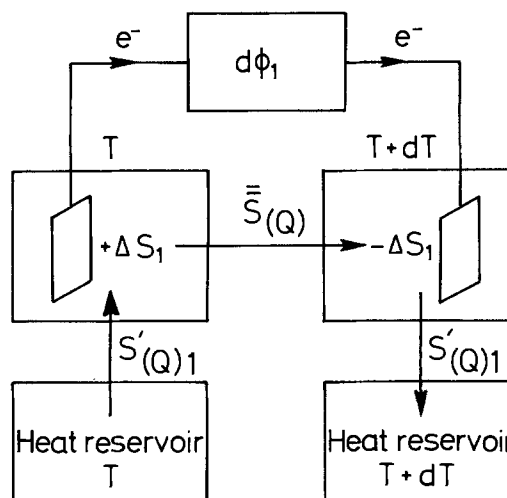

Fig. 4. Entropy balance for a thermogalvanic cell. ΔS_1 is entropy change due to change in composition. ΔS_1 is obtained from changes in state functions. $\bar{S}_{(Q)}$ is transported entropy caused only by the transport of electric charge in the electrolyte. $\bar{S}_{(Q)}$ depends on mechanism of charge transport. $S'_{(Q1)}$ is entropy supplied to or from heat reservoirs in equilibrium with sections of the cell. $S'_{(Q1)} \cdot T$ is the Peltier heat.

can be treated in a similar way. The reaction at the left-hand side electrode is now

The entropy change at the left-hand side of the cell is

$$\Delta S_2 = \frac{1}{4} S_{\text{O}_{2(\text{g})}} + \frac{1}{2} S_{\text{H}_2\text{O(g)}} - t_{\text{NaOH}} S_{\text{NaOH}}^\circ \quad [28]$$

where the last term is the same as the last term in Eq. [22]. With $P_{\text{O}_2} = 0.8$ atm and $P_{\text{H}_2\text{O}} = 0.2$ atm, we have

$$\Delta S_2 = 170.2 \text{ JK}^{-1} \text{ F}^{-1} - t_{\text{NaOH}} S_{\text{NaOH}}^\circ \quad [29]$$

An entropy balance gives (compare Eq. [23])

$$S'_{(\text{Q})2} = \Delta S_2 + \bar{S}_{(\text{Q})} \quad [30]$$

where $\bar{S}_{(\text{Q})}$ has the same value as in Eq. [24]. Thus, the thermoelectric EMF $d\phi_2/dT$ is given by

$$\begin{aligned} \frac{d\phi_2}{dT} &= -(\Delta S_2 + \bar{S}_{(\text{Q})}) \\ &= -170.2 \text{ JK}^{-1} \text{ F}^{-1} + t_{\text{NaOH}} S_{\text{NaOH}}^\circ - \bar{S}_{(\text{Q})} \end{aligned} \quad [31]$$

This completes the analysis of the heat change at the separate electrodes and how this change can be obtained experimentally by EMF measurements. When we need to know the details of the thermoelectric power, additional experiments must be performed to obtain t_{NaOH} and $\bar{S}_{(\text{Q})}$, but, at present, the analysis given above is sufficient for our purpose.

It remains to be shown how the thermoelectric powers of the thermocells [8] and [9] are related to the EMF of the formation cell [5].

Thermogalvanic Electric Power and Isothermal Temperature Coefficient

It will be shown below that the EMF of the two thermocells [8] and [9] are related to the temperature coefficient $d\phi_3/dT$ of the isothermal cell [5]. Consider for this purpose the simple combination of cells given by Fig. 5. In this case, all electrodes contain the same metal, Pt. If, further, the junctions between Pt and other leads (e.g., Cu) are all at the same temperature, one can see that the reversible heats absorbed both at T_1 and T_2 cancel. It is shown in Fig. 5 how the transfer of charge results totally in zero transfer of heat. This heats Δq_{1T_1} in Fig. 5, corresponding to the last term $\Delta q'(Q)$ in Eq. [15]. This gives for the complete circuit

$$\Delta\phi_1 + \Delta\phi_3 + \Delta\phi_2 + \Delta\phi_4 = 0 \quad [32]$$

under the condition for the junctions given above. Further

$$\Delta\phi_1 = \frac{d\phi_1}{dT} \Delta T; \quad \Delta\phi_2 = -\frac{d\phi_2}{dT} \Delta T \quad [33]$$

and

$$-\Delta\phi_3 = \Delta\phi_4 + \frac{\partial\phi_3}{\partial T} \Delta T \quad [34]$$

Fig. 5. A combination of thermocells and formation cells which together give zero EMF, T_1 and T_2 are temperatures while q_1 and q_1 are absorbed heats.

Thus

$$\frac{d\phi_1}{dT} - \frac{d\phi_2}{dT} = \frac{d\phi_3}{dT} \quad [35]$$

This relation makes possible a consistency check on separate measurements, since all terms in Eq. [35] can be measured independently of each other.

Interpretation of Flux Equations for the Formation Cell

The results obtained from the analysis of the thermogalvanic cells [8] and [9] can be related to electrolysis—conditions in the isothermal cell given by Eq. [5]. Since the electrolyte is almost pure NaOH(l), $\nabla\mu_{\text{NaOH}} = 0$. The electric force of Eq. [10]-[12] is now related to the observed EMF by Eq. [4]

$$\nabla\phi = \nabla\phi^{\text{obs}} - \left(-\nabla\mu_{\text{H}_2\text{O}} + \frac{1}{2} \nabla\mu_{\text{H}_2} \right) \quad [36]$$

with traces of H_2 and O_2 present anywhere along with local test electrodes, we can assume local equilibrium and

$$\frac{1}{2} \mu_{\text{H}_2} = \frac{1}{2} \mu_{\text{H}_2\text{O}} - \frac{1}{4} \mu_{\text{O}_2} \quad [37]$$

We are then obliged to reduce the number of components by one, and have chosen to exclude O_2 . Formation of $1/4 \text{ O}_2$ is then described as formation of $1/2 \text{ H}_2\text{O}$ and removal of $1/2 \text{ H}_2$. This means that we may regard the total electrode reaction as a transfer of H_2O and H_2 . The limits for the chemical potential of H_2 are the value at the cathode and given from Eq. [37] at the anode. This means by inserting into Eq. [36] and integrating for isothermal conditions that

$$\begin{aligned} \Delta\phi &= \Delta\phi^{\text{obs}} - \left[-\Delta\mu_{\text{H}_2\text{O}} \right. \\ &\quad \left. + \frac{1}{2} \left(\mu_{\text{H}_2(2)} - \mu_{\text{H}_2\text{O}(1)} + \frac{1}{2} \mu_{\text{O}_2(1)} \right) \right] \end{aligned}$$

or

$$\Delta\phi = \Delta\phi^{\text{obs}} - \Delta G \quad [38]$$

where ΔG is the Gibbs free energy change of the formation cell, and $\Delta\mu_{\text{H}_2\text{O}} = 0$. By inserting Eq. [38] into Eq. [12], we can find an expression for $\Delta\phi^{\text{obs}}$. An equation like [34] cannot be written for the entropy, and it is thus not possible to eliminate O_2 as a component when reversible entropy changes are considered. The reversible transfer of entropy is as before the sum of the entropy changes at the electrodes and the entropy of transport in the electrolyte and metallic leads.

With a temperature gradient across the cell [5], the processes taking place will in total be identical to the processes taking place in a cell [8] with the temperature gradient in series with an isothermal cell [5]. The processes in both these cells can then be described by Eq. [10]-[12]. Alternatively, the entropy balance may be analyzed in a way similar to that shown in Fig. 4. It should be noticed, however, that, since the transport mechanism in the electrolyte is different in cell [5] from that in cells [8] and [9],

t_{NaOH} , ΔS_1 , ΔS_2 , and $\bar{S}_{(Q)}$ will have different values and thus the reversible entropy $S_{(Q)}$ absorbed from the heat reservoirs will be different. For this type of thermogalvanic cell with different electrodes, the entropy absorbed from the left-hand side heat reservoir is different from the entropy donated to the right-hand side heat reservoir.

In this section, we have focused attention on the effect of heat transport, and how this can be described when no concentration gradients are present. The presence of concentration gradients will give irreversible heat changes. Soret equilibrium is defined when migration balances diffusion ($J_i = 0$). This condition can easily be introduced in the flux Eq. [10]-[12], and can be used to quantify diffusional heat effects. This is outside the practical scope of this case.

Experimental

The thermogalvanic cell was constructed as shown in Fig. 3. Molten sodium hydroxide was contained in two separate high purity α -alumina beakers (SSA-S, 99.5%), and their electrolytic contact was achieved by a porous α -alumina bridge, which was completely wetted by molten sodium hydroxide.

A gas mixture of either H_2O and H_2 or H_2O and O_2 was supplied through a high purity α -alumina pipe to make a three-phase zone on the platinum working electrode submerged in the molten sodium hydroxide in the right-hand-side beaker. A gas mixture was prepared by passing H_2 or O_2 gas through a water pool maintained at a fixed temperature. The composition was determined by the flow rate measurement of H_2 or O_2 before passing through the water pool, together with the weight gain of a CaCl_2 column due to the absorption of the water in the gas mixture coming out from the cell. The composition determined in these ways coincided well with the value estimated from the vapor pressure data of the water. A sodium/ β -alumina reference electrode was prepared by making a liquid sodium pool at the bottom of the β -alumina tube. This tube was connected to a high purity β -alumina pipe by using alumina cement. Argon gas was supplied into the tube as a cover gas to prevent the oxidation of the liquid sodium. To obtain reversibility of the reference electrode, cathodic and anodic currents were applied alternatively through the reference electrode before thermoelectric power measurements. By this pre-treatment, wetting of the inner and outer surface of the β -alumina tube by liquid sodium and molten sodium hydroxide, respectively, was achieved to ensure good electrolytic contact.

The temperature of furnace 1 was set at a constant temperature T_1 and the temperature T_2 of furnace 2 was raised, and the electromotive force between the platinum working electrode and the sodium/ β -alumina reference electrode was measured at various T_2 values.

Results and Calculations

The results are presented in Fig. 6 and 7. From these figures, we obtain

$$\frac{d\phi_1}{dT} = -1.05 \pm 0.02 \text{ mV K}^{-1} = -101 \pm 2 \text{ JK}^{-1} \text{ F}^{-1} \quad (T_1 = 340.5^\circ\text{C}) \quad [39]$$

and

$$\frac{d\phi_2}{dT} = -1.19 \pm 0.04 \text{ mV K}^{-1} = -115 \pm 4 \text{ JK}^{-1} \text{ F}^{-1} \quad (T_1 = 336^\circ\text{C}) \quad [40]$$

These results can be checked for internal consistency by application of Eq. [35]. The isothermal temperature coefficient is

$$\frac{d\phi_3}{dT} = \frac{1}{4} S_{\text{O}_2} + \frac{1}{2} S_{\text{H}_2} - \frac{1}{2} S_{\text{H}_2\text{O}} = \Delta S \quad [41]$$

where ΔS refers to 1F. For the present conditions ($P_{\text{O}_2} =$

Fig. 6. Electromotive force of thermogalvanic cell consisting of two hydrogen electrodes (cell 8). \circ : Measured when $(T_2 - T_1)$ was increased. \bullet : Measured when $(T_2 - T_1)$ was decreased.

Fig. 7. Electromotive force of thermogalvanic cell consisting of two oxygen electrodes (cell 9). \circ : Measured when $(T_2 - T_1)$ was increased. \bullet : Measured when $(T_2 - T_1)$ was decreased.

0.8 atm, $P_{\text{H}_2} = 0.8$ atm, $P_{\text{H}_2\text{O}} = 0.2$ atm)

$$\begin{aligned} \Delta S &= \frac{1}{2} \left(150.7 + R \ln \frac{1}{0.8} \right) + \frac{1}{4} \left(226.3 + R \ln \frac{1}{0.8} \right) \\ &\quad - \frac{1}{2} \left(212.9 + R \ln \frac{1}{0.2} \right) = 20.2 \text{ JK}^{-1} \text{ F}^{-1} \end{aligned}$$

This result may be compared to the difference between the experimental results $115 - 101 = 14 \text{ JK}^{-1} \text{ F}^{-1}$ (see Eq. [35]).

A more complete analysis of the thermogalvanic cells would include independent measurements of t_{NaOH} and the entropy of transport $\bar{S}_{(Q)}$. The most important thing is, however, to estimate the single electrode heat changes at each electrode and not their difference. When the entropy of transport is to be included in the calculation of electrode compartment heat changes, they are found from Eq. [31] and [26]. Partial pressures of hydrogen and water vapor in the cathodic compartment of 0.8 atm and 0.2 atm, respectively, give 63 kJ F^{-1} evolved at the cathode. Partial pressures of oxygen and water vapor in the anodic compartment of 0.8 and 0.2 atm, respectively, give 72 kJ F^{-1} absorbed at the anode. In both cases the charge transferral is 1F at 623 K.

Conclusion

A theoretical procedure has been developed for the purpose of calculating the heat evolution at each electrode in electrochemical reactors. The heat change at the electrode includes the Peltier heat and heat reversibly transferred by the electrolyte. Thermoelectric power measurements can be interpreted by the sum of these heat changes and the heat change due to the entropy of transport.

The procedure has been illustrated by using the results obtained for water electrolysis in molten sodium hydroxide. For the conditions given, the total heat changes in the electrode compartments are 63 kJ F⁻¹ at the cathode and -72 kJ F⁻¹ at the anode.

The Mechanism of Electrodeposition of Cadmium Sulfide on Inert Electrodes from Diethylene Glycol Solutions

A. S. Baranski* and W. R. Fawcett*¹

Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1

ABSTRACT

The mechanism of electrodeposition of CdS from diethylene glycol solutions containing a cadmium salt and elemental sulfur was investigated. At fresh gold and platinum electrodes, the potential at which CdS is formed is strongly dependent on Cd²⁺ concentration and independent of sulfur concentration; the opposite is true at an electrode covered with a coherent layer of CdS. The properties of the electrodeposited films are strongly dependent on the nature of the anion in the electrolyte. In the presence of Cl⁻ and Br⁻ anions, mixed Cd-CdS films are formed under specified conditions. A detailed analysis of the effect of Cl⁻ anion showed that the results obtained were due to a change in the nature of the predominant form of Cd(II) in solution from Cd²⁺ to CdCl₂⁻.

Recently, a simple electrochemical method for depositing thin polycrystalline films of metal sulfides and selenides on conducting substrates was developed in this laboratory (1-4). In this technique, metal chalcogenides are electrodeposited at the cathode in a cell containing a solution of the metal salt and elemental chalcogen at an elevated temperature. There is a limited choice of solvents from which deposition is possible. Moreover, as one would expect, the structural and electrical properties of

the deposit are strongly dependent on the nature of the electrolyte and solvent, and composition of the solution. In a previous paper (2), it was shown that CdS grown from dimethylsulfoxide (DMSO) solutions exhibits high specific resistivity and has a tendency to crack. Similar problems exist if DMSO is replaced by other highly basic solvents such as N,N-dimethylformamide, pyridine, hexamethylphosphoramide or 1-methyl-2-pyrrolidone. However, deposition from solvents of low basicity, such as propylene carbonate, acetonitrile, or ethanol, results in the formation of a Cd-CdS mixed film. It was subsequently discovered that CdS could be grown from ethyl-

ene glycol (EG) or diethylene glycol (DEG) solutions with much better physical properties suitable for use in photovoltaic devices. DEG is more convenient in this regard because of the higher solubility of sulfur.² The physical properties of CdS film grown from DEG solutions containing 10% water by volume and saturated with sulfur have been characterized (5). In the present paper, we report the results of a study of the mechanism of CdS deposition from DEG solutions.

Experimental

The electrochemical measurements were carried out with a PAR Model 173 potentiostat. In most cases, the working electrode was a Pt wire, 0.25 mm diam and 1.5 cm long. In some experiments, a gold electrode with an area of 0.12 cm² or a glassy carbon electrode with an area of 0.3 cm² was employed. The counterelectrode was a Pt cylinder with an area of 3 cm². The reference electrode was constructed from a Cd rod immersed in a 0.05M Cd(ClO₄)₂ solution in DEG. The reference electrode system was kept at the same temperature as the main cell and was connected to it through a sintered glass disk. The temperature was maintained constant to within ±0.1°C by circulating paraffin oil from a constant temperature bath through a jacket surrounding the cell and reference electrode.

The solvent, diethylene glycol, was dried for 24h over 4Å molecular sieves and then distilled under argon at reduced pressure from a Vigreux column 1m high. The purified salts, Cd(ClO₄)₂, CdCl₂, LiClO₄, and NaI were dried for 24h at 120°C under vacuum. NH₄Cl, NH₄Br, and NH₄ClO₄ were dried for 24h at 60°C under vacuum. Sublimated sulfur was recrystallized from benzene and dried at 60°C.

Results and Discussion

The electrochemical studies of the mechanism of CdS deposition were carried out by cyclic voltammetry in DEG solutions containing LiClO₄ as supporting electrolyte in the temperature range 70°-130°C. In this medium, sulfur is reduced quasi-reversibly at gold and glassy carbon electrodes and irreversibly at platinum. The current-voltage curves were similar to those observed in other nonaqueous media for the reduction of S₈ (6): accordingly, it is assumed that the first step in the reduction process is the formation of the S₈^{•-} anion. The standard potential for the reaction S₈ + 2e → S₈^{•-} in DEG at 100°C was 0.055V against the Cd/Cd²⁺ reference electrode. Noting that the potential for the reaction Cd²⁺ + 2e → Cd is 0 V against the same reference electrode when the concentration of Cd²⁺ is 0.05M, and that the free energy of formation of CdS from metallic Cd and sulfur in a saturated DEG solution at 100°C is -139.6 kJ mol⁻¹, the reversible potential for the reaction

is 0.72V at 100°C. The potential for this process and the reduction of sulfur both depend very little on temperature.

Typical current-voltage curves observed in a DEG solution containing 0.05M Cd(ClO₄)₂ and 0.2M LiClO₄, and saturated with S₈ at various electrodes at 120°C are shown in Fig. 1. At a fresh Au electrode, a distinct prepeak is observed at 0.56V. At Pt, the peak occurs at a less positive potential and is not as sharp. In addition, the potential of the prepeak depends strongly on Cd²⁺ concentration, the potential shift being 80 mV for a tenfold increase in Cd²⁺ concentration at Pt. However, the peak potential is virtually independent of sulfur concentration (Fig. 2). If the metallic electrode is already covered with a coherent layer of CdS, the prepeak does not appear. Similar observations were made earlier for deposition from DMSO solutions (7). On the basis of the present results and those obtained earlier (7), it is concluded that the prepeak is due to the reduction of Cd²⁺ at a pre-existing layer of metal sulfide formed by reaction of the metal electrode with

² The solubility of sulfur at 120°C is 0.62 and 0.14g per 100 ml of DEG and EG, respectively.

Fig. 1. Cyclic voltammograms for the electrodeposition of CdS at (a) gold, (b) platinum, (c) glassy carbon, and (d) CdS (thickness ~1 μm) on Pt. The electrolyte solution contained 0.05M Cd(ClO₄)₂, 0.2M LiClO₄, and saturated sulfur in diethylene glycol; the sweep rate was 50 mV s⁻¹, and temperature 120°C. The electrode areas were 0.12 cm² for Pt, Au, and CdS, and 0.3 cm² for glassy carbon.

sulfur in solution; the electrode reaction results in the metal sulfide being converted to CdS. Representing the metal composing the electrode (Au or Pt) as M, the reaction scheme may be written

Strong chemisorption of sulfur on Au and Pt from DEG solutions was demonstrated experimentally in the same way as described previously for DMSO solutions (7). However, this process does not occur at glassy carbon, no prepeak being observed at this electrode.

The present investigation was chiefly directed to determination of the mechanism of CdS deposition on an electrode already covered with a coherent film of CdS. In this case, the nature of the substrate electrode has no influence on the electrode process. The study was carried out by analyzing Tafel plots (ln *i* against electrode potential) obtained for different solution compositions and at various temperatures. The electrode was prepared by covering a Pt wire (surface area ~0.12 cm²) with a layer of CdS ~1 μm thick;³ the CdS layer was deposited from the system under investigation at a constant current density of 0.25 mA cm⁻². Then, the electrode was polarized with a linearly changing potential, typically at a rate of 20 mV s⁻¹, and the current-potential curve recorded. During the experiment, the solution resistance was carefully compensated, and concentration polarization avoided by stirring the solution using a magnetic stirrer. Furthermore, only currents less than one-tenth of the limiting current were considered in the analysis. Under these conditions, the current-voltage curves were independent of the thickness of the CdS layer, the potential sweep rate, and the rate of solution stirring.

³ The thickness of the deposit was estimated assuming that the electrodeposition process consumed 100% of the charge passed, and that the density of the CdS film is the same as bulk CdS (4.82 g cm⁻³).

Fig. 2. The dependence of the half-peak potential on (a) Cd^{2+} concentration and (b) sulfur concentration for the prepeak corresponding to CdS deposition on Pt at 120°C in a DEG solution containing (a) 0.2M LiClO_4 , saturated with sulfur and varying concentrations of Cd as indicated or (b) 0.1M $\text{Cd}(\text{ClO}_4)_2$, 0.2M LiClO_4 , and varying concentrations of S_8 as indicated.

In all cases, it was found that the electrode process was controlled by irreversible electron transfer. The experimental transfer coefficient calculated from the slope of the Tafel plots was 0.57 ± 0.05 . Tafel plots obtained for

different sulfur concentrations in DEG solutions containing 0.02M $\text{Cd}(\text{ClO}_4)_2$ and 0.24M LiClO_4 are shown in Fig. 3. As the sulfur concentration increases, the plots are shifted in the direction of positive potentials. The change in the logarithm of the current density was linear with that of the sulfur concentration at constant potential; the order of the electrode process with respect to sulfur, determined from the slope of this plot, is 1.05 ± 0.1 .

In another experiment, the concentration of sulfur was kept constant and that of $\text{Cd}(\text{ClO}_4)_2$ varied from 0 to 0.1M , the ionic strength of the solution being maintained constant by addition of the appropriate concentration of LiClO_4 . The resulting Tafel plots showed no effect of Cd^{2+} concentration on the electrode process (Fig. 4). However, when the solution contained no Cd^{2+} ions, a decrease in the Tafel slope was observed at high currents. The latter result is probably due to strong adsorption of the $\text{S}_8^{=}$ anion on the CdS electrode. This adsorption may have an auto-inhibiting effect on further sulfur reduction. The Tafel plot for the reduction of sulfur on Pt from a DEG solution containing 0.3M LiClO_4 is also shown in Fig. 4. It is interesting to note that the reduction of sulfur is much more irreversible on CdS than on Pt.

On the basis of the data presented in Fig. 3 and 4, the following mechanism for CdS deposition on CdS is proposed

S_7 and other sulfur species containing less than eight sulfur atoms are expected to be more reactive than S_8 (8), and may undergo subsequent electron transfer processes

The deposition of CdS from DEG solutions was very strongly temperature dependent. Tafel plots obtained for deposition of CdS from DEG solutions containing 0.1M $\text{Cd}(\text{ClO}_4)_2$, 0.1M LiClO_4 , and saturated with sulfur are shown at various temperatures in Fig. 5. On the basis of these data, the enthalpy of activation of the electrodeposition process was found to be $95 \pm 20 \text{ kJ mol}^{-1}$.

It is interesting to note that, except at the highest temperatures, the deposition of CdS occurs at potentials more negative than the reversible potential for the

Cd/Cd⁺⁺ system. It was found that the deposition of Cd on CdS in the absence of sulfur is a fast diffusion-controlled process in this potential region. However, x-ray analysis of deposits obtained from DEG solutions at 90°C containing 0.002M S_8 , 0.1M $LiClO_4$, and varying concentrations of $Cd(ClO_4)_2$ in the range from 0.005-0.1M showed no excess of Cd in the CdS deposit. Apparently, when sulfur is present in solution, the reduction of Cd⁺⁺ is strongly inhibited by the adsorption of molecular sulfur on the surface of the CdS electrode.

In previous work (5), it was found that addition of small amounts of water to the electroplating solution significantly improved the adhesion of the electrodeposited CdS film to the substrate. In the present study, it was shown that addition of water in quantities up to a mole fraction of 0.57 (~20% H_2O by volume) had a surprisingly

small effect on the deposition process (Fig. 6). The observed change in the slope of the Tafel plots is probably caused by a change in double layer structure at the semiconductor/solution interface.

The role of the supporting electrolyte in the electrode process was also studied. It was shown that the cation does not play any significant role, the same Tafel plots being obtained when Li^+ was replaced by Na^+ , K^+ , or NH_4^+ . However, the role of the anion is very important. Replacement of ClO_4^- by BF_4^- , $CH_3SO_3^-$, Cl^- , or Br^- usually resulted in the formation of a dark dendritic deposit composed of a mixture of Cd and CdS. The effect of halide ions was particularly interesting and was studied in more detail. In this regard, the percentage of metallic Cd in a mixed Cd-CdS deposit was determined by chronopotentiometry. When a mixed film is deposited at

The ordinate scale is logarithmic.

Fig. 6. Tafel plots for the deposition of CdS on a Pt electrode covered with a coherent film of CdS at 110°C from a DEG solution saturated with sulfur and containing 0.1M $\text{Cd}(\text{ClO}_4)_2$, 0.1M LiClO_4 , and different amounts of water: (a) 0; (b) 5%; and (c) 20% by volume. The ordinate scale is logarithmic.

constant current by reduction, only the metallic Cd is oxidized when the current is reversed. Thus, the ratio of the transition time in the oxidation process to the reduction time is equal to the mole fraction of Cd in the deposit. This experiment was carried out under conditions for which the mixed deposit is not too thick, thereby ensuring that all available Cd was oxidized on current reversal. Chronopotentiometric experiments were run with varying concentrations of NH_4Cl , NH_4Br , NaI , and water at different temperatures. Some of the results are presented in Fig. 7. The addition of iodide anion had no effect on the ratio of Cd to CdS in the deposit, pure CdS being formed over the entire concentration range studied. However, in the cases of Cl^- and Br^- anions, pure CdS can be electrodeposited only when the concentration of these ions is very low or very high. Lowering the temperature, or adding water to the deposition bath results in a slight decrease in range of concentrations over which pure CdS can be deposited, but the general characteristics of the dependence remain the same.

In order to investigate the role of halide ions further, the stability constant for formation of the CdX_4^{2-} ion was determined on the basis of EMF measurements using the following cell

where X represents Cl^- , Br^- , or I^- , and the solvent contained 10% H_2O by volume. In the presence of the large excess of halide ions the tetrahalocadmium(II) ion (CdX_4^{2-}) was formed with the logarithm of the stability constant ($\log \beta_4$) equal to 8.4, 9.0, and 9.9 for Cl^- , Br^- , and I^- , respectively, at 110°C. In Fig. 8, the equilibrium potentials for the $\text{Cd}/\text{CdCl}_r^{2-r}$ system (curve a) and the potentials for deposition of CdS at a current density of 0.5 mA cm^{-2} (curve b) are shown as a function of the Cl^- ion concentration in the DEG solution. It is noteworthy that for Cl^- concentrations less than $0.002M$, the deposition of pure CdS occurs at a potential about 100 mV more negative than the equilibrium potential for the $\text{Cd}/\text{CdX}_r^{2-r}$ system. This was attributed to strong inhibition of Cd^{++} reduction by adsorbed molecular sulfur on the CdS sur-

face. However, as the Cl^- ion concentration increases, the inhibition by sulfur becomes less effective, probably because Cl^- ions are coadsorbed on the CdS surface and provide bridging sites for the adsorption of Cd^{++} (9). As a result, a mixture of Cd and CdS is formed in the electrode process, and the overpotential decreases. For higher Cl^- ion concentrations, a substantial shift in the $\text{Cd}/\text{CdCl}_r^{2-r}$ equilibrium potential in the negative direction is observed due to formation of the complex ions CdCl^+ , CdCl_2 , CdCl_3^- , and CdCl_4^{2-} . Finally, when the $\text{Cd}/\text{CdCl}_r^{2-r}$ potential becomes more negative than the potential for CdS formation, pure CdS is deposited in the electrode process. The higher overpotential for CdS formation in the presence of high Cl^- ion concentrations is attributed to the inhibiting effect of adsorbed Cl^- ions on the reduction of sulfur.

Fig. 7. The percentage of CdS in mixed Cd-CdS deposits obtained from solutions containing halide ions against the logarithm of the halide ion concentration. The electrolyte solution in DEG was saturated with sulfur and contained 0.05M $\text{Cd}(\text{II})$ and 10% H_2O by volume. The deposition current was 0.5 mA cm^{-2} , and the temperature 110°C.

Fig. 8. A plot of (a) the equilibrium potential for the $\text{Cd}/\text{CdCl}_x^{2-x}$ couple and (b) the deposition potential for mixed Cd-CdS films against the logarithm of chloride ion concentration in the electroplating bath. The electrolyte solution in DEG was saturated with sulfur and contained 0.05M Cd(II) and 10% H_2O by volume. The deposition current was 0.5 mA cm^{-2} , and the temperature 110°C .

The addition of Cl^- ions to the electroplating bath causes marked changes in the orientation of the electrodeposited CdS crystallites (5). For Cl^- ion concentrations less than 0.005M, the crystallites are randomly oriented, but for Cl^- ion concentrations greater than 0.5M, they are strongly oriented with the c-axis perpendicular to the substrate. It is reasonable to assume that the extent of Cl^- ion adsorption varies with the crystallographic orientation of the exposed CdS face. This will result in differences in the rate of growth of different faces of the crystallites, and consequently, the promotion of one orientation in thicker deposits.

Conclusions

The growth of CdS during electrodeposition from DEG solution at a CdS surface is controlled by the reduction of sulfur. The anion formed in the electrode process, presumably S_8^{2-} , subsequently reacts with Cd^{2+} , causing the deposition of CdS. The process is strongly affected by the nature of the anions in the electrolyte. In the case of ClO_4^- anion, which is probably not strongly adsorbed on the electrode, the deposition of CdS occurs at potentials more negative than the standard potential of the Cd/Cd^{2+}

system. However, the reduction of Cd^{2+} and subsequent formation of a Cd-CdS mixture is inhibited, most likely, by the adsorption of molecular sulfur on the CdS surface. This inhibition is not as effective in the presence of Cl^- or Br^- anions. In this case, the deposition of pure CdS is only possible if the equilibrium potential of the $\text{Cd}/\text{Cd(II)}$ system is shifted by complex ion formation to a potential more negative than the reduction potential of S_8 at CdS.

The formation of the first monolayer of CdS on metallic electrodes occurs by a different mechanism. In this case, the rate of reaction is independent of sulfur concentration but depends strongly on Cd^{2+} concentration. These observations are attributed to the initial formation of a monolayer of metallic sulfide on the metal electrode which is reduced to CdS at the appropriate potential in the presence of Cd^{2+} ions. The initial stages of the formation of CdS in DMSO were also studied at gold electrodes by Roe *et al.* (10), who concluded that the first monolayer was formed by reaction of sulfur with cadmium already on the electrode as a result of underpotential deposition. No evidence in support of their proposal was obtained in our earlier work (7) or in that reported here.

Thin Film CdSe Electrodeposited from Selenosulfite Solution

Michael Cocivera,* Andrzej Darkowski, and Bruce Love

Guelph Waterloo Center for Graduate Work in Chemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1

ABSTRACT

Thin film CdSe on titanium is electrodeposited by reduction of an aqueous solution containing the selenosulfite anion and a nitrilotriacetate complex of cadmium ion. Films having thickness between 1.3 and 2.6 μm and surface areas of 1 cm^2 give photoconversion efficiencies between 5.5% and 5.9% when used in a photoelectrochemical cell and illuminated with an ELH lamp.

A number of workers (1-4) have reported the preparation of thin film CdSe for solar cells by means of electrodeposition from an aqueous solution containing Cd^{2+} and H_2SeO_3 . A substantial excess of selenium is detected in

*Electrochemical Society Active Member.

films prepared in this manner (1, 3). To remove a major portion of this excess, the films must be annealed at temperatures as high as 750°C (3).

It has been suggested that selenium incorporation occurs according to the reaction

Consequently, use of a selenium precursor that is formally in a lower valence state might avoid undesirable side reactions of this type. For this purpose, we have developed (5) an electrodeposition process that involves the reduction of selenium, which is in the form of the selenosulfite anion SeSO_3^{2-} . This species is prepared *in situ* by dissolving elemental selenium in an aqueous sodium sulfite solution. The selenosulfite anion has also been employed to form CdSe films by a chemical process rather than an electrochemical process (6). In addition, thin film CdSe has been electrodeposited from cyanide solution in which elemental selenium has been dissolved; however, the reported efficiencies are low (7).

We find that electrodeposition of CdSe from aqueous selenosulfite solutions results in films having a Cd/Se ratio close to 1. The process consistently provides 1 cm² films having efficiencies between 5.5% and 5.9% for conversion of light power into electrical power using unfiltered light from an ELH lamp. Furthermore, the solution seems fairly stable since a 24h old solution provides films that also have efficiencies around 5.5%. Selenosulfite electrodeposited films appear to adhere quite well to titanium, whereas flaking has been reported for films electrodeposited from H_2SeO_3 solutions (4). A similar problem has been found for films grown by the chemical bath process using selenosulfite solution unless the film is grown in stages (6). In addition, the chemical bath solutions apparently cannot be used for periods longer than about 1h (6). Selenosulfite has been used previously under conditions that are different from those presented below to electrodeposit CdSe films, which were reported to be of inconsistent quality and had a maximum of only 1% light conversion efficiency (8).

Experimental

Electrodeposition of CdSe.—Thin film CdSe is deposited at a titanium cathode at room temperature using a two-electrode cell in which the anode is cadmium metal. A constant potential of 0.30V between these electrodes was maintained using a Bioanalytical Systems (BAS) CVIB. Under these conditions, there is an initial transient reduction current that decays to near zero in about 10s. The current density then gradually increases to 0.34 mA/cm² over a period of ca. 100s and continues to increase gradually to 0.47 mA over a period of 15 min. By including a saturated calomel electrode (SCE) in the cell, we find that the titanium electrode potential is -1.07V vs. SCE .

The electrodeposition solution is prepared by mixing 30 ml of aqueous selenosulfite solution with 10 ml of aqueous cadmium nitilotriacetate solution. The selenosulfite solution is prepared by dissolving 0.120g of elemental selenium powder (0.050 molar) in an aqueous solution containing 3.0g of sodium sulfite (0.75 molar) at pH 9. The cadmium solution was prepared by dissolving 0.20g of $\text{CdCl}_2 \cdot 2.5\text{H}_2\text{O}$ (0.088 molar) into an aqueous solution containing 0.103M sodium nitilotriacetate (NTA) at pH 8. After mixing, the combined solution remains clear and colorless over a period of about 8h. Over a period of 24h, a very thin redish brown film of either CdSe or Se forms on the walls of the flask; however, the solution remains clear and colorless. The electrodeposition is performed at pH 9 and room temperature using an air-saturated solution. The anode is not isolated from the cathode. Magnetic stirring is maintained during deposition.

Preparation of the titanium electrode prior to film deposition involved abrading the rectangular titanium plates using no. 400 emery paper. The plate was then soaked in chromic acid at 90°C for 3 min, rinsed in distilled water, and soaked in ca. 1M sodium hydroxide at 80°C for 5 min. It was then rinsed in distilled water and dried.

Electrolysis for 1h provides a film thickness of 1.3-1.6 μm . This thickness is determined in two ways. First, the weight of the film scraped from molybdenum foil was compared with the tabulated density of CdSe (9). Second, a Sloan Dektak stylus-type device was used at two posi-

tions on a CdSe film deposited on indium tin oxide-coated glass. Based on the weight of the film and the number of coulombs passed, the electrodeposition appears to be 88% efficient. The weight of the film was determined after the film has been annealed at 500°C. At this temperature, vaporization of the film does not appear to be extensive.

Cyclic voltammetry.—Cyclic voltammetry (CV) at the titanium electrode was performed with the BAS CVIB in a three-electrode cell containing the SCE as the reference electrode and cadmium metal as the auxiliary electrode. In addition to the electrodeposition solution, measurements were made at room temperature on a solution containing only the selenosulfite, on a solution containing only the cadmium complex, and on a solution of cadmium ion in the absence of NTA.

Composition of CdSe film.—Two methods were used to determine the composition of the film: polarography and Rutherford backscattering spectroscopy (RBS). For the polarographic determination, the analytical solution was prepared by treating the film on titanium with nitric acid at 50°C to dissolve cadmium as Cd^{2+} and selenium as H_2SeO_3 . The $E_{1/2}$ for the reduction waves for Cd^{2+} and H_2SeO_3 occur at -0.745 and -1.500 (SCE). The polarographic analysis gives a Cd/Se ratio of 1.2. Preliminary RBS analysis of the surface composition of the CdSe film indicates a similar ratio (1.1 ± 0.1). More extensive studies of surface and depth profiles will be reported later. For this analysis, a 3 MV Van de Graaff accelerator provided 1.6 MeV helium nuclei.

Surface morphology.—An Etec Autoscan scanning electron microscope that employs the backscattered electron technique was used to observe the surface structure of the film before and after various annealing treatments. Photographs of the micrographs were taken on Kodak FXP/20 film using a Graphex lens and aperture.

Performance.—The photoresponse of the CdSe film was determined in a photoelectrochemical cell (PEC) using an aqueous solution containing 1/1/1M $\text{Na}_2\text{S}/\text{S}/\text{NaOH}$. The two-electrode cell contained the CdSe photoanode connected by a variable resistor (EICO resistance decade box) to a cathode that consisted of brass wire mesh coated with Cu_2S (10). No external bias was applied. The voltage across the load was measured with a digital voltmeter. Unfiltered light from a 300W CGE Quartzline ELH lamp was used. Power output from the lamp was determined with an Eppley thermopile. Prior to power measurements, the films were etched in 9N HCl, soaked in 1N NaCN, and treated with 1M ZnCl_2 (11).

Results and Discussion

The selenosulfite anion and the cadmium complex are made *in situ* in separate solutions, which are then mixed. The selenosulfite anion is prepared by dissolving elemental selenium in 0.6M sodium sulfite. The cadmium complex is prepared by dissolving cadmium chloride in 0.028M sodium nitilotriacetate. The cadmium complex [stability constant $10^{9.8}$ (12)] is used to reduce the concentration of free cadmium ion. Otherwise, the chemical reaction (6, 13)

occurs to an appreciable extent during the time of the electrolysis. By means of this complex, the solution remains stable for at least 24h. Furthermore, control experiments indicate that this chemical reaction provides no detectable CdSe film on the titanium during the period used for the electrolysis.

The CdSe film is electrodeposited at a titanium cathode from an air-saturated aqueous solution containing 0.02M selenosulfite anion and 0.02M cadmium cation complexed to nitilotriacetate anion. This deposition is performed at room temperature and pH 9 using a two-electrode cell in which cadmium metal is employed as the anode. A constant potential of 0.30V is maintained be-

tween the electrodes, giving a current density that gradually rises from 0.34 to 0.47 mA/cm² during the deposition period. A time period of 1h provides a film thickness between 1.3 and 1.6 μm . So far, these conditions provide the CdSe film with the best light power to electrical power conversion efficiency (5.5-5.9%) for this system. Furthermore, these conditions provide consistent quality films from one solution to the next. Five solutions gave films having efficiencies between 5.5% and 5.9%. An added advantage is that the solutions are sufficiently stable so that electrolyses can be repeated several times. In addition, solutions left overnight without any special protection provide films with photoconversion efficiencies as good as those obtained from fresh solutions.

The film on titanium appears dark gray with a slight sheen. It adheres well to titanium. Adhesion to other substrates, such as molybdenum, platinum, and indium tin oxide-coated glass, is not as good. Polarographic analysis indicates that the ratio Cd/Se is 1.2 in the film, and Rutherford backscattering spectroscopy indicates a ratio of 1.1 ± 0.1 using the surface energy approximation (14). Based on this composition, comparison of the weight of the films with the number of coulombs passed indicates that the efficiency of the electrodeposition process is 88%. For this determination, the film was annealed at 500°C for 30 min.

Prior to photoconversion efficiency measurements, the CdSe film was annealed in air to 550°C for 30 min to activate it. We found that this temperature provided suitable activation without causing substantial loss of material due to vaporization. A similar observation has been reported earlier (6). Careful temperature control seems to be important since films annealed at 500° and 550°C give photoconversion efficiencies of 4.5% and 5.8%, respectively, at 70 mW insolation. Above 550°C, vaporization appears to become significant. After annealing, the surface of the film was prepared by etching with 9N HCl, soaking in 1N NaCN, and treatment with 1M ZnCl₂ (10).

The efficiency for the conversion of light power into electrical power was determined using a photoelectrochemical cell (PEC) that contained an aqueous solution of Na₂S/S/NaOH in the molar ratio 1/1/1. In this cell, the CdSe photoanode was connected by a variable resistor to the counter electrode, which consisted of brass mesh coated with Cu₂S (11). No external biasing was applied. The photovoltage across the resistor was measured using a digital voltmeter. Unfiltered light from a Quartzline ELH lamp was used for excitation. The photovoltage measured in this manner for the film were quite stable with no appreciable variation during irradiation for periods up to 15 min. Dark voltages were negligible at all loads below 1 k Ω . Above 1 k Ω , the dark voltage increased with resistance to a maximum value around 50 mV at open circuit.

Fig. 1. Photocurrent/photovoltage results for 1 cm² CdSe films at two thicknesses: (□) 1.3 and (X) 2.6 μm . Conditions: PEC containing aqueous polysulfide; 70 mW unfiltered light from an ELH lamp; no externally applied bias.

Figure 1 illustrates the photocurrent/photovoltage characteristics for two CdSe films having thicknesses of ca. 1.3 and 2.6 μm . There appears to be little difference between the results at the two thicknesses. For three 1 cm² CdSe films (ca. 1.3 μm thick) deposited from three separate fresh solutions, the average efficiency for the conversion of light power to electrical power is $5.74 \pm 0.09\%$ for 70 mW insolation. For these samples and those discussed below, the dark voltages were usually negligible, *i.e.*, no more than one or two millivolts except at open circuit, for which the dark voltage could be as large as 50 mV. Open-circuit photovoltages at 70 mW insolation are typically between 600 and 700 mV. Variation between 40 and 100 mW insolation gave open-circuit photovoltages in this range also. The photoresponse of each film was quick; response time appeared to be limited by the response of the voltmeter. At all loads, the photovoltage/photocurrent was stable during the illumination period, typically about 15 min. Short-circuit current density at 70 mW insolation was in the range 12.4-14.4 mA/cm² and fill factors were in the range 0.40-0.47. Figure 2 illustrates the photoresponse as a function of light power. The conversion efficiency decreases somewhat as the light intensity increases. Thus at 40, 70, 80, and 100 mW insolation, the conversion efficiency is 5.9%, 5.9%, 5.1%, and 4.7%, respectively, for a film having a surface area of 1 cm². When the surface area was increased to 3.2 cm², the efficiency decreased to 4.0% at 70 mW. Aging the electrolysis solution does not appear to adversely affect the quality of the film. Thus a conversion efficiency of 5.4% is obtained for a film grown from a solution that has been exposed to air for 24h at room temperature.

The effect of other conditions on the properties of the CdSe film are currently under study. Preliminary results indicate that current densities higher than 0.500 mA/cm² give films having efficiencies somewhat lower (ca. 5.0%). Larger selenosulfite anion concentrations have a similar effect.

Scanning electron microscopy reveals the effect of temperature on the surface morphology of the CdSe film. Figure 3A illustrates the surface morphology of the CdSe film on titanium after deposition for 1h and prior to any temperature treatment. At the present time, it is not clear if the cracks occur during electrodeposition or if they result when the film is dried at room temperature. The characteristic cauliflower appearance (3) found for H₂SeO₃-grown CdSe is not evident with our film. Annealing at 500°C for 30 min followed by 9N HCl etch gives the surface illustrated in Fig. 3B. The consequences of the annealing on the surface are not clear at this time.

A cyclic voltammogram (CV) of the deposition solution at room temperature is illustrated in Fig. 4. Second and subsequent scans exhibit currents higher than the first one given in Fig. 4, and the first peak shifts 70 mV in the positive direction. The CV's were obtained under condi-

Fig. 2. Photocurrent/photovoltage results as a function of light flux for 1 cm² CdSe film 1.3 μm thick in PEC containing aqueous polysulfide. □: 40 mW + 70 mW. ◇: 80 mW. △: 100 mW.

tions very close to those employed for film preparation, *i.e.*, same concentrations and electrode except the surface area of the titanium was reduced to 0.08 cm².

For several reasons, the details of the electrodeposition process are not clear at this time. First, CV of Cd²⁺ + NTA exhibits a peak at potential close to that in Fig. 4. Second, CV of SeSO₃²⁻ exhibits peak 200 mV more negative than first peak in Fig. 4. Third, in both these cases, the current is not enhanced on the second and subsequent scans. Fourth, polarographic studies of the reduction of the various species alone and when mixed indicates that the mixture exhibits an additional wave that may result from an interaction between SeSO₃²⁻ and either free or complexed cadmium ion. Consequently, the results thus far indicate several possibilities that are currently under study.

Reduction of CO₂ on n-GaAs Electrodes and Selective Methanol Synthesis

K. W. Frese, Jr.* and D. Canfield

SRI International, Materials Research Laboratory, Menlo Park, California 94025

ABSTRACT

Faradaic efficiencies and current voltage characteristics for the reduction of CO₂ to CH₃OH on n-GaAs (111 As) single-crystal electrodes have been determined. The yield of CH₃OH is ~ 100% for current densities of ~ 140 μA/cm² at -1.2 to -1.4V vs. SCE. The excess current due to CO₂ was found to have a threshold at pH ~ 3.6 and a maximum at pH ~ 4.3. The current also exhibited a rotation-independent *j/v* characteristic that is interpreted as a rate-determining surface chemical combination step involving adsorbed H atoms and a carbon containing intermediate. The pH dependence of the saturation current is modeled with a kinetic scheme involving the parallel reduction of H⁺ and CO₂.

Over the past 40 years, there have been a number of studies dealing with CO₂ reduction at metal electrodes (1, 2). Recently, we have been investigating the reduction of CO₂ at semiconductor electrodes. One goal of the semiconductor approach is to utilize the electrochemical properties of p-type photocathodes to convert sunlight and CO₂ into useful fuels. It is known that CO₂ can be reduced to methanol and small amounts of methane on certain semiconductor electrodes in aqueous solutions (3-6). Our results (7) on electrolysis of CO₂ solutions using n- or p-GaAs and p-InP electrodes show that methanol is the major product (pH 4-6). These studies involving semiconductor electrodes, however, have mainly concerned product identification and yield.

Our purpose is to investigate aspects of the kinetics of CO₂ reduction on semiconductor electrodes. In this paper, we report measurements of the current voltage characteristics of a rotating disk n-GaAs electrode as a function of pH and rotation rate in the presence of N₂ and CO₂.

The faradaic efficiency for CH₃OH as a function of current density has also been determined. The results, especially the saturation current for CO₂ reduction, are modeled by kinetic analysis of a set of tentative elementary steps.

Experimental

Single-crystal disks, 5 mm diam, were mounted in a Pine Rotating-ring disk arrangement. Rotation speed was controlled by means of a Pine analytical rotator.

The crystal face was n-GaAs (111 As). The electrodes were first etched with 1% Br₂/CH₃OH and rinsed for 10s with 1M HCl. The GaAs electrodes were further etched in 1% sodium hypochlorite/0.1M Na₂ EDTA at pH 10. All etching was done with a wet cotton tip applicator. Finally, all electrodes were rinsed with distilled water.

All solutions were prepared with distilled, deionized water and reagent-grade chemicals, unless otherwise noted. High purity N₂ was passed through the electrolyte to remove dissolved oxygen. The electrode potential was swept at 1 V/min by means of a Pine RDE-3 potentiostat. The initial voltage for all sweeps was -0.5V SCE. All experiments were performed at room temperature, 22°C.

Electrolyte pH was controlled by addition of H₂SO₄ or NaOH solutions. When pH was varied, it was checked before and after each scan to make sure it had not changed.

Experimental Results

Current-voltage curve.—Current-voltage curves for n-GaAs (111)As in N₂-saturated and CO₂-saturated 0.2M Na₂SO₄ electrolyte (pH = 4.0) are shown in Fig. 1. Before these curves were obtained, the rotating disk electrode was held at -1.2V vs. SCE in the same N₂-saturated electrolyte but with pH = 3.4 and 1600 rpm rotation speed. It was observed that the current increased with time until a steady current of 2.5 mA/cm² was reached after a period of about 10 min. A typical current-time curve is shown in the inset

in Fig. 1. This pretreatment was chosen because we wanted to make measurements with the surface conditions close to those obtained in our extended electrolysis experiments (7) that are performed at -1.2 to -1.4V vs. SCE in a similar electrolyte (pH = 4-5). In those experiments, we always observed changes in the initial current voltage characteristics for about 30-60 min, then steady conditions are found for at least 70h. The probable cause for the longer current transient is that the pH is higher than in the present case.

Returning to Fig. 1, the onset for excess current due to CO₂ is -0.95V. Both curves with N₂ or CO₂ showed saturation behavior starting to -1.1 to -1.2V. This portion of the curve corresponds to diffusion-limited H⁺ reduction, and in the case of CO₂ solution to the simultaneous reduction of H⁺ and CO₂. Beyond -1.4V, a steep rise in current was observed with either gas present. This current is apportioned between H₂O and CO₂ reduction. It should be noted that the pH of the electrolyte was constant before and after each measurement. The saturation currents (N₂ present) depended on rotation speed, but the magnitude of the excess current due to CO₂ was almost constant up to -1.4V at pH 4.

Effect of rotation speed.—Figure 2 illustrates the dependence of the excess current in the presence of CO₂ as a function of rotation rate and electrode potential. These curves were constructed by direct subtraction of points on the N₂ and CO₂ curves at each voltage. The rotation rate was varied from 100 to 2500 rpm. This electrode was also pretreated as in Fig. 1. It can be seen that at pH 4.2, the excess CO₂ current was independent of rotation speed and showed saturation behavior over a voltage range between -1.15 and -1.40V. The saturated current density was ~ 1.4 × 10⁻⁴ A/cm². At potentials negative of -1.4V,

an increase in excess current was observed. This characteristic also appeared to be independent of rotation rate.

A more detailed study of the rotation dependence of the cathodic current in the presence of N₂ or CO₂ was made. The results are shown in Fig. 3. With only N₂ present at pH = 4.2, a diffusion-limited H⁺ reduction wave was obtained as shown by the linear plot of i vs. (rpm)^{1/2}. A diffusion coefficient of 7.0×10^{-5} cm²/s was calculated from the slope assuming a proton activity coefficient (8) of 0.76. This diffusion coefficient was obtained at 22°C; correction to 25°C using 3.1 kcal/mol (9) activation energy yields 7.4×10^{-5} cm²/s, in good agreement with data obtained in KCl electrolyte (9). When the electrolyte was saturated with CO₂, plots of i vs. (rpm)^{1/2} were again linear with nearly the same slope as in the N₂-saturated case. Importantly, the intercepts of these plots were nonzero and depended on the electrode potential. A plot of the intercept vs. potential is shown in the inset to Fig. 3. Note the similarity of this i-V curve obtained in CO₂-saturated solution and those shown in Fig. 2 that were calculated by difference from data pairs in CO₂ and N₂ saturated electrolytes at constant rotation speed.

Effect of pH.—Cathodic current vs. pH and electrode potential was measured in both N₂- and CO₂-saturated electrolytes. The results for a rotation speed of 400 rpm are shown in Fig. 4. The lower curves in each panel correspond to the N₂ case, and the upper curves to the CO₂ case. In order to obtain reproducible results over the whole pH range that we investigated, we had to etch the

crystal before each i-V scan at a given pH. Therefore, the electrode was given the same etch pretreatment before each data point in Fig. 4. This treatment consisted of a 2s rinse in 1M HCl, 10s distilled H₂O rinse, followed by a 20s etch with 1% v/v sodium hypochlorite in pH 9 aqueous solution, and final H₂O rinse. In all cases, the etched electrodes shed rinse water immediately on contact. Generally, these surfaces are considered to be much closer to stoichiometric than the cathodically pretreated ones (Fig. 1-3). In the pretreated case, some surface roughening and cathodic corrosion giving at least a Ga monolayer is expected.

Inspection of the curves in Fig. 4 reveals that excess CO₂ current was first detected at pH values of 3.6, 3.7, 3.7, and 3.9 for -1.1, -1.2, -1.3, and -1.4V, respectively. The reaction orders for H⁺ reduction with N₂, $d \log i/dpH$ were 0.37, 0.95, 0.91, and 0.97 for the same electrode potentials. The numbers were calculated from the straight lines in the most acid region of the plot. These unit reaction orders are consistent with diffusion-controlled reduction of hydrogen ions. Another approximate calculation of D_{H^+} was performed by extrapolation of the current at -1.3V (N₂ present) to pH = 0. A diffusion coefficient of 7.0×10^{-5} cm²/s was found, in good agreement with our earlier determination. Under less acidic conditions, the reaction order approached zero and then came close to unity again. The deviation in reaction order with respect to the hydrogen ion may be caused by reduction of a thin (perhaps mono) layer of adsorbed species which are more stable at certain pH values. We assume this effect is constant for both N₂- and CO₂-saturated electrolytes. The electrolyte was saturated with CO₂, and the i-V curves at each pH were determined, again, after a standard etch for each pH value. The general pattern was that the apparent reaction order with respect to hydrogen ion decreased when CO₂ was present.

Then, plots of $i_{CO_2} - i_{N_2}$ vs. pH at a fixed potential were constructed; the results are shown in Fig. 5. The excess current began at a pH of 3.5-3.9 and increased to a maximum at pH 4.3 and then, depending on voltage, increased sharply again.

Finally, the $i_{CO_2} - i_{N_2}$ data were plotted vs. electrode potential with pH as a variable, as shown in Fig. 6. Strikingly different i-V curves at each pH were observed. The onset potential was similar to that already observed in Fig. 1 and 2, namely, $\sim -1.0V$. At pH 4.0, a saturation current was also found between -1.2 and -1.4V. As the pH increased, the saturation portion narrowed and a sharp increase became very noticeable. At pH 6, the saturation characteristics completely disappeared. Tafel plots of the

ferent Na_2SO_4 electrolytes that were saturated with CO_2 , initial pH 4.2. The details of these experiments, analytical procedures, and more complete results have been tabulated (7). The objective was to determine the reduction products and obtain faradaic efficiencies.

Analysis for methane, methanol, formaldehyde, and CO was performed. The electrolysis was conducted at various current densities (based on geometrical area) using n-GaAs (111)As crystals similar to those that were used in the *i-V* measurements reported above.

Occasionally, only traces of CH_4 were observed. Faradaic efficiencies for formaldehyde were always very low, $< 1\%$. Also, efficiencies for CO were usually $\sim 1\%$. However, the efficiencies for methanol were high and depended on current density, as shown in Fig. 7. Note that in an electrolyte made from 99.999% Na_2SO_4 and high purity water, no methanol was formed. This effect will be discussed more fully in later reports. The results with the Ga (111) face were similar except that methanol was produced in either reagent-grade or high purity electrolyte.

At a current density of $\sim 1.4 \times 10^{-4} \text{ A/cm}^2$, the efficiency for methanol was 100%. At $5 \times 10^{-4} \text{ A/cm}^2$, the methanol efficiency dropped to low values with either face.

Electrolysis of similar electrolytes at pH 5.8-6, gave some formate ion product, as shown by qualitative analysis using the mercuric chloride test (10). Formate has been shown to be the major product on Hg electrodes (11) in this same pH range. Methanol has also been found at pH up to 6.7 with current efficiencies $> 10\%$.

Discussion

In this section, we will discuss our results in light of a plausible reaction mechanism for CO_2 reduction. A number of key experimental observations can be summarized as follows. The excess current due to CO_2 saturates at $\sim 140 \mu A/cm^2$ (cathodically pretreated surface, Fig. 2 and 3) and at $\sim 90 \mu A/cm^2$ on an as-etched surface (Fig. 6). This saturation current is independent of rotation speed from 100 to 2500 rpm. This behavior suggests that the current is controlled by a chemical surface reaction with nearly saturation coverage with adsorbed intermediates. The faradaic efficiency for CH_3OH reaches 100% at a current density of $\sim 140 \mu A/cm^2$. This value is remarkably close to the saturation current for a similarly activated electrode. Also, the pH has a pronounced influence on the excess current, $i_{CO_2} - i_{N_2}$. Two critical pH values were found (Fig. 5); a low value when the excess current is immeasurably small, and a higher value where a maximum occurs. Finally, the reduction of H^+ is diffusion controlled in the presence of CO_2 (Fig. 3). According to the analysis of Pleskov (12), plots of current density vs. $(rpm)^{1/2}$ like those in Fig. 3 (CO_2 present) indicate that rapid diffusion-controlled H^+ reduction occurs in parallel with a slower

Fig. 7. Faradaic efficiency for CH_3OH on n-GaAs in CO_2 -saturated $0.2M \text{ Na}_2\text{SO}_4$. Open symbols = reagent grade salt/distilled water. Solid symbols = 99.999% salt/ $1.7 \times 10^7 \Omega \cdot \text{cm}$ water. $10^{17} \text{ donors/cm}^2$.

activation-controlled process. This factor is used in formulating the parallel reaction mechanism below. An increase in current at more cathodic voltages (Fig. 2 and 6) indicates a change in mechanism. At pH values 5-6, Tafel slopes of 220-230 mV/decade were observed. We will first focus on the saturation current and the effect of pH.

The data presented here do not, of course, allow for identification of the chemical species involved in all the mechanistic steps. However, the data do provide important clues concerning the overall reaction sequence and the rate-determining step in CO₂ reduction to methanol.

In the following discussion, we will assume that under reaction conditions, the GaAs rotating disk electrode surface contains adsorbed hydrogen atoms. It is further assumed that the steady-state coverage with hydrogen, θ , is mainly controlled by the convective diffusion of H₃O⁺ ions. The value of θ will depend on the rate of removal of H atoms and the diffusion properties. In the following, the subscript "a" indicates adsorbed on the surface. When the combination reaction is rate determining in the hydrogen evolution reaction, HER, we have

By equating the current for Eq. [1] with the Levich equation (12), we obtain

$$\theta = \left(\frac{A}{k_c} \right)^{1/2} (\text{rpm})^{1/4} (\text{H}^+)^{1/2} \quad [2]$$

where $A = 0.017 (D_{\text{H}^+})^{2/3}$, D and H^+ are expressed in units of 10⁻⁵ cm/s and mol/liter, respectively. Similarly, when the electrochemical desorption is rate determining

and

$$\theta = \frac{A(\text{rpm})^{1/2}}{k_g} \quad [4]$$

According to Eq. [2], the hydrogen coverage depends on the square root of the proton concentration and depends slowly on rotation rate. For the second case of electrochemical desorption, θ is independent of H^+ and varies more strongly with stirring.

Now, consider the following elementary scheme of steps to account for the saturation of $j_{\text{CO}_2} - j_{\text{N}_2}$ and its pH dependence.

followed by four additional hydrogenation steps to give methanol via additional intermediates, I. We have no specific evidence for the identity of these intermediates, I. For example, I in step [IV] could be CO_{ad}. For H₂ and CH₃OH reduction products, n would equal seven. Adsorbed formate radicals are believed to be the precursor to CO₂ in the oxidation of formic acid (13) and to be the product of the one electron reduction of CO₂ on Hg electrodes (11, 14).

The key to explaining the saturation current and its pH dependence is the assumption that the rate of CO₂ reduction (methanol formation) is limited by a surface chemical reaction involving H_a. For simplicity let us say that step [IV] is rate limiting. The total current in the presence of CO₂ is then given by

$$j_{\text{CO}_2} = 2k_c\theta^2 + 6k_4\theta\gamma \quad [5]$$

where γ is the surface coverage with formate radicals. An expression for γ can be obtained by the usual steady-state method. Under saturation conditions, we simply write $\theta + \gamma = 1$. Other analogous rate-determining steps involving H_a and species I would lead to a relation similar to Eq. [5] (consecutive step reaction). Using our expression for θ (combination reaction) Eq. [2], and conservation of sites, we obtain the following expression for the experimentally determined $j_{\text{CO}_2} - j_{\text{N}_2}$

$$j_{\text{CO}_2} - j_{\text{N}_2} = 6k_3B(\text{H}^+)^{1/2} [1 - B(\text{H}^+)^{1/2}] \quad [6]$$

where

$$B = [A/k_c]^{1/2} (\text{rpm})^{1/4}$$

According to Eq. [6], the excess current should go to zero when $(\text{H}^+)_0 = k_c/A(\text{rpm})^{1/2}$; and it should be maximum at $(\text{H}^+)_{\text{max}} = k_c/4A(\text{rpm})^{1/2}$. In addition, the model predicts $\text{pH}_{i=\text{max}} - \text{pH}_{i=0} = \log 4$. From Fig. 5, we see that for -1.2V, the excess current is maximum at pH = 4.3 and goes to zero at pH = 3.6. Therefore $\Delta\text{pH} = 0.7$ agrees with the predicted value $\log 4 = 0.6$.

We can calculate a value for k_c in current density units by applying the equation for $(\text{H}^+)_{\text{max}}$ just mentioned above. Using the appropriate constants for A , and an activity coefficient of 0.76, we obtain $k_c = 3.2 \times 10^{-4}$ A/cm². Using this value of k_c , we can calculate $B = 62.4M^{-1}$. Returning to Eq. [6] and noting the saturation current at pH = 4.2 of 90 $\mu\text{A}/\text{cm}^2$ (Fig. 6), we can calculate that $k_4 = 6.1 \times 10^{-5}$ A/cm².

It is of interest to compare the surface combination rate constants determined here with those deduced (15) from limiting current behavior for Cl₂ evolution. Here, the reaction rate is limited by combination of Cl atoms on the surface. On oxide-free Pt electrodes in anhydrous trifluoroacetic acid, k_c ranges from 300 to 1500 $\mu\text{A}/\text{cm}^2$, depending on coverage of Cl atoms. Our values, particularly for the H atom combination are in the same range. A more realistic comparison would involve rate calculations based on details of the energy surfaces for the adsorbed H_a and COOH_a on the GaAs electrode. Unfortunately, these are not available.

At this stage, we can calculate the complete pH dependence of the saturation current using Eq. [6] and our rate constants. The inset to Fig. 5 shows the model prediction (solid line) and the data points for -1.2V. The fit is seen to be good. If θ were determined by the electrochemical desorption in the HER Eq. [4], no maximum is predicted in the saturation current vs. pH. At pH > 5, the observed current is slightly above the calculated curve; this is probably due to a faster process taking over. This also explains why the -1.4V peak (Fig. 5) appears larger than the -1.2 and -1.3V peaks.

We now consider some other features of the $j_{\text{CO}_2} - j_{\text{N}_2}$ curve. As we have seen, at more cathodic potentials (Fig. 2, 5, and 6), different i-V characteristics were observed. At pH 4.2, a rotation-independent increase in excess current was found, beginning at -1.4V (Fig. 2). The Tafel shapes for these two plots are 152 and 134 mV/decade. It is not clear if these slopes depend on rotation rate or if the data is imprecise. At pH 5-6, the i-V curves are dominated by characteristics with Tafel slopes of 220-230 mV/decade (400 rpm) and no saturation effect is observed.

From the earlier discussion concerning the saturation current, it is clear that under our reaction conditions the surface is nearly saturated with adsorbed intermediates. Therefore, Temkin-type analysis with the possibility of activated adsorption must be applied (16).

We have not done a complete analysis of these effects, and, therefore, a detailed interpretation of the Tafel slopes must be postponed. However, we note that Tafel slopes of 224 mV/decade were already observed (14) for CO₂ reduction on Hg electrodes in NaHCO₃ solution. In that case (11, 14), the rate-determining step ($j > 10^{-5}$ A/cm²) was concluded to be

The reaction product was stated to be formate (98% current efficiency). At $\text{pH} > 5$, it is reasonable to expect that the coverage on GaAs with H_{ad} is also low and hydrogen has to be obtained from H_2O .

Now consider the effect of current density on the faradaic efficiency, $F_{\text{CH}_3\text{OH}}$, for methanol. These measurements were made at -1.3 to -1.4V (SCE) in CO_2 -saturated solutions with an initial pH of 4.1-4.2. There is a close correspondence between this current density of $F_{\text{CH}_3\text{OH}} = 100\%$ and the saturation current in Fig. 2 for a cathodically pretreated electrode. Both these values are $\sim 140 \mu\text{A}/\text{cm}^2$. If the total current is increased beyond this value, the yield of methanol should drop if the limiting rate of methanol formation corresponds to the saturation current. This appears to be the case as shown in Fig. 7. Apparently, another CO_2 reduction product is formed at high current densities as demonstrated by the drop in methanol yield and the simultaneous rise in excess current, as shown in Fig. 2. This current may correspond to the reduction of the adsorbed formate radicals that were postulated to be reactants in the surface chemical rate-limiting step of methanol synthesis.

According to our model, the yield of CH_3OH will depend on the coverage of H atoms. Recall that we assume only H_a and I, which may be $\cdot\text{COOH}$, are the only important intermediates in the mechanism. Using Eq. [5] and the observed rate constants, k_c and k_3 , we can write

$$F_{\text{CH}_3\text{OH}} = \frac{6k_4\theta\gamma}{j_{\text{CO}_2}} = \frac{1}{1 + 1.75 \left(\frac{\theta}{1 - \theta} \right)} \quad [7]$$

It may be seen that methanol yield increases as θ decreases. For $\theta = 0.5$ and 0.1 , $F_{\text{CH}_3\text{OH}}$ is 0.36 and 0.84, respectively. Even though $k_4 < k_c$, the yield of methanol can reach high values as found experimentally. In the limit of $\theta = 0$, Eq. [7] is undefined.

The question of the acidity of the postulated adsorbed formate radicals is not completely answerable at this time. It has been suggested that adsorbed CO_2^- is the dominant first electron product based on the reported pK_a of 1.4 (18) for free aqueous formate radicals. However, the value of 3.9 has also been reported (19) for the same radical. We reason that is more appropriate to estimate the acidity of adsorbed formate radicals by analogy to organic acids. There appears to be little quantitative data on the pK_a 's of metalcarboxylic acids (20, 21); however, many organic acids with different hydrocarbon substituents have been studied. In many cases (22), the pK_a 's are in the range of 4.7 to 5.0. In addition, substituent effects can change the K_a 's by an order of magnitude. If bonding of radicals occurs to the more electropositive Ga atoms on the surface, then the pK_a of the adsorbed radical might exceed 5.0. The negative charge at the cathodic surface may also act to further increase the pK_a . For example (22), introduction of the $-\text{CO}_2^-$ group for a methyl hydrogen in acetic acid raises pK_a from 4.76 to 5.69. Finally, adsorbed CO_2^- would be less favorable, owing to lateral repulsions on the surfaces. In summary, because of the above chemical and physical effects, protonated CO_2^- radicals are a distinct possibility as suggested in our mechanism, step [III], for $\text{pH} \leq 5$.

Summary

Carbon dioxide can be reduced to methanol on n-GaAs (111 As) electrodes with high faradaic efficiencies for current densities of $\sim 150 \mu\text{A}/\text{cm}^2$. Methanol synthesis appears to be limited by a surface chemical step involving adsorbed hydrogen and an unidentified surface intermediate. Possible intermediates are CO_{ad} ; formyl, $-\text{COH}$; hydroxycarbene, $-\text{CH}-\text{OH}$; hydroxymethyl, CH_2-OH ; or methoxy, $-\text{O}-\text{CH}_3$.

Analysis of the pH dependence of the saturation current led to information on the HER. We used the assumption that hydrogen is formed by the combination reaction. This step was already proposed as part of the HER on GaAs electrodes (17). A chemical rate constant of $3.2 \times 10^{-4} \text{A}/\text{cm}^2$ for the H_2 combination was obtained. The pH dependence of the saturation current in the presence of CO_2 could be fit with parameters derived from the data. The analysis gave a chemical rate constant of $6.1 \times 10^{-5} \text{A}/\text{cm}^2$ for the rate-determining step.

The results given here show that very complex catalytic reactions can be performed on semiconductor surfaces in electrochemical cells. A start has been made towards understanding such mechanisms as CH_3OH synthesis. There appears to be pH and voltage range for certain mechanisms or products.

The onset potentials for CH_3OH synthesis are quite cathodic, which means, the energy efficiency, for the process is low. The use of p-type cathodes and/or n-type photoanodes in electrolysis cells could significantly alter this situation.

Manuscript submitted July 11, 1983; revised manuscript received June 8, 1984. This was Paper 517 presented at the San Francisco, California, Meeting of the Society, May 8-13, 1983. This work was supported by the Gas Research Institute.

ABSTRACT

In situ infrared spectroscopy and mass spectrometry were used to investigate the gas and liquid phases in lithium-sulfur oxyhalide cells driven into anode-limited reversal at 1.5 mA/cm². In the lithium-thionyl chloride system the species HCl, CS₂, SO₂, S₂O, SCl₂, and SO₂Cl₂ were identified in the gas phase and HCl, AlCl₃OH⁻, SO₂, SO₂Cl₂, and SOCl⁺ AlCl₄⁻ in the liquid phase. A species giving rise to three absorption bands at 1337, 1070, and 665 cm⁻¹ was observed in the liquid phase of that system during anode-limited reversal only, and in the lithium sulfuryl chloride system during normal discharge and during reversal; this compound was tentatively identified as Li(SO₂, SO₂Cl₂)⁺ AlCl₄⁻ and is analogous to the well-known complexes involving LiAlCl₄, SO₂, and SOCl₂. The lithium-sulfuryl chloride cell behaved similarly to the thionyl chloride cell, specifically with respect to formation of SO₂- and SOCl⁺-like species—the latter tentatively identified as SO₂Cl⁺. Indirect evidence suggests that chlorine may accumulate in both systems at -20°C, but at 25°C its accumulation in the cells is prevented by its reaction with SO₂ to form SO₂Cl₂.

In the ten years since the feasibility of lithium-sulfur oxyhalide cells was first recognized (1), remarkable progress has been made in hardware development; however, their widespread use has been impeded, owing to the safety hazards associated with their relatively high energy density. Conflicting reports exist as to the cause of several explosions involving the lithium-thionyl chloride system. Explosions have been observed in anode-limited cells driven into reversal (2); a hazard also exists in cathode-limited cells since they contain both lithium and sulfur at the end of discharge, and the highly exothermic formation of Li₂S may be possible at elevated temperatures (3, 4). In addition, poor mechanical design is suspected in some cases.

The lithium-sulfuryl chloride cell which does not form any sulfur during discharge is potentially safer than Li/SOCl₂ (5). However, the relatively high corrosion rate of lithium in that system limits its use to special high rate reserve applications.

Resolution of the unpredictable safety hazards associated with these systems may only be possible by analytical determination of their causes, and several investigations have been conducted along these lines. Istone and Brodd (6) have performed an *in situ* infrared study of the electrolyte of Li/SOCl₂ cells and observed that only two absorption bands change in intensity during normal discharge, one at 1335 cm⁻¹ due to SO₂ formation, the other at 689 cm⁻¹ which they assigned to S₂O. Elemental sulfur was also seen to deposit on the spectroscopic cell walls. These authors proposed a mechanism involving formation of SO₂ and S₂O with subsequent decomposition of the S₂O to sulfur and SO₂. This mechanism had been previously rejected on the basis of stoichiometry by Schlaikjer *et al.* (7), who postulated instead the formation of a sulfur monoxide polymer according to the reaction

followed by decomposition of the polymer to produce elemental sulfur and SO₂.

Spectroelectrochemical studies first carried out by Abraham and Mank (8) then by Salmon *et al.* (9) have provided evidence that the principal reaction at the anode current collector on reversal is

Salmon *et al.* further speculated that several electrochemical reactions involving SO₂ were also occurring

¹Present address: Gould, Incorporated, Micro Power Products Division, Eagan, Minnesota 55121.

IR absorption bands at 1070 and 690 cm⁻¹ were assigned by these authors to SO⁺⁺ and Cl₂O, respectively. Abraham and Mank had observed the 1070 cm⁻¹ band in their investigation but assigned it to an S-O stretching vibration of a sulfur-oxy compound. Under the same conditions, they also observed a band at 1415 cm⁻¹, which they assigned to SO₂Cl₂.

Evidence for a significant involvement of aluminum chloride species in the IR absorption spectrum was obtained by Bailey and Blomgren (10), who identified several aluminates in Li₂CO₃-AlCl₃/SOCl₂ electrolyte giving rise to absorptions at 3200-3400 (AlCl₃OH⁻), 800, and 695 cm⁻¹. The last two bands were assigned to the oxychloroaluminate species with the suggested structure Li₂(AlCl₃)₂O. They corroborated their results using ²⁷Al NMR spectroscopy.

More recently, McDonald (11) was able to show by mass spectroscopy the generation of substantial amounts of hydrogen and nitrogen in Li/SOCl₂ batteries.

In order to clarify these issues, we have re-examined the IR absorption spectrum of the electrolytes of lithium thionyl chloride and lithium-sulfuryl chloride cells during normal discharge and anode-limited reversal, at current densities between 1 and 5 mA/cm², and temperatures between -20° and 25°C. Furthermore, we have carried out a mass spectrometric analysis of the gases evolved from a Li/SOCl₂ cell during discharge and anode-limited reversal at 25°C.

Experimental

The cell.—The electrochemical cell used for all our experiments is shown in Fig. 1. It consists of two concentric electrodes supported within a nickel cylinder. The cathode is a thin (20 cm² × 20 mil) carbon-Teflon porous electrode pressed on a nickel grid spot welded to the wall of the cylinder. The lithium anode (8 cm² × 5 mil) is pressed on a nickel foil substrate spot welded around a stainless steel central post. The electrodes are about 0.5 cm apart and separated by a double layer of 0.005 in. glass mat. The cell can be coupled directly to a mass spectrometer via a valve system, as shown in Fig. 2, or to an IR spectroscopic cell via a pump to circulate the electrolyte between the electrochemical cell and the spectroscopic cell. The volume of solution in the cell is 14 ml. An additional volume of 2 ml is circulating through the pump and spectroscopic cell. The head space volume is 1 ml.

Mass spectra.—A Perkin-Elmer (PE270) mass spectrometer with a home-built all-glass gas inlet system was used

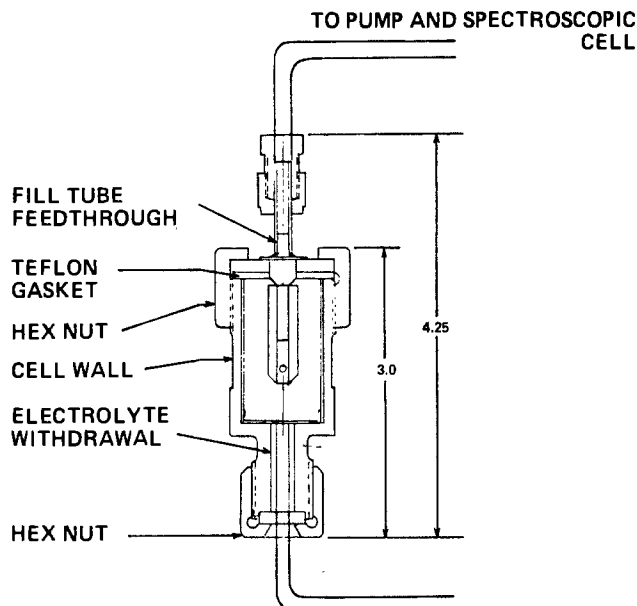

Fig. 1. Electrochemical cell for flowing electrolyte system

for *in situ* gas-phase analysis (Fig. 2). This sampling system consists of two (V_1 and V_2) stainless steel shut-off nonrotating stem valves from Circle Seal. The sampling volume contained between V_1 and V_2 is approximately 0.5 cm^3 . The glass inlet system includes four Teflon stopcocks (V_3 - V_6), with V_4 providing access to a roughing pump and V_6 leading to the mass spectrometer ion source. V_5 gives access to a perfluorokerosene (PFK) reservoir, which is used in the calibration of the mass scale. Exact mass experiments were performed on an AEI MS-30 double focusing mass spectrometer equipped with an Anatron peak matching unit. These measurements were carried out with known perfluorokerosene fragments as the mass reference (12). Intensity *vs.* time data were obtained with 80 eV electron energy on the PE270 mass spectrometer and with 70 eV electron energy on the MS-30 mass spectrometer.

Infrared spectra.—The IR absorption spectra were obtained with a Nicolet 5MX/1200S FTIR spectrometer. Silver chloride windows were used for the spectroscopic cell with a 0.1 mm optical path length. All spectral fre-

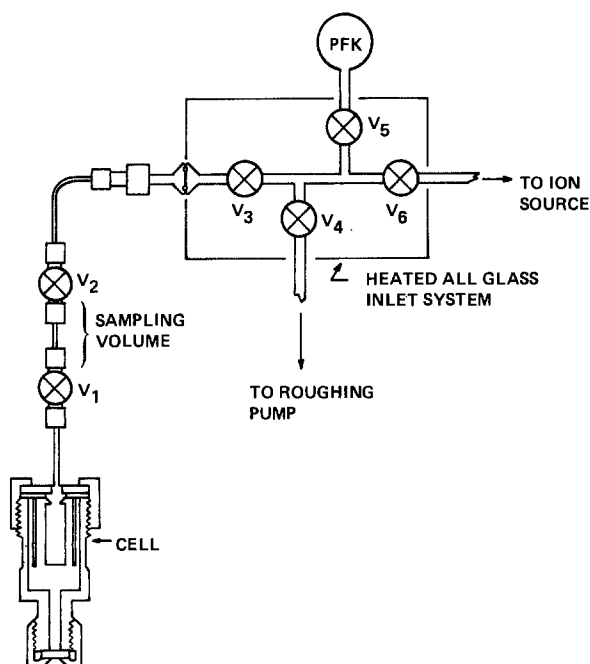

Fig. 2. Mass spectrometric sampling system

quencies are accurate to within $\pm 4 \text{ cm}^{-1}$; for the purpose of quantitative analysis, peak heights above the base line were measured. For badly overlapping bands, we used the tangent line technique to obtain reproducible results, or spectral subtractions.

Chemicals.— SOCl_2 and SO_2Cl_2 were double-distilled before use. LiAlCl_4 was used as received from Anderson Physics.² The electrolyte solutions, 1.4M LiAlCl_4 in SOCl_2 and 1.5M LiAlCl_4 in SO_2Cl_2 were prepared in a dry room shortly before filling the electrochemical cell.

Spiking and calibration experiments.—Mixtures of known composition were used for calibration and identification of possible products of discharge. These mixtures were prepared in a dry room or glove box and transferred to the spectroscopic cells in a dry environment. The calibration for SOCl_2 was obtained by dissolving known amounts of AlCl_3 in pure thionyl chloride, assuming 100% conversion of the AlCl_3 to $\text{SOCl}^+\text{AlCl}_4^-$.

S_2O synthesis.—We attempted to synthesize S_2O in a vacuum line using the reaction between SOCl_2 and Ag_2S at 160°C , as described by Nickless (13).

Results and Discussion

Qualitative IR studies.—Typical spectra of electrolyte from Li/SOCl_2 and $\text{Li}/\text{SO}_2\text{Cl}_2$ cells driven into anode-limited reversal are shown in Fig. 3(a) and 3(b). The most prominent absorption bands are tabulated in Table I together with their most likely assignment based on previously published results (6-10, 14) or the present work. The spectra for these electrolytes during normal discharge show only the formation of SO_2 at these relatively low current densities of 1-5 mA/cm².

To identify the various absorption bands, we spiked several solutions of SOCl_2 or SO_2Cl_2 with known compounds and compared the resulting IR spectra with the electrolyte spectra during normal discharge and reversal. The results of these tests are shown in Table II.

Water has a substantial effect on the absorption spectrum of SOCl_2 . Addition of water to pure SOCl_2 results in the formation of HCl (2790 cm^{-1}) and SO_2 (1335 and 1144 cm^{-1}). However, the same addition to 1.4M $\text{LiAlCl}_4/\text{SOCl}_2$

²Anderson Physics Laboratory, Urbana, Illinois 61801.

^d Frequencies observed in addition to those in SO₂Cl₂/LiAlCl₄.

electrolyte gives rise to two more absorption bands at 694 and 3400 cm⁻¹ (AlCl₃OH⁻). The addition of AlCl₃ and water to SOCl₂ results in the formation of AlCl₃OH⁻ (3400 cm⁻¹), but the absorption band at 694 cm⁻¹ does not appear, while two other poorly resolved bands at 803 and 822 cm⁻¹ appear instead.

Absorption bands at 3400, 800-820, and occasionally 694 cm⁻¹ are evident in both the LiAlCl₄/SOCl₂ and LiAlCl₄/SO₂Cl₂ electrolyte spectra, indicating water contamination (HCl is not formed in the Li/SO₂Cl₂ system) (13). The same absorptions have been observed by Bailey and Blomgren in the Li₂CO₃-AlCl₃/SOCl₂ system and were assigned to AlCl₃OH⁻ (3400 cm⁻¹) or oxychloroaluminate species (800, 695 cm⁻¹). With great precaution, we were able to reduce considerably the absorption at 694 cm⁻¹ during normal discharge, but it was nearly impossible to eliminate water contamination completely, and its effects were more noticeable towards the end of the relatively long period of reversal.

The addition of AlCl₃ to SOCl₂ gives rise to strong absorption bands at 1115 and 557 cm⁻¹ owing to the complex SOCl⁺AlCl₄⁻ (2). On reversal, the Li/SOCl₂ cell shows the same absorption bands, indicating formation of SOCl⁺AlCl₄⁻. An analogous SO₂Cl⁺AlCl₄⁻ (15) compound is formed in the Li/SO₂Cl₂ system upon addition of AlCl₃

or during anode-limited reversal, with characteristic absorption bands at 1090 and 1053 cm⁻¹ reflecting the two S-O stretching frequencies expected from SO₂Cl⁺. Any absorption band at the lower frequency range would be hidden under the strong SO₂Cl₂ absorption band at 570 cm⁻¹.

Addition of SCl₂ or S₂Cl₂ to LiAlCl₄/SOCl₂ in the presence of SO₂ results in a slow increase in the IR absorptions at 1070, 665, and 1337 cm⁻¹, together with the formation of SO₂Cl₂, as evidenced by the characteristic absorption bands at 1408 and 570 cm⁻¹. [The IR absorptions due to the sulfur chlorides (13) occur below 550 cm⁻¹ and cannot be detected by our instrument.] The same effect is observed with addition of SO₂Cl₂ and SO₂ to LiAlCl₄/SOCl₂. This characteristic triplet (1070, 665, 1337 cm⁻¹) appears only during anode-limited reversal in the Li/SOCl₂ system, while it is observed during normal discharge in the Li/SO₂Cl₂ system.

A compound with this characteristic IR spectrum was isolated from SO₂Cl₂ or SOCl₂ electrolytes following evaporation of the solvent. This compound decomposes abruptly at 40°C, releasing SO₂. It appears that its formation requires the presence of SO₂Cl₂, SO₂, and either LiAlCl₄ or AlCl₃. A reasonable assignment for the bands might be the S-O stretching vibrations and Al-Cl stretching modes of a complex similar to those observed by Barbier (16) between SO₂, SOCl₂, and LiAlCl₄. Subsequently, we refer to this complex as Li(SO₂, SO₂Cl₂)⁺AlCl₄⁻.

In our attempt to synthesize S₂O, we were only able to observe one (1168 cm⁻¹) of the three absorption bands characteristic of this compound (13). Attempts to condense S₂O in SOCl₂ at 77 K resulted only in the formation of a red polysulfur oxide which decomposed to S and SO₂ upon heating to room temperature. We concluded that the absorption which Istone and Brodd (6) observed at 688 cm⁻¹ and assigned to S₂O, in effect, must have been due to the interaction of water with neutral electrolyte. Salmon's assignment of a 690 cm⁻¹ absorption to Cl₂O (9) also overlooks the strong interaction of water with the electrolyte, which may, if excessive, mask the absorption band at 665 cm⁻¹ formed only during anode-limited reversal in the Li/SOCl₂ system. Actually, mass spectrometry shows the presence of small amounts of S₂O in the gas phase but no trace of Cl₂O (see below).

In situ mass spectrometry.—The Li/SOCl₂ systems was studied mass spectrometrically using the apparatus shown in Fig. 2. The *in situ* experiment, which lasted 69.25h, involved the discharge of a single cell at 8 mA (1 mA/cm² based on the anode) for a period of about 20h, followed by a period of reversal at 50 mA which lasted approximately 50h (Fig. 4).

The quantity of gas used in sampling was significant with respect to the head space, and the effect is shown in Fig. 4 as the short-term "sampling spikes." There was no

Fig. 4. Discharge curve of Li/SOCl₂ cell used for mass spectrometric analysis.

pause between end of discharge and the onset of cell reversal. The rate of discharge was increased sixfold during reversal in order to accelerate reaction progress. Infrared analysis had already shown that this change in current density did not affect the reaction mechanism, but rather simply accelerated the reaction progress.

Fifteen sets of mass spectra were recorded from time zero at the beginning of the discharge through time 69.25h at the end of the experiment. No spectra were recorded on the complete cells stored without discharge. Reversal occurred at time $t = 21$ h, and the reversal process was continued through $t = 66$ h. The last set of spectra was recorded at time $t = 69.25$ h. Tabulated intensities for nominal masses appearing between masses 35 and 138 are given in Table III.

Masses below mass 35 were not included because these masses primarily arise from residual gases in the mass spectrometer and inlet system. The cell used in this study contained SOCl_2 in excess, and the vapor pressure remained essentially constant during the experiment reported here. Therefore, the partial pressures of the various species can be estimated using the known vapor pressure of SOCl_2 , the ion intensities reported in Table III, and estimates of the relative ionization cross sections. All intensity data are relative to the intensity of mass 83 (SOCl^{35+}) which is set arbitrarily at 100. The uncertainty in the intensity data is estimated to be $\pm 20\%$.

Pure samples of SCL_2 , SOCl_2 , and SO_2Cl_2 were introduced into the mass spectrometer, their spectra recorded and the peak intensities were entered in Table IV. The inlet system used in these experiments contributed to the peak at mass 36. This peak arises from the reaction between the chlorine containing sample and adsorbed water and/or hydrocarbons in the inlet system. Under the carefully controlled inlet conditions used with these samples, the intensity of mass 36 remained constant to within 20%. Thus, in subsequent experiments, it will be assumed that the inlet reactions are constant to within 20% and that large changes in the intensity of mass 36 are due to factors other than the inlet system. All of these spectra were recorded with an electron energy of 80 eV.

Three exact mass experiments at nominal masses 50, 76 and 80 yielded the following exact mass values: 49.99597 (± 30 ppm), 75.94528 (± 20 ppm), and 79.94057 (± 20 ppm), respectively.

The results clearly show the presence of molecular HCl, SO_2 , CS_2 , S_2O , SCL_2 , SOCl_2 , and mass 134 species (mainly SO_2Cl_2 , with, probably, some S_2Cl_2). The data also reveal the presence of high levels of chlorine fragments as well as low concentrations of CF_2^+ fragments. Species with nominal mass exceeding 140 were also observed toward the later stages of reversal.

The plots of intensity vs. time of HCl and Cl^+ (Fig. 5 and 6) indicate that their concentrations remain constant in the gas phase during normal discharge but increase during anode-limited reversal after an induction period of 5h. We have investigated the contribution to mass 36 and have found that the intensity of the mass 36 (HCl) signal can be reduced by improving the inlet system to the mass spectrometer. However, not all of the mass 36 can be removed by the improved inlet; thus, part of mass 36 may arise from cell components containing chlorine and hydrogen. Water contamination may, in part, be introduced from the cathodes which are formed by an aqueous process.

The plots of CS_2 and S_2O (Fig. 7 and 8) show little variation in the concentration of these species with time during both discharge and reversal, while the plots for SCL_2 (Fig. 9) and SO_2Cl_2 (Fig. 10) indicate that these compounds are only formed during reversal, also following a 5h induction period.

The increase in the concentration of HCl following reversal indicates a source of hydrogen which may be the residual water in the electrolyte or, more likely, the adsorbed water on the carbon cathode.

The mass spectrometric analysis of SO_2 confirms our infrared results: SO_2 appears to be the major product of discharge. If the data for SO^+ and SO_2^+ intensities are plotted (Fig. 11), interesting results are obtained. This figure clearly shows that the SO_2^+ rate of increase is larger than that for SO^+ fragments. Furthermore, it is seen that the difference in concentration between SO_2^+ and SO^+ increases rapidly after the onset of reversal and then reaches a steady value. It is worth noting that the ratio of SO^+ to SO_2^+ intensities is approximately 0.5 for pure SO_2 (18). Thus, it is clear that the SO^+ intensity in the discharge mode is higher than that accounted for by SO_2 fragmentation alone. Upon reversal, the $\text{SO}^+/\text{SO}_2^+$ ratio decreases and approaches its limiting value predicted by SO_2 fragmentation only.

*Most intense peak.

Thus, the foregoing analysis indicates that during discharge SO^+ intensity results from at least two major contributions. The first is from SO_2 fragments, and the second arises from SOCl_2 fragmentation. However, as the cell is brought into reversal, the SO_2 becomes the major source of SO^+ production.

Fig. 12. Mass 50 (CF₂⁺) vs. time (h)Fig. 11. Mass 48 and 64 (SO⁺ and SO₂⁺) vs. time (h)

Mass 80 was identified as S₂O by exact mass measurements. This is not surprising, as Meshi and Myer (17) had previously identified both S₂O and CS₂ as products in a discharge-tube reaction between elemental sulfur and SO₂. Furthermore, thermal decomposition of SOCl₂ has been shown to yield S₂O as a product (17). It is worth noting, however, that the amount of S₂O in the gas phase remains fairly constant throughout the experiment and appears independent of any electrochemical process.

The mass triplet 102, 104, and 106, characteristic of SCl₂, appears only in reversal after an induction period of 5h. The species giving rise to masses 67 and 69 (Table III) can arise from fragmentation of SCl₂. However, since no SCl₂ parent is detected at and prior to *t* = 26h, the intensities measured for this doublet at and prior to *t* = 26 do not arise from SCl₂. This result also implies that species other than SCl₂ give rise to masses 67 and 69 in the cell. It is important to note that chlorine dioxide (ClO₂, mass 67, 69) can give rise to these masses. However theoretical isotopic abundance considerations neither confirm nor rule out ClO₂ as species giving rise to masses 67 and 69. It is also noteworthy that the absence of both parent (masses 86, 88, and 90) peaks and fragments (masses 51, 53) in the mass spectrum strongly suggests that Cl₂O is not present in measurable concentration in this system.

The mass triplet 134, 136, 138 also detected during reversal after a 5h induction period could arise from either S₂Cl₂ or SO₂Cl₂. S₂Cl₂ has been suggested as a possible reaction product by Schlaikjer *et al.* (7) as follows

Thus S₂Cl₂ may be present in this system, but our infrared results suggest that SO₂Cl₂ is the major component. Mass 50 (Fig. 12) was positively identified as CF₂⁺ by exact mass analysis. Its presence throughout the periods of discharge and reversal implies a chemical or electrochemical attack on the Teflon binder at the cathode during both discharge and reversal.

Quantitative FTIR studies.—Li/SOCl₂, normal discharge.—A total of eight cells were discharged and driven into reversal under various conditions ranging from -20° to +25°C and 1.5 mA/cm².

During normal discharge, the only noticeable change is the increase in SO₂ concentration. At 25°C, SO₂ appears to increase linearly until the cell is fully discharged then levels off. At -20°C, a slight curvature is noticeable at the beginning of the discharge. This also holds true for the Li/SO₂Cl₂ system. Typical results are shown in Fig. 13. Average results for four of the cells are tabulated in Table V. In every case, the amount of SO₂ produced during normal discharge was always found to be only a fraction of that predicted by the usually accepted equation for the discharge of this cell

Li/SOCl₂, anode-limited reversal.—On reversal, the most noticeable changes in the IR spectrum are due to formation of SO₂Cl₂ (1408 and 580 cm⁻¹), SOCl⁺ (1115 and 557 cm⁻¹), and what we tentatively identified as the weakly bound complex Li(SO₂, SO₂Cl₂)⁺AlCl₄⁻ absorbing at 1070, 665, and 1337 cm⁻¹ (this last band appears as a shoulder on the very large SO₂ peak). Typical results are plotted in Fig. 14 and 15 for ambient temperature operation, and in Fig. 16 and 17 for operation at -20°C.

A small amount of water contamination is always present and is the cause for the three broad bands at 3400 cm⁻¹ (AlCl₃OH⁻), 2900 cm⁻¹ (HCl), and 800-820 cm⁻¹ (oxychloroaluminate).

At room temperature, SO₂Cl₂ increases steadily after a short induction period then appears to level off. SOCl⁺ starts increasing immediately, levels off to a steady-state value, and disappears fairly rapidly after the current is turned off. The peaks at 1070 and 665 cm⁻¹ also show an initial increase, then an apparent leveling off.

At low temperature (-20°C), one should note the immediate and sharp increase in the SOCl⁺ species (0.65 mol/Faraday) (see Fig. 17). Obviously, at room temperature regenerative processes are fast and prevent accumulation of large amounts of SOCl⁺. The SO₂Cl₂ concentration (see

Fig. 13. SO₂ formation during discharge of anode-limited Li/SOCl₂ cells: *i* = 40 mA (5 mA/cm²).

Table V. SO₂ production during normal discharge

Cell	Discharge conditions	SO ₂
SC-69	(5 mA/cm ² , 25°C)	0.14 mol/Faraday
SC-71	(5 mA/cm ² , 25°C)	0.17 mol/Faraday
SC-77	(1 mA/cm ² , 25°C)	0.17 mol/Faraday
SC-81	(1 mA/cm ² , -20°C)	0.13 mol/Faraday

Fig. 17) levels off at a fairly low value. However, upon heating to room temperature, a dramatic jump in SO₂Cl₂ concentration occurs, pointing to the accumulation of unstable species (most likely Cl₂) during the reversal period at low temperature. Water contamination and the large SOCl⁺ concentration precluded our plotting the increases in absorption of 665 and 1070 cm⁻¹ for the low temperature run.

Li/SO₂Cl₂.—As with the *Li/SOCl₂* system, the major reaction product during normal discharge is SO₂. Its concentration appears to increase linearly at room temperature, but somewhat nonlinearly at -20°C. The SO₂ concentration levels off after reversal (see Fig. 18).

Qualitatively, the results are identical at room temperature and at -20°C, but at -20°C an analysis of the potential evolution, especially during reversal, shows a small plateau at -2.8V and a larger one not very flat at -5.5/-6V followed by a sharp decrease after about 15h to -12V at which point the current is cut off (see Fig. 19). When the cell is allowed to recover, the voltage stabilizes at -0.8/-0.6V, then goes to 0V upon warming up to room temperature. This small polarization left on recovery at low temperature could be attributed to the formation of a species stable at -20°C.

Absorption bands at 1070, 1337, and 665 cm⁻¹ appear during normal discharge and continue increasing slowly in intensity during reversal (see Fig. 20). The three peaks appearing during the normal discharge as they do in a

Fig. 14. Formation of (a) SO₂Cl₂, (b) SOCl⁺, and (c) Li(SO₂, SO₂Cl₂)⁺AlCl₄⁻ during reversal of anode-limited Li/SOCl₂ cell. *i* = 40 mA (5 mA/cm²). *T* = 25°C.

Fig. 15. Formation of (a) SO₂Cl₂, (b) SOCl⁺, and (c) Li(SO₂, SO₂Cl₂)⁺AlCl₄⁻ during reversal of anode-limited Li/SOCl₂ cell. *i* = 7.4 mA (1 mA/cm²). *T* = 25°C.

Fig. 17. Formation of SOCl⁺ during reversal of anode-limited Li/SOCl₂ cell at -20°C. *i* = 40.5 mA (5 mA/cm²).

mixture of SO₂, LiAlCl₄, and SO₂Cl₂ without the passage of current suggest a chemical reaction. The appearance of the same peaks in the Li/SOCl₂ cells on reversal is probably due to the formation of SO₂Cl₂ during the over-discharge and its subsequent reaction with LiAlCl₄ and SO₂. The product of this reaction has been tentatively identified as Li(SO₂, SO₂Cl₂)⁺AlCl₄⁻.

Additional peaks appear on reversal at 1090 and 1059 cm⁻¹, which quickly disappear on recovery. Those facts

Fig. 18. Formation of SO_2 during discharge and reversal of anode-limited $\text{Li}/\text{SO}_2\text{Cl}_2$ cell at 25°C . $i = 40 \text{ mA}$ ($5 \text{ mA}/\text{cm}^2$).

suggest the formation of a complex analogous to $\text{SOCl}^+\text{AlCl}_4^-$ in the Li/SOCl_2 system. This complex is proposed to be $\text{SO}_2\text{Cl}^+\text{AlCl}_4^-$ (15) and may be formed as follows

Conclusions and Summary

Mass spectrometry and infrared spectroscopy have been used to investigate both the gas and liquid phases in lithium-sulfur oxyhalide cells during normal discharge and anode-limited reversal.

By measuring the spectra *in situ*, we were able to minimize the interaction of moisture with the electrolyte. Quantitative and reproducible results have been obtained and definite trends have been demonstrated. With the two techniques, we were able to corroborate our results.

In the lithium-thionyl chloride system, the species HCl , CS_2 , SO_2 , S_2O , SOCl_2 , and SO_2Cl_2 were identified in the gas phase, and HCl , AlCl_3OH^- , SO_2 , SO_2Cl_2 , $\text{SOCl}^+\text{AlCl}_4^-$ in

the liquid phase. A species giving rise to absorptions at 1337 , 1070 , and 665 cm^{-1} was observed in the liquid phase during anode-limited reversal; this last compound is tentatively identified as $\text{Li}(\text{SO}_2, \text{SO}_2\text{Cl}_2)^+\text{AlCl}_4^-$ and is analogous to the complexes characterized by Barbier (16) involving LiAlCl_4 , SO_2 , and SOCl_2 instead of SO_2Cl_2 .

The gas phase concentrations of CS_2 and S_2O were essentially constant throughout the experiment. These species may not necessarily arise from electrochemical processes but are probably minor products of chemical reactions either in the cell or the inlet system. Fragments identified as CF_2^+ were observed in measurable amounts. The origin of these fragments is most likely the Teflon binder used in the construction of the porous carbon electrode.

The sulfonyl chloride cell behaved similarly to the thionyl chloride cell, specifically with respect to formation of SO_2 and the formation of SOCl^+ -like species tentatively identified as SO_2Cl^+ . Moreover, this system exhibited the same sensitivity to water and the same behavior at -20°C as the thionyl chloride system. During normal discharge a compound absorbing at 665 , 1070 , and 1337 cm^{-1} was formed immediately upon generation of SO_2 . This compound was isolated from SO_2Cl_2 solutions containing LiAlCl_4 and SO_2 , it decomposes at approximately 40°C with evolution of SO_2 , and is the same as the $\text{Li}(\text{SO}_2, \text{SO}_2\text{Cl}_2)^+\text{AlCl}_4^-$ complex observed in the thionyl chloride system.

The formation of chlorine in both systems is quite likely but its accumulation in the cells at room temperature is prevented by reaction with SO_2 to form SO_2Cl_2 . At low temperatures, chlorine does accumulate but reacts quite rapidly on warming up to form SO_2Cl_2 .

Finally the effect of water contamination was characterized. Water tends to form strongly IR absorbing species with AlCl_3 or AlCl_4^- . This fact should be taken into account in interpreting the results of previous investigations.

Electrochemical Behavior of Water in Immobilized Salt Electrolytes

I. Electrical Conductivity and Thermal Measurements

Rachel Parash, Frederico Broitman, Uri Mor, Dan Ozer, and Armand Bettelheim

Nuclear Research Center-Negev, Beer-Sheva, Israel

ABSTRACT

The meaning of moisture content of a pelletized LiCl-KCl-MgO mixture is discussed in terms of different states of interaction in which water may exist in the specimen. According to electrical conductivity measurements, differential thermal analysis, and thermogravimetric experiments in the ambient to $\approx 400^\circ\text{C}$ range, water comes off the pellet by an endothermic process that involves the migration of water to the surface of the pellet where it vaporizes ($T = 25^\circ\text{--}130^\circ\text{C}$). Exothermic reactions involving oxide ions and traces of water and hydrogen chloride are suggested to exist in the $130^\circ\text{--}250^\circ\text{C}$ range. This is followed ($T > 250^\circ\text{C}$) by a hydrolytic and endothermic reaction, which converts chloride ions to hydroxide ions and hydrogen chloride.

The investigation of water in pelletized LiCl-KCl-MgO mixtures is of interest for the development of primary as well as secondary batteries for load leveling and electric vehicle applications. The presence of water as well as contaminants formed near the electrodes during exposure to humid air could affect cell performance and accelerate self-discharge (1).

To prevent direct reaction between the anolyte and catholyte, a separator must be employed to physically separate the anode from the cathode, which in most cases consists of a lithium alloy and FeS_x ($x = 1$ or 2), respectively (2). An effective separator must be ionically conducting and chemically inert to all the cell components. Two concepts were considered for the separators (2, 3): (i) a refractory powder compact composed of the electrolyte (usually a LiCl-KCl eutectic mixture) and binder (such as SiO_2 or MgO) and (ii) separator pads fabricated from boron nitride or yttria fiber pads impregnated with electrolyte. The choice of the binder is based upon its ability to gel or immobilize the electrolyte, which would otherwise flow when subjected to the battery operation temperature, some 150°C above the electrolyte melting point. In the present study, the separator is a pelletized mixture of electrolyte composed of LiCl + KCl (64:36 mole percent [m/o]) in the presence of MgO (50 weight percent [w/o]) as binder.

The most troublesome aspect of preparing a pure electrolyte fusion arises from the highly deliquescent property of the lithium chloride. Unless special precautions are taken, hydrolytic decomposition occurs as the temperature is raised

Consequently, the melt becomes contaminated with alkaline products (4-7). Various methods have been proposed and used to prevent hydrolytic decomposition during the preparation of anhydrous and fused alkali metal chlorides. The difficulty of removing the last traces of residual moisture from the salts has often necessitated rather arduous drying procedures (8, 9). A high degree of purity of the LiCl-KCl melts has been achieved by treating the fused salt with hydrogen chloride gas (10) or chlorine (11).

The extreme sensitivity of electrical methods of analysis to chemical and structural transformations has been highlighted in several publications (12-14). From an application viewpoint, the practical potential of electrochem-

ical methods such as electrical conductivity measurements has been demonstrated in a wide variety of geological problems related to underground resources (15). It is the purpose of this paper to seek a correlation between the trends observed in the electrical and thermal behavior of pelletized LiCl-KCl-MgO mixtures containing various amounts of water. A wide variety of techniques, an electrical conductivity (EC), thermogravimetric analysis (TGA), and differential thermal analysis (DTA), was employed for the detection and characterization of the different states of water in the specimen.

Experimental

AR-grade LiCl, KCl, and MgO (Merck) were used.

The water content of the LiCl-KCl-MgO mixtures after weighing, blending, and mixing was determined by Karl Fisher titrations (16). Pellets of variable water concentrations were obtained by heating the pellet at $\approx 150^\circ\text{C}$ for several hours in a dry glove box ($\text{RH} \leq 0.5\%$). Water concentration after pelletizing was calculated by weight-loss measurements.

A schematic diagram of the electrical conductivity (EC) apparatus and furnace arrangement are illustrated in Fig. 1. The apparatus described here can be used for EC measurements on pressed disks up to a maximum temperature of about 500°C . The furnace is a ceramic block, and temperature is detected by two Chromel-Alumel thermocouples. One of them controls the rate of temperature rise via a proportional band temperature programmer; the other measures the temperature of the pellet and its EMF output is recorded on the X-axis of a Type 3078 Yokogawa X-Y recorder.

The samples were pressed in the form of disks using a stainless steel piston and die and a Beckman 30 ton hydraulic press. The disks, 28.6 mm diam and 4.5 mm thick, were held by a spring between two stainless steel electrodes.

AC electrical conductivity (EC) measurements were carried out using a Wayne Kerr B642 or B605 bridge. No control of the sample chamber atmosphere was necessary because of its geometry, the atmosphere surrounding the sample was essentially a "self-generated" one containing water vapor (17).

Differential thermal analysis (DTA) and thermogravimetric analysis (TGA) were performed on a Netzsch differential thermo-analyzer 404 and a Setaram thermo-

Fig. 1. Cell for EC measurements. a: Furnace. b: Thermocouples. c: Glass cell. d: Glass joint. e: Stainless steel electrodes. f: Stainless steel electrodes guide. g: Stainless steel spring. h: Pellet.

balance, respectively. Dehydration conditions in the sample chamber of the DTA and TGA were similar to those used in the EC measurements, *i.e.*, a self-generated atmosphere of water vapor. Alumina crucibles containing small portions (< 20 mg) of the pelletized salts were used for the thermal methods.

A Shaw hygrometer (Model Sha-3) with a medium (yellow spot) sensor range was used to detect water vapor evolved from a pellet subjected to heat-treatment in the apparatus shown in Fig. 1.

Results and Discussion

Room temperature measurements made at 1.5 kHz between two metallic collectors positioned at opposite sides of a pellet (Fig. 1) showed an increase in the ac conductance when the pellet was exposed to ambient atmosphere (RH = 50%). Passing a dry gas (air or argon, RH < 0.5%) through the porous structure of the pellet at ambient temperature caused a decrease in conductance, as shown in Fig. 2. Moreover, this procedure caused a gradual decrease in weight, probably due to loss of surface adsorbed water. A total weight loss of about 0.3 w/o was detected for a pellet initially containing 2 w/o water.

Figure 3 shows the electrical conductance of a LiCl-KCl-MgO pellet as function of temperature, measured at three different frequencies. The increase in electrical conductivity with temperature can be related to ohmic conduction which follows the well-known relationship (18)

$$\sigma_{\text{ohmic}} = \sigma_0 \exp(-E_a/RT) \quad [2]$$

where E_a is the activation energy for the mobility of the current carriers, and σ_0 , the pre-exponential factor, is related to the lattice vibration frequency. Conductivity in alternating current fields, however, is the sum of ohmic and polarization components expressed as

$$\sigma_{\text{total}} = \sigma_{\text{ohmic}}(T) + \sigma_{\text{pol}}(\nu, T) = \sigma_0 \exp(-E_a/RT) + 2\pi\nu\epsilon'' \quad [3]$$

where σ_{pol} represents the contribution of polarization current to the total conductivity σ_{total} , ν is the operating frequency, and ϵ'' is the loss factor. As can be seen from Fig. 3, the conductivity in the temperature range 25°-250°C increases by a factor of about two when the frequency is increased by two orders of magnitude. This indicates that the ohmic conductivity is the dominant factor in the total conductivity of the pellet. Polarization effects superimposed on the ohmic contribution to the conductivity are found only at temperatures below 70°C, as indicated by the small peaks in the conductivity curves at low frequencies (19).

As with other dynamic thermoanalytical techniques, the EC curve of a sample was influenced by the heating rate. At higher heating rates, the peaks were much smaller and broader. Low heating rates allow more time for the dissociation of hydrates and for bulk water vapor to diffuse to the vicinity of the electrodes.

Peaks I and II (appearing at 60°-65° and 80°-110°C, respectively) are correlated with the loss of absorbed water (peak I) and vaporization of liquid water which is in equilibrium with hydrates (peak II). Similar EC results were reported for the $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ salt (17). For lithium chlo-

ride, the dehydration process could be described by the following scheme

According to Duval (20), a water molecule is associated with two lithium chloride molecules, *i.e.*, $n = 1/2$. The presence of liquid water, as given in reaction [4], forms a saturated solution, which permits an increase in current flowing through the sample. As this water vaporizes, the current decreases to the level of the original substance (17).

The process taking place at region III in the EC curve (Fig. 3) will be described in the context of the DTA and TGA results. The conductance rises at $T > 250^\circ\text{C}$ (not shown in the figure) until a steady value is obtained at the melting point of the electrolyte (about 370°C for the present composition of LiCl-KCl). At 450°C, the conductivity of the LiCl-KCl-MgO mixture is about one order of magnitude lower than the reported value in the absence of binder (21): 0.13 and 1.5 $\text{mho} \cdot \text{cm}^{-1}$, respectively. It should be noted that part of the samples showed a tendency to exhibit conductivity that "smeared" over a broad temperature region extending from 200° to 400°C. The loss of resolution in region III is presumably due to overlapping of the temperature regimes of the processes contributing to the electrical conductivity in the intermediate region 200°-250°C (processes II, III, and high ionic mobility above 250°C).

The EC curves in the 25°-125°C range for pellets containing various initial water concentrations are shown in Fig. 4. Conductivity in this temperature range increases when the water content in the pellet is increased and decreases in subsequent heating cycles. The disappearance of peaks I and II in the absence of water seems to be related to the lack of mobility of the current carriers ($\sigma_{\text{ohmic}} \rightarrow 0$ in Eq. [2]). As it can be seen from Fig. 4, the relative heights of peaks I and II vary independently on the total

Fig. 2. The decrease of conductance at 1.5 kHz as function of time for a pellet (50 w/o electrolyte + 50 w/o MgO) at room temperature when a dry (RH = 0.5%) gas (air or Ar) is allowed to flow (rate = 1 liter/min⁻¹) through the sample (initial water concentration \approx 2 w/o).

Fig. 3. Conductance vs. temperature at different frequencies, (a) 0.1, (b) 1, (c), 10 kHz, for a pellet (50 w/o electrolyte + 50 w/o MgO) containing an initial water concentration of 3 w/o.

water content in the various pellets. This is probably due to the variation of the time required to prepare the different samples, and hence to the different amounts of adsorbed water in the specimen.

For comparison of the trends observed in the electrical behavior, DTA experiments were carried out on pellets of the same composition (50 w/o electrolyte and 50 w/o magnesia). The first heating cycle yielded (Fig. 5) endothermic

mic effects at 80°, 120°, 320°, and 382°C (peaks I, II, IV, and V, respectively). The last endothermic peak (peak V), appearing at 382°C in the first heating cycle and 370°C in the second cycle, and the reverse (exothermic) process at 320°C (peak V') are attributed to the solid-liquid and liquid-solid transitions, respectively. The shift of the electrolyte melting point to a higher temperature in the heating part of the first cycle could arise from changes of thermal conductivity or strain effects in nucleation. The first heating-cooling treatment probably eliminates effects arising from sample compaction due to sintering (12). The hysteresis in the transformation temperature in

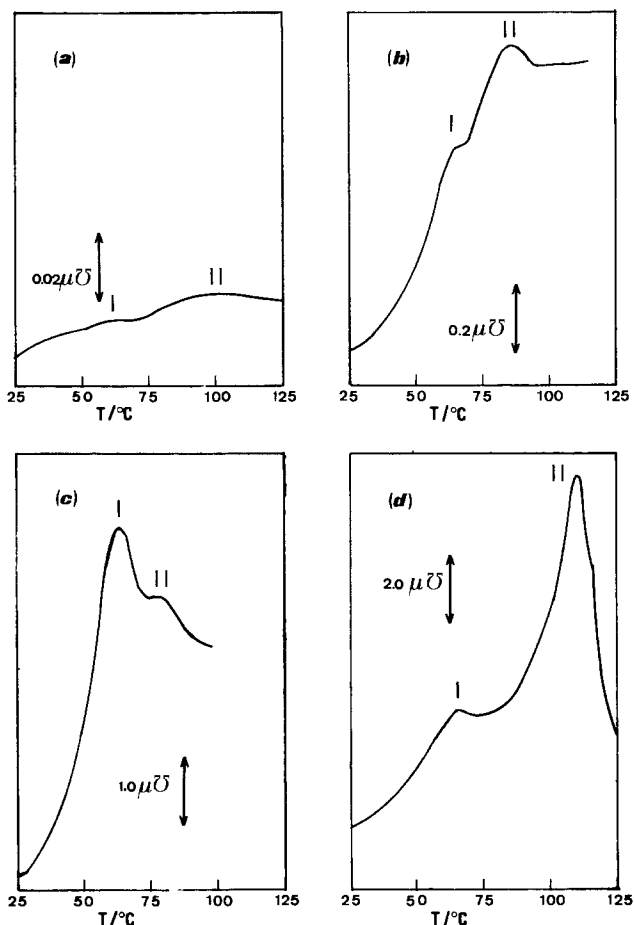

Fig. 4. Conductance vs. temperature at 1.5 kHz for pellets initially containing (a) 0.5, (b) 1.3, (c) 1.8, and (d) 2.6 w/o water.

Fig. 5. DTA curves (first and second heating-cooling cycles) for a 50 w/o electrolyte + 50 w/o MgO mixture (heating-cooling rate = $5^{\circ}\text{C} \cdot \text{min}^{-1}$).

the two directions could be reduced by reducing the heating-cooling rate.

Since the endothermic peaks at 80° and 120°C (peaks I and II) appeared only in the first heating cycle, they seem to be due to processes involving water being expelled during the first heating cycle. The origin of the first two effects is the same as described for the EC behavior in regions I and II (Fig. 3 and 4). The exothermic broad effect at 200°-250°C (region III in Fig. 5) seems also to be related to an increase in electrical conductance (region III in Fig. 3). The following exothermic reactions are consistent with the EC and DTA results and are known to occur in similar electrolytes (10, 11)

Moreover, for LiCl-KCl mixtures in the absence of MgO, only endothermic peaks corresponding to the loss of adsorbed water (peak I), vaporization of liquid water (peak II), and to the electrolyte solid-liquid transition (peak V) were observed. This is in accordance with the suggestion that the exothermic effect (peak III) is related to reactions involving oxide and hydroxide ions (such as reactions [5] and [6]). The endothermic process IV taking place between regions III and V is suggested to be the result of the hydrolytic decomposition, in which the electrolyte becomes contaminated with alkaline products and HCl is lost from the system, *i.e.*, reaction [6] from right to left. Such reaction occurring at temperatures near fusion has been reported in several publications (10, 11).

The weight loss temperature dependence of the alkali chlorides has been investigated by Duval (20) using a thermogravimetric balance. An almost horizontal stretch between 80° and 96°C in the TGA curve of lithium chloride was interpreted to correspond to the composition $\text{LiCl} \cdot \frac{1}{2}\text{H}_2\text{O}$ (20). A typical TGA curve for the LiCl-KCl-MgO mixture is shown in Fig. 6. The lost weight processes found at 50°-70°C and 70°-130°C correspond to the loss of surface adsorbed water and the evolution of water vapor after hydrate dissociation. Moreover, the overall weight loss in the ambient-130°C range is quite identical to the initial water content of the sample, determined by a Karl Fisher titration to be 2.5 w/o. The surprisingly large weight loss (≈ 6 w/o) found in the 130°-170°C region seems to correspond to the conductance increase in region III (Fig. 3) and to the exothermic activity (peak III in Fig. 5) observed after dehydration. Since this TGA effect in region III was neither reported for LiCl (20) nor detected in the present study for LiCl-KCl in the absence of MgO, it seems to be related to a reaction consuming oxide ions and converting to a volatile product, *i.e.*, water. This suggestion is also consistent with the EC results, since electrical conductivity is sensitive to water evolution.

To detect water vapor in the gas evolved from pellets subjected to heat-treatment, a hygrometer was connected to the apparatus shown in Fig. 1 and relative humidity

Fig. 6. TGA curve for a sample (50 w/o electrolyte + 50 w/o MgO) initially containing ≈ 2.5 w/o water.

Fig. 7. Relative humidity vs. temperature of the gas evolved from a pellet (50 w/o electrolyte + 50 w/o MgO) which has been preheated and cooled (150°-25°C) several times. The system was continuously flushed with dry argon ($\text{RH} < 0.5\%$, flow rate = $2 \text{ cm}^3 \cdot \text{min}^{-1}$).

was recorded as function of temperature. Contrary to the EC, DTA, and TGA experiments, a small and constant flow of dry argon ($\text{RH} < 0.5\%$) was allowed to flush the system (the electrodes also serving as gas inlets). To eliminate the contribution of water evolved in the 25°-150°C region to the relative humidity, several heating-cooling cycles were applied until a constant value of RH was obtained in this temperature range. The RH vs. temperature curve obtained (Fig. 7) showed an increase in relative humidity at $T > 150^\circ\text{C}$, confirming water vapor evolution in this temperature range.

Conclusions

Electrical conductance as function of temperature of several eutectic mixtures has been reported in the literature. However, all reported data concern temperatures above melting point of the electrolyte (21). In the present study, ac conductivity measurements were particularly conducted below the melting temperature of the pelletized LiCl-KCl (64-36 m/o) mixture in the presence of MgO. The electrochemical data were compared to those obtained using differential thermal and thermogravimetric analysis and were related to the various states of water present in the pelletized mixture. There are distinct changes taking place at temperatures right from the ambient value, and at least three main different processes seem to be related to the presence of water in the pellet; the processes are listed below.

1. Initially, the pellet dries by a process that involves the migration of water to the surface of the pellet, where it vaporizes ($T = 25^\circ\text{-}130^\circ\text{C}$).

2. In the temperature region 30°-250°C, exothermic reactions give rise to an increase in electrical conductivity and to a large weight loss effect. Hygrometric measurements indicate the evolution of water in this temperature range. This is suggested to be the product of the thermochemically favorable reaction between oxide or hydroxide ions and hydrogen chloride (reaction [6] from left to right). However, the intensity of the EC, DTA, and TGA effects in region III is much larger than expected to arise from the small amounts of HCl present in the electrolyte (5). Further studies are needed to investigate the exact nature of the processes involved in these temperatures.

3. Further heating ($T > 250^\circ\text{C}$) causes hydrolytic decomposition of the electrolyte, *i.e.*, equilibrium [6] is shifted from right to left, yielding hydrogen chloride and hydroxide ions. The voltammetric detection of water as well as

hydrolytic products in fused pelletized electrolytes ($T > 370^{\circ}\text{C}$) will be described in a future publication (22).

Corrosion of the Wet-Seal Area in Molten Carbonate Fuel Cells

I. Analysis

ABSTRACT

Severe corrosion can occur in the seal area between the cell housing and the electrolyte tile of a molten carbonate fuel cell even if an optimal selection of the active cell materials has been made. Thermodynamic calculations and an approximate mixed-potential analysis indicate that several minor corrosion cells are active at open circuit, and a major corrosion cell is established when the cell is under load. Extensive corrosion can be expected on the anode side of the wet seal, although effects at the cathode side are minor.

The available literature related to gas-seal techniques and methods of minimizing corrosion, particularly in the seal area of a molten carbonate fuel cell, is very limited. In early work on cell development, several types of assemblies comprising all-ceramic components were used, e.g., by Broers *et al.* (1), Salvadori (2), and Kronenberg (3), but such assemblies are bulky and have low resistance to thermal shock. More recently, investigators have used cells and cell stacks formed by pressing together a series of flat-plate cell components (filter-press arrangement) and utilizing a wet seal (4, 5).

In the wet-seal technique, metal flanges are pressed against the flat surface of an electrolyte "tile," i.e., a porous, inert matrix filled with electrolyte. At the cell operating temperature, sufficient free liquid is present to wet the metal surfaces and form a gas seal, as schematically represented in Fig. 1. The concept was first applied by Davtyan (6) when working with "solid electrolyte" fuel cells in 1946. Later investigations by Broers (6) revealed that the electrolyte was not really a solid but contained molten salts such as phosphates and tungstates. Chambers and Tantram (7), using a eutectic mixture of lithium and sodium carbonates held in a porous, sintered magnesia disk, formed a cell or battery by sandwiching the disk, with its attached electrodes, to metal flanges. Similar sandwich-type cells were investigated by Peattie and

Trachtenberg (8). The wet-seal approach was also used in a previous project carried out at IGT (9). Critical improvements in seals and seal design for single, flanged cells are described in patent citations (10, 11). A review of more recent developments is given by Pigeaud *et al.* (5).

Because the wet-seal technique involves metal-electrolyte contact in a gas-deficient region of the cell, one may expect one or more corrosion cells to form. Experience with single, flanged cells has shown that corrosion of the seal-area metal can be severe and may lead to a poor seal and rapid deterioration of cell performance as a result of gas leakage. Severe corrosion in the wet-seal area also aggravates carbonate loss from the tile and may cause catastrophic failure (4). In fuel-cell stacks the cells are separated by a bipolar plate, which forms a wet seal with the electrolyte tile in each cell of the stack. The bipo-

lar plate, for which stainless steel is a candidate material, experiences similar corrosion problems as the anode and cathode flanges in a single cell.

Although wet-seal corrosion and its prevention have received some attention in the electrochemical literature (12), no systematic study has been made of the corrosion mechanism and of the corrosion rates at various points in the wet-seal area. In this paper, we compare thermodynamically the corrosion cells operating in the wet-seal area and report corrosion rates under conditions simulating those in a fuel cell. A further objective is to clarify how corrosion can be prevented and to determine the level to which corrosion rates can be reduced. In this paper, the possible mechanisms of corrosion are presented and analyzed. This analysis cannot predict the actual corrosion rates, for which experiments are necessary. The experimental results are presented in the following paper (13).

Conversion and Corrosion Reactions

The main electrode reactions occurring in a molten carbonate fuel cell are at the fuel (negative) electrode or anode

and at the oxygen (positive) electrode or cathode

The overall cell reaction is

Although the cell also converts CO, the direct electrochemical oxidation of CO, analogous to Eq. [1], appears to be very slow. It is generally assumed that CO oxidation takes place via the water-gas shift equilibrium

The fuel electrode and the negative flange of the cell housing (Fig. 1) are continuously in contact with fuel gas containing H₂, CO, H₂O, and CO₂, with N₂ constituting the balance. The oxygen electrode and the positive flange are continuously in contact with oxidant gas containing O₂, CO₂, and a small amount of H₂O, with N₂ constituting the balance. The gas compositions used here to illustrate corrosion processes are shown in Table Ia; they correspond to reformed naphtha as fuel and standard oxidant (70% air, 30% CO₂) as oxidant gas.

A large cell operating under an electrical load has an appreciable degree of conversion, typically 75% for the fuel gas and 50% for the oxidant. The resulting outlet compositions of fuel and oxidant are also shown in Table Ia.

The local driving force for conversion, Eq. [3], is determined by the equilibrium potentials of electrode reactions [1] and [2], which depend on the local gas compositions. This is illustrated in Table Ib, based on standard thermodynamic data (14, 15). The reference potential is that of oxygen reduction, Eq. [2], the reference oxidant consisting of 33% oxygen and 67% CO₂. Because the equilibrium potentials of Eq. [1] and [2] vary from point to point along the electrodes, the driving force for conversion, Eq. [3], varies correspondingly. Consequently, the distribution of the current in a cell with appreciable conversion is nonuniform. Analyses of current distribution in scaled-up cells have been presented by Sampath *et al.* (16) and Wilemski *et al.* (17).

Variations in local gas composition also cause variations in the local driving force for corrosion. The negative half (flange) of the cell housing is in contact, over its entire interior surface, with fuel gas of varying composition. Likewise, the inside of the positive half contacts oxidant of varying composition. In addition, both halves are in contact with ambient air, at and around the open end of the wet seal, where some electrolyte creepage usually occurs. The equilibrium potential of oxygen reduction from air is included in Table Ib.

Table Ia. Compositions of gases used in this work (m/o)

	H ₂	CO ₂	H ₂ O	CO	N ₂	O ₂
Fuel inlet	60.9	8.4	21.6	9.1	—	—
Fuel outlet	10.3	39.6	45.4	4.6	—	—
Air	—	0.03	2.5	—	Bal	20.5
Oxidant inlet	—	29.2	2.8	—	53.7	14.3
Oxidant outlet	—	18.7	3.6	—	68.8	9.0
Reference gas	—	66.7	—	—	—	33.3

Table Ib. Equilibrium potentials of reactions [1] and [2] with respect to standard oxygen electrode (33.3% oxygen, 66.7% CO₂)

	Reaction	Potential at 923 K
Fuel inlet	1	-1121
Fuel outlet	1	-960
Air	2	-310
Oxidant inlet	2	-50
Oxidant outlet	2	-76

Corrosion cells are formed by local oxidation (dissolution) and reduction reactions occurring in adjacent areas of the same, electronically conducting surface. In the present case, these adjacent areas are located on the inside surface of the anodic or cathodic flange and on the porous electrode enclosed by the flange. The oxidation (dissolution or corrosion) reactions can be represented in a general way by the following equations written for a two-valent metal

Similar reactions may be written for a trivalent metal. The reduction reactions contributing to corrosion cells are gas-electrode reactions, principally oxygen reduction, Eq. [2], and possibly reduction of H₂O by the reverse reaction of Eq. [1].

In the treatment of corrosion presented here, the possibility of carbide formation (carburization) is not considered, although carbides can form in the metal phase beneath the oxide scale, if the oxygen activity is very low. Rapp *et al.* (21) have analyzed the conditions for carbide formation in detail and confirmed their predictions experimentally. Shores and Singh (22) have demonstrated the presence of carburization in laboratory cell current collectors. However, it is unlikely that the oxygen activity in the wet seal area will be low enough to cause carburization, except possibly very close to the inner edge of the anode-side flange, at open-circuit conditions or at very small conversions. The experimental results to be presented in Part II (13) show that this assumption is correct.

The electrode reactions, Eq. [5]-[8], are not independent. They involve dissolved gases and ionic species which locally participate in dissociation and hydrolysis equilibria

The water-gas shift equilibrium, Eq. [4], is also applicable. All of these reactions are rapid, at least compared with the rate of corrosion reactions [5]-[8], so that local equilibrium may be assumed. Thus, at any point of the flange surfaces, the equilibrium potentials of electrode reactions [5]-[8] are identical, and we may evaluate the potential by the Nernst equation applied to one of them; for example, Eq. [8]

$$E = E^0(\text{MO}, \text{CO}_2/\text{M}, \text{CO}_3^{2-}) + RT/2F \ln \frac{(\text{MO})(\text{CO}_2)}{(\text{M})(\text{CO}_3^{2-})} \quad [11]$$

The oxide MO is assumed to be insoluble, or sparingly soluble, so its activity is equal to, or close to, unity. In fact, stainless steel passivates; that is, it forms a coherent, conducting oxide layer that reduces the corrosion rate appreciably (18). This oxide layer may consist in part of mixed oxides such as LiFeO_2 and LiCrO_2 , which are also insoluble or sparingly soluble and do not significantly affect the electrode potential. In the transpassive region, these surface layers disintegrate under formation of loosely adherent metal oxides; in a strongly oxidizing, basic (*i.e.*, alkali oxide-rich) environment, such as exists at the cathode under load, chromium may be oxidized further to the very soluble chromate ion

$$E = E^0(\text{CrO}_4^{2-}, \text{CO}_2/\text{Cr}, \text{CO}_3^{2-}) + RT/6F \frac{(\text{CrO}_4^{2-})(\text{CO}_2)^4}{(\text{Cr})(\text{CO}_3^{2-})^4} \quad [13]$$

In Table II, the equilibrium potentials of various metals according to Eq. [11], based on standard thermodynamic data (14, 20), are collected; the gas compositions are those of Table Ia. Iron, chromium, and nickel are of interest not only as constituents of Type 300 stainless steels, but also as electrode materials. In the latter category, copper and cobalt are of interest. The table also includes structural materials such as tantalum, vanadium, and other refractory metals. Among the light metals included are aluminum and titanium, which form insulating oxides.

From Tables Ib and II, one can immediately ascertain which corrosion cells are thermodynamically possible. For example, all three components of stainless steel will have a tendency to corrode at those points of the flange where contact with air and electrolyte occurs. The driving force for these corrosion cells is, from Tables Ib and II

Chromium	-310 -(-1834) = 1524 mV
Iron	-310 -(-1346) = 1036 mV
Nickel	-310 -(-1087) = 777 mV

However, whether corrosion really takes place and, if so, at what rate, depends on the actual electrode potential at the point in question. Corrosion takes place only if the actual electrode potential is more positive than the equilibrium potential of the anodic (dissolution, corrosion) reaction. The rate of corrosion depends on the available driving force (actual potential minus equilibrium potential of the anodic reaction). Therefore, one may expect important differences in the corrosion picture when the cell is under load, as compared to that at open circuit. Thus, it is well known that at high current densities the porous anode material, mainly consisting of nickel, may become oxidized. Table II indicates that this is only possible if the actual electrode potential of the anode, with respect to a 33% oxygen, 67% CO_2 reference electrode, is more positive than, for example, -862 mV if the CO_2 partial pressure is 0.084 atm, as for reformed naphtha at inlet conditions. Such an electrode potential, though unacceptably high (positive) for state-of-the-art fuel cell anodes under standard operating conditions (4), may occasionally be

reached at very high current densities. However, from Table Ib it can be seen that in a cell at open circuit, oxidation of nickel by the reverse reaction of Eq. [1] is thermodynamically impossible unless the H_2O and CO_2 partial pressures in the fuel gas are increased far in excess of those in reformed naphtha at 75% conversion.

In a cell at open circuit, the negative and positive flanges are not electronically connected. Each flange then assumes a mixed potential corresponding to zero net current of the various electrochemical reactions that exchange electrons via the flange. The mixed potential is the result of a complex interaction between the electrochemical reactions (corrosion and reduction) and the supply, by diffusion, of dissolved gases to various points of the wet-seal area. In the carbonate fuel cell at open circuit, a small fraction of the feed gas on both sides is continually being consumed by chemical reaction; that is, there is a small but stationary flux of dissolved gas into the tile toward the opposing electrode or toward the air interface of the wet seal. Hydrogen diffusing from the fuel electrode toward the oxygen electrode and the air/tile interface reacts with oxygen and is consumed (chemical discharge). Furthermore, a small fraction of the feed gases on either side may be involved in corrosion cells (circuits); on the cathode side, some oxygen is reduced, and on the anode side, some H_2O may be reduced. These corrosion cells are parasitic or cooperative, depending on whether or not they consume part of the feed gases. At open circuit, the changes in gas composition are usually of no practical significance. Corrosion cells involving oxygen from air are indifferent with respect to conversion.

In all of the above cases, only those corrosion reactions (dissolution or oxidation) can take place whose equilibrium potential is more negative than the mixed potential assumed by the flange.

The same applies to a fuel cell under load, that is, producing a current. However, the analysis is easier because the electrode potential is controlled externally through the load rather than through the spontaneous interaction of diffusion and reactions in the wet-seal area. The corrosion cells (circuits) are now superimposed on the main cell current, due to fuel conversion, as schematically shown in Fig. 2. One may still distinguish cooperative, parasitic, and indifferent corrosion cells. Thus, a corrosion cell restricted to the anode flange, in which some H_2O is reduced to hydrogen, decreases fuel conversion for a given cell current; it is, therefore, cooperative. Corrosion cells that involve both flanges may also be established, as shown in Fig. 2; such cells parallel the main cell reaction and increase the external current, while also increasing oxidant conversion for a given main cell current due to fuel conversion.

In reality, of course, the various corrosion cells (circuits) do not exist as separate entities in the overall current distribution between the flanges. The resulting current distribution at the flanges can be interpreted in terms of corrosion cells. This is convenient in cases like the present one, where the exact, quantitative analysis of the potential distribution would require much mathematical effort.

Table II. Equilibrium potentials at 925 K vs. standard oxygen reference electrode (33.3% oxygen, 66.7% CO_2)

Material	Reaction	Potential (mV)

Fig. 2. Types of corrosion cells existing in the wet-cell area. Left: current distribution in the electrolyte. Right: schematic in terms of corrosion cells. The bold arrow represents the main cell current due to fuel conversion in the absence of corrosion.

Corrosion Regions and Solute Fluxes

To distinguish the various corrosion cells in the wet-seal area, we identify first the approximate gas compositions adjacent to various regions of the cell housing. These are schematically indicated in Fig. 3.

Surrounding the anode is region A, which has a high concentration of H_2 and CO , and which also contains a considerable amount of H_2O (see Table Ia). From this region, H_2 and CO diffuse toward the edge of the flange. From the edge of the flange (regions C and F), O_2 (as air) diffuses toward region A. H_2 and O_2 react in a zone (indicated by a dotted line) at region B where, consequently, the H_2O concentration is high. Because the solubility and diffusivity of H_2 are appreciably larger than those of O_2 in molten carbonate (17), the location of region B is closer to the outer edge of the seal area than to the inner edge.

The reaction zone between H_2 (or CO) and O_2 within the tile is schematically indicated by the dotted line in Fig. 3. From region B, this line curves toward that part of the tile that lies between the electrodes. The reaction zone is region G, which is closer to the cathode than to the anode.

Region D, near the edge of the cathode, contains a relatively high concentration of O_2 and CO_2 , while region F, near the outer edge, contains a high concentration of O_2 but is low in CO_2 . The concentration of H_2O goes from relatively low in region D to very low in region F. This is schematically indicated in Table III. Region E, unlike the opposite region at the anode side (region B), is characterized by conditions that are not very different from adjacent regions.

To analyze the corrosion effects, it is desirable next to assess the relative importance of the various fluxes of

Fig. 3. Regions in the wet seal according to major dissolved-gas species

Table III. Dissolved gas concentrations in various regions of the wet seal (schematically) in percent of total gas pressure

Region	$H_2 + CO$	CO_2	O_2	H_2O
A	70	8	0	22
B	0	(8)*	0	(92)
C	0	0.1	19	0.1
D	0	29	14	3
E	0	(10)	(17)	(1)
F	0	0.1	19	0.1

* The concentrations in regions B and E are determined by the reaction of converging fluxes, and could be estimated by a rather involved mathematical analysis. The values in parentheses are rough estimates only for purpose of illustration.

dissolved gas in the wet-seal area. These fluxes may reinforce or may counteract the corrosion cells that arise spontaneously. The concentration differences (Table III) and the distances between various regions lead us to conclude that certain fluxes are very important and others secondary, as indicated by solid and dashed arrows in Fig. 4. It should be noted that the tile thickness is only about one-fifth of the length dimension of the flange, so fluxes across the tile are relatively more important than those along the flanges. Also, H_2O fluxes are in first approximation equivalent to CO_2 fluxes because of the hydrolysis equilibrium (Eq. [10]).

Analysis: Corrosion at Open Circuit

The corrosion picture at open circuit is simplified by the observation that in cells of reasonably large size, the open-circuit potentials of the fuel electrode and the oxidant electrode are practically equal to the equilibrium potentials of the respective conversion reactions, that is, H_2 oxidation (reaction [1]) and O_2 reduction (reaction [2]). Therefore, we can make use of Table IV, in which are collected the equilibrium potentials of the primary corrosion and reduction reactions in the various regions.

At the anode side, little iron dissolution should be expected in regions A and B. Only if the fuel gas is richer in H_2O and CO_2 than assumed in Table Ia will it be likely that there is a strong corrosion cell between regions A and B. However, between regions B and C, the conditions are fulfilled for dissolution of iron under simultaneous reduction of O_2 . The driving force for this cell, indicated by i_1 in Fig. 5, is considerably larger than that for corrosion between regions A and B (i_3).

Chromium dissolution can occur over the entire anode wet seal, compensated for by reduction of O_2 from air in region C. Corrosion of chromium, like that of iron, will be most intense just outside region B.

Fig. 4. Primary fluxes (solid arrows) and secondary fluxes (dashed arrows) of dissolved gas at open circuit.

Table IV. Equilibrium potentials of electrode reactions in various regions of the wet seal (in mV at 925 K vs. the 33% oxygen, 66.7% CO₂ reference electrode)

Region	H ₂ O/H ₂	O ₂ , CO ₂ /CO ₃ ²⁻	FeO/Fe	Cr ₂ O ₃ /Cr	NiO/Ni
A	-1120		-1120	-1610	-860
B			-1050	-1611	-864
C		-310	-1350	-1830	-1090
D		-50	-1070	-1560	-810
E		-50	-1110	-1603	-856
F		-310	-1350	-1830	-1090

Figure 5 indicates schematically how the positive and negative areas on the anode side of the wet seal are distributed, corresponding to the prevailing fluxes (H₂O from B to C and E; CO₂ from B to C; O₂ from C to B; and H₂ from A to B).

At the cathode side, where the open-circuit potential is very close to -50 mV, metal dissolution compensated by oxidant reduction is possible everywhere. It is most likely to be intense in region D, where the distance to the cathode itself is shortest. The distribution of positive and negative sites indicated in Fig. 5 is in agreement with a CO₂ flux from region D to E. In region D, one would expect corrosion to be serious, since the driving force for metal oxidation is very large (Table IV). However, the compensating oxygen reduction apparently proceeds at a very small rate: the cathode open-circuit potential is close to equilibrium for this reaction. This suggests that the corrosion rate may, after all, be quite small compared to that at the anode because the kinetics of O₂ reduction in molten carbonate are known to be very much slower than those of H₂ oxidation (15).

Analysis: Corrosion under Load

In a cell under load, some changes may be expected in the picture of Fig. 3. Region B, where H₂ from (A) combines with O₂ from (C), will be located closer to (A) because the concentration of H₂ at (A) is now lower, except at the fuel inlet. At the cathode, the flux of CO₂ from region D, via (E) to (F), will be smaller than at open circuit for similar reasons. The flux of H₂O across the tile, although still very prominent, will be smaller than at open circuit and shifted toward the inner edge of the wet seal.

Again considering the equilibrium potentials shown in Table IV, we note that these are valid only at the feed gas inlet points. The potentials at outlet may be found from Tables I and II; they are graphically illustrated in Fig. 6.

The most important differences, however, have to do with the actual electrode potentials of anode and cathode. These are considerably different from the open-circuit

Fig. 5. Corrosion cells in the wet-seal area as open circuit

values (Fig. 6). Also, anode and cathode are connected electronically through the load, thereby opening the possibility of cross-tile corrosion cells. The consequences of the new situation are shown schematically in Fig. 7.

At the anode side, where the operating potential is -950 mV, corrosion cell i₁, in region C, is likely to extend further toward the inner edge of the wet seal. Also, under fuel outlet conditions the H₂O concentration at (A) may be high enough to make the anodic leg of corrosion cell i₃, at and near (B), extend further toward the inner edge of the seal. This is equivalent to an increase of corrosion current i₃ and a decrease of fuel conversion (cooperative corrosion). Nevertheless, i₃ remains quite small because the driving force is small.

The salient feature of Fig. 7, however, is the corrosion cell across the tile, between regions B and E. This is a major corrosion cell because the driving force is large and the distance over which it operates is small. Cell i₅ is made possible by the electronic connection between the flanges. The current is in first approximation inversely dependent on the load, as is the main conversion current of the fuel cell. We note also that the corrosion current i₅ is reinforced by the flux of H₂O, and equivalently of CO₂ by equilibrium (10), across the tile from region B to E.

At the cathode side, the corrosion cell i₂ is weakened or suppressed, as is cell i₄, by the negative shift of the electrode potential under load (cathodic protection).

To quantify the various corrosion tendencies in first approximation, we observe that the driving force for cor-

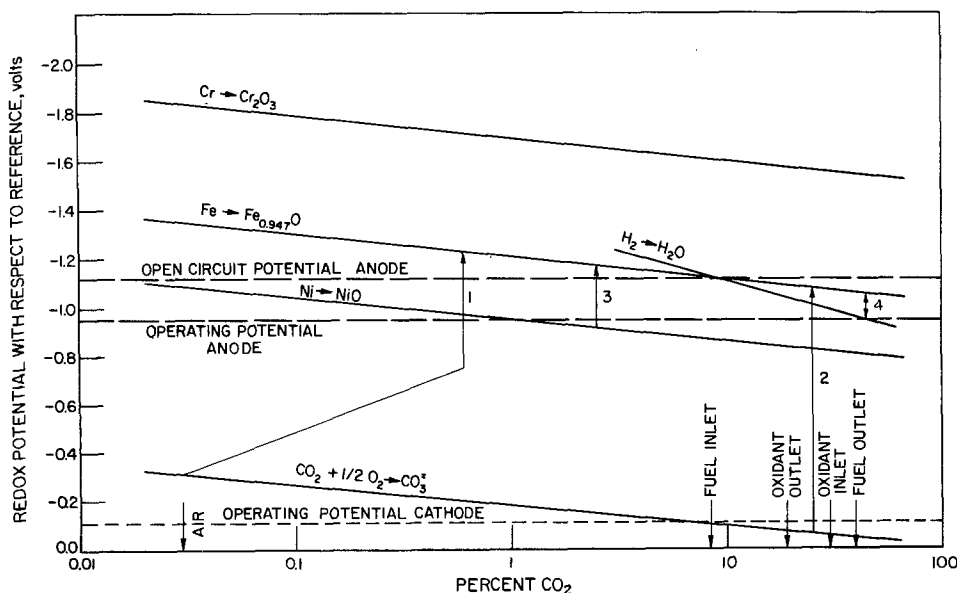

Fig. 6. Equilibrium potentials of electrode reactions vs. the 33.3% oxygen and 66.7% CO₂ reference electrode as a function of CO₂ partial pressure. Operating potentials of anode and cathode, as well as anode open-circuit potential, are indicated.

Fig. 7. Corrosion cells in the wet-seal area under load

rosion cell i_2 of Fig. 7 is, for iron corrosion, approximately $-50 - (-1110) = +1060$ mV at open circuit, but decreases to $-100 - (-1110) = 1010$ mV under load, similarly for cell i_4 . The principal corrosion cell on the anode side is at open-circuit cell i_1 , which has a driving force of $-310 - (-1050) = +740$ mV; however, under load the principal corrosion cell is i_5 , with driving force $-100 - (-950) = +850$ mV over a much smaller distance.

Thus, corrosion at the cathode side of the wet seal should be decreased and the anode side should experience more intense corrosion. Correspondingly, the corroded area of the anode side may be expected to increase under load, although the cathode side should be largely immune.

Corrosion of Various Metals in an Operating Cell

At the anode operating potential of -950 mV, chromium and iron will be oxidized (Fig. 6), but nickel, cobalt, and copper will not (Table II). The thermodynamic data also indicate that somewhat less corrosion of iron should be observed at the fuel outlet side of the cell because the equilibrium potentials for metal oxidation become more positive with increasing partial pressure of CO_2 (Fig. 6). In terms of the corrosion cells of Fig. 7, this means a strong cathodic component of i_3 (H_2O being reduced in region A) and possibly a shift of the anodic leg of i_3 , as well as i_5 , toward the outer edge of the wet seal. However, this does not necessarily imply that the total rate of corrosion in the wet-seal area is less.

For the corrosion of chromium, fuel inlet or outlet conditions make little difference because the driving force for corrosion is large. If, as has been suggested (19), corrosion of stainless steel takes place by intergranular attack of chromium, there would not be any significant effect of fuel gas composition. However, the picture is complicated by the formation of mixed oxides, such as LiCrO_2 and LiFeO_2 , whose solubility and conductivity are influenced by the basicity of the melt and by the relative concentrations of the alkali ions. For lack of adequate information about these fundamental chemical aspects of corrosion in molten carbonates, the present approximate analysis must suffice.

The analysis in this paper is based primarily on tendencies indicated by thermodynamic equilibria combined with a semi-quantitative assessment of the actual corrosion cells in the wet-seal area. A more exact prediction of the intensity of corrosion and its distribution would follow from a complete mathematical model of the potential, current, and species concentration distributions in the wet-seal area and adjoining regions. Solving such a model would require not only extensive computational effort, but also reliable kinetic information, for example, on the dissolution and passivation of stainless steel and the reduction of oxygen at steel or various metal oxides.

Under these conditions, it is easier to simulate wet-seal conditions experimentally in a model cell. The results of model experiments are reported in the second part of this paper (13).

Summary

A semi-quantitative analysis of the mixed-potential conditions in the wet-seal area of a molten carbonate fuel cell leads to the following conclusions.

1. At open circuit, the anode side will corrode mostly near the center of the wet seal compensated by reduction

of atmospheric O_2 near the outer edge. Corrosion close to the inner edge of the seal is only expected if the fuel is very rich in H_2O and CO_2 . The cathode side will corrode near the inner edge of the seal, compensated by reduction of oxidant in the porous cathode.

2. Under load, anode wet-seal corrosion will take place much more intensively than at open circuit and over a greater area. The compensating reaction is reduction of oxidant gas, or atmospheric oxygen, at the cathode flange. Corrosion of the cathode side is less intensive than at open circuit owing to cathodic protection under load.

3. Under higher H_2O and CO_2 partial pressures at fuel outlet conditions, somewhat more corrosion should be observed at the inner edge of the anodic wet seal near the fuel outlet than at fuel inlet. This effect should be very clear if the corrosion process involves iron oxidation directly, if it takes place via chromium oxidation, the differences should be minor.

ABSTRACT

Experimental results for anode wet-seal corrosion in molten carbonate fuel cells generally agree with postulated mechanisms that involve corrosion couples acting along or across the seal area. The corrosion rate of Type 316 stainless steel in the anode wet-seal area under all test conditions is unacceptably high. Substitution of an aluminum containing alloy, such as Kanthal A-1, reduces the anode wet-seal corrosion by at least two orders of magnitude. The corrosion rate of Type 316 stainless steel in the cathode wet seal is about two orders of magnitude lower than in the anode wet seal.

In Part I (1), we presented an approximate thermodynamic analysis of the mechanisms that cause corrosion of the molten carbonate fuel cell hardware. Two corrosion cells of relatively minor intensity should be active at open circuit: flange metal/air at the anode side and flange metal/oxidant gas at the cathode side. A major corrosion cell, anode-side flange metal/cathode-side oxidant, should be established under load. The analysis predicted a greater corrosion rate of the anode wet seal than of the cathode wet seal.

In this part, we present the results of corrosion experiments carried out to test the thermodynamic predictions, and we identify practical solutions to the wet-seal corrosion problem. The experiments were carried out at varying electrode potential (cell at open circuit or under load), fuel utilization (inlet or outlet), and material (316 stainless steel or Kanthal A-1).

Apparatus and Experimental Conditions

As discussed in Part I, several corrosion cells may be expected to operate in the wet-seal area of molten carbonate fuel cells (1). Because of the design limitations of scaled-up cells, such as the difficulty of access for reference electrodes, the corrosion mechanism cannot be studied quantitatively in actual operating cells. Therefore, out-of-cell testing is required. However, great care must be taken to assure that the characteristic design parameters controlling corrosion rates, for example, tile thickness, diffusion path lengths, and local gas compositions, are comparable to those in actual cells. Several test configurations were evaluated and tested before the design shown in Fig. 1 was adopted. In the test-stand design of Fig. 1, the test-specimen (J) for the anode wet seal, 3.8 cm diam, was welded to a ring (L) previously welded to a Type 316 stainless-steel tube. An electrolyte tile (I) was placed on the specimen. The test specimen was 0.64 cm larger in diameter than the electrolyte and was welded around the edge of the ring to minimize any changes in the grain structure that could occur during the welding operation. The specimen was then machined to accommodate a ring-shaped anode. Perforations in the specimen provided fuel access to the electrode. The cathode compartment was similar to that of the anode, except that a hole in the center of the cathode and a cathode current collector was provided for the reference electrode. The electrolyte and the wet-seal area, 0.64 cm wide, had the same thickness and width, respectively, as in a working cell. The active cell area was 2.5 cm²; the electrodes were 1.91 cm diam with a 0.66 cm diam center hole.

The corrosion tests were operated at 923 K (650°C) for 1000h using electrolyte tiles 0.178 cm thick. The carbonate content of the electrolyte tiles was approximately 60

weight percent (w/o). A Li₂CO₃/K₂CO₃ eutectic carbonate mixture (62 mole percent [m/o] Li₂CO₃/38 m/o K₂CO₃) was used. The compositions of the test gases are presented in Table I. In the tests operated under load, the anode potential was potentiostatically kept constant at -1000 mV with respect to the 67% CO₂/33% O₂-gold reference electrode described by Borucka (2) and Argano *et al.* (3).

Results

Corrosion at open circuit.—Tests at open circuit were carried out to observe the corrosion caused at the anode side by the metal/air and the metal/fuel corrosion cells (i₁ and i₃ in Fig. 5 of Part I). Both cells cause corrosion in the wet-seal area of the test cell, but the metal/fuel cell would cause more corrosion near the inner edge of the wet-seal area.

Typical corrosion results at open circuit are shown in Fig. 2. The sampling locations are indicated in Fig. 3. Figure 2 demonstrates that the most severe corrosion occurs at sites 3 and 4, which are at the edge of the tile and

Fig. 3. Sampling sites (1-5)

nearest to the ambient air environment. This agrees with the analysis (1), which predicted that the affected area would be beyond the center of the wet seal: the metal/air corrosion cell, i_1 , is stronger than the metal/ H_2O cell, i_3 . The corrosion in areas 3 and 4 is very similar to that caused by excess OH^- and O^{2-} ions, as described by Andersen (4), who worked with basic alkali carbonates and alkali oxides. Corrosion at the center (site 1) and the inside (site 2) of the wet seal is much less severe.

Corrosion under load.—Corrosion testing under load conditions was carried out at fuel inlet and fuel outlet conditions. Photomicrographs from test cells are shown in Fig. 4 and 5. In both types of tests, very severe corrosion is observed. A much greater rate of corrosion is observed at the inside of the anode wet seal (site 2) and its central portions (site 1) than at the outer edge; repeat tests showed similar results. Corrosion rates at these same sites (1 and 2) were much smaller in our experiments at open circuit, where the metal/air cell (i_1) had a limited operating range. Clearly, there is a shift in potential distribution in

Fig. 4. Test results for Type 316 SS under load at fuel inlet conditions

Fig. 5. Test results for Type 316 SS under load at fuel outlet conditions

the wet-seal area upon electrically loading the cell; this is caused by a new, across-tile metal/oxidant corrosion cell (i_5). The latter is the principal corrosion-causing cell when an external current is drawn.

The test cells also show somewhat greater corrosion rates at fuel outlet conditions than at fuel inlet. As our analysis predicted (1), at fuel inlet conditions corrosion cell i_3 (metal/ H_2O) is relatively ineffective because of the high H_2 activity in the gas phase. This protection decreases with the conversion of the fuel, and at the fuel-outlet conditions iron will tend to corrode over a much wider area adjacent to the porous anode. Therefore, it is likely that the somewhat greater corrosion observed at fuel-outlet conditions in our experiments is indeed the result of the much lower H_2/H_2O ratio than at fuel inlet (0.85, compared to 2.82 at inlet).

Careful visual examination of the cathode coupon was carried out after termination of each test. In all the tests, a brownish, rust-like, apparently thin, oxide layer covered the surface of the coupon; the oxide layer was very uniform, with almost no sign of corrosion. To verify this, we sectioned the cathode wet-seal coupon from one test operated at open circuit. Corrosion (caused by the metal/oxidant cell, i_2) is expected to be at a maximum under these conditions. The corrosion observed at the cathode wet seal (Fig. 6) is not severe and is uniform across the sample. The corrosion morphology of the specimen nearest the porous cathode did not differ significantly from that closer to the tile-air interface.

Rates of Corrosion

Experiments under load at -1000 mV vs. the 67% $CO_2/33\%$ O_2 reference electrode show that the most severe corrosion of the Type 316 stainless-steel wet seal occurs at the anode side and at the inner portion of the seal. The rate of corrosion caused by the metal/oxidant cell, i_5 , across the tile, was an order of magnitude greater than

^d Maximum for fuel outlet gas conditions.

that caused by the metal/air cell, i_1 , and the metal/H₂O cell, i_3 , at open circuit. The corrosion rate under load at the anode side was two orders of magnitude greater than that by the metal/oxidant cell, i_2 , at the cathode wet seal under open-circuit conditions.

Corrosion rates measured in 1000h of testing under the same gas environment are collected in Table II. The metal/oxidant cell across the tile, i_5 , combined with the metal/H₂O cell, i_3 , under load causes 0.43-0.62 mm of corrosion. This is to be compared with the metal/H₂O cell, i_3 , alone at open circuit, which is responsible for 0.036-0.040 mm, and the metal/air cell, i_1 , alone at open circuit, which causes 0.08-0.11 mm of corrosion in 1000h. A somewhat greater rate of corrosion of Type 316 stainless steel is observed under fuel outlet conditions (0.45 to 0.97 mm) than under inlet conditions (0.43 to 0.62 mm). On the cathode side, at open circuit, the metal/oxidant cell, i_2 , does not cause more than 0.01 mm. The latter, very low corrosion rate indicates that most of the driving force of this cell (1022 mV at open circuit) is spent in overcoming a high ohmic resistance caused by the oxide layer.

Corrosion Protection by Alumina

The corrosion rates reported above for the anode side of the wet seal are prohibitive, both at open circuit and under load. Since the largest amount of corrosion is clearly associated with the metal/oxidant cell, i_5 , across the tile, corrosion protection by means of an insulating gasket covering the wet-seal faces would be an obvious solution. Such a gasket would function as a barrier to the ions and dissolved gas molecules diffusing or migrating across the tile in the wet-seal area. However, a gasket would not offer long-term protection unless it was intimately bonded to the base metal of the wet-seal flanges. Various possibilities were explored, of which alumina or compounds derived from alumina appeared most promising.

In long-term laboratory cell testing, dense alumina has been shown to be stable for over 40,000h (5). However, its direct use in the wet-seal area would be impractical from the viewpoint of thermal expansion matching in scaled-up cells, and it would also be expensive. Therefore, indirect means of forming a protective oxide layer

based on Al₂O₃ were explored. Alloys known to form protective layers of aluminum oxide and aluminized metals were tested. At 923 K, the redox potential of aluminum in an air atmosphere (0.03% CO₂) is -2675 mV with respect to the (67% CO₂, 33% O₂) reference electrode. In a fuel inlet or outlet atmosphere (Table I), its potential is -2450 or -2389 mV, respectively. These potentials indicate that in an operating cell (anode potential -950 mV or more positive), aluminum will readily be oxidized, possibly at a faster rate than chromium, because the latter has a more positive redox potential. To investigate this possibility, we operated test cells with a Kanthal A-1 (Fe-Cr-Al alloy containing 5% aluminum) anode wet seal.

Visual examination of the Kanthal wet seal revealed no points of high, localized corrosion; this was confirmed by photomicrographs (Fig. 7). An almost-uniform corrosion from the fuel side to the air side of the wet seal is observed; the intensity of the corrosion is small, even though the cell was accidentally operated at 1098-1123 K for 8-15h, during which time corrosion might be expected to be accelerated by the higher temperature.

Thus, Fe-Cr-Al alloys are definitely more suitable than austenitic stainless steels as anode wet-seal material. A further possibility would be that corrosion protection could be achieved by a metallic diffusion coating of aluminum on stainless steel. This was investigated next in assemblies in which the flange surfaces had been treated by aluminum diffusion (5). Aluminized wet seals, which form an insulating layer of Al₂O₃ and or LiAlO₂ *in situ* during the thermal start-up of the cell, have shown negligibly small corrosion rates (less than 0.025 mm in 5000h of testing) (6). This indicates that the cell endurance desired for economic viability (40,000h) can be achieved inasmuch as wet-seal corrosion is concerned.

Summary

The experimental results presented in this paper confirm the validity of the thermodynamic and mixed-potential analysis presented earlier (1). Much greater corrosion of the anode wet seal than of the cathode wet seal is observed; for Type 316 stainless steel, the corrosion rates in a cell under load are greater by two orders of magnitude than open-circuit values. Typically, anode wet-seal corrosion of 316 stainless steel proceeds at a rate of 0.5-1 mm/1000h.

Kanthal A-1 steel (Fe-Cr-Al alloy containing 5% aluminum) was tested to assess the effectiveness of an alumina or aluminate barrier interrupting the principal, cross-tile, metal/oxidant corrosion cell. The rate of corrosion of Kanthal A-1 was small and almost uniformly distributed (0.02 mm/1000h). The results indicate that aluminum diffusion coatings are effective corrosion barriers. In long-term tests of aluminized wet seals, negligible corrosion (less than 0.025 mm in 5000h) was observed (6). This satisfies economic viability requirements.

The low rate of corrosion at the cathode side of the wet seal indicates that Type 316 stainless steel satisfies endurance requirements for molten carbonate fuel cell stacks without further modifications.

Styrene Production from Ethylbenzene on Platinum in a Zirconia Electrochemical Reactor

J. N. Michaels*¹ and C. G. Vayenas²

Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The vapor-phase electrochemical oxidative dehydrogenation of ethylbenzene on platinum-paste electrodes was studied at 575°-600°C in a stabilized-zirconia electrochemical reactor. Styrene and carbon dioxide were the major products. The dehydrogenation rate increased markedly with anodic current, reaching an ethylbenzene-concentration-dependent asymptote at large current densities. The rate of deep oxidation of ethylbenzene to CO and CO₂ was linear in current density. Both rates were strongly inhibited by gas-phase hydrogen. These results can be rationalized by an electrode mechanism in which the dominant charge-transfer reaction is exchange between chemisorbed oxygen on the electrode and oxygen ions in the electrolyte lattice. Styrene and CO₂ were formed primarily by catalytic reactions of ethylbenzene and neutral dissociatively adsorbed oxygen, although at least one other parallel charge-transfer reaction was evident. The current dependence of the dehydrogenation rate results from an oxidative dehydrogenation reaction on the surface whose rate is sensitive to the amount of oxygen on the electrode surface. A simple kinetic model is presented which quantitatively describes these experimental observations.

Styrene is presently produced commercially by the vapor-phase dehydrogenation of ethylbenzene over promoted iron oxide, molybdenum oxide, or mixed iron-oxide/molybdenum-oxide catalysts (1, 2). The reaction is endothermic and equilibrium-limited; under operating conditions of 580°C and atmospheric pressure, the equilibrium constant is 0.19 (3). Ethylbenzene is, therefore, diluted 1:15 in steam to increase the equilibrium conversion to styrene and to maintain the reaction temperature. Under these conditions, conversion is 55%-60% per pass (2).

A significant fraction of the cost of styrene manufacture lies in the separation of styrene from unreacted ethylbenzene. For this reason, alternative processes have been sought which increase the per-pass yield of styrene. The most widely studied among these is oxidative dehydrogenation with a suitable oxidant, such as oxygen or sulfur dioxide (4-10). A second alternative is coproduction of styrene and propylene oxide via the Oxirane process (11).

This work is part of an investigation of a third alternative, electrochemical oxidative dehydrogenation of ethylbenzene. In this process, ethylbenzene is fed to a solid-oxide electrolytic cell, reacting with electrochemically supplied oxygen to form styrene and water. This process offers three potential advantages over the conventional dehydrogenation process. First, because the overall reaction in this cell is the oxidative dehydrogenation of ethylbenzene by oxygen, the equilibrium limitation is eliminated. Second, electricity can be directly cogenerated with styrene production at an efficiency which is not Carnot-limited. Third, because of the absence of equilibrium or flammability limits, dilution of ethylbenzene is unnecessary, permitting construction of smaller reactors.

It should be noted that the economic desirability of cogenerating electricity is not obvious. Recent work by Spillman *et al.* (28) suggests that net expenditure of electrical energy to boost styrene production might be preferable to power cogeneration. Our work does not aim to evaluate the economics of electro-oxidative dehydrogenation. Rather, it attempts to illustrate the physical feasibility

of the process and to understand the electrochemical kinetics of partial and complete oxidation of ethylbenzene. For this reason, no effort has been made to optimize the electrochemical reactor, nor to characterize the sources of electrical inefficiency.

The electro-oxidative dehydrogenation process is shown schematically in Fig. 1. The electrochemical reactor consists of two porous electrodes flanking a section of an oxygen-ion conducting solid electrolyte, such as yttria-stabilized zirconia. At the cathode, molecular oxygen is reduced to oxygen ions. These ions pass through the electrolyte to the anode, where they subsequently react with ethylbenzene to form styrene, water, and other by-products.

This work is an investigation of the anodic kinetics and reaction mechanism of electro-oxidative dehydrogenation of ethylbenzene. Such a study is useful in guiding the choice of suitably active and selective electrocatalysts for this process. We believe that the anodic electrode mechanism in such a system is likely to be a complex combination of electrochemical and purely catalytic steps. The simplest type of mechanism is one in which the sole charge-transfer reaction is exchange between chemisorbed oxygen on the electrode and oxygen ions in the electrolyte. In Kroger-Vink notation, this electrochemical step is

where O_o^x is a lattice oxygen, $V_o^{\cdot\cdot}$ is an oxygen ion vacancy in the electrolyte, $O(a)$ is a chemisorbed oxygen atom on the electrode surface, and e' is an electron. In this mechanism, the oxidation of ethylbenzene and other reactive species occurs by reactions with neutral chemisorbed oxygen. On the other hand, multiple charge-transfer reactions of other chemisorbed, oxidizable species with oxygen ions may occur simultaneously. For example, chemisorbed carbon monoxide or hydrogen may participate in the following reactions

Such charge-transfer reactions have been observed in similar electrochemical systems (19, 24).

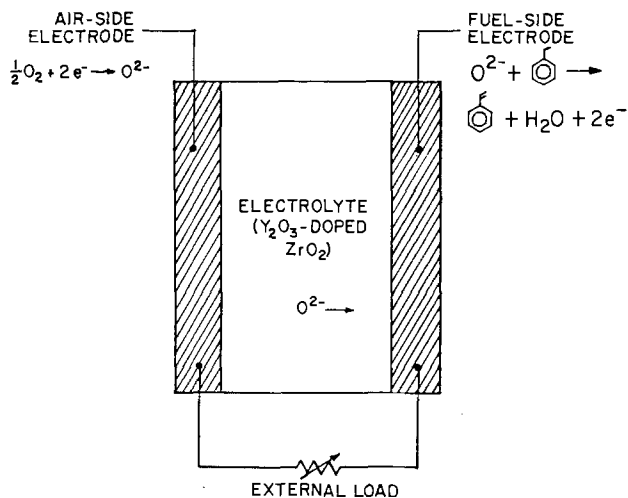

Fig. 1. Schematic of electro-oxidative dehydrogenation

This paper discusses the anode kinetics of the electrochemical cell

Platinum has been chosen as the electrocatalyst in this investigation because of its activity for ethylbenzene dehydrogenation (12) and the simplicity of depositing porous, conductive films onto zirconia (13). The kinetics of styrene formation and carbon dioxide formation are discussed, and a simple electrode mechanism is proposed which quantitatively models these results. Particular attention is paid to determining the major steps in the electrode mechanism and whether multiple charge-transfer reactions occur on platinum.

Experimental

Two electrochemical reactors were constructed from 8 weight percent (w/o) yttria-stabilized zirconia tubes (Zircona Products) having dimensions 46 cm long, 1.9 cm od, and 1.6 cm id. One of these reactors, shown schematically in Fig. 2, was designed to minimize the occurrence of homogeneous reactions of ethylbenzene; it was used in all experiments at 600°C. The active volume of this reactor was reduced from 19.5 to 2.13 cm³ by insertion of a 44 cm long, 1.5 cm diam fused-quartz rod; the rod was centered in the zirconia tube with gold shims. Platinum-paste working electrodes were deposited on the center 10 cm of the inside and outside tube surfaces. Each working electrode was flanked by two 1 cm² platinum-paste reference electrodes. Platinum-paste leads were deposited from each electrode to the appropriate ends of the zirconia tube. The second reactor, used in all experiments below 600°C, had neither reference electrodes, nor a quartz rod. The active volume of this reactor was 19.5 cm³. Each reactor was heated by a Lindberg Sola Basic tubular furnace controlled by a Love Controls Corporation Model 49 proportioning temperature controller.

Platinum-paste electrodes were deposited by painting the cleaned, masked-zirconia surfaces with one to three coats of Engelhard A-3788 fluxed platinum ink. Each coat was air dried at 60–70°C, then calcined in air at 850°C for 30 min. The temperature was raised from room temperature to 850°C at approximately 200°C/h. Freshly deposited electrodes were dull gray in color and adhered well to the electrolyte surface. Their specific surface area was approximately 300 cm²/(cm² superficial area) (13). The end-to-end resistance of the working electrodes at 25°C ranged between 1 and 2.5Ω. External connections to these electrodes are discussed in detail elsewhere (14).

Each reactor was shielded from extraneous electrical noise by insertion into a grounded 30 cm long, 3.8 cm od stainless steel tube. Air flowed through the annular space between the shield and reactor at a nominal flow rate of 100 cm³ (STP)/min. At this flow rate, both the pressure drop and external mass transfer resistance were negligi-

ble, and the oxygen partial pressure at the cathode surface remained constant at 0.21 atm.

The reactors were controlled galvanostatically by an AMEL Model 549 potentiostat/galvanostat. The current and voltages between any pair of electrodes were measured with Fluke Model 8600A digital multimeters (voltmeter input impedance 10⁷Ω). The cell working voltage and the anodic overpotential were monitored continuously with a two-pen chart recorder (input impedance 10⁶Ω). The anodic overpotential was measured using the adjacent downstream reference electrode. Because these electrodes were made of the same material and, therefore, catalyzed the same electrode reactions, the measured overpotential was insensitive to the overall conversion of ethylbenzene.

In a typical experiment, feed conditions and the cell current density were set, and the system was allowed to reach steady-state conditions. The approach to steady state was followed by monitoring the cell working voltage and, when possible, the anodic overpotential. When the voltages stabilized, the feed and product-stream compositions were analyzed by on-line gas chromatography, and the cell current, the feed and product volumetric flow rates, and all relevant voltages were measured. All results discussed below are steady-state results.

The reactors were differential with respect to ethylbenzene conversion; total conversion was limited to 15% or less in all experiments. Reaction rates, therefore, were calculated directly from product flow rates. Reaction rates, rate constants, and cell current are normalized by the area of active electrolyte.

The experimental flow system and gas-chromatographic analytical system are discussed in detail elsewhere (14, 15).

Results

Three experiments are discussed below. In the first, ethylbenzene diluted with helium was fed to the reactor, and the rates of product formation were measured as a function of current density. In the second, hydrogen was added to the ethylbenzene/helium feed stream, and the same measurements repeated. In the third, oxygen was added to the ethylbenzene/helium feed stream, and the rates of product formation were measured at open circuit.

In all experiments, detectable products included H₂, CO, CO₂, water, methane, ethylene, benzene, toluene, and styrene. Neither working electrode lost electrochemical activity during the duration of the experiments. The carbon atom balance closed to within ±2%, suggesting that coke formation on the anodic surface is insignificant.

The overall reactions which occur in the electrolytic cell may be summarized as follows

This list is not exhaustive; rather, it represents the predominant reactions responsible for the final product distribution. Because this reaction system is so complex, it is convenient to lump the production of CO and CO₂ and that of benzene and toluene in the analysis of the rate data. The rate of formation of CO and CO₂ is termed the

Fig. 2. Stabilized-zirconia electrochemical reactor: annular geometry

“deep oxidation” rate and is designated by r_{DO} ; the rate of benzene and toluene formation is called the “dealkylation” rate and is designated by r_{DA} . The rate of styrene production is synonymous with the “dehydrogenation” rate and is designated by r_{DH} .

Due to the diversity of the experimental measurements, the discussion of results is divided into two subsections. The division is based on the primary goals of this work: elucidation of the prominent steps in the electrode mechanism; and detection of the predominant charge-transfer reactions. The behavior of the dehydrogenation, deep oxidation, and dealkylation rates are discussed in the first subsection. These measurements are summarized in Fig. 3-6. The current-voltage characteristics of the anode and the effect of gas-phase oxygen on the reaction rates, summarized in Fig. 7 and 8, are discussed in the second subsection.

Electrode mechanism.—Dehydrogenation.—When no hydrogen or oxygen is present within the feed, the dehydrogenation rate is strongly current dependent, as shown in Fig. 3a. At low ethylbenzene concentrations and moderate current densities, the rate of styrene production is as much as six times larger than that at open circuit; the enhancement of the dehydrogenation rate saturates at large current densities. This behavior suggests that dehydrogenation of ethylbenzene occurs by two pathways on the platinum electrode. The first pathway is a nonoxidative reaction which produces styrene and hydrogen. The second pathway is an oxidative pathway which ultimately produces styrene and water, whose rate is dependent on the supply of oxygen to the electrode surface.

Further evidence of this dual-pathway dehydrogenation mechanism is furnished by the experiments with hydrogen/ethylbenzene mixtures. As shown in Fig. 4a, the dehydrogenation rate at a given current density decreases as the hydrogen concentration in the feed increases. This indicates that dehydrogenation of ethylbenzene is inhibited by hydrogen. This inhibition is evident only at nonzero current densities; the open-circuit dehydrogenation rate is independent of the hydrogen concentration. These results suggest that styrene is formed in two parallel, independent surface reactions: a nonoxidative pathway which is insensitive to current density and hydrogen concentration; and an oxidative pathway which is current dependent and strongly inhibited by gas-phase hydrogen.

Deep oxidation.—The deep oxidation rate in the absence of gas-phase hydrogen is linear in current density and zero order in ethylbenzene, as shown in Fig. 3b. Oxygen atom balances indicate that all of the electrochemically supplied oxygen is accounted for by the formation of CO, CO₂, and water; no oxygen is detected in the gas phase. The linearity of the rate, therefore, is simply a consequence of Faraday's law. The rate of production of all oxygenated species must be proportional to the current density and independent of gas-phase composition. Although

small amounts of water are produced by oxidative dehydrogenation of ethylbenzene, all of the oxides of carbon and most of the water are produced by deep oxidation. Therefore, the deep oxidation rate should be nearly linear in current and independent of ethylbenzene concentration, as observed. It is interesting to note that the absence

of oxygen evolution at the anode implies that the deep oxidation of ethylbenzene is oxygen limited.

As shown in Fig. 4b, the deep oxidation rate is strongly inhibited by addition of hydrogen to the gas phase. In contrast to the dehydrogenation rate, the deep oxidation rate is reduced to zero by large hydrogen concentrations. This behavior is suggestive of simple competition between hydrogen and ethylbenzene for available oxygen on the electrode surface in parallel surface reactions. The large inhibition of r_{do} implies that oxidation of hydrogen on the surface is significantly faster than that of ethylbenzene.

Dealkylation.—In contrast to the dehydrogenation and deep oxidation rates, the dealkylation rate is independent of current density. This is shown in Fig. 3c. This behavior suggests that dealkylation is a nonelectrochemical, catalytic reaction which occurs in parallel with dehydrogenation and deep oxidation of ethylbenzene.

Selectivity to styrene.—The experimental results shown in Fig. 3 and 4 may be simply summarized by plotting the selectivity to styrene as a function of current density. This has been done in Fig. 5 and 6, respectively, where some of the data shown in Fig. 3 and 4 have been removed for clarity. The selectivity to styrene in these figures is defined as the ratio of the dehydrogenation rate to the total rate of consumption of ethylbenzene.

In the absence of gas-phase hydrogen, the selectivity decreases markedly with current density, as shown in Fig. 5. This current dependence is the result of deep oxidation of ethylbenzene. The selectivity decreases with decreasing ethylbenzene concentration at nonzero current densities because the deep oxidation rate is zero order in ethylbenzene, while the dehydrogenation rate is positive order. At open circuit, no CO_2 is formed, and the selectivity is 78% and is concentration independent; this value is determined by the relative rates of dehydrogenation and dealkylation, which are each first order in ethylbenzene.

The selectivity in the presence of significant amounts of gas-phase hydrogen is shown in Fig. 6. The selectivity increases and becomes less sensitive to changes in current density as the hydrogen concentration increases. Both of these effects are due primarily to the inhibition of the deep oxidation rate by hydrogen.

Charge-transfer reactions.—The results discussed above present an overview of the important steps in the anode reaction mechanism. It is clear that some steps in this mechanism are nonoxidative and, therefore, purely catalytic. However, among the oxidative reactions, it is not possible to distinguish between catalytic reactions with neutral chemisorbed oxygen and charge-transfer reactions with oxygen ions. This question is addressed most directly by measurement of the anodic overpotential. Tafel plots of the anodic overpotential measured at 600°C are shown in Fig. 7. These measurements are not compensated for the ohmic drop between the reference and working electrodes; this is the source of the curvature of the plots. Unfortunately, the ohmic resistance was not determined by current interruption; therefore the data were fit by the high-field limit of the Butler-Volmer equation, modified to account for the significant ohmic contribution to the overpotential.

$$\eta_m = \frac{RT}{\alpha F} \ln(i/i_0) + IR_E$$

where η_m is the measured overpotential, η is the activation overpotential, α is the transfer coefficient, i_0 is the exchange-current density, F is the Faraday constant, R is the gas constant, T is the absolute temperature, I is the total cell current, and R_E is the uncompensated resistance. The solid lines in Fig. 7 are calculated with $\alpha = 1.0$, $R_E = 5.5\Omega$, and exchange-current densities of 0.015, 0.028, and 0.060 A/m² at feed ethylbenzene mole fractions of 0.0047, 0.0086, and 0.0194, respectively. As discussed in detail in the following section, a transfer coefficient of unity is consistent with oxygen oxidation/reduction's being the major anodic charge-transfer reaction. On the other hand,

the ethylbenzene-concentration dependence of i_0 suggests that an additional exchange reaction also occurs in the electrode mechanism.

The variation of the open-circuit dehydrogenation and deep oxidation rates with oxygen partial pressure also suggests that oxygen exchange is the dominant anodic charge-transfer reaction. As shown in Fig. 8, the dehydrogenation rate increases rapidly to a constant value as the oxygen pressure increases, and the deep oxidation rate is first order in oxygen. Furthermore, oxygen is fully consumed in the production of CO , CO_2 , and water. These results are qualitatively similar to the electrochemical results shown in Fig. 3. This similarity suggests that the reactions of oxygen and ethylbenzene are insensitive to the source of oxygen. This is consistent with an electrode mechanism in which ethylbenzene reacts with neutral chemisorbed oxygen in nonelectrochemical steps.

Discussion

These results strongly suggest that electro-oxidation of ethylbenzene on platinum occurs mainly by chemical, rather than electrochemical, steps. Oxygen ions are rapidly oxidized to neutral adatoms, and these subsequently react with ethylbenzene and hydrogen to form styrene, CO_2 , and water. Dehydrogenation of ethylbenzene occurs by two parallel surface reactions, one nonoxidative, the other oxidative. Deep oxidation of ethylbenzene and hydrogen are rate limited by oxygen supply to the electrode surface. Small amounts of toluene and benzene are formed in parallel, purely catalytic reactions.

These ideas are incorporated into the following kinetic model, which quantitatively describes the observed electrode kinetics. This model does not attempt to describe all of the reaction steps and intermediates involved in ethylbenzene dehydrogenation and deep oxidation. That would be a formidable task and is not justified by the extent of the data. Rather, emphasis is placed on developing the simplest model which captures the important aspects of the qualitative mechanism described above and adequately describes the experimental observations. Additional details of this model are presented in Ref. (15). For simplicity, the dealkylation reactions are ignored due to their small contribution to the overall conversion of ethylbenzene. Deep oxidation of styrene and production of carbon monoxide are also neglected.

This model contains three major assumptions. First, oxygen exchange is the sole charge-transfer reaction. Second, two forms of uncharged oxygen coexist on the platinum surface. The first form is mobile, chemisorbed oxygen, which reacts with adsorbed hydrocarbons and hydrogen to form CO_2 and water. The second form is a surface "oxide" which oxidatively dehydrogenates adsorbed ethylbenzene to styrene and water. This assumption is supported by studies of cyclohexane dehydrogenation on platinum single crystals; these studies show the dehydrogenation rate to be enhanced by preoxidation of the crystal surface (15, 27). The third assumption is that interchange between the two forms of oxygen is rapid and can be modeled as an equilibrium. Thus, an increase in the coverage of chemisorbed oxygen increases the coverage of the oxide and concomitantly increases the oxidative-dehydrogenation rate.

The catalytic surface is therefore modeled to have two types of sites, S1 and S2. All gas-phase species adsorb and react on S1 sites. Nothing in the gas-phase adsorbs on S2 sites. Rather, S2 sites are "oxidized" by available chemisorbed oxygen and subsequently react with adjacent adsorbed ethylbenzene molecules to form styrene and water. Ethylbenzene and styrene are assumed to be in adsorption equilibrium on S1 sites at suitably low coverages such that their isotherms are linear. This assumption appears to be justified by the low desorption temperature of benzene on clean and carbon-covered platinum surfaces (18). Hydrogen and oxygen adsorb dissociatively on the S1 sites; hydrogen is assumed to be in adsorption equilibrium and at low coverage (25, 26).

Because the deep oxidation reactions are oxygen limited, oxygen is not in adsorption equilibrium.

In the absence of gas-phase oxygen, the sole source of oxygen atoms to S1 sites on the anode is the oxygen-exchange reaction

Since this is the only charge-transfer step in the mechanism, Faraday's law requires that the rate of oxygen adsorption on S1 sites equals the oxygen ion flux to the anode, $j_o = i/2F$. Once adsorbed on the anode, the oxygen atoms can react with adsorbed ethylbenzene and hydrogen to produce CO_2 and water. It is assumed that the rate-determining step in each reaction is first order in the adsorbed reactants with the rate constants shown in Eq. [2] and [3]

These reactions are written nonstoichiometrically to emphasize the molecularity of their rate-determining steps. Furthermore, chemisorbed oxygen can oxidize S2 sites. It is assumed that surface oxidation is rapid and that equilibrium between adsorbed oxygen and the oxidized surface is achieved at steady state. If the oxide has stoichiometry S20, this equilibrium is written

where K_* is the oxidation equilibrium constant.

Finally, ethylbenzene dehydrogenation is assumed to occur by two parallel reactions. The first is a nonoxidative surface reaction whose rate-determining step is first order in adsorbed ethylbenzene

The second is an oxidative reaction which is first order in ethylbenzene and oxidized sites

k_{DH} and k_* are the rate constants of the nonoxidative and oxidative dehydrogenation rate-determining steps, respectively.

Reaction rates and selectivities calculated with this model are shown by the solid lines in Fig. 3-6. Because hydrogen conversion in most measurements is large, calculation of the rates required integration of the appropriate rate expressions over the hydrogen profiles in the reactor. Details of these calculations are presented elsewhere (14, 15). The model correctly predicts the "Langmuir-type" behavior of the dehydrogenation rate and the ethylbenzene-concentration independence of the deep oxidation rate at low hydrogen concentrations. The inhibitory effect of hydrogen is also correctly described. The "break" in the selectivity at the intermediate hydrogen concentration shown in Fig. 6 is a real effect. This occurs at the current density at which the hydrogen conversion first reaches 100%. At larger current densities, the hydrogen concentration is zero in an increasing fraction of the reactor, and the deep oxidation rate is uninhibited in the same region. Because the uninhibited rate is so much greater than the rate in the presence of hydrogen, quantitative conversion of hydrogen in the latter stages of the reactor results in a dramatic loss of selectivity to styrene. The large discrepancy between the measured selectivity and calculated selectivity at the highest hydrogen concentration is caused by inaccurate measurement of very small carbon dioxide concentrations.

This model oversimplifies the electrochemistry at the platinum anode by assuming a single charge-transfer re-

action. If the only exchange reaction at the electrode-electrolyte interface were oxygen exchange (Eq. [1]), the anodic overpotential would be well described by the Butler-Volmer equation with transfer coefficients of unity (19-23)

$$i = i_o [\exp(\eta F/RT) - \exp(-\eta F/RT)] \quad [7]$$

This agrees well with the measured overpotential. However, the exchange current density should vary with the surface coverage of chemisorbed oxygen, according to (20)

$$i_o = 2eK_r[\theta_o(1 - \theta_o)]^{1/2} \quad [8]$$

where e is the electronic charge, K_r is the geometric average of the forward and reverse rate constants of reaction [1], and θ_o is the oxygen surface coverage at open circuit. At the temperatures of interest, the coverage of chemisorbed oxygen should be small (18), and the exchange current should decrease monotonically with decreasing oxygen coverage. Since deep oxidation of ethylbenzene is oxygen limited, increasing the ethylbenzene concentration should decrease the steady-state oxygen coverage by increasing the surface reaction rate. Thus, i_o should decrease with increasing ethylbenzene concentration. The measured exchange current density displays the opposite behavior. Therefore, it appears that a second exchange reaction occurs in parallel with reaction [7]. Because of the extent of deep oxidation and dehydrogenation of ethylbenzene, it is likely that there is a significant amount of hydrogen on the electrode surface. Thus, a possible charge-transfer reaction is direct oxidation of adsorbed hydrogen atoms

This exchange reaction has been observed previously on nickel electrodes (24). When the surface coverage of hydrogen is small, the exchange current of this reaction should increase with increasing hydrogen coverage. Thermal programmed desorption results suggest that hydrogen is in dissociative-adsorption equilibrium and is at low coverages under conditions of interest (25, 26); therefore, hydrogen coverage increases with increasing hydrogen partial pressure. Because the dehydrogenation rate is positive order in ethylbenzene, the average hydrogen concentration in the reactor increases and increasing ethylbenzene concentration. For this reason, the exchange current of reaction [1] also should increase with increasing ethylbenzene mole fraction.

Conclusion

The dehydrogenation rate of ethylbenzene is significantly enhanced by electrochemical supply of oxygen to a platinum-paste anode. In the absence of significant amounts of gas-phase hydrogen, the major by-product is CO_2 . Addition of hydrogen to the reactor feed inhibits dehydrogenation and deep oxidation; in the limit of large hydrogen partial pressures, the dehydrogenation rate approaches its value at open circuit, and the deep oxidation rate approaches zero.

The anodic electrode kinetics are well described by a model which assumes that the sole electrochemical reaction is exchange of dissociatively adsorbed oxygen and oxygen ions in the electrolyte lattice. Electrochemically supplied oxygen adatoms subsequently react with adsorbed ethylbenzene and hydrogen to form carbon dioxide and water, or with the platinum surface to form a surface oxide. Adsorbed ethylbenzene reacts with this oxide in an oxidative-dehydrogenation reaction to form styrene and water. This surface reaction is responsible for the electrochemical enhancement of the dehydrogenation rate.

This kinetic model oversimplifies the anodic electrode mechanism by assuming oxygen exchange is the sole charge-transfer reaction. The current-voltage characteristics of the anode suggest that oxygen exchange is indeed an important step in the mechanism. However, at least one other parallel charge-transfer reaction is apparent.

From a practical standpoint, the performance of these reactors is hampered by platinum's activity as a non-specific oxidation catalyst. A better choice for the anodic material might be an active and selective oxidative-dehydrogenation catalyst with suitably large electrical conductivity. Another possible improvement is suggested by the inhibitory effect of hydrogen. If a hydrogen-rich mixture of styrene and ethylbenzene were produced in the vicinity of a platinum anode, hydrogen could be selectively oxidized from the mixture electrochemically, shifting the equilibrium toward styrene and potentially generating electricity. This could be accomplished by packing a platinum-anode solid-oxide fuel cell with a commercial dehydrogenation catalyst. Preliminary work with both of these approaches is reported elsewhere (14).

ABSTRACT

A limiting current model for the potential and concentration distribution for a flow-by porous electrode of infinite length to width ratio is developed and compared to previous models of Alkire and Ng and Fedkiw. For flow-by electrodes of practical interest, the maximum solution phase potential drop is shown to be dependent upon one relevant parameter: the product of the electrode width and the reciprocal of the penetration depth, αd . Criteria delineating the optimal electrode configuration are given using this potential difference as a basis for comparison. Results of the comparison show that the criteria are dependent upon reactant conversion but independent of any specific mass-transfer correlation.

Packed-bed porous electrodes have become increasingly attractive in the past several years for use in a number of industrially important processes. These electrodes have been suggested for such diverse applications as removal of dilute metal ions from waste streams (1), electro-organic synthesis (2), and off-peak energy storage (3).

Two principal configurations for packed-bed electrodes have been developed: the flow-through configuration, where fluid flow and current are parallel; and the flow-by configuration, where the fluid flows perpendicularly to the current. Both configurations are illustrated in Fig. 1, where the porous electrodes are represented by rectangles and the separators by dashed lines. For simplicity, we choose to represent the counterelectrodes as planar electrodes; however, in general, the counterelectrodes can also be porous electrodes.

Figure 1a illustrates a flow-through electrode with an upstream counterelectrode. An upstream counterelectrode is favored over a downstream counterelectrode in the flow-through configuration, because it gives a lower ohmic potential drop, particularly at high conversions (4). The Y direction denotes the direction of fluid flow in the figure. For the flow-through configuration, the flow is divided as it enters and flows in different directions through the working electrode and counterelectrode. Current generated within the porous electrode flows in the same spatial direction as the fluid flow.

Figure 1b illustrates a flow-by configuration. For the flow-by configuration, the fluid flow is again divided, but here the flow to the working electrode and counterelectrode remains in the same direction. In this configuration, current generated within the porous electrode travels generally in the X direction, which is perpendicular to the direction of the fluid flow.

Bennion and Newman (1) developed a one-dimensional model for the flow-through electrode assuming its performance to be limited only by the transport of reactants from the bulk stream to the surface of the electrode. More realistic one-dimensional models for the flow-through electrode not restricted to this "limiting current" assumption have subsequently been developed (5). These models incorporate equilibrium constraints, finite rate kinetics, and parasitic side reactions in addition to the transport of reactants.

Because the fluid and current travel in the same direction in the flow-through configuration, the analysis remains one-dimensional even in the general case. In the

flow-by configuration, however, the general analysis is necessarily two-dimensional. The absence of a common space variable for the fluid and current flow requires that the analysis be formulated in terms of partial differential equations, unless simplifications are made.

Alkire and Ng (6, 7) simplified the analysis of the flow-by electrode by assuming current flow to travel directly perpendicular to the fluid flow. This assumption reduces the equation for the potential distribution from a partial differential equation to an ordinary differential equation. Recently, Fedkiw (8) analyzed the special case of a flow-by electrode at the limiting current by including the two-dimensional nature of the current distribution and the effects of the finite electrode length. However, he included in his analysis a single specific dependence of the mass-transfer coefficient on velocity. Stork *et al.* (8, 9), in two recent papers, give theoretical and experimental results for the potential distribution in a flow-by electrode. The theoretical model they present is essentially the same limiting current analysis given by Fedkiw. Some experimental measurements of the potential distribution inside a flow-by electrode are also given which compare well with results of their calculations.

Alkire and Ng (6, 7), Trainham and Newman (2), and Fedkiw (8) have all considered the selection of the optimum electrode configuration for a given application. Trainham and Newman developed a method, applicable below the limiting current, to select the optimum con-

¹Present address: Acurex Corporation, Aerotherm Division, Mountain View, California 94039.

figuration. Alkire and Ng, followed by Fedkiw, considered the choice of the optimum configuration at the limiting current. Alkire and Ng maximized the volumetric current density to compare the two configurations. Fedkiw compared the maximum solution-phase potential drop for the flow-through configuration to the maximum solution phase potential for the flow-by electrode. Equal electrode volumes and identical flow velocities were chosen as fixed quantities for these two comparisons. At the limiting current, the maximization of the volumetric current density or the minimization of the maximum ohmic potential drop lead to the same result.

The results of Alkire and Ng and Fedkiw can be reconciled by an order-of-magnitude analysis. This can be useful in determining the approximate conditions under which the flow-by configuration is superior to the flow-through configuration at the limiting current. Consider a flow-through and a flow-by electrode of equal dimensions and feed flow rates and with identical packings and feed compositions. Each reactor has a length L , width d , and height W . At the limiting current, the reactant flows through the electrode and reacts at a rate determined solely by the type of packing and the magnitude of the fluid flow. The distribution of the reaction and the total current will therefore be identical in the two reactors. For high conversions of reactant to product, most of the reactant will be depleted in a region very near the front of the electrode. The characteristic length of this region is the penetration depth, denoted by $1/\alpha$. Most of the current in the flow-through electrode with an upstream counter-electrode, must travel an approximate distance $1/\alpha$, through an area of Wd . The majority of the current in the flow-by electrode, however, need only travel a distance comparable to the width of the electrode d , through an area of W/α . The superior electrode configuration is the configuration that yields a lower ohmic potential drop. The ohmic potential drop is the product of the total current times the length of travel divided by the cross sectional area to current flow. A comparison of the ohmic drop shows that the flow-by electrode configuration is preferred for high conversions if the approximate condition

$$\alpha d < 1 \quad [1]$$

is satisfied. This result is identical to the result obtained by Alkire and Ng when they maximized the volumetric current density to compare configurations.

At low conversions, however, the penetration length eventually becomes comparable to the electrode length. In this limit, the current in the flow-through electrode now flows a distance L , rather than $1/\alpha$. Likewise, in the flow-by electrode, the current flows through an area of WL . Equating the ohmic potential drop in the low-conversion limit results in the criterion that the flow-by configuration is favored for

$$\frac{L}{d} > 1 \quad [2]$$

Equation [1] shows that, at high conversions, the parameter αd is of primary importance in distinguishing the optimum electrode configuration and in determining the maximum potential drop in the flow-by configuration. At low conversions, Eq. [2] shows L/d can be expected to be the parameter of primary importance in determining the optimum configuration.

In this paper, we propose a limiting form solution to the two-dimensional potential distribution for large αd . This solution shows that the maximum solution-phase potential drop for the flow-by electrode is primarily dependent upon the parameter αd , with only a secondary dependence upon L/d . We then reexamine potential distribution derived by Fedkiw to determine the conditions under which the two-dimensional nature of the current distribution and the effects of the finite electrode should be included. This new solution, along with the expressions derived by Fedkiw and Alkire and Ng, is presented in a

form that is not restricted to the single mass-transfer correlation presented by Fedkiw.

Finally, the flow-by and flow-through configurations are compared using the maximum solution phase potential drop as a basis for comparison. Criteria are given delineating the optimum electrode configuration which depend upon reactant conversion. Results of this comparison show that the two configurations can be compared independent of any specific mass-transfer relationship.

Potential Distribution

The starting point for the analysis will be the theoretical framework for porous electrodes developed by Benion and Newman (1) and extended by Newman and Tiedemann (11). The porous electrode is treated as a superposition of two continua, representing the fluid phase and the solid phase. A single reaction of the form

will be assumed to occur within the electrode. Under these assumptions, the electrode reaction appears as a homogeneous source or sink term within the conservation of species equation. A solution with excess supporting electrolyte and a uniform solution conductivity will be assumed as well as a dilute solution of reacting species. Diffusion and dispersion will be neglected. Also, the velocity within the electrode is assumed to be plug-flow, one-dimensional in the Y direction only. Under these conditions, at steady state, conservation of the reactant species for both the flow-through and flow-by electrode can be expressed as

$$v \frac{dc}{dy} = -ak_m c \quad [4]$$

with the boundary condition

$$\text{at } y = 0, c = c_f \quad [5]$$

Solution of Eq. [4] subject the boundary condition of Eq. [5] yields

$$c = c_f e^{-\alpha y} \quad [6]$$

where

$$\alpha = \frac{ak_m}{v} \quad [7]$$

The reciprocal of the parameter α can be thought of as a penetration length. The penetration length defines the distance where the reactant is depleted to $1/e$ of its inlet composition, or, as an order of magnitude, the length of the region where most of the reaction occurs within the electrode.

At the end of the bed ($y = L$), the concentration of the flowing stream will have reacted to the largest extent. Here, the concentration of the reactant will be denoted as c_L . Equation [6] then gives at the end of the bed

$$c_L = c_f e^{-\alpha L} \quad [8]$$

This may be rearranged for αL in terms of the inlet and outlet concentrations as

$$\alpha L = \ln \frac{c_f}{c_L} \quad [9]$$

Equation [9] shows that the parameter αL effectively specifies the conversion of reactant within the electrode.

Now that the concentration distribution has been established, the solution to the potential distribution may proceed. For a uniform conductivity and negligible diffusion potential, Ohm's law governs the potential distribution within the fluid phase

$$i_2 = -\kappa \nabla \Phi_2 \quad [10]$$

Faraday's law relates the transfer current to the local rate of mass transfer within the electrode

$$j = \frac{nFak_m c}{s_R} \tag{11}$$

One must also employ the relationship

$$\nabla \cdot i_2 = j \tag{12}$$

which defines the transfer current as the divergence of the total current. Substituting the concentration distribution obtained in Eq. [6] into Eq. [11] and using Eq. [10] and [12], we obtain

$$\nabla^2 \Phi_2 = - \frac{nFak_m c_F}{s_R \kappa} e^{-\alpha y} \tag{13}$$

In contrast to the solution for the concentration distribution, the solution to the potential distribution depends upon the electrode configuration.

Bennion and Newman (1) solved Eq. [13] for a one-dimensional flow-through electrode. Alkire and Ng (6) solved Eq. [13] for the flow-by electrode assuming potential variation only in the direction perpendicular to fluid flow. This assumption reduces Eq. [13] from a partial differential equation to an ordinary differential equation. Fedkiw (8) solved Eq. [13] for two-dimensional current flow in a flow-by electrode of finite length.

Here, we propose to examine the limiting case of a flow-by electrode with an infinite aspect ratio. Thus, our case will reflect the condition

$$R = \frac{L}{d} \rightarrow \infty \tag{14}$$

The potential distribution is obtained by solving Eq. [13] subject to the boundary conditions

$$\text{at } y = 0, \frac{\partial \Phi_2}{\partial y} = 0 \tag{15}$$

$$\text{as } y \rightarrow \infty, \frac{\partial \Phi_2}{\partial y} \rightarrow 0 \tag{16}$$

$$\text{at } x = 0, \frac{\partial \Phi_2}{\partial x} = 0 \tag{17}$$

and

$$\text{at } x = d, \Phi_2 = V \tag{18}$$

Solution to Eq. [13] by separation of variables subject to the boundary conditions in Eq. [15] through [18] yields

$$\frac{\Phi_2 - V}{\frac{nF c_F V^2}{s_R \kappa a k_m}} = \left(\frac{\cos \alpha x}{\cos \alpha d} - 1 \right) e^{-\alpha y} + 2\alpha d \sum_{n=0}^{\infty} (-1)^n \left(\frac{1}{\lambda_n^2} - \frac{1}{\lambda_n^2 - (\alpha d)^2} \right) e^{-\lambda_n y/d} \cos \lambda_n x/d \tag{19}$$

where

$$\lambda_n = \frac{(2n + 1)\pi}{2} \tag{20}$$

To the designer, the maximum variation in solution phase potential may be a quantity of greater interest rather than the potential distribution within the electrode. To relate the relevant design variables to the maximum variation in solution potential, the results of the potential distribution will be used. For the flow-by electrode configuration, the semi-infinite potential distribution indicates that the maximum solution phase potential drop occurs at the front of the electrode, $y = 0$, between the two electrode boundaries, $x = 0$ and $x = d$. This is the position where the greatest current is flowing. The maximum solution phase potential difference in dimensionless form is given as

$$\frac{\Phi_2(x = 0, y = 0) - V}{\frac{nF c_F V^2}{s_R \kappa a k_m}} = \frac{\Delta \Phi_2}{nF c_F V^2} = \frac{\Delta \Phi_2}{\epsilon n F c_F D_0} \frac{Sh}{Pe^2} = \frac{1}{\cos \alpha d} - 1 + 2\alpha d \sum_{n=0}^{\infty} (-1)^n \left(\frac{1}{\lambda_n^2} - \frac{1}{\lambda_n^2 - (\alpha d)^2} \right) \tag{21}$$

This result can be compared to the results obtained by other investigators. The Alkire-Ng approximation gives for the maximum solution phase potential difference

$$\frac{\Phi_2(x = 0, y = 0) - V}{\frac{nF c_F V^2}{s_R \kappa a k_m}} = \frac{\Delta \Phi_2}{\epsilon n F c_F D_0} \frac{Sh}{Pe^2} = \frac{1}{2} (\alpha d)^2 \tag{22}$$

The solution obtained by Fedkiw, which includes the effects of the finite electrode length, can be represented as

$$\frac{\Phi_2(x = 0, y = 0) - V}{\frac{nF c_F V^2}{s_R \kappa a k_m}} = \frac{\Delta \Phi_2}{\epsilon n F c_F D_0} \frac{Sh}{Pe^2} = f(\alpha d, \alpha L) \tag{23}$$

where $f(\alpha d, \alpha L)$ represents a complicated function of the variables αd and αL previously derived by Fedkiw (8).

For the flow-through electrode, the maximum solution-phase potential drop occurs between the front and the rear of the electrode, $y = 0$ and $y = L$. From Bennion and Newman (1), this is

$$\frac{\Phi_2(y = 0) - \Phi_2(y = L)}{\frac{nF c_F V^2}{s_R \kappa a k_m}} = \frac{\Delta \Phi_2}{\epsilon n F c_F D_0} \frac{Sh}{Pe^2} = 1 - e^{-\alpha L} (1 + \alpha L) \tag{24}$$

In Fig. 2, we have plotted the dimensionless maximum potential drop times the ratio of the Sherwood number to the square of the Péclet number for a flow-by electrode. The variable αd has been chosen as the independent variable. We have included curves for a semi-infinite electrode and curves for electrodes of finite aspect ratio. Curves for the finite aspect ratio electrodes were obtained from the work of Fedkiw. In addition, the solution given by Alkire and Ng is shown. These curves are independent of any specific mass-transfer relationship.

The dotted lines plotted on Fig. 2 represent the limiting behavior of the flow-by electrode potential distribution for large values of αd . We have determined these by solving the following problem which is suggested by the limiting physical behavior of the electrode. For a fixed bed aspect ratio R , a large value of αd implies a large value of αL , and consequently a high conversion. Reactants are therefore consumed in a region very near the front of the electrode. For a reactor of very large αL , the volume of the reactor where a significant portion of

Fig. 2. Dimensionless maximum potential drop times the ratio of the Sherwood number to the square of the Péclet number for the flow-by electrode of various aspect ratios as a function of αd .

the reaction occurs approaches zero. The current generated within the bed can then be approximated as a uniform line source of current along the front of the reactor, and Laplace's equation can be used to solve for the potential distribution within the bed. Details of the problem formulation and the calculations are given in the Appendix.

Figure 2 clearly demonstrates five points.

1. The dimensionless maximum potential drop times the ratio of the Sherwood number to the square of the Péclet number calculated by the finite-electrode solution, the semi-infinite-electrode solution, and the Alkire and Ng solution all approach the same limit as αd becomes small.

2. The maximum dimensionless potential drop times the ratio of the Sherwood number to the square of the Péclet number approaches a limit for R becoming large. At large values of αd and large aspect ratios this relationship becomes proportional to αd . In the limit of small αd , this relationship approaches a value given by $1/2(\alpha d)^2$.

3. The maximum dimensionless solution phase potential drop times the ratio of the Sherwood number to the square of the Péclet number for finite R asymptotically becomes proportional to αd at large values of αd . The value of this proportionality constant is determined by the magnitude of R .

4. The effect of the finite electrode length is important only for values of R approximately less than one and then only at large values of αd .

5. The Alkire and Ng one-dimensional solution is seen to reflect the limit as the aspect ratio of the flow-by electrode tends toward zero for all values of αd . This contrasts with earlier work, which has suggested the Alkire and Ng solution results only as the aspect ratio R goes to infinity (8).

If the maximum dimensionless solution phase potential drop times the ratio of the Sherwood number to the square of the Péclet number for the flow-through electrode were plotted on this graph, the resulting curves would be horizontal straight lines. Equation [24] shows that for the flow-through electrode this quantity is not dependent upon the parameter αd .

Comparison of Configurations

As a first approximation, the optimum electrode configuration for a specified conversion might be found by assuming that the dimensionless potential drops times the ratio of the Sherwood number to the square of the Péclet number are equal. We satisfy this requirement by fixing equal potential drops for each configuration and by assuming that each electrode is constructed from the same materials and processes solutions with identical properties. Additionally, we restrict the comparison to equal ratios of the Sherwood number to the square of the Péclet number. This last constraint requires both the flow-through and flow-by electrodes to have identical volumes, flow rates, and consequently, equal pressure drops. In Fig. 3, we have plotted the values of αd and R (as functions of αL) which give equal dimensionless maximum potential drops times the ratio of the Sherwood number to the square of the Péclet number for the flow-through electrode and for the flow-by electrode. We have also designated the regions where each type of configuration is preferred. Again, the variable αL can be used to represent the reactor conversion. The maximum dimensionless potential drop times the ratio of the Sherwood number to the square of the Péclet number for the flow-through electrode has been calculated using Eq. [24]. We have included the three possibilities for evaluating this quantity for the flow-by electrode. First, the flow-by electrode is assumed to be infinitely long, and Eq. [21] is used. We can also assume the one-dimensional potential variation of Alkire and Ng might be appropriate and use Eq. [22]. Finally, the effects of the finite electrode length also can be included. The relationship given by Fedkiw could also be used. For this finite electrode case, an additional constraint must be imposed since this function ex-

Fig. 3. Values of αd and R for equal dimensionless potential drops times the ratio of Sherwood number to the square of the Péclet number for the flow-through electrode and the flow-by electrode using: order-of-magnitude expressions, Alkire and Ng expression, semi-infinite electrode, and Fedkiw expression. These two representations are equivalent since $R = \alpha L/\alpha d$.

PLICITLY depends on the aspect ratio. The value of R is computed from

$$R = \frac{L}{d} = \frac{\alpha L}{\alpha d} \quad [25]$$

Thus, the value of αd and the value of R are found for each value of αL such that the maximum dimensionless potential drops times the ratio of the Sherwood number to the square of the Péclet number are equal. For comparison, we have also included the results of the order of magnitude analysis which were derived in the introduction.

We emphasize here that this comparison of the two electrode configurations does not require that we specify a mass-transfer coefficient relationship. This comparison does not depend upon the Sherwood-Péclet number relationship. Fedkiw compared the two configurations in a similar way, except that he introduced a specific Sherwood-Péclet number relationship in his comparison. The comparison presented here is considered to be preferable because it is not restricted to a single correlation.

Figure 3 establishes several important points. At low values of αL and, consequently, low conversion, the aspect ratio and the value of αd for equal potential drops are independent of the flow-by potential drop relationship. The Alkire and Ng one-dimensional approximation, the semi-infinite electrode approximation, and the finite electrode relationship all predict the same geometry. In this low conversion range, $\alpha L < 1$, the aspect ratio for equal potential drops is seen to approach one. The value of αd , given equal electrode cost, is seen to approach a limiting relationship of

$$\alpha d = \alpha L \quad [26]$$

The conclusion to be made here is that a flow-by electrode is favored at low conversions if it can be constructed with an aspect ratio greater than one. Otherwise, a flow-through electrode would be a better choice. Equation [26] is identical to Eq. [2], obtained by the order-of-magnitude analysis in the introductory section.

At higher conversions, values of αL greater than about 2, the criterion that specifies the optimum configuration changes. In this region, the value of R delineating the optimum electrode configuration no longer is constant. Also, the one-dimensional Alkire and Ng approximation deviates from the two-dimensional solutions. Since the one-dimensional approximation overpredicts the potential drop, it results in a criterion giving a lower flow-by aspect ratio. The two-dimensional potential distributions

are thus seen to affect the choice of electrode configurations only at high conversions. From Fig. 3, we can see that at high conversion one would choose a flow-by electrode only if the resulting aspect ratio is greater than 0.45 times αL . According to Fedkiw (8), the flow-by configuration was preferred over the flow-through configuration for

$$R \geq 5 \quad [27]$$

One can see, however, that this relationship holds only for values of αL near 10. In terms of αd , the flow-by electrode is superior at high conversions only if

$$\alpha d < 2.218 \quad [28]$$

Except for the factor of 2.218, Eq. [28] is consistent with Eq. [1], obtained by an order-of-magnitude estimate in the introductory section. This factor accounts for the variation of current across the flow-by electrode and the two-dimensional current flow, which was not included in the earlier analysis.

Figure 3 also demonstrates another significant point. The curves for the optimum electrode configuration given by the finite length electrode or the semi-infinite electrode are very nearly the same. At high and low conversions, the criterion becomes independent of whether one considers the finite electrode length. Only for a region of αL near one, does the effect of the finite electrode length on the criterion become noticeable. From Fig. 2, one can see that only when the aspect ratio approaches one at high conversions does the effect of the finite electrode length on the potential drop become noticeable. But at large conversions, or large αL , it is impractical to construct a flow-by electrode with an aspect ratio near one. Consequently, considering the potential distribution in a flow-by electrode of finite length is not really important for practical flow-by designs when the maximum potential drop is used as a basis for comparison. The potential distribution for an electrode with an infinite aspect ratio gives results which are practically identical, but in a less complicated expression.

Conclusions

The two-dimensional potential distribution for a flow-by porous electrode of infinite length to width ratio operating at the limiting has been derived. It is shown that the maximum solution-phase potential drop depends primarily on the ratio of the electrode width and the penetration depth αd . The potential drop for practical flow-by designs depends only weakly upon the length-to-width ratio. This result has been compared to the potential drop for a finite length electrode given by Fedkiw and the one-dimensional potential drop of Alkire and Ng.

The flow-through and flow-by electrode configurations have been compared at the limiting current using the maximum solution-phase potential difference as a basis for comparison. This comparison is independent of any specific mass-transfer coefficient correlation. Criteria delineating the optimal electrode configuration have been given which depend upon the reactant conversion. At low conversion, a flow-by electrode is favorable, providing that it can be constructed with a length-to-width ratio greater than one. At high conversions, however, a flow-by electrode is favorable if the ratio of the electrode width and penetration depth is less than 2.218.

APPENDIX

Asymptotic Solutions for Large Values of αd

Consider a flow-by reactor with a given aspect ratio R . For large enough values of αd and large αL , most of the reactant will be consumed in a region very close to the electrode entrance. Consequently, the current will appear to be generated from a uniform line source near the front of the electrode. The applicable differential equation is thus Laplace's equation

$$\nabla^2 \Phi_2 = 0 \quad [A-1]$$

subject to the boundary conditions

$$\text{at } y = 0, \quad \frac{\partial \Phi_2}{\partial y} = -\frac{i_2}{\kappa} \quad [A-2]$$

$$\text{at } y = L, \quad \frac{\partial \Phi_2}{\partial y} = 0 \quad [A-3]$$

$$\text{at } x = 0, \quad \frac{\partial \Phi_2}{\partial x} = 0 \quad [A-4]$$

and

$$\text{at } x = d, \quad \Phi_2 = V \quad [A-5]$$

The solution to the above problem is

$$\begin{aligned} \frac{\Phi_2(x=0, y=0) - V}{\frac{nF c_F v^2}{s_R \kappa \alpha k_m}} &= \frac{\Delta \Phi_2}{\frac{\epsilon n F c_F D_0}{s_R \kappa}} \frac{\text{Sh}}{\text{Pe}^2} \\ &= \alpha d \sum_{n=0}^{\infty} \frac{2(-1)^n}{\lambda_n^2 \tanh \lambda_n R} \quad [A-6] \end{aligned}$$

where

$$\lambda_n = \frac{(2n+1)\pi}{2} \quad [A-7]$$

The above equation thus shows that at fixed R , the dimensionless potential drop times the ratio of the Sherwood number to the square of the Péclet number becomes proportional to αd at large αd . The constant of proportionality is determined the value of R . These are the dotted lines plotted in Fig. 2.

LIST OF SYMBOLS

a	specific interfacial surface area (cm^2/cm^3)
c	pore averaged concentration (mol/cm^3)
d	flow-by electrode bed width perpendicular to fluid-flow direction (cm)
D_0	free stream diffusion coefficient of reacting species (cm^2/s)
F	Faraday constant (96,485 C/eq)
i_2	total current density within electrolyte phase (A/cm^2)
j	transfer current density (A/cm^2)
k_m	mass transfer coefficient (cm/s)
L	bed depth in direction of fluid flow (cm)
M	arbitrary species
n	number of electrons transferred in reaction
Pe	Péclet number ($V/\alpha D_0$)
R	bed aspect ratio (L/d)
Sh	Sherwood number ($\epsilon k_m/\alpha D_0$)
s_R	stoichiometric coefficient of reactant
v	superficial fluid velocity (cm/s)
V	reference potential of flow-by electrode at $y = d$ (V)
z	charge number (eq/mol)

Greek characters

α	reciprocal of penetration length ak_m/v (cm^{-1})
$\Delta \Phi_2$	maximum allowable solution potential drop (V)
ϵ	bed porosity or void fraction
κ	conductivity of fluid phase in bed ($(\Omega \text{ cm})^{-1}$)
λ	dimensionless eigenvalue
Φ_2	solution potential, V

Subscripts

i	species number
n	eigenvalue number
F	feed condition
L	exit condition

Electrochemical Studies of Antitumor Antibiotics

V. An Electrochemical Method of Measurement of the Binding of Doxorubicin and Daunorubicin Derivatives to DNA

James A. Plambeck* and J. William Lown

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

ABSTRACT

A procedure has been developed for the measurement in aqueous solution of the association constant with native DNA of an agent which is electrochemically reducible. A fresh mercury drop is extruded into a solution containing both the agent and DNA, surface adsorption is reproducibly conditioned ($-0.4V \leq E \leq -1.0V$, 90s, followed by $-0.4V$, 90s), and the peak current is measured during a rapid voltage scan. A suitable plot of current as a function of DNA concentration yields the desired constant. Data are given for a significant series of substituted daunorubicin and doxorubicin compounds and for control compounds.

Since the concept of intercalation into DNA was first formulated by Lerman (1) in 1961, it has become widely recognized that many compounds of pharmacological interest, including anticancer drugs and antibiotics as well as certain carcinogens, function by binding to duplex nucleic acids (2). The anthracyclines (*e.g.*, adriamycin, daunorubicin, aclacinomycin) constitute one of the most widely studied types of such drugs owing to their established clinical efficacy against a wide range of malignancies; they are regarded as amongst the most promising of anticancer drugs (3, 4). The molecular mechanism of action of the anthracyclines is complex and appears to involve free radical generation (5, 6), lipid peroxidation (7), DNA damage (8, 9), and possible covalent attachment (10), as well as intercalative binding (2-4, 11). Nevertheless, the ability of anthracyclines to undergo intercalative binding to DNA has shown a consistent correlation with antitumor properties (3, 4, 11).

One of the parameters which characterizes this phenomenon is the binding constant K_b (12), also known as the apparent association constant K_{app} . Other parameters include sequence preference or specificity and spatial and functional group parameters determining molecular recognition (2, 3, 11, 12). Consequently, there is an urgent need for a direct, sensitive, and accurate method to quantify the binding to DNA of the growing number of new anthracyclines which are being prepared in order to improve their therapeutic index or especially to combat their main clinical limitation, severe cardiotoxicity (13, 14).

The methods which have been developed to measure binding constants of anthracyclines and other drugs fall into two categories (i) those that follow changes in properties of the drug, and (ii) those that monitor changes in the polynucleotide (12). Methods of the first type include measurement of (i) changes in the UV and visible absorption characteristics of the anthracycline chromophore (2, 15-17), (ii) changes in the fluorescence of the chromophore (15, 18-20), and (iii) circular dichroism characteristics (21-23). In addition, those methods for determining K_b values which depend on properties of the DNA include (i) viscosity changes (15, 16, 24), (ii) buoyant density and sedimentation coefficient differences (15, 16, 24), (iii) melting temperature changes (11, 24, 25), (iv) equilibrium dial-

ysis (16, 22, 26), and (v) removal of the supercoiling in native covalently closed circular DNA (2, 27).

Many of these methods are tedious experimentally or require either rather large amounts of the anthracyclines or expensive circular DNA's. Moreover, the reported association constants for daunorubicin (12) cover the range 1.3 to 9.3×10^6 liter/mol, indicating a lack of agreement using the different methods. In this paper, we describe a new method based on the electrochemical characteristics of both free and intercalatively bound drugs. The method is experimentally convenient and sensitive so that it requires only small amounts of materials. In principle, it can be applied to a wide range of intercalating drugs, provided they bear an electrochemically active moiety. We report also further studies upon DNA and the drugs required to establish this technique.

Early applications of electroanalytical techniques to solutions of nucleic acids have been reviewed (28, 29). Of the four bases present in deoxyribonucleic acid (DNA), adenine and cytosine are reducible at mercury electrodes whether free or bound to the nucleotide chain. Native DNA is not reducible at the dropping mercury electrode because the stability of the intact double helix makes the reducible bases inaccessible to the electrode. When the integrity of the double helix is altered, as by heating above the melting point or by induced breaks in the helix, reduction of bases can be observed.

AC methods have been employed by Barker (30) and Malfroy and Reynaud (31-33). Valenta and Nürnberg (34-44) have employed dc voltammetric methods in the fast sweep mode at a stationary mercury electrode and reviewed the results (45-47). Of significance to this work is their finding that native DNA can be reduced at mercury electrodes after adsorption and unwinding of the double helix (39, 47). Less extensive studies have also been carried out by Berg and co-workers (48, 49).

Theory

The constant to be measured is the equilibrium constant for the formation of the anthracycline-DNA complex (ADNA) from unbound anthracycline (A) and uncomplexed DNA (DNA), which in terms of concentrations may be written as

$$K = c(\text{ADNA})/c(\text{A}) c(\text{DNA})$$

*Electrochemical Society Active Member.

None of these species is easily measured directly, but the total concentration of anthracycline, $cT(A)$, and the total concentration of DNA, $cT(DNA)$, are established as conditions of the experiment and by definition

$$cT(A) = c(A) + c(ADNA)$$

$$cT(DNA) = c(DNA) + c(ADNA)$$

To express units consistently, if $cT(A)$ is in units of mol/dm^3 , and each molecule of anthracycline is understood to occupy one binding site, then $cT(DNA)$ must be expressed in units of binding sites/ dm^3 rather than mol/dm^3 . The number of binding sites/ dm^3 will depend upon the molecular weight of the DNA and its concentration, which are expressible as $\text{mol bases}/\text{dm}^3$, and the number of bases required to form a binding site. Since the molecules are intercalated in the helix, a minimum of four bases (two pairs) is required to form a binding site. However, it is improbable that the intrinsic binding to all types of four-base sites with different base pair compositions is identical, and the effect of bases other than nearest neighbors upon the binding may be significant (2). At the very low levels of saturation used in this study, only the most favorable sites should be occupied, and as a consequence the constants measured here should refer to an average of only the most favorable sites. Thus, the interaction constants measured by this method should be smaller than those measured by methods involving saturation of the DNA and should be more comparable to clinically realizable conditions.

When the concentration of DNA is expressed in this way and only a small proportion of the possible binding sites are occupied, then $c(ADNA)$ is much less than $cT(DNA)$ so that $c(DNA)$ is approximately equal to $cT(DNA)$. Thus measurement of the $c(ADNA)/c(A)$ ratio establishes the value of the binding constant K

$$K cT(DNA) = c(ADNA)/c(A)$$

Experimentally, we find that for at least all of the antibiotics reported here, and for others of different structure but containing at least one group reducible at a potential not more negative than -1.25V against SCE, application of the method described in this paper yields a curve of current against sweep potential having one (occasionally more) peaks at approximately the polarographic or cyclic voltammetric reduction potential of the anthracycline. The current I at this peak is directly proportional to $cT(A)$ in the absence of DNA, and thus to $c(A)$. In no case is an additional peak observed in the presence of DNA save for the reduction of DNA itself and consequent hydrogen evolution, but these are too negative to interfere with measurement of I ; addition of DNA reduces the value of I , but the potential of the peak remains unaffected.

Since the current I arises from reduction of A whether bound or unbound

$$I = k'c(A) + k''c(ADNA)$$

In the presence of A and absence of DNA, there can be no contribution from the bound anthracycline and such a value $I(0)$ equals $k'c(A)$ which is also $k'cT(A)$. At the other extreme of an infinite excess of DNA, the concentration of unbound anthracycline must go to zero and thus such a value $I(\text{inf.})$ equals $k''c(ADNA)$. Then

$$I(0) - I = k'cT(A) - (k'c(A) + k''c(ADNA))$$

$$I(0) - I = (k' - k'') c(ADNA)$$

$$I - I(\text{inf.}) = k'c(A) + k''c(ADNA) - k''c(ADNA) = k'c(A)$$

$$[I(0) - I]/[I - I(\text{inf.})] = c(ADNA)/c(A) = K cT(DNA)$$

Experimental

The experiments were carried out using a Princeton Applied Research (PAR) Polarographic Analyzer Model 174A, PAR Controller Model 315, and Static Mercury Drop Electrode Model 303, a Biomation Model 805 Waveform Recorder, and a Houston Instrument Type

2000 X-Y recorder. Both McIlvane and acetate buffers were used; 0.1M McIlvane buffers of pH 5.6 and 6.0 were prepared using reagent-grade dibasic sodium phosphate and citric acid. The ionic strength of the McIlvane buffers was adjusted to 1.0M using reagent-grade potassium chloride (29). The 0.1M acetate buffers of pH 5.6 and 6.0 were prepared using sodium acetate, acetic acid, and 10^{-4}M disodium EDTA dihydrate in 0.1M KCl. All buffers were prepared from triply distilled water. The acetate buffer of pH 5.6 so prepared was used in all experiments unless otherwise specified.

Calf thymus DNA was obtained from Sigma Chemical Company, *E. coli* DNA from Aldrich Chemical Company, and *B. subtilis* DNA (Grade A) from Calbiochem. The antibiotic daunorubicin **1b** was obtained from Sigma Chemical Company; its anhydrous molecular weight was 564.0. Compound AD32, **1o**, was kindly provided by Dr. M. Israel of the Sidney Farber Cancer Institute. Other anthracyclines were obtained from Dr. E. M. Acton of SRI International. Their structures are given in Fig. 1.

The procedure used was similar to those established by Nürnberg *et al.* (50). The "conditioning" potential E_c , the "deposition" potential E_s , and the final potential E_f were set on the potentiometers of the Model 315. The "deposition" potential and time are so noted on the Model 315, which was designed for use in anodic stripping voltammetry, but here represent only a second stage of conditioning. Both the "conditioning" time t_c and "deposition" time t_s were 90s. The internal switch in the PAR Model 174A was set to the position for 10 times higher sweep rates, which permits sweep rates of up to 5 V/s.

The Model 303 was set to HMDE mode with large drop size, each drop having a surface area of $2.83 \times 10^{-2} \text{cm}^2$. A fresh drop was used for each measurement. The reference electrode was AgCl/Ag-saturated KCl in a glass frit; all potentials were measured and are given with respect to this reference. A platinum wire served as an auxiliary electrode. All measurements were made at room temperature under an atmosphere of purified nitrogen after deaeration with nitrogen.

For 90s, the mercury drop was subjected to a constant applied "conditioning" potential whose values could be varied between -0.40 and -1.60V . After 90s, the potential was stepped to a constant "deposition" potential of -0.40V and was held there for a further 90s. Finally, the potential was driven by a rapid cathodic sweep with a rate of 1 or 5 V/s to the negative limit of potential at about -1.8V . The current values were stored in the Biomation Model 803 which was set for pretriggered recording with 1800 delay interval and single triggering mode. The stored voltammogram was plotted, using the Houston recorder in x-t mode, as provided by the Biomation Model 803; typical curves are shown in Fig. 2. The Biomation unit was triggered from the pen-drop switch closure of the Model 315 using an external battery. Similar results, though with less precise output, were obtained using an R564B storage oscilloscope (Tektronix).

For all of the solutions studied, the experimental curves were superimposable for successive fresh drops of the same size (as provided by the mechanical operation of the Model 303) in the same solution. Drops of nonreproducible size, or use of the same drop twice, gave totally nonreproducible results. Replicate runs on new solutions and using fresh drops were within $\pm 4\%$ - 5% on the basis of peak height.

The functions of peak current derived in the theory section of this paper were calculated and plotted against the concentration of DNA either manually or by computer (Amdahl 470/V7, Calcomp plotter, *IG package at University of Alberta Computing Services). Typical plots are given in Fig. 5 and 6. The association constant is obtainable from the linear portion of the slope of Fig. 5. In terms of originally measured quantities, this slope has the units of μg anthracycline complexed per cm^3 of DNA stock solution added, but use of the original anthracycline concentration (nominally $5.0 \times 10^{-6} \text{mol}/\text{dm}^3$), the concentration of the DNA stock solution (nominally $1.050 \text{mg}/\text{cm}^3$

calf thymus DNA of od 21 measured at 260 nm), and the relationship that one od unit is equivalent to $50 \mu\text{g}/\text{cm}^3$ or 1.49×10^{-4} mol phosphate/dm³ or mol bases/dm³ permits calculation of the association constant in molar quantities, liter/mol phosphate or liter/mol bases.

Coulometric measurements were made upon the recorder output curves using a planimeter and converted to the original input time base. The method of obtaining the base line for the peaks near -1.5V was that of Valenta and Grahmann (37). In the peaks at -0.65V , the base line of the output curves with base electrolyte alone and the base

lines of the curves with DNA and/or daunorubicin **1b** were the same. Planimeter measurements were also made upon molecular models of **1b** to establish the area they would occupy. A single molecule of **1b** can occupy a surface area of ca. 1.50 nm^2 (flat) and ca. 0.64 nm^2 (on edge).

Results

Preliminary tests were made using 1.0×10^{-4} mol/dm³ Cd(II) in pH 5.6 McIlvane buffer. At a conditioning potential of, or positive of, -1.0V , a single sharp asymmetric peak (sharp rise, exponential fall) was observed at a peak

Fig. 2. Typical biomation output plots. Data for 5×10^{-6} mol/dm³ doxorubicin (**1a**) in acetate buffer, conditioning potential -0.4V . Curve A: no added DNA. B: calf thymus DNA concentration $10.4 \mu\text{g}/\text{cm}^3$. C: calf thymus DNA concentration $59.4 \mu\text{g}/\text{cm}^3$. Vertical scale of C, only, exaggerated by a factor of 2.5.

potential (E_p) of $-0.63 \pm 0.01V$. At "conditioning" potentials more negative than $-1.0V$, the current no longer fell exponentially. This is expected because the conditioning potential is now sufficiently negative to deposit more cadmium onto (or into) the HMDE than is removed during the "deposition" time at $-0.4V$. Addition of sufficient EDTA to give a 0.02 mol/dm^3 solution shifted the cadmium reduction peak negative to $-1.70V$; its fall then merged with the solvent discharge current. In the EDTA solution, the peak shape and height were not affected by the "conditioning" potential. This behavior is expected for aqueous Cd(II) and its EDTA complex, which are reversibly reduced on mercury.

DNA.—Calf thymus DNA was used both in McIlvane and acetate buffer. The addition of DNA to buffer caused the appearance of a single sharp asymmetric peak at about $-1.5V$ and a positive shift of the onset of hydrogen evolution from ca. $-1.83V$ (pH 6.0, $0.1M$ acetate buffer + $0.1M$ KCl) to ca. $-1.6V$ (same system + DNA). The bacterial DNA gave sharper peaks, as expected, owing to its lower molecular weight. All three forms of DNA gave only a single peak at about $-1.5V$ at all values of the conditioning potential less than $-1.5V$. Its height increased with scan rate, and varied with the type and concentration of DNA used (Table I). This peak is attributed to the reduction of the adenine and cytosine bases of the adsorbed DNA (34-47); for DNA alone, our results are comparable to those of Nürnberg *et al.*

Anthracyclines.—Solutions of **1b** in the absence of DNA gave a single, sharp, well-defined, approximately symmetric peak at $-0.625 \pm 0.005V$ (full width at half-maximum $0.08 \pm 0.02V$, except for extremely low concentrations). The peak potential did not change with **1b** concentration or with scan rate. The peak current was directly proportional to the concentration of **1b** up to about 2 mol/dm^3 , at which point the current increase be-

Fig. 3. Effect of concentration upon daunorubicin (**1b**) reduction. Aqueous buffer. Open circles (A) obtained at 5 V/s. Closed circles (B) obtained at 1 V/s. Log-log plot. Peak potential: $-0.65V$.

came less than proportional (Fig. 3). Direct proportionality is found from 10 nmol/dm^3 to over 500 nmol/dm^3 (Fig. 4); the lower limit is due to inability to easily distinguish the peak from base-line noise. Solutions of **1b** which contained no DNA also gave a peak or shoulder at the approximate potential of reduction of the bases of DNA, $-1.535V$. This is due to the additional reduction of **1b** at these more negative potentials (53, 54). The behavior of the other anthracyclines studied paralleled that of daunorubicin. In all cases, the easiest reduction of the anthracyclines is sufficiently positive of either their own second reduction or the reduction of DNA that the current returns to the base line before these processes begin.

Fig. 4. Effect of low concentrations of daunorubicin (**1b**) upon peak current. Aqueous buffer. Open circles (A) obtained at 5 V/s. Closed circles (B) obtained at 1 V/s. Peak potential: $-0.65V$. Point on A at 500 nmol/liter is at $10.0 \mu\text{A}$, offscale.

DNA-anthracycline complexes.—The electrochemical behavior of solutions containing both DNA and the individual anthracycline is similar to the sum of the behavior of separate solutions of the two components. The first reduction of **1b** at $-0.625V$ shifts negative in the presence of DNA by not more than 50 mV; the peak is broadened and slightly reduced in height as compared to **1b** alone. The second reduction of **1b** is indistinguishable from the reduction of the adsorbed adenine and cytosine bases of DNA near $-1.55V$. As a consequence, we are unable to measure the effect of the anthracycline upon the DNA present, although at relatively low levels of anthracycline that effect is, within experimental error, absent. The sharp drop-offs in peak current and charge as the "conditioning" potential becomes more negative than $-1.3V$ are due to partial reduction of the adsorbed material while the "conditioning" potential is still held, well before the onset of the recorded voltammetric sweep. These observations apply to all of the other anthracyclines studied as well.

The association constants of the anthracyclines with DNA were calculated according to the procedure described from the values of the peak current as a function of DNA concentration. These are given in Tables II-V. The values reported in Tables II-IV are arbitrarily given to three places following the decimal point to ensure that any real differences in potential dependence are not lost. The reproducibility of completely separate experiments on different solutions is of the order of 5%, and the

¹ Percent response in effectively "infinite" DNA excess as compared to total absence of DNA.

smaller number of figures given in the summary of Table V reflect this.

This procedure has been optimized for daunorubicin by adjusting the DNA increments and values to give a slope of about 50° in the plots of the type given in Fig. 5. For association weaker or stronger than that of daunorubicin by a factor greater than ten, the line approaches horizontal or vertical. Classes of compounds with much stronger association than daunorubicin, which may be those of greatest anticancer interest, are better studied with smaller or more dilute DNA additions.

The number of moles of bases of DNA per mole of anthracycline can be calculated from the total stoichiometric ratio in the solution. A plot of this ratio against the signal due to unbound anthracycline, which can be taken as proportional to the ratio of the peak current, less the peak current at an infinite excess of DNA, to the peak current measured in the absence of DNA, can give an indication of the number of base pairs of the DNA involved in direct interaction with the antibiotic (Fig. 6). This is essentially a titration of the anthracycline with DNA; the estimation of the number of bases/binding site uses only the initial rapid decrease.

In all cases, the number of bases per anthracycline calculated from the intercept of diagrams such as Fig. 6 was between 5 and 8.

Fig. 5. Typical plots used to obtain association constants. Strong association, open circles (1j); moderate association, closed circles (1a); weaker association, open squares (1f). All in aqueous solution, conditioning potential $-0.4V$, scan rate 5 V/s.

Additional electrochemical studies of these compounds are given elsewhere (59).

Discussion

The interfacial mercury/aqueous electrolyte region has been used as a model for electrically charged biological membranes, the interactions of DNA with the electrode being then taken as relevant to the interactions of cellular DNA with cell membranes. While doubly helical native DNA is not reducible from solution, it can undergo the sequence adsorption, dehydration, strand separation, and base reorientation which renders the reducible adenine

Fig. 6. Typical plot of moles of DNA base/mol agent. Data for 1a, aqueous solution, conditioning potential $-0.4V$, scan rate 5 V/s.

and cytosine bases accessible to electron transfer (43). Their irreversible reduction to strongly adsorbed products blocks the surface of the electrode to further adsorption of DNA. These products, in common with other nitrogen heterocyclic compounds, are catalysts for hydrogen evolution on mercury. The parameters known to affect the adsorption, and hence observable reduction, of DNA on fresh mercury electrodes include ionic strength, pH, percentage of A-T content in the DNA, and molecular weight, in addition to the experimentally adjustable parameters of adsorption time, potential of the electrode during adsorption, and rate of the voltammetric scan (43). Denatured DNA, in which the bases are already accessible, and mononucleotides are reducible through the latter part of the same mechanism. The data of this study for solutions of DNA alone are consistent with previous studies (43) and the above mechanism.

Anthracyclines.—Generation of fresh drops in the solution containing both the DNA and the anthracyclines known (51-54 and references therein) to interact with it, followed by the double potential step-sweep method under the conditions already established (50) as appropriate for study of DNA itself should demonstrate any effect of interaction with DNA upon the reduction of DNA. At the lowest anthracycline concentrations used, no such effect is observed.

If the behavior of the anthracyclines alone under the same conditions is established, any effect of interaction with DNA upon the redox properties of the anthracyclines should also be noticeable. This second factor is relevant to the possible reductive activation of an anthracycline once bound to DNA (51-54). We find no evidence of any such effect. The results obtained show that for anthracyclines alone the initial reduction studied by this method occurs at the same potential as is observed in the more conventional techniques of polarography and cyclic voltammetry. For daunorubicin either alone or in the presence of DNA, the peak current gives a linear response to concentration down to about 10 nmol/dm³, suggesting further development of this technique as a clinical analytical method.

DNA-anthracycline complexes.—The data presented by Berg and co-workers on the association constant of actinomycin with DNA obtained by pulse polarography (49) and of other anthraquinones with DNA obtained by classical polarography (55) employed experiments in which the decrease of polarographic response to a fixed total concentration of the antibiotic upon successive additions of calf thymus DNA was interpreted as being due to the complexation of the antibiotic with DNA. The complex was taken as having no polarographic response (55) or (49) as having a response at the same potential as the uncomplexed antibiotic with, however, a much slower rate of diffusion due to the attachment of DNA. This interpretation seems unlikely; it is more probable that the effects observed are due to time-dependent (and possibly also potential-dependent) competitive adsorption of the antibiotic and DNA, which would also account for the observed diminution of antibiotic response with increasing DNA concentration. Such effects, while necessarily present in dc polarographic techniques, are not a complication in the present procedure only because the equilibration time at constant potential is long enough to achieve equilibrium (or at least a highly reproducible steady state), while the scan rate is fast enough to prevent significant change from equilibrium before the measurement is complete. We have found 90s a practical minimum equilibration time and 1 V/s the minimum useful scan rate to obtain reproducible results with calf thymus DNA.

Molinier-Jumel *et al.* (58) gave a value of 0.78×10^5 liter/mol phosphate for 1b with sonicated calf thymus DNA using ac polarography in aqueous solution. The compound was added in increments to a solution with a fixed DNA concentration. Our comparable value using

the reverse procedure described here is 0.52×10^5 , in reasonable agreement.

Electrode coverage by mononucleotides is undoubtedly greater than for DNA, if only because the guanine and thymine bases in DNA are not reducible though they are presumably also adsorbed. In acid (pH 3.0 ± 0.5) aqueous solution, the protonated mononucleotide adenosine gives a reduction charge of $40 \mu\text{C}/\text{cm}^2$ for the adsorbed material between -0.2 and -0.4V (36); values higher than this are obtained for the compact stage of adsorption. Protonated cytidine has about half the occupied area of adenosine (56, 57). Our values are at or below these limits (Table I).

The charge expected for a two-electron reduction of a complete or maximum daunorubicin monolayer with molecules oriented parallel to the electrode surface is $21.4 \mu\text{C}/\text{cm}^2$, while $50 \mu\text{C}/\text{cm}^2$ could be expected for the less likely perpendicular orientation. This is quite consistent with the values of 13-17 $\mu\text{C}/\text{cm}^2$ actually obtained for daunorubicin in the absence of DNA.

Conclusion

The method described herein seems well suited to studies of the influence of structural variations in both anthracycline and sugar to the binding of the anthracyclines to DNA. The association constants do not vary significantly with potential when the conditioning potential ranges from -0.4 to -1.0V against SCE, nor does the addition of 3% acetonitrile alter their values (although 30% decreases them significantly). The configuration of DNA on the electrode surface is therefore reproducibly established by the experimental conditions used and it is to that configuration that the binding occurs.

The association constant reported herein for doxorubicin (**1b**) is significantly higher than that for daunorubicin (**1a**). The same difference is found for the corresponding pairs **1d**, **1c** and **1f**, **1e**, leading to the conclusion that replacement of the hydroxyl group at R3 with hydrogen reduces binding to DNA. This is in accord with the greater ΔT_m value observed for doxorubicin than for daunorubicin, but not in accord with all of the values reported by other methods (12), which generally give values for doxorubicin of 20% lower than for daunorubicin. Values obtained with solution rather than electrode methods also tend to be consistently higher and may refer to DNA of a considerably more accessible (to anthracyclines) configuration than that on electrode surfaces.

Binding of the aglycones **2a-2d** is much less than for the anthracyclines with attached sugars. The ratio of $I(\text{inf})/I(0)$ is greater than 30%, indicating that much of the aglycone remains unbound even at mole ratios greater than 300:1 bases:aglycone. It is clear that the sugar materially assists in the binding of the anthracyclines to DNA.

ABSTRACT

Flatband potential (V_{FB}) of (100)-oriented n-GaAs electrodes in various aqueous solutions have been determined by ac impedance measurements. The Nernstian variation of V_{FB} with pH (-60 mV/pH) was verified in both indifferent electrolytes and redox-couple solutions. Taking into account this pH dependence, the barrier height ϕ_B of the n-GaAs/liquid junction with various redox couples could be calculated. ϕ_B was determined at the point of zero zeta potential (PZZP), where the voltage drop due to specific adsorption of OH groups vanishes. A pH (PZZP) of 2.8 was estimated from published data for the electron affinity of GaAs. The variation of ϕ_B as a function of redox potential at the GaAs/liquid junction could then be quantified through the slope S of the ϕ_B (V_{redox}) straight line. A value of $S \approx 0.8$ was found, showing that Fermi level pinning is much weaker than at the GaAs/metal junction, at which one has $S \approx 0.05$. The behavior is confirmed by published data on p-GaAs and polymer-coated n-GaAs. We discuss these results within the framework of recent works on the semiconductor/metal Schottky barrier.

Considerable attention has been brought recently to the problem of Fermi level pinning at semiconductor/liquid junctions. A recent report of the Institute for Science Information on the 1980 Chemistry papers most cited in 1980-1982 (1) showed that an article by Bard *et al.* (2) devoted to this problem has been cited 60 times during that period. In this article, was presented a model to account for the fact that the photovoltage measured on semiconductor electrodes (n-GaAs, p-GaAs, and p-Si) in acetonitrile solutions of various redox couples did not follow a linear variation as a function of the redox potential as would be expected according to the classical (Schottky) model for semiconductor/liquid junction, in which the band-edge positions at the semiconductor surface are fixed with respect to the solution levels (3). The modified model advanced by Bard *et al.* referred to the concept of Fermi level pinning due to surface states, which had been first proposed by Bardeen (4) to explain the observation that for most covalent semiconductors (Si, Ge, GaAs, InP, ...) the semiconductor/metal barrier height is independent of the metal.

More recently, measurements have been reported on n-GaAs photoanodes protected against photocorrosion with various polymer films: polypyrrole (PPy) (5), polystyrene pendant $\text{Ru}(\text{bpy})_3^{2+}$ (PSt-bpy-Ru) (6), and poly-3-methylthiophene (PMeT) (7). Open-circuit voltages V_{oc} greater than 1V have been reached with such electrodes. Furthermore, a quasi-linear variation of V_{oc} with redox potential is observed, suggesting that Fermi level pinning does not occur. The question then arises whether this behavior is characteristic of the n-GaAs/liquid junction or comes from modifications in the surface states when a conducting polymer is put between the semiconductor and the solution.

However, recent investigations on the semiconductor/metal interface led to the conclusion that the phenom-

enon responsible for the narrow range of barrier heights observed on GaAs/metal junctions is not the presence of intrinsic surface states (the so-called Tamm and Shockley surface states) at the semiconductor surface. Brillson (8) attributes this narrow range to a microscopic charge redistribution at the semiconductor/metal interface that depends on the chemical reactivity of the metal coverage. More recently, measurements on (110)-cleaved GaAs in ultrahigh vacuum (UHV) led Spicer *et al.* (9) to think that the pinning is due to extrinsic surface states due to defects produced at the semiconductor surface by the presence of the metal adatoms. Bolmont *et al.* (10) think that these surface states are rather due to a reconstruction of the GaAs surface by chemical bondings of the metal atoms with the semiconductor atoms. It thus seems established that the presence of the metal is necessary to induce the surface-state distribution leading to Fermi level pinning. Since the chemical reactivity of a liquid electrolyte is different from that one of a metal, one can expect a different behavior between the two kinds of junctions as far as the barrier formation is concerned. In this paper, we report flatband potential and open-circuit potential measurements performed on PMeT-coated and bare n-GaAs in contact with aqueous solutions of various redox couples. The results suggest that Fermi level pinning is much less important at the n-GaAs/liquid junction than at the n-GaAs/metal junction. This result is compared to recently published data on p-GaAs/liquid junctions and discussed within the framework of recent theories on the semiconductor/metal junction.

Experimental

Nonintentionally doped n-type (100)-oriented GaAs single-crystal slices were purchased from RTC (Caen, France). Ohmic contacts were made by vacuum evaporating Ge (12 weight percent [w/o]) Au alloy and annealing at

400°C under N_2 . The electrodes were then mounted on glass tubes with Torr Seal (Varian) resin and the active surface polished with 1 μm diamond paste. Before each measurement, the electrode surface was chemically etched in either $H_2SO_4:H_2O_2:H_2O$ (1:1:1 volume ratio) mixture or in Br_2 -MeOH solution. Both of these etching procedures led to similar experimental results.

Electrodeposition of polymer films was performed under illumination in 0.1M supporting salt, 1M distilled 3-methylthiophene, acetonitrile solutions, as described in a previous paper (7). The thickness of the film was monitored by measuring the charge with a digital coulometer. Typical thickness was about 0.1 μm .

Electrolytic solutions were prepared with reagent-grade chemicals and doubly distilled water. The various redox couples employed are listed in Table IV. For $[Fe(CN)_6]^{4-/3-}$ and $Fe^{2+/3+}$ couples, the concentrations were 0.1M. I^-/I_3^- and Br^-/Br_2 couples were obtained by adding 0.01M I_2 and 0.1M KI, and 0.01M Br_2 and 0.1M KBr, respectively, to 0.1M H_2SO_4 solutions. $Fe^{II/III}$ citrate was prepared by adding 0.1M $Fe(ClO_4)_2$ to a solution containing 1M NaH_2 citrate and 1M $NaClO_4$. The solution was then buffered to pH 9.4 by adding ammonia. S^{2-}/S_n^{2-} solutions were obtained by equimolar dissolution of Na_2S and S in KOH or NaOH solutions. The preparation of Se^{2-}/Se_2^{2-} solutions has been described elsewhere (11).

Impedance measurements were made in a classical three-electrode cell with a saturated calomel (SCE) reference and a Pt counterelectrode. Impedance was determined over a wide frequency range by using a 1174 Solartron frequency response analyzer equipped with a data management system.

Results

The correlation between the open-circuit voltage (taken as the difference between the photocurrent onset potential V_{on} and the redox potential V_{redox}) and V_{redox} for polymer-coated n-GaAs-based PEC cells is shown in Fig. 1. The data were taken from Ref. (6) for PSt-bpy-Ru- and Ref. (7) for PMeT-protected electrodes. The slope of the least squares fit straight line is 0.81, a value close to unity. This suggests that very weak Fermi level pinning occurs at polymer-coated n-GaAs/liquid junction. A similar behavior has been reported for n-GaAs/PPy electrodes (5), although no data were given for this system.

In order to determine whether this behavior is brought by the polymer film or is characteristic of the n-GaAs/liquid junction, measurements of the flatband potential V_{FB} were carried out on PMeT-coated and bare

electrodes in various redox couples. V_{FB} was obtained by ac impedance measurements over a wide frequency range (25 Hz-250 kHz). Impedance data were analyzed by means of a nonlinear least squares fit method, according to the equivalent circuits given in Fig. 2. In the complete circuit (Fig. 2a) the Helmholtz layer capacitance C_H is generally omitted since it is at least two orders of magnitude greater than the space charge layer capacitance C_{sc} . Analyses according to this complete circuit led to low values for the dispersion capacitance C_{ss} ($C_{ss}/C_{sc} < 0.1$), suggesting a low density of surface states. Consequently, most of the impedance data could be analyzed according to the simplified circuit given in Fig. 2b. Typical values for the series and parallel resistances R_s and R_p are 10 $\Omega \cdot \text{cm}^2$ and 10,000 $\Omega \cdot \text{cm}^2$, respectively. Good linear Mott-Schottky (M-S) plots for C_{sc} were obtained in all cases, for both polymer-coated and bare electrodes. The average of the slopes gave a donor concentration of $2.8 (\pm 0.2) \times 10^{16} \text{ cm}^{-3}$. The value given by the manufacturer is $1.9 \times 10^{16} \text{ cm}^{-3}$. This slight increase corresponds to a roughness factor of 1.2.

Table I gives the values for V_{FB} obtained on bare and PMeT-coated n-GaAs in I^-/I_3^- , $Fe^{2+/3+}$, and Br^-/Br_2 solutions. If we discard the measurement on coated electrode in $Fe^{2+/3+}$ solution, a mean value of $-0.88 \pm 0.04 \text{ V/SCE}$ is obtained. The mean deviation is inside the range of experimental error (a mean deviation of $\pm 0.5 \text{ V}$ is generally taken for impedance determinations of V_{FB}) and two main results can then be deduced from the data given in Table I: (i) V_{FB} is equivalent at bare and PMeT-covered electrodes. Again, a similar invariance has been observed on PPy- (5) and PSt-bpy-Ru-coated n-GaAs (6). (ii) V_{FB} does not depend upon the redox potentials, at least over the potential range covered by the three redox couples used.

It was, of course, necessary to extend the potential range of our V_{FB} determinations towards more negative values of V_{redox} , but some preliminary measurements had to be done in order to check the dependence of the flatband potential upon two other parameters of the solution: pH and redox-ion concentration.

The variation of V_{FB} with pH in indifferent electrolyte solutions is shown in Fig. 3. Data were obtained on (100)-oriented n-GaAs. Other data on the same orientation reported by Janietz *et al.* (12) and Haroutiounian *et al.* (13) are also drawn in Fig. 3, together with data reported by Lafere *et al.* (14) on (111)-oriented GaAs surface. The slope of the least squares fit straight line is -60 mV/pH with a correlation factor of 0.997. The well-known Nernstian behavior (3) is then observed on both surface orien-

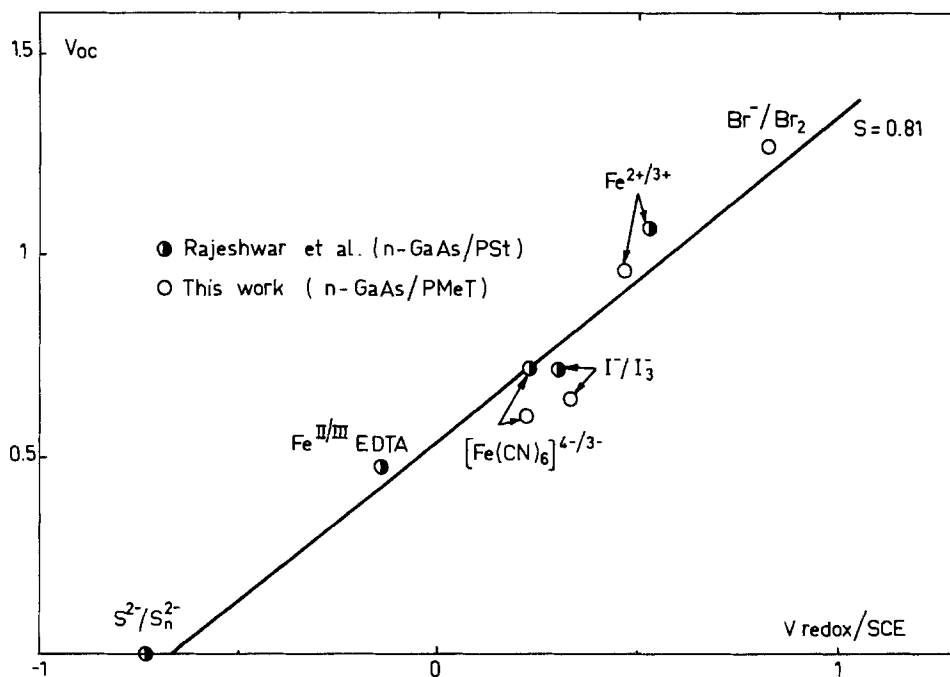

Fig. 1. Variation of the open-circuit potential V_{oc} (taken as the difference between the onset potential and redox potential) at PMeT- and PSt-bpy-Ru-coated n-GaAs in aqueous solutions of various redox couples. Data for GaAs/PSt taken from Rajeshwar *et al.* (6).

tations. This result disagrees with that one reported by Rajeshwar and Mraz (15), who found a slope of -15 mV/pH on (100)-oriented n-GaAs.

The pH variation of V_{FB} was also measured with a redox couple added to the solution. The ideal redox couple for such a measurement is $[\text{Fe}(\text{CN})_6]^{4-/3-}$, which is soluble at all pH. Furthermore, its redox potential remains constant at $+0.22$ V/SCE, except at $\text{pH} < 2$, where it shifts towards positive potentials. Figure 3 shows that V_{FB} is shifted to positive potentials in the presence of $[\text{Fe}(\text{CN})_6]^{4-/3-}$ couple. Importantly, V_{FB} still follows a Nernstian behavior:

Fig. 3. Variation of the flatband potential V_{FB} as a function of the pH of the solution, for redox-free, and $[\text{Fe}(\text{CN})_6]^{4-/3-}$ and $\text{S}^{2-}/\text{S}_n^{2-}$ containing solutions. Dotted line shows the determination of the PZZP (see text). Data were taken from Ref. (12-14). All data on (100) GaAs unless otherwise stated.

Table I. Redox and flatband potentials of bare and PMeT-covered n-GaAs in three different redox couples. All solutions have a pH of 0.9 (0.1M H_2SO_4)

Redox couple	$V_{\text{redox}}/\text{SCE}$	V_{FB}/SCE	
		Bare	PMeT-coated
I^-/I_3^- $\text{Fe}^{2+}/\text{Fe}^{3+}$ (H_2SO_4 0.1M)	0.33	-0.81	-0.87
	0.42	-0.89	-0.71
	0.83	-0.91	-0.92

the slope of the least squares fit straight line is -59 mV/pH, which is the exact theoretical value. The variation of V_{redox} at low pH does not induce any deviation of V_{FB} . This confirms the independence of V_{FB} with V_{redox} .

Similar experiments were made with $\text{S}^{2-}/\text{S}_n^{2-}$ couple at pH 12 and 14. No significant shift of V_{FB} is observed when this redox couple is added to the solution, and a similar pH dependence is obtained. We shall then assume in the following that the flatband potential always follows a Nernstian variation with pH for all redox couples added to the solution.

The last preliminary verification was to check the variation of V_{FB} with redox-ion concentration. Experiments were made with various concentrations of $[\text{Fe}(\text{CN})_6]^{4-/3-}$ at pH 13 (0.1M KOH) and $\text{S}^{2-}/\text{S}_n^{2-}$ at pH 14 (1M KOH). Results are given in Table II and III. A mean value of -1.90 ± 0.04 V/SCE is obtained with $\text{S}^{2-}/\text{S}_n^{2-}$ couple: this variation is within the experimental error. As far as $[\text{Fe}(\text{CN})_6]^{4-/3-}$ couple is concerned, the variation occurring between 10^{-3} and 10^{-4} M corresponds to the shift observed in Fig. 3: the flatband potential behaves as if the effect of the redox-couple disappears when its concentration is lower than 10^{-3} M. Anyhow, we are still far from the -59 mV/decade variation reported by Ginley and Butler (16) for the CdS/ Na_2S junction, which was attributed to an adsorption of HS^- ions at the CdS surface. We can then assume that V_{FB} is insensitive to the redox ion concentration.

The flatband potential was determined for two more redox couples: $\text{Se}^{2-}/\text{Se}_2^{2-}$ (pH 14) and $\text{Fe}^{\text{III}}/\text{citrate}$ (pH 9.4). All our results are gathered in Table IV. The value corresponding to H_2/H^+ couple was taken from Fig. 3. In order to compare the results obtained for all redox couples, V_{FB} data were recalculated at $\text{pH} = 2.8$ by assuming a variation of -59 mV/pH. The reasons for this choice will be explicated in the discussion section. All data obtained on bare electrodes are plotted in Fig. 4, together with the values measured on PMeT- and PSt- [from Ref. (6)] coated n-GaAs. The redox-potential range is now almost 2V, and a slight variation of V_{FB} can be noted, with a slope of ca. 0.2.

Discussion

The classical model of the semiconductor/metal barrier was first developed by Schottky (17). This model pre-

dicts that the barrier height ϕ_B should be given (for an n-type semiconductor) by the difference between the metal work function ϕ_m and the semiconductor electron affinity χ_s . The concept of Fermi level pinning was first introduced by Bardeen (4) to explain the observed independence of the barrier height upon the metal work function for some semiconductors. This phenomenon was believed to result from a significant density of intrinsic (Tamm and Shockley) surface states at the semiconductor surface. Later, Cowley and Sze (18) showed that the Schottky and Bardeen models are the limiting cases of a more general expression for the barrier height that can be reduced to Eq. [1]

$$\phi_B = S\phi_m + \text{const.} \quad [1]$$

where S is dimensionless parameter depending on the semiconductor. From the study of the value of S for a large number of semiconductors, Kurtin *et al.* (19) showed that S can be quantitatively related to the ionicity of the semiconductor, which they measured as the difference ΔX in the electronegativities of the two constituents

Fig. 5. Variation of the Schottky barrier height ϕ_B of a GaAs/metal junction as a function of the metal work function ϕ_m . Data for ϕ_B taken from Ref. (20), and for ϕ_m from Ref. (21).

of the semiconductor compounds (ΔX is taken as 0 in the case of an element semiconductor): S remains small for $\Delta X < 0.7$ and then changes rapidly to a value equal to unity when $\Delta X > 0.7$. A fundamental difference was then shown between ionic (*e.g.*, oxide) and covalent (*e.g.*, III-V compound) semiconductors. A similar result was obtained by Brillson (8) by taking the heat of compound formation as the measure of the ionicity.

The variation of ϕ_B with ϕ_m for GaAs is shown in Fig. 5. Data for ϕ_B were taken from Ref. (20). They were obtained by capacitance measurements on vacuum-cleaved surfaces. Recent determinations of metal work functions were taken from Ref. (21). A value of S of 0.07 is obtained for n-type and 0.04 for p-type GaAs. A quantitative comparison of Fermi level pinning at GaAs/metal and GaAs/liquid junctions can be made by calculating the value of S at the GaAs/liquid junctions. Figure 6 shows how ϕ_B can be determined from the value of V_{FB} . The dependence of the flatband potential as a function of the

Fig. 4. Variation of the flatband potential with the redox potential at bare and polymer-coated GaAs. Values of V_{FB} recalculated for a pH of 2.8 by assuming a variation -59 mV/pH. Data for PSt-coated GaAs taken from Ref. (6).

Fig. 6. Energetic diagram of an n-type semiconductor/liquid junction at equilibrium (a) general case and (b) at the point of zero zeta potential. Flatband (V_{FB}) and redox (V_{redox}) potentials are referred to SCE level; semiconductor electron affinity χ_s is defined with respect to the vacuum level. Energy and potential scales may be related through the equation: $E = E_0 + qV$, where q is the absolute electron charge. The meaning of other symbols is given in text. The variations of the vacuum level represent the existence of local electric fields.

pH is taken into account through a potential drop ΔV_{pH} due to specific OH groups adsorption (Fig. 6a). As pointed out by Butler and Ginley (22), there exists a value of the pH where $\Delta V_{pH} = 0$, called the point of zero zeta potential (PZZP) (Fig. 6b). This point can be determined from the value of the electronic affinity of the semiconductor χ_s through Eq. [2]

$$\chi_s = E_0 + q[V_{FB}(PZZP) - \Delta V_{fc}] \quad [2]$$

where E_0 is a constant relating the reference electrode to the vacuum level and $\Delta V_{fc} = (kT/q) \ln(N_c/N_d)$ the difference between the Fermi and the bottom of the conduction band (N_c is the density of states at the bottom of the conduction band, and N_d the donor impurity concentration). For n-GaAs and $N_d = 10^{16} \text{ cm}^{-3}$, one has $\Delta V_{fc} = 0.07 \text{ V}$. ϕ_B can then be calculated by using Eq. [3]

$$\phi_B = q[V_{redox} - V_{FB}(PZZP) + \Delta V_{fc}] \quad [3]$$

For the SCE a value of 4.75 eV is often taken for E_0 (23). More recent determinations gave $E_0 = 4.97 \text{ eV}$ (24). We shall take a value of 4.9 eV for E_0 . The electron affinity of GaAs has been reported from photoelectric measurements to be 4.07 eV for the (110) face (25) and 3.63 eV for the (111) face (26).

A discussion on Schottky-barrier height measurements by Geppert *et al.* led to a value of 3.57 eV (27). However, a theoretical value for χ_s can be calculated according to Mulliken (28) and Nethercot (29) by using the following relations

$$\chi_s = E_F^i - 1/2 E_g \quad [4]$$

$$E_F^i = (M_A M_B)^{1/2} \quad [5]$$

$$M_A = 1/2 (I_1 + A_r) \quad [6]$$

where E_F^i is the intrinsic Fermi level, E_g the bandgap, M_A the Mulliken potential of element A, I_1 the first ionization potential, and A_r the atomic electron affinity. Values for I_1 and A_r can be found in Ref. (21) and (30). We calculated an electron affinity of 3.40 eV for GaAs. From these four different determinations, a reasonable value of 3.60 eV can be assumed for χ_s . It can now be seen that at the PZZP we have $V_{FB} = (\chi_s - E_0)/q + \Delta_{fc} = 3.60 - 4.9 + 0.07 = -1.23 \text{ V/SCE}$. By carrying this value in Fig. 3, the point of zero potential is found to occur at pH = 2.8.

Values for ϕ_B calculated from Eq. [3] are given in Table IV, along with the redox "work function" ϕ_{redox} , which we define as

$$\phi_{redox} = E_0 + qV_{redox}$$

A plot of these data is given in Fig. 7. A value of $S = 0.78$ is obtained. This value is very close to that one deduced from V_{oc} measurements (Fig. 1) and again suggests a very slight Fermi level pinning at the n-GaAs/aqueous solution interface.

Also shown in Fig. 7 are values of the barrier height at a p-GaAs/acetonitrile-solution junction, calculated from flatband potential measurements recently reported by Nagasubramanian *et al.* (31). Equation [3] was used for this calculation, with $\Delta V_{fc} = 0.12 \text{ V}$. Data were not corrected for a ΔV_{pH} because this kind of correction is not likely to occur in acetonitrile solutions. A value of $S = 0.69$ is obtained. The mean difference between the two straight lines for n- and p-type GaAs is 1.40 eV, a value very close to the bandgap (1.43 eV). However, this result may be fortuitous because of the uncertainty on the values for χ_s and E_0 . Moreover, the SCE scale may be shifted from water to acetonitrile solutions.

Fig. 7. Same as Fig. 5 for a GaAs/liquid junction. ϕ_B taken from Table IV for n-GaAs and calculated from data in Ref. (31) by using Eq. [2] for p-GaAs. Dotted line gives the values of ϕ_B that would be expected in the absence of Fermi level pinning.

Fig. 8. Same as Fig. 1 for a bare p-GaAs electrode. Data taken from Ref. (32-34).

Finally, Fig. 8 shows the variation of the open-circuit potential for a p-GaAs/aqueous solution junction. Data were taken from Ref. (32-34). As previously, V_{oc} was taken as $V_{on} - V_{redox}$. Negative values of V_{oc} correspond to systems unable to work as energy converters. The slope of the straight line is -0.67 (this slope is negative because we are now dealing with a p-type semiconductor), in excellent agreement with the value deduced from flatband potential measurements.

The dispersion of the data in Fig. 8 can be explained by the fact that the onset potential of a semiconductor/liquid junction is not uniquely determined by the position of the bandedges at the semiconductor surface but also by the kinetics of electron transfers at the interface. A similar dispersion may be observed in Fig. 1.

A quantitative comparison of Fermi level pinning between GaAs/metal and GaAs/liquid junctions can now be made with the help of the parameter S . Figures 5 and 7 unambiguously show that Fermi level pinning at GaAs/liquid junction is considerably less pronounced than at GaAs/metal junction. This is the main result of this paper and it will now be discussed. From the classical Bardeen theory of Fermi level pinning by intrinsic surface states, one should expect from Fig. 5 a distribution of surface states centered at about 0.5 eV above the top of the valence band. From results of several experimental groups, it now appears firmly established that there is no intrinsic surface states in the bandgap of GaAs [see, e.g., Ref. (9) and references therein]. This is explained by a lattice rearrangement (or relaxation) of the surface, which moves the surface states out of the bandgap. The Fermi level pinning is then attributed to extrinsic surface states brought by the metal deposition, either through defects produced at the semiconductor surface (9) or by a restoration of the initial (nonrelaxed) surface (10). However, Brillson (8) suggests that the concept of Fermi level pinning should be replaced by that of microscopic charge redistribution at the semiconductor/metal junction, controlled by the degree of chemical reactivity between the semiconductor and metal atoms. The common characteristic of these models is that the "Fermi level pinning" at the semiconductor/metal junction is mainly induced by chemical reactions between the semiconductor and the metal overlayer. From our results and the preceding models, it can be concluded that the chemical reactivity of an aqueous electrolyte with GaAs sur-

faces is not able to induce a surface-state distribution sufficiently high to promote full Fermi level pinning.

However, a slight degree of Fermi level pinning is observed at GaAs/liquid junctions. Some ideas can be put forward to give the beginning of an explanation for this phenomenon: (i) Recent investigations on the kinetics of charge transfer at both n-type (35) and p-type (34) GaAs/liquid junctions under illumination suggest that (extrinsic or intrinsic) surface states do exist at the GaAs surface, but that the occupation rate of these states depends on kinetic factors. This is proved particularly by the shift of V_{FB} under illumination, and the fact that no surface states can be detected in the dark. (ii) A GaAs surface in contact with an aqueous or acetonitrile solution is far more "dirty" than a UHV-cleaved face. The formation of oxides has been shown to occur by simply dipping GaAs in water (36). The presence of extrinsic surface states is then likely, since it has been shown that the chemisorption of a submonolayer of oxygen suffices to induce such states (9).

As a final remark, the weak Fermi level pinning at the GaAs/liquid junction should permit high open-circuit voltages. Such high values have been already observed at polymer-protected n-GaAs electrodes with oxidizing redox couples such as $Fe^{2+/3+}$, I^-/I_3^- , or Br^-/Br_2 . Similar results can be expected with p-GaAs and reducing redox systems. This idea is supported by a value of 0.7V measured by Memming (32) on a p-GaAs/ $Eu^{2+/3+}$ cell. This result is noteworthy since the barrier height at p-GaAs/metal junction is always lower than 0.5V.

Acknowledgments

The authors are very grateful to Dr. C. A. Sebenne (Laboratoire de Physique des Solides, Université Pierre et Marie Curie, Paris, France) and Dr. F. Garnier (Laboratoire de Photochimie Solaire, CNRS, Thiers, France) for valuable discussions. This work was supported by the GRECO 130061 of the CNRS.

Mathematical Modeling of Liquid-Junction Photovoltaic Cells

I. Governing Equations

Mark E. Orazem¹ and John Newman*

Materials and Molecular Research Division of Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The equations which govern the liquid-junction photovoltaic cell are presented in the context of a one-dimensional mathematical model. This model treats explicitly the semiconductor, the electrolyte, and the semiconductor-electrolyte interface in terms of potentials and concentrations of charged species. The model incorporates macroscopic transport equations in the bulk of the semiconductor and electrolyte, coupled with a microscopic model of the semiconductor-electrolyte interface. Homogeneous and heterogeneous recombination of electron-hole pairs is included within the model. Recombination takes place at the semiconductor-electrolyte interface through interfacial sites, which can enhance the recombination rate. The coupled nonlinear ordinary differential equations of the model were posed in finite-difference form and solved numerically. The results are presented in succeeding papers.

The liquid-junction photovoltaic cell is an electrochemical system with one or two semiconducting electrodes. This system has undergone intense study since the early 1970's as a means of converting solar energy to chemical or electrical energy (1-8). A number of articles review the physics of the liquid-junction cell, the role of the semiconducting electrode, and the literature [see e.g., Ref. (9-19)].

A mathematical model is presented here which treats explicitly all components of the liquid-junction photovoltaic cell. The results of the model, obtained through numerical computation, are used to gain insight into the cell behavior and into the factors influencing cell design.

Development of a mathematical model constitutes an important step toward understanding the behavior and predicting the performance of the liquid-junction photovoltaic cell. Coupled phenomena govern the system, and the equations describing their interaction cannot, in general, be solved analytically. Two approaches have been

taken in developing a mathematical model of the liquid-junction photovoltaic cell: approximate analytic solution of the governing equations and numerical solution. These are reviewed elsewhere (20).

The use of a digital computer in the numerical solution of the equations governing the liquid-junction cell eliminates the need for restrictive assumptions. The numerical approach was taken in this work (20) and has been used in the modeling of solid-state devices (21-26). Laser and Bard (27-30) developed a computer program which was used to calculate open-circuit photopotentials, the transient behavior of the system following charge injection, and the time dependence of photocurrents in liquid-junction cells. Time-dependent material balances of holes and electrons and Poisson's equation described the semiconductor. The interface was included in terms of charge and flux boundary conditions. The model was limited by lack of convergence for electrode thicknesses greater than that of the space-charge region and did not treat explicitly the electrolyte and counterelectrode.

A number of computer programs related to the liquid-junction photovoltaic cell have been developed. Leary et al. (31), for example, calculated carrier concentrations in

* Electrochemical Society Active Member.

¹ Present address: Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia 22901.

polycrystalline films using a numerical solution of Poisson's equation coupled with overall charge neutrality within spherical grains. Their model was used for analysis of semiconductor gas sensors. A computer program has been presented by Davis and colleagues (32-34) which uses simultaneous calculation of surface and solution equilibrium states to obtain the equilibrium condition of electrical double layers.

Physical Model

A one-dimensional representation of the liquid-junction photovoltaic cell is presented in Fig. 1. This model includes macroscopic representations of the counterelectrode, the electrolytic solution, and the semiconductor coupled with a microscopic representation of the interface between the semiconductor and the solution. The semiconductor-electrolyte interface couples the macroscopic equations which govern the adjacent bulk phases.

The interface is represented by four planes, inner and outer Helmholtz planes on the electrolyte side of the interface and inner and outer surface states on the semiconductor side. The outer Helmholtz plane (OHP) is the plane of closest approach for (hydrated) ions associated with the bulk solution. The inner Helmholtz plane (IHP) passes through the center of ions specifically adsorbed on the semiconductor surface. The outer surface state (OSS) represents the plane of closest approach for electrons (and holes) associated with the bulk of the semiconductor. The inner surface state (ISS) is a plane of surface sites for adsorbed electrons.

This model of the semiconductor-electrolyte interface is an extension of the classical diffuse-double-layer theory (35-37). Charge adsorbed onto the IHP and the ISS planes is balanced by charge in the diffuse region of the electrolyte and the space-charge region of the semiconductor. The net charge of the interface, including surface planes and diffuse and space-charge regions, is equal to zero.

Within the model, single-step reactions relate concentrations and potentials at interfacial planes. A continuous spectrum of energy levels at the ISS is represented by three discrete energy levels (designated *v*, *t*, and *c*). Conduction electrons are adsorbed via reaction [1] (see the interface in Fig. 1) from the OSS to high-energy sites at the ISS, via reaction [10] to intermediate energy sites at the ISS, and via reaction [11] to low energy sites at the ISS. Via reaction [2], low-energy electrons at the ISS can oc-

cupy vacancies in the valence band, or holes, at the OSS. Intermediate energy electrons can transfer from the ISS to the OSS through reaction [12], and high energy electrons can transfer through reaction [13]. Reactions [3] and [4] allow the shifting of electrons from one energy level to another.

Ionic species from the solution are adsorbed into the IHP by reactions [8] and [9]. Two adsorbed species are considered here. It is assumed that other ionic species in the solution do not adsorb and do not participate in the electrochemical reactions. Relaxation of this assumption involves the inclusion of additional ion-adsorption and charge-transfer reactions. Reactions [5], [6], and [7] are the charge-transfer reactions that take place among adsorbed ions at the IHP and adsorbed high, intermediate, or low energy electrons at the ISS. Charge-transfer reactions allow passage of electrical current from the semiconductor to the solution.

Theoretical Development

The equations governing the liquid-junction photovoltaic cell in the dark or under steady-state illumination are developed here in terms of the model presented above. The governing relationships can be developed separately for the semiconductor and the electrolyte. The microscopic model of the semiconductor-electrolyte interface couples the equations governing the macroscopic systems.

Semiconductor.—The electrochemical potential of a given species can arbitrarily be separated into terms representing a reference state, a chemical contribution, and an electrical contribution

$$\mu_i = \mu_i^0 + RT \ln (c_i f_i) + z_i F \Phi \quad [2]$$

where Φ is a potential which characterizes the electrical state of the phase and can be arbitrarily defined. The potential used here is the electrostatic potential which is obtained through integration of Poisson's equation (38). Equation [2] can be viewed as the defining equation for the activity coefficient, f_i .

The flux of an individual species within the semiconductor is driven by a gradient of electrochemical potential, which corresponds to gradients of potential and concentration [see *e.g.*, Chap. 11 in Ref. (39) and Gerischer (40)]. Under the assumption that the individual ionic activity coefficients are constant with a value of one,² the flux of holes is given by

$$N_{h^+} = -u_{h^+} F p \frac{d\Phi}{dy} - D_{h^+} \frac{dp}{dy} \quad [3]$$

and the flux of electrons by

$$N_{e^-} = u_{e^-} F n \frac{d\Phi}{dy} - D_{e^-} \frac{dn}{dy} \quad [4]$$

The concentrations of electrons and holes are represented by n and p , respectively, and the mobilities u_i are related to the diffusivities D_i by the Nernst-Einstein equation

$$D_i = RT u_i \quad [5]$$

Homogeneous reaction takes place in the semiconductor; thus a material balance for a given species, say holes,³ yields

² The assumption of constant activity coefficients, valid for dilute solutions, is appropriate for most semiconductors. The carrier concentrations in semiconductors is usually less than 0.0001M, which is low as compared to dilute aqueous solutions. The assumption of constant activity coefficients is in harmony with a Boltzmann distribution of electrons and holes. Use of Fermi-Dirac distributions for these charged species results in activity coefficients that are functions of concentration [see Ref. (46)].

³ The development presented here, while applicable to p-type semiconductors, is oriented toward analysis of an n-type semiconductor in which holes are the minority carrier. Material balances of holes and electrons are not independent, and conservation of the minority carrier was chosen to improve the numerical computational accuracy.

Fig. 1. Mathematical model of the liquid-junction photovoltaic cell

$$\frac{dN_{h^+}}{dy} = R_{h^+} \quad [6]$$

where R_{h^+} is the net rate of production of holes under steady-state conditions.

The rate of production of holes is, by stoichiometry, equal to the rate of production of electrons and is governed by three concurrent processes: generation by absorption of light, generation by absorption of heat, and recombination of electrons and holes (*i.e.*, transfer of an electron from the conduction band to the valence band)

$$R_{h^+} = G_L + G_{th} - R_{rec} \quad [7]$$

Mathematical models of the homogeneous recombination process have been developed which incorporate single-step electron transfer from one energy level to another. They differ in the assumption of the presence or absence of impurities within the semiconductor which allow electrons to have energies between the conduction and valence-band energies (41, 42).

Most semiconducting materials contain impurities or imperfections within their lattice structure which may be described as fixed sites with valence-band electron energies within the semiconductor bandgap. The trap-kinetics model allows recombination to occur through these sites (see Fig. 2). Absorbed radiation drives an electron from the valence band to the conduction band, and all recombination and thermal generation reactions are assumed to occur through trap sites. This model results in

$$R_{h^+} = \eta m q_0 e^{-m\nu} - \frac{N_t k_2 (np - n_i^2)}{\frac{k_1(N_v - p) + k_3(N_c - n)}{k_4} + \frac{k_2}{k_4} p + n} \quad [8]$$

where k_1 , k_2 , k_3 , and k_4 are the rate constants for the corresponding reactions shown in Fig. 2. The intrinsic concentration is given by

$$n_i = \left[\frac{k_1 k_3 (N_c - n)(N_v - p)}{k_2 k_4} \right]^{1/2} \quad [9]$$

The electron and hole concentrations are generally small as compared to the respective conduction and valence-band site concentrations. The intrinsic concentration is therefore constant, and the reaction rate can be characterized with three lumped rate constants [$N_t k_2$, $(k_1 N_v + k_3 N_c)/k_4$, and k_2/k_4]. Homogeneous electron-hole recombination was assumed in the mathematical model to occur through trap sites (Eq. [8] and [9]).

The expression for the intrinsic concentration (Eq. [9]) is consistent with the expression derived through statistical-mechanical models (see Eq. [32] of Chap. 6, Ref.

Thermal Generation and Recombination Through Trap Sites

Individual Reaction Rates

$$G_L = \eta m q_0 e^{-m\nu}$$

$$R_1 = k_1(N_v - p)(N_T - n_T)$$

$$R_2 = k_2 n_T p$$

$$R_3 = k_3 n_T (N_c - n)$$

$$R_4 = k_4 n (N_T - n_T)$$

Fig. 2. Schematic representation of single-trap recombination kinetics in the semiconductor.

(20)). The intrinsic concentration can be considered to be a constant for a given semiconductor only if the ratios n/N_c and p/N_v are negligibly small as compared to unity. This condition is consistent with the assumption of unity activity coefficients for electrons and holes. The value of the intrinsic concentration derived from statistical-mechanical arguments serves as a relationship among the kinetic parameters in Eq. [9].

The divergence of the current is zero at steady state; therefore the fluxes of holes and electrons are related by

$$\frac{dN_{e^-}}{dy} - \frac{dN_{h^+}}{dy} = 0 \quad [10]$$

A material balance on electrons, analogous to Eq. [5], could be used to replace Eq. [10].

Poisson's equation

$$\frac{d^2\Phi}{dy^2} = - \frac{\mathbf{F}}{\epsilon_{sc}} [p - n + (N_d - N_a)] \quad [11]$$

relates the potential to the charge distribution. The concentrations of ionized electron donors and acceptors are represented by N_d and N_a , respectively. The Debye length

$$\lambda_{sc} = [\epsilon_{sc} RT / \mathbf{F}^2 (N_d - N_a)]^{1/2}$$

characterizes the distance over which the potential varies in the semiconductor. It typically has a value of 1×10^{-6} to 2×10^{-5} cm.

The degree of ionization of donors or acceptors is dependent upon the concentrations of charged species within the semiconductor and upon the temperature. Complete ionization has been assumed in this work. This assumption is reasonable at room temperatures and is consistent with the assumption of unity activity coefficients.

Electrolyte.—For a one-dimensional case, neglecting convective effects, the flux of an ionic species is governed by potential and concentration gradients

$$N_i = -z_i u_i c_i \mathbf{F} \frac{d\Phi}{dy} - D_i \frac{dc_i}{dy} \quad [12]$$

Under the assumption that homogeneous reactions do not take place, conservation of mass yields a uniform flux at steady state, *i.e.*

$$\frac{dN_i}{dy} = 0 \quad [13]$$

The potential and concentrations of charged species are related by Poisson's equation

$$\frac{d^2\Phi}{dy^2} = - \frac{\mathbf{F}}{\epsilon_{sol}} \sum_i z_i c_i \quad [14]$$

Electroneutrality of the electrolyte is not assumed here because the diffuse region near the interface plays an important role in the microscopic model of the interface. The Debye length in the solution is given by

$$\lambda_{sol} = [\epsilon_{sol} RT / \mathbf{F}^2 \sum_i z_i^2 c_{i,\infty}]^{1/2}$$

and typically has a value of 1×10^{-8} to 1×10^{-7} cm.

The relationships presented above are sufficient to describe the electrolytic solution. An additional relationship yields the current density as a function of the ionic fluxes

$$i = \mathbf{F} \sum_i z_i N_i \quad [15]$$

Within the semiconductor, this can be regarded as an integrated form of Eq. [10].

Semiconductor-electrolyte interface.—A general interfacial reaction can be expressed as

where s_i is the stoichiometric coefficient of species i , M_i is a symbol for the chemical formula of species i , and n is the number of electrons transferred. [See Chap. 8 in Ref. (39).] For single-step reactions, n is equal to one.

The rate of a single-step reaction 1 at the interface is given by

$$\begin{aligned} r_l = & k_{f,l} \exp \left[\frac{(1 - \beta_l) F \Delta \Phi_l}{RT} \right] \prod_i c_i^{p_{i,l}} \\ & - k_{b,l} \exp \left[\frac{-\beta_l F \Delta \Phi_l}{RT} \right] \prod_i c_i^{q_{i,l}} \end{aligned} \quad [17]$$

where β_l is a symmetry factor (usually assumed to be equal to 1/2), $k_{f,l}$ and $k_{b,l}$ are forward and backward reaction rate constants, respectively, and $\Delta \Phi_l$ is the potential driving force for the given reaction, l . The potential driving force enters into reactions involving charge transfer from locations of one potential to locations of another.

The reaction orders for a given species i in the forward and reverse directions are $p_{i,l}$ and $q_{i,l}$, respectively. They are determined from the stoichiometric coefficients, $s_{i,l}$

$$\text{If } s_{i,l} = 0; p_{i,l} = 0, \text{ and } q_{i,l} = 0$$

$$\text{If } s_{i,l} > 0; p_{i,l} = s_{i,l}, \text{ and } q_{i,l} = 0$$

$$\text{If } s_{i,l} < 0; p_{i,l} = 0, \text{ and } q_{i,l} = -s_{i,l}$$

The reaction rates are written in terms of the equilibrium constants as

$$\begin{aligned} r_e = & k_{b,l} \left\{ K_l \exp \left[\frac{(1 - \beta_l) F \Delta \Phi_l}{RT} \right] \prod_i c_i^{p_{i,l}} \right. \\ & \left. - \exp \left[\frac{-\beta_l F \Delta \Phi_l}{RT} \right] \prod_i c_i^{q_{i,l}} \right\} \end{aligned} \quad [18]$$

The equilibrium constant used here is the ratio of the forward and backward rate constants

$$K_l = \frac{k_{f,l}}{k_{b,l}} \quad [19]$$

Six of the 13 equilibrium constants are independent and can be calculated as functions of equilibrium interfacial concentrations and potentials

$$K_l = \exp \left[-\frac{F}{RT} \Delta \Phi_l \right] \prod_i c_i^{-s_{i,l}} \quad [20]$$

A discussion of the calculation of equilibrium concentrations and potentials and the subsequent calculation of equilibrium constants is presented elsewhere [see Chap. 6, Ref. (20)]. The remaining constants can be calculated from Eq. [20] or from the following identities

$$K_4 = \frac{K_3(N_d - N_a)^2}{K_1 K_2 n_i^2} \quad [21a]$$

$$K_6 = K_7 / K_3 \quad [21b]$$

$$K_7 = K_8 / K_4 \quad [21c]$$

$$K_{10} = K_1 K_4 \quad [21d]$$

$$K_{11} = K_{10} / K_3 \quad [21e]$$

$$K_{12} = K_8 / K_3 \quad [21f]$$

and

$$K_{13} = K_{12} K_4 \quad [21g]$$

Within the parametric studies which follow (44), one independent rate constant is assumed to be characteristic of each of four groups of interfacial reactions. The four groups, shown in Fig. 1, are reactions [1], [2], [10]-[13]

(OSS-ISS), reactions [3] and [4] (ISS), reactions [5]-[7] (ISS-IHP), and reactions [8] and [9] (IHP-OHP). The individual rate constants for each reaction l are related to the characteristic rate constant by

$$k_{b,l} = k_l^0 K_l^{-1/2} \quad [22]$$

and

$$k_{f,l} = k_{b,l} K_l = k_l^0 K_l^{1/2} \quad [23]$$

where k_l^0 is the pre-exponential part of the rate constant, with a characteristic value for a given reaction type, and β was given a value of one-half. These equations are consistent with Eq. [18] and [19].

Material balances govern the interface under steady-state conditions. These are expressed by continuity of flux at the OSS and the OHP

$$N_{e^-}|_{\text{oss}} = \sum_l -s_{e^-} r_{l,\text{iss}} \quad [24]$$

$$N_{\text{H}^+}|_{\text{oss}} = \sum_l -s_{\text{H}^+} r_{l,\text{iss}} \quad [25]$$

and

$$N_i|_{\text{ohp}} = \sum_l -s_{i,l} r_l \quad [26]$$

and material balances for each adsorbed species i at the ISS and the IHP

$$\sum_l s_{i,l} r_{l,\text{iss}} = 0 \quad [27]$$

and

$$\sum_l s_{i,l} r_{l,\text{iHP}} = 0 \quad [28]$$

Gauss's law can be applied to the region between the OSS and ISS

$$(\Phi_{\text{oss}} - \Phi_{\text{iss}}) = \frac{\delta_1}{\epsilon_{\text{sc}}} \left[\frac{\epsilon_2}{\delta_2} (\Phi_{\text{iss}} - \Phi_{\text{iHP}}) + \mathbf{F} \left(\sum_{\text{iss}} \gamma_i - g_{\text{iss}}^+ \right) \right] \quad [29]$$

and between the ISS and the IHP

$$(\Phi_{\text{iss}} - \Phi_{\text{iHP}}) = \frac{\delta_2}{\epsilon_2} \left[\frac{\epsilon_{\text{sol}}}{\delta_3} (\Phi_{\text{iHP}} - \Phi_{\text{ohp}}) - \mathbf{F} \left(\sum_{\text{iHP}} z_i \gamma_i \right) \right] \quad [30]$$

The evaluation of Gauss's law in the region between the OSS and the ISS includes a term for a fixed positive charge at the ISS, q_{iss}^+ , which was set equal to zero in this study.

Boundary conditions.—The semiconducting electrode is bounded at one end by the electrolyte and at the other end by a metallic current collector. The boundary conditions at the semiconductor-electrolyte interface are incorporated into the model of the interface. The boundary conditions at the semiconductor-current collector interface are that the potential is zero, the potential derivative is equal to a constant, determined by the charge assumed to be located at the semiconductor-current collector interface (this constant was set equal to zero in this study), and all the current is carried by electrons (the flux of holes is zero). The boundary conditions in the electrolytic solution are set a fixed distance (10 Debye lengths) from the interface. This distance may be considered to be a diffusion layer. The boundary conditions are that the potential gradient is continuous and that all concentrations have their bulk value.

Counterelectrode.—In the region sufficiently far from the interface that electroneutrality holds, the potential distribution is linear and is a function of current density. The potential drop in the region between the counterelectrode and the outer limit of the diffusion layer is given by

$$V_{IR} = \frac{Li}{\kappa} \quad [31]$$

where κ is the solution conductivity and L is the distance between the counterelectrode and the outer edge of the diffusion layer. The conductivity of dilute solutions is related to ionic mobilities and concentrations by

$$\kappa = F^2 \sum_i z_i^2 u_i c_i \quad [32]$$

The potential drop across the counterelectrode-electrolyte interface is given by

$$V_{CE} = V_{CE}^0 + \eta_{CE} \quad [33]$$

where V_{CE}^0 is the equilibrium potential drop across the interface and η_{CE} is the total counterelectrode reaction overpotential. The total overpotential is related to the current density through the Butler-Volmer reaction model (39, 43)

$$i = i_0 \left\{ \left[1 - \frac{i}{i_{a,lim}} \right] \exp \left[\frac{(1 - \beta)nF}{RT} \eta_{CE} \right] - \left[1 + \frac{i}{i_{c,lim}} \right] \exp \left[- \frac{\beta nF}{RT} \eta_{CE} \right] \right\} \quad [34]$$

where i_0 is the exchange current density associated with the bulk concentrations of reactants, $i_{k,lim}$ is the diffusion-limited current density associated with species k , and n is the number of electrons transferred in the counterelectrode reaction.

Conclusion

The equations which govern the liquid-junction photovoltaic cell are presented in the context of a one-dimensional mathematical model. This model treats explicitly the semiconductor, the electrolyte, and the semiconductor-electrolyte interface in terms of potentials and concentrations of charged species. The model incorporates macroscopic transport equations in the bulk of the semiconductor and electrolyte, coupled with a microscopic model of the semiconductor-electrolyte interface. Homogeneous and heterogeneous recombination of electron-hole pairs is included within the model. Recombination takes place at the semiconductor-electrolyte interface through interfacial sites, which can enhance the recombination rate. The coupled nonlinear ordinary differential equations of the model were posed in finite-difference form and solved numerically (44). Such numerical solution of the governing equations reduces the number of restrictive assumptions needed to solve the problem. The model can be used to gain insight into the effect of cell parameters on cell performance (44) and can be coupled with primary resistance calculations to optimize cell configurations (45).

Mathematical Modeling of Liquid-Junction Photovoltaic Cells

II. Effect of System Parameters on Current-Potential Curves

Mark E. Orazem¹ and John Newman*

Materials and Molecular Research Division of Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The one-dimensional mathematical model presented in a previous paper was used to calculate the effect of system variables on the performance of an n-type GaAs semiconducting anode in contact with an 0.8M K₂Se, 0.1M K₂Se₂, 1.0M KOH electrolytic solution. The performance of the semiconductor electrode is influenced by kinetic limitations to interfacial reactions, dopant concentration, semiconductor thickness, the direction of illumination, and the amount of light absorbed in the semiconductor. An optimal dopant concentration and semiconductor thickness can be calculated for a given system.

The liquid-junction photovoltaic cell is an electrochemical system with one or two semiconducting electrodes. This system has undergone intense study since the early 1970's as a means of converting solar energy to chemical or electrical energy (1-8). A number of articles review the physics of the liquid-junction cell, the role of the semiconducting electrode, and the literature. See *e.g.*, Ref. (9-19).

A mathematical model of the liquid-junction photovoltaic cell was presented in a previous paper (20). The results of the model, obtained through numerical computation, are used here to gain insight into the cell behavior and into the factors influencing cell design. This model can also be coupled with primary resistance calculations to optimize the design of cell configurations (21).

A one-dimensional mathematical model of the liquid-junction photovoltaic cell has been developed (20) which treats explicitly the semiconductor, the electrolyte, and the semiconductor-electrolyte interface in terms of potentials and concentrations of charged species. A one-dimensional representation of the model is presented in Fig. 1 of the first paper in this series (*This Journal*, p. 2569). This model includes macroscopic representations of the counterelectrode, the electrolytic solution, and the semiconductor coupled with a microscopic representation of the interface between the semiconductor and the solution. The semiconductor-electrolyte interface couples the macroscopic equations which govern the adjacent bulk phases.

Semiconductor-electrolyte interface.—A description of the semiconductor-electrolyte interface appears on page 2571 of *This Journal*.

Numerical method.—The coupled nonlinear ordinary differential equations of the model were posed in finite-

Table I. Input parameters for the semiconductor

Semiconductor: n-GaAs	N_v	$1.16 \times 10^{-5} \text{ mol/cm}^3 (7 \times 10^{18} \text{ cm}^{-3})$
Valence band site concentration	N_c	$7.80 \times 10^{-7} \text{ mol/cm}^3 (4.7 \times 10^{17} \text{ cm}^{-3})$
Conduction band site concentration	E_g	1.4 eV
Bandgap	$N_d - N_a$	$9.96 \times 10^{-8} \text{ eq/cm}^3 (6 \times 10^{16} \text{ cm}^{-3})$
Dopant concentration	D_{e-}	222.0 cm ² /s
Electron diffusivity	D_{h+}	6.46 cm ² /s
Hole diffusivity	ϵ_{sc}	$1.06 \times 10^{-12} \text{ C/V-s}$
Permittivity	m	$4.40 \times 10^5 \text{ cm}^{-1}$
Solar absorption coefficient	η	0.3735
Solar spectrum efficiency	q_0	$7.139 \times 10^{-7} \text{ mol/cm}^2\text{-s}$
Total incident radiation (AM-2)		882 W/m ²
	N/k_2	$1.89 \times 10^9 \text{ s}^{-1}$
Homogeneous recombination rate constants	$(k_1 N_v + k_2 N_c)/k_4$	100
	k_2/k_4	$2.56 \times 10^{-3} \text{ cm}^3/\text{mol}$

difference form and solved numerically for the cell under equilibrium and steady-state conditions (25). The equations were properly linearized, posed in finite-difference form, and solved using Newman's BAND method (28), coupled with Newton-Raphson iteration. Calculation of a current-potential curve involved iterative solution of the system of coupled equations for input values of solar illumination and current density. Numerical accuracy was enhanced by definition of concentration variables that are uniform under equilibrium conditions. The concentration and potential variables in the semiconductor were²

$$AN = \frac{n}{N_d - N_a} e^{-\phi}$$

and

$$P = \frac{p}{N_d - N_a} e^{\phi}$$

where

$$\phi = \frac{F\Phi}{RT}$$

Under equilibrium conditions, the dimensionless potential varied in the semiconductor from zero to around 40.

Numerical accuracy was further improved by partial decoupling of the three equations governing the semiconductor. The large number of equations associated with the semiconductor-electrolyte interface involve variables that appear only at that location. These equations were transformed into a smaller number of equations involving only bulk phase variables in a local inversion routine. A general method for local inversion is presented by White (48).

Results

Computed results for the mathematical model of the liquid-junction photovoltaic cell are presented in the following section. The parameter values chosen for the model are consistent with an n-type GaAs anode in contact with a 0.8M K₂Se, 0.1M K₂Se₂, 1.0M KOH solution. The redox couple was assumed to be Se₂²⁻/Se²⁻, and the semiconductor was illuminated at the semiconductor-electrolyte interface. Input parameter values are as presented in Tables I-III unless stated otherwise. Dependent parameters calculated from the input data are presented in Table IV.

The n-type GaAs system was chosen for analysis to allow comparison to the experimental work of Heller and Miller (8, 27, 28). Their cell achieved a 12% power efficiency based upon incident radiation, an open-circuit potential of 0.7V, and a closed circuit current of 24 mA/cm². A description of their experimental electrodes, cell, and measuring techniques is presented in Ref. (29). Their cell efficiency includes the effects of reflection losses and electrolyte resistance. The influence of kinetic

and mass-transfer limitations to current flow at the counterelectrode were reduced by using a counterelectrode to semiconductor area ratio of 50. The Se₂²⁻/Se²⁻ redox couple was chosen to limit the corrosion of GaAs under 1000 W/m² illumination to a few micrometers per year (approximately 0.04 mA/cm²) (30-32).

The discussion of the effect of kinetic, bulk semiconductor, and interfacial parameters does not include the effect of IR drop in the electrolyte or kinetic and mass-transfer limitations at the counterelectrode (see the "Counterelectrodes" section of the previous paper). The

contribution of these phenomena is discussed in the "Cell Design" section (see also the next paper).

Interfacial kinetic limitations.—The values of the interfacial rate constants can affect the open-circuit cell potential, the value of the limiting current, and the shape of the current-potential curve. Most (> 99%) of the recombination under open-circuit illumination occurs at the interface. Homogeneous recombination is included in the model, but does not play a major role for the range of parameters studied.

Ion-adsorption reactions.—Current-potential curves are presented in Fig. 1 with the interfacial rate constant for adsorption and desorption of ions onto the inner Helmholtz plane as a parameter (reactions [8] and [9] in Fig. 1 of the first paper). In each case, the cell potential is a maximum at open circuit (700.5 mV) and decreases as the anodic current increases. A limiting current is observed due to limitations of mass transfer and generation of holes in the semiconductor.

The ion-adsorption rate constant influences the limiting current and the shape of the current-potential curve. A dramatic decrease in the maximum power obtained from this system is observed for the cases with small ion-adsorption rate constants. Kinetic limitations to ion adsorption are seen to have a major effect on cell performance.

Concentration distributions of holes and electrons in the semiconductor are presented in Fig. 2 and 3 for a system with no interfacial kinetic limitations and for a system with kinetic limitations to ion adsorption, respectively. The equilibrium and illuminated open-circuit concentration distributions for the two cases are identical. Under equilibrium conditions, the concentration of holes (curve a) is essentially zero in the bulk of the semiconductor and increases near the negatively charged interface. Conduction electrons are depleted near the interface and reach a value of 0.328 dimensionless units at the current collector, where the concentrations are scaled by the dopant concentration ($N_d - N_a$). The electron concentration in a neutral region of the semiconductor would have a value essentially equal to 1.0. The equilibrated semiconductor of Fig. 2 can therefore be described as having an inversion region extending from the semicon-

Fig. 1. Computed current-potential curves for an n-type GaAs anode with ion-adsorption rate constant as a parameter.

Fig. 2. Concentration distribution for the liquid-junction cell with no kinetic limitations ($k_{ads} = 1.0 \times 10^{26} \text{ s}^{-1}$). Curve a, open circuit in the dark; curve b, open circuit under illumination; and curve c, near short circuit ($i = -23.1 \text{ mA/cm}^2$) under illumination.

ductor-electrolyte interface to 0.5 Debye lengths from the interface and a depletion region extending to the current collector.

The positive background charge density has a value of 1.0; the semiconductor has a net positive charge which is balanced by charge associated with the diffuse region of the electrolyte and the interface. System electroneutrality is maintained. The potential gradient, the driving force for migration of charged species, is balanced by the concentration gradient, which drives diffusion. The net flux of each species in the semiconductor is equal to zero at equilibrium.

Illumination under open-circuit conditions produces electron-hole pairs, which are separated by the potential

Fig. 3. Concentration distribution for the liquid-junction cell with kinetic limitations to ion adsorption ($k_{ads} = 4.0 \times 10^6 \text{ s}^{-1}$). Curve a, open circuit in the dark; curve b, open circuit under illumination; and curve c, near short circuit ($i = -23.1 \text{ mA/cm}^2$) under illumination.

gradient. The concentration of holes increases near the interface, and the concentration of electrons increases near the current collector (curve b). As the system without kinetic limitations approaches short circuit (curve c in Fig. 2), the concentrations of holes and electrons approach the equilibrium distributions. The system under kinetic limitations to ion adsorption, in contrast, experiences an increase in hole concentration at large current densities (curve c in Fig. 4).

The model also allows calculation of the potential distribution in the semiconductor and throughout the cell. Kinetic limitations at the interface are compensated by increased changes of potential across the reaction planes. A small ion-adsorption rate constant is therefore compensated by increased potential and concentration driving forces at the interface. In this way, kinetic limitations influence the cell performance.

Charge-transfer reactions.—Current-potential curves are presented in Fig. 4 with the rate constant for charge transfer from the inner surface states of the semiconductor to the inner Helmholtz plane as a parameter (reactions [5], [6], and [7] in Fig. 1 of the previous paper). The cell potential has a maximum value under open-circuit illumination and decreases as the anodic current increases. Kinetic limitations to charge transfer adversely influence the power performance of the cell. A small charge-transfer rate constant is compensated by increased potential and concentration driving forces.

Electron-adsorption reactions.—The influence of electron-adsorption rate constants (reactions [1], [2], [10], [11], [12], and [13] in Fig. 1 of the previous paper) upon the current-potential curve is presented in Fig. 5. A small electron-adsorption rate constant reduces the net rate of recombination of holes and electrons at the surface and thus increases both the cell potential and the value of the limiting current.

Surface-shift reactions.—The rate constants for reactions which allow electrons to move from one energy level at the interface to another (reactions [3] and [4] in Fig. 1 of the previous paper) do not have any independent effect upon the cell potential or the value of the limiting current.

Fig. 4. Computed current-potential curves for an n-type GaAs anode with charge-transfer rate constant as a parameter.

Fig. 5. Computed current-potential curves for an n-type GaAs anode with electron-adsorption rate constant as a parameter.

rent. These rate constants affect only the path by which recombination may take place.

Bulk semiconductor properties.—Bulk semiconductor properties can greatly influence the performance of the liquid-junction photovoltaic cell. Some properties which can be controlled in semiconductor manufacture and cell design are the dopant concentration, the thickness of the semiconductor, and the amount of light absorbed in the semiconductor. The influence of the solar absorption coefficient is also presented. This parameter is generally fixed for a given semiconductor.

Dopant concentration.—Current-potential curves are presented in Fig. 6 for concentrations of positive background charge ranging from 0.0396×10^{-7} to 2.500×10^{-7} eq/cm³ (2.4×10^{15} to 1.5×10^{17} cm⁻³) and for a semiconductor thickness of 10 Debye lengths. For low to moderate levels of doping, the open-circuit cell potential is independent of dopant concentration. The open-circuit cell potential decreases with very large doping levels due to a decrease in the equilibrium flatband potential. For low to moderately large levels of doping, the charged portion of the equilibrated semiconductor adjacent to the interface consists of an inversion region and a depletion region. Electroneutrality of the interfacial region can be satisfied in the very highly doped semiconductor by a region of low electron concentration. No inversion layer is observed, and the potential variation in the semiconductor (*i.e.*, the flatband potential) is reduced.

The short-circuit current is independent of dopant concentration for the highly doped semiconductor and is reduced at very low dopant levels because of enhanced homogeneous recombination of electron-hole pairs. This effect is dependent upon the rate constants for homogeneous recombination.

The semiconductor Debye length is inversely proportional to the square root of the dopant concentration. If the semiconductor thickness were held constant at a value of 1.69×10^{-5} cm, as opposed to 10 Debye lengths, similar results would be observed for high dopant concentrations. At low dopant concentrations, the semiconductor thickness would be smaller than the space-charge region thickness, and the cell potential would be reduced

Fig. 6. Computed current-potential curves for an n-type GaAs anode with dopant concentration as a parameter.

(see next section). A change in the Debye length influences the utilization of the incident radiation (see the "Solar absorption coefficient" section below), but the change in cell performance due to this effect is small.

Maximization of power density yields an optimal dopant concentration for the n-GaAs system of about 9.0×10^{-8} eq/cm³. The donor concentration in the work presented by Heller and Miller (27,28) was 6×10^{16} carriers/cm³ (or 9.96×10^{-8} eq/cm³).

Semiconductor thickness. The effect of semiconductor thickness on the cell performance is presented in Fig. 7 for a characteristic depth of light adsorption of 228.2 Å

Fig. 7. Computed current-potential curves for an n-type GaAs anode with semiconductor thickness as a parameter.

(corresponding to 1.35 Debye lengths). The cell potential increases as the thickness increases from 5 to 13 Debye lengths. The current-potential curve is essentially unchanged for an increase in thickness from 13 to 30 Debye lengths. A very thick semiconductor is expected to decrease the system performance because of resistive losses in the semiconductor. For the system described here, however, the resistance losses should be insignificant, even for 1 mm thick crystals. A semiconductor thickness less than the normal space-charge region is associated with saturation of charge in the semiconductor. All mobile electrons are driven from the semiconductor in response to the negatively charged interface, and a large potential gradient across the semiconductor cannot be sustained. This may be regarded to be a limitation to the flatband potential and, therefore, a limitation to the cell potential.

Solar absorption coefficient.—The characteristic length for absorption of light can be compared to the Debye length by the dimensionless absorption coefficient $m\lambda_{sc}$. The open-circuit cell potential is presented in Fig. 8 as a function of the dimensionless absorption coefficient. A maximum in cell potential is observed in the region where the characteristic length for absorption of light is of the same order as the Debye length. The cell potential is relatively insensitive to the dimensionless absorption coefficient within the range of 0.2 to 3.0. Variation of dimensionless absorption coefficient from 0.04 to 10 (two-and-one-half orders of magnitude) results in a deviation from an average open-circuit cell potential of only 14 mV. The optimal value for the dimensionless absorption coefficient was around 0.425, where the characteristic length for light absorption is 2.4 Debye lengths. The absorption coefficient for single-crystal GaAs, averaged over photons with energy greater than the bandgap energy, is 4.4×10^5 cm⁻¹. This value corresponds to a dimensionless absorption coefficient of 0.743 and to a characteristic absorption depth of 1.35 Debye lengths.

Solar flux.—The amount of light absorbed within the semiconductor has a strong effect on cell performance. As seen in Fig. 9, light scattering or reflective losses can reduce the limiting current from -23.2 mA/cm² under full AM-2 irradiation (modeled here with a single mean absorption coefficient) to -14.0 mA/cm² under 60% AM-2 irradiation. The 40% decrease in limiting current is accom-

Fig. 8. Open-circuit cell potential as a function of dimensionless solar absorption coefficient.

Fig. 9. Computed current-potential curves for an n-type GaAs anode with fractional absorption of incident AM-2 radiation as a parameter.

panied by a 1% decrease in open-circuit cell potential. The amount of light absorbed within the semiconductor is directly related to the generation of the limiting species, holes, and therefore primarily affects the limiting current.

Cell design.—Under electrolyte-side illumination and without interfacial kinetic limitations, electrolyte resistance, and counterelectrode effects, the maximum power efficiency of the cell was calculated to be 15.0%. This is the value that one might observe if the power density is calculated using a potential drop measured between the semiconductor electrode and a reference electrode reversible to the redox reaction and located just outside the diffusion region. The resistance of the electrolyte, mass-transfer and kinetic limitations at the counterelectrode, and the choice of front- or back-illumination will affect this value.

Electrolyte and counterelectrode.—Resistance in the electrolyte and kinetic and mass-transfer effects at the counterelectrode decrease the maximum power-density of the liquid-junction photovoltaic cell. The current-potential curve for a system with no interfacial kinetic limitations (see Fig. 2) is presented in Fig. 10 with electrolyte resistance included. The conductivity of the electrolyte was assumed to be $0.3 \Omega^{-1} \text{ cm}^{-1}$. The cell potential at a given current is reduced by an amount which is proportional to the current density and to the distance L between the counterelectrode and the semiconductor. A 10 cm separation between the counterelectrode and the semiconductor reduces the maximum power efficiency of the cell to 4.0%.

The same base current-potential curve is presented in Fig. 11 and 12 with the effect of kinetic and mass-transfer limitations at the counterelectrode included. The reaction

was assumed to follow the sequence

Fig. 10. Computed current-potential curves for an n-type GaAs anode with the separation between the counterelectrode and the semiconductor as a parameter. Solution resistance has been included.

Under the assumption that the second step is equilibrated, the current density at the counterelectrode can be expressed by

$$i = i_0 \left\{ \left[1 - \frac{i}{i_{4,\text{lim}}} \right] \exp \left[\frac{(1-\beta)F}{RT} \eta_{\text{CE}} \right] - \left[1 + \frac{i}{i_{3,\text{lim}}} \right]^{1/2} \exp \left[-\frac{\beta F}{RT} \eta_{\text{CE}} \right] \right\} \quad [4]$$

where i_0 is the exchange current density associated with the bulk concentrations of reactants

$$i_0 = F k_{\text{a},\text{f}} c_{\text{a},\text{f}} c_{4,\infty}^{\beta} \left[\frac{k_{\text{a},\text{b}} k_{\text{c},\text{b}}^{1/2}}{k_{\text{b},\text{f}}^{1/2}} c_{3,\infty}^{1/2} \right]^{(1-\beta)}$$

$i_{3,\text{lim}}$ is the diffusion-limited current density associated with species Se_2^{2-} , $i_{4,\text{lim}}$ is the diffusion-limited current density associated with species Se^{2-} , and n is equal to one.

The effect of diffusion limitation to currents at the counterelectrode is presented in Fig. 11 with diffusion-limited current density at the counterelectrode as a parameter. Diffusion-limited current densities of 20 mA/cm² for Se_2^{2-} and 80 mA/cm² for Se^{2-} correspond to a Nernst stagnant diffusion layer thickness of about 0.010 cm. An exchange-current density of 100 mA/cm² was assumed. The influence of the exchange current density on the current-potential curve is presented in Fig. 12. Diffusion-limited currents of 20 and 80 mA/cm² were assumed for the Se_2^{2-} and the Se^{2-} species, respectively. Kinetic limitations, either at the counterelectrode or the semiconductor, cause an inflection point in the current-potential curve.

The calculated maximum power efficiency is 11.8% for a cell with a 1.0 cm gap between the semiconductor and the counterelectrode, an exchange current density of 100 mA/cm², and diffusion-limited currents of 20 and 80 mA/cm² at the counterelectrode for the Se_2^{2-} and the Se^{2-} species, respectively. Reduction of illumination due to absorption in the electrolyte and reflection were not included.

Fig. 11. Computed current-potential curves for an n-type GaAs anode with diffusion-limited current density at the counterelectrode as a parameter. Curve a, counterelectrode effects not included; curve b, $i_{lim,3} = 20 \text{ mA/cm}^2$ and $i_{lim,4} = 20 \text{ mA/cm}^2$; curve c, $i_{lim,3} = 10 \text{ mA/cm}^2$ and $i_{lim,4} = 40 \text{ mA/cm}^2$; curve d, $i_{lim,3} = 5 \text{ mA/cm}^2$ and $i_{lim,4} = 20 \text{ mA/cm}^2$.

Front- and back-illumination.—The semiconductor can be illuminated at the semiconductor-electrolyte interface (front illumination) or at the semiconductor-current collector interface (back illumination). The influence of the

Fig. 12. Computed current-potential curves for an n-type GaAs anode with counterelectrode exchange-current density as a parameter. Kinetic and mass-transfer effects at the counterelectrode have been included.

Fig. 13. Computed current-potential curves for an n-type GaAs anode with the direction of illumination (front or back illumination) as a parameter.

direction of illumination is strongly dependent upon the relative rates of recombination in the bulk and at the interfaces involved.

Under the conditions of a negligible surface recombination at the semiconductor-current collector interface and of a small rate of homogeneous recombination as compared to the rate of recombination at the semiconductor-electrolyte interface, back-illumination increases the power output. This effect is illustrated in Fig. 13, where current-potential curves for the case with no interfacial kinetic limitations are presented for the semiconductor under front and back-illumination. The limiting current under back-illumination is -25.6 mA/cm^2 , and the maximum power efficiency is 17.0%. The limiting current under front-illumination is -23.2 mA/cm^2 , and the maximum power efficiency is 15.0%. Generation of electron-hole pairs in regions where recombination is facilitated reduces the power output.

Discussion

Experimental results reported in the literature show the general shape of the current-potential curves presented in this paper. Small scale systems are generally designed with large counterelectrode areas (to minimize any limitation to current flow at the counterelectrode) and a small depth of electrolyte over the semiconductor surface (to minimize losses of illumination by absorption in the electrolyte). Current-potential curves thereby obtained include effects of electrolyte resistance and illumination losses.

Inflection points are observed for many experimental systems, e.g., TiO_2 in 1.0M NaOH (33), TiO_2 in 0.1M Na_2SO_4 at pH less than 10 (adjusted with NaOH and H_2SO_4) (34), $\text{PbFe}_{12}\text{O}_{19}$, $\text{Hg}_2\text{Ta}_2\text{O}_7$, CdFe_2O_4 , and $\text{Pb}_2\text{Ti}_{1.5}\text{W}_{0.5}\text{O}_{6.5}$ in 0.2M NaOH (35), n- and p-type GaP in liquid ammonia (36), p-GaP in 0.5M H_2SO_4 (37), WO_3 in 1M sodium acetate (38), KTaO_3 in 8.6M NaOH (39), CdS in 0.1M NaOH (40), CdS in 1.0M NaI, 1.0M $\text{Na}_2\text{S}_2\text{O}_3$, and 0.1M I_2 (41), and untreated polycrystalline GaAs with a selenium redox couple (8). These inflection points are indicative of kinetic limitations to charge-transfer or to ion-adsorption reactions at the semiconductor-electrolyte interface (as shown by the

parameter variation in Fig. 1 and 2 in the "Interfacial kinetic limitations" section). Other systems, e.g., ruthenium-treated polycrystalline GaAs (8, 42) and single-crystal GaAs (43) in contact with a selenium redox couple, CdS and Bi₂S₃ in contact with a sulfide-polysulfide redox couple (44), CdS in 1M KCl, 0.8M CH₃COOH, and 0.2M CH₃COOH (45), and p-InP in contact with a vanadium redox couple (8), do not exhibit inflection points. The interfacial reactions are equilibrated for these systems.

The results of the mathematical model presented in this paper are compared to experimental results in Fig. 14. The solid line represents the experimental current-potential curve for a ruthenium-treated n-GaAs photoanode in contact with a selenium redox couple (27, 28). The dashed lines are calculated results in which interfacial reactions were assumed to be equilibrated. Both calculated curves include a 7% loss of illumination; the lower curve includes an electrolyte resistance of 3 Ω-cm². The model parameters are presented in Tables I, II, and III. Bulk transport properties were obtained from the literature; values were assumed for properties characteristic of the semiconductor-electrolyte interface. The model agrees with the experimental results near open circuit, but exhibits a sharper limiting current plateau than the experimental results indicate. This discrepancy may be due to convective overpotential losses due to the textured surface of the semiconductor electrode. An increase in the homogeneous recombination rate constants decreases the sharpness of the potential drop near limiting current but also decreases the cell potential.

Some of the model parameters are associated with characteristics of the current-potential curve. In the absence of counterelectrode effects, the magnitude of the limiting current is determined by the intensity of illumination, and the shape of the curve is determined by kinetic parameters. Kinetic limitations to charge-transfer and to ion-adsorption reactions result in an inflection point. Kinetic limitations at the counterelectrode can also cause an inflection point. The magnitude of the open-circuit potential is a function of the equilibrium potential difference between the semiconductor and the solution. Within the model, this parameter is represented by the equilibrium OSS potential. The surface site energy distribution also influences the open-circuit cell potential. These parameters could be varied by selection of different semiconductor-electrolyte combinations. The open-circuit cell potential is also affected by semiconductor properties, such as bandgap energy and absorption coefficient.

Analytic models of the liquid-junction cell are described in Ref. (46). These models can match experimental current-potential curves but show maxima in electron and hole concentrations near the boundary between space-charge and neutral regions. These maxima were

Fig. 14. Comparison of computed current-potential curves (dashed lines) to experimental results (solid line) for an n-type GaAs anode in contact with a selenium redox couple.

not seen in the results of the mathematical model and are probably due to imposition of boundary or matching conditions between those regions.

Conclusions

Kinetic limitations to interfacial charge-transfer and ion-adsorption reactions drastically reduce the power output of the liquid-junction cell. A small interfacial rate constant is compensated by increased potential and concentration driving forces, thus influencing the cell performance.

The cell performance is strongly influenced by bulk-semiconductor and cell-design properties such as the dopant concentration, the semiconductor thickness, and the amount of light adsorbed in the semiconductor. An optimal dopant concentration and semiconductor thickness can be calculated for a given semiconductor system. The resistance of the electrolyte and kinetic and mass-transfer limitations at the counterelectrode influence cell performance and may play an important role in the optimal design of a liquid-junction photovoltaic cell.

Mathematical Modeling of Liquid-Junction Photovoltaic Cells

III. Optimization of Cell Configurations

Mark E. Orazem¹ and John Newman*

Materials Molecular Research Division of Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A one-dimensional mathematical model of the liquid-junction photovoltaic cell was coupled with primary resistance calculations to predict the optimal performance of three cell configurations. Two cells are considered in which the semiconductor is illuminated from the electrolyte side and one in which the semiconductor is illuminated from the current-collector side. An economic analysis is presented based upon these results. The performance of the liquid-junction photovoltaic cell is dependent upon the design, surface area, and placement of the counterelectrode and current collectors.

Most studies of the liquid-junction photovoltaic cell have been oriented toward developing an understanding of the semiconducting electrode which characterizes the cell [see, e.g., Ref. (1-19)]. This work describes the design and optimization of liquid-junction photovoltaic devices. The advantages and problems inherent in the liquid-junction cell are reviewed, and a mathematical model of the liquid-junction cell (20, 21) is used to predict the optimal performance of various cell configurations. An economic analysis is presented based upon these results.

The liquid-junction photovoltaic cell has appeal because, in contrast to solid-state junctions, the junction between electrolyte and semiconductor is formed easily and allows use of polycrystalline semiconductors. The electrochemical nature of the cell allows both production of electricity and generation of chemical products which can be separated, stored, and recombined to recover the stored energy. These features could make the liquid-junction cell an economical alternative to solid-state photovoltaic devices for solar energy conversion.

Liquid-junction cells also have the advantages that are attributed to other photovoltaic devices. Photovoltaic power plants can provide local generation of power on a small scale. The efficiency and cost of solar cells is independent of scale, and overall efficiency is improved by locating the power plant next to the load. Nuclear and fossil-fuel burning plants, in contrast, are economical only if built on a large scale (on the order of 1000 MW) (22).

The design of a liquid-junction photovoltaic cell requires selection of an appropriate semiconductor-

electrolyte combination and design of an efficient cell configuration. The selection of a semiconductor is based upon the bandgap, which provides an upper limit to the conversion efficiency of the device, and the choice of electrolyte is governed by the need to limit corrosion. The optimal design of the liquid-junction photovoltaic cell is aided by use of mathematical models.

Bandgap.—Photovoltaic cells rely on the unique properties of semiconductors to convert incident radiation to electrical current. The semiconductor property of interest is the moderate gap between the valence and the conduction-band energy levels. Incident photons of light with energy greater than or equal to the bandgap energy transfer their energy to valence-band electrons, producing conduction-band electrons and vacancies in the valence band.

An upper limit to the efficiency of photovoltaic devices can be established, based upon the bandgap and the solar spectrum, without consideration of cell configuration. This "ultimate efficiency" is given by (11)

$$\eta_{\text{ult}} = \frac{E_g \int_{E_g}^{\infty} N(E) dE}{\int_0^{\infty} E N(E) dE} \quad [1]$$

where E_g is the semiconductor bandgap energy, E is the photon energy, and $N(E)$ is the number density of incident photons with energy E . The fraction of the power in the solar spectrum that can be converted to electrical power is a function of the bandgap of the semiconductor. Photons with energy less than the bandgap cannot produce electron-hole pairs. Photons with energy greater than the bandgap yield the bandgap energy (23-25).

* Electrochemical Society Active Member.

¹Present address: Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia 22901.

The "ultimate efficiency" of Eq. [1] represents an upper limit to conversion of solar energy (11, 26, 27); factors such as reflection and absorption losses of sunlight, kinetic and mass-transfer limitations, and recombination will reduce the efficiency. These effects are included in the "cell configuration" section. A bandgap between 1.0 and 1.5 eV is generally considered to be appropriate for efficient conversion of solar energy.

Corrosion.—The application of liquid-junction technology to photovoltaic power conversion is limited by problems associated with the semiconductor-electrolyte interface. Primary among these problems is corrosion. Efficient conversion of solar energy requires a bandgap between 1.0 and 1.5 eV and most semiconductors near this bandgap corrode readily under illumination. Semiconductors with large bandgaps (4-5 eV) tend to be more stable, but cannot convert most of the solar spectrum.

Among the approaches taken to solve this problem, the most successful concern the matching of an electrolyte to the semiconductor. The rate of corrosion is reduced if the semiconductor is in equilibrium with the corrosion products. The rate of corrosion can also be reduced by using a redox couple which oxidizes easily. The oxidation of the redox couple $\text{Se}_{r+2-}/\text{Se}_{r2-}$, for example, has been shown to compete successfully with photocorrosion reactions for holes in n-type GaAs electrodes (8, 28).

p-Type semiconductors used as cathodes are more stable than the more common and generally more efficient n-type semiconducting anodes. The inefficiency of p-type photocathodes has been attributed to the presence of surface states near the valence band energy. A stable p-type photocathode has been developed, however, with a solar conversion efficiency of 11.5% (29). Protective films have been proposed to be a solution to electrode corrosion. The electrode, in this case, would be a small bandgap semiconductor covered by a film composed of either a more stable large bandgap semiconductor, a conductive polymer, or a metal. A large Schottky barrier is frequently present at such semiconductor-metal and semiconductor-semiconductor interfaces which blocks the flux of holes from the semiconductor to the electrolyte. In cases where the photocurrent is not blocked, corrosion can take place between the semiconductor and the protective film (17, 30). Menezes *et al.* (31) discuss the difficulties in avoiding absorptive losses in the metal film while maintaining sufficient integrity to serve the semiconductor corrosion protection function. Frese *et al.* (32) have, however, reported a measurable improvement in the stability of GaAs with less than a monolayer gold metal coverage. Thin conductive polypyrrole films appear to be successful in inhibiting corrosion in some electrolytes (33-38). In addition, insulating polymer films deposited on grain boundaries can improve the performance of polycrystalline semiconductors by reducing surface recombination rates (39).

Mathematical model.—Development of a mathematical model constitutes an important step toward design and optimization of the liquid-junction photovoltaic cell. A one-dimensional mathematical model has been developed (20, 21) which treats explicitly the semiconductor, the electrolyte, and the semiconductor-electrolyte interface in terms of potentials and concentrations of charged species. The model incorporates macroscopic transport equations in the bulk of the semiconductor and electrolyte. Homogeneous and heterogeneous recombination of electron-hole pairs is included within the model. Recombination takes place at the semiconductor-electrolyte interface through interfacial sites, which can enhance the recombination rate. Surface sites at the semiconductor-metal interface were not included within the model.

The coupled nonlinear ordinary differential equations of the model were posed in finite-difference form and solved numerically. The mathematical model can be used to gain insight into the operation of cells with semiconducting electrodes, and to optimize their design. The model was used here to calculate the effect of cell design

Table I. Counterelectrode parameters

Diffusion-limited current density	$i_{s,lim}$	20.0 mA/cm ²
	$i_{e,lim}$	80.0 mA/cm ²
Exchange current density	i_0	100.0 mA/cm ²

on the performance of an n-type GaAs semiconducting anode in contact with an 0.8M K_2Se , 0.1M K_2Se_2 , 1.0M KOH electrolytic solution. The choice of this semiconducting electrode system was based upon the work of Heller and associates (8, 40-42). Cell design parameters are presented in Table I, and the parameters used in modeling the liquid-junction cell are presented elsewhere (20, 43).

Cell Configuration

The optimal design of liquid-junction photovoltaic cells shares constraints with solid-state photovoltaic cells (44, 45). Current collectors cast shadows and can reduce the amount of sunlight absorbed in the semiconductor. A constraint unique to the liquid-junction cell is the placement of the counterelectrode relative to the semiconductor-electrolyte interface. Mass-transfer and kinetic limitations at the counterelectrode and resistance of the electrolyte can play important roles in the optimal design of the liquid-junction photovoltaic cell. These considerations are treated qualitatively by Parkinson (46).

Under electrolyte-side illumination and without illumination losses, interfacial kinetic limitations, electrolyte resistance, and counterelectrode limitations, the maximum power efficiency of the cell was calculated (43) to be 15.3%. The corresponding value under back (or current-collector) side illumination was calculated (43) to be 17.2%. These are the values that one might calculate using a potential drop measured between the semiconductor electrode and a reference electrode reversible to the redox reaction and located just outside the diffusion region. The resistance of the electrolyte, illumination losses, and mass-transfer and kinetic limitations at the counterelectrode affect these values and are influenced by cell design. The difference between front and back illumination is due to the assumption that facilitated recombination does not take place at the semiconductor-current collector interface.

The performance of three cell configurations was calculated for operation under AM-2 solar illumination (882 W/m²). The semiconductor was assumed to be in the form of a thin film [see Mitchell for a review of thin-film photovoltaic technologies (47)]. Interfacial kinetic limitations were not included (20, 43). The one-dimensional model of the liquid-junction cell was coupled with the resistance to current flow associated with the two-dimensional systems. Some methods for calculation of this resistance were reviewed by Fleck *et al.* (48).

System 1: wire counterelectrode.—The liquid-junction photovoltaic cell with a wire-grid counterelectrode is presented in Fig. 1a. The cell consists of a semiconductive film supported on a metallic current collector, a wire-grid counterelectrode, and a transparent glass cover plate. The space between the cover plate and the semiconductor is filled with the electrolyte. The glass plate is an essential part of the cell because it keeps the system clean and allows optimal orientation of the cell for collection of sunlight. This cell is designed for conversion of solar energy into electrical energy; no provision is made for separation of chemical products. A two-dimensional representation of the cell is presented in Fig. 1b.

Sunlight absorbed in the semiconductor must pass through the cover plate, past the counterelectrode, and through the electrolyte. Reflection at each of the interfaces (air-glass, glass-electrolyte, and electrolyte-semiconductor), absorption in the glass and electrolyte, and screening by the counterelectrode decrease the amount of light which can be used for generation of electron-hole pairs. Absorption losses in the electrolyte can be limited by maintaining a small gap between the counterelectrode and the semiconductor. A wide spacing

Fig. 1. Design of the liquid-junction photovoltaic cell. System 1: wire counterelectrode.

of counterelectrode elements reduces the screening of the semiconductor but also increases the influence of kinetic and mass-transfer effects at the counterelectrode as well as ohmic drop.

The one-dimensional model of the liquid-junction photovoltaic cell was used with averaged uniform current density and solar flux. The shadow of the counterelectrode was implicitly assumed to be diffuse. Resistive losses in the electrolyte were calculated from a two-dimensional solution of Laplace's equation (49-53). The potential drop in the electrolyte was given by Eq. [14] in Ref. (53). The current density at the counterelectrode was assumed to be uniform and was related to the semiconductor current density by

$$i_{ce} = i_{sc} \left(\frac{L}{\pi D} \right) \quad [2]$$

and the counterelectrode shadow was assumed to reduce the magnitude of incident light by a factor of $(1 - D/L)$. The effective solar flux was therefore given by

$$q_{sc} = q_0 \left(1 - \frac{D}{L} \right) (1 - \rho_{air-glass}) e^{-(m_x)_{glass}} (1 - \rho_{glass-soln}) e^{-(m_x)_{soln}} (1 - \rho_{soln-sc}) \quad [3]$$

where ρ_{j-k} is the reflectance associated with the interface $j - k$ and m is the extinction coefficient for a given phase of depth x .

The design parameter for this cell design is the ratio of the counterelectrode element spacing to the counterelectrode element diameter, L/D . When L/D has a value of one, the semiconductor is completely shaded from illumination; when L/D is very large, counterelectrode limitations dominate.

The power density of the cell with a counterelectrode radius of 0.05 cm is presented in Fig. 2 as a function of current density with L/D as a parameter. The maximum power density is presented in Fig. 3 as a function of L/D . The separation between the cover plate and the counterelectrode was 0.5 cm, and the separation between the semiconductor and the counterelectrode was 0.5 cm. The electrolyte depth was therefore 1.1 cm. The optimal value of L/D is 14, and the maximum power density obtained is 63.5 W/m². The current density under the optimal condition is 11.8 mA/cm² delivered at a cell potential of 538.7 mV. The maximum power efficiency of the wire-counterelectrode cell was 7.2%.

Kinetic limitations at the counterelectrode further reduce this efficiency. An exchange current density of

Fig. 2. Power density as a function of current density for system 1 with a counterelectrode element diameter of 0.10 cm.

Fig. 3. Maximum power density as a function of L/D for system 1 with a counterelectrode element diameter of 0.10 cm.

1 mA/cm² leads to a 5.5% power efficiency at an optimal L/D of 10.

System 2: slotted semiconductor.—The liquid-junction cell configuration with a slotted-semiconductor electrode is presented in Fig. 4. A glass cover plate protects the cell. Sunlight passes through the cover plate and the electrolyte to illuminate the semiconductor surface. Electrical current passes between the semiconductor and the counterelectrode through slots cut in the semiconductor. This configuration has the advantage that no shadows are cast upon the semiconductor; furthermore, reaction products can be separated if a membrane is placed between the semiconductor and the counterelectrode.

The primary current distribution and the resistance of a cell containing a slotted electrode were calculated using numerical methods coupled with the Schwarz-Christoffel transformation (20, 54). The cell resistance is a function of three geometric ratios, chosen to be t/G , h/G , and L/h

Fig. 4. Design of the liquid-junction photovoltaic cell. System 2: slotted semiconductor.

where L is the half-length of the protruding electrode assembly, t is the thickness of the protruding electrode assembly, G is the half-gap between the electrode assemblies, and h is the separation between the electrode and the upper insulating wall. h is also the separation between the counterelectrode and the lower edge of the semiconductor-electrode assembly.

The performance of this cell is a function of four geometric parameters. The distance between the counterelectrode and the semiconductor assembly was chosen to be 0.5 cm, and the semiconductor assembly thickness was assumed to be 0.1 cm. The primary resistance for this system is presented in Fig. 5 as a function of L/D with h/G as a parameter. The maximum power density is presented in Fig. 6 as a function of L/h and h/G as a parameter. L/h was varied by varying the half-length; h/G by varying the half-gap. The maximum power density for this system is obtained with a small gap. For $h/G = 0.5$ ($G = 1$ cm), the maximum power density was 47.8 W/m^2 , and the maximum power efficiency was 5.4%. The current density under maximum power conditions was 15 mA/cm^2 delivered at 477.6 mV. For $h/G = 10$ ($G = 0.05$ cm), the maximum power density was 67.7 W/m^2 , and the maximum power efficiency was 7.7%. At maximum power, the current density 15.2 mA/cm^2 delivered at 534.6 mV.

System 3: back-illuminated semiconductor.—A cell design is presented in Fig. 7, in which the semiconductor is illuminated from the current-collector side. The semiconducting film is deposited on a pane of transparent conducting glass. A current collecting grid is used to offset the low conductivity of the glass. The semiconductor is separated from the counterelectrode by a gap

Fig. 5. Primary cell resistance as a function of L/h for system 2 with h/G as a parameter.

Fig. 6. Maximum power density as a function of L/h for system 2 with h/G as a parameter.

Fig. 7. Design of the liquid-junction photovoltaic cell. System 3: back-illuminated semiconductor.

filled with electrolyte. This design could be used with a membrane within the gap, which would allow separation of reaction products at each of the electrodes.

The potential drop between the semiconductor and the current collecting grid can be obtained through application of the general solution to the resistance of a rectangular conductor with arbitrarily placed electrodes presented by Moulton (55, 56).

The transparent conducting support for the semiconducting film was assumed to be SnO_2 , which is commonly used as a transparent electrode. SnO_2 is a large bandgap semiconductor and is essentially transparent to light with energy below 3.7 eV. The properties of SnO_2 have been reviewed by Jarzebski and Marton (57-59). The conductivity of the transparent material was assumed to be 50 mho/cm, and the total absorption and reflection losses at the air- SnO_2 interface for a 1/8 in. thick plate were assumed to be 8%. The reflectance at the SnO_2 -GaAs interface was assumed to be 5%. The separation between the counterelectrode and the semiconductor was 0.5 cm.

The maximum power density is presented in Fig. 8 as a function of the ratio of the current-collector-element

Fig. 8. Maximum power density as a function of L/D for system 3 with a current-collector element thickness of 0.01 cm.

spacing to the element width L/D . When L/D is equal to one, the semiconductor is completely blocked, and the power density is zero. When L/D is large, the resistance of the SnO_2 becomes important. The optimal value of L/D is around 100; the maximum power density is 118.5 W/m^2 , and the power efficiency is 13.4%. The current density under optimal operating conditions is 21.0 mA/cm^2 delivered at a cell potential of 564.3 mV.

The excellent performance of this cell design as compared to systems 1 and 2 can be misleading. Facilitated recombination at the semiconductor-metal interface was not included in the model. The back-illuminated system does have inherent advantages over front-illuminated cells. Optical losses, for example, can be smaller, and separation of electrochemical products is feasible. The relative rates of electron-hole recombination at the semiconductor-metal and the electrolyte-semiconductor interfaces, however, will influence the relative merit of front and back illumination.

Intensity of Illumination

The intensity of solar illumination varies with location, cloud cover, day of year, and time of day. In addition, mirrors and lenses can be used to concentrate the sunlight and reduce the amount of semiconducting material incorporated into the cell. The prediction of the performance of a given design of the liquid-junction photovoltaic cell must therefore consider the effect of the intensity of illumination.

The maximum power efficiency is presented as a function of illumination intensity in Fig. 9, 10, and 11 for systems 1, 2, and 3, respectively. The cells were designed with the design parameters calculated to be optimal under AM-2 illumination. The power efficiency decreases with increasing illumination due to the influence of electrolyte resistance and kinetic and mass-transfer limitations at the counterelectrode. These phenomena become increasingly important as current densities increase, and mass-transfer limitations at the counterelectrode result in an upper limit for cell currents.

The maximum power efficiency for systems 2 and 3 without counterelectrode limitations is also presented in Fig. 10 and 11. These results are appropriate for cells with porous counterelectrodes. A porous counterelectrode may not be feasible for system 1 because of the need in this system to pass sunlight through the counterelectrode. The efficiency still decreases with illumination intensity due to electrolyte resistance.

The maximum cell current obtained under large magnitudes of illumination depends upon the ratio of the counterelectrode area to the semiconductor area. This ratio must be large for liquid-junction photovoltaic cells designed for large intensities of illumination. Replacement of the flat-plate counterelectrode with a porous electrode (60) can increase the counterelectrode area of systems 2 and 3. Inclusion of a cooling system in the cell design be-

Fig. 9. Maximum power efficiency as a function of the fraction of AM-2 illumination (882 W/m^2) for system 1 with $L/D = 14$.

comes important under these conditions. The electrolyte itself can serve as a heat-exchange medium in photoelectrochemical systems.

Discussion and Economic Analysis

The cells discussed in the previous sections can be divided into two groups, front and back illuminated, within which they can be compared fairly. The comparison of front- and back-illuminated cells depends upon the relative rates of recombination at the semiconductor-metal

Fig. 10. Maximum power efficiency as a function of the fraction of AM-2 illumination (882 W/m^2) for system 2 with $h/G = 10$ and $L/h = 0.5$.

Fig. 11. Maximum power efficiency as a function of the fraction of AM-2 illumination (882 W/m^2) for system 3 with a current-collector half-width of 0.01 cm and with $L/D = 100$.

and electrolyte-semiconductor interfaces, and these rates will differ from one system to another.

The calculated power efficiencies are presented in Table II for the front-illuminated systems. Semiconductor effects, such as recombination, reduce the power efficiency from a value of 37%, based solely upon bandgap, to 15.3%. Reflection losses, with an arbitrarily chosen 8% efficiency of illumination, reduce this value to 12.2%. This value can be compared to the 12% efficiency obtained in the experimental work of Heller and Miller (8, 40, 41). The effect of cell design and illumination losses is to reduce the performance to 7.2% for system 1 and 7.7% for system 2.

The calculated power efficiencies are presented in Table III for the back-illuminated system. Semiconductor effects reduce the power efficiency from a value of 37%, based solely upon bandgap, to 17.2%. Enhanced recombination at the semiconductor-current collector interface was not included in these calculations. The effect of cell design and illumination losses is to reduce the power efficiency to 13.4%.

The calculated performance could be improved by making distances between semiconductor and counter-

Table II. Power efficiency under front illumination

	No illumination losses	Illumination losses*	Experimental results
Optimal bandgap	45	36 (80%)	
GaAs bandgap	37	30 (80%)	
Semiconductor-electrolyte junction	15.3	12.2 (80%)	12.0
Cell design (1)	10.1	7.2 (55.4%)	
Cell design (2)	9.8	7.7 (71.6%)	

* In some cases, the number in parenthesis represents the fraction of AM-2 illumination (above the bandgap) which actually enters the semiconductor, after accounting for reflection, shadowing, and absorption in the intervening phases. In other cases, where detailed calculations were not made, it represents the ratio to column 1 because the nonlinear effect of illumination could not be assessed.

Table III. Power efficiency under back illumination

	No illumination losses	Illumination losses*
Optimal bandgap	45	36 (80%)
GaAs bandgap	37	30 (80%)
Current collector and semiconductor-electrolyte junction	17.2	13.8 (80%)
Cell design (3)	15.4	13.4 (86.5%)

* In some cases, the number in parenthesis represents the fraction of AM-2 illumination (above the bandgap) which actually enters the semiconductor, after accounting for reflection, shadowing, and absorption in the intervening phases. In other cases, where detailed calculations were not made, it represents the ratio to column 1 because the nonlinear effect of illumination could not be assessed.

electrode smaller, reducing the effect of electrolyte resistance. The values chosen for this analysis were based primarily on mechanical considerations. A spacing of 0.5 cm was used between all cell elements. A smaller spacing could result in shorting of the counterelectrode and the semiconductor and/or trapping of gas bubbles. The influence of the counterelectrode could be reduced by increasing the flow rate or degree of mixing near the counterelectrode, thereby increasing the limiting current. Kinetic limitations at the semiconductor-electrolyte interface were not considered here and may greatly reduce the performance of some semiconductor systems.

Current-potential curves are presented in Fig. 12 for the front-illuminated cells. The optimally designed cells of systems 1 and 2 are compared to the cell without interfacial kinetic limitations, counterelectrode limitations, and electrolytic resistance. The cell with a slotted semiconductor has a larger power efficiency than the wire-grid counterelectrode cell and can be designed for separation of chemical products. The analysis of the system designed for separation of chemical products would include the electrical resistance of the membrane.

Fig. 12. Cell potential as a function of current density for (a) a front-illuminated semiconductor without kinetic, electrolyte-resistance, and counterelectrode limitations; (b) system 1 with a counterelectrode element diameter of 0.10 cm and with $L/D = 14$; and (c) system 2 with $h/G = 10$ and $L/h = 0.5$.

Fig. 13. Cell potential as a function of current density for (a) a back-illuminated semiconductor without kinetic, electrolyte-resistance, and counterelectrode limitations; and (b) system 3 with a current-collector element half-thickness of 0.01 cm and with $L/D = 100$.

Current-potential curves are presented in Fig. 13 for the back-illuminated cell. The optimally designed cell of systems 3 is compared to the cell without interfacial kinetic limitations, counterelectrode limitations, and electrolytic resistance. The back-illuminated design is appealing because chemical products can be separated and because of reduced losses of illumination.

The following discussion of cell economics is appropriate for all photovoltaic devices. The allowable capital investment for the cell is given by

$$I = 8.76 P_{in} \eta \Delta c y_e \quad [15]$$

where P_{in} is the annual incident illumination intensity average over 24h in watts per square meter, η is the cell efficiency, Δc is the difference in selling price and operating cost in dollars per kilowatt-hour, and y_e is the break-even point in years. This equation is presented as a nomogram in Fig. 14. The power output of the liquid-junction cell is presented in Fig. 14a as a function of the incident solar illumination with the average efficiency of the device as a parameter. The incident solar illumination is averaged over a 24h period. On this basis, the average insolation of the continental United States is 200-250 W/m^2 (11). Lenses or mirrors could be used to increase the amount of sunlight striking the semiconductor surface. The annual return on investment is presented in Fig. 14b as a function of the power output with power cost as a parameter. The total initial investment is presented in Fig. 14c as a function of the averaged annual investment with cell break-even period as a parameter.

Based upon a 7.7% power efficiency (averaged over 24h), 250 W/m^2 incident illumination (averaged over 24h), 0.05 dollars/kWh profit, and a break-even period of 5 yr, an investment of 42 dollars/ m^2 is justified for the complete cell. Based upon a 13.4% power efficiency (averaged over 24h) an investment of 73 dollars/ m^2 is justified for the complete cell.

An increase of solar illumination by a factor of five while reducing the efficiency to 6% (system 2 with a porous counterelectrode) yields an acceptable initial investment of 164 dollars/ m^2 . An efficiency of 10.4% (sys-

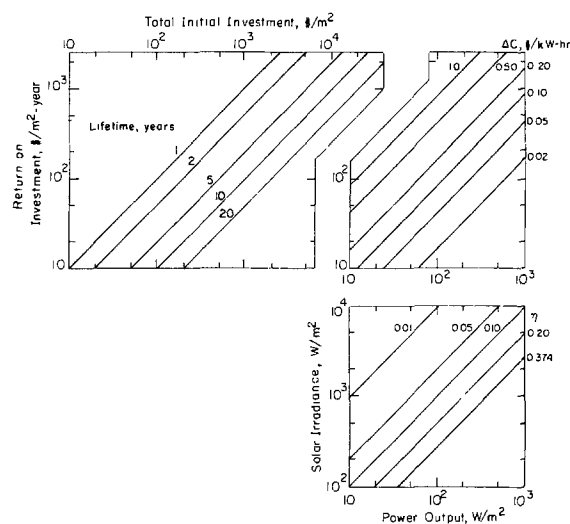

Fig. 14. Economic analysis of the liquid-junction photovoltaic cell. a (bottom): Power output as a function of the incident solar illumination with power efficiency as a parameter. b (top right): Averaged annual return on investment as a function of the power output with power cost as a parameter. c (top left): Total initial investment as a function of averaged annual return on investment with cell lifetime as a parameter.

tem 3 with a porous counterelectrode) yields an acceptable initial investment of 285 dollars/ m^2 . If the mirrors and lenses needed to concentrate sunlight are cheaper than the semiconducting film, the cell may be most economical under high illumination. Maintenance of a high efficiency under high illumination is possible only with the back-illuminated cell of Fig. 7 and the front-illuminated cell of Fig. 4, both coupled with porous counterelectrodes.

The values presented here can be compared to the estimate presented by Weaver *et al.* (61) of 0.34 dollars/peak W. This estimate is based on materials cost and assumes a cell efficiency of 13%. Under AM-2 illumination, this value corresponds to 39 dollars/ m^2 .

Conclusions

The optimization of the liquid-junction photovoltaic cell depends upon the choice of semiconductor, electrolyte, and cell design. The system studied in this work, n-GaAs with a Se_2^{-2}/Se^{-2} redox couple, is close to optimal with respect to utilization of solar irradiation and therefore provides a best-case estimate of liquid-junction cell efficiency. This system, however, exhibits a small rate of corrosion under illumination (a few micrometers per year) (62).

The performance of the liquid-junction photovoltaic cell is strongly dependent upon the design, surface area, and placement of the counterelectrode and current collectors. This system may be economical under concentrated illumination or where the power produced has high value.

Electrochemical Studies of Chromium in Molten LiF-NaF-KF (FLINAK)

Toshinobu Yoko¹ and Ronald A. Bailey

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The mechanism of the reduction of Cr(III) in molten FLINAK was studied using cyclic voltammetry and chronopotentiometry over a temperature range of 612°-983°C and a Cr(III) concentration of 0.07 to 0.13 mol/l. Two reduction and two oxidation steps were observed, but extensive differences in the electrochemistry were seen over the measured temperature range. Cr(III) is reduced to Cr(II) followed by a two-electron reduction of Cr(II) to Cr metal and both reduction processes are quasi-reversible. The product of the first reduction process is soluble at 983°C, but is insoluble at lower temperatures.

Electroplating of refractory metals (IV, V, and VI transition groups) from molten salts has been explored for several years, most notably in the work of Senderoff and Mellors in the 1960's (1-8). More recently, there has been renewed interest in this technique (9, 10). In spite of the earlier work (2, 3, 4, 8), however, it is hard to say that the mechanisms of the electroplating of these refractory metals from molten salts are completely understood, especially for chromium (8, 11-14). The primary objective of this research is to elucidate the mechanisms of the electrode reduction of Cr(III) in molten LiF-NaF-KF eutectic (46.5 mole percent [m/o] LiF, 11.5 m/o NaF, 42.0 m/o KF, [FLINAK]) based on the results of cyclic voltammetry and chronopotentiometry.

Experimental

Each fluoride salt used was reagent grade. After being well mixed and dried in a vacuum oven at 160°C for over a week, the powdered mixture was melted, then filtered in an argon atmosphere to remove black material using a nickel crucible which had many layers of platinum screen welded over a hole in its bottom. The filtered salt was pre-electrolyzed at about 1.5V using a vitreous carbon anode and a stainless steel cathode until the current density of the cathode dropped to around 0.3 mA/cm²; this eliminated metal ion impurities. After pre-electrolysis, the background voltammograms for pure melts were flat between +1.0 and -1.0V. That is, there were no reduction or oxidation waves detectable at the highest sensitivity used over the voltage range scanned in the experiments.

Cr(III) was added either as CrF₃ (Cerac, 99.5%), or as K₃CrF₆, which was prepared by the method of Christensen (15). The K₃CrF₆ was examined using x-ray diffraction analysis, and no other lines were detected. Analysis of one preparation gave 18.5% Cr (18.4% calculated). Both materials gave identical electrochemical behavior.

Figure 1 shows a schematic diagram of the cell assembly used. To minimize the effect of cell resistance between the electrodes, a three-electrode system was employed. For both measurements, a vitreous carbon (Atomergic Chemicals Corporation) auxiliary electrode (1/4 in. diam) and a small Pt plate (1 × 1 cm, area 2 cm²) quasi-reference electrode were used. A very fine Pt microelectrode (0.12 mm diam, 5 mm long) and a Pt cylindrical working electrode (2.3 mm diam, 11.3 mm long) were used as the working electrodes for cyclic voltammetry and chronopotentiometry, respectively.

Although attempts were made to use a boron nitride insulator for the working electrode to obtain a precise area, this failed because of the conductivity of the BN above 600°C, probably as a result of porosity due to leaching of the binder.

The controlled potential cyclic voltammeter used was designed and built in this laboratory. With this instrument, scan rates from 0.01 to 80 V/s are available, and cell

¹Present address: Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie-Ken, 514, Japan.

currents up to 500 mA can be measured. A constant current power supply (HP Model 6212A) was used for chronopotentiometry. Waves were recorded by means of either a Tektronix Type 564 storage oscilloscope or an Omnigraphic Series 2000 X-Y recorder. Data were measured either from the large X-Y recorder chart or from enlarged photographs; transition times were evaluated according to Kuwana's method (16), and those reported for the second wave are measured from the end of the first wave.

All measurements were done in an argon atmosphere.

Results and Discussion

Both cyclic voltammetry and chronopotentiometry were performed over a temperature range of about 600° to 1000°C and a Cr(III) concentration of 0.07-0.13 mol/l. Figure 2 shows typical results taken at a Cr(III) concentration of 0.1 mol/l at temperatures of 983°, 716°, and 612°C. As shown in all of these figures, two reduction and two oxidation steps are evident. The first reduction step and the second oxidation step became indistinct at lower temperatures and lower scan rates, eventually almost merging with the others. This is mainly due to the tendency of the second reduction and first oxidation peaks to shift anodic with decreasing scan rate, decreasing temperature, and increasing concentration of Cr(III).

The shape of the first reduction wave in cyclic voltammetry is not in the form of a peak, but is a simple plateau at lower scan rates and lower temperatures. However, at higher scan rates, and especially at higher temperatures, it develops into a peak. The nature of the first reduction wave will be discussed later in more detail.

In Fig. 3, relationships between $i_0\tau^{1/2}$ and current density i_0 obtained from chronopotentiometry are shown for both reduction steps at different temperatures; $i_0\tau^{1/2}$ varies with current density at higher temperature and lower current density values, especially for the second reduction step, but becomes constant at higher current density. In Fig. 4, transition time constants, $i_0\tau^{1/2}/C$, where C is the concentration of Cr(III), at different temperatures are shown plotted against concentration of Cr(III) for both reduction steps. It is seen from Fig. 4 that the transition time constant of the first reduction step is substantially invariant at each temperature, in spite of some scatter of the data. The data for the second step show more deviation. In view of the high temperatures involved and the consequent possibility of convection, we do not consider that these deviations from constant values are unreasonable or represent real trends. That is, these results do not provide any indication that the electrode reaction of either reduction step has complications related to adsorption or coupled homogeneous chemical reactions (17, 18), although a reversible charge transfer followed by a re-

versible chemical reaction (ErCr) would also give a constant value. The deviation of $i_0\tau^{1/2}$ from the constancy observed at lower current density in Fig. 3 probably also is due to the convection of the bath melt. This is supported by the results from cyclic voltammetry.

In Fig. 5, relationships between peak current, i_p , of the cyclic voltammograms and the square root of the scan rate, $V^{1/2}$, are shown for both reduction steps at different temperatures. The value of i_p for the second wave was ob-

Fig. 3. Plots of $i_0\tau^{1/2}$ vs. i for the first and second reduction steps of Cr(III) in molten FLINAK. Concentration of Cr(III): 0.11 mol l⁻¹. Pt working electrode area: 0.98×10^{-4} m².

Fig. 4. Plots of $i_0\tau^{1/2}/C$ vs. C [concentration of Cr(III)] for the first and second reduction steps.

tained by extrapolating the first wave to provide a new base line; this was relatively straightforward at low scan rates, but involved more uncertainty at high scan rates and high temperatures, where a peak appeared on the first wave. A good linear relationship between i_p and $V^{1/2}$ is observed for the first reduction step, except at higher temperatures and lower scan rates. However, for the second reduction, the deviation from this relationship becomes significant at both lower and higher scan rates. The deviation of i_p at lower scan rates seems to be due to

the same cause as that of $i_0\tau^{1/2}$ at lower current density. The deviation of i_p at higher scan rates might suggest a slower reaction in the second reduction step, but may also reflect more uncertainty in the extrapolated base line for the second wave. The dependence of i_p on the concentration of Cr(III) for both reduction steps is shown in Fig. 6; i_p at each scan rate satisfies a linear function of Cr(III) concentration which goes through the origin over a wide range of concentrations of Cr(III). These observations mean that both reduction processes are diffusion or kinetically controlled, but are not adsorption or catalytic ones as just mentioned above (19). At the same time, this fact shows that there is no significant effect of uncompensated resistance between the electrodes (19).

In Tables I and II, scan rate and concentration dependence of the peak potentials (E_p) and current density and

20.0	-0.234	-0.857	46.0	-0.244	-0.656

concentration dependencies of the quarter-wave potential ($E_{p/4}$) are shown for both reduction steps. As seen from these tables, for both reduction steps, E_p and $E_{p/4}$ shift cathodic with increasing scan rate and current density and anodic with increasing concentration of Cr(III). None of logarithmic plots of cyclic voltammograms and chronopotentiograms such as $\log(i_p/i - 1)$, $\log(i - i_p)$, $\log(\tau^{1/2}/t^{1/2} - 1)$, and $\log(\tau^{1/2} - t^{1/2})$ are linear with potential, and it is clear that neither reduction step can be reversible.

As we cannot estimate from the slopes of such plots how many electrons are involved in each reduction step, we have to resort to another means to determine this. Berzins and Delahay (20) derived the equation which predicts the number of electrons involved in the stepwise diffusion-controlled electrode process

$$\frac{\tau_2}{\tau_1} = 2 \frac{n_2}{n_1} + \left(\frac{n_2}{n_1}\right)^2 \quad [1]$$

where τ_1 and n_1 are the transition time and number of electrons in each step, respectively. As $n_1 + n_2$ equals 3 in our case, the two different values of n_1 and n_2 are considered as follows

$$\text{Case I: if } n_1 = 1 \text{ and } n_2 = 2 \text{ then } \frac{\tau_2}{\tau_1} = 8$$

$$\text{Case II: if } n_1 = 2 \text{ and } n_2 = 1 \text{ then } \frac{\tau_2}{\tau_1} = 1.25$$

The average values measured at different temperatures are listed in Table III. The values at higher temperatures are nearly 8 and correspond to case I. Indeed, this is the expected mode of behavior of Cr(III), and has been observed earlier in this melt (8). However, while the behavior at 983°C is as expected, at lower temperature reduction must occur in a more complicated manner as considered later. Equation [1] applies strictly only to diffusion-controlled electrode processes.

In order to clarify the nature of the first reduction step further, reversal techniques were employed for both chronopotentiometry and cyclic voltammetry. Ratios of the forward to the reverse transition time, τ_f/τ_r , for the first wave measured at various temperatures are listed in Table IV. This value is a very powerful tool for determining whether the product of the electrode reaction is soluble or insoluble (18). At 983°C, the ratio τ_f/τ_r is nearly 3, which means that the reduced product is soluble. However, this value becomes nearly unity below 893°C, so the product of the first reduction step is considered to be insoluble. This result agrees with the result previously mentioned: that is, at lower temperatures the ratio τ_2/τ_1 ,

shown in Table III gets larger than 8 with decreasing temperature, owing to the formation of the insoluble product of the first reduction step. There is less diffusion of the product of step 1 from the electrode surface, therefore leading to a larger amount of material available for the second reduction step. Smith (21) has obtained similar chronopotentiometric behavior in this system.

Cyclic voltammograms of only the first wave were taken at 893° and 983°C. Following Nicholson's semiempirical method (22), ratios of the anodic to the cathodic peak current, i_{ap}/i_{cp} , were obtained and given in Table V with the peak separation potentials. As seen from this table, peak separation gets larger with increasing scan rate, although at lower scan rates it approaches the value which is predicted for the reversible system. The ratio of i_{ap}/i_{cp} increases to more than unity with increasing scan rate, and shows the value of about 1 at lower scan rates. Both quantities show smaller values than expected for reversible behavior at the lowest scan rates examined, especially at 983°C. Peak current ratios of less than 1 can be rationalized on the basis of nonreversible behavior, while the cause of small peak separations may arise from uncertainties in determining peak position as the wave becomes flatter and less well defined at low scan rates.

When the results obtained for the first reduction wave are compared with the diagnostic criteria for typical electrode processes (Table VI), it is seen that the closest agreement is with either a quasi-reversible case, or with an ErCr process (for example, a reaction of Cr(II), perhaps with F⁻, to form a metal cluster compound). Behavior of the i_{ap}/i_{cp} and τ_f/τ_r ratios is not consistent with the latter mechanism, however, so that a quasi-reversible process is considered most probable on the basis of the discrepancy of these ratios.

We cannot overlook the possibility that the Cr(II) might disproportionate by the following reaction

as pointed out by Mellors and Senderoff (8), and Redman (23). We also found that 8 weight percent of CrF₂ added into molten FLINAK for electrolysis did disproportionate and small amounts of Cr metal deposited on the surface of the Ni container after a week's experiment. The electrochemical results for a solution made from CrF₂ were qualitatively the same as when Cr(III) was used. However, it is believed that this disproportionation reaction is slow and is not detected within the range of the scan rates used in our experiments. Since our experiments have been carried out at a relatively high temperature (600°-1000°C) and the effect of convection in the melt becomes significant, reproducible measurements cannot be obtained at lower scan rates (≤ 1.0 V/s) and lower current density where the detection of a catalytic reaction might be feasible.

Table VII. Temperature dependence of the ratio of the transition time of the second reduction to the first oxidation step τ_{2d}/τ_{1r} . Concentration of Cr(III): 0.09 mol l⁻¹

Temp. (°C)	983	893	804	716	612
τ_{2d}/τ_{1r}	0.58	0.66	0.86	0.98	1.1

The ratios of the transition times of the second reduction to the first oxidation step, τ_{2d}/τ_{1r} , obtained at different temperatures are listed in Table VII. At lower temperatures, this ratio is very close to unity, but decreases with increasing temperature. Since the second reduction step has been found to be a quasi-reversible reduction of Cr(II) to Cr metal, this value should be unity. Possibly, alloy formation of deposited Cr metal with the Pt electrode might be responsible for the reduction of the ratio at higher temperatures.

Manning and Dale (11) have carried out voltammetric measurements on Cr(II) (as CrF₂) in LiF-BeF₂-ZrF₄ at 500°C and found that the reduction of Cr(II) to Cr metal in this melt is a quasi-reversible process. Their result reasonably agrees with ours.

The diffusion coefficient, D , of the electroactive species can be estimated from the Sand equation (24)

$$i_0 \tau^{1/2} = \frac{nFC(DD)^{1/2}}{2} \quad [2]$$

where i_0 is the current density, τ the transition time, C the concentration of electroactive species, and the re-

Fig. 7. Plots of $\ln D$ vs. $1/T$ for Cr(III) in molten FLINAK

maining terms have their usual significance. The result is shown plotted as the logarithm against the reciprocal of absolute temperature in Fig. 7; the result is a straight line. The diffusion coefficients of Cr(III) obtained in molten FLINAK seem to be low (983°C: 1.84×10^{-6} , 893°C: 1.19×10^{-6} , 804°C: 0.95×10^{-6} , 716°C: 0.59×10^{-6} , 612°C: 0.36×10^{-6} cm²/s), even allowing for some uncertainty ($\pm \sim 20\%$), mainly in the surface area of the working electrode and the concentration of Cr(III). The activation energy for the diffusion of Cr(III) calculated from the slope in Fig. 7 is 9.5 kcal/mol. Although small diffusion coefficients and large activation energies have been found for some other transition metals in molten FLINAK, the diffusion coefficients are still a factor of 5 or more greater than those obtained here (25, 26). This may suggest the existence of a large and stable complex anion like CrF₆³⁻ in the melt; Cr(III) does exhibit a maximum in ligand field stabilization energy and consequently in complex stability and inertness to ligand exchange.

In summary, Cr(III) in molten FLINAK is reduced in two steps over the temperature range 600°-983°C. The first step is the relatively slow reduction of Cr(III), to give a product which is soluble at 983°C and insoluble, but still electroactive, below 893°C. This step is most probably quasi-reversible, although the behavior of some parameters is not totally straightforward and some complications from chemical reactions are possible. The second step is the reduction of Cr(II) to Cr(O). This is also quasi-reversible, with indications from voltammetric peak currents that it is slow especially at higher temperatures.

In electroplating of Cr from molten FLINAK, there is a correlation between the physical nature of the electrodeposited metal and the changing nature of the electrochemistry with temperature. At low temperatures, the deposit consists of extensive dendrites imbedded in the salts. At high temperatures, dendrite formation is reduced and smoother plates are obtained. The results of the Cr electroplating will be reported separately.

ABSTRACT

Cathode overpotentials for the plating of aluminum from ethylbenzene toluene 1:1, 50 weight percent AlBr_3 electrolytes have been measured as a function of current density, temperature, and specific conductances. The exchange current density (i_0) and the heat of activation (ΔH), were determined to be 10^{-3} A/cm² and 2.6 to 4.5 kcal/mol, respectively. Stoichiometries of plating are proposed, and the observed transfer coefficient of 1.3 is shown to be consistent with monomeric aluminum complexes as the active plating species. Solutions prepared from anhydrous alkyl benzene and AlBr_3 are shown to be insufficiently conductive for aluminum plating. HBr increases the conductivities for optimal plating conditions.

The use of alkylbenzene electrolytes for the electro-deposition of aluminum and aluminum-copper alloys has been extensively studied in our laboratories during the past few years (1-10).

The plating solution consists of a 1:1 mixture (by volume) of ethylbenzene and toluene, containing 50 weight percent (w/o) AlBr_3 . Some gaseous HBr is added to insure a specific conductance of $2.4 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$ and to provide bromide ions to complex the excess of aluminum ions obtained whenever cathode efficiencies are lower than 100%.

From the faradaic cathodic efficiencies obtained in our electroplating work (3, 8), the range of conductivities mentioned above is considered optimal for plating. All our kinetic data were determined, therefore, over this conductivity range.

The object of this paper is to describe and interpret cathode polarization experiments on the above-described system. The basic measurements were cathode overpotential as a function of current density, temperature, and specific conductance. The results are interpreted in terms of the exchange current density (i_0), the heat of activation (ΔH), and the transfer coefficient α . Plating stoichiometries are proposed.

Some aromatic complexes of aluminum.—When aluminum halides are dissolved in aromatic hydrocarbons, dif-

ferent types of complexes are formed, depending on the number and type of constituents used for their formation.

Binary mixture.—Brown and Wallace (11) and Brown and Brady (12) suggested that π complexes form when aluminum bromide is dissolved in an aromatic solvent such as benzene or toluene, *i.e.*

where ArH is an aromatic hydrocarbon and X a halide.

These complexes have a very low degree of dissociation because their saturated solutions have specific conductances of the order of $10^{-9} \Omega^{-1} \text{cm}^{-1}$ when prepared from rigorously dried AlBr_3 and aromatic solvents (13). Lebedev and Korshak (14-16) suggested that the formula for the complex compound of aluminum halides with an organic solvent is

where slv denotes solvent.

Kessler and co-workers (17) considered this scheme to be the most probable and adopted the value of 2 for n .

Ternary mixtures.—Brown and Wallace (18) reported on the basis of vapor pressure compositions-phase studies the formation of σ complexes or salts of carbonium ions (ArH_2^+) and Al_2X_7^- or AlX_4^- when hydrogen bromide and

*Electrochemical Society Active Member.

aluminum bromide react with the aromatic hydrocarbons, *i.e.*

or

However, benzene and toluene could only produce dimeric complexes at room temperature as in Eq. [3], whereas solvent molecules having more or larger lateral chains such as *m*-xylene, and mesitylene, produced more readily the monomeric form of the aluminum complex as in Eq. [4].

The formation of these ions can explain the good conductivity of the solution when the hydrogen halide is added to an electrolyte containing aluminum bromide dissolved in an aromatic solvent.

Electrodeposition of aluminum from aromatic hydrocarbons.—Levinskieve and Simanavicius (19) suggested the following scheme for the electrodeposition of aluminum from a xylene-AlBr₃-HBr system

This is in agreement with the Lebedev and Korshak suggestion (Eq. [2]) and the Brown and Wallace findings (Eq. [4]).

This paper is essentially an investigation into cathode overpotentials at different current densities, temperatures, and specific conductances, with the aim of understanding to a greater extent the aluminum electroplating process.

Experimental

The experimental cell and auxiliary equipment used in the experiments have been described in a previous paper (5). The cell consists essentially of a cylindrical glass body with (i) working electrodes occupying the cross section of the cell at each end and (ii) a reference electrode behind the cathode, penetrating to the front through a 0.8 mm glass-lined hole. The thickness of the glass lining has been measured to be 0.001 cm, and it represents the distance between the capillary tip and the cathode surface. The amount of IR voltage drop for electrolytes having conductivities of 2 and 4 × 10⁻³ Ω⁻¹ cm⁻¹ at current densities of 10 mA cm⁻² are 5 and 2.5 mV, respectively, from the equation

$$E_{\text{IR}} = \frac{i_c \delta}{K} \quad [6]$$

where *i*_c is the cathodic current density, δ the glass wall thickness, and *K* is the specific conductance of the electrolyte (20). However, no corrections were made since the actual values of the *E*_{IR} are likely to be considerably lower due to edge effects which tend to increase the potential around the cathode hole due to field distortion (21, 22) and also because the capillary tip is displaced horizontally from rather than in front of the cathode.

Materials.—Aluminum bromide was prepared from super-pure aluminum (99.99%) and Fisher reagent-grade bromine. Ethylbenzene and toluene were both Fisher reagent-grade products. Preparation of the electrolyte has been described elsewhere (1-4). The conductivity of the plating solution was adjusted by bubbling gaseous HBr through the solution.

Procedure.—One liter of freshly prepared electrolyte, conditioned by 5-8h of aluminum plating at 10 mA/cm² in order to remove traces of more noble metals (impurities), was used in all the experiments. The cathode area was 30 cm². Four anodes of the same surface area were placed around the cathode (3).

The cell was protected from moisture in a closed system. After filling the cell, the first experimental step was to plate aluminum onto the platinum cathode and reference electrode for 30-60 min. Once this was done, the elec-

trodes were connected in their working and measuring circuits and plating was begun under controlled current density conditions. The electrolyte near the cathode was stirred by means of a micromagnetic Teflon-covered bar. The overpotentials were measured by a galvanostatic (point by point) procedure. Plating was carried out for 1 min before the cathode overpotential was measured.

Following each measurement, the current density was increased and the procedure was repeated at the new current density. After each set of experiments at one temperature, the cell was emptied, cleaned, filled with fresh electrolyte (from the 1 liter batch), and the experiments were repeated at a higher temperature. All the overpotentials reported were measured against a reference (reversible) aluminum electrode (RAI) located behind the cathode, containing the same solution under study and at the same temperature (5).

Results and Discussion

The polarization studies showed (Fig. 1) that the cathode overpotential (η) as a function of current density is significantly lowered with increasing specific conductance. However, at specific conductance greater than 8 × 10⁻³ Ω⁻¹ cm⁻¹, under galvanostatic conditions, the aluminum coating on the platinum cathode redissolved. At specific conductances of 1 × 10⁻³ Ω⁻¹ cm⁻¹, however, there was such an ohmic drop across the cell that it was impossible to reach the 15 mA/cm² current density with the potentiostat maximum output of 20V. Furthermore, when the aluminum bromide and the alkylbenzene were rigorously dried by redistillation under nitrogen in a dry box, current densities were not higher than 1 mA/cm² even for potentials up to 20V applied between the anode and the cathode. The specific conductance was of the order of 10⁻⁹ Ω⁻¹ cm⁻¹.

Thus, the polarization study complements that on the beneficial effect of HBr on the faradaic cathode efficiency in the region of conductances from 2 to 4 × 10⁻³ Ω⁻¹ cm⁻¹, as reported in previous papers (3, 8).

The effect of specific conductance on overpotentials.—The observed decrease in cathode overpotential

Fig. 1. Cathode overpotentials vs. current density for ethylbenzene-toluene 1:1 vol:50 w/o AlBr₃-HBr at the specific conductances shown.

with increasing specific conductance (Fig. 1 to 4) can be explained in terms of an increase in the concentration of the active aluminum bearing ions, *i.e.*, π complexes (Eq. [7]). These complexes are formed by the addition of HBr on the alkylbenzene and AlBr_3 electrolyte, as shown in Eq. [7], which is a combination of Eq. [2] and [4]

The Butler-Volmer equation gives

$$i = i_0(e^{\alpha F\eta/RT} - e^{-\alpha F\eta/RT}) \quad [8]$$

where

$$i_0 = \text{FKc} \text{CA}^{n+} e^{-\alpha F\eta/RT} = \text{FKcCD} e^{\alpha F\eta/RT}$$

and i is the net current density, i_0 the exchange current density, Kc the rate constant, CA^{n+} the positive

electroactive ion concentration, CD the reduced ions concentration, α the cathodic transfer coefficient, $\bar{\alpha}$ the anodic transfer coefficient, η the $\Delta\phi - \Delta\phi_e$ overpotential, $\Delta\phi_e$ the equilibrium potential, $\Delta\phi$ the applied potential, and F , R , and T have their usual significance.

Equation [8] predicts that an increase in the concentration species " CA^{n+} ," *i.e.*, the π complex in Eq. [7], causes an increase in current density at any applied cathodic potential, $\Delta\phi$. Similarly, an increase in CA^{n+} means that a lower potential $\Delta\phi$ is required to achieve any desired current density. Since $\eta = \Delta\phi - \Delta\phi_e$, where $\Delta\phi_e$ is the equilibrium rest potential across the electrode interface, the lower required applied potential $\Delta\phi$ (for any current density) is equivalent to the presence of a lower overpotential η at the cathode.

Tafel plots.—Figures 2, 3, and 4 present the (point by point) galvanostatic current overpotential relationship, for the cathodic reduction of aluminum at four different temperatures in alkylbenzene- AlBr_3 -HBr electrolytes,

Fig. 2. Tafel plot of the temperatures shown, for ethylbenzene-toluene 1:1 vol:50 w/o AlBr_3 -HBr at a specific conductance of $2.0 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$.

Fig. 3. Tafel plot at the temperatures shown, for ethylbenzene-toluene 1:1 vol:50 w/o AlBr_3 -HBr at a specific conductance of $3.0 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$.

Fig. 4. Tafel plot at the temperatures shown, for ethylbenzene-toluene 1:1 vol:50 w/o $\text{AlBr}_3\text{-HBr}$ at a specific conductance of $4.0 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$.

having HBr added to yield specific conductances of 2, 3, and $4 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$, respectively.

These plots display a linear relationship between the cathode overpotentials and the log of the current density, above overpotential values of 30 mV. This is to be expected if the Tafel equation

$$\eta = \frac{2.30RT}{\alpha F} \log i_0 - \frac{2.30RT}{\alpha F} \log i_c \quad [9]$$

is obeyed and there is a controlling charge-transfer step.

Exchange current density.—The values of the exchange current density (i_0) were calculated by extrapolating the Tafel line to $\eta = 0$. For the three experimental electrolytes studied (specific conductance 2.0, 3.0, and $4.0 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$) and the data at 40°C (Fig. 2, 3, and 4), the i_0 values were found to be approximately $2 \times 10^{-3} \text{A/cm}^2$ (Table I).

Mechanism of aluminum deposition.—It is difficult to isolate the precise mechanism of aluminum deposition as there are numerous views on the types of complexes which can form between aluminum halides and aromatic hydrocarbons. However, the basic differences between the structures suggested are that, in one case, aluminum bromide exists in a monomeric form exemplified by the complex $(\text{AlBr}_2 \cdot n\text{ArH})^+$ (Eq. [2]) and, in the other, aluminum bromide would combine into a dimeric form, e.g., $(\text{Al}_2\text{Br}_5 \cdot n\text{ArH})^+$ (Eq. [1]).

Brown and Wallace (18) and Choi and Brown (23) found that unbranched or lower branched aromatic solvent molecules such as benzene and toluene produced mostly dimeric complexes (Eq. [3]). Solvent molecules with more or larger lateral chains, such as xylene and mesitylene, or alkyl benzenes having a higher basicity than toluene, generate mainly monomeric complexes, as shown in Eq. [4].

Table I. Calculated kinetic parameters from Tafel lines (40°C)

Specific conductance ($\Omega^{-1} \text{cm}^{-1}$)	i_0 (mA cm^{-2})	Tafel slope (V decade)	Cathodic transfer coefficient* (α)
4.0×10^{-3}	2.2	0.046	1.35
3.0×10^{-3}	2.0	0.048	1.3
2.0×10^{-3}	1.9	0.050	1.25

* Transfer coefficient: $\alpha = 2.3 RT/bF$, where b is Tafel slope.

Ethylbenzene provides highly basic alkylbenzenes such as diethylbenzene, ethylmethylbenzene, etc., through disproportionation reactions (10).

Capuano and Davenport, in an early publication (1), presented photographs showing the effects of several aromatic solvents on the quality of aluminum coatings. In fact, one can notice in Fig. 2 in Ref. (1) that no acceptable aluminum coatings are obtained from unbranched or lower branched solvents such as benzene or toluene. The quality of the aluminum coating improved, however, with xylene, and became excellent with ethylbenzene. This is consistent with the formation of monomeric aluminum complexes in solvent molecules having more or larger lateral chains than benzene and toluene. This supports the hypothesis that the presence of an aluminum complex in its monomeric form is prerequisite for aluminum electrodeposition in alkylbenzene- $\text{AlBr}_3\text{-HBr}$ electrolytes.

The slope of the experimental Tafel lines yields an average cathodic transfer coefficient $\bar{\alpha}$ of 1.3, close to 1.5. Similar values for the anodic transfer coefficient $\bar{\alpha}'$, are then predicted for Eq. [10]

$$\bar{\alpha} + \bar{\alpha}' = \frac{n}{\nu} \quad [10]$$

These results indicate that if n (the total number of electrons transferred in the overall reaction) is equal to 3, i.e., if aluminum is present in a monomeric form, ν (the number of times the rate-determining step takes place for the overall reactions to occur once) equals 1.

Assuming then from the foregoing discussion that an ethylbenzene-toluene- $\text{AlBr}_3\text{-HBr}$ electrolyte produces monomeric aluminum complexes, the following plating reaction is proposed

Considering the fact that the Br^- is not likely to be in a free state, Eq. [11] can be written as

This is in agreement with Brown and Wallace (18) (Eq. [4]), Lebedev and Korshak (14-16) (Eq. [2]), and Levinskieve and Simanavicius (19) (Eq. [5]).

Heat of activation.—An electrochemical Arrhenius plot at some typical electrode overpotentials as derived from

Fig. 5. Current density vs. $1/T$ (where T is the absolute temperature) plot adopted from Fig. 2, in order to determine the heat of activation (ΔH) _{η} at the overpotentials shown.

Fig. 6. Current density vs. $1/T$ (where T is the absolute temperature) plot adopted from Fig. 4, in order to determine the heat of activation (ΔH) _{η} at the overpotentials shown.

Fig. 2 and Fig. 4 is presented in Fig. 5 and Fig. 6. The heat of activation as given by the differential $(\partial \log i/\partial 1/T)_{\eta_0}$ lies between 2.6 and 4.5 kcal, depending on the electrode potential and the specific conductance. The complete results are given in Table II. These results compare well with the values obtained (4 kcal/mol) by Simanavicius *et al.* (24) for the Hurley and Wier (25) electrolyte (aluminum bromide and an ethyl-pyridinium bromide in toluene). It has been generally agreed (26) that the heat of activation in the electrodeposition of metals from aqueous solution is of the order of 10-30 kcal/mol. The values from the present work and values obtained by Simanavicius *et al.* (24) indicate, however, that the activation energies for plating metals from organic electrolytes are almost an order of magnitude less than the heats of activation for plating from aqueous electrolytes.

This result suggests that the bond energy of aluminum bromide in the alkylbenzene complexes is considerably lower than the hydration energy of metal ions in aqueous solutions.

Conclusions

1. A study of cathodic overpotentials of ethylbenzene-toluene $\text{AlBr}_3\text{-HBr}$ electrolyte showed that charge-transfer overpotentials were of the order of 40 mV at current density of 10 mA/cm². The overpotentials decrease with increasing specific conductances and temperature of the electrolyte.

2. Exchange current density (i_0) at specific conductances of $2.4 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$ and a temperature of 40°C are approximately $2 \times 10^{-3} \text{A/cm}^2$, and the heat of activation (ΔH) _{η} varies from 2.6 to 4.5 kcal/mol. The relatively high values of exchange current density and the relatively low value of heat of activation indicate that aluminum is

Table II. Calculated heat of activation for some typical electrode overpotentials at different specific conductances for the temperature range of 300-354 K

Specific conductance ($\Omega^{-1} \text{cm}^{-1}$)	Cathode overpotentials (mV)	Heat of activation (kcal/mol)
2×10^{-3}	30	4.5

released rather easily from its organic complexes to plate on an aluminum cathode.

3. A cathodic transfer coefficient α of 1.3 is consistent with monomeric aluminum complexes being the active species during plating.

4. Solutions prepared from anhydrous alkylbenzene and aluminum bromide are not conductive enough for electroplating aluminum.

HBr is a suitable reagent for adjusting the conductivity of the solution to its optimum operating condition.

Electrochemical Properties of $\text{WO}_3 \cdot x(\text{H}_2\text{O})$

III. Complex Plane Analysis of the Film on SnO_2

Nobuyuki Yoskiike, Masatake Ayusawa, and Sigeo Kondo

Matsushita Electric Industrial Company, Limited, Central Research Laboratory, Moriguchi, Osaka 570, Japan

ABSTRACT

Complex plane analysis of evaporated WO_3 films on SnO_2 coated glass substrate has been performed in propylene carbonate electrolytes as a function of frequency from 100 kHz to 100 mHz at various applied voltages. It has been confirmed that the electron injection process at the SnO_2 electrode/ WO_3 film interface, the electrochemical charge-transfer process in the WO_3 film and a diffusion-controlled process in the bulk are important processes at high ($f > 1$ kHz), medium ($1 \text{ kHz} > f > 3 \text{ Hz}$), and low frequencies ($f < 3 \text{ Hz}$), respectively. The change of electrochromic activity of various $\text{WO}_3 \cdot x(\text{H}_2\text{O})$ films depends mainly on the charge-transfer process in the film; the charge-transfer impedance increases with hydroxylation of WO_3 layer and, furthermore, increases drastically with hydrated crystallization.

WO_3 is one of the most useful materials for electrochromic displays (ECD) (1-6). A model for coloration by Faughnan *et al.* (3) explained reasonably well that double injection of electrons and protons into the film accompanies the formation of tungsten bronze. (The bronze has a stable memory effect and can be switched back into the original colorless state by reversing the current.) Recent studies (7-13) have confirmed that water in the film plays an important role for the coloration and bleaching mechanism.

The states of water in the WO_3 film may be classified into three groups: physisorbed water, chemisorbed water as hydroxylation, and hydrated water having a crystal structure. We (14, 15) have recently confirmed the influence of these three states on the electrochemical properties of evaporated WO_3 films. In particular, we have reported that water adsorbed on the film from ambient air after the ventilation of the vacuum evaporation chamber not only provides a fast electrochromic reaction at first, but also reacts gradually with WO_3 by hydroxylation and/or hydrolysis to shift the potential of the cathodic reaction to negative potentials. Then the hydroxylated film loses the electrochromic coloration density at the same applied voltage as before (14). We have also reported that the formation of tungstate crystals ($\text{WO}_3 \cdot \text{H}_2\text{O}$ and/or $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$) by storing in high humidity air causes remarkable deterioration of the electrochromic activity of the film (15). The relationship between the electrochromic activity and the state of the water in $\text{WO}_3 \cdot x(\text{H}_2\text{O})$ has been clarified, but it is still not clear what kind of processes in the electrochromic reaction are being affected.

The mechanism and the coloration dynamics of the WO_3 film have been roughly clarified by many authors. Faughnan *et al.* (3, 16) measured a $t^{-1/2}$ dependence of current flow during the coloration reaction of the WO_3 film in H_2SO_4 aqueous solutions under low applied voltage and suggested a barrier-limited current of proton transport across the WO_3 /electrolyte interface as controlling. They (17) found $t^{-3/4}$ and $V^{1/2}$ dependence of current flow during the bleaching process under other constant applied voltages and suggested a field-driven space-charge-limited current of proton in those cases.

Mohapatra (18) also reported similar dynamics in the $\text{Li}_x\text{WO}_3/\text{Li}$ system. Green *et al.* (19-20) studied the thermo-

dynamics of the diffusion process with WO_3 /solid electrolyte and WO_3 /liquid electrolyte junctions using the galvanostatic method. However, although complex plane analysis is a most useful method, there are few studies of WO_3 film using this method. Ho *et al.* (21) have reported kinetic data such as chemical diffusion coefficient, partial ion conductivity, and thermodynamic enhancement factor, with $\text{Li}_x\text{WO}_3/\text{LiAsF}_6$ in propylene carbonate/Li system using this method. They suggested that the interfacial charge-transfer reaction at the WO_3 /electrolyte interface is important at short time ($t < 0.5\text{s}$), but at longer times the rate of Li injection is determined by the diffusion kinetics.

This paper describes studies on $\text{WO}_3 \cdot x(\text{H}_2\text{O})$ using complex plane techniques. The relationships between reaction processes and various states of water in $\text{WO}_3 \cdot x(\text{H}_2\text{O})$ are discussed for the actual operating conditions of display devices.

Experimental

Preparation of WO_3 films.— WO_3 films were deposited on SnO_2 -coated glasses ($100 \Omega/\text{cm}^2$) by an electron beam evaporation method. WO_3 targets (99.99%) were supplied by Furuuchi Kagaku Company, Limited. The deposition rate was 4 to 5 Å/s, the deposition angle was varied within 40° with a planetary rotation, and the substrate temperature was usually maintained at 80°C after being kept at 110°C for 5 min. The total gas pressure in the chamber during the evaporation process was controlled by a gas-introduction method at $4\text{-}5 \times 10^{-5}$ torr. Deposited WO_3 films were analyzed by electron diffraction and found to be amorphous. Packing density of the film calculated from film thickness and weight was $5.3\text{-}5.7 \text{ g/cm}^3$. The refractive index deduced from the interference patterns of visible absorption and film thickness was 1.85.

For the purpose of investigating the influence of humidity on the evaporated films, the films were stored in humidity- and temperature-controlled air at different conditions (Nagano Kagakukikai, Model NEW LH-20).

Electrochemical measurements.—Complex plane analyses were made using a pseudo-three-electrode configuration. The working electrode was the WO_3/SnO_2 electrode, in which the WO_3 film thickness and area were 3000Å and 0.3 cm^2 , respectively. In order to avoid interference arising from the SnO_2 /electrolyte interface, the SnO_2 elec-

trode surface was coated by a thin glass-plate insulator exposing only a part of the WO₃ film (0.3 cm²). The counterelectrode was a carbon electrode plate having a large surface area (the specific surface area of the carbon was 220 m²/g). The potential drift of the electrode during the measurements was negligibly small ($\Delta V < 1$ mV), so that the counter and reference electrode leads were combined (hence, pseudo-three electrode). The potential of the counterelectrode was monitored by a saturated calomel electrode (SCE).

The electrolytes were propylene carbonate (PC) solutions containing 0.3M LiClO₄ and 0.03M LiBF₄. PC (Wako Junyaku) was freshly distilled under vacuum. LiClO₄ (purity 99%, Mitsuwa Kagaku) and LiBF₄ (purity > 98%, Morita Kagaku) were used. Ar gas was bubbled before measurements.

Frequency response analysis was performed with the working electrode held at constant voltage by an electrochemical interface (Solartron Model 1186, England). A small alternating signal from a frequency response analyzer (Solartron Model 1170) was then superimposed on the constant voltage.

The amplitude of the signal which was applied to the sample was always 5 mV, and the frequency range covered extended from 100 kHz down to 100 mHz. Output data were the average values of ten sampling times and were plotted through a plotter interface (Solartron Model 1180).

Cyclic voltammetry measurements were performed with a potentiostat (Hokuto Denko, Model HA-301), which was supplied with voltage from a function generator (same company, Model HB-104). The counterelectrode was a Pt plate and the reference a SCE. The electrolyte was the same as the electrolyte used for complex plane measurements.

H₂O content of the electrolytes was checked in each case by an aquacounter (Hiranuma Seisakusho, Model AQ-3B). The concentrations were typically 0.03-0.05M.

Results and Discussions

Complex impedances of the WO₃ (3000Å thick) film on SnO₂ stored in air at 25°C for 1h after the evaporation were measured under various applied voltages, as shown in Fig. 1 and 2.

Figure 1 shows the complex impedance data under conditions of working electrode potentials from +500 to +300 mV vs. SCE, and counterelectrode potential constant at +370 mV vs. SCE. Figure 2 shows the complex impedance data for more negative working electrode potentials between +250 and -200 mV vs. SCE. In Fig. 1 and Fig. 2, the first semicircle was observed from 100 down to 1 kHz. It became small at more negative potentials of the working electrode and too small to be recognized at potentials more negative than +100 mV vs. SCE. The second semicircle was observed clearly from 1 kHz down to 3 Hz at potentials more negative than +400 mV and corresponds to a charge-transfer-controlled process. The second one also became small with more negative potential conditions.

The impedance plots for frequencies lower than 3 Hz approached a line parallel to the imaginary axis and were therefore assigned to finite diffusion control rather than a semi-infinite diffusion-controlled process.

These impedance results can be represented, as a rule, by the circuit of Fig. 3 (21-25). In Fig. 3, R_1 is the uncompensated ohmic resistance of the electrolyte and electrode. C_1 and θ_1 are the capacitance and the resistance associated with the first semicircle, respectively. C_2 and θ_2 are the capacitance and the charge-transfer resistance, respectively, associated with the second semicircle, and Z_w is a complex impedance arising from the diffusion of the electroactive species, associated with the straight line for lower frequencies.

Furthermore, θ_1 can be obtained from the following equation

$$\left(R - R_1 - \frac{\theta_1}{2}\right)^2 + X^2 = \left(\frac{\theta_1}{2}\right)^2 \quad [1]$$

Fig. 1. Complex impedance data of the WO₃ film (3000Å thick, 0.3 cm²) stored in air at 25°C for 1h. I is the first semicircle, and II is the second semicircle. *1 and *2 are 1.1 kHz and 3.5 Hz, respectively.

where R and X are the real and imaginary parts of the complex impedance, respectively.

C_1 can be obtained from the following equation

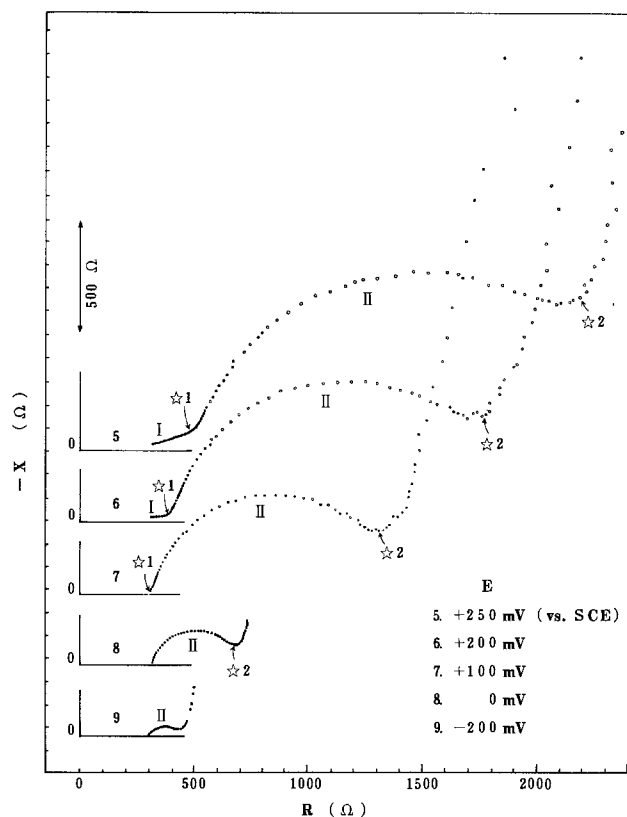

Fig. 2. Complex impedance data of the same sample as shown in Fig. 1.

Fig. 3. Admittance plots for the circuit containing two R-C circuits and a finite diffusion-controlled process.

$$C_1 = \frac{1}{\theta_1 \omega_1} \quad [2]$$

where ω_1 is the radial frequency corresponding to the top of the first semicircle.

θ_2 can be obtained from

$$\left(R - R' - \frac{\theta_2}{2}\right)^2 + X^2 = \left(\frac{\theta_2}{2}\right)^2 \quad [3]$$

where $R' = R_1 + \theta_1$.

C_2 can be obtained from

$$C_2 = \frac{1}{\theta_2 \omega_2} \quad [4]$$

where ω_2 is the radial frequency corresponding to the top of the second semicircle.

The equivalent circuit shown in Fig. 3 is independent of the counterelectrode, because the counterelectrode was a large surface carbon electrode having a large double layer capacity (more than 1 mF). Thus, the complex impedance is determined by the reaction processes on the WO_3 electrode only. R_1 was about 290Ω , and was independent of the electrode potential.

In order to clarify the properties of the two semicircles, complex impedances of various WO_3 films having different thickness (500–5000Å) were measured. R_1 and θ values for each semicircle were calculated using a computer method in which three ideal plots for the semicircle were chosen and Eq. [1] and/or [3] were used. R_1 was $270 \pm 30\Omega$ and was independent of the thickness of the WO_3 films. The θ values for films of various thickness are shown in Fig. 4 and 5 as a function of the WO_3 electrode potential. In Fig. 4, the θ_1 values, corresponding to the first semicircle observed from 100 kHz down to 1 kHz, increase with the potential of the WO_3 electrode. The θ_1 value of 5000Å thickness WO_3 film was not obtained because of unstable plots.

The θ_1 values were independent of the WO_3 film thickness between 500 and 3000Å, so that θ_1 can be assigned to the charge-transfer impedance at the SnO_2 electrode/ WO_3 interface or the WO_3 /electrolyte interface, but not to a bulk property.

We consider the following four points: (i) the coloration of WO_3 is caused by the double injection of electrons from the electrode and cations from the electrolyte (3), and not caused by an electrochemical reaction such as a reaction $\text{W} = 0$ to W-O-H at the WO_3 /electrolyte interface; (ii) the

Fig. 4. Potential dependence of the resistance (θ_1) corresponding to the first semicircle (I). The thickness of the WO_3 films (0.3 cm^2) are 500 (Δ), 1000 (□), and 3000Å (○).

Fig. 5. Potential dependence of the resistance (θ_2) corresponding to the second semicircle (II). The thickness of the WO_3 films (0.3 cm^2) are 500 (Δ), 1000 (□), 3000 (○), and 5000Å (▽).

first semicircle is found at high frequency (1 kHz to 100 kHz); (iii) the interface of the WO_3 /electrolyte is not a flat plane, but a porous xerogel structure (12), so that the interface taking part in the cation injection process will increase with the WO_3 film thickness; and (iv) the small capacitance can exist at the electrode/ WO_3 interface in which WO_3 was evaporated as grains on the electrode surface (25) because of the following two reasons: the energy level of the conduction band of n- SnO_2 does not overlap the level of n- WO_3 , and, strictly speaking, the contact of n- SnO_2 /n- WO_3 may not be an ohmic contact; electron transfer from the SnO_2 electrode to the WO_3 layer may be slightly blocked at grain boundaries of WO_3 (25). There-

fore, it may be reasonable to say that the first semicircle results from a circuit involving the capacitance (C_1) and the resistance (θ_1) corresponding to the electron injection process at the electrode/WO₃ interface.

In Fig. 5, the θ_2 , corresponding to the second semicircle observed from 1 kHz down to 3 Hz, increases with the potential of the WO₃ electrode and increases with film thickness. However, the injection of cations into the WO₃ film would not only occur at the WO₃ surface interface, but also occur at voids in the porous WO₃ film (12). Then the semicircle corresponding to the cation injection process would be dependent on the WO₃ film thickness.

Therefore, θ_2 would be the charge-transfer impedance corresponding to an electrochemical reaction process such as the cation injection.

Various WO₃ · x(H₂O).—We prepared the following four kinds of WO₃ · x(H₂O) films after evaporation on SnO₂ electrodes: (i) as-deposited WO₃ film containing small amount of H₂O; (ii) WO₃ · x(H₂O) film containing much physisorbed water by storing in air at 25°C 50% (relative humidity) for 16h (14); (iii) hydroxylated WO₃ · x(H₂O) film having many OH groups by storing in air at 25°C 50% (RH) for 168h (14); and (iv) hydrated WO₃ · x(H₂O) film having WO₃ · H₂O and/or H₂WO₄ · H₂O crystal structures by storing in air at 40°C 95% (RH) for 24h (15).

Cyclic voltammograms of these WO₃ · x(H₂O) films were measured in PC electrolyte and are shown in Fig. 6. The cathodic current is associated with coloration of the film and the anodic current is associated with bleaching. WO₃ · x(H₂O) films containing much physisorbed water have a fast electrochromism (EC) and both hydroxylated WO₃ · x(H₂O) films and hydrated WO₃ · x(H₂O) films having crystal structures lose EC activity. We earlier discussed these properties in more detail (14, 15).

Complex impedances of these films were measured at various working electrode potentials. Both C_1 and C_2 values were calculated by Eq. [2] or [4] and are shown in Fig. 7. The capacitance of the WO₃ thin film bulk layer (C_2) was several μF , which was about 30 times the magnitude of the capacitance (C_1) of the electrode/WO₃ interface. The θ values of each process were calculated and are shown in Fig. 8 and 9.

Compositions (x) of M_xWO₃ bronze (M: H⁺ or Li⁺) under the various working electrode potentials were calculated from the injected charge and are shown in Fig. 10 as a function of the electrode potential. Both θ_1 and θ_2 are represented as a function of composition (x) in Fig. 11.

From these results, we conclude first concerning the fast electron injection process at the electrode/WO₃ interfaces that (i) the interface of an as-deposited film may be in a nonequilibrium state, thus giving rise to unstable complex impedances; (ii) the impedance decreases to

one-half with an increase of physisorbed water in the WO₃ film and doubles with hydroxylation of the film and is relatively insensitive to hydrated crystallization; (iii) there is a linear relationship between the impedance and the composition, x , of M_xWO₃ bronze; and (iv) the capacitance is about 10⁻⁷ F and not strongly dependent on the condition of water in the WO₃ · x(H₂O).

Second, concerning the charge-transfer process such as the cation injection process in the WO₃ film: (i) the as-deposited film is unstable; (ii) the electrochemical charge

Fig. 9. Potential dependences of θ_2 . Sample numbers represent the same samples shown in Fig. 8.

Fig. 10. Coulometric titration curve for M_xWO_3 . Sample numbers represent the same samples shown in Fig. 8.

transfer impedance in the film is about one order of magnitude larger than the electron injection impedance; and (iii) it decreases to about one-sixth to one-seventh with an increase of physisorbed water and increases about three times with hydroxylation of the film and about ten times with hydration. θ_2 values for four kinds of $WO_3 \cdot x(H_2O)$ films, in case of a composition $x = 0.01$ of M_xWO_3 bronze, are tabulated in Table I.

Conclusion

The coloration reaction process was separated into three processes using complex plane analysis; the electron injection process at the electrode/ WO_3 interface hav-

Table I. θ_2 values in case of a composition $x = 0.01$ of M_xWO_3 bronze

	$WO_3 \cdot x(H_2O)$	θ_2 (Ω)
1	As-deposited film	1.6×10^3
2	Containing physisorbed water	4×10^2
3	Hydroxylated film	9×10^2
4	Hydrated film	4.5×10^3

Fig. 11. Composition dependences of θ_1 and θ_2 . Sample numbers represent the same samples shown in Fig. 8.

ing the double layer capacitance ($10^{-7}F$) ($100 \text{ kHz} > f > 1 \text{ kHz}$), the electrochemical charge transfer through the cation-injection process in the WO_3 film having an impedance one order of magnitude larger than the electron injection impedance ($1 \text{ kHz} > f > 3 \text{ Hz}$), and a slow diffusion-controlled process in the bulk ($f < 3 \text{ Hz}$).

Remarkably, the fast electron injection process at the interface is not influenced by the condition of the water incorporation in the WO_3 films, but the electrochemical charge-transfer process in the WO_3 film clearly is. The electrochemical charge-transfer process in the WO_3 is the most important process in determining EC reaction speed for display devices.

Technical Notes

The Decomposition of Propylene Carbonate in a Lithium/Metal Phthalocyanine Cell

M. Arakawa, J. Yamaki,* and T. Okada

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki-ken, 319-11, Japan

Recently, considerable attention has been focused on batteries composed of lithium anodes, cathodes, and organic electrolytes. This has been particularly true of lithium secondary batteries employing topochemical reactions (1-3).

We have reported on metal phthalocyanine (MPc) as a cathode active material, and its charge and discharge characteristics (4). Gas evolution, however, was observed in lithium batteries using MPc as the cathode active material. Gas evolution from the graphite electrode in lithium batteries was first reported by Dey *et al.* (5). However, the electrochemical characteristics and the gas evolution reaction mechanism were not clarified sufficiently.

Studies of the effect of MPc on electrocatalysis have been widely carried out for O₂ reduction reactions in aqueous electrolytes (6, 7). The decrease of electrocatalytic activity was reported in the order: Fe > Co > Ni > Cu > H₂ (8). This indicates a significant dependence of the central metal on electrocatalytic activity, though its role is not yet sufficiently understood.

In this paper, we report the catalytic effect of MPc on the gas evolution reaction.

Experimental

The experimental setup is schematically shown in Fig. 1. Test cell is set in the vacuum line and evacuated. A constant current discharge and stepwise potentiostatic discharge were then carried out, using a constant current and a constant voltage source (Hokuto Denko Company). The volume of gas evolved during the discharge test was measured using the oil manometer of the vacuum line, and its components were identified with a mass spectrometer.

The test cell was composed of a lithium anode, a cathode, and a reference electrode as shown in Fig. 2. The cathode was made up of MPc (M = H₂, Li₂, Na₂, CrF, Mn, Fe, Co, Cu, GaCl, Ag, Cd) (Eastman Kodak Company), carbon powder (Akzo Corporation, Ketjenblack EC), and polytetrafluoroethylene (PTFE, Daikin Kogyo Company Limited, F103). The mixing ratio of MPc, carbon powder, and PTFE was 49, 48, and 3 weight percent (w/o), respectively. The mixture (0.05g) was pressed at 30 kg/cm² to form a 13 mm diam disk. The lithium electrode was 13

mm diam and 0.24 mm thick disk. Lithium metal was also used for the reference electrode. Propylene carbonate (PC) containing 1M LiClO₄ (Tomiyama Pure Chemical Industries Limited) was used as the organic electrolyte. Water content was less than 20 ppm. All test cells were constructed in a dry box filled with dry argon gas.

Results and Discussion

Discharge tests were carried out galvanostatically at 3 mA for cathodes containing several kinds of MPc. Gas evolution volume during discharge down to 0.5V is summarized in Table I. A typical gas evolution curve is shown in

Fig. 1. Block diagram of gas evolution measurement system

Fig. 2. Cell for gas evolution measurement.

Fig. 3. A typical gas evolution characteristic in Li/MPc cell. M = Fe, 3 mA constant current discharge.

Fig. 4. Dependence of gas evolution rate on discharge voltage in Li/FePc cell with 1M LiClO₄/PC. (1): 0.2V stepwise discharge. (2): 0.1V stepwise discharge. (3): 0.05V stepwise discharge.

Fig. 3. The principal component of the evolved gas was identified as propylene from mass peaks ($m/e = 39, 41,$ and 42). In the cells containing FePc, CoPc, or MnPc, the evolved gas volume was very large. The effect of carbon on gas evolution cannot be neglected in the low voltage region. However, under the conditions reported here, the contribution from the carbon is estimated from the blank test to be less than 0.30 ml. A detailed study of the effect of carbon is now being carried out.

Table I. Gas evolution characteristics of various MPc's

MPc	Gas volume (V _g)* (ml)	Ratio (R)** (%)	Discharge capacity (Q _d) (mA·h)	Net capacity (mA·h)
H ₂ Pc	0.19	5.05	9.0	8.55
Na ₂ Pc	0.08	4.25	4.5	4.31
Li ₂ Pc	0.02	0.90	5.3	5.25
CrFPc	0.58	15.88	8.7	7.31
MnPc	1.27	24.70	11.1	8.36
FePc	3.15	55.42	13.6	6.06

CdPc	0.04	0.89	5.3	5.25

* V_g is converted into the volume at 0°C, 1 atm.

** R is derived from Eq. [3].

A lithium cell containing FePc (Li/FePc) was employed to investigate the gas evolution reaction more closely. Stepwise potentiostatic discharge (0.05, 0.1, and 0.2V, respectively) was carried out at intervals of 30 min. The results are shown in Fig. 4. A simple relation was not observed between the gas evolution rate and discharge voltage. The rate varied according to the changes in the constant voltage step width. Namely, the gas evolution rate depends on not only the cathode voltage, but also the discharge condition. This indicates the electrochemical charge transfer process is not the rate-determining step for the gas evolution reaction.

This view is supported by the results of discharge tests performed galvanostatically at 1, 3, and 6 mA for Li/FePc cells. The evolved gas volume was plotted against discharge capacity (Fig. 5). The gas volume was proportional to the discharge capacity and independent of discharge current. This indicates that the rate-determining step of the gas evolution reaction is a reaction product formation process. The electrochemical reaction product (FePcLi_r) from FePc and Li⁺ may react chemically with PC and produce gas (Eq. [1] and [2])

This was confirmed by adding PC to the FePcLi_r, which was formed by the reaction of FePc with n-butyl lithium.

Fig. 5. Dependence of evolved gas volume on discharge capacity. □: 1 mA constant current discharge (CCD). ○: 3 mA CCD. △: 6 mA CCD.

Fig. 6. Gas evolution ratio (R) derived from Eq. [3] plotted against the first oxidation potential of MPc taken from Ref. (9).

PC was added, and it immediately reacted to generate propylene gas.

Based on these results, the activity of MPcLi_x was estimated using the ratio (R) given by Eq. [3]. R means the ratio of the quantity of electricity for gas evolution to discharge capacity

$$R = \frac{2 \times 26.8 V_g / 22.4}{Q_d} \quad [3]$$

where V_g and Q_d represent gas volume and discharge-capacity, respectively. The ratios for several MPc are shown in Table I. Remarkable activity is observed for FePc and CoPc.

Gas evolution ratios (R) were plotted against the first oxidation potentials of MPc (Fig. 6). The data reported by Manassen and Bar-Ilan were used for first oxidation po-

tential values of the various MPc's (9). The relation shows that group VIII central metal MPc's have higher gas evolution activity than the other group. However, the reason for this activity difference has not been investigated in this work. Within the same group, the gas evolution activity increased with a decrease of oxidation potential. This may indicate that the order of the first oxidation potential of MPcLi_x is similar to that of MPc, and that the reactivity of reaction represented by Eq. [2] depends on the first oxidation potential of MPcLi_x ; that is, the reaction (Eq. [2]) proceeds more easily when the charge transfer from MPcLi_x to PC occurs more easily.

Conclusion

Gas evolution from the phthalocyanine electrode in lithium batteries was observed. During the discharge tests, the evolved gas volume was proportional to the discharge capacity. The principle component of the gas was identified as propylene. The activity of MPc was estimated based on discharge capacity. The activity decreased in the order of $\text{FePc} > \text{CoPc} > \text{MnPc} > \text{NiPc} > \text{CrPc} > \text{AgPc}$. H_2Pc , Li_2Pc , Na_2Pc , GaClPc , and CdPc did not have much activity. Propylene gas is probably generated by the chemical reaction between PC and the discharge product of phthalocyanine.

Electronic Conductivity Decrease in Porous NiO Cathodes during Operation in Molten Carbonate Fuel Cells

Charles E. Baumgartner*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

The electronic conductivity of nascent and doped NiO has been extensively examined over the past several decades (1-16). Stoichiometric NiO is an insulator at room temperature with a specific resistivity of $\sim 10^{13} \Omega \text{ cm}$ (1, 5). The introduction of monovalent ions, such as lithium, into the NiO lattice on Ni lattice sites can decrease the room temperature resistivity by as much as 13 orders of magnitude. This pronounced effect was first explained by Verwey *et al.* (1-3), who postulated that coincident with the incorporation of each Li^+ ion was the formation of a trivalent nickel ion (Ni^{3+}) located on a Ni^{2+} lattice site, thereby reserving the overall crystal charge neutrality. The observed conductivity enhancement results from the mixed valency of nickel atoms located on equivalent, adjacent lattice sites. Following this mechanism, it was postulated, and later proven by Verwey (3), that doping NiO with equimolar concentrations of both a monovalent and a foreign trivalent species would yield an electronic con-

* Electrochemical Society Active Member.

ductivity resembling undoped NiO. This result has been subsequently demonstrated by other authors (6, 15) and is, in part, responsible for the differences in absolute Li-doped NiO conductivity values found in the literature. A recent review by Jarzebski (17) historically details the published NiO electronic conductivity data.

A state-of-the-art molten carbonate fuel cell (MCFC) utilizes a porous Li-doped NiO cathode. The structure is typically prepared by the oxidation of a porous nickel plaque *in situ* to the fuel cell cathode compartment, the lithium dopant originating from the $\text{Li}_2\text{CO}_3 \cdot \text{K}_2\text{CO}_3$ electrolyte. The resulting porous structure, containing an equilibrium Li concentration of approximately 0.02 cation fraction, possesses a 923 K (MCFC operating temperature) specific conductivity of $\sim 2 (\Omega \text{ cm})^{-1}$. In most present fuel cell designs, the cathode is in intimate contact with a ribbed stainless steel current collector which, during cell operation, oxidizes to form a scale containing predominantly Fe_2O_3 , LiFeO_2 , Li_2CrO_4 , and K_2CrO_4 . The chromates

are highly soluble in the molten alkali carbonate electrolyte and therefore dissolve from the cathode/current collector interface to leave behind a predominately iron oxide scale. The incorporation of either Fe^{+3} or Cr^{+3} into the NiO structure, from either the current collector or its dissolved corrosion products, would be expected to significantly decrease the cathode's electronic conductivity and thereby increase, with time, the voltage drop associated with cell operation.

This communication quantifies the specific conductivity penalty associated with Fe^{+3} addition to 0.02 cation fraction Li-doped NiO samples (i.e., $\text{Li}_{0.02}\text{Fe}_x\text{Ni}_{0.98-x}\text{O}$) and estimates this mechanism's impact on MCFC performance from Fe and Cr analysis of post-cell-tested NiO cathodes.

Experimental

Fe_2O_3 -doped $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$ powders were prepared by the thermal decomposition (823 K) of reagent-grade $\text{FeOH}(\text{C}_2\text{H}_3\text{O}_2)_2$, $\text{Li}(\text{C}_2\text{H}_3\text{O}_2) \cdot \text{H}_2\text{O}$, and NiCO_3 powders which were previously well mixed in an acetone/acetic acid vehicle. Following decomposition, samples were air fired for 10h at 1023 K and washed in dilute acetic acid to remove nonincorporated Li salts. Elemental analysis was performed by atomic absorption spectroscopy, and the Ni^{+3} content obtained independently using the method described by Goodenough *et al.* (18).

Electronic conductivity measurements were made using a standard four-probe, ac impedance technique on pressed, sintered pellets using the apparatus diagrammed in Fig. 1. The pellets, 1.25 cm diam \times \sim 0.6 cm thick, were prepared by pressing the powders at \sim 120 MPa and sintering under a blanket of powder of the same composition in air at 1325 K for 1h. Chemical analysis showed the pellets' composition to be unchanged by sintering. Following sintering, the faces of the pellets were polished smooth, sputtered with \sim 1 μm gold, and two gold wires were attached to each face using silver paint (du Pont conductor composition 4922). The samples, supported using alumina holders (not shown in Fig. 1) and contained within an alumina tube furnace under a 30% CO_2 /air atmosphere, were heated to 823 K overnight to cure the silver paint. Sample conductivities were obtained as a function of signal frequency (50-20,000 Hz) during both heating (823-1123 K) and cooling (1123 K to ambient) cycles using a PAR 5204 Lock-In Analyzer coupled to a PAR 371 Signal Source (Princeton Applied Research, Princeton, New Jersey).

Fig. 1. Four-probe ac impedance measurement apparatus

Post-cell-tested NiO cathodes were obtained from MCFC's operated at 923 K for times between 50-10,080 h.¹ All cells were assembled using a Ni (10 weight percent [w/o] Cr) anode, a hot-pressed $\text{LiAlO}_2/\text{Li}_2\text{CO}_3/\text{K}_2\text{CO}_3$ electrolyte structure, and a porous nickel cathode. The cathode oxidized during heat-up to the 923 K cell operating temperature to form a porous NiO structure; lithium incorporated into the NiO lattice from the Li_2CO_3 containing electrolyte gave a final cathode composition of 0.02 ± 0.002 cation fraction Li (i.e., $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$). Cathode current collectors were fabricated using 316 stainless steel in all cases.

Cathodes, obtained following cell testing, were thoroughly freed of $\text{Li}_2\text{CO}_3 + \text{K}_2\text{CO}_3$ electrolyte by washing with 50% aqueous acetic acid under a vacuum of $\sim 10^{-2}$ torr. The cathodes were then sectioned according to their structural location within the cell and analyzed for Fe and Cr by Auger electron spectroscopy (Physical Electronics Industries Model 548 ESCA/Auger spectrometer).

Results and Discussion

The composition of prepared Fe^{+3} -doped $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$ samples (i.e., $\text{Li}_{0.02}\text{Fe}_x\text{Ni}_{0.98-x}\text{O}$) are given in Table I. Total Fe, Ni, and Li concentrations were obtained by atomic absorption spectroscopy, and the Ni^{+3} content obtained titrimetrically using the method of Goodenough *et al.* (18). Lithium concentrations were maintained at 0.02 cation fraction while iron was varied between 0.00 and 0.02 cation fraction. Samples prepared with Fe concentrations exceeding \sim 0.015 cation fraction possessed a Ni^{+3} concentration below the quantitative detection limit; however, it is apparent from the results presented in the table that Fe enters the NiO lattice as Fe^{+3} , thereby quantitatively reducing the Ni^{+3} concentration. This is in agreement with Verwey and others (1, 3, 12, 15).

The specific conductivity measured at 1 kHz as a function of temperature for the various samples is shown in Fig. 2. Frequencies between 50 and 20,000 Hz were scanned at each temperature with less than 2% frequency dependence observed, confirming that the measured values were indeed the samples' bulk conductivity. The measured 923 K specific conductivity at 1 kHz decreased from 33.0 to 3.5×10^{-2} ($\Omega \text{ cm}$)⁻¹ as the Fe^{+3} concentration increased from 0.00 to 0.02 cation fraction. In addition to a decrease in the magnitude of the conductivity, Fe^{+3} addition also resulted in changes to both the nature and the slope of the conductivity/temperature relationship. Prior to Fe^{+3} addition, two activation energies are apparent, with the transition from one to the other occurring at \sim 625 K. Activation energies of 0.68 and 3.9 kcal/mol obtained at temperatures above and below the transition temperature, respectively, are in reasonable agreement with Nowotny and Wagner's results (15) of 1.56 and 5.4 kcal/mol obtained for a 0.008 cation fraction Li-doped NiO sample.

It is evident from the data presented above that the incorporation of current collector corrosion products (e.g., Fe^{+3} , Cr^{+3}) into the lattice of a Li-doped NiO cathode would impact significantly on fuel cell performance. The measured porous cathode specific conductivity of $2(\Omega \text{ cm})^{-1}$ presently leads to a one-dimensional IR loss at a

¹The 10,080h sample was supplied by the Institute of Gas Technology, Chicago, Illinois.

Fig. 2. Temperature dependence of specific conductivity for various compositions of Fe^{3+} , doped $\text{Li}_{0.02}\text{Ni}_{0.98-x}\text{O}$.

current density of 160 mA/cm^2 of about 3 mV for the 0.038 cm thick cathode. Conductivity decreases, as determined above for samples doped with 0.02 cation fraction Fe^{3+} , would increase this resistive drop by almost three orders of magnitude if the dopant were uniformly distributed throughout the structure. Both the iron and chromium content of porous NiO cathodes obtained from MCFC's were analyzed via Auger electron spectroscopy (AES) following alkali carbonate removal from the cathode structure by acetic acid washings. Chromates, present in the electrolyte by dissolution of Li_2CrO_4 and K_2CrO_4 corrosion products, are also entirely removed from the porous structure during this washing. Following washing, the cathodes were sectioned into four distinct areas according to their location within the cell. These areas were: region 1, in direct contact with the stainless steel current collector; region 2, adjacent to region 1, in contact with the open gas passage; region 3, located within the body of the cathode; and region 4, in contact with the electrolyte structure.

Nine cathodes were analyzed, encompassing cells operated between 50 and $10,080 \text{ h}$. All samples showed similar results in that all regions in direct contact with the current collector (region 1) contained iron within the NiO lattice. No iron was found in regions 2, 3, or 4, and no chromium was observed in any specimen. Chromates were, however, present in the electrolyte of several samples, as noted by the yellow color of the acetic acid wash solutions. Figure 3 displays a typical AES result, Fig. 3A showing the spectrum obtained on region 1 of a cathode on test for 2485 h , and Fig. 3B showing the spectrum obtained from region 2 of the same sample. The two spectra are virtually identical with the exception of the iron peak in area 3A. From this spectrum, an iron concentration of between 0.03 and 0.04 cation fraction was estimated; such a concentration is more than sufficient to neutralize the conductivity gain associated with the 0.02 cation fraction Li incorporation. No correlation was found between the observed iron level and the length of cell test.

The cathode AES results, coupled with the previous conductivity determinations, would lead to the prediction that a fairly resistive interface could exist between the cathode and current collector in operating MCFC's. The thickness of this resistive layer was determined for several cathodes from cells operated for various lengths of time by repetitive Auger analysis following argon ion etching. The results obtained on cathodes from cells

Fig. 3. Auger electron spectra of Li-doped NiO cathode from MCFC operated 2485 h . Region 1 was in contact with stainless steel current collector: region 2 was the adjacent location in contact with open gas channel.

tested for 515 , 2485 , and $10,080 \text{ h}$ are shown in Fig. 4. All samples possessed initial Fe levels similar to that shown in Fig. 3, and the depth profiles are therefore plotted on a relative ordinate. Whereas the absolute Fe level found at the NiO surface could not be correlated with the duration of cell test, longer cell tests did show a greater Fe penetration depth. However, even after $10,080 \text{ h}$ on test, iron has penetrated only superficially into the NiO grains, diffusing to a depth of $\sim 10 \text{ nm}$. Therefore, even though Fe^{3+} or Cr^{3+} incorporation into a $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$ MCFC cathode

Fig. 4. Fe penetration profiles into the NiO lattice obtained by AES with Ar^+ milling. All samples were cathode regions in direct contact with the stainless steel current collectors.

could dramatically reduce fuel cell performance by decreasing cathode conductivity, such a mechanism apparently plays an insignificant role as neither impurity readily enters the Li-doped NiO cathode structure under experimental fuel cell operating conditions.

Conclusions

The 923 K specific electronic conductivity of 0.02 cation fraction Li-doped NiO ($\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$) was shown to decrease from 33.0 to $3.5 \times 10^{-2} (\Omega \text{ cm})^{-1}$ upon the addition of an equivalent doping level of Fe^{+3} . However, the impact of this conductivity degradation mechanism on the performance of MCFC's containing $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$ cathodes was shown to be insignificant from iron and chromium analyses of post-tested cathodes. Although appreciable iron impurity levels were found within the NiO lattice in regions where the cathode contacted the stainless steel current collector, iron penetration into the grains was restricted to a distance of only 10 nm in 10,080h. The results indicate that impurity diffusion into the cathode should have little or no impact on fuel cell performance.

Improved H_3PO_4 Corrosion Resistance of Graphite/Phenolic Composites Suitable for 190°C Hydrogen/Air Fuel Cells

J. T. Hoggins and M. L. Deviney

Ashland Chemical Company, Ventures Research Division, Dublin, Ohio 43017

Electrocatalyst life, bipolar plate chemical resistance to hot H_3PO_4 , and bipolar plate mechanical strength and dimensional stability have been identified as the major obstacles to the long-term service life of the hydrogen-air fuel cell (1-3). Composite bipolar plates prepared by molding graphite powder with phenol-formaldehyde resin binder have been studied by the Army and its contractors (4-6).

In an earlier Ashland investigation (7) concerned with fabrication of improved bipolar plates, two phenolic resins, Arofene® 877LF (Ashland Chemical Company) and A-33 (an experimental styrenated resin), were shown to exhibit good corrosion resistance to hot H_3PO_4 . A near optimum graphite powder loading for the composite was established along with a high density blend composition. In addition, an improved two-step molding technique was developed. The purpose of the present study was to further investigate the fabrication processes for the resin/graphite composite bipolar plates. As part of this investigation, we examined methods of treating bipolar plates so that essentially all etchable substances and possible poisons could be removed prior to fuel cell operation.

It was suspected that corrosion products from the phenolic resin could leach from the acid reservoir in the bipolar plate and be deposited on the catalyst. These could block the active sites, thus poisoning the catalyst.

Experimental

The initial experimental program consisted of monitoring the corrosion of test composite coupons fabricated

from C^{14} labeled resins and the graphite powder mixture. This was done by liquid scintillation counting of solution extracts from composite plates immersed in hot H_3PO_4 . The radiochemical procedure for monitoring corrosion offered two advantages. First, different positions of the resin molecular structure could be labeled; thus, the point of attack could be determined. Second, by monitoring the concentration of resin products in acid, problems in measuring accurate weight losses in these graphite composites were avoided.

Later in the program, an alternative method to monitor corrosion was developed to eliminate the costly and time consuming step of radio-labeled resin synthesis. It was observed that the color of the acid samples corresponded well with the concentration of resin in the acid. Therefore, optical (visible) spectrometry was studied as a potential method for measuring the concentration of resin in the acid. The optical spectrometry method was calibrated using the samples from the test with radio-labeled coupons. There was a linear correspondence between optical spectrometric absorption and radiochemically determined concentration. This good agreement allowed the use of commercially available resins in corrosion studies. Another advantage of visible spectrometry over the radio-tracer method is that visible spectrometry takes advantage of the color quenching which must be corrected for in the radiochemical method.

Synthesis of C^{14} labeled Arofene 877LF and A-33 resins.—The methylene "bridging" position was chosen as the C^{14} labeling position because the "bridge" was con-

sidered a likely point of attack (probably leading to polymer chain scission) by hot H₃PO₄.

The laboratory synthesis procedures used were scaled-down versions of commercial Ashland procedures. About 700g of resin was synthesized in each batch. The only significant synthesis modification was the addition of the C¹⁴ labeled formaldehyde earlier, and at a lower temperature, than the main formaldehyde charge. The purpose of this modification was to minimize volatility losses and to insure complete utilization of the C¹⁴ labeled formaldehyde. Radiochemical yields were about 90%. The physical property data on the Arofene 877LF and A-33 resins related to the present study are presented in Table I. The test methods used were all ASTM procedures.

Molding coupons and bipolar plates.—The conditions for fabrication of the coupons were as described in Ref. (7). A vacuum (~10⁻¹ torr) postcuring was applied on some coupons.

Corrosion tests.—These coupons (25 × 75 × 3 mm) were suspended by Teflon (trademark of E. I. du Pont de Nemours and Company) strings into a Teflon cup containing 93.5 ml of (85.6%) H₃PO₄ (Baker Chemical Company). The assembly was placed in an oven at 190°C for extended periods of time (up to 2000h). At various intervals, 0.3 ml of acid was removed for measurement of the concentration of resin dissolved in the acid and was replenished by 0.3 ml of fresh preheated acid.

Counting procedures for corrosion tests.—The 0.3 ml acid sample was diluted 9 to 1 with H₂O. Then 1 ml of diluted etching product was placed in 10 ml dioxane scintillation cocktail (for more concentrated samples, less of the diluted acid was used to reduce color quenching). The dioxane solutions were counted in a Beckman LS-100 liquid scintillation counter. A spiking procedure was used to determine the counting efficiency. This procedure required 50 μl of C¹⁴ radiochemical standard (New England Nuclear lot no. 697-242, containing 4.5 × 10⁶ dpm/ml activity) in each sample cocktail solution. Counting efficiency was calculated by comparison of the spiked solution counts with raw counts from the sample.

Table I. Physical properties of resin

A-33 pilot plant lot 7214	77	264	60	114

* Determined with 10% hexamethylenetetramine added to the resin.

Visible optical spectrometry.—The 0.3 ml samples from the corrosion test were diluted with 9.7 ml of fresh H₃PO₄. A portion of the diluted sample was put in a cuvette and then placed in a Bausch and Lomb Spectrometer Model 100 tuned to 590 nm. This wavelength was determined to be the optimum wavelength by a broad scan of the sample. Fresh acid was used as a reference. The absorbance of the sample was then measured. For calibration, the absorbances were measured on samples of known concentrations. These concentrations were determined from C¹⁴ radiochemical measurements of corrosion extracts.

Results and Discussion

The results for several coupons from the initial tests are shown in Table II. First, it was apparent that some coupons exhibited very good corrosion resistance (less than 0.2% weight loss of the resin), while others, supposedly molded under identical conditions, showed poor corrosion resistance (more than 5% weight loss). Physical examination of the coupons after corrosion tests showed that the more corroded coupons had swelled considerably (up to about 17% increase in thickness). The scatter in

these early results prompted a more thorough investigation into optimizing the curing conditions for the composites and more careful control over the molding and curing processes.

A second observation was that the corrosion process is complete in about 300h, regardless of the amount of total etching. A possible mechanism for this passivation is that H_3PO_4 attacks both low molecular weight resin and resin with a low cross-link density. Apparently, the etching ceases when low molecular weight resin materials are depleted, and only fully cross-linked material remains in the coupon. The total amount leached may be a function of both the total amount of low cross-link density resin and the total surface area in contact with the phosphoric acid. To minimize the exposed surface area, it is necessary for the resin to wet the graphite particles as well as possible. Two methods to achieve better wetting were investigated. The first was through enhanced flow characteristics of the resin, and second involved the use of a wetting agent. Molding techniques were varied to increase the flow during curing, but to no avail (see Table II).

Other possible sources of corrosion products are unreacted phenol and formaldehyde, and impurities such as low molecular weight phenol-formaldehyde reaction species. To minimize these, post curing was done in a vacuum furnace. This vacuum curing treatment resulted in some improvement in corrosion resistance. However, the corrosion of some coupons was unacceptably high: > 2.5% in two cases.

It was apparent from the data that an improvement in resin flow properties during molding (in the early stages of cure where the cross linking degree is low) was very desirable. Resin flow is usually enhanced when the free phenol content of the resin is low. The phenol was removed from the resin by steam stripping as a last step during synthesis. The coupon, M-18, prepared from low phenol resin (Arofene 555) showed good corrosion resistance.

The use of a chemical additive, furfural, to improve particle wetting resin flow during molding was another approach investigated. Initial results indicated much lower corrosion of test coupons in $190^\circ C H_3PO_4$. To check reproducibility, several additional coupons containing this flow enhancing additive were tested, and results were very favorable. Fairly consistent, low (< 0.3% weight loss) results were obtained in most cases. The earlier problems of higher corrosion rates and inconsistent results thus appeared to have been due to insufficient resin flow in the mold before cross linking becomes the dominant factor. Use of the resin formulations with slower cure rate properties and an additive for improved particle wetting and resin flow appear to be the keys to enhanced corrosion resistance for bipolar plates.

The mechanism for passivation is unknown, but, as noted before, essentially all corrosion takes place in the first 300h as shown in Fig. 1. This was also observed in a test where the acid was changed for each sampling (coupon T-22). Therefore, pre-etching the bipolar plate acid reservoir with H_3PO_4 could be beneficial. However, pre-etching with an organic solvent, acetone (note coupon M-30, Table II), was extremely deleterious. The coupon severely cracked and corrosion was very pronounced.

Conclusions

Arofene A-33 and 877LF, when molded and cured using the improved techniques developed in this study, are promising candidates for use in preparing composite (graphite powder/phenolic resin) bipolar plates, which are highly resistant to corrosion by $190^\circ C H_3PO_4$. These results suggest that a hot H_3PO_4 pretreatment of the bipolar plate reservoir area could result in little or no etching by H_3PO_4 in subsequent fuel cell operations. The main features of the modified curing/molding procedure developed (but not fully optimized) here for bipolar plate fabrication are the use of a chemical additive, furfural, molding techniques to improve particle wetting and resin flow properties during cure, and the employment of an

Fig. 1. w/o Resin leach from typical test coupons vs. time in H_3PO_4 at $190^\circ C$. +: Coupon T-16 (see Table II), coupon L-7. ∇: Coupon L-9. ∇: Coupon M-4. o: Coupon T-59. x: Coupon T-22.

extended (20h) vacuum oven postcure of the plates. Improved particle wetting and resin flow during molding can lead to a stronger, less permeable composite. Therefore, it may be possible to lower the bipolar plate resin content below 25% (the amount used in this study). This could result in greater electrical conductivity for the bipolar plate, without introducing increased plate porosity (which would lead to increased H_2 permeability and greater susceptibility to H_3PO_4 attack). This would require verification.

Steam stripping of the phenolic resin to remove excess phenol and reaction by-products may be a useful technique for improving test coupon resistance to hot H_3PO_4 . This approach is suggested by the limited results obtained here, but considerably more work is needed for verification.

Acknowledgments

The authors wish to express their gratitude to several persons whose assistance contributed greatly to the success of this project: Corbett L. Taylor, for performing the majority of the experimental work, particularly in the radiochemical analysis and resin curing areas; G. Fred Watts, for his expert counseling services in phenolic resins chemistry area; Alan H. Boyer, who carried out most of the synthesis of radio-labeled resins; and John E. Martin, who provided important counsel concerning experimental techniques developed during their previous related fuel cell contract.

Adsorption of Hydroxide and Sulfide Ions on Single-Crystal n-CdSe Electrodes

K. W. Frese, Jr.* and D. G. Canfield

SRI International, Menlo Park, California 94025

ABSTRACT

Flatband potentials were determined for n-CdSe (11 $\bar{2}$ 0) electrodes as a function of OH⁻ and SH⁻ concentrations. Surface coverage was calculated from the observed flatband potential shift. The Frumkin isotherm was applied to the data, and thermodynamic parameters were determined. The standard free energies of adsorption for OH⁻ and S⁻ were found to be -2.3 and -6.9 kcal/mol, respectively. At high SH⁻ concentrations, there was evidence for a decrease in the repulsive interactions of the S⁻ and OH⁻ ions.

The n-CdSe/sulfide electrolyte redox system has been studied extensively in relation to solar-to-electrical energy conversion devices. Although it is known that this system possesses a high degree of stability with respect to photoanodic corrosion, the details of the corrosion-redox competition processes are not completely understood.

An important detail of the electron-transfer process in this system is surface adsorption and dissolution of sulfide and sulfur species, respectively. We have begun a study of the adsorption properties of the CdSe/sulfide electrolyte system. Because the alkaline polysulfide electrolyte can be complicated by different polysulfide species with perhaps different adsorption characteristics, we thought it useful to first study the adsorption process under simpler conditions. These conditions obtain in NaOH/Na₂SO₄ electrolytes and in NaOH/Na₂S electrolytes without dissolved sulfur. In this report, we focus on measurements of flatband potentials at room temperature in the dark. A distinction has to be made between measurements in the dark and under illumination. In the former case, the corrosion of the electrode and thus changes in the surface caused by the measurements are minimized, whereas in the latter case, corrosion products and the effect of illumination could significantly complicate the characteristics of the system.

Experimental

All measurements were made on single-crystal n-CdSe (11 $\bar{2}$ 0) electrodes (Cleveland Crystals). The donor densities were 1×10^{17} cm⁻³. The electrode surface was chemomechanically polished with 1% (V/V) Br₂/CH₃OH. After mounting in epoxy (Epoxy Patch) and in between capacitance/voltage measurements, the crystals were rinsed with 1M HCl to remove sulfide layers, and then cleaned with a cotton-tip applicator soaked in 1% Br₂/CH₃OH mixed with 50% by volume 1M HCl. This cleaning was followed by rinsing with distilled deionized water. All chemicals were reagent grade.

Capacitance/voltage sweep measurements were made at 50 kHz using a lock-in amplifier. A constant ac current was passed through the cell, and the 90° out-of-phase component of the voltage across the CdSe-Pt foil electrode was measured. AC voltages were typically 1-10 mV. Previous capacitance measurements (1) on these same crystals showed that the space-charge capacitance was independent of frequency (10³-10⁵ Hz). High purity N₂ was

*Electrochemical Society Active Member.

passed through the electrolyte before and during the measurements. All capacitance measurements were made within 15 min of the time of introduction of the electrode into the electrolyte.

Theory

Flatband potential and surface coverage.—The flatband potential, V_{FB} , is a property of a semiconductor-electrolyte system that is essentially a measure of the energy of the conduction band of the material. In general, the measured flatband potential can be related to its value when no excess charge exists on the surface, V_{FB}^0 , and the voltage drop across the Helmholtz double layer when net charge resides on the electrode surface. We can express this relationship as

$$V_{FB} = V_{FB}^0 \pm \frac{Q_{ad}}{C_H} \quad [1]$$

where C_H is the integral capacitance of the Helmholtz double layer. The chemical and physical structure of this interfacial region at the semiconductor-liquid junction is not fully known. It is expected that the concepts of inner and outer Helmholtz planes (2) that were developed for metal/electrolyte interfaces apply in the semiconductor electrode case. The shift in V_{FB} relative to the neutral condition is positive or negative, depending on the sign of the net surface charge. The quantity Q_{ad} (C/cm²) is assumed to be given by

$$Q_{ad} = q_0 (\sum z_i n_i^+ - \sum z_j n_j^-) \quad [2]$$

where n is the number of adsorbed species per square centimeters and q_0 is the elementary charge. z is the integral charge on the ion. If there are N total sites for adsorption, the surface coverage, θ , for the i th species is given by $\theta_i = n_i/N$. When $n_i = N$, θ is θ_{sat} , the saturation coverage.

Now consider the simplification that only one negatively charged species adsorbs on the electrode surface, e.g., OH⁻, with surface coverage, θ .

Then

$$V_{FB} = V_{FB}^0 - \frac{q\theta N}{C_H} \quad [3]$$

and the flatband potential saturates at

$$V_{FB}^{sat} = V_{FB}^0 - \frac{qN}{C_H} \quad [4]$$

By solving Eq. [3] for θ , and eliminating qN/C_H by means of Eq. [4], we find

$$\theta = \frac{V_{FB} - V_{FB}^0}{V_{FB}^{sat} - V_{FB}^0} \quad [5]$$

This simple result states that the fractional occupancy of surface sites is given by the ratio of the shift in flatband potential relative to the neutral condition to the total shift from neutral to saturation condition. Application of Eq. [5] assumes that V_{FB}^{sat} can be observed experimentally. Calculation of V_{FB}^{sat} appears to be unreliable at present. However, V_{FB}^0 values can be predicted with reasonable accuracy (3).

Isotherms.—The thermodynamic equilibrium constant for the adsorption process

is

$$K_0 = \frac{a_s}{a_v a_{el}} \quad [7]$$

where a_s and a_{el} are the activities of the adsorbing species on the surface and in the electrolyte, respectively, and a_v is the activity of vacant sites. According to the general isotherm of Frumkin (4), $a_s = \theta e^{f\theta}$, $a_v = (1 - \theta)$, and $a_{el} = a_{x-}$. For simple adsorption such as reaction [6], the Frumkin isotherm is

$$\ln \left(\frac{\theta}{1 - \theta} \right) + f\theta = \ln K_0 + \ln a_{x-} \quad [8]$$

The parameter f , in units of kT , represents the interaction energy between adsorbed particles. This energy may be repulsive ($f > 1$) or attractive ($f < 1$).

The parameter, f , generally depends on coverage and the density of electrons or holes on the electrode surface. In the case of semiconductors in the dark, the electrode charge is normally quite small (low density of ionized electronic surface states). At the flatband condition, the space charge is zero by definition. To a first approximation, neglect of electronic (as opposed to adsorbed) charge is permissible. If so, then f may be related to various models of the interface. For example, according to the induced dipolar heterogeneity model of Boudart (5)

$$f = \frac{2\pi q_0 N M_0}{kT \left(1 + \frac{9\alpha}{a^3} \theta \right)} \quad [9]$$

where N is the density of available sites, M_0 is a dipole moment normal to the surface, α is the polarizability of the adsorbing particles, and a is the distance between dipoles. For 10^{14} particle/cm², $M_0 = 1.0$ Debye, and $\alpha = 0$, $f = 7.3$, a very reasonable value (6, 7). Mutual polarization effects will lower f depending on α , a , and the coverage.

The Bockris-Devanathan-Müller isotherm (2, 8), that describes ion-ion interactions, can also provide an estimate of f . When the electrode charge is negligible

$$f = \frac{M' q_0^2 \tau_{ion}^2 (z N)^{3/2}}{\epsilon kT} \theta^{1/2} \quad [10]$$

where M' is a geometrical factor, τ is the radius of the adsorbing ion, and the dielectric constant, $\epsilon \approx 6$. Using $M = 15.3$ (8), $N = 10^{14}$ cm⁻², $z = 1$, and $\tau_i = 2.5 \times 10^{-8}$ cm, we find $f = 8.9$ for $\theta = 1$. Both models predict reasonable values of f and are useful for rationalizing and predicting changes in adsorption characteristics as system properties vary.

Surface substitution reaction.—Now consider a situation where the electrode is saturated with an adsorbed charged species and another more strongly adsorbing species is introduced into the electrolyte. Specifically, consider the equilibrium

where M stands for an adsorption site.

The equilibrium constant for this substitution reaction may be written

$$K_s = \frac{\theta_2 e^{f_2 \theta_2} a_{H_2O}}{\theta_1 e^{f_1 \theta_1} a_{SH^-}} \quad [12]$$

where the subscript 2 refers to adsorbed S^- ion and 1 refers to adsorbed OH^- ion. According to our data (see Fig. 2 and the results below), the CdSe surface is saturated with OH^- at the time SH^- ions were introduced into the 1M NaOH electrolyte. Therefore we describe the system by reaction [11]. Accordingly, it is assumed that $\theta_1 + \theta_2 = 1$. When the surface contains two interacting species, such as S^- and OH^- , the f 's have a more complicated meaning than that implied in Eq. [9] or [10]. A theory that counts the interaction between different kinds of particles is needed to describe the system.

For the present, we have to assume that like and unlike ion interactions are included in the f 's in Eq. [12]. Assuming a_{H_2O} is unity and $\theta_1 + \theta_2 = 1$, Eq. [12] may be written using θ_{S^-} for θ_2

$$\theta_{S^-} + \frac{1}{f_1 + f_2} \ln \left(\frac{\theta_{S^-}}{1 - \theta_{S^-}} \right) = \frac{1}{f_1 + f_2} \ln a_{SH^-} + \frac{f_1}{f_1 + f_2} + \ln K_s \quad [13]$$

This equation will be applied below.

Results

Adsorption of OH^- .—Typical Mott-Schottky plots for CdSe (11 $\bar{2}0$) in 0.1M Na₂SO₄ are shown in Fig. 1. The concentration of OH^- was varied by the addition of NaOH. The plots were linear over a wide voltage range. The measured capacitance followed the $1/C^2$ relation for surface barriers as small as 0.2V. This behavior suggests that the density of active electronic surface states in the upper part of the bandgap is quite low. Our previous measurements (1) with the same crystals in neutral Na₂SO₄ solution indicated interface state densities of 10^{12} - 10^{13} cm⁻² at 0.1-0.5 eV below the conduction bandedge. The interface is assumed to be formed by the CdSe and a thin (perhaps permeable and chemically active) layer of elemental Se. The Se results from the oxidative etch with Br₂. Apparently, the more-alkaline conditions, as in Fig. 1, play a role in reducing the interface state density. A possible explanation is that OH^- ions bond to sites with Cd²⁺ character and thus remove the postulated acceptor-state levels.

The flatband potentials determined from Fig. 1 were plotted against OH^- concentration, and the results are shown in Fig. 2. The inset to Fig. 2 shows how V_{FB} varies with $\log [OH^-]$. Interpolated values of V_{FB} are listed at various OH^- concentrations in Table I. The flatband po-

Fig. 1. Mott-Schottky plots for n-CdSe (11 $\bar{2}0$) in 0.1M Na₂SO₄ at 50 kHz. NaOH added. $N_0 = 7.6 \times 10^{16}$ cm⁻³.

Fig. 2. Flatband potential vs. $[\text{OH}^-]$ for n-CdSe (11 $\bar{2}$ 0) in 0.1M Na_2SO_4 . Data from Mott-Schottky plots at 50 kHz.

tential was strongly dependent on $[\text{OH}^-]$, and at sufficiently large concentrations, a saturation V_{FB} of -1.22V vs. SCE was observed. The results suggest a strong adsorption of OH^- ions on the CdSe surface.

The behavior of V_{FB} in the pH range 4-11 is unusual. We (1) and others (9) have reported that V_{FB} is -0.7V vs. SCE and is independent of $[\text{OH}^-]$ in this intermediate pH range. Therefore, in the discussion to follow we will assume that OH^- or H^+ are not strongly adsorbing for $[\text{OH}^-] < 10^{-3}\text{M}$. And accordingly, we will assume that $V_{\text{FB}} = -0.7\text{V}$ corresponds to the neutral surface charge (adsorbed) condition, i.e., $V_{\text{FB}}^0 = -0.7\text{V}$ (see below).

Adsorption of S^{2-} .—The adsorption of sulfide ions was studied by measuring the flatband potential shift as a function of Na_2S in 1M NaOH. Mott-Schottky plots are shown in Fig. 3. These parallel plots of $1/C^2$ vs. V indicate that the addition of Na_2S leads to a further negative shift in V_{FB} . We assume that S^{2-} replaces OH^- on the surface until saturation is reached.

The results of V_{FB} determinations are plotted in Fig. 4 as a function of Na_2S concentration. Interpolated values are given in Table II.

Discussion

OH^- adsorption.—The surface coverage with OH^- was calculated using Eq. [5] and $V_{\text{FB}}^0 = -0.70$ and $V_{\text{FB}}^{\text{sat}} = -1.22\text{V}$. The results are plotted in Fig. 5 according to the logarithmic form of the Frumkin isotherm, Eq. [8]; the interaction parameter was calculated from the slope, $d\theta/d \ln c$ and found to be 1.7. This value indicates a weak interaction between the adsorbed OH^- ions. A value of the equilibrium constant for adsorption can be made by direct calculation by means of Eq. [8], for $\theta = 0.5$. Using an

activity coefficient of 0.8 for 0.058M OH⁻ (Fig. 5), K_0 is found to be 50.4. The standard free energy change was calculated to be -2.3 kcal/mol. This value can be compared with $\Delta G^\circ = -3.7, -3.4,$ and $+2.6$ calculated (10) for adsorption of OH⁻ on Au, Ag, and Hg electrodes, respectively.

Aqueous sulfide chemistry.—Before detailed interpretation of the flatband potential data, the chemistry of Na₂S solutions has to be briefly considered. The addition of Na₂S to an aqueous solution results in nearly complete hydrolysis leading to an essentially equimolar solution of SH⁻ and OH⁻. The equilibrium constant for the hydrolysis (11)

is $\sim 1.1 \times 10^3$. In 1M OH⁻, $\sim 0.1\%$ of sulfide is present as S²⁻. This means that SH⁻_(aq) is the dominant precursor to adsorbed S²⁻.

Another important aspect is the very probable large increase in acidity of SH⁻ when adsorbed on the surface. The chemical evidence for this expectation is the following. First, the pK_a for SH⁻ is 17.1 at room temperature (11). The pK_a of AgSH is 5.3 (12). Thus, the K_a increases by ~ 12 orders of magnitude by interaction of SH⁻ with a metal that is adjacent to Cd in the periodic table. Next, consider the enhancement in acidity of SH⁻ when it complexes with sulfur atoms to form polysulfide species. The pK_a 's for HS₂⁻, HS₃⁻, HS₄⁻, and HS₅⁻ were calculated to be 9.5, 7.4, 6.2, and 5.6, respectively (13). Clearly, complexation of SH⁻ with metals or nonmetals greatly increases its acidity. The above discussion allows us to conclude that any adsorbed SH⁻ will be nearly quantitatively converted to S²⁻_{ad} in 1M NaOH.

The coverage with sulfide was calculated on the assumption that $\theta_{OH^-} + \theta_{S^{2-}} = 1$, and the results are shown in Table II. Equation [3] was used with $qN/C_H = 0.46V$ and θ was replaced by $(1 + \theta_{S^{2-}})$. The value 0.46 is one-half the shift in V_{FB} from -0.70 to -1.62V, the saturation value for S²⁻. Saturation with S²⁻ with a double-negative charge should cause a shift twice that for saturation with OH⁻, a single-negative species, if the number of sites is constant. Comparison of ΔV_{FB} of 0.52 (OH⁻) with 0.92 (S²⁻) shows that this expectation is found experimentally. The coverage values, $\theta_{S^{2-}}$, were plotted vs. log [SH⁻], as shown in Fig. 4. The slope of the linear portion gives a first approximation to $(f_1 + f_2)^{-1}$. Various values of $f_1 + f_2$ were chosen until Eq. [13] was satisfied. The best fit was obtained for $f_1 + f_2 = 12.4$. For $\theta_{S^{2-}} > 0.6$, the data did not fit Eq. [13], as discussed below. This large $f_1 + f_2$ value compared to $f_{OH^-} \approx 2$ is not too surprising. The large negative charge and size of S²⁻ causes $f_{S^{2-}}$ to be larger (Eq. [10]). In addition, f_{OH^-} is increased because OH⁻ ions interact with some S²⁻ on

the surface. However, S²⁻ ions interact with OH⁻, and thus $f_{S^{2-}}$ is probably decreased. In order to calculate the equilibrium constant for the surface substitution reaction [11], an estimate of f_{OH^-} in the presence of S²⁻_{ad} is needed. We reasoned that this number should be greater than 2 but less than 1/2 ($f_1 + f_2$) = 12.4. A midrange value of 5 was assumed to be a reasonable compromise. Now K_s can be calculated using Eq. [13], $\theta = 0.5$, $C_{SH} = 2.0 \times 10^{-3}$, and an activity coefficient of 0.75 for SH⁻ ion in 1M NaOH solution. The calculation gives $K_s = 1.9$ and $\Delta G_s^\circ = -0.37$ kcal/mol.

A calculation of the free energy change for adsorption of S²⁻ can also be made using the thermodynamic data derived here. Consider the following series of reactions and corresponding standard free energy changes.

The value of ΔG° for adsorption of S²⁻ is found to be -6.9 kpm.

There is one other aspect of the sulfide coverage data that is of interest that is not predicted by Eq. [13]. The increase in slope of the θ vs. log C plot for $\theta \geq 0.6$ is unusual. Normally, the Frumkin isotherm with repulsive interaction shows a decrease in slope, leading to saturation for $\theta \geq 0.8$. Evidently, the nature of the interaction between the adsorbed ions changes in the direction of less repulsion as θ increases before saturation of the surface. A possible explanation is that a new phase forms on the surface, such as CdS or a sulfur layer. The former may require removal of Se, while the later may require at least partial oxidation of the adsorbed sulfide ions. Both of these processes, sulfur-selenium exchange and sulfur layer formation, are thought to occur on CdSe surfaces in contact with sulfide electrolytes in photoelectrochemical solar cells.

Summary

The adsorption of OH⁻ and S²⁻ ions on n-CdSe single-crystal electrodes was studied. Both ions reach saturation coverage for concentrations of 0.1-0.7M. Standard free energies of adsorption were -2.3 and -6.9 kcal/mol for OH⁻ and S²⁻, respectively. The corresponding quantity for the substitution reaction involving OH⁻_{ad} and S²⁻_{ad} was -0.37 kcal/mol. The repulsive interaction of S²⁻ (and possibly OH⁻) appears to weaken at high Na₂S electrolyte concentrations. The formation of a new phase in the near surface region may be implicated.

Effects of Additives on ZnO-B₂O₃-SiO₂ Passivation Glasses

Yutaka Misawa

Hitachi Limited, Hitachi Research Laboratory, Hitachi, Ibaraki, Japan

ABSTRACT

The addition of BaO, Sb₂O₃, or Bi₂O₃ to glass A with composition (weight percent [w/o]) 65.4 ZnO-24.5 B₂O₃-10.1 SiO₂ resulted in more negative surface charge density and increase in the thermal expansion coefficient (α). The glass B, 63 ZnO-29 B₂O₃-8 SiO₂ (w/o) showed finer crystals by the addition of ZnO (1 w/o) or glass A without affecting the surface charge density or α . The effects of additives on the DTA characteristic temperatures of the two glasses are also presented.

ZnO-B₂O₃-SiO₂ glasses are suitable passivants for high voltage silicon power devices such as thyristors, transistors, and diodes. One advantage of using this glass is that surface charge density of the glass/Si system can be controlled by changing the glass composition (1), i.e., the surface electric fields of the devices can be modified on demand. However, a new problem occurred when the ratios of B₂O₃ to SiO₂ were increased to shift the surface charge density in the negative direction (2). The problem consisted of an increase in crystal size.

Thus, to produce the passivation glass with a large negative surface charge density and fine crystals for high power devices, two approaches have been considered.

In method 1, a shift to more negative surface charge density of the glass with a small negative surface charge density and fine crystals is achieved by addition of another material. In method 2, forming finer crystals of the glass with a large negative surface charge density and large crystals is also achieved by addition of another material. For ZnO-B₂O₃-SiO₂ glass, Moriguchi *et al.* (3) reported that Sb₂O₃, CeO₂, and PbO were additives which lower the flowing point and crystallization point for the DTA curve and make the thermal expansion coefficient larger. However, Ta₂O₅ was an additive which did not change the flowing point, crystallization point, or thermal expansion coefficient, but did shift the surface charge density slightly in the positive direction.

In this report, method 1 was examined adding various metal oxides to glass A (ZnO:65.4, B₂O₃:24.5, SiO₂:10.1 w/o). Method 2 was investigated adding glass A or ZnO to glass B (ZnO:63, B₂O₃:29, SiO₂:8 w/o).

Experimental

Glass preparation.—In method 1, metal oxide components of glass A and 5 w/o of BaO, Al₂O₃, Ga₂O₃, SnO, PbO, ZrO₂, Sb₂O₃, Bi₂O₃, TiO₂, V₂O₅, Nb₂O₅, or Ta₂O₅ additive were mixed in a revolving mixer and used as glass materials. V₂O₅, Sb₂O₃, and PbO, which are low melting point materials, were heated at 500°C, while other materials were heated at 850°C to remove water and organic contaminations before weighing. Subsequent preparation procedures were the same as reported before (1, 2).

In method 2, glass A, with crystallized glass A or ZnO as additive, was mixed with glass B in a revolving mixer. Crystallized glass A was prepared as follows. Glass A powder was fired at 740°C for 40 min in air and then ground to give the same mean particle size distribution as glass A. ZnO was used like the glass materials.

Measurements.—Physical properties of glasses were measured by differential thermal analysis (DTA), thermal expansion coefficient measurements, and scanning electron microscope (SEM) observations.

Surface charge densities of the glass/silicon system were measured with metal-glass-silicon (MGS) capacitors.

Sample preparation and measurement methods have been reported previously (1, 2).

Results and Discussion

The effects of additives for glass A with a small negative surface charge density and fine crystals are shown in Fig. 1. as DTA curves of glass A and glass A with added Sb₂O₃. For the latter, a second crystallization point (T_{c2}) was not distinctly observed. Table I shows characteristic points for DTA curves of glass A with various metal oxides added. Characteristic points such as softening point (T_s), crystallization starting point (T_{cs}), and first crystallization point (T_{c1}) shift to lower temperatures on addition of any of the metal oxides. The oxides seemed to act as nucleating agents. Furthermore, the second crystallization points were not distinctly observed for all additives except TiO₂. Glass A with added TiO₂ showed distinct DTA characteristics. The boundary between T_c and T_{cs}

* Numbers in parentheses are peak height in arbitrary units.

was unclear, and T_{ct} was very low in comparison with those of other glasses. Figure 2 shows typical photomicrographs for glasses fired on silicon at 700°C. Crystals in these glasses were different; they were larger than those in glass A and finer than those in glass B. Table II shows thermal expansion coefficients of glasses fired at 680° or 700°C. The thermal expansion coefficients for glass A with added metal oxide were all larger than that of glass A alone, except for ZrO₂ and Ga₂O₃ additives. It was expected that the thermal expansion coefficients of glass A with added metal oxide would be lower than that of glass A alone, because the crystallization points of these modified glasses were all lower than that of glass A alone. However, the results contradicted the expectations. The effects of metal oxides on the thermal expansion coefficients were larger than that of the degree of crystallization.

Table III shows the surface charge densities of glasses fired on n-type silicon at 680° or 700°C. The additives which shifted the surface charge density in the positive direction and accumulated the surface of n-type silicon are Al₂O₃, Ga₂O₃, SnO, PbO, TiO₂, ZrO₂, Nb₂O₅ and Ta₂O₅. These additive metals are from groups IIIB, IV, and VA of the periodic table. The additives which shifted the surface charge density in the negative direction and inverted the surface of n-type silicon are BaO, Sb₂O₃, and Bi₂O₃. These are from groups IIA and VB of the periodic table.

The effects of additives on the properties of glass B with large negative surface charge density and large crystals are shown in Fig. 3 as determined from DTA curves.

Softening points of all the glasses changed hardly at all with additions. Crystallization starting point, first, and second crystallization point first decreased sharply and then by a slow increase by the addition of the additives. This tendency is independent of additives. Thus the additives were functioning as nucleating agents as stated before. However, T_{cz} did not disappear. And in particular,

Fig. 3. Effects of additives on characteristic points of glass B as determined from DTA curves.

Fig. 4. Typical micrographs for glasses fired on silicon at 680°C or 700°C for 40 min.

variations of T_{c1} and T_{c2} were large with addition of only a small amount of additive. For 1 w/o additive, T_{c3} and T_{c1} did not differ for different additives. However, the variation of T_{c2} for glass B with crystallized glass A added was the largest. That is, crystallized glass A was most effective as a nucleating agent.

Phases of crystallization were observed by SEM. Figure 4 shows several photomicrographs for the glasses fired on silicon at 680° or 700°C. Large needlelike crystals were observed in glass B, as reported before (2). However, in glass B with additives, fine crystals were observed, as in glass A alone. Fine crystals formed because crystallization proceeded easily.

Figure 5 shows the relationship between the ratio of additives and thermal expansion coefficient of glass B fired at 680° or 700°C. Thermal expansion coefficients of glass B with added ZnO or crystallized glass A decreased with the ratio of additive. The thermal expansion coefficient of glass B with crystallized glass A was smaller than that with ZnO. This could be attributed to the difference in T_{c2} . The effect of the additive on the thermal expansion coefficient of glass B was opposite of

Fig. 5. The relationship between amount of additive and thermal expansion coefficient of glasses fired at 680° or 700°C.

Fig. 6. The effect of amount of additive and surface charge density of glasses fired at 680°C.

that for glass A. This could be assumed to originate from the difference in the addition methods.

Figures 6 and 7 show the relationships between ratio of additive and surface charge density of the glass fired on silicon at 680° or 700°C. Surface charge density shifted in the positive direction with increasing ratio of additive. The shift was smallest for the glass B with added glass A.

Figure 8 shows the relationship between surface charge density and glass firing temperature. Surface charge density shifted to a more negative charge with higher firing temperature. This tendency was the same as that of glasses with no additive (1).

Conclusions

The effects of additives on DTA characteristics, crystal morphology, thermal expansion coefficient, and surface charge density of ZnO-B₂O₃-SiO₂ glasses were investigated.

Fig. 7. The effect of amount of additive and surface charge density of glasses fired at 700°C.

Fig. 8. The effect of firing temperature on surface charge density of glass B with 1 w/o crystallized glass A added.

The addition of metal oxides influenced the properties of glass A, which had a small negative surface charge density and fine crystals, as follows. Characteristic points such as T_s , T_{cs} , and T_{c1} of glass A decreased, and T_{c2} was not distinctly observed on addition of metal oxide. The thermal expansion coefficients of glass A increased. The surface charge density of the glass/silicon system shifted negatively with the addition of metal oxides, if the metal

belonged to groups IIA or VB (e.g., BaO, Sb₂O₃, or Bi₂O₃). It shifted to positive with the addition of metal oxides, if the metal belonged to groups IIIB, IV, or VA (e.g., Al₂O₃, Ga₂O₃, SnO, PbO, TiO₂, ZrO₂, V₂O₅, Nb₂O₅, or Ta₂O₅).

The addition of glass A or ZnO influenced the properties of glass B, which had a large negative surface charge density and large crystals, as follows. T_{cs} , T_c , and T_{c2} of glass B decreased, and the crystals in the glass were finer. The thermal expansion coefficient of glass B decreased with increasing ratio of additive. The surface charge density shifted positively with increasing ratio of additive. However the shift was negligible in the case of the glass with 1 w/o additive. Hence, glass B with 1 w/o additive meets the objectives of this work, which was the development of a glass with large negative surface charge and fine crystals.

Electrical Characteristics of the RF Magnetron-Sputtered Tantalum Pentoxide-Silicon Interface

Shunji Seki, Takashi Unagami, and Bunjiro Tsujiyama

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki 319-11, Japan

ABSTRACT

Tantalum pentoxide (Ta₂O₅) films were deposited onto single-crystalline silicon as gate insulators by RF magnetron sputtering. Capacitance-voltage characteristics were measured to determine the interface properties between Ta₂O₅ and Si. After annealing at 450°C in H₂ ambient, a negative interface charge that is fully localized in the low dielectric constant transition layer at the interface was observed. It has also been clarified that the rest of the film is homogeneous, whose dielectric constant is almost close to that of the bulk of Ta₂O₅. It has been shown that Ta₂O₅ gate insulator with relatively good interface properties can be fabricated at low temperatures using RF magnetron sputtering.

In recent years, tantalum pentoxide (Ta₂O₅) film is of interest for use as a gate insulator in MOS devices. The higher dielectric constant of Ta₂O₅, compared with that of SiO₂, makes it attractive for the fabrication of high quality MOS devices with high transconductance and low threshold voltage. Furthermore, since high quality Ta₂O₅ films can be fabricated at low temperatures using RF magnetron sputtering (1), it also offers the opportunity for removing some of the problems encountered with conventional MOS devices with thermally grown SiO₂ as a gate insulator.

The characteristics of MOS devices will be strongly dependent on the interface properties between the gate insulator and the silicon layer, in addition to the quality of the gate insulator itself. Because of its excellent properties, thermally grown SiO₂ has been used for years as gate insulators in MOS devices. However, since the thermal

oxidation is performed at 900°C or higher, the oxidation process prohibits the use of the thermal oxide on devices fabricated on a low melting point substrate. Furthermore, the high temperature oxidation generates stacking faults and dislocations in the silicon substrate, and it also changes the impurity distribution previously formed in the substrate. These structural defects and the variation of the impurity profiles induce the degradation in the performance of MOS devices. In order to remove these problems, gate insulator fabrication processing at low temperatures becomes necessary.

Several attempts have been made to employ Ta₂O₅ films as gate insulators in MOS devices, using chemical vapor deposition (2) and thermal oxidation of a deposited Ta film (3, 4). However, the interface properties between Ta₂O₅ and Si fabricated by these processes were inferior to those between SiO₂ and Si. More than -5 to -10×10^{11}

cm^{-2} interface charge density remained at flatband condition, which was much higher than that between SiO_2 and Si. In order to obtain high quality MOS devices, it is necessary to reduce the interface charge density between Ta_2O_5 and Si.

The authors have investigated the interface properties between the silicon layer and the Ta_2O_5 gate insulator formed by RF magnetron sputtering. This paper reports the results of these experiments, and also shows the ability to produce a relatively good quality Ta_2O_5 gate insulator at low temperatures using RF magnetron sputtering.

Experimental

Al/ Ta_2O_5 /Si structure devices were used to investigate the interface behavior. All of the MOS capacitors were fabricated on p-type, $\langle 100 \rangle$ -oriented, 1.2-1.8 $\Omega\text{-cm}$ silicon wafers. Si wafers were chemically cleaned using mixtures of H_2O_2 and H_2SO_4 (volume ratio of $\text{H}_2\text{O}_2/\text{H}_2\text{SO}_4 = 1/4$). Then, they were rinsed in deionized water. Immediately before being installed into the sputtering chamber, the wafer was dipped into dilute HF to remove the oxide formed during previous processing steps. Sputtering was performed using an ULVAC SBH-2204 RS RF magnetron sputtering system. Instead of a conventional oil diffusion pump, a 3000 liter/s cryogenic pump was used to eliminate contamination. The Ta_2O_5 target was 10 cm diam and 5 mm thick. The target to substrate distance was kept at 5 cm. The sputtering gas consisted of mixtures of argon and oxygen (partial pressure ratio of $\text{Ar}/\text{O}_2 = 8/2$). The sputtering chamber was evacuated to less than 1×10^{-7} torr prior to sputtering, and then backfilled with the sputtering gas. The sputtering pressure was varied from 4×10^{-3} to 2×10^{-2} torr. The Ta_2O_5 target was presputtered for at least 1h. Typical deposition rate ranged from 2 to 6 nm/min. Aluminum dot electrodes of 300 μm diam were electron-beam deposited onto the sputtered Ta_2O_5 surface. To minimize the radiation damage produced during the MOS capacitor fabrication steps, the wafers were annealed in the hydrogen ambient. After a final H_2 anneal, the high frequency capacitance-voltage characteristics were measured with automatic capacitance meters (HP 4275A and HP 4274A). These measurements were performed for more than 20 MOS capacitors fabricated on the same silicon substrate.

In-depth composition profiles of the deposited Ta_2O_5 were measured by Auger electron spectroscopy (AES) with simultaneous Ar sputtering. For the AES measurements, samples were taken from the sputtering chamber and were then mounted in an ultrahigh vacuum chamber of the AES measurement equipment (Φ 590). Measurements were performed under conditions of a 5 kV excitation voltage and a 0.5 μA beam current. Typical sputtering rate of Ta_2O_5 films was 3 nm/min for a 3 kV sputtering voltage and a 5 mA emission current.

Experimental Results

H_2 annealing effect.—To find H_2 annealing effect on the interface charge density, capacitance-voltage characteristics of MOS capacitors, which had been annealed in the hydrogen ambient at different temperatures, were measured at frequencies ranging from 1 kHz to 1 MHz. In these cases, annealing was performed after the aluminum electrode deposition, which is hereafter referred to as the postmetallization annealing. Annealing temperatures were varied from 350° to 450°C, and the annealing time was retained for 30 min. Figure 1 shows capacitance-voltage characteristics for MOS capacitors which were not annealed. A strong frequency dispersion was observed in their C-V curves. This is due to the existence of the high density of interface states with various response time constants. Two parameters were used to indicate the H_2 annealing effect: the interface charge density calculated from the flatband voltage measured at 1 MHz, and the flatband voltage difference between the low frequency C-V curve taken at 1 kHz and the high frequency C-V curve taken at 1 MHz.

Fig. 1. Frequency dispersion in capacitance-voltage characteristics for MOS capacitors without the postmetallization annealing. The Ta_2O_5 thickness is 110 nm. The interface charge density, calculated from the V_{FB} measured at 1 MHz and the ΔV_{FB} inserted in the figure, were used to indicate the annealing effect.

Figure 2 shows variations in the interface charge density and the flatband voltage difference with annealing temperatures. The interface charge density decreases monotonically as the annealing temperature goes up from 350° to 450°C. After annealing at 450°C, the interface charge polarity changed to negative, and the value of $-3.1 \times 10^{11} \text{ cm}^{-2}$ was obtained. Flatband voltage difference also decreases uniformly with increasing annealing temperature. After annealing at 450°C, the flatband voltage difference in between low and high frequency C-V curves was reduced to less than 0.04V. It has been clarified that H_2 annealing has a great effect on the reduction in the interface charge density in Al/ Ta_2O_5 /Si structures.

In order to make the interface charge density much lower, the annealing process was newly introduced after the Ta_2O_5 deposition process. The purpose of this annealing process, hereafter referred to as the postsputtering annealing, is to reduce the radiation damage produced during the sputtering process. In these cases, wafers were annealed at 450°C in the hydrogen ambient for 30 min before the aluminum metallization, and the postmetallization annealing temperature was varied.

Figure 3 shows the variations in the interface charge density and the flatband voltage difference with postmetallization annealing temperatures. The interface

Fig. 2. Variations in interface charge density Q_{ss}/q and flatband voltage difference ΔV_{FB} with changes in postmetallization annealing temperature. The Ta_2O_5 thickness is 80 nm.

Fig. 3. Variations in Q_{ss}/q and ΔV_{FB} with changes in postmetallization annealing temperature. Samples had been annealed at 450°C in the hydrogen ambient before metallization. The Ta_2O_5 thickness is 80 nm.

charge density and the flatband voltage difference on the case involving postsputtering annealing without postmetallization annealing were $4.2 \times 10^{11} \text{ cm}^{-2}$ and 0.19V, respectively. Differing from the results shown in Fig. 2, the interface charge polarity changed to negative, even though the postmetallization annealing temperature was 350°C. The value of interface charge density decreases as the postmetallization annealing temperature rises from 350° through 450°C. After annealing at 450°C, the interface charge density was reduced to as low as $-1.4 \times 10^{11} \text{ cm}^{-2}$. Flatband voltage difference was made as low as 0.03V almost invariable in the postmetallization annealing temperature over 350°C. And the reproducibility of these results was good. It has become clear that the interface charge density can be reduced to as low as $-1.4 \times 10^{11} \text{ cm}^{-2}$ by the optimum combination of postmetallization annealing with postsputtering annealing. These are the lowest values which have been reported so far. These results imply that postsputtering annealing has an effect on the reduction of the radiation damages induced during the sputtering process.

The surface-state density was calculated from the high frequency (1 MHz) capacitance-voltage characteristics using the Terman method (5). The surface-state density distributions, before and after annealing in the hydrogen ambient, are compared in Fig. 4. The surface-state density for as-deposited samples was on the order of 10^{12} states $\text{cm}^{-2} \text{ eV}^{-1}$ in the middle of the energy gap and increased rapidly toward the bandedges. After the samples had been annealed at 450°C in the hydrogen ambient, the surface-state density was reduced to as low as 1.5×10^{11} states $\text{cm}^{-2} \text{ eV}^{-1}$ near the midgap, which is one order of magnitude lower than that reported previously (3).

Interface charge density dependence on gate insulator thickness.—It has become clear from the results mentioned in the previous section that the interface charge after annealing at 450°C in the hydrogen ambient is characterized by a negative charge and behaves like fixed charges in the Al/ Ta_2O_5 /Si structures. To clarify the charge distribution in the gate insulator, variations in the interface charge density with changes in the gate insulator thickness were investigated. Results are shown in Fig. 5. The interface charge density is within the range from -3.0×10^{11} to $-3.8 \times 10^{11} \text{ cm}^{-2}$ as varying the gate insulator thickness from 17 to 110 nm. The interface charge density is independent of the gate insulator thickness in the thickness range studied. If the charge distribution were uniform in the gate insulator, the interface charge density would increase monotonically with increasing gate insulator thickness. Hence, these results indicate that the charge distribution is not uniform in the gate insulator.

Fig. 4. Surface-state density distribution for Al/ Ta_2O_5 /Si MOS capacitors. Combination of postsputtering annealing with postmetallization annealing reduced the surface-state density to as low as $10^{11} \text{ cm}^{-2} \text{ eV}^{-1}$. The Ta_2O_5 thickness is 110 nm.

Dielectric constant dependence on gate insulator thickness.—In order to clarify dielectric properties of Ta_2O_5 sputtered on single-crystalline Si, the relationship between the dielectric constant of the gate insulator and the gate insulator thickness was studied. The dielectric constant of the gate insulator was calculated from the capacitance of MOS capacitors in the accumulated region measured at 1 MHz. Figure 6 shows the variations in gate insulator dielectric constant with changes in thickness. The dielectric constant increases monotonically with increasing gate insulator thickness. For the sample 17 nm thick, the dielectric constant is 3.9, which is much lower than that of Ta_2O_5 itself and is close to that of SiO_2 . As the thickness increases, the dielectric constant becomes higher and reaches 12.5 for the 110 nm thick sample. These results imply that the dielectric constant is not uniform throughout the whole thickness of deposited Ta_2O_5 .

Fig. 5. Variation in interface charge density with changes in Ta_2O_5 gate insulator thickness. The interface charge density was calculated from the flatband voltage measured at 1 MHz.

Fig. 6. Variation in Ta_2O_5 gate insulator dielectric constant with changes in the gate insulator thickness. Dielectric constant was calculated from the capacitance in the accumulated region at 1 MHz.

To clarify the reason for the variation in the dielectric constant, the dielectric constant profile within the deposited film was calculated from the results shown in Fig. 6. Figure 7 shows the dielectric constant profile, which was obtained by approximating the film with a series of discrete homogeneous layers. The bars shown in Fig. 7 represent the average value of the dielectric constant for each layer. The lowest average value was taken as the dielectric constant for the sample with the Ta_2O_5 thickness of 17 nm. The dielectric constant for the second layer was then obtained by reevaluating the dielectric data, using a multilayer model consisting of the first layer and the second layer. This calculation was repeated for each successive layer. The results indicate the existence of low dielectric constant layer near the $\text{Ta}_2\text{O}_5/\text{Si}$ interface. It has also been shown that the dielectric constant is almost uniform throughout the rest of the film and is almost close to that of the bulk of Ta_2O_5 .

To confirm the correctness of the model, etch-back experiments were performed. The sample with the oxide

Fig. 7. Variation in dielectric constant with changes in distance from gate insulator/silicon interface. Data were obtained by approximating the Ta_2O_5 film with a series of discrete homogeneous layers.

thickness of 110 nm was etched back to 50 nm. Following the etch-back step, aluminum electrodes were deposited on it to fabricate the MOS capacitor. From the measurement of the capacitance, the dielectric constant of the oxide was calculated to be 8.5. This value fits well with the results shown in Fig. 6. It is, therefore, concluded that the outer part of the film is homogeneous, and that the thickness of the transition layer is independent of the total thickness of gate insulator.

Composition profiles.—AES measurements of in-depth composition profiles are shown in Fig. 8. The vertical axis is proportional to the relative concentration, and the sputtering time indicated by the horizontal axis is related to the depth counted from the outer surface.

A remarkable feature is that the relative composition ratio of Ta/O is fairly constant through the whole thickness of the film, except for near the silicon interface, where the relative composition ratio becomes larger. This is not unique to the case of this film, but has been observed for other films with different thicknesses as well. The variation of the relative composition ratio of Ta/O near the interface is assumed to be related to the formation mechanism of tantalum oxide on silicon.

Discussion

The results shown in Fig. 7 can be explained by a model with a relatively narrow transition layer at the interface, where the rest of the film is homogeneous. This transition layer is considered to be attributed to the imperfect tantalum compound formed in the early stage of Ta_2O_5 formation on silicon. It is assumed that the dielectric constant becomes lower in this transition layer, owing to its structure imperfection. Following the transition layer formation, nearly perfect tantalum oxide will form on it. Hence, the outer part of the film becomes homogeneous, and the value of the dielectric constant in this region is close to that of the bulk of Ta_2O_5 .

This model is confirmed by in-depth composition profiles obtained from the AES measurements. As shown in Fig. 8, the composition profile of the film is divided into two regions based on the relative composition ratio of Ta/O: (i) the outer part of the film, where the relative composition ratio of Ta/O is constant, and (ii) the region near the silicon interface, where the relative composition ratio becomes larger. Results shown in Fig. 8 indicate that the deposited film is homogeneous except for transition region near the interface. From the composition profiles, the thickness of this transition region is estimated to be in the range from 10 to 15 nm. Based on the assumption that the composition of the outer part of the film is Ta_2O_5 , the larger relative composition ratio implies the existence of the imperfect tantalum compound or lower tantalum oxide in the transition region.

It has already been reported by Revez *et al.* (2) and Smith *et al.* (3), that the interface charge is also negative

Fig. 8. In-depth composition profiles of Ta_2O_5 deposited on silicon. The sample was annealed at 450°C in the hydrogen atmosphere. Sputtering rate for Ta_2O_5 was 3 nm/min.

in the Ta₂O₅/Si system, when Ta₂O₅ gate insulator is fabricated with thermal oxidation of deposited Ta on Si. They investigated variations in refractive index of the film with changes in the film thickness in detail. However, the spatial distribution of these negative charges and the origin of these negative charges have not been clarified. The results shown in Fig. 5 indicate the fully localized distribution of the negative charge near the interface. As the interface charge density for the sample with 17 nm gate insulator thickness is almost the same as that for the sample with thicker gate insulator, the negative charge distribution will be localized within a thin layer at the Ta₂O₅/Si interface, which is less than 17 nm thick.

Taking the aforementioned results into consideration, it has become clear that the negative charges are fully localized in the low dielectric constant, narrow transition layer formed at the silicon interface. Even though the Si wafer is etched with dilute HF just before sputtering, oxide will reform quickly. The transition layer will be formed as the result of the interaction of this initial Si oxide film and/or Si surface with sputtered particles. If the transition layer consists of imperfect tantalum compound and/or lower tantalum oxide, it is suspected that the negative charge is due to the structure imperfections, such as the nonbridging oxygens, which are known to act as electron traps (6).

Conclusion

In the present study, Ta₂O₅ films have been deposited onto single-crystalline Si wafers using RF magnetron sputtering, and capacitance-voltage characteristics have been measured to determine the interface properties between Ta₂O₅ and Si. After annealing at 450°C in the hydrogen ambient, the interface charge in Al/Ta₂O₅/Si structures is characterized by a negative charge and is found to behave like a fixed charge. To obtain good quality interface, the postsputtering annealing has been newly introduced in addition to the conventional postmetallization annealing. At the optimized annealing conditions, the interface charge density was reduced to as low as $-1.4 \times 10^{11} \text{ cm}^{-2}$ at flatband, and the surface-state density of $1.5 \times 10^{11} \text{ cm}^{-2} \text{ eV}^{-1}$ was obtained near the midgap. These

are the lowest values in the Ta₂O₅/Si system which have been reported so far.

It has been clarified that the deposited oxide consists of two regions: a low dielectric constant, narrow transition layer at the silicon interface, and the higher dielectric constant, homogeneous layer. The thickness of this transition layer is in the range 10-15 nm, which is independent of the total thickness of Ta₂O₅ film. Moreover, it has been shown that the negative charges are fully localized in this transition layer. From the results of the present work, it has been pointed out that the negative charge in the Ta₂O₅/Si system results from imperfect tantalum compound formed in the early stage of Ta₂O₅ formation on single-crystalline silicon.

In the present Ta₂O₅ gate insulator fabrication processes, the highest temperature was restrained to under 450°C in the postannealing process. The present work demonstrates that a relatively good quality Ta₂O₅ gate insulator can be fabricated at low temperatures using RF magnetron sputtering.

Wetting Angles and Surface Tension in the Crystallization of Thin Liquid Films

Eli Yablonovitch and Tom Gmitter

Exxon Research and Engineering Company, Annandale, New Jersey 08801

ABSTRACT

The behavior of thin liquid films is known to be dominated by surface tension forces. We show that the crystallization of thin liquid films requires that two wetting angle conditions be simultaneously satisfied: (i) relating to the liquid-vapor interface, and (ii) relating to the crystal-liquid interface. The balance between capillary pressure and thermal gradient forces shows that the equilibrium freezing point of thin films is actually depressed below the bulk freezing point. The magnitude of the effect is 1 K in an 800Å thick film. These observations suggest that small-scale thickness fluctuations may be responsible for the initiation of subgrain boundaries in the growth of crystalline silicon films.

The crystallization of thin liquid silicon films is a promising method (1) for producing single-crystal films of good electronic quality. These films will have important device applications in radiation hardening, dielectric isolation, high voltage integrated circuits, etc.

It is well known (2) that capillary forces, surface tension, and wetting play a vital role in the behavior of thin liquid films. In this article, we will derive the wetting angle requirements which permit the crystallization of thin liquid films to proceed. We will see that the success with liquid silicon films encapsulated in silicon dioxide is the result of a particularly fortuitous combination of wetting angles for those two materials.

Wetting Angle Requirements

In general, there is no assurance that a thin liquid film will be stable. There is the well-known tendency for the liquid film to "ball up" and form droplets on the surface of the substrate. The condition for spreading of the liquid film on a substrate is that its wetting angle should be identically zero. Since this is very rare, a different approach is used. We will show that a solid capping layer on the liquid film greatly relaxes this severe wetting angle constraint, and permits wetting under more easily satisfied conditions.

For practical stability, the liquid film should spread to fill any possible voids in the film, as shown in Fig. 1. Let

Capping Layer

Fig. 1. A vertical cross-section through the thin liquid film. The liquid-vapor wetting angle, θ , is required to provide absolute stability against any voids which might be present in the film. The crystal-liquid angle α is required for high quality crystal growth and to prevent heterogeneous nucleation on the substrate. Note the radius of curvature r .

γ_{ls} and γ_{lc} be the surface energy (or tension) of the liquid with respect to the substrate and capping layer. Let γ_{vs} and γ_{vc} be the surface energy of the bare substrate and capping layer, respectively. The spreading of the liquid film should result in a net reduction of surface energy. Therefore

$$\gamma_{ls} + \gamma_{lc} - (\gamma_{vs} + \gamma_{vc}) < 0 \quad [1]$$

The Young-Dupre equation (2) for wetting angles, $\gamma_{vs} - \gamma_{ls} = \gamma_{vl} \cos \theta$, may be used to simplify inequality [1]

$$\cos \theta_1 + \cos \theta_2 > 0 \quad [2]$$

Inequality [2] states the wetting condition; the sum of the cosines of the wetting angles with respect to the substrate and the capping layer must be greater than zero. If the substrate and capping layer are made of the same material, then inequality [2] simply says that the wetting angle θ must be less than 90° . The wetting angle of liquid silicon on silica at the melting point has been independently measured (3) to be 87° , i.e., barely within the regime of stability! This must be regarded as extremely fortuitous. Of course, without a capping layer we go back to the condition $\theta_1 = 0$, i.e., wetting would be almost hopeless.

Since the surface tension γ_{vs} of the silica surface is thought to drop with increasing temperature, the angle θ_1 is thought (4) to become $> 90^\circ$ at temperatures 50-100 K above the silicon melting point. This probably explains the very narrow temperature window of stability in the crystallization of liquid silicon films on pure fused silica substrates. As a practical matter, it was found that the addition of a small amount of nitrogen (1) to the SiO_2 permitted the wetting conditions to be satisfied much more readily. The wetting angle of liquid silicon on Si_3N_4 is much less than 90° , having been measured (5) to be around 25° . It is understandable then that the addition of a small amount of Si_3N_4 to the SiO_2 might lower the wetting angle away from the condition of borderline stability, therefore broadening the temperature window of stability.

Thus far, we have considered wetting angles at the liquid-vapor interface, which controls the stability of the liquid film. Now we want to consider the crystal-liquid wetting angles, which will control the quality of crystal growth. It is a maxim (6) among crystal growers that the growth front should be convex away from the crystal. This permits any spurious crystal orientations to grow out to the edge and terminate there. A convex shape is guaranteed by wetting angles α_1 and α_2 both less than 90° . When α is greater than 90° , the Young-Dupre equation implies that γ_{xs} , the crystal-substrate interfacial energy, would be small, permitting easy heterogeneous nucleation of spurious grains at the surface of the substrate. In addition, the leading edge of the crystal growth would be

a cusp at one or both interfaces. Good crystalline quality is inherently unstable at such a cusp.

Therefore, the wetting angle requirement for good crystalline quality is that the angle α_1 enclosed by the liquid at the interface between the crystal and the substrate should be less than 90° . Likewise, the angle α_2 with respect to the capping layer should be less than 90° .

Recently, Celler (8) observed the angle formed by liquid silicon between crystalline silicon and silica. The angle he observed is $60^\circ < \alpha < 90^\circ$, again fortuitously in the favorable range for good crystal growth. The two wetting angle conditions may now be summarized as (i) $\cos \theta_1 + \cos \theta_2 > 0$, and (ii) $\alpha_1 < 90^\circ$ and $\alpha_2 < 90^\circ$.

Capillary and Thermal Gradient Forces

The convex interface in Fig. 1 between the crystal and the liquid experiences a pressure due to its curvature. This is a type of capillary pressure which can be computed from the equation of Young and Laplace (2)

$$P = \gamma_{xl} \left[\frac{1}{r} + \frac{1}{R} \right] \quad [3]$$

where γ_{xl} is the interfacial tension between crystalline and liquid silicon, r is the radius of curvature in the plane of Fig. 1, and R is the radius of curvature in the orthogonal plane coming out of the page. The smaller radius, r , may also be written as $r = t/2 \cos \alpha$, where t is the thickness of the film.

If the growth front is straight (looking down at the film from above) then $R = \infty$. A top view of the growing crystal-liquid interface in Fig. 2(a) shows not that the growth front is straight, but, rather that it is scalloped. The growing front is made up of a series of curved sections joined at cusps. The grain boundaries between adjacent crystal domains meet the growth interface at the tip of the cusps, as indicated schematically in Fig. 2(b). Because of this scalloped structure, the convex radius of curvature R of each scallop is finite.

The structure we observe differs from the faceted structure seen in the beautiful photographs by Geis *et al.* (1). We have found that the structure of the crystallization front depends on the speed of growth. At low speeds, $\approx 10^{-3}$ cm/s, the growth front is scalloped, as shown in Fig. 2(a). At higher speeds, some fraction of the cusps become deep, V-shaped facets. As the growth speed increases, more of the cusps become faceted. At a speed of 3×10^{-2} cm/s, the entire growth front is faceted, similar to Fig. 6 of Ref. (1). The facets are $\langle 111 \rangle$ crystal faces which form because of the kinetic barrier against crystal growth on that face. When the sample scanning direction is reversed, the facets disappear, but the scalloped structure remains. The reversibility of the scalloped structure indicates that it is

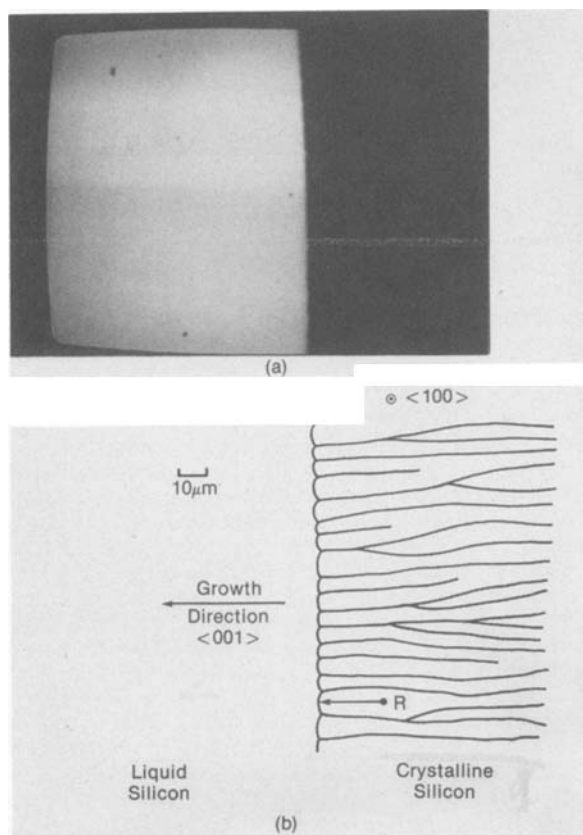

Fig. 2. (a) A video photograph of the crystal-liquid interface as seen in top view of the film. The crystal is the dark region on the right. Notice the presence of "scallop" on the growth front. The scallops join together at small pointed cusps, which are also seen on the growth front. (b) A schematic illustration of the grain boundary structure which might be visualized behind the growth front of Fig. 2(a). This grain boundary structure is typical of thin film crystal growth and has been observed in our experiments as well as others. It is implicit that the grain boundaries meet the growth front at the cusps. Note that R is the radius of curvature of a "scallop." A key question is: what is responsible for the nucleation of fresh grain boundaries in single-crystal material?

a minimum free energy configuration. In this article, we will explore mostly the regime of slow crystal growth. Nevertheless, we expect that many of the conclusions will apply equally well to more rapid crystal growth, where kinetic growth limitations begin to play a role.

In addition to the interfacial pressure due to the two radii of curvature r and R , Eq. [3], there is also a pressure term associated with the thermal gradient. Let z be the direction of crystal growth. The free energy associated with supercooling a layer of material of thickness dz is

$$\Delta G = \Delta S (T - T_m) dz dA \quad [4]$$

where ΔS is the entropy of melting per unit volume, T_m is the melting temperature, and dA is the area of the growth front. Assuming a linear temperature gradient, $(T - T_m) = (z - z_m)dT/dz$, Eq. [4] may be rewritten as an equation for interfacial pressure

$$P = \Delta S \frac{dT}{dz} (z - z_m) \quad [5]$$

where z_m defines the melting temperature isotherm. The pressure in Eq. [5] tends to push the crystal-liquid interface toward the position of the macroscopic melting point. That force is counteracted by the curvature pressure of the Young-Laplace Eq. [3], which pulls in the direction of supercooling. The actual amount of supercooling to be expected can be obtained by combining Eq. [3] and [5]

$$\Delta S \frac{dT}{dz} (z - z_m) = \gamma_{sl} \left[\frac{1}{r} + \frac{1}{R} \right] \quad [6]$$

Equation [6] gives the balance between capillary pressure and thermal gradient forces. Of the two terms on the right-hand side, the most important is $1/r$, since it is largest. If the other term is temporarily neglected, and $r = t/2 \cos \alpha$, then Eq. [6] simplified to

$$\Delta S \frac{dT}{dz} (z - z_m) = \gamma_{sl} \frac{2 \cos \alpha}{t} \quad [7]$$

Equation [7] shows that the equilibrium freezing point is depressed by surface tension forces in thin films. This may be seen even more clearly by substituting for the right-hand side of Eq. [7] using the Young-Dupre equation

$$\Delta S \frac{dT}{dz} (z - z_m) t = 2(\gamma_{xs} - \gamma_{ls}) \quad [8]$$

Equation [8] shows that the difference in surface free energy on the substrate between crystal and liquid is balanced by the volume free energy of supercooling. The equilibrium freezing point of thin films is therefore depressed by surface energy contributions. In the next section, we describe an experimental determination of the magnitude of this effect.

Freezing Point Depression

Equation [8] shows that fluctuations in thickness t can lead to variations in the positioning of the crystal growth front. Because of the importance of this phenomenon, we have made direct experimental confirmation of the effect and its magnitude.

In our experiment, thin films of silicon are deposited on top of fused quartz substrates and capped with SiO_2 . As shown in Fig. 3, the substrates are heated from below by CO_2 laser radiation, and the melt front is observed from above by a high power optical microscope. Since SiO_2 is opaque to CO_2 laser radiation, the silicon films are heated only indirectly by conduction. A knowledge of the thermal conductivity of quartz and the gaussian mode parameters of the laser beam permits a calculation of the radial temperature distribution on top of the substrate. We observe the effect of thickness variations on the microscopic position of the melting front and the freezing front of the thin film. In order to make a more precise measurement, we found it advantageous for both a thick film and a thin film to be present simultaneously. The thick film was 7000Å of polycrystalline Si deposited by chemical vapor deposition (CVD). This was capped by 2000Å of CVD SiO_2 . A second thin silicon layer only 800Å thick was then deposited and patterned by photolithography into stripes 35 μm wide. The whole structure was then capped again by 2000Å of CVD SiO_2 . A cross section of the final structure is shown in Fig. 4(b). By making the upper layer

Fig. 3. The experimental arrangement used to produce the photographs in Fig. 2(a) and 4(a) was very simple. The CO_2 laser was fully absorbed in the fused quartz substrate, and the heating was by conduction.

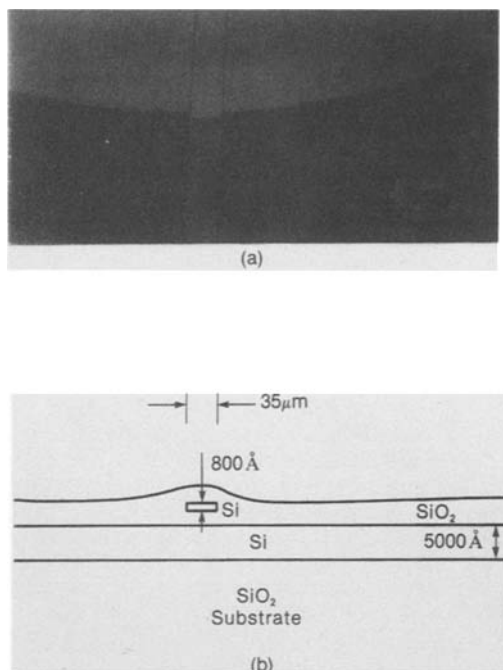

Fig. 4. (a) This photograph shows the depression of the freezing point in a thin film stripe in comparison to the thick film on which it rests. The dark region is crystalline silicon, and its crystallization front lags behind by approximately 1 K in the thin region relative to the thick region. The overall curvature is due to the round laser spot. (b) The cross section of the double layer structure of the film in Fig. 4(a). The Si, SiO₂, and Si layers were deposited in sequence. Then the thin silicon layer was patterned, and a final SiO₂ layer was applied.

in the form of narrow thin stripes, the position of the melt front in both the thin film and the thicker film can be observed simultaneously. Since the SiO₂ interlayer is only 2000 Å thick, the temperature difference between the two films due to thermal radiation from the top surface is only 0.02 K, which is much smaller than the temperature shift we are seeking.

A micrograph of the position of the two crystallization fronts is shown in Fig. 4(a). The overall curvature of the growth front is indicative of the round melted spot produced by the laser beam. Away from the center of the melted region the temperature drops. From Fig. 4(a) the freezing point temperature is clearly lower in the thin stripe than in the thicker material beneath it.

The shift in the freezing point of the thin stripe relative to the thick film was a strong function of the thickness of the stripe. There was no shift if the stripe had the same thickness as the underlying thick film. As the stripe thickness was reduced, the temperature shift rose roughly as the reciprocal of thickness t , in good agreement with Eq. [7].

Owing to the opacity of the substrate to the CO₂ laser, strong thermal gradients are produced, and thermal conductivity rather than radiation is the dominant thermal transport mechanism. We present a calculation of the radial thermal conductivity of a disk heated by a gaussian laser beam in the Appendix to this article. The result of that calculation is that the radial temperature gradient is given by

$$\frac{dT}{dr} = \frac{2r}{\omega^2} \frac{K_{av}}{RK(T)} \Delta T \quad [9]$$

where r is the radial distance from the center of the heated spot, ω is the gaussian radius of the laser beam, $K(T)/K_{av} = 1.17$ is the ratio of the thermal conductivity (9) of fused quartz at the melting point to the average thermal conductivity up to the melting point, $R = 2.02$ is the numerical value of an exponential integral, and ΔT is the overall temperature difference between the center of the heated spot and the edge of the fused quartz disk. The

temperature gradient in Fig. 4(a) is approximately 0.15 K/ μ m.

As the molten zone in Fig. 4(a) was moved back and forth, for example by moving the sample relative to the laser beam, a hysteretic effect was observed, *i.e.*, the thickness-induced shift in freezing point was different from the corresponding shift in melting point. Upon freezing of a stripe about 800 Å thick, the freezing point was depressed by 1 K relative to the thicker film beneath it. Upon remelting that same stripe, the melting point was virtually unchanged relative to the thicker film beneath it. Such hysteresis is common (2) in wetting angle measurements. An important distinction is therefore made between advancing wetting angles and receding wetting angles.

Such hysteresis is thought to be due to a change in surface energy of an interface due to its previous history. A freshly made crystal-SiO₂ interface has fairly high energy. After a period of time, there is probably significant reconstruction which lowers the surface energy. This may play the following role in our experiment. When the crystal advances into the liquid, it is forced to make a fairly energetic interface with the SiO₂, lowering the freezing point. When the liquid silicon advances into the crystal, it eliminates a low energy reconstructed crystal-SiO₂ interface. In that case, there is little or no melting point depression. Since we are interested in the crystallization of thin films, we will deduce the surface energies from freezing measurements rather than melting measurements.

Substituting the observed freezing point shift of thin stripes into Eq. [8] and using $\Delta S = 2.5 \text{ J/K cm}^3$ for the entropy of melting, we obtain for $(\gamma_{ss} - \gamma_{ls})$ the value of 80-100 erg/cm². As far as we know, there are no previous measurements that this numerical value might be checked against.

There are two precautions that should be mentioned in making this measurement. At the melting temperature of silicon, amorphous SiO₂ is a glass with a finite viscosity and is not absolutely rigid. We found that it was necessary to complete the measurements fairly quickly (< 10s at the melt) in order to avoid severe thickness distortions of the thin stripe. The thickness was double-checked after freezing by profilometry and interferometry. The second precaution has to do with the initial melting of the polycrystalline film. As we have mentioned, there is little or no melting point depression of the crystallized film. Nevertheless, there is a large melting point depression of the as-deposited polycrystalline silicon. This is probably due to the excess free energy associated with the large grain boundary density in the as-deposited film. These observations, which monitor the initial polycrystalline film rather than the crystallized film, are not incorporated with the data in this paper. Only the results on the crystallized film are summarized in Table I.

Instability of the Crystallization Front

We have learned from the previous section that the freezing point is a function of film thickness. Equation [8] connects the film thickness with the position z of the crystal growth front. A local fluctuation in film thickness can cause the crystal growth front to move forward or backward locally relative to the rest of the front. The key question in thin film crystal growth is how to produce the largest possible single-crystal domains. In this

Table I. The hysteresis between freezing and melting is thought to be due to reconstruction of the crystalline silicon-SiO₂ interface, lowering its surface energy

	Temperature depression in an 800 Å thick film relative to bulk ΔT	Surface energy difference with respect to SiO ₂ substrate $(\gamma_{ss} - \gamma_{ls})$

section, we suggest that locally concave regions of the growth front caused by local thickness fluctuations may be the birthplace of fresh subgrain boundaries. This would tend to limit the maximum possible crystal-domain size.

As indicated schematically in Fig. 2(b), and has been observed in virtually all thin film crystallization experiments, grain boundaries run together and recombine during crystal growth. Simultaneously, fresh grain boundaries initiate in previously single-crystal material. Both processes are shown schematically in Fig. 2(b), which is representative of typical (1,10) photographs of grain boundary structure. It is the second of these two processes, the birth of fresh grain boundaries, which we must confront.

In the second section of this article, we mentioned the crystal grower's maxim (6) that the growth front should always be convex away from the crystal. It is very difficult to visualize how a fresh subgrain boundary may nucleate from single-crystal material. What we propose here is that concave regions of the growth front are the birthplace of fresh subgrain boundaries. In these regions, dislocations would tend to become locked into place and lead eventually to small-angle grain boundaries.

Although the growth front might be concave in top view, nevertheless, a cross-section view as shown in Fig. 1 would still remain convex, as demanded by the second wetting angle condition. Therefore, the actual three-dimensional geometry of that region is a saddle point. We are actually proposing that crystal growth at saddle points permits the initiation of small-angle grain boundaries.

As discussed in the third section and shown in Fig. 2(a), the growth front itself is scalloped, meeting the pre-existing subgrain boundaries at cusps. Each scallop represents a single crystal domain and has a finite radius of curvature R . This convex curvature tends to stabilize the domain structure and inhibit the birth of fresh subgrain boundaries. A local thickness fluctuation will have no effect unless it is deep enough to retard the growth front sufficiently to change it from convex curvature to locally concave. If the scallop radius of curvature R is very small, it would take an extremely deep and spatially localized thickness fluctuation to change it from convex to concave. Conversely, if the scallop is wide, representing a large crystal grain, the scallop radius of curvature R is large indicating a relatively straight growth front. In that case, even a small thickness fluctuation can change R from convex to concave. Thus, large grains are relatively unstable to grain boundary nucleation and they tend to split in two. Meanwhile, small grains tend to be stable and to avoid further subdivision. Therefore, the grain boundary structure represented in Fig. 2(b) tends to be stabilized around a certain crystal-domain width.

In conclusion, we have shown that thickness fluctuations could be responsible for the initiation of subgrain boundaries by producing locally concave regions of the growth front. A scalloped growth front, consisting of a series of domains of convex curvature, tends to be stable against growth front fluctuations. The balance between these two tendencies produces the actual grain structure that is observed.

Conclusions

The crystallization of thin liquid films demands that two wetting angle conditions be simultaneously satisfied: (i) regarding the liquid-vapor interface on the substrate, and (ii) regarding the crystal-liquid interface on the substrate.

The position of the crystal growth interface is determined by the balance between capillary forces, which tend to push the growth front to temperatures below the bulk freezing point, and thermal gradient forces which tend to pull the growth front toward the freezing point. The balance between these forces results in an equilibrium depression of the freezing point of thin films of about 1 K for an 800Å thick film. This implies a surface

tension difference ($\gamma_{xs} - \gamma_{ls}$) of approximately 80-100 erg/cm².

The coupling between thickness and growth front position provides a mechanism for a crystal-growth instability. Thickness fluctuations can produce locally concave regions of the growth front, where subgrain boundaries could initiate. The convex curvature of the scalloped growth front counteracts this effect and tends to stabilize the crystal domain structure.

APPENDIX

In this Appendix, we derive the thermal gradient produced in a thermally conducting disk by a gaussian laser beam. The CO₂ laser is absorbed within 10 μm of the surface of fused quartz. In principle, both conduction and radiation could play a role in transporting this heat. For the $t = 0.75$ mm thickness fused quartz plates used in these experiments, radial thermal conduction plays the major role, owing to the strong thermal gradient induced by the laser beam with radiative heat loss being only a small correction.

The power per unit area absorbed from a gaussian laser beam is

$$P(r) = \frac{2P_0}{\pi\omega^2} \exp\left\{-\frac{2r^2}{\omega^2}\right\}$$

where ω is the gaussian radius of the laser beam, about 2.8 mm in our case. P is its total power, about 30W and r is the distance from the central axis of the beam. The total power inside a spot of radius r is

$$H(r) = P_0 \left(1 - \exp\left\{-\frac{2r^2}{\omega^2}\right\}\right)$$

The thermal conduction equation in the radial direction is

$$H(r) = \frac{K(T) 2\pi r t dT}{dr} \quad [\text{A-1}]$$

where $K(T)$ is the temperature dependent thermal conductivity of fused quartz. Integrating Eq. [A-1] yields

$$\frac{P_0}{2\pi t} \int_0^r \left(1 - \exp\left\{-\frac{2r'^2}{\omega^2}\right\}\right) \frac{dr'}{r'} = \int_{T_{\max}}^{T_{\min}} K(T) dT \quad [\text{A-2}]$$

The integral in Eq. [A-2] is an "Exponential Integral," which is (11) approximately $R = [\ln(2r^2/\omega^2) + 0.577]/2 = 2.02$ in our geometry. Let us write the difference between the temperature T_{\max} at the center of the laser spot and T_{\min} the temperature at the edge of the fused quartz disk as $\Delta T = T_{\max} - T_{\min}$. Then the integrated heat flow equation can be written

$$\frac{P_0}{2\pi t} = \frac{K_{av} \Delta T}{2.02} \quad [\text{A-3}]$$

Simplifying [A-1] by taking $r < \omega$ we obtain

$$\frac{dT}{dr} = \frac{P_0}{2\pi t} \frac{2r}{K(T) \omega^2} \quad [\text{A-4}]$$

Substituting [A-4] in [A-3]

$$\frac{dT}{dr} = \frac{2r}{\omega^2} \frac{K_{av}}{RK(T)} \Delta T$$

which is the same as Eq. [9] in the text.

ABSTRACT

Optical and electrical properties of lightly Si-doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ($x \approx 0.2$) layers grown by molecular beam epitaxy under various V/III flux ratios (1 to 4) and at various substrate temperatures ($720^\circ\text{--}780^\circ\text{C}$) have been studied by low temperature ($\approx 4\text{ K}$) photoluminescence and Hall measurements. Bound exciton (BE) peak intensity and Hall mobility increase with decreasing flux ratio and increasing substrate temperature. An excess reduction in the flux ratio causes the condensation of group III metals on epilayers. An optimum flux ratio was found to be 2.3 for the highest substrate temperature investigated here, 780°C . The peak intensity of the defect complex has been shown to be correlated with the growth conditions. It is suggested that the defect complex includes defects dominant under excess arsenic population. Reflection electron diffraction patterns from the growing $\text{Al}_{0.2}\text{Ga}_{0.8}\text{As}$ layers have been related to the growth conditions and the qualities of the epitaxial layers. A sample with the highest BE peak intensity and smooth surface has been grown with a metal-rich structure (3×1) present on the surface. A structure (1×1) has reproducibly been observed at intermediate amounts of group V/III composition on the surface between those for the (3×1) and the arsenic-stabilized (2×4) structures. Growth conditions which result in surfaces with a (1×1) structure are found to cause surface roughening on the epilayers.

Novel devices with $\text{Al}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}$ heterostructures, such as the high electron mobility transistor and lasers with extremely low threshold current density, have been fabricated by virtue of excellent controllability of film thickness and doping profile of molecular beam epitaxy (MBE) (1, 2).

The quality of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ is important for high performance devices (3). The substrate temperature during growth affects optical properties of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers grown by MBE (4, 5). The group V/III flux ratio is also an important growth parameter because it influences formation of nonstoichiometric defects that act as nonradiative centers (6). From a view of device applications of MBE-grown $\text{Al}_x\text{Ga}_{1-x}\text{As}$, in-depth understanding of the effect of the growth conditions on optical and electrical properties and surface morphologies is necessary, but little information has been available, particularly about the relation between the V/III flux ratio and the properties of $\text{Al}_x\text{Ga}_{1-x}\text{As}$.

Reflection electron diffraction (RED) patterns have often been used as indicators of growth conditions for GaAs growths on (001)-plane GaAs substrates by MBE. By real-time observation of RED patterns, empirical relationships have been established between the relative and absolute incident fluxes of Ga atoms and arsenic molecules and the surface reconstruction as a function of the substrate temperature (7, 8). This has enabled conditions to be defined for growth of stoichiometric epitaxial GaAs. In contrast, the relation between RED patterns and the growth conditions for $\text{Al}_x\text{Ga}_{1-x}\text{As}$ has not been reported.

In this paper, we report the effect of the V/III flux ratio and the substrate temperature on the optical and electrical properties of lightly Si-doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers grown by MBE. The layers were characterized by low temperature ($\approx 4\text{ K}$) photoluminescence (PL) and Hall measurements. The results show that both the optical and electrical qualities improve with decreasing flux ratio and increasing substrate temperature. We have also inves-

tigated RED patterns from growing $\text{Al}_{0.2}\text{Ga}_{0.8}\text{As}$ layers and have related these patterns to the growth conditions and the qualities of the epitaxial layers. We have found that high quality $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers with smooth surfaces are grown with the appearance of a (3×1) reconstruction pattern on the surface.

Experimental

The $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers were grown on semi-insulating (001)-plane GaAs substrates in a Varian MBE/GEN II system. The structure of samples consisted of a $2\ \mu\text{m}$, undoped GaAs buffer; a $1\ \mu\text{m}$, Si-doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layer ($n \approx 1 \times 10^{16}\ \text{cm}^{-3}$); and a $250\ \text{\AA}$, undoped GaAs cap layer. Elemental Al, Ga, As, and Si were used as source materials. All the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers were grown under group V/III flux ratios, $\gamma = \text{As}_4/(\text{Al} + \text{Ga})$, from 1 to 4 by changing the arsenic pressure and at substrate temperatures from 720° to 780°C . The molecular beam fluxes were estimated from pressure readings of an ion gauge that could be placed at the growth position of the substrate (9). The Al and Ga pressures were determined before elevating the cell temperature of the arsenic source. The growth rate of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers was approximately $1\ \mu\text{m}/\text{h}$. The Al mole fraction, x , in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers was determined from the energy of the BE emission and was found to be 0.19–0.25. The substrate temperature was measured by a spring-loaded thermocouple (W-Re) pressed to the rear of a Mo heating block, on which the substrate was mounted. The substrate temperature was also checked by a pyrometer with emissivity setting at 0.6. To assure the accuracy of the temperature, we observed the removal temperature of the native oxides from GaAs substrates and determined it to be about 590°C , which is close to previously reported datum, 580°C (10). Peak heights of the dominant residual gasses of $^{16}\text{H}_2\text{O}^+$ and $^{28}\text{CO}^+$ in the growth chamber, determined by a quadrupole mass analyzer, were always kept low during growth.

Table I. The electron concentrations and Hall mobilities of lightly Si-doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers grown under various growth conditions

Sample	x	Substrate temp ($^{\circ}\text{C}$)	Flux ratio	n (10^{15} cm^{-3})	μ ($\text{cm}^2 \text{ V}^{-1} \text{ s}^{-1}$)
(a)	0.22	750	1.1	1.4	3870
(b)	0.21	750	1.4	1.4	1820
(c)	0.19	750	1.9	Highly resistive	
(d)	0.22	780	2.3	8.8	3520
(e)	0.23	780	2.8	9.4	3030
(f)	0.21	780	3.8	10	3010

PL measurements were made at liquid helium temperature ($\approx 4 \text{ K}$). The 6471\AA line of a Kr ion laser was used as the excitation source. The incident excitation intensity was approximately 1 W/cm^2 . Luminescence was analyzed by a 1-m monochromator and detected with a cooled photomultiplier with an S-1 response. The slit width was adjusted to $100 \mu\text{m}$ or less, resulting in a resolution of less than 1\AA .

Hall measurements (van der Pauw technique) were made on cloverleaf-shaped samples at room temperature.

Surface structures were examined *in situ* by glancing incidence reflection electron diffraction at an accelerating voltage of 8 keV .

Results and Discussion

Table I summarizes measured free electron concentrations and mobilities of the samples grown under various V/III flux ratios and at substrate temperatures, 750°C and 780°C . Si atoms are dominantly incorporated as donors in MBE-grown $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers. Although the Si cell temperature of 1050°C was maintained over the growths, the electron concentrations for the samples (d), (e), and (f) grown at 780°C were higher than those for the samples (a), (b), and (c) grown at 750°C , indicating a decrease of compensation of the donors by acceptors. The dependence of electron concentration on the flux ratio is small at 780°C . On the contrary, the samples grown at 750°C and under high flux ratios ($\gamma > 1.9$) were highly resistive, and Hall measurements were not possible. This is probably caused by a full depletion of the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layer owing to low carrier concentrations (11).

The principal result shown in Table I is that lower flux ratios yield higher electron mobilities. The dependence of mobility on the flux ratio is small at 780°C , whereas the mobility for samples grown at 750°C decrease rapidly with the flux ratio. We attribute the reduction in the mo-

bility of the relatively compensated sample (b) to the scattering of free electrons by increased space-charge regions at the heterostructure interface and the surface, as suggested by Stringfellow (12).

PL spectra in Fig. 1(a)-1(f) are from the samples (a) to (f) in Table I. The PL spectra show peaks due to the BE transition, the Si donor to carbon acceptor (DA) pair recombination, and the defect complex in order of increasing wavelength. These assignments have been made according to our previous work (13).

The half-widths of the BE peaks, 4 meV in Fig. 1(a) and 1(d), are comparable to the half-widths observed in high quality GaAs with a similar carrier concentration, indicating the high quality of the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers. The BE peak intensities are dominated by excitons bound to silicon donors. We assume that high BE peak intensities reflect high qualities of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers. It is known that the intensity of the BE peak relative to intensity of the other recombination peaks depends on doping concentration and the laser excitation (14). Since the doping and laser excitation were not changed in this work, only residual impurities and defects that act as nonradiative recombination centers and deep level emission centers will reduce the peak intensity.

We studied the BE intensity as a function of the flux ratio and the substrate temperature to determine the optimum growth condition. The results are shown in Fig. 2, including additional data with x ranging from 0.19 to 0.25. Figure 2 shows that the BE peak intensity increases with decreasing flux ratio and increasing substrate temperature. We note that the curve for $T_s = 780^{\circ}\text{C}$ exhibits a maximum at the flux ratio of 2.3. The degradation at the lower flux ratio, 1.2, is caused by condensation of group III metal on the surface due to extremely high evapora-

Fig. 1. PL spectra from the samples (a) to (f) from Table I

Fig. 2. BE peak intensity as a function of the flux ratio for substrate temperatures of 750°C and 780°C .

tion of arsenic molecules. Thus, in order to obtain high quality $\text{Al}_x\text{Ga}_{1-x}\text{As}$, the flux ratio should be adjusted to near 2.3. The results are consistent with the results of the Hall measurements; sample (d) among the samples grown at 780°C has the highest electron mobility. Samples grown at a substrate temperature, 720°C , and under flux ratios ranging from 1 to 2.5, had lower PL intensities than those in Fig. 1.

The carbon acceptor-related emission intensity increases monotonically with decreasing flux ratio and increasing substrate temperature, as shown in Fig. 1. This is mainly due to reduction of nonradiative centers, as indicated by BE intensity changes in Fig. 2. This reveals that the carbon incorporation rate is relatively insensitive to the growth conditions but gradually increases with decreasing flux ratio and increasing substrate temperature. The flux ratio dependence of the carbon incorporation rate agrees with the case of GaAs (15).

The defect complex luminescence in GaAs has been suggested to be associated with carbon impurities (16). However, the detailed nature of the defect complex has not been determined even in the case of GaAs (16). Figure 1 shows that the defect complex peak intensity closely correlates with the growth conditions; the intensity decreases with decreasing flux ratio and is not observed at high substrate temperatures and low flux ratios. A slight shift of the complex peak toward a higher energy with an increased excitation intensity is observed, indicating that the peak is due to DA pair recombination (17). It is natural to attribute the donor to Si. The acceptor could be attributed to defects dominant under excess arsenic conditions.

Figure 3 shows RED patterns in $[\bar{1}\bar{1}0]$ azimuth from $\text{Al}_{0.2}\text{Ga}_{0.8}\text{As}$ surfaces which were grown at T_s equal to (a) 700° , (b) 750° , and (c) 780°C and under a constant flux ra-

Fig. 3. RED patterns in $[\bar{1}\bar{1}0]$ azimuth, for $\text{Al}_{0.2}\text{Ga}_{0.8}\text{As}$ surfaces growing at a rate of $1 \mu\text{m/h}$ and under a flux ratio of 1.7. The substrate temperatures are (a) 700° , (b) 750° , and (c) 780°C .

tio of 1.7. To determine the structures, RED patterns in $[\bar{1}\bar{1}0]$ azimuth were also observed. It was revealed that the RED patterns in Fig. 3 corresponded to (a) (2×4) , (b) (1×1) , and (c) (3×1) structures. However, it was difficult to distinguish diffraction features associated with centered structures in common with other RED work (8). Thus, we will refer only to primitive two-dimensional lattice structures. This does not mean that centered structures were not present, only that RED did not distinguish, for instance, $c(2 \times 8)$ and (2×4) (8).

The structures shown in Fig. 3 could be reversibly changed from one to another by changing the substrate temperature only. These structures could be reproducibly observed from wafer to wafer. The metal-rich reconstruction (4×2) commonly observed for (001)-plane GaAs surfaces was not observed for $\text{Al}_x\text{Ga}_{1-x}\text{As}$ surfaces in the temperature range studied here. It could, however, be observed by depositing Al and Ga without the arsenic flux on the (3×1) surface but immediately changed to a (1×1) structure due to the lack of surface mobility of metal atoms (18).

The structures shown in Fig. 3 also depend on the flux ratio. Figure 4 shows the map where the flux ratios that provide the structures are plotted as a function of the substrate temperature. In Fig. 4, points A and D correspond to the growth conditions of samples (a) and (d) in Table I that have the highest mobilities and BE peak intensities for substrate temperatures of 750° and 780°C , respectively. The surface of sample (d) is smooth, as is shown in Fig. 5a. The samples grown at the point marked by an asterisk, only 15% below the flux ratio at point D, exhibit matt surfaces due to condensation of group III metals. Therefore, we believe that excess arsenic evaporates during growth under the conditions corresponding to the (3×1) structure.

The (1×1) structure shown in Fig. 3(b) has not been observed for GaAs, but is common with surfaces including Al (18). The (1×1) structure suggests roughness of the surface. Figure 5 shows surface morphologies of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers ($x \approx 0.2$) grown under conditions of (T_s , γ) equal to 780°C , 2.3 (a), 750°C , 2.3 (b), and 720°C , 3.0 (c). These growth conditions are found, in Fig. 4, to be associated with (a) (3×1) , (b) (1×1) , and (c) (2×4) structures.

Fig. 4. Relationship between surface structures of growing $\text{Al}_{0.2}\text{Ga}_{0.8}\text{As}$ and growth conditions. The structures are $\bullet = (2 \times 4)$, $\otimes = (1 \times 1)$, and $\circ = (3 \times 1)$, as indicated. Characters A and D indicate the growth conditions for samples (a) and (d) in Table I and Fig. 1. Samples grown under the condition marked by the asterisk exhibit matt surfaces.

Fig. 5. Phase contrast photomicrographs of $1\ \mu\text{m}\ \text{Al}_x\text{Ga}_{1-x}\text{As}$ ($x \approx 0.2$) layers grown under the conditions of (T_s, γ) equal to (a) $(780^\circ\text{C}, 2.3)$, (b) $(750^\circ\text{C}, 2.3)$, and (c) $(720^\circ\text{C}, 3.0)$.

The (2×4) and (3×1) structures correspond to the smooth surfaces, but surface roughening is observed for the (1×1) structure, as shown in Fig. 5. Morkoc *et al.* have demonstrated that the surface morphology first degrades and later improves with increasing substrate temperature from 620° to 700°C for $x > 0.4$ and a constant V/III flux ratio of 4 (19). Our results show that such degradation occurs also for $x \approx 0.2$ under flux ratios lower than 3. These results now manifest that the growth condition for high quality $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers with smooth surfaces is rather critical and is restricted to the vicinity of point D in Fig. 4.

Conclusions

The effect of the growth conditions, V/III flux ratio, and substrate temperature on low temperature PL spec-

tra and Hall mobilities of lightly Si-doped $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers ($x \approx 0.2$) grown by MBE has been investigated. The Hall mobility and PL intensity increase with decreasing flux ratio increasing substrate temperature. The optimum flux ratio, 2.3, was obtained at a substrate temperature of 780°C . The peak intensity of the defect complex has been shown to be correlated with the growth conditions. It is suggested that the defect complex includes defects dominant under excess arsenic population.

The RED patterns from the growing $\text{Al}_{0.2}\text{Ga}_{0.8}\text{As}$ layers have been investigated and related to the growth conditions and the qualities of the epitaxial layers. The results show that the sample with the highest BE peak intensity and smooth surface has been grown with the (3×1) structure present on the surface.

Behavior of the Evaporated WO₃ Film in Li-Salt PC Electrolytes

Nobuyuki Yoshiike, Yasuo Mizuno, and Shigeo Kondo

Matsushita Electric Industrial Company, Limited, Central Research Laboratory, Moriguchi, Osaka 570, Japan

ABSTRACT

Electrochemical properties of evaporated amorphous WO₃ films on conductive glass substrates have been studied in propylene carbonate electrolytes, and the degradation of the electrochromic activity of the WO₃ film on storage in the electrolyte and the prevention of the degradation of the film have been investigated by cyclic voltammetry. The WO₃ films have also been analyzed by XPS, SIMS, and FT-IR spectra. We have confirmed that the thermodynamic degradation is accelerated by H₂O and LiClO₄ in the electrolyte. It is proposed that: first, H₂O contributes to the change of WO₃ into W(OH)_x; second, Li⁺ exchanges with the H⁺ of W(OH)_x; and then these reactions result in the formation of Li₂WO₄; and, consequently, in the negative shift of the cathodic reaction potential of the film. We have also confirmed that the degradation is prevented by addition of an acid, such as H₃PO₄ or acrylic acid, to the LiClO₄ PC electrolyte and by using LiBF₄ as a supporting electrolyte in place of LiClO₄.

Since the important paper of Deb (1), there have been numerous studies (2-8) of the electrochromic (EC) properties of WO₃ films. Electrochromic displays (ECD) using WO₃ thin films will be classified into three groups: WO₃/liquid electrolyte, WO₃/solid electrolyte, and WO₃/dielectric layer systems. The WO₃/liquid electrolyte systems have been studied frequently, and EC properties of this system, such as response and memory, are superior to other systems. Faughnan (5) reported a WO₃/glycerol-H₂SO₄ liquid electrolyte system which had a fast response, but it had problems of the dissolution of the WO₃ film on the shelf and the corrosion of transparent electrode during color/bleach cycling (9). In order to overcome these problems, nonaqueous organic solvents have been investigated as the electrolyte solvent. Randin (9) reported that evaporated WO₃ film dissolved about 10% under storage for 90 days at 50°C in acetonitrile and dimethylformamide, etc., but the film dissolution was negligibly small in γ -butyrolactone and propylene carbonate (PC) under the same conditions. Furthermore, Li salts have been used in the supporting electrolytes as a cation source in place of protons because the mobility of Li is the next highest. Problems of the dissolution and the corrosion have been solved by using LiClO₄ PC electrolyte.

However, even in the WO₃/LiClO₄ PC system, the problem of degradation of electrochromic activity on storage for long time and/or cyclic drive still remained.

Schlottter *et al.* (10) reported that the degradation with cycling was caused by ion exchange between Li and protons of W(OH)_x. Morita *et al.* (11) also reported that the origin of the mechanism dominating the degradation was essentially the accumulation of Li in the film with SIMS data and Auger analysis.

In this paper, the mechanism of degradation of the WO₃ film on storage in Li salt-PC electrolytes and preventive methods for the degradation will be described.

Experimental

Preparation of WO₃ films.—WO₃ films were deposited by an electron beam evaporation method. WO₃ targets (99.99%) were supplied by Furuuchi Kagaku Company, Limited. The deposition rate was 4-5 Å/s the deposition angle was varied within 40° with a planetary rotation, and the substrate temperature was usually maintained at 80°C after keeping at 110°C for 5 min. The total gas pressure in the chamber during the evaporation process was controlled by N₂ gas-introduction method to be 5-6.5 × 10⁻² Pa. Deposited WO₃ films were analyzed by electron diffraction and found to be amorphous. The packing density of the film calculated from film thickness and weight was 5.38 g/cm³, and the refractive index evacuated from the interference patterns of visible absorption and film thickness was 1.85.

The substrates were In₂O₃-coated glass (20 Ω/cm²) used for electrochemical measurements, XPS, and SIMS analyses, and Si wafers for IR spectra.

Electrochemical measurements.—Cyclic voltammetry measurements were performed with a potentiostat (Hokuto Denko, Model HA-301), which was supplied with voltage from a function generator (same company, Model HB-104). Coulometric measurements were performed with a coulomb meter (same company, HF-201). The WO₃ film thickness and area were 3000 Å and 0.3 cm², respectively. The counterelectrode was a Pt plate, and the reference electrode was a saturated calomel electrode (SCE). The electrolytes were propylene carbonate (PC) solutions containing 0.3M LiClO₄. PC (the first grade, Wako Junyaku) was freshly distilled under vacuum, LiClO₄ (purity 99%, Mitsuwa Kagaku) was used. Ar gas was bubbled before measurements.

H₂O content in the electrolytes was checked in each case by the Karl-Fisher method with an Aquacounter (Hiranuma Seisakusho, Model AQ-3B), and these concentrations were typically 0.01-0.03M.

Analyses of WO₃ films.—IR spectra were taken with a FT-IR spectrometer (Nihon Denshi, Model JIR-40D). For these measurements, the film thickness of WO₃ on a Si wafer was 3000 Å. Resolution was 8 cm⁻¹, and the number of sampling for one measurement was 400 cycles.

X-ray photoelectron spectroscopy (XPS) measurements were performed using a VG ESCALAB-5 electron spectrometer with Al K α x-ray sources (10 kV, 20 mA). The energy resolution for the Ag 3d_{5/2} photopeak was 1.1 eV at 20 eV pass energy. The normal pressure in the analyzer chamber was below 6 × 10⁻⁸ Pa.

Three kinds of powder, WO₃ (99.9%, Mitsuwa Kagaku) H₂WO₄, and Li₂WO₄ (Superfine grade, Kanto Kagaku), were used for IR and XPS analyses as reference samples.

Secondary ion mass spectrometry (SIMS) measurements were performed using a CAMECA IMS-3F, the primary ion was O₂⁺, and its ion beam current and energy were 500 nA and 8 keV, respectively.

Preparation of ECD cells.—ECD cells used for life test were constituted as follows: In₂O₃ (20 Ω/cm²)/WO₃ (3000 Å, 1.9 cm²)/Li salt-PC electrolyte (2 ml)/carbon counterelectrode.

Results and Discussions

Degradation of WO₃ film in LiClO₄ PC electrolytes.—The electrochemical properties of the WO₃ films which were stored in 0.3M LiClO₄ PC electrolytes containing H₂O less than 0.01M were investigated. The storage experimental conditions were as follows: WO₃ films (3000 Å thick, 0.3 cm²) evaporated on In₂O₃-coated glass were dipped completely in 1 ml of PC electrolytes in glass tubes (8 mm diam), air in the tubes was replaced by Ar gas, the glass tubes were sealed by melting and stored at 70°C for various storage times. After storage, the WO₃ films were taken out from the tube and rinsed quickly with acetone, then dried with a N₂ gas blower. Cyclic voltammograms of the WO₃ films were measured in

freshly prepared 0.3M LiClO₄ PC electrolyte, and shown in Fig. 1.

In Fig. 1, the cathodic current is associated with the coloring process of the film and the anodic current following scan reversal with the bleaching process. The starting potential (E_c) where the cathodic current of the WO₃ film begins to flow, was about +360 mV vs. SCE for the as-deposited WO₃ film, whereas that of the WO₃ film stored in the LiClO₄ PC electrolyte for 20h at 70°C was +50 mV vs. SCE; that is, the starting potential (E_c) was drastically shifted to the negative side by storage in the LiClO₄ PC electrolyte at high temperature for relatively short time. The shift continued gradually with storage time after the initial drastic shift. These cathodic shifts result in the decrease of the injection charge in the coloration reaction, which contributes to the degradation of electrochromic activity of the WO₃ film. With respect to the anodic oxidation of the colored WO₃ film, the anodic reaction become fast with the storage.

The thickness of the WO₃ film stored in the electrolyte at 70°C for 500h (Fig. 1, curve 5) was confirmed to be unchanged, so that the dissolution of the WO₃ film was negligibly small. In spite of various kinds of WO₃ films having various E_c corresponding to the states of water in WO₃ (12 ~ 13), the potential shifts of these WO₃ films had the same tendency.

The relationship between the cathodic reaction potential shift and the quantity of LiClO₄ PC electrolyte in glass tubes was investigated and shown in Fig. 2. It is shown that the potential shift is increased with increase of amount of LiClO₄ PC electrolyte used for storage. There-

Fig. 1. Cyclic voltammograms for WO₃ films (3000Å, 0.3 cm²) in the freshly prepared 0.3M LiClO₄ PC electrolyte at 0.2 V/s scan rate. 1: As-deposited. 2: Stored in 3 ml 0.3M LiClO₄ PC electrolyte at 70°C for 20h. 3: Stored for 43h. 4: Stored for 113h. 5: Stored for 500h.

Fig. 2. Plots of starting potentials of cathodic reactions for WO₃ films at 0.2 V/s scan rate as a function of storage time at 70°C in 0.3M LiClO₄ PC electrolyte. The quantity of the electrolyte for the storage was (1) 0.3, (2) 3, and (3) 15 ml.

fore, the degradation of electrochromic activity the WO₃ film is accelerated with the quantity of the electrolyte.

The decrease of the injected charge on storage in PC electrolyte also depends on the concentration of the supporting electrolyte (LiClO₄), as shown in Fig. 3. In Fig. 3, Q_w is the cathodic injected charge of the WO₃ film stored in PC electrolytes for 15h at 70°C under the condition of the cyclic voltammetry from +1.0V to -600 mV vs. SCE with 200 mV/s scan rate, and Q_{w0} is the initial value.

In actual electrochromic display (ECD) cells, the degradation of electrochromic activity on storage at high temperature was observed and is shown in Fig. 4. In Fig. 4, Q_w is the cathodic injected charge, which is proportional to coloration optical density under the condition of applied pulse voltage between the WO₃ working electrode and the counterelectrode for 1s and Q_{w0} is the initial value, after the aging of cells at 70°C for 15h.

We confirmed that the potential shift of the counter-electrodes of the cells after the aging was negligibly small, so that the degradation of the electrochromic activity of ECD cells on storage at high temperature corresponds to the cathodic potential shift of the WO₃ film. Therefore, the degradation is accelerated with H₂O in PC electrolyte, as shown in Fig. 4.

The temperature dependence of the degradation of ECD cells is shown in Fig. 5. In Fig. 5, there is a linear relationship between $\log(t)$ and $1/T$, where t is storage time and T is storage temperature (K).

However, the Arrhenius equation for the rate constant k is

$$k = Ae^{-E_a/RT} \quad (1)$$

where A is a constant, R is the gas constant, and E_a is the activation energy of the reaction.

If we postulate that the degradation function $f(x)$ is represented as follows

$$f(x) = kt \quad (2)$$

we obtain

Fig. 3. Plots of Q_w/Q_{w0} as a function of LiClO₄ concentration in the electrolyte used for the storage.

Fig. 4. Plots of Q_w/Q_{w0} of various ECD cells as a function of storage time at 60°C. H₂O concentration in the 0.3M LiClO₄ PC electrolyte was (1) 0.014, (2) 0.017, (3) 0.035, and (4) 0.072M.

Fig. 5. $1/T$ dependence of lifetime of ECD cells until (1) the degradation $Q_w/Q_{w0} = 0.9$ and (2) $Q_w/Q_{w0} = 0.8$. Storage in $0.3M$ $LiClO_4$ + $0.036M$ H_2O PC electrolyte at $70^\circ C$.

$$t = \frac{1}{A} f(x) e^{E_a/RT} = ce^{E_a/RT} \quad [3]$$

where $c = 1/A f(x)$, and $f(x)$ is equal to Q_w/Q_{w0} , so that we can obtain the quantity of E_a using Eq. [3]. From the slope in Fig. 5, E_a was estimated to be 4.5 kcal/mol.

Consequently, from the results mentioned above, the degradation of the electrochromic activity on storage corresponds to the cathodic potential shift, which is caused by some thermodynamic reactions of the WO_3 layer with Li content and H_2O content.

Mechanism of degradation.—SIMS of the WO_3 films stored in PC electrolyte were measured, and their depth profiles are shown in Fig. 6. In Fig. 6, sample 1 was only washed with PC solvent and acetone successively, and it was dried by a N_2 gas blower. Sample 2 was dipped in $0.3M$ $LiClO_4$ PC electrolyte containing $0.01M$ H_2O for 10s and then treated the same as sample 1. Sample 3 was stored in $0.3M$ $LiClO_4$ PC electrolyte containing $0.01M$ H_2O in a sealed glass tube for 120h at $70^\circ C$, and then treated the same as sample 1.

A molecular ion of OLi^+ (mass = 22) was used for the evaluation of Li content in WO_3 film, because of two facts that secondary ion intensities of Li^+ (mass = 7) and Li^+ isotope (mass = 6) were too strong to get a good linearity between Li content and the signal intensity, and that OLi^+ (mass = 23) overlaps Na (mass = 23).

Each signal intensity of OLi^+ was normalized using a signal intensity of a main component, W^+ isotope (mass = 184). It can be said that Li^+ permeates smoothly into the WO_3 layer by quick dipping in the electrolyte for relatively short time (10s) and accumulates homogeneously in the film, and that the permeation of Li into the layer is accelerated by storing at high temperature.

It was difficult to wash away Li in the layer, even in the case of sample 2.

In spite of smooth permeation of Li, ClO_4^- did not permeate into the WO_3 layer (see the Cl depth profiles in Fig. 6). From these results, the degradation of the WO_3 film would correspond to an accumulation of Li in the film, but the degradation will not directly depend on Li concentration in the film. This is because if the degradation which associates with the negative potential shift of the cathodic reaction potential were only caused by accumulation of Li in the film, the negative potential shift of the WO_3 film by quick dipping in $LiClO_4$ PC electrolyte would be observed, compared with the potential of the WO_3 film in non-Li electrolyte (e.g., H_2SO_4 solution); but,

Fig. 6. SIMS depth profiles of WO_3 films. 1: No treatment. 2: Dipped in the $LiClO_4$ PC electrolyte for 10s. 3: Stored in the electrolyte for 120h at $70^\circ C$.

in fact, the cathodic reaction potential of as-deposited WO_3 film in $LiClO_4$ PC electrolyte is located at the more positive side about 250 mV more than that of same film in H_2SO_4 electrolyte (12). Therefore, it is better for the degradation process to be discussed on the basis of Li which can be separated from free Li^+ , remains in the void of the film, and/or is injected in Xerogel structure (10) and has a interaction with W-O such as W-O-Li.

FT-IR spectra of the WO_3 film stored in $0.3M$ $LiClO_4$ PC electrolyte at $70^\circ C$ for 500h in a sealed glass tube are shown in Fig. 7.

The O-H stretching broad peak at 3400 cm^{-1} was decreased, and the W-O stretching broad peak (~ 650 cm^{-1}) changed to a broad peak having several shoulders on storage.

IR spectra of WO_3 , H_2WO_4 , and Li_2WO_4 powders are shown in Fig. 8 for comparison.

From these results, IR spectrum of the degraded WO_3 film may be similar to a mixed spectrum of H_2WO_4 and a small amount of Li_2WO_4 , so that it seems that the internal surface of $W(OH)_x$ would change to Li_2WO_4 on storage in $LiClO_4$ PC electrolyte.

The $W_{4f_{7/2}}$ electrons binding energy and O_{1s} electrons binding energy of WO_3 film and powders of WO_3 derivatives were measured using XPS analysis and are shown in Fig. 9-10 with reference data of WO_3 , H_2WO_4 , and Li_2WO_4 (14-21).

The uncertainty of measured binding energy was estimated to be ± 0.3 eV, and the electron escape depth of $W_{4f_{7/2}}$ electrons was estimated approximately to be 20Å by Penn's equations (22).

The $W_{4f_{7/2}}$ and O_{1s} electrons binding energies of the WO_3 film which was stored in air for 144h after the evaporation will be in agreement with those of $WOOH$ (14) within the experimental error. The surface of the WO_3 film before dipped in PC electrolyte will be a $W(OH)_x$ structure as shown in Fig. 9, 10 and Ref. (10, 12).

The $W_{4f_{7/2}}$ electrons binding energy of the WO_3 film stored in $0.3M$ $LiClO_4$ PC electrolyte for 144h at $70^\circ C$ is essentially identical with that of WO_3 and Li_2WO_4 powder measured in our laboratory. It can be said that the surface of the degraded WO_3 film is constructed with WO_3 or Li_2WO_4 ; however, if we consider the SIMS and IR experimental results, the surface of the degraded WO_3 film will be constructed with Li_2WO_4 .

Consequently, it seems reasonable to assume that the surface state of the WO_3 film is changed by the H-Li ion exchange in $LiClO_4$ PC electrolyte such as in the following thermodynamic reaction

and this exchange reaction will result in the formation of Li_2WO_4 .

Fig. 7. FT-IR spectra of WO₃ films (1) as-deposited and (2) stored in 0.3M LiClO₄ PC electrolyte at 70°C for 500h.

Prevention of degradation.—Cyclic voltammograms of WO₃ films which were stored in various kinds of electrolytes in sealed glass tubes were measured and are shown in Fig. 11-12. The storage experimental conditions were as follows: WO₃ films (3000Å thick, 0.3 cm²) on In₂O₃-coated glass were dipped completely in PC electrolytes in glass tubes (8 mm diam), air in the tubes was replaced by Ar gas, the glass tubes were sealed by melting, and then stored at 70°C for various storage times. After storage, the WO₃ films which were taken out from the electrolyte were rinsed quickly with acetone and dried with a N₂ gas blower.

In Fig. 11, the starting potential (E_c) of the cathodic reduction of the WO₃ film was shifted to negative side about 300 mV on storage in 0.3M LiClO₄ PC electrolyte at 70°C for 1000h, but that of the WO₃ film stored in 0.3M LiClO₄ PC electrolyte containing 0.01 volume percent (v/o) H₃PO₄ under the same condition was scarcely shifted and the degradation of electrochromic activity was not observed.

In Fig. 12, the starting potential (E_c) of the cathodic reduction of the WO₃ film stored in 0.3M LiClO₄ PC electrolyte containing 5 v/o acrylic acid was also scarcely shifted to negative side.

From these results, the degradation of the WO₃ film in Li salt PC electrolyte, corresponding to the ion exchange between Li and H of W(OH)_x, will be prevented by the addition of an acid to the electrolyte. However, propylene carbonate is easy to decompose under coexistence of acids; therefore, it is undesirable to add a strong acid to the electrolyte.

Furthermore, we have found that the degradation of the WO₃ film is also prevented by using LiBF₄ as a supporting electrolyte.

Cyclic voltammograms of the WO₃ films stored in 0.3M LiBF₄ PC electrolyte containing 0.01M H₂O in sealed glass tubes at 70°C were measured and are shown in Fig. 13. The storage experimental conditions were as same as mentioned above.

In Fig. 13, compared to the case of LiClO₄ supporting electrolyte, as shown in Fig. 11, curve 2, the starting potential (E_c) of the cathodic reduction of the WO₃ film was rarely shifted to negative side by the storage at 70°C for 1000h. Moreover, there was no observation of gas evolution by decomposition of PC solvent.

The preventive effect on the degradation of the WO₃ film in LiBF₄ PC electrolyte can be attributed to the facts that LiBF₄ is especially effective in this regard, as can be

Fig. 8. FT-IR spectra of (1) WO₃ powder, (2) H₂WO₄ powder, and (3) Li₂WO₄ powder.

Fig. 9. XPS spectra of W_{4f} . 1: As-deposited WO_3 films. 2: Stored in $0.3M LiClO_4$ PC electrolyte at $70^\circ C$ for 144h. 3: WO_3 powder. 4: Li_2WO_4 powder. 5: H_2WO_4 powder. Reference data (14-21).

seen from aqueous PH determination (generally acidic, if hydrolyzed) (23), and that $LiBF_4$ is able to dissociate H^+ from H_2O containing in the electrolyte.

An FT-IR spectrum of the WO_3 film on a Si wafer stored in $0.3M LiBF_4$ PC electrolyte in a sealed glass tube at $70^\circ C$ for 500h is shown in Fig. 14 with reference IR data.

In Fig. 14, showing long-time storage in $LiBF_4$ PC electrolyte, the shoulder of O-H stretching broad peak at 3400 cm^{-1} was decreased as same as in $LiClO_4$ PC electrolyte, while the W-O stretching broad peak at 650 cm^{-1} was rarely changed. WO_3 film in $LiBF_4$ PC electrolyte was more stable than in $LiClO_4$ PC electrolyte.

Fig. 10. XPS spectra of O_{1s} of the same samples as shown in Fig. 9. Reference data (14-21).

A SIMS depth profile of the WO_3 films stored in $0.3M LiBF_4$ PC electrolyte is shown in Fig. 15.

Sample 1 was merely dipped in $0.3M LiClO_4$ PC electrolyte for 10s; sample 2 was stored in $0.3M LiBF_4$ PC electrolyte for 120h at $70^\circ C$; and sample 3 was stored in $0.3M LiClO_4$ PC electrolyte for 120h at $70^\circ C$.

Molecular ion of OLi^+ (mass = 22) was used for the evaluation of Li content in WO_3 films, and each signal inten-

sity of OLi was normalized using a signal intensity of a main component W⁺ (mass = 184).

Li content of the WO₃ film stored in LiBF₄ PC electrolyte was about one-half smaller than that of the case of LiClO₄ (Fig. 15). Considering the free Li⁺ remaining in the void of the WO₃ film by merely dipping in LiClO₄ PC electrolyte (Fig. 15, curve 2), it can be assumed that the ion exchange between Li⁺ and H⁺ of W(OH)₂ is depressed in LiBF₄ PC electrolyte.

Fig. 14. FT-IR spectra of WO₃ films on Si wafers. 1: As-deposited. 2: Stored in 0.3M LiBF₄ PC electrolyte at 70°C for 500h. 3: Stored in 0.3M LiClO₄ PC electrolyte at 70°C for 500h.

Fig. 15. SIMS depth profiles of WO₃ films. 1: Dipped in 0.3M LiClO₄ PC electrolyte for 10s. 2: Stored in 0.3M LiBF₄ PC electrolyte for 120h at 70°C. 3: Stored in 0.3M LiClO₄ PC electrolyte for 120h at 70°C.

In actual ECD cells, the degradation of electrochromic activity on storage at 70°C was investigated and is shown in Fig. 16.

The electrolytes of samples 1 and 2 were 0.3M LiBF₄ and 0.3M LiClO₄ PC solutions, respectively. The quantities of cathodic injected charge into the WO₃ films were measured under the condition of applied pulse voltages between the WO₃ electrode and the counterelectrode for 1s. Q_{w0} is the initial value of the quantity of cathodic injected charge into the WO₃ film after aging for 15h at 70°C, and Q_w is that of stored for various storage times after aging, in which Q_w is approximately proportional to coloration optical density. The potential drift of counterelectrode of the cells on storage at 70°C for 1000h after the aging was negligibly small. In Fig. 16, it is confirmed that the degradation of the electrochromic activity of ECD cells using LiBF₄ as the supporting electrolyte was remarkably small, compared with that of using LiClO₄.

The temperature dependence of the degradation of the ECD cells is shown in Fig. 17. There are linear relationships between $\log t$ and $1/T$, where t is storage time until $Q_w/Q_{w0} = 0.9$, and T is storage temperature (K). From the slopes of straight lines in Fig. 17, the activation energies of the degradation reaction of ECD cell using LiBF₄ PC electrolyte and LiClO₄ PC electrolyte were estimated 7.0 and 4.5 kcal/mol, respectively. Therefore, LiBF₄ PC sys-

Fig. 16. Plots of Q_w/Q_{w0} of ECD cells as a function of storage time at 70°C in the electrolyte. 1: 0.3M LiBF_4 + 0.2M H_2O . 2: 0.3M LiClO_4 + 0.3M H_2O .

tem has a larger amount of the activation energy for the degradation reaction corresponding to the ion exchange between Li^+ and H^+ of $\text{W}(\text{OH})_x$ than that of LiClO_4 PC system. It is, therefore, preferable to use LiBF_4 as the supporting electrolyte for ECD cells using WO_3 film.

Conclusion

The cathodic reduction potential of the evaporated WO_3 film is shifted to negative side on storage in LiClO_4 PC electrolyte, and this causes the degradation of the electrochromic activity of the film.

The degradation depends not only on the H_2O concentration, but also on the LiClO_4 supporting electrolyte concentration.

It seems reasonable, for the degradation, to assume that H_2O in the electrolyte contributes at first to the change of WO_3 into $\text{W}(\text{OH})_x$ and then Li^+ exchanges with the H^+ of $\text{W}(\text{OH})_x$, and that the exchange results in the formation of Li_2WO_4 .

The degradation of the WO_3 film in Li salt PC electrolyte caused by the ion exchange between Li^+ and H^+ of $\text{W}(\text{OH})_x$ can be prevented by the addition of acids and/or acidity compounds (e.g., LiBF_4) to PC electrolyte; however, an acid is undesirable for an additional agent because it causes decomposition of PC, then LiBF_4 is a preferable supporting electrolyte to prevent not only the ion exchange, but also the decomposition of PC.

Acknowledgments

We are grateful to Dr. E. Hirota, the Assistant-Director of Central Research Laboratory for permission to publish the paper and for encouragement. We thank S. Kohiki, K. Tsukamoto, and M. Kamikawaji, members of TechnoResearch Department, for performing the XPS, SIMS, and FT-IR observations and for helpful discussions.

The Etching of InP in HCl Solutions: A Chemical Mechanism

P. H. L. Notten

Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

ABSTRACT

The etch rate of InP in solutions of high HCl concentration was shown to be independent of the applied potential in a wide potential range negative with respect to the flatband value. Dissolution of the solid led to the formation of PH₃. The etch rate, which was not mass-transport controlled, was first order in molecular HCl concentration. The results lead us to conclude that, in HCl etchants, InP is dissolved by a purely chemical mechanism. The influence of chemical etching on the anodic behavior of InP in these electrolytes is described.

Aqueous etching of III-V materials is often an important step in device technology (1, 2). While anodic etching is sometimes used (3), the necessity of making electrical contact to slices of small dimensions is invariably a disadvantage. Methods not involving an external current or voltage source are therefore favored (1, 2). Such methods can be divided into two classes: "electroless" and "chemical" dissolution. Electroless dissolution involves two separate potential-dependent electrochemical reactions: the oxidation of the solid and the reduction of an oxidizing agent. The principle is illustrated in Fig. 1 for the etching of a p-type III-V semiconductor (4). For these materials, holes in the valence band are required at the surface for bond breaking. As a result, the anodic dissolution current increases at potentials close to the flatband value (V_{fb}) as shown in curve (a). For electroless dissolution, holes must be supplied by an oxidizing agent in solution. If the distribution function of the oxidizing agent overlaps with the valence band of the semiconductor, then reduction via hole injection into the valence band is expected [curve (b)]. Here, we have assumed that the reduction reaction is diffusion controlled, i.e., the cathodic partial current is independent of potential. Curve (c) represents the total measured current-potential curve in the electrolyte containing the oxidizing agent. At the rest potential, the anodic and cathodic partial currents are equal. If the potential is changed from this value using an external source, then the etch rate of the semiconductor will, of course, also change.

Gerischer and co-workers (5, 6) have shown that semiconductors can be dissolved by a purely chemical mechanism, which is characterized by the absence of any influence of the surface carrier concentration on the etch rate. Such behavior is observed with bifunctional agents, such as halogen or H₂O₂ molecules, which are capable of forming two new bonds with the semiconductor surface more or less simultaneously. For GaAs dissolution in bromine solution, for example, they suggest a coordinated reaction sequence involving the breaking of Ga-As and Br-Br bonds and the simultaneous formation of Ga-Br and As-Br bonds.

Etchants based on HCl are widely used for InP semiconductor devices (7, 8). The presence of other acids in the HCl solution has a significant influence on the etch rate. However, InP does not dissolve in conventional etchants involving simple oxidizing agents. In order to resolve the question of the dissolution mechanism, we studied both the etching and electrochemistry of p-InP in various HCl solutions.

Experimental

The p-type InP slices used in this work were made from liquid-encapsulated Czochralski material with a carrier

density in the range $1-2 \times 10^{18} \text{ cm}^{-3}$. The (100) face was exposed to the solution. The diameter of the electrodes was 3 mm, with the exception of the InP rotating disk, which had a diameter of 4 mm.

The current-potential measurements were carried out under potentiostatic control in a conventional cell using a Pt counterelectrode and a saturated calomel electrode (SCE) as reference. All potentials are given with respect to this SCE. A Solartron 1172 Frequency Response Analyser was employed for determining the flatband potentials. All impedance measurements were carried out at a frequency of 10 kHz.

The total dissolution rate of InP at various potentials was determined analytically by measuring the indium concentration in the etching solution by inductively-coupled-plasma (ICP) emission spectrometry. The etchant was passed over the InP electrode, which was mounted in a glass microelectrochemical flow cell as described by Haroutiounian *et al.* (9). Indium concentrations as low as 0.5 ppm could be determined with a relative accuracy of about 5%. An LKB Varioperpex peristaltic pump was used to pump the solution through the flow cell. The flow rate of the solution, mainly deter-

mined by the lower limit of the indium detection, was in the range from 0.2 to 1.0 ml/min.

The gas was analyzed qualitatively using the color-detector tube method ("Dräger" tube), which in our case gave a color reaction specific for phosphine. A gas burette was used for the quantitative gas analysis.

Results

Flow-cell experiments.—In Fig. 2, results are given for the potentiostatic etching of p-InP in the dark in HCl solutions. Figure 2a shows the current-potential curves of this electrode in 3M and 6M HCl. At negative potentials the current is very low in both cases. In the vicinity of the flatband potential ($V_{FB} = 0.73V$ vs. SCE) the anodic current increases, as expected. It should be noted that the anodic curve for the 6M HCl solution is shifted slightly in the cathodic direction with respect to that for the 3M solution.

The total dissolution rate, according to the ICP analysis, is shown in Fig. 2b as a function of the potential. For the 3M HCl solution, the dissolution rate follows the current closely. At negative potentials the etch rate (r_t) is very low and increases considerably near the flatband potential. If we assume that in this case etching is due solely to anodic dissolution, then it can be easily shown that six holes are required to dissolve one InP entity. The total etch rate potential curve for the 6M HCl case differs markedly from that of the corresponding current-potential curve. This difference is most obvious at negative potentials, at which the InP dissolves at a rate essentially independent of applied potential. Since no cathodic reaction occurs in this range, we must conclude that InP is chemically dissolved by HCl. If we assume that anodic dissolution in 6M HCl here also requires six holes per InP, then the chemical etch rate can be calculated from the total etch rate and the measured anodic current. Figure 2c shows that the chemical etch rate (r_{chem}) remains

Fig. 2. Potentiostatically measured current-potential curves (a), total etch rate as a function of the electrode potential (b), and chemical etch rate as a function of the electrode potential (c) for a p-InP electrode in the dark in a 3M HCl (●) and 6M HCl (x) solution in water.

constant, even at potentials at which the electrode dissolves anodically.

A further example is shown in Fig. 3 for 1.5M HCl in concentrated acetic acid solution. Etchants based on HCl and acetic acid are often used in InP technology (7). Figure 3a shows the current-potential curve, and Fig. 3b the calculated chemical etch rate as a function of the electrode potential. The results in the cathodic region are similar to those found with 6M HCl solution; the current is low and a high chemical etch rate is found. The slow increase of the chemical etch rate with potential is probably due to a roughening of the electrode surface during the experiment. The increase in the anodic current at potentials near V_{FB} is considerably lower than that found in a HCl solution of the same concentration but without acetic acid. A dramatic decrease of the chemical dissolution rate is observed when the anodic dissolution starts. In this potential range, we observed the formation of an orange-colored film at the electrode surface. Phosphorus was found in this film by EDAX analysis. Obviously, a passivating film is formed during anodic dissolution. This film inhibits both the anodic and the chemical dissolution reactions.

It should be noted that the chemical dissolution rate depends markedly on the surface condition of the InP electrode. Since induction effects are observed, care must be taken to ensure a constant dissolution rate before measurements are made. This can be done by pre-etching the electrode in the same etching solution.

The results shown so far suggest that the chemical etch rate of InP is strongly dependent on HCl concentration. This dependence was studied by varying the HCl concentration over a wide range for two different systems. An InP crystal was chemically etched in these solutions in the flow cell (the measured current was zero), and the chemical dissolution rate was again analytically determined by ICP emission spectrometry. The results are shown in Fig. 4. For curve (a), the concentration was varied by diluting concentrated HCl with water. At 9M HCl, the chemical dissolution rate is high and decreases rapidly as the HCl concentration is lowered. For a 5M HCl

Fig. 3. Potentiostatically measured current-potential curve (a) and chemical etch rate as a function of the electrode potential (b) in the dark for a p-InP electrode in a solution of 1.5M HCl in concentrated acetic acid.

Fig. 4. Chemical etch rate as a function of the HCl concentration for a p-InP crystal in the dark. The HCl concentration was varied by diluting with water [curve (a)] and concentrated acetic acid [curve (b)].

concentration, the etch rate is less than 40 Å/min and even lower for more dilute solutions. For curve (b), concentrated HCl was diluted with concentrated acetic acid. It is striking that here a linear relationship between etch rate and HCl concentration is observed and that the etch rate is significantly higher than in the corresponding HCl-H₂O solutions.

To decide whether the dissolution is a diffusion or a kinetically controlled process, the etch rate was measured as a function of the rotation rate using a p-InP rotating disk electrode at open circuit. Figure 5 shows that the chemical etch rate measured in a 3M HCl in concentrated acetic acid solution is essentially independent of the rotation rate (N). This means that the rate of the dissolution reaction is kinetically controlled.

Gas analysis.—When an InP crystal was dissolved at the rest potential in a concentrated HCl solution, gas evolution was observed at the solid surface. Using the color-detector method, we showed that this gas was phosphine. A clear color change was indeed observed even with the most insensitive tubes. We determined the gas

Fig. 5. Chemical etch rate in the dark as a function of the rotation speed of a p-InP electrode in a solution of 3M HCl in concentrated acetic acid.

quantitatively with a gas burette and showed that the phosphorus is converted for 100% ($\pm 1\%$) as PH₃.

Electrochemical measurements.—The current-potential curves of p-InP in 1N H₂SO₄ and in different HCl solutions in the dark are shown in Fig. 6. In all cases, the blocking current in the cathodic region was very low (< 0.02 mA/cm²). The onset of the anodic current in the case of 1N H₂SO₄ [curve (a)] occurs near the flatband potential ($V_{FB} = 0.73$ V), as expected. The anodic current for 1M HCl [curve (b)] is shifted some 150 mV in the negative potential direction with respect to the H₂SO₄ case. With an increase in the HCl concentration, this effect becomes more pronounced. For the 9M HCl solution, the shift amounts to about 350 mV. When the curve was measured again in 1N H₂SO₄ after the HCl experiments, exactly the same result was obtained as in the first measurement [curve (a)].

We also measured the Mott-Schottky plots for each of the solutions used in Fig. 6. The flatband potential did not depend on the HCl concentration: $V_{FB} = 0.725 \pm 0.050$ V in all cases. The slope of the Mott-Schottky plots decreased somewhat as the HCl concentration was increased. This is probably due to an increase in the surface area of the electrode due to roughening as a result of etching. A similar effect can also be seen in Fig. 3b.

Discussion

From Fig. 2 and 4, it is obvious that chemical dissolution occurs in aqueous solution when the HCl concentration exceeds a certain critical value. The rate is strongly dependent on the HCl concentration and becomes very low at values lower than 5M [see Fig. 4, curve (a)]. This suggests that the etch rate depends on the degree of dissociation of HCl molecules. Although it is clear that at low concentrations the dissolution of HCl is complete, there is a considerable discrepancy in the literature with respect to higher concentrations (10). Calculations based on vapor pressure measurements and on Hammett functions show that the concentration of undissociated HCl begins to increase significantly above 5 mol/l (11, 12). In order to avoid the uncertainty involved when HCl is diluted with water, we studied the dissolution rate in HCl-acetic acid solutions. The dissociation constant of HCl in acetic acid ($K_a = 10^{-8.55}$) is much lower than in water ($K_a = 10^{-3}$) (13). Consequently, the degree of dissociation of HCl in acetic acid is negligible, even at low HCl concentrations. The chemical etch rate could therefore be studied as a function of the molecular HCl concentration. The linear dependence of the chemical dissolution rate on the HCl concentration in concentrated acetic acid [Fig. 4, curve (b)] indeed confirms that chemical dissolution is determined by the molecular HCl concentration. The

Fig. 6. Current-potential curves for a p-InP electrode in the dark in 1N H₂SO₄ (a), 1M HCl (b), 5M HCl (c), 7M HCl (d), and 9M HCl (e) in water. Scan rate: 10 mV/s.

high etch rate of HCl solutions diluted with concentrated acetic acid compared to that for aqueous solutions, also found by Adachi (7), can be understood in this way. Figure 5 shows that the etch rate is independent of the rotation rate of an InP electrode meaning that the chemical etch rate is kinetically determined by these HCl molecules.

The mechanism presented by Gerischer and Wallem-Mattes for the chemical dissolution of semiconductors involves symmetrical bifunctional etching agents such as H_2O_2 and halogen molecules (5, 6). Although we are, in the present work, dealing with an asymmetrical HCl molecule, we propose a reaction scheme similar to that for symmetrical agents. The first step involves a synchronous exchange of bonds: In-Cl and P-H bonds replace the original H-Cl and In-P bonds. This is very likely the rate-determining step

Since the indium and phosphorus atoms at the surface are triply bonded to neighboring atoms, two further bonds must be broken in an analogous manner to remove each atom from the lattice

Indium is therefore dissolved as hydrolyzed $InCl_3$ and PH_3 is evolved as a gas. Such a mechanism can account for the etching results observed.

The chemical etch rate of InP in HCl solution is independent of potential. At potentials near the flatband value (Fig. 2 and 3) the p-InP electrode dissolves anodically. The rate of the anodic etching increases as the surface hole concentration is increased, *i.e.*, as the potential is made more positive. In aqueous HCl solutions, we have shown that six holes are required to dissolve one In-P entity. This means that both In and P are oxidized to the trivalent state, as is common for III-V materials (3-6). With a considerable concentration of acetic acid in the HCl solution, however, a film is formed on the electrode which inhibits both the chemical and anodic dissolution (Fig. 3). EDAX measurements have shown that this layer contains phosphorus but no indium or chlorine. We suspect that, in this case, phosphorus is not oxidized directly during anodic dissolution

A similar three-hole mechanism has been shown for GaP (14).

It is obvious from Fig. 6 that the chemical dissolution rate strongly influences the electrochemical behavior of InP. Anodic dissolution starts at a more negative potential as the HCl concentration is increased, although the flatband potential does not change. This must mean that the activation energy for electrochemical dissolution is lowered by chemical etching. A similar effect has been demonstrated by Gerischer and Wallem-Mattes (6) for the dissolution of GaAs in bromine solution. As in the GaAs case, this result can be explained if we assume that rup-

ture of the first In-P surface bond is rate determining for anodic dissolution

If this bond is broken during a chemical attack by HCl, then the remaining bonds are more easily attacked anodically and the onset potential for anodic dissolution is consequently lowered, indicating that it is, indeed, likely that the first step is the rate-determining dissolution step.

Conclusions

The dissolution of InP in concentrated HCl solutions follows a chemical mechanism in which undissociated HCl molecules play a decisive role. It seems likely that other etchants for InP, such as HBr and Br_2 (7, 8), are based on a similar mechanism. The reason why InP does not undergo electroless dissolution in conventional etchants containing oxidizing agents is probably related to the presence of a thin, highly resistant oxide layer on the semiconductor (15). Such a layer, which can inhibit either the dissolution of the solid or hole injection from the oxidizing agent, is unlikely to be present at the high HCl concentrations used here.

Diffusion of Ion-Implanted Arsenic in Thermally Grown SiO₂ Films

R. Singh,¹ M. Maier, H. Kräutle, D. R. Young,² and P. Balk*

Institute of Semiconductor Electronics, Technical University Aachen, D-5100 Aachen, Germany

ABSTRACT

The diffusion of As implanted in thermally grown SiO₂ was studied at temperatures in the range 1000°-1200°C using N₂ and O₂ as ambients. Concentrations were between 3×10^{15} and 3.5×10^{16} As⁺ ions cm⁻². Energies of 60 and 340 keV were used. Because of As loss due to evaporation, significant quantitative data could only be obtained for deep implants. N₂-annealed samples exhibit low diffusion rates at high concentrations (above the middle of the 10^{19} cm⁻³ range). Larger diffusion rates are observed at lower concentrations. In the samples treated in O₂, the opposite concentration dependence of the diffusivity is observed. The shape of the profiles suggests that in both cases a high and a low concentration phase exists. A model is presented assuming that in O₂ a fully oxidized structure and in N₂ an oxygen deficient network is obtained as a first step in the annealing process. There are indications that the ambient also affects the diffusion rate during further high temperature treatment of these structures, probably through the concentration of oxygen vacancies.

Dopants introduced into gate oxide films during implantation of the channel in MOSFET devices or by out-diffusion from a polysilicon gate may act as trapping centers for charge carriers (1). For this reason, it is of interest to know the diffusion behavior and understand the trapping properties of such elements in thermally grown SiO₂.

In a recent study in this laboratory (2) on electron trapping in As-implanted SiO₂, different trapping states were found after annealing depending on the nature of the co-implant (O⁻ or Si⁺) or on the annealing ambient (O₂ or N₂). This was interpreted to mean that the conditions under which the implantation damage is being annealed determine the "microscopic location" of the As in the oxide structure. It may be expected that the diffusion mechanism of As will also depend on its mode of incorporation into the SiO₂ network.

Indeed, it had been reported by Wada and Antoniadis (3) that the diffusion rate of As implanted in SiO₂ is concentration and ambient dependent. Specifically, an enhancement of the As diffusion (compared to that in a N₂ ambient) was reported for the case that the process was carried out in O₂ and the silicon substrate was being oxidized simultaneously. The enhancement was attributed to the flow of oxygen through the oxide or, as a more likely cause, to the generation of some point defect at the Si-SiO₂ interface during oxidation. However, it was concluded that the mere presence of excess oxygen in the oxide does not suffice to create the faster rate of diffusion.

In the present study, we have attempted to shed some further light on the question of the diffusion mechanism of As in SiO₂. With some exceptions, we have confirmed the observations of Wada and Antoniadis. However, to arrive at a correct interpretation of the data, it is necessary to recognize that diffusion of implanted As is a two-step process: incorporation of As into the SiO₂ network and diffusion of the incorporated As. Both steps may, in principle, be affected by the experimental conditions, specifically by the annealing ambient. It will be shown in this paper that, even though a number of questions remain open, a consistent picture of the overall process is obtained by taking these aspects into account.

Experimental

To study the diffusion of implanted As in SiO₂, concentration profiles were determined for four groups of diffusion experiments. In the first two, some of the experiments of Wada and Antoniadis were repeated to clarify the role of the rate of oxidation in O₂ on the diffusion process. In the third experiment, the effects of implanted dose, annealing temperature, and ambient, and in the fourth that of "mixed" annealing treatments, using O₂ and N₂ consecutively, were studied. Annealing temperatures were 1000°, 1100°, and 1200°C.

²Present address: IBM Research Center, Yorktown Heights, New York 10598.

All substrates were (100)-oriented 22-32 Ωcm p-type silicon wafers. For the first experiment, to determine the effect of an ongoing oxidation process, these substrates were first oxidized in dry O₂ at 1000°C to approximately 100 nm. Subsequently, some of these samples were implanted with a dose of 10^{16} As⁺ ions (60 keV) cm⁻². Half of the latter group was additionally implanted with 5×10^{15} N₂⁺ ions (80 keV) cm⁻², giving a nitrogen profile with centroid at the Si-SiO₂ interface to block further oxidation. The inhibition or retardation of oxidation by this method, caused by the formation of a nitride layer near the interface and first demonstrated by Josquin and Tamminga (4), was confirmed by us. For example (Fig. 1), starting with an initial oxide of 102 nm, after 8h of further oxidation at 1000°C the N₂⁺-implanted oxide had become thicker by only 15 nm, and that of the sample implanted with As⁺ but not with N₂⁺ had increased by an amount more than ten times larger, i.e., 177 nm. Since for oxidation times > 10h the oxide thickness started to increase significantly, we limited the diffusion experiment at 1000°C to 8h only. All values of SiO₂ film thickness quoted were determined by ellipsometry with an accuracy of ± 1%.

For the second experiment, to explore the interaction between the oxidation and diffusion processes, samples with different oxide thicknesses (177 and 1040 nm) and

Fig. 1. Inhibition of oxidation by N₂⁺ implantation (5×10^{15} cm⁻³ at 80 keV) for samples with and without As⁺ implant (10^{16} cm⁻² at 60 keV). Insert: as-implanted profiles.

Fig. 2. As concentration vs. sputtering time for as-implanted (10^{16} cm^{-2} at 60 keV) sample and upon annealing in N_2 or O_2 at 1000°C (8h); the fourth sample had additionally been implanted with N_2^+ (5×10^{15} cm^{-2} at 80 keV) to inhibit oxidation. Position of SiO_2/Si interface is indicated (as-implanted and annealed in N_2 : 102 nm, N_2 implanted and annealed in O_2 : 117 nm).

thus different rates of oxidation during O_2 annealing were prepared. The oxidation was carried out in wet O_2 at 1000°C and was followed by 30 min of N_2 annealing at the same temperature. The As^+ implant was again of the same dose (10^{16} cm^{-2}) and at the same energy (60 keV) as in the first case.

The samples used for the third and fourth experiments had a 934 nm thick oxide, grown at 1000°C in wet O_2 ; they were again given a preimplantation N_2 anneal at 1000°C . As implants As^+ doses of 3.5×10^{16} and 3×10^{15} cm^{-2} at 340 keV were selected.

Concentration-depth profiles were determined from SIMS measurements using an Atomika instrument. A 10 keV O_2^+ primary ion beam, incident at an angle of 10° with respect to the surface normal, was employed for sputter erosion of the samples. The quadrupole mass spectrometer of the SIMS instrument was tuned to $^{75}\text{As}^+$ secondary ions and to $^{28}\text{Si}_2^+$ secondary ions of the matrix for reference purposes. The interference of $^{29}\text{Si}^{30}\text{Si}^{16}\text{O}^+$ molecular ions (mass 75) with the $^{75}\text{As}^+$ ions was suppressed by appropriate energy filtering. To minimize the charge up of the SiO_2 surface, the oxide was simultaneously bombarded with 2 keV electrons incident at 60° with respect to the surface normal. The change of intensity of the Si_2^+ ion signal at the SiO_2/Si interface was used to calibrate the sputter-time scale in terms of a depth scale. The error in the depth scale is about $\pm 5\%$. A calibration of the $^{75}\text{As}^+$ signal intensity normalized to the $^{28}\text{Si}_2^+$ signal was obtained by equating the integrals of the background-subtracted depth profiles to the implanted dose of the unannealed samples, which is known with an accuracy of $\pm 5\%$. The integrals of the depth profiles of unannealed samples were reproducible within $\pm 15\%$. The resulting error in the As concentration scale is $\pm 20\%$. As a check, some RBS measurements were also carried out. Even though the RBS analysis yields a somewhat poorer depth resolution than SIMS, all qualitative features of the profiles were confirmed. However, for determination of the total amount of As present in the samples, the RBS method offers greater accuracy. The RBS data led to the conclusion that the loss of As due to outdiffusion was underestimated in some cases (by as much as 10% of the total amount present) in the SIMS study.

Results and Discussion

Effect of ongoing oxidation process.—Results from the first group of experiments, where we studied the effect of retarded oxidation by a nitride layer prepared by N_2^+ ion implantation near the $\text{Si}-\text{SiO}_2$ interface, are presented in Fig. 2. The energy of the implanted As^+ ions had been chosen to place the maximum of the distribution in the middle of the oxide film at a projected range of 46 nm.

This value is close to the values of 47 nm from photo I-V measurements and 46 nm from a SIMS analysis for samples with the same implant as reported by earlier workers (1). The profile obtained after an 8h N_2 anneal at 1000°C shows some narrowing at higher concentrations compared to the As-implanted distribution and exhibits a pronounced tail in the lower concentration range. It should be noticed that the tail lies mainly in the Si substrate. This tailing, but also the narrowing at higher concentrations, could possibly be explained from the relatively high value of the diffusion coefficient of As in the Si substrate [4×10^{-15} cm^2s^{-1} at 1000°C (5), compared to 3×10^{-17} cm^2s^{-1} for As in SiO_2 (3)], which acts as a sink for the dopant.

The profile for the samples annealed for the same length of time at the same temperature in O_2 exhibit a strikingly different appearance. They are broad and flat at the top and do not show a corresponding smear-out at low concentrations. The profile for the sample without N_2^+ implant is somewhat narrower at high concentrations, which cannot be explained from out-diffusion into the substrate, since the interface has moved outside the range of the figure (from 102 to 279 nm) as a consequence of the oxidation process taking place during the O_2 anneal. Comparing the profiles for samples with and without N_2^+ implantation, which exhibit oxidation rates differing by more than an order of magnitude during the diffusion process in O_2 , it must be concluded that, even though we do observe the speed up compared to a N_2 anneal, as reported by Wada and Antoniadis, there is no evidence in our data that the rate of the oxidation process affects the diffusion.

To exclude the possibility that the presence of nitrogen or the damage caused by implantation of this element in the SiO_2 would enhance the diffusion rate, thereby "compensating" for a very slow rate of diffusion in pure and defect-free SiO_2 , the diffusion of implanted As in a thin (177 nm) and thick (1040 nm) sample were compared (Fig. 3). In this case, the average oxidation rates of the samples during O_2 annealing differed by a factor of nearly three, and in the early stages of the process by even more. However, again any indication of a correlation between oxidation rate and diffusion rate fails. Also, during the N_2 anneal (in this experiment annealing times of 30h at 1000°C were used, instead of 8h, as in the first experiment), there is a distinct change of profile, but certainly not so pronounced as upon O_2 annealing.

It is difficult to derive quantitative information from the data in Fig. 2 and 3 since our measurements indicate that during some of the diffusion experiments considerable amounts of As are lost, most likely because of evapo-

Fig. 3. Diffusion of As (10^{16} cm^{-2} and 8×10^{14} cm^{-2} at 60 keV) in thin (177 nm) and thick (1040 nm) oxides in O_2 at 1000°C (30h). For comparison, diffusion in N_2 at same conditions is also shown.

ration, as also mentioned by Wada and Antoniadis (3). This loss is particularly pronounced for the shallow implants used in experiments 1 and 2. It amounts to 50% (0%) for the O_2 -annealed samples and 30% (25%) for the N_2 -annealed sample with high (low) As dose of Fig. 3, to 35%-40% for the samples annealed in O_2 in Fig. 2, whereas upon the N_2 treatment, no loss could be detected. For this reason, we used in the experiments described below considerably deeper As⁺ implants (340 keV) and consequently thicker oxide films (934 nm).

Ambient dependence.—Having established that the diffusion rate of As in SiO_2 does not depend on the rate of an oxidation process of the silicon taking place simultaneously, we will deal with the difference in diffusion rate for N_2 and O_2 ambients. Figures 4-7 show profiles observed for different annealing temperatures (1000°, 1100°, and 1200°C) and for two (3.5×10^{16} and 3×10^{15} As ions cm^{-2}) deep (340 keV) implants.

The profiles obtained upon N_2 anneal at 1000°C (30h), 1100°C (17h), and 1200°C (5h) (Fig. 4 and 5) clearly show two regions: one at higher concentrations (for example, $> 3 \times 10^{19}$ cm^{-3} at 1200°C), where the profile narrows down, and a second region at concentrations below these limits, where relatively rapid diffusion occurs. The concentration around the maximum does not change at all, or, for the lower concentration implant, only in a modest

fashion. This behavior suggests the presence of a stable high concentration phase, as also proposed by Wada and Antoniadis (3), which acts as a source for the diffusion into the low concentration range. The diffusion coefficients in the low concentration range amount to 6.2×10^{-17} cm^2s^{-1} at 1000°C, to 1.0×10^{-15} cm^2s^{-1} at 1100°C, and to 1.1×10^{-14} cm^2s^{-1} at 1200°C. Contrary to the samples of Fig. 4, where there was no measurable loss of As due to evaporation (RBS yielded 6% outdiffusion), in Fig. 5 the loss amounted to 6% at 1000°, 15% at 1100°, and 30% at 1200°C. This ties in with the change of profile near the surface in the latter case.

The corresponding data for O_2 annealing are shown in Fig. 6 and 7. Particularly striking is the flat appearance of the distribution obtained for the high concentration implant; at 1000°C, only diffusion near the top of the distribution is visible. Apparently, at all temperatures the rate decreases towards lower concentrations. The measured loss of As is quite in line with these observations: for the 3.5×10^{16} cm^{-2} implant, it increases from 7% to 1000°C to 24% at 1100°C and 35% at 1200°C. For the 3×10^{15} cm^{-2} implant (Fig. 7), it ranged from 0% at 1000°C and 1100°C to 14% at 1200°C. The diffusion coefficients at lower concentrations are 4.0×10^{-16} cm^2s^{-1} at 1100°C and 2.7×10^{-15} cm^2s^{-1} at 1200°C.

It thus appears that the concentration dependences of the diffusion rates in O_2 and N_2 show opposite trends.

Fig. 4. As diffusion in 934 nm oxide in N_2 at 1000° (30h), 1100° (17h), and 1200° (5h). Implant: 3.5×10^{16} cm^{-2} at 340 keV.

Fig. 5. As diffusion in 934 nm oxide in N₂ at 1000° (30h), 1100° (17h), and 1200°C (5h). Implant: $3 \times 10^{15} \text{ cm}^{-2}$ at 340 keV.

This complex behavior was further investigated in the fourth group of experiments.

The diffusion mechanism of implanted As.—In order to obtain a better understanding of the diffusion mechanism of As implanted in SiO₂ it is important to consider the following: upon implantation of As in SiO₂, the solid has become disordered. The oxygen available in the material does not suffice to reach the fully oxidized stage for both Si and As. This can only be achieved by introducing additional oxygen into the structure, for example, by annealing in O₂, which would lead to the formation of an arsenic silicate ((As₂O₃)_x-(SiO₂)_{1-x}) ($x \approx 0.04$, 1200°C) glass. In contrast, when annealing in N₂, Si and As will compete for oxygen. It is not clear whether here an arsenic silicate glass plus interstitial Si and As will form or if an incompletely oxidized network containing configuration like O₃ ≡ As-Si ≡ O₃³ with direct bonding between As and Si are obtained. However, it appears likely that the rate of diffusion should depend on the manner in which the As has been built into the network. Once a thermodynamically stable atomic configuration has been attained, there

³Here and in the following, the symbol O₃ ≡ As-Si ≡ O₃ is used to indicate an oxygen-deficient silicon oxide configuration O₃ ≡ Si-Si ≡ O₃ (fully oxidized oxide: O₃ ≡ Si-O-Si ≡ O₃), where one Si atom has been replaced by an As atom. The question of the different valency of As (3 to 5) compared to that of Si (4) is not being discussed; only the presence of direct As-Si and Si-Si bonds (or possibly also of As-As bonds) is being alluded to.

could, in principle, be a second effect of the ambient, namely, on the diffusion of the As built into the network, via the stoichiometry (vacancy content) of the oxide structure.

To explore this question, a fourth set of experiments was carried out. Again, implants of 3×10^{15} and 3.5×10^{16} As⁺ ions cm⁻² in thick oxide films (934 nm) were used, and annealing for 5h at 1200°C was studied. It may be seen that for the 3.5×10^{16} cm⁻² implant (Fig. 8), a 5 min O₂ anneal followed by a 5h N₂ treatment has nearly the same effect as a treatment for 5h in O₂ only. Apparently, a very brief O₂ anneal is sufficient to reach a fully oxidized state of the oxide system. In fact, such a transition requires only the presence of a slight amount of O₂ in the neutral ambient: it was observed that starting the annealing step in a neutral ambient without previously thoroughly flushing the furnace tube after introducing the sample led to oxygen-saturated behavior. The subsequent diffusion step appears to be nearly independent of the ambient. Even though a 5 min N₂ anneal may be able to restore the network in a manner typical for the N₂ ambient, the following 5h O₂ anneal appears to first turn the system into the more stable fully oxidized state. Consequently, again the profile characteristic for the network structure obtained for an O₂ treatment is observed.

The loss by evaporation was 35% for 5h O₂ anneal only, 47% for 5 min O₂ + 5h N₂, and 43% for 5 min N₂ + 5h O₂; these values are relatively large but hardly distinguishable.

Fig. 6. As diffusion in 934 nm oxide in O₂ at 1000° (30h), 1100° (17h), and 1200°C (5h). Implant: $3.5 \times 10^{16} \text{ cm}^{-2}$ at 340 keV.

Fig. 7. As diffusion in 934 nm oxide in O_2 at $1000^\circ C$ (30h), $1100^\circ C$ (17h), and $1200^\circ C$ (5h). Implant: $3 \times 10^{15} \text{ cm}^{-2}$ at 340 keV.

ble. For the case of 5h annealing in N_2 only, in the sample of Fig. 4 could no loss be detected. During 5 min treatment in O_2 or N_2 , no measurable diffusion could be observed; the profiles were identical to the as-implanted distribution.

In the samples with lower concentration implants (Fig. 9), slight differences between the "mixed annealing" and O_2 annealing steps become visible. The samples which had been exposed to N_2 in a "mixed anneal" exhibit a somewhat wider profile (*i.e.*, faster diffusion at lower concentrations) than those which had been treated with O_2 only. Thus, the slope of these profiles is less steep and becomes closer to that of the samples annealed in N_2 only. Accordingly, the diffusion coefficient of the "mixed annealed" samples lies between O_2 and N_2 ($3.7 \times 10^{-15} \text{ cm}^2 \text{ s}^{-1}$). The samples which had been exposed to O_2 experienced a smaller loss of As (22% for 5 min O_2 + 5h N_2 , 19% for 5 min N_2 + 5h O_2 , 12% for the sample treated in O_2 only) compared to 30% for treatment in N_2 only.

The diffusion constants derived from our data in the lower concentration range have been plotted in Fig. 10. They show the lower values for the O_2 than for the N_2 ambient (by roughly a factor of three). An intermediate value is found for mixed ambients. It may be seen that this behavior is opposite to that reported in Ref. (3). The reason for this discrepancy is not clear to us.

Summing up, the findings of this section support the concept that upon annealing in N_2 or O_2 implanted As^+

ions are incorporated into the oxide system in a different fashion. In fact, it appears that N_2 anneal gives rise to two types of structures. One of these is observed only if As concentrations in the 10^{20} cm^{-3} range or higher are introduced. In this structure, the dopant is effectively immobilized. Parallel to the dopant incorporated in the first type of structure, As is also taken up in a second "site," where it diffuses at relatively high speeds. In the case of O_2 anneal, the situation is reversed: here there is a strong broadening of the profile at high concentrations, but slower diffusion at low concentrations. The behavior during N_2 anneal is suggestive of the presence of two phases; this could also be the case in the O_2 -treated samples.

It is worth noting that the diffusion behavior of As using a N_2 ambient is not specifically related to this ambient; annealing in Ar for 5h at $1200^\circ C$ led to a profile indistinguishable from that obtained in N_2 . Moreover, N incorporation into the bulk of the oxide film was not found within the detection limit (10^{18} cm^{-3}) for this element in SiO_2 using SIMS.

Incorporation of As on different sites upon O_2 or N_2 anneal was also suggested in Ref. (2): for an O_2 anneal, formation of an "As-O complex" was proposed, whereas the two centers found upon N_2 anneal were tentatively equated with As incorporated on Si sites, since their concentrations were reduced when Si was implanted simultaneously with As. It was assumed that the remaining As would occupy interstitial sites in the latter case. In

Fig. 8. As diffusion in 934 nm oxide at $1200^\circ C$ in N_2 (5h), O_2 (5h), O_2 (5 min) plus N_2 (5h) or N_2 (5 min) plus O_2 (5h). Implant: $3.5 \times 10^{16} \text{ cm}^{-2}$ at 340 keV.

Fig. 9. As diffusion in 934 nm oxide at 1200°C in N₂ (5h), O₂ (5h), O₂ (5 min) plus N₂ (5h) or N₂ (5 min) plus O₂ (5h). Implant: 3×10^{15} cm⁻³ at 340 keV.

comparing these data with ours, it should be remembered that the implantations in Ref. (2) were done at a dose of only 8×10^{12} cm⁻² at 80 keV, leading to maximum concentrations at least two orders of magnitude smaller than the lowest in our experiments. Thus, the conclusions in Ref. (2) are only relevant for the low concentration range in our data.

From a study of As₂O₃-SiO₂ glasses, used as diffusion sources, it is known that phase separation occurs when the As₂O₃ concentration in the arsenic silicate layer reaches a few mole percent (6). This suggests that, like observed for the phosphosilicate (7, 8) and borosilicate glasses (9), the high concentration phase is probably a liquid at the annealing temperature. It should be noted that one is dealing here with fully oxidized systems, like in our case of O₂ annealing.

Finally, it has been reported (10) from an XPS study of P-implanted SiO₂ that N₂ and O₂ annealing lead to differ-

ent spectra. In both cases, P appears to be incorporated in the lattice in PO₄ configurations; upon N₂ annealing an additional peak, indicative of P-Si bonds, appears. In Ref. (10), this peak is attributed to interstitial phosphorus, but in our opinion these data do not exclude the possibility of the occurrence of O₃ = Si-P = O₃ configurations.

The above considerations lead to the following tentative interpretation of our experimental data: upon O₂ annealing of As-implanted SiO₂, the system becomes fully oxidized and an arsenic silicate glass forms. Since there is no direct evidence that As exists in the form of As₂O₃ in this glass, its composition will be designated by (As₂O₃)_v-(SiO₂)_v. In analogy to the phosphosilicate glass system, we will assume that As replaces Si in the oxide network. This would also explain its low diffusivity. At higher concentrations, a second phase will form, which presumably is liquid at the temperature of annealing. During annealing, this phase will dissolve SiO₂ from both sides until it reaches the composition of the liquidus resulting in the flat and broad profile observed in our data.

We propose that the N₂-annealed samples most likely contain direct Si-As bonds in the form of O₃ = Si-As = O₃ configurations. Such bonds are probably relatively weak, so that O₃ = Si and O₃ = As dangling bond configurations are obtained. As atoms should be able to move through the network by reaction of O₃ = As with O₃ = Si-Si = O₃ configurations to form O₃ = Si-As = O₃ and O₃ = Si. This is responsible for the relatively rapid diffusion at lower As concentrations. Even though diffusion via interstitial As atoms cannot be excluded, the rather similar values obtained for the activation energies for diffusion in N₂ and O₂ appear to support the above mechanism. The immobile phase observed at high concentrations should also be oxygen deficient. Because of the very low diffusivity of As in this phase, it should be a solid, with As incorporated in the network. However, at the present time, we have no clear ideas about the structure of this phase.

It appears feasible that the ambient will additionally affect the rate of diffusion once the O-deficient or fully oxidized systems have formed. Most likely, a N₂ anneal creates a small concentration of oxygen vacancies (2) of the form O₃ = Si - Si = O₃. Such "stretched Si-Si-bonds" (11) are of the same nature as the O₃ = Si-As = O₃ configuration and should enhance the rate of As diffusion in the system. This should become particularly apparent in the fully oxidized system where the initial concentration of vacancies is low. Indeed, the data of the region of low As concentration for the samples submitted to a "mixed" 5 min O₂ plus 5h N₂ anneal suggest that this enhancement does indeed occur. However, further experiments would be necessary to substantiate this point.

Fig. 10. Arrhenius plot of diffusion constants for As diffusion in SiO₂ in different ambients. For comparison, data from Ref. (3) are also shown. Full lines connect open symbols (N₂ ambient), dashed lines closed symbols (O₂ ambient). Dashed line through O₂ squares from this study was drawn parallel to the corresponding line from Ref. (3).

Conclusions
