

Mathematical Model for Design of Battery Electrodes

II. Current Density Distribution

W. G. Sunu* and B. W. Burrows*

Gould Research Center, Rolling Meadows, Illinois 60008

ABSTRACT

A model that predicts the current density and potential distributions as a function of depth of discharge, discharge rate, and grid design has been developed for application to lead-acid batteries. The calculated potential distributions are in excellent agreement with the observations reported in a companion paper. The effects of the ohmic resistance of electrodes on capacity and distributions of potential, current density, and local active material utilization are discussed. It is demonstrated that the model can be used to optimize the design of grids or current collectors commonly used in lead-acid batteries.

In a prior paper (1), a mathematical model was described for predicting the potential distribution over the surface of electrodes. This model was an extension of that introduced by Tiedemann *et al.* (2). In this model, the current density was assumed to be uniform over the electrode surface. Excellent agreement was found between the potential distribution predicted by the model and that measured experimentally in lead-acid cells immediately after the start of discharge, *i.e.*, for plates in the fully charged state. While extremely valuable in evaluating various grid designs, one would also like to know the current density distribution and hence the distribution of active material utilization during discharge. To obtain this information the assumption of uniform current density distribution must be removed.

Previously (3), we reported potential distributions measured on lead-acid electrodes of the motive power type and calculated the corresponding current density distribution based on the model of Tobias and Wijsman (4). This approach is limited, however, to simple current collector geometries and to steady-state conditions.

In this paper, we extend the model described in a companion paper (1) to handle a nonuniform distribution of current density. Our approach is similar to those reported by Vaaler and Brooman (5) and by Tiedemann and Newman (6). Vaaler and Brooman presented a model without the restriction of uniform current density distribution by treating the negative electrode as an equipotential surface. Later, Tiedemann and Newman reported a more comprehensive model which included the effect of cell polarization derived from a porous electrode model. Their mathematical descriptions were derived for symmetrical electrodes. Applications of these models have also been reported (7, 8).

The model presented here describes the details of grid design variations in asymmetrical electrodes (both electrically and geometrically). Cell polarization correlation was taken from experimental data. The model includes the effects of active material conductivity, electrode polarization, nonuniform current density distribution, and grid design variations (number of hori-

zontal and vertical members, plate dimensions, single or multiple tabs and their locations, taper members, and diagonals of varying length, size, and their locations). It predicts (i) cell voltage, (ii) potential distributions on both positive and negative electrodes, (iii) current density distributions, and (iv) distribution of local active material utilization over the electrode surface all as a function of the discharge time, discharge rate, and grid design.

Experimental

A 12V automotive battery was assembled in the laboratory using factory-pasted plates. The battery contained six cells connected electrically in series in which each cell had five positive and six negative plates. The positive grid was 1.6 mm thick and weighed 58.9g. The negative grid was 1.2 mm thick and weighed 45g. Both grids were 120 mm high and 142 mm wide. The weight of the pasted positive electrode was 156g and the pasted negative weighed 119g.

To allow measurement of resistances of terminals, intercell connectors, and tabs, Teflon coated gold wires were attached to both ends of each component. The specific gravity of the electrolyte solution was adjusted to 1.265 g/cm³ after formation. The terminal voltages and potential losses across the terminals, tabs, and intercell connectors were measured during discharge at different rates (25-500A) and temperatures (22°, 50°, and -18°C). The terminal battery voltages obtained at room temperature were used for comparison with model predictions. The potentials measured at various locations on positive and negative electrodes were reported previously (1).

To solve the grid model, it is necessary to measure the resistance of each grid segment between two adjacent nodes. The positive grid consists of 27 horizontal members and 10 vertical members, resulting in a total of 243 (27 × 9) horizontal segments and 260 (26 × 10) vertical segments. Likewise, the negative grid contains 220 (20 × 11) horizontal segments and 228 (19 × 12) vertical segments. The resistance of each of these grid segments was measured from horizontal and vertical bars cut from standard grids.

Mathematical Model

The overall mathematical framework used in this study is summarized in the flow diagram in Fig. 1.

* Electrochemical Society Active Member.

Key words: lead-acid battery, grid, current collector, modeling, optimization.

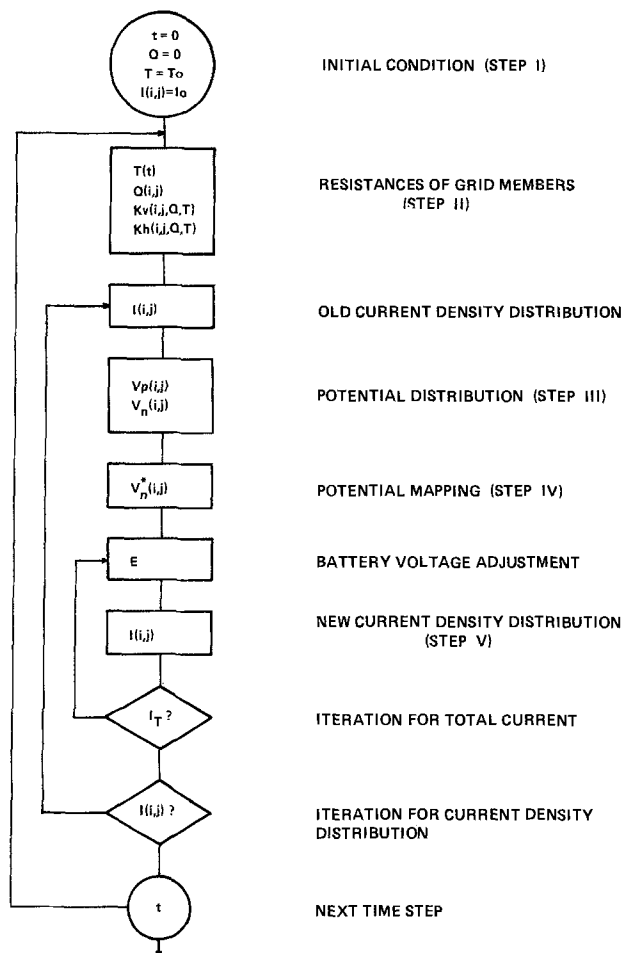

Fig. 1. Flow diagram showing the calculation steps used in this model.

The indices i and j represent i th horizontal and j th vertical members, respectively, counted from a corner closest to the tab location. The model is described by several calculation steps. As an initial condition, a uniform current density distribution was assumed (Step I). The resistance of each grid segment at (i, j) and contributions of the active material conductivity were determined for a given temperature T , and the state of discharge, Q (Step II). Using the current density distribution calculated in the previous iteration step, the potential distribution on the positive plate, $V_p(i, j)$, and that on the negative plate, $V_n(i, j)$, were calculated (Step III). In Step IV the potential distributions on the negative plate were superimposed over each location of the positive node to get $V_n^*(i, j)$. In Step V, the current density distribution $I(i, j)$ was determined at each positive node using an empirical voltage-current-time relationship. The battery voltage E was adjusted until the integral of the current density distribution, I_T , equaled the applied current density. Steps III-V were repeated with respect to current density distribution.

The convergence criterion was 10^{-5} , which is defined by the ratio of the difference between two successive current densities at each node to the present value. If this condition is satisfied at all nodes, the computation continues to the next time step of discharge, namely, Step II. Usually, iteration steps of less than four were needed for a converged solution at each time step. Detailed descriptions of each step are given below.

Grid member resistances.—Step II.—The cell temperature and the amount of active material (PbO_2 in the positive and Pb in the negative electrode) vary with time during discharge. Thus, the resistance of

each grid segment has to be corrected for the cell temperature change and for the active mass contribution. The grid member conductance, the reciprocal of the resistance, at a given temperature can be estimated by

$$K_h(i, j) = \frac{K_{hg}(i, j) + K_{ha}(i, j, Q)}{1 + B_t(T - 298)} \quad [1]$$

$$K_v(i, j) = \frac{K_{vg}(i, j) + K_{va}(i, j, Q)}{1 + B_t(T - 298)} \quad [2]$$

where T is the cell temperature in K; $K_{hg}(i, j)$ is the conductance of the horizontal grid segment between nodes (i, j) and $(i, j + 1)$; $K_{vg}(i, j)$ is the conductance of the vertical grid segment between nodes (i, j) and $(i + 1, j)$; $K_{ha}(i, j, Q)$ and $K_{va}(i, j, Q)$ are horizontal and vertical components of the active material conductance of a pellet, respectively; B_t is the temperature coefficient of resistance.

The temperature of the lead-acid cell was estimated by a simple heat balance equation of

$$\frac{dT}{dt} = \frac{hA}{mC}(T - T_a) + \frac{3600}{4.184} \frac{Q}{mC} \quad [3]$$

where

$$Q = I_c \left[E_o - \frac{T}{nF} \left(\frac{\partial S}{\partial w} \right)_{P,T} - E \right]$$

where T is the average cell temperature (K); T_a is the ambient temperature; t is the discharge time in hours; m is the weight of the cell (3548g); C is the heat capacity per unit weight of the cell (cal/g/K); Q is the heat generation rate (J/sec); hA is the overall heat transfer coefficient, h , multiplied by the surface area of the cell, A ; I_c is the current per cell (A); n is the number of electrons in the cell reaction; F is the Faraday constant; E_o is the reversible cell potential; E is the terminal voltage of a cell; S is the entropy; w is the reaction progress variable. The heat capacity of the present test cell in the fully charged state was estimated as 0.222 cal/g/K and the hA as 394 cal/K/hr.

The effect of the active material conductivity on the plate resistance was included using the method discussed in the previous paper (1). The active material conductivity, K_a ($\Omega^{-1} \text{cm}^{-1}$), is defined by the conductivity of a porous active mass element of a unit volume. With this definition of K_a , the vertical (K_{va}) and horizontal (K_{ha}) components of the active material conductance of a pellet can be determined from

$$K_{va}(i, j, Q) = K_a(Q) \frac{d_t a}{b} \quad [4]$$

$$K_{ha}(i, j, Q) = K_a(Q) \frac{d_t b}{a} \quad [5]$$

$$K_a(Q) = K_o \left[1 - \frac{Q(i, j)}{Q_o} \right] \quad [6]$$

where d_t is the plate thickness and a and b are lengths of the vertical and horizontal grid segments, respectively; K_o is the conductivity of a porous active material at the fully charged state and 25°C ; Q_o is the theoretical ampere-hours of active material at the fully charged state; Q is the ampere-hours removed from the active material at (i, j) . The conductivity of the porous active material, K_a , was approximated by a linear function with the depth of discharge at each node, $Q(i, j)$. The active mass conductivity at the fully charged state, K_o , was reported as $1969 \Omega^{-1} \text{cm}^{-1}$ for the negative and $32 \Omega^{-1} \text{cm}^{-1}$ for the positive electrode (1).

Potential distribution of grids.—Step III.—A mathematical model for predicting the potential distribution of a plate was reported in our previous paper (1),

assuming that the current density is uniform over the plate. The grid was treated as a resistance network of connecting nodes where the grid members intersect and Kirchoff's law was applied to each node. Four equations were used to describe four different situations shown in Fig. 2, which could arise with the presence of diagonal members. The same equations were used in this paper except for the term "apparent current density." The apparent current density used in paper I was the constant value, I , but this was replaced with $I(i, j)$ to describe the apparent current density as a function of the location of each node. The equations corresponding to Eq. [1]-[4] of paper I are rewritten as

$$[V(i, j) - V(i-1, j)] K_v(i-1, j) + [V(i, j) - V(i, j-1)] K_h(i, j-1) + [V(i, j) - V(i, j+1)] K_h(i, j) + [V(i, j) - V(i+1, j)] K_v(i, j) + 2I(i, j) A(i, j) = 0 \quad [7]$$

$$[V(i, j) - V(i, j-1)] K_h(i, j-1) + [V(i, j) - V(i-1, j)] K_v(i-1, j) + [V(i, j) - V(i, j+1)] K_h(i, j) + [V(i, j) - V(i+1, j)] K_v(i, j) + [V(i, j) - V_d(i-1, j-1)] K_d(i-1) + [V(i, j) - V_d(i+1, j)] K_d(i) + 2I(i, j) A(i, j) = 0 \quad [8]$$

$$[V(i, j) - V(i, j-1)] K_h(i, j-1) + [V(i, j) - V(i-1, j)] K_v(i-1, j) + [V(i, j) - V_d(i, j)] K_h(i, j) (b/c) + [V(i, j) - V(i+1, j)] K_v(i, j) + 2I(i, j) A(i, j) = 0 \quad [9]$$

$$[V_d(i, j) - V(i, j)] K_h(i, j) (b/d) + [V_d(i, j) - V(i-1, j)] K_d(i-1) + [V_d(i, j) - V(i, j+1)] K_h(i, j) (b/e) + [V_d(i, j) - V(i+1, j+1)] K_d(i) = 0 \quad [10]$$

where $V(i, j)$ is the potential at the node (i, j) ; $V_d(i, j)$ is the node potential of a diagonal member at an intersection between (i, j) and $(i, j+1)$; $K_h(i, j)$ is the conductance of the horizontal grid segment between nodes (i, j) and $(i, j+1)$; $K_v(i, j)$ is the conductance of the vertical grid segment between nodes (i, j) and $(i+1, j)$; $K_d(i)$ is the conductance of a diagonal member segment between the i th row and the $(i+1)$ th row; $I(i, j)$ is the apparent current density at node (i, j) ; $A(i, j)$ is the area bounded by dotted lines (see Fig. 2) from which the node (i, j) collects current from the active material; $a, b, c, d,$ and e are the distances of segments as shown in Fig. 2.

Thus, a grid which has M horizontal members, N vertical members, and N_d additional nodes created by diagonal members can be described by $MN + N_d$ equations and by an $[MN + N_d, 2(N + d) + 1]$ matrix where d is the number of diagonal members. Refer to paper I for a detailed explanation.

The resultant matrix was solved with an HP9835 minicomputer using the technique described by Prokopius (9). At a specified discharge time and temperature and with the given resistances of grid members and the given current density distribution, the potentials in each electrode can be determined independently at all nodes. As the nodes in the negative electrode are not aligned with those in the positive electrode, the calculated grid potentials in the negative electrode were superimposed, with a linear approximation, over the location of the positive nodes. In this way, potential losses in both electrodes were determined at each location of positive nodes.

Voltage-current-time-relationship.—From the potential losses in both electrodes, the current density

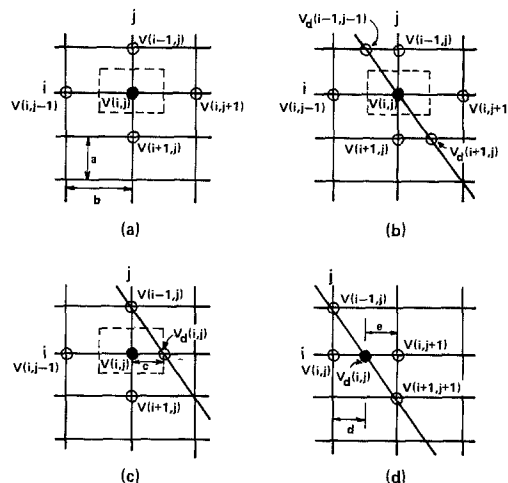

Fig. 2. Notation for indexing of nodes: (a) orthogonal intersections; (b), (c), and (d) represent three situations for diagonal members intersecting horizontal segments.

can be calculated at each positive node if a well-defined voltage-current-time relationship is given. The relationship used in this study was the four parameter analytical expression reported by Shepherd (10)

$$E = E_s - N_s I_c - \frac{R I_c}{1 - \frac{(I_c t)}{Q}} \quad [11]$$

where $E_s, N_s, R,$ and Q are fitting parameters; I_c is the current per cell in amperes; t is the time of discharge in hours; and E is the terminal voltage of the cell. This equation was derived such that the parameters $E_s, N_s I_c, R I_c,$ and Q represent equilibrium cell potentials, resistive potential losses in the cell, activation overpotentials at the fully charged state, and the cell capacity in Ah, respectively (10).

Equation [11], however, is inadequate to determine the effect of grid potential losses on the current density distribution along the electrode surface, as it is described by an overall terminal voltage E and a total current applied to the cell, I_c . In order to describe the local current density distribution, Eq. [11] was rewritten as

$$E = E_s - V_p(i, j) - V_n^*(i, j) - N I(i, j) A_s - \frac{R I(i, j) A_s}{1 - \frac{t I(i, j) A_s}{Q}} \quad [12]$$

where A_s is the total apparent surface area of positive electrodes in a cell, $I(i, j)$ is the apparent current density at node (i, j) , E is the terminal voltage of a cell, $N I(i, j) A_s$ is the resistive loss in the cell other than from the grid resistance, $V_p(i, j)$ is the potential loss in the positive grid between a tab and a node (i, j) , and $V_n^*(i, j)$ is the potential loss in the negative grid between a tab and a hypothetical node at the same location as the positive node (i, j) .

The overall applied current per cell, I_c , used in Eq. [11] is replaced with the local current density, $I(i, j)$, multiplied by the total apparent surface area of positive electrodes per cell, A_s . The grid resistance is excluded from N_s of Eq. [11] and represented with $V_p(i, j)$ and $V_n^*(i, j)$. The parameter N in Eq. [12] is then regarded as the resistive component in the cell other than grids.

Equation [12] becomes identical to Eq. [11] for an ideal cell of zero grid resistance, where the potential losses in the grids are absent and the current density is uniform over the plate. Under this conditions, the

term, $I(i, j)A_s$, equals I_c with the term $V_p(i, j) + V_n^*(i, j)$ being zero.

The fitting parameters (E_s , N , R , and Q) can be determined in two ways. Experimentally, they can be determined from polarization curves of an ideal cell of zero grid resistance using small cells (e.g., with an apparent surface area of 1 cm^2) or cells having highly conductive plates (e.g., lead-coated copper grids). Alternatively, they can be determined from a best fit between model predictions and polarization curves of cells of finite grid resistance. The latter approach was used here.

Current density distribution.—Step V.—The local current density at node (i, j) can be calculated from Eq. [12] for a given cell voltage E . The total current per plate, I_T , then can be determined from the integral of the current density over the electrode surface

$$I_T = \sum_{i=1}^M \sum_{j=1}^N A(i, j) I(i, j) \quad [13]$$

where $A(i, j)$ is the area from which a node (i, j) collects current from active materials. The $A(i, j)$ is $\frac{1}{4}$ ab at the corner of the plate, $\frac{1}{2}$ ab at the node on the frame, and ab at the node other than on the frame members. If the calculated total current, I_T , is different from the applied current, I_c/N_p , where N_p is the number of positive plates per cell, then the cell voltage E was adjusted to calculate a new set of current density distributions. This calculation was repeated until the calculated total current, I_T , agreed with the applied current (I_c/N_p) within $10^{-3}\%$ deviation.

Results

Fitting parameters (E_s , N , R , and Q) in Eq. [12] were determined from a best fit between model predictions and discharge curves of a standard 12V battery measured at different rates (25-500A). They were $E_s = 2.0468$, $N = -0.00153$, $R = 0.09167$, and $Q = 48.0794$. The voltage of a 12V battery was evaluated from

$$E_b = 6E + R_b I_c$$

where E_b is the terminal voltage of a 12V battery, E is the voltage of a cell, I_c is the current per cell, and R_b is the sum of resistances of two terminals, five intercell connectors, and tabs used in battery assembly. The R_b was measured as $1.865 \text{ m}\Omega$.

The calculated and measured polarization curves are compared in Fig. 3. The dashed lines represent predicted polarization curves of a battery containing ideal

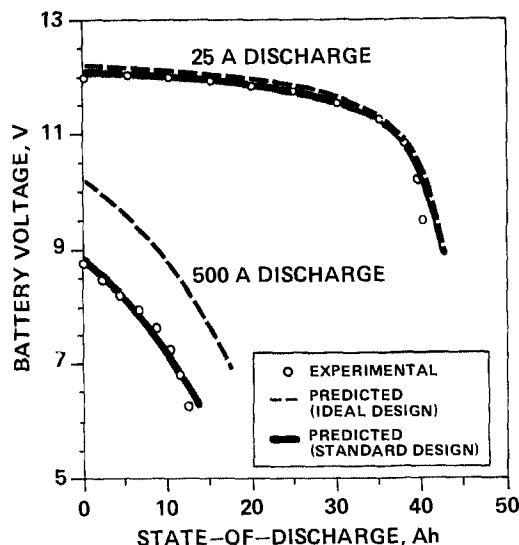

Fig. 3. Comparison between observed and predicted polarization curves for a 12V automotive battery containing 11 plates per cell.

plates of zero grid resistance and thus correspond to Eq. [11]. Solid lines represent the polarization curves predicted for a battery consisting of standard plates. A good agreement was found between data and predictions except for near the end of discharge where polarization increases rapidly.

Figure 3 shows that the ideal zero resistance grid has a negligible effect on the low rate capacity at 25A (or 14.7 mA/cm^2) but results in a significant capacity improvement at 500A (or 293 mA/cm^2). At a cut-off voltage of 7.2V, the predicted cranking capacity of the standard battery is 10 Ah and that of a battery employing the ideal grid design is 16.4 Ah, leading to a possible 64% improvement. This is an upper limit which may be obtained by grid design modifications with no changes in the plate thickness and apparent current density.

In Fig. 4, the potential distributions predicted at the fully charged state are compared with data (dashed curves) reported in our previous paper (1). The model predictions were obtained using resistances measured from each grid member segment and without the assumption of uniform current density distribution over the plate surface. It is shown that the agreement is excellent with an average deviation being less than 5%.

Normalized current density distributions predicted for different states of discharge are shown in Fig. 5 and 6. At 500A, the initial current density distribution is extremely nonuniform, being 51-73% higher near the

Fig. 4. Comparison of initial grid potential distribution (in mV) between prediction (solid line) and data (dashed line) for discharge at 500A per battery or 100A per plate at 22°C .

Fig. 5. Normalized current density distribution plotted at different states of discharge at 500 A/battery or 100 A/plate. Average current density is 293 mA/cm^2 .

Fig. 6. Normalized current density distribution plotted at different states of discharge at 25 A/battery or 5 A/plate. Average current density is 14.67 mA/cm^2 .

tab compared to the average current density and 27% lower near the bottom. As discharge continues, the current density distribution becomes more uniform because the upper part of the plate, which has been deeply utilized, polarizes more than the bottom. After a 60 sec discharge or 8.33 Ah, the cell voltage drops to 7.5V with the current density distribution being nearly uniform.

During constant current discharge at 25A, the current density distribution at the fully charged state is less pronounced than the case of 500A discharge but still is substantial, being 31-43% higher near the tab than the average and 17% lower near the bottom (see Fig. 6A). The current density distribution becomes essentially uniform after 0.5 hr of discharge or 12.5 Ah. After 1.5 hr of discharge (or 37.5 Ah), the current density near the bottom is significantly higher than that near the tab. Clearly, electrode polarization, which depends on the local active material utilization, is the major controlling factor compared to grid resistive losses in determining the current density distribution near the end of 25A discharge.

The local active material utilization at a node can be calculated by integrating the current density of the same node with respect to time. The results are shown in Fig. 7 and 8. The local active material utilization (Ah/cm²) was multiplied by the total surface area of positive plates in the 11-plate cell (i.e., 1700 cm²) for the purpose of comparing directly with the overall ampere-hours discharged. With a discharge rate of 500A, the distribution of the active material utilization was highly nonuniform throughout the discharge even after 60 sec. The active material near the bottom of the plate is utilized much less compared to that near the top (see Fig. 7B). Discharge could continue further to more fully utilize the active material in the lower portion of the electrode but the battery voltage would be less than 7.2V, a voltage considered as a lower limit for engine starting.

During discharge at 25A, the distribution of active material utilization is more uniform compared to that of 500A discharge but still is significantly nonuniform as shown in Fig. 8A. However, near the end of discharge, the active material is more evenly utilized over the plate surface (see Fig. 8B). As most of the

active material has been deeply utilized, further discharge would lead to a rapid voltage drop caused by the depletion of electrolyte in the pores of the electrode.

Discussion

In optimizing the design of batteries for high specific power applications, the aim is to maximize the high rate performance while minimizing the weight of grids. The high rate performance of a plate of a given electrode thickness can be improved by reducing the plate resistance. Reducing the weight of grids is desirable as it makes it possible to provide more active material in a given electrode volume, thus increasing the overall electrode capacity. Therefore, it is important to quantify the relationships between resistive losses in the grid, grid weight, grid design variations, and the high rate performance.

Experimental quantification of the effect of grid design variations requires a large number of tests and in practice is impractical in view of time and effort involved in preparing grids of various designs. These effects were illustrated here using the model predictions. The eight different grid configurations studied in our previous paper (1) were used for purposes of comparing the effects of different grid designs. These were selected to illustrate the effects on the cell performance of varying (i) number, length, and location of diagonal members; (ii) number and location of tabs; and (iii) number and size of internal grid members.

In our earlier work (1), we used the tab-to-corner potential difference as a measure for the cell performance. In the present work, the calculated cell capacity to a 7.2V cutoff is used. The detailed grid configurations of interest were shown in Fig. 1A of our companion paper (1). The grid weight of each configuration was calculated based on the data in Table III of the same paper (1). The model was applied to eight different 11-plate batteries containing negative and positive plates of the same kind, namely; E-B, F-A, G-D, O-L, P-M, Q-N, U-R, and V-S (see Fig. 1A of paper I). Also included was the combination E-A, a configuration presently being used in automotive batteries and used as an experimental reference in this work.

The predicted cranking capacities (at 500A per battery with a 7.2V cut-off voltage at 22°C) for these eight different grid configurations are plotted in Fig. 9 against the total weight of grids in the batteries. The ideal case is that of grid with zero resistance. The capacity for such a hypothetical situation is 16.4 Ah and is shown as the dashed line in Fig. 9. The capacity of the battery using production grids (combination E-A) was 10 Ah both as measured and as predicted from the model. For a double tab design (combination Q-N) the cranking capacity is predicted to be 14.2 Ah but with an increase of 7% in total grid weight. This improvement in capacity is due to the reduction in grid potential losses to 160 mV per cell from 305 mV per cell in the standard design. The light weight grid configuration (V-S combination) has a tab at the 1/4W position from the corner, two diagonals, and more than half of the internal horizontal members removed. A battery design of this configuration results in the reduction of the grid weight by 35% or 1.2 kg/battery with the cranking capacity no less than obtained with the standard battery.

The accuracy of the model was verified by the good agreement between measured and predicted potential distributions. To use the model as a means of predicting the cell capacity, Shepherd's voltage-current-time relationship was used with fitting parameters evaluated near the range of the current of interest. Generally, this equation was quite satisfactory. But near the end of discharge or during high rate discharge where the cell voltage drops rapidly, a greater de-

viation occurred which reduces the accuracy of the capacity predictions in Fig. 9.

The present model can be used to predict the effects on the cell performance of a variety of grid design variations such as tab location, number and location of diagonal members, number and size of grid members, tapered configuration of frame and internal grid members, and the size of each pellet. However, the present model does not predict the effects on the cell voltages of electrode design or operation variables such as plate thickness, porosity, paste density, active surface area, thickness of the separator, and initial electrolyte concentration. A model for describing these electrode effects is being developed and will be reported in the future.

Conclusion

A mathematical model was developed that predicts the transient, two-dimensional (along the width and

the height of the electrode) behaviors of lead-acid cells (i.e., cell voltage, current density distribution, grid potential losses, the distribution of local active material utilization, and cell capacity) as a function of the depth of discharge, discharge rate, and grid design variations. An excellent agreement was found between data and predicted potential distributions. It was demonstrated that the model can be used (i) to describe detailed physical changes occurring in the electrode during discharge, (ii) to quantify the interactions between grid design, grid weight, and the cell performance, and (iii) to optimize the design of grids or current collectors for a variety of applications through a computer-aided design approach.

ABSTRACT

When oxidized in a nonaqueous cell containing 1.0M LiClO₄ in propylene carbonate, polyacetylene develops a voltage of 3.4-4.0V vs. Li/Li⁺ ClO₄⁻. Oxidation levels at least as high as [CH(ClO₄)_{0.10}]_x can be produced electrochemically and then reduced to the undoped state with nearly 100% coulombic efficiency. The electrochemical doping (oxidation) process is only efficient when carried out with a minimum of liquid electrolyte under ultraclean conditions. Similar results are observed with a LiAsF₆ electrolyte. Polyacetylene is an extraordinary material of great importance for electrochemistry. However, on the basis of this and other published research, it is not yet clear that it offers major advantages over current electrodes for high energy density nonaqueous batteries.

Polyacetylene is a fascinating new material with extraordinary electrochemical properties. It is a simple conjugated organic polymer which can easily be synthesized by the catalytic polymerization of acetylene. Polyacetylene films can be chemically oxidized and reduced by a variety of species, such as halogens (I and Br) and various organo-alkali metal reagents, such as n-butyl lithium and sodium naphthalide. These reactions are generally referred to as p-doping (oxidation) or n-doping (reduction). They produce compounds of the type (CHX_y)_x and (M_yCH)_x, in which y is typically in the range of 0-0.1. What is most unusual about polyacetylene is that p- or n-doping transforms it from a virtual electronic insulator into a lustrous polymer with an electronic conductivity typical of metals (1).

The reversible oxidation and reduction of polyacetylene can also be carried out electrochemically in nonaqueous electrolytes containing appropriate dissolved anions or cations. These reactions were first described by Nigrey *et al.* (2). The electrochemical potentials of oxidized polyacetylene films (X = I, AsF₆, Br, ClO₄) are typically 3-4V vs. the Li/Li⁺ electrode. The potentials of the reduced films (M = Li, Na) are about 0.5-1.5V vs. that of Li/Li⁺. Nigrey *et al.* (2) and MacInnes *et al.* (3) first suggested that the oxidized and reduced polyacetylenes might be used as high voltage anode/cathode couples in nonaqueous electrochemical cells.

The general goals of our research have been to examine those aspects of the chemistry and electrochemistry of polyacetylene which influence its potential application in batteries. This paper summarizes our investigations of the stability and electrochemical oxidation of polyacetylene in propylene carbonate containing LiClO₄ or LiAsF₆.

Stability

Polyacetylene exists in *cis* and *trans* isomers (Fig. 1). *Trans* polyacetylene is the thermodynamically stable form. The *cis* isomer can be produced by polymerization at low (-78°C) temperatures, but it is unstable toward isomerization, which can be induced by heating or by doping with various chemical species (5, 6, 7). Polyacetylene also self-reacts, forming cross-links and defects. These reactions occur rapidly at elevated temperatures (150°-260°C) (5).

The stability of polyacetylene has been studied by various authors (8, 9, 10, 11). In the absence of a

Key words: cathode, current efficiency, discharge, polymers.

supply of counterions, virgin and doped polyacetylene are extremely reactive with oxygen. When films are exposed to small concentrations of oxygen for short times, the reaction appears to be reversible. However, during longer exposure, oxygen irreversibly attacks the polymer chain and degrades the conjugated bond network. Oxidation also embrittles the material. Similar reversible and irreversible reactions are observed with other oxidants. We have observed that iodine-doped polyacetylene irreversibly degrades above 60°C, and films doped with bromine irreversibly degrade above about 40°C (11). There are initial indications (11, 12) that films doped with AsF₆⁻ and ClO₄⁻ are somewhat more stable.

Electrochemical Experiments

MacDiarmid *et al.* first demonstrated that films of polyacetylene prepared by the Shirakawa technique can be readily doped to semiconducting and metallic states with a wide variety of chemical species (13, 14, 15). Interest in the electrochemistry of polyacetylene began with the demonstration by Nigrey *et al.* (2) that polyacetylene can be electrochemically oxidized to

Fig. 1. Polyacetylene isomers

the metallic state in reactions that are the electrochemical equivalents of the chemical doping reactions. Many additional investigations of the electrochemical reactions of polyacetylene have been reported (16-21).

Our research has examined the oxidative (p-doped) electrochemical reactions of polyacetylene in propylene carbonate containing LiClO_4 or LiAsF_6 . Its principal goals have been to explore the reversibility, coulombic efficiency, and electrochemical potentials associated with the reactions at various levels of doping (values of y in $[\text{CHX}_y]_x$).

The polyacetylene films used in these experiments were prepared by the technique first described by Shirakawa (4). Polyacetylene was transferred and stored under vacuum, and manipulated and studied in an inert atmosphere dry box.

Experiments were carried out with electrochemical

Fig. 3. Sealed electrochemical cell of small electrolyte volume

cells of the types shown in Fig. 2 and Fig. 3. Electrolytes were prepared from Burdick and Jackson propylene carbonate which was distilled and then percolated through neutral activated alumina (Fisher or Woelm). The electrolyte salts were LiAsF_6 (U.S. Steel, Electrochemical Grade), LiClO_4 (Alfa-Ventron), and LiClO_4 (Anderson Physics). The salts were dried at 180°C before use. After the salts were dissolved, the electrolyte solutions were purified by a second percolation through activated alumina.

Results

Series A.—The first series of experiments was carried out using the electrochemical cell shown in Fig. 2 and electrolytes prepared from LiAsF_6 and from LiClO_4 obtained from Alfa-Ventron. Data from one set of experiments using LiAsF_6 are described first. These experiments used a sample of polyacetylene of about 0.7 cm^2 in area (2.8 mg), held in Pt mesh, along with approximately 10 cm^3 of 0.95M LiAsF_6 in propylene carbonate.

The cell was first studied without any polyacetylene in order to determine the electrochemical stability of the electrolyte. The working electrode was a large piece of Pt mesh, about 2 cm^2 in area, normally used to hold the sample of polyacetylene. While the potential was slowly swept from 2.7 to 4.0V vs. Li/Li^+ at 2 mV/sec, background currents of less than $3\text{ }\mu\text{A}/\text{cm}^2$ were observed between 3.2 and 3.75V. Around 3.8V, the current began to rise and reached a value of about $20\text{ }\mu\text{A}/\text{cm}^2$ at 4.0V. The solvent had a good window of stability in the potential range of 3.2 to 3.75V vs. Li/Li^+ , but decomposed at an increasing rate at higher potentials.

With the polyacetylene sample in place, appreciable oxidation began at around 3.4V and the current rose to just over $3\text{ mA}/\text{cm}^2$ at 4.0V. Reduction was observed when the sweep was reversed.

The polyacetylene sample was then repeatedly oxidized and reduced to determine the maximum oxidation level which could be achieved and the reversibility of the reaction. To oxidize the film, the potential was increased in 100 mV steps from 3.5 to 3.9V. The experiment was first carried out without a sample of polyacetylene. The control experiment demonstrated that negligible background current passed up to potentials of 3.9V. With a sample in place, currents upon initial polarization were much larger, typically $0.5\text{--}1\text{ mA}/\text{cm}^2$, on the basis of the geometric area of one side of the polyacetylene. At each potential, the current decayed rapidly to a value that remained approximately constant. The magnitude of the limiting current increased with increased polarization voltage (see Table I).

A separate experiment under essentially identical conditions was designed to determine the coulombic efficiency of the oxidation/reduction process. This experiment started with a fresh sample of polyacetylene, which attained an open-circuit voltage of 2.49V vs. Li/Li^+ . The film was oxidized (charged) by increasing its potential from 2.6 to 3.7V in 100 mV steps. At any given potential, the potential was increased when the current had decayed to approximately 10% of its peak value. To reduce the film (discharge), the po-

tential was stepped immediately to 3.6V and then to 3.0V in 100 mV steps. Again, the potential was decreased whenever the current decreased to 10% of its initial value at any potential. A final discharge step at 2.5V was carried out for 24 hr. Table II summarizes the results. The maximum oxidation level attained (y in $[\text{CHX}_y]_x$) was 0.11, based on the total charge passed. However, the total charge recovered during discharge indicated a real y value of only 0.023. This yielded an apparent efficiency of charge storage and recovery only about 22%.

We observed similar results in other experiments of this type. Because this behavior might have been the result of some curious chemistry of the AsF_6^- ion, the experiments were repeated with an electrolyte of 1.0M LiClO_4 in propylene carbonate. However, all of the results were consistent, regardless of the electrolyte salt. In all cases, the coulombic efficiency of the polyacetylene electrode was very low. The charge recovered upon reduction indicated that a maximum oxidation level of no greater than 0.02-0.03 could be achieved before the oxidation process became very inefficient.

Series B.—The results of Series A are inconsistent with previous reports by MacDiarmid and co-workers (see, for example, 2, 16-21) which have indicated that polyacetylene can be oxidized to y values of 0.07 with coulombic efficiencies of over 90%. They obtained these results with electrochemical cells containing very small amounts of electrolyte.

We evaluated one cell of this type, which was prepared by members of Professor MacDiarmid's research group. It contained a polyacetylene electrode about 1.12 cm^2 in area (2.7 mg). The polyacetylene was separated from a lithium electrode with Celgard™, a porous polymeric separator. The electrode package was packed into the upper part of a small glass cell (see Fig. 3). The lower part was filled with activated alumina.

The cell had undergone five charge-discharge cycles before it was given to us under the conditions of 0.050 mA/cm^2 charge followed by discharge at 0.500 mA/cm^2 and an additional exhaustive controlled potential discharge at 2.5V vs. Li/Li^+ . We then carried out seven additional cycles. Table III summarizes the results.

In each cycle, the polyacetylene electrode film was oxidized at a constant current of 50 $\mu\text{A}/\text{cm}^2$. During

oxidation, the potential of the cell slowly rose from about 3.79V at $y = 0.03$ to 3.9V at $y = 0.07$. The cell was then discharged at three different currents: 500 $\mu\text{A}/\text{cm}^2$, 250 $\mu\text{A}/\text{cm}^2$, and 120 $\mu\text{A}/\text{cm}^2$, in separate experiments. At all three discharge currents, the cell potential immediately fell to about 3.4V. It then continued to decrease until it reached 2.5V. The constant-current discharge was changed to an extended controlled-potential discharge at that potential.

About 50% of the charge could be removed during the constant current discharge at 500 $\mu\text{A}/\text{cm}^2$ before the cell potential reached 2.5V. At the lower discharge currents, 60-65% of the charge was removed before the potential reached 2.5V. The initial peak currents during controlled potential discharge were 500-800 $\mu\text{A}/\text{cm}^2$. After about 1 hr, the current decayed to less than 50 $\mu\text{A}/\text{cm}^2$. After 15 hr at 2.5V, the current was less than 1 $\mu\text{A}/\text{cm}^2$. The controlled potential discharges extracted an additional 30-40% of the initial oxidation charge, which yielded overall coulombic efficiencies of 85-95%.

Series C.—Another cell of this design (Fig. 3) was prepared. It used a polyacetylene sample of 1.3 cm^2 (2.86 mg) supported on Pt mesh of about 2 cm^2 . The lithium counterelectrode was formed by pressing lithium ribbon into a nickel support mesh, and was about 3 cm^2 in area. The electrodes were separated by a Celgard K-442 polypropylene sheet. The cell contained about 1g of activated alumina (Woelm) as a continuous getter for impurities and about 1 cm^3 of electrolyte prepared from Burdick and Jackson UV-grade propylene carbonate which had been vacuum distilled and contained 1.0M LiClO_4 . After one freeze-pump-thaw cycle, the cell was sealed under vacuum.

The cell was charged at a constant current density of 50 $\mu\text{A}/\text{cm}^2$ (based on the area of one side of the polyacetylene) and later discharged in two steps, first at 500 $\mu\text{A}/\text{cm}^2$ until the potential reached 2.5V, and then in an extended controlled-potential discharge at 2.5V. The controlled-potential discharge was generally carried out for about 16 hr, during which the cell current decayed to less than 1 $\mu\text{A}/\text{cm}^2$. A typical plot of current vs. time during controlled-potential discharge is shown in Fig. 4.

The results of this experiment are summarized in Table IV, which presents the final open-circuit voltage attained after charging as a function of oxidation level. It also indicates the fraction of charge recovered during constant-current discharge and the total charge recovered at constant current and controlled potential. The data are listed in the order of increasing oxidation level. The real order in which the experiments were carried out is indicated by the numbers in brackets after each value of y . Figure 5 plots the open-circuit voltage after charging as a function of oxidation level.

The results on coulombic efficiency clearly demonstrate that nearly all of the charge injected during oxidation can be recovered if the reduction begins immediately. However, regardless of the oxidation level, only about half of the charge can be recovered under the constant-current conditions used (500 $\mu\text{A}/$

cm²). The remainder can only be extracted at lower rates.

To measure the rate of self-discharge of the cell, the polyacetylene was first charged to a y level of 0.03 and then discharged using the usual constant-current/controlled-potential sequence. In one experiment the discharge began immediately, in the other it was delayed while the cell stood on open circuit for 40 hr. The results are summarized in Fig. 6. Immediate constant current discharge recovered 41% of the

charge; an additional 56% was recovered during the subsequent controlled-potential discharge for a total coulombic efficiency of 97%. The initial open-circuit potential was high, but dropped sharply as the result of cell resistance when the discharge current was applied. In the other experiment, the 40 hr delay resulted in a decrease in the open-circuit potential of the cell. No change in the cell IR drop was observed. But, constant current discharge recovered only 21% of the initial charge. A total of 61% was recovered after the controlled-potential step.

Discussion

Our experiments confirm previous reports of MacDiarmid *et al.* (16-19) that polyacetylene can be reversibly oxidized (p-doped) to compositions of (CH[ClO₄]_{0.10})_x and then reduced with nearly 100% coulombic efficiency. The results also illustrate several aspects of the stability, variation in electrochemical potential, and electrochemical reversibility of polyacetylene. These are discussed in this section, which also reviews the prospects for polyacetylene as a cathode material in nonaqueous batteries.

Our results confirm that the oxidation of polyacetylene is highly efficient if carried out with a minimum of electrolyte under ultraclean conditions (for example, 2-3 mg of polyacetylene with about 1 cm³ of electrolyte sealed under vacuum with Al₂O₃—experimental Series B and C). However, poor coulombic efficiencies were observed when the same amount of film was in contact with about 10 cm³ of electrolyte in a cell which was not sealed under vacuum, but merely operated in a dry box. We assume that the inefficiency observed with the latter cell was the result of impurities in the electrolyte, although no thorough study of the impurity content of the various electrolytes used in this investigation has been carried out.

The observation that even cells which use a minimum of electrolyte can yield poor coulombic efficiencies during initial oxidation/reduction cycles (see, for example, Table IV, cycle 1) suggests that polyacetylene is extremely sensitive to the presence of traces of impurities in the electrolyte. The first oxidation/reduction cycles with a polyacetylene electrode may actually help purify the electrolyte. Whether impurities are in fact the major cause of poor efficiency, however, cannot be confirmed without a more detailed study of electrolyte/polyacetylene interactions.

* 100y in (CHX_y)_x; ** at constant current of 500 μA/cm²; † constant current plus additional controlled potential discharge at 2.5V.

We have also observed that only about 50% of the charge stored in oxidized polyacetylene ($x = \text{ClO}_4$) at a current density of $50 \mu\text{A}/\text{cm}^2$ can be recovered at a constant-current discharge of about $500 \mu\text{A}/\text{cm}^2$ before the potential of the electrode drifts sharply toward negative values. The remainder of the stored charge appears to be accessible, but only upon extended controlled-potential discharge at 2.5V vs. Li/Li^+ . These results imply that slow diffusion of ClO_4^- in polyacetylene may hinder the recovery of a large fraction of the stored charge. Results which also imply that the slow diffusion of anions in polyacetylene may limit the rate of its electrochemical reactions have been presented by Will (23).

The results shown in Fig. 6 also suggest that even under carefully controlled conditions, oxidized polyacetylene ($x = \text{ClO}_4$) undergoes considerable loss of charge upon standing on open circuit for 40 hr. This might be the result of the diffusion of ClO_4^- species deep into the polyacetylene fibrils or of slow self-discharge with the nonaqueous electrolyte. It might also be caused by the irreversible chlorination of polyacetylene by ClO_4^- .

There is no doubt that many of the oxidized polyacetylene compositions are thermodynamically unstable toward irreversible oxidation of the conjugated-polymer backbone. As mentioned earlier in this paper, irreversible halogenation begins at $40^\circ\text{--}60^\circ\text{C}$ with Br^- or I^- as the doping ion. The stability of ClO_4^- -doped compositions appears to be considerably greater, although recent reports of Abe *et al.* (24) and Winkle *et al.* (25) indicate that extended electrochemical cycling of polyacetylene with ClO_4^- may slowly result in its irreversible chlorination. It may be that the degree of irreversible oxidation of polyacetylene is negligible if it is cycled within a carefully defined potential range. Further investigations of its long-term cycle life as a function of doping level are needed to resolve this point.

In measuring the open-circuit potential of ClO_4^- -doped polyacetylene as a function of ClO_4^- content (see Fig. 5), we observed two potential plateaus. This behavior contrasts with the smooth increase in open-circuit potential with doping level reported by Kaneto *et al.* (16). Our data were obtained at somewhat lower currents than those used by Kaneto *et al.* ($20 \mu\text{A}/\text{mg}$ film [$50 \mu\text{A}/\text{cm}^2$] vs. up to $100 \mu\text{A}/\text{mg}$ film) and are also based on complete oxidation/reduction cycles to oxidation levels chosen in a semi-random order. The data are quite consistent. They were not obtained at inappropriately high current densities or electrode potentials. Why two plateaus are observed is not clear. However, Abe *et al.* (24) have recently reported similar results. Perhaps two plateaus are an artifact, perhaps not. Nevertheless, these results underscore the need for a careful study of the interrelationship of the preparation conditions, structure, and morphology of polyacetylene and its electrochemical characteristics.

All of these results underscore the fact that the most desirable properties of polyacetylene—high electronic conductivity, oxidizing and reducing power, and utility as an electrochemical electrode—are observed with compositions that often are highly reactive or unstable. Polyacetylene is an extremely sensitive electrode material which must be handled carefully during cell assembly, used only with highly pure electrolytes, and cycled within strict potential limits.

Possible battery applications of polyacetylene have been widely discussed. Three types of batteries using polyacetylene as an electrode material have been suggested (3). The first uses p-doped polyacetylene as a cathode material, most likely with a lithium or similarly high energy-density anode; the second uses n-doped polyacetylene as an anode in combination with a cathode such as TiS_2 ; and the third is an all-poly-

acetylene battery in which the n-doped material is the anode and the p-doped form is the cathode.

On the basis of the information which has been published so far, two major factors appear to impede the application of polyacetylene in high energy-density rechargeable batteries. The first is the instability of both virgin and doped polyacetylene, which has already been discussed in this paper. The other is its apparently low gravimetric- and volumetric-energy-densities, in either the p-doped (cathode) or n-doped (anode) form.

To put polyacetylene in perspective, Table V compares the characteristics of a typical oxidized polyacetylene cathode composition, $[\text{CH}(\text{ClO}_4)_{0.10}]_x$ with TiS_2 , and a polyacetylene anode composition, $[\text{Li}_{0.10}\text{CH}]_x$ with pure Li. Note that it takes about twice the weight and nearly ten times the volume of the oxidized polyacetylene to store the same charge as TiS_2 . The characteristics of n-doped polyacetylene are similar.

These calculations consider only charge and not cell voltage. To include voltage, Table VI summarizes four possible battery couples involving the anodes and cathodes drawn from Table V. The characteristics presented for polyacetylene n-doped with Li are based on currently available experimental results. Kaner *et al.* (26) and Huq *et al.* (27) have indicated that n-doping of polyacetylene occurs readily in a highly pure electrolyte of 1.0M LiClO_4 in tetrahydrofuran (THF). Coulombic efficiencies for charge and immediate discharge are nearly 100% for doping levels up to 0.08. Above $y = 0.08$, the efficiency decreases in this particular electrolyte. The potential of the $(\text{Li}_y\text{CH})_x$ electrode varies from about 1.5V at $y = 0.01$ to 0.5V for $y = 0.08$.

As Table VI shows, the voltage of a $\text{Li}/[\text{CH}(\text{ClO}_4)_{0.10}]_x$ cell is about 50% higher than a comparable Li/TiS_2 cell. Its price is increased weight and volume. Similarly, cells involving $(\text{Li}_y\text{CH})_x$ anodes sacrifice considerable potential, weight, and volume compared to their Li counterparts. One additional difference between the cathode materials is worth noting. Cells using TiS_2 have an invariant salt concentration in the electrolyte, whereas cells using polyacetylene cathodes inject additional electrolyte salt (here LiClO_4) into the electrolyte during the discharge process. Sufficient solvent must be present to accommodate the additional salt.

We have not attempted to estimate energy densities for complete cells. In such estimates, much depends on the specifics of design. It is especially difficult to extrapolate the characteristics of active materials to the performance of a finished system when a radically different electrode material is being considered. Never-

Table V. Theoretical gravimetric and volumetric energy densities of selected electrodes

Voltages are estimated operating voltages.

theless, the results currently available for the electrochemical performance of polyacetylene cathodes and anodes suggest that they are considerably less interesting as high energy density cathode and anode materials than materials such as TiS_2 (28) and Li.

We have also made no attempt to estimate the potential power densities that might be achieved with polyacetylene electrodes. If energy densities are difficult to estimate, power densities are more so, since power density is largely an engineering parameter. However, current data do not indicate that polyacetylene is a major breakthrough in achieving high power densities.

All of these estimates would be changed if the maximum oxidative doping level of polyacetylene could be increased to 0.20 or 0.30 with high coulombic efficiency. On the basis of what we currently know, increasing the doping level would require either decreasing the voltage of the polyacetylene cathode or identifying a non-aqueous electrolyte that is stable at potentials above 3.9-4.0V vs. Li/Li^+ . Currently, the charging process in propylene carbonate containing LiClO_4 becomes inefficient above $y = 0.10$. In this range, the electrode potential is greater than 3.9V vs. Li/Li^+ , and the non-aqueous electrolyte begins to decompose. Similarly, n-doped polyacetylene would be a more attractive anode if it could store more charge at potentials closer to that of pure lithium.

Unfortunately, too little is understood about the electrochemical reactions of polyacetylene to know whether, for example, the present doping levels are limited by an intrinsic characteristic of the doped state or by an extrinsic factor such as the morphology of the polymer. Logical directions for polyacetylene research include a search for new dopants and electrolytes which will permit the material to be cycled efficiently to higher doping levels. In addition, the relationship between the structure of doped polyacetylenes and their electrochemical behavior must be understood to determine whether the currently achieved capacities might be increased by changing the physical characteristics of the material.

To understand the structural/compositional/property relationship in polyacetylene is an exciting challenge for electrochemical research. Perhaps polyacetylene or some other polymer yet to be discovered will revolutionize batteries; perhaps not. Regardless, polyacetylene is a remarkable material which opens up new areas of electrochemistry and deserves continued research.

ABSTRACT

Anodic dissolution of aluminum in hot chloride solutions produces a high density of fine etch tunnels that extend along [100] directions. Tunnels evolve from cubic etch pits when all but one of the pit wall surfaces become passivated; dissolution then occurs at the one active face at a rate that may initially be as high as 20 A/cm². Tunnels have square cross sections with sides ~1 μm and aspect ratios as high as 100:1. Tunnel growth may be considered a unique form of pitting corrosion in which dissolution and passivation occur simultaneously with a sustained balance between the two processes.

Anodic dissolution of aluminum in hot chloride solutions produces a high density of fine tunnels that extend along [100] directions. Tunnel etching is used commercially to process tonnage quantities of foil for use as electrodes in aluminum electrolytic capacitors. The tunnels in these foils are typically 1-2 μm wide, 40-50 μm long, and present at a density of the order 10⁷ cm⁻² (1, 2).

Tunnel attack of aluminum was first reported in a study of tap water corrosion of 2S alloy (3). Edeleanu studied these structures in some detail, as part of a larger study on the propagation of corrosion pits (4). Corrosion scientists have generally not paid much attention to tunnel attack, perhaps because it appears to be a secondary feature of pitting attack at room temperature.

Tunnel growth is difficult to study because it is accompanied by general crystallographic attack that masks tunnel initiation and confounds measurements of tunnel length. We were fortunate to find a combination of pretreatment/etch/metal that produces a uniform dispersion of nucleation sites with a high probability that each site develops into a tunnel. This made possible a detailed and quantitative study of tunnel growth and morphology without interference from general crystallographic attack. We present here the results of that study and we discuss the phenomenon as it may relate to pitting corrosion. A model describing electrochemical events in the tunnels is under development by the authors.

Experimental

Specimens were 100 μm-thick, 0-temper, 99.99% Al capacitor-grade foil from Toyo Aluminum Company.² This foil is fabricated to have a high cubicity texture, so the surface is composed mostly of (100) planes and tunnels grow normal to the surface. Similar foil is available from other major aluminum suppliers, but each may require a different pretreatment to get a uniform dispersion of tunnels.

Specimens were cleaned by immersion for 10 min at room temperature in either 1N NaOH or 1N HCl, rinsed, and then immediately transferred to the electrochemical cell. Anodic dissolution was in 1N HCl at a constant nominal cd of 50 or 200 mA/cm² for times between 0.1 and 100 sec, and at temperatures 40°-97°C. The potential was measured vs. a saturated calomel

electrode at room temperature, using a Luggin probe with tip placed 1-2 mm from the Al surface.

This high-purity metal did not undergo general corrosion in the HCl etchant, even at elevated temperatures, during the time required for these experiments. The distribution of initial etch pit sites is more uniform in HCl than in NaCl solutions, and no solid oxidation product is formed in bulk solution in HCl. The appearance of the tunnels produced in acid and neutral chloride solutions is identical.

Tunnel features were studied by examination of oxide replicas in the scanning electron microscope (SEM). Barrier oxide films 75 nm thick were deposited on the specimen surface and then the metal was dissolved in warm Br₂-methanol solution. The outside film surface was mounted on the specimen stub so that the tunnels extended toward the viewing direction. These films are self-supporting and consume only 25 nm of Al metal, so no significant smoothing effects are introduced at the magnifications used in this study.

Results

Qualitative aspects of tunnel growth.—The sequence of tunnel growth is illustrated in Fig. 1 for specimens that had been cleaned in NaOH and then etched at 90°C, 200 mA/cm². At 0.2 sec, only a dispersion of small cubic pits is present; the shallow scallops covering the surface are from the NaOH pretreatment. At 1.0 sec, the pit depth is significantly greater than width, i.e., the tunnel structure has started. At 90°C, and also at lower temperatures, initially only cubic pits are present and tunnels become evident between 0.5 ~ 1.0 sec.

At 5.0 sec, tunnels are well-developed along the three (100) directions. The tunnels extending parallel to the original surface lie just under the surface and originate from a side wall of a cubic pit. Small etch pits are seen that started some time after the first pits and will develop into later generations of tunnels. No general surface attack is evident.

At 10 sec, the tunnel array has a density of vertical tunnels on the order 10⁶ cm⁻² and exhibits a range of lengths and widths. Tunnels are straight, symmetrical, and usually tapered, although parallel-sided tunnels are frequently seen. At 90°C, the tunnel width at the base is generally 1.0 ~ 2.5 μm on a side, but occasionally some wider tunnels are seen. If etching at 90°C is continued, say, for 30 sec, tunnels will be 70-80 μm long and will have tapered to a width of ~0.25 μm.

Width measurements at specified tunnel heights for short tunnels superpose similar data for long tunnels.

That lateral dimensions do not change with time means that all dissolution takes place at the tunnel tip. This is a critical feature of tunnel growth. Dissolution occurs in one direction and wall surfaces are passive.

Figure 2 shows some structural details of tunnels grown at 70°C, 200 mA/cm² for 5 sec. The tunnels have square cross section and the tip surface is smooth, although sometimes what appears to be growth facets are present, as on the right. There is a well-defined right angle edge between tip face and wall; no rounded contours are evident. Crystal structure not only determines the direction of tunnel growth, but the tunnels grow by crystallographic dissolution. In contrast to the flat, generally featureless tip surface, the walls are highly rippled with matching contours on adjacent walls. The wall-ripple density is the same at 90° and 70°C, $\sim 10^5$ cm⁻¹.

It was thought that because of the active nature of

the tunnel tip dissolution might occur for some interval that would alter the tip appearance after the external current was shut off. To prevent any open-circuit attack, an etch was performed at 90°C in which the current was stepped to a cathodic pulse of 50 mA/cm² for 20 msec prior to open circuit. The appearance was unchanged by this procedure, suggesting no significant open-circuit attack. A more thorough evaluation of the potential distribution following current reversal is needed to determine how much dissolution may occur during the reversal transient.

The structural details of tunnels from an etch in 1N NaCl (5) were found to be identical to those of the tunnels from an HCl etch. The electrolyte composition in the restricted geometry of the tunnels is determined mostly by the dissolution rate of aluminum and will be a concentrated AlCl₃ solution, independent of the nature of the cation in the bulk solution.

Lower temperatures tend to produce wider tunnels. The widest tunnels observed in this study were about 7 μm, in samples etched at 60° and 65°C. No tunnels initiated if the temperature were below 60°C, confirming an observation made by Jackson (2). However, tunnels would continue to grow at lower temperature after tunnels had started at a higher temperature. For example, after 5 sec at 90°C, the temperature was lowered to 40°C by rapid addition of cold etchant, and the etch was continued for 20 sec. A tunnel that propagated during this period is shown in Fig. 3. The wider end section of the tunnel developed during the 40°C etch.

Quantitative aspects of tunnel growth.—Tunnel lengths were measured from micrographs like those in Fig. 1. Using the convention that the longest tunnels had initiated when the current was switched on, length vs. time was determined for these first generation tunnels. Different etch conditions were used and

Fig. 2. Tunnel tips at 70°C, 200 mA/cm², 5 sec

Fig. 3. Effect of temperature decrease from 90°C to 40°C during etch at 200 mA/cm². NaOH pretreatment.

the several sets of data are plotted in Fig. 4. At longer times, the tunnel density is so high that the location of a tunnel base is obscured in 45° views. In those cases, the specimens were examined in cross sections prepared with conventional metallographic techniques.

From Fig. 4, it is seen that neither pretreatment nor nominal cd had an effect on individual tunnel growth rate, although tunnel density and tunnel width depended on these particular conditions. Conditions that affect tunnel initiation do not necessarily have any effect on subsequent tunnel growth.

The initial tunnel growth rate increased with increasing temperature. At 70° and 80°C, the growth rate was constant up to ~55 μm length and decreased slightly at longer lengths. The dashed portion of the 70° curve indicates that tunnels perforated the specimen at 80 sec. Therefore, a longer tunnel length would have been recorded if a thicker foil had been used.

Tunnel growth at 90° and 97°C was quite different than at the lower temperatures. Up to 65-70 μm, the length increased as $t^{0.7}$, and the growth stopped when tunnels reached a length of 70-90 μm.

Initial growth rate vs. $1/T$ is shown in Fig. 5. An additional data point at 60°C (not shown in Fig. 4) is also included. An apparent activation energy of 15 kcal/mol describes the process over the whole temperature range.

The relationship between growth rate and cd at the tunnel tip is given by the relation

$$i = \left(\frac{zF\rho}{M} \right) \frac{dl}{dt} \quad [1]$$

Fig. 4. First generation tunnel lengths. Open symbols for HCl pretreatment and filled symbols for NaOH pretreatment. ○: 70°C, 200 mA/cm²; △: 80°C, 200 mA/cm²; ◇: 90°C, 50 mA/cm²; □: 90°C, 200 mA/cm²; *: 97°C, 200 mA/cm².

Fig. 5. Initial growth rate vs. reciprocal absolute temperature

For Al, $z = +3$, $\rho = 2.7$ g/cm³, and $M = 27$, so i (A/cm²) = $2.9 dl/dt$ (μm/sec). At 97°C, the initial cd was more than 20 A/cm², and at 60°C the initial cd was more than 2 A/cm². The latter is still quite high.

The metal weight loss during etching is 10-15% greater than calculated for the Faradaic charge. There is also a quantity of H₂ evolved from the surface that is equivalent to the excess weight loss. The gas may be evolved from the tunnels, but this has not been directly observed. This occurs to the same extent in neutral NaCl solutions as in the acid solutions used here.

The open-circuit potential was in the range -1.03 to -1.08V (SCE). Upon application of the current, the potential increased to ca. -0.8V SCE and then remained constant (± 5 mV). The voltage rise at 50 mA/cm² is shown in Fig. 6. The potentials include 10 ~ 20 mV IR drop between foil and Luggin probe, depending on the probe location with each specimen. A plateau during the first second is prominent at 70°C but gets smaller as temperature increases. This could be associated with either pit nucleation or tunnel initiation. Steady-state tunnel growth occurs at constant electrode potential.

When the cd was increased to 200 mA/cm² in 50 mA/cm² steps, the potential increased in equal increments, and the slope of the polarization line was close to the value estimated for the ohmic drop between Luggin probe and working electrode. Thus, ohmic polarization controls the i - V curve. This is in agreement with the observation that tunnel growth rate did not vary with nominal cd (Fig. 4). Extrapolation of such

Fig. 6. Electrode potential (SCE) vs. time at 50 mA/cm² and several temperatures.

Fig. 7. Dependence of electrode potential on cd at 70°C and 80°C.

data to zero cd, as in Fig. 7, gives an estimate of E_{A1} free of external IR, but includes the IR drop within the tunnels. Measurements at temperatures from 60° to 90°C gave a temperature dependence of E_{A1} of about -1 mV/degree.

Effect of open-circuit and step changes.—To get an idea of how rapidly tunnel growth can be quenched, the galvanostatic etch was interrupted for brief open-circuit intervals. For example, at 90°C and 200 mA/cm², the etch was interrupted at 5 sec for an interval of 43 msec and then continued for a total etch time of 10 sec. The longest tunnel length seen in this specimen was 30 μ m, which is typical of a 5 sec etch period (see Fig. 4). This experiment was repeated at 70°C and 200 mA/cm², applying a 43 msec interrupt at 15 sec with a total etch time of 30 sec. The tunnel lengths were characteristic of a 15 sec etch period.

Thus, 43 msec on open circuit is sufficient to quench tip dissolution. This was the shortest interval used in these experiments and may be longer than the minimum time needed for tip passivation.³ At the time the open-circuit interval was applied, the tip cd was 15 and 5.5 A/cm² at 90° and 70°C, respectively.

Instead of an open-circuit interval, the nominal cd was reduced from 200 to 50 mA/cm² over the 43 msec span. An etch for 5 sec at each cd (10 sec total) produced tunnels 50 μ m long. This is the same as for a steady cd, indicating that the step had no effect on tip cd. The reduction in nominal cd was accommodated by an instantaneous reduction in active area, as shown in Fig. 8. The nonactive tip area was repassivated at the same potential that supported active dissolution on the rest of the tip face.

³ Conditions recently described for a commercial etch process using pulsed d.c. indicate that an open-circuit interval of about 1 msec may cause tip passivation (13).

Fig. 8. Step change in cd from 200 mA/cm² (5 sec) to 50 mA/cm² (5 sec) at 90°C.

An increase in temperature causes a wide tunnel to break up into smaller tunnels. Figure 9 shows tunnels that were grown first at 65°C and then had hot etchant rapidly added to raise the temperature to 90°C. For smaller tunnels to form it is necessary for passive zones to develop on the wide tunnel tip. From this, we infer that the passivation process occurs more readily at higher temperature. The limiting tunnel length at 90° and 97°C (Fig. 4) must be owing to passivation of the tip occurring more easily at these temperatures than at lower temperatures.

Discussion

There are many common features of tunnel dissolution and pitting corrosion. Tunnel growth occurs in the neighborhood of the pitting potential (2, 6), and in this potential region the aluminum undergoes crystallographic attack (7). Dissolution at a high cd in restricted geometry creates a local electrolyte composition substantially different from the bulk. In this environment hydrogen evolution accompanies metal dissolution. Repassivation is a rapid process and occurs at the dissolution potential under some conditions (8).

Tunnel growth may be considered a special form of pitting corrosion. Its unique features are simultaneous dissolution and passivation on adjacent surfaces, and sustained balance between these two processes.

In our experiments, pit nucleation and growth during the first tenths of a second are similar to the events reported for initial pitting of iron and nickel (9) in that crystallographic pits with characteristic dimensions of a few microns are produced. The tunnel structure starts when dissolution becomes limited to one pit face due to passivation of the other faces. An elevated temperature seems necessary for this passive film to nucleate.

The reactions taking place at the tunnel tip are most likely the same as occur during conventional

Fig. 9. Effect of temperature increase from 65°C to 90°C at 200 mA/cm².

pitting at this potential. This would be dissolution across an adsorbed chloride layer or perhaps a thin barrier salt layer (9, 10); any thicker layer is precluded by the crystallographic nature of the attack. Tip passivation may result from transport of water across this film to the metal surface to form an oxide monolayer that blocks metal ion transport.

It is difficult to determine whether the etch tunneling process proceeds under transport or under activation control. Seeming to point to activation control are data at and below 80°C for which the tunnels grow at a constant rate as etching proceeds. However, since there is a significant *IR* drop along a tunnel, the potential at the tunnel tip must decrease during etching but still have no effect on dissolution rate. For example, at 80°C the growth rate is constant at 10 A/cm²; if the solution resistivity is 1 Ω-cm, then the *IR* drop increases 1 mV per μm of tunnel length.

At 90°C, the tunnels grow at a decreasing rate, at constant potential, as etching proceeds. One might, therefore, expect the growth rate to decline as $t^{1/2}$ under diffusion control, or as t^1 under ohmic control. The observed dependence of $t^{0.7}$ is intermediate between these and suggests mixed control.

The activation energy over the temperature range under study was found to be 15 kcal/mol. This is in the lower range of values associated with chemical reactions, and is higher by severalfold than values associated with diffusion or conduction through liquids. However, because an activation energy of 15 kcal/mol is in the range observed for diffusion in solids, one could not rule out diffusion control in a salt film formed at the tunnel tip.

There are two ways to sustain tunnel growth. The first is to have parallel reactions of tip dissolution and wall passivation. The rate at which a unit step is dissolved must equal the rate at which a unit length is passivated. There appears to be no inherent limitations in fitting any of the experimental observations to such a model. The presence of a passivating wall film that can spread relatively easily may be the necessary qualitative difference between wall and tip that sustains tunnel growth. Any model based on this idea

must provide a means for limiting one reaction to the wall and another to the tip.

The second way to make a tunnel is by sequential dissolution and passivation. A sequence consists of initiation of a pit at the tunnel tip, pit growth to fill the tunnel cross section, and passivation of this new surface. A new breakdown event on the tip face then starts the next cycle. Within the context of this model, the wall ripples may be the height of each sequence step and the tip facets are stages in pit growth. A serious shortcoming of this hypothesis is that since each sequence step requires initiation of wall passivation, it cannot easily account for continued tunnel growth after a step change to low temperature. Also, it is not clear why the center line of the tunnel remains fixed during growth. Dissolution on the tip face is expected to spread symmetrically from the breakdown point. This does not happen. Instead, dissolution stops near the previous wall boundary, independent of the point of initiation.

Tunnel growth during anodic dissolution is not unique to aluminum. A high density of microscopic tunnels propagating along crystallographic directions has been observed in stainless steel during stress-corrosion cracking (11), and in GaP and n-type GaAs during dissolution in methanolic Cl solution (12). These are not cubic systems, as is aluminum. It is not known if these all form by a similar mechanism.

A Simple Phase Transition Model for Metal Passivation Kinetics

G. L. Griffin

Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, Minnesota 55455

ABSTRACT

We present a minimal parameter kinetic model which describes the corrosion and passivation of metal surfaces. Two elementary steps are included, namely, the oxidation of surface metal atoms to produce adsorbed cations, and the subsequent dissolution of these cations into the electrolyte. Oxide layer formation is represented by two-dimensional condensation of adsorbed cations to produce a continuous phase; statistics of the condensation process are treated at the mean field level. The structure and magnitude of the i - V curve in the active-passive transition region is calculated for two cases: the limit of maximum passivation hysteresis (spinodal decomposition of the oxide phase), and the limit of zero hysteresis (equilibrated phase transition). Methods for analyzing experimental i - V curves to yield the rate constants associated with the model are presented.

Passivation plays a crucial role in the corrosion resistance and electrochemical behavior of many metals. The remarkable nature of the passivation effect is shown most clearly by polarization curves (i - V plots) of the active-passive transition region, which reveal that the oxidation current passes through a maximum and then actually decreases with increasing anodic polarization.

Detailed measurements of the passivation process have been performed for metals covering much of the periodic table (1, 2), using a variety of experimental techniques, many of which are considerably more sophisticated than simple i - V curve measurements (3). These results have provided both qualitative and quantitative evidence for a wide range of microscopic reactions, reflecting the fact that the formation of passive layers in real systems involves a complex and inter-related set of processes.

As a result of this complexity, there appears to be a shortage of experimentally useful kinetic models that are simple enough to provide an overall description of the active-passive transition region with a minimal number of kinetic parameters, but which contain parameters that have an interpretable physical significance (4-9). Such models, provided that their limitations and assumptions are clearly understood, can be a valuable aid to the experimenter.

In this paper, we describe a simple kinetic model for the passivation process which nevertheless can account for all of the characteristic features of the classical i - V curve for the active-passive transition. The model contains only two elementary rate processes, namely, the oxidative hydrolysis of surface metal atoms to produce adsorbed cations, and the dissolution of these cations away from the electrode surface. Passivation is effected by assuming that the rate of cation dissolution decreases as the cation coverage increases, due to the stabilizing influence of oxide lattice bond formation. After developing the model, we next examine the predicted i - V curves for two extremes of passivation behavior: the limit of maximum hysteresis, where the phase transition between isolated cations and a condensed oxide layer occurs via spinodal decomposition; and the limit of a fully equilibrated phase transition, where the i - V curve will track the "tie line" describing a first-order phase transition between dilute and condensed cation layers. For each limit, equations are developed which permit the kinetic parameters of the model to be determined directly from experimentally measured i - V curves.

Development of the Model

We begin by assuming that there are two elementary steps which determine the overall mechanism of corrosion and passivation: oxidative hydrolysis of surface metal atoms to form adsorbed cations

Key words: metals, electrode, corrosion, passivity.

followed by dissolution of cations into the electrolyte phase. The latter process may involve cations that are isolated on the electrode surface

as well as cations incorporated into the oxide layer

In particular, we do not explicitly consider the elementary steps by which isolated cations are incorporated into the oxide layer.

Instead, we further assume that the only feature which distinguishes an isolated adsorbed cation from a cation in the oxide layer is the presence of a full complement of nearest neighbor cations. This permits us to treat the surface adsorbate layer as a lattice gas of interacting cations, for which isolated cation behavior is obtained in the limit as $\theta \rightarrow 0$ and oxide-like behavior is obtained as $\theta \rightarrow 1$.

Finally, we assume that the dissolution rate constants defined in reactions [2] and [3] can actually be thought of as the two limiting extremes of a single, coverage dependent dissolution rate constant, $k_{dis}(\theta)$

$$k'_{dis} = k_{dis}(\theta = 0) \text{ and } k''_{dis} = k_{dis}(\theta = 1) \quad [4]$$

The coverage dependence of $k_{dis}(\theta)$ is assumed to arise from the fact that the difficulty of dissolving a cation will increase with the number of nearest neighbor cations, due to the formation of lattice oxide bonds. With this assumption, it becomes possible to describe cation dissolution using a single rate constant, which does, however, depend strongly on the average cation coordination number at each value of θ .

The exact form of an analytic expression used for $k_{dis}(\theta)$ will depend on the nature of the microscopic interactions and on the level of approximation used to solve the population statistics of the cation layer lattice. For our present purposes, the assumption of pairwise additive interactions in the mean field approximation provides a suitable illustration of the effects we wish to describe. At this level of approximation, the average desorption energy associated with cation dissolution, E_d , will be linearly proportional to cation coverage

$$E_d = E_d^0 + n_s \omega \theta \quad [5]$$

where n_s is the saturation number of nearest cation neighbors surrounding a surface cation in the oxide lattice, and ω is the effective interaction energy between neighboring cations. The latter will include the decrease in solvation energy produced by exclusion of water ligands from a cation when a new oxide

bond is formed, as well as the metal-oxygen bond energy. Other factors which influence passive layer stability (e.g., anion concentration, pH, etc.) will also be included in the effective value of ω .

If Eq. [5] is assumed to describe the average cation dissolution energy, then the rate constant for cation dissolution becomes

$$k_{\text{dis}} = k^{\circ}_{\text{dis}} \exp(-\beta\theta) \quad [6]$$

where $\beta = n_s\omega/RT$ and k°_{dis} represents the dissolution rate constant for an isolated adsorbed cation. Since this average rate constant describes the dissolution of all cations (isolated and oxide-incorporated), the rate expression for the dissolution current, i , becomes

$$i = k^{\circ}_{\text{dis}}\theta \exp(-\beta\theta) \quad [7]$$

At steady state, of course, this will equal the rate of cation formation by reaction [1]. We expect that reaction [1] will only occur on that fraction of the metal surface which is not covered by adsorbed cations. Further, we expect that the rate constant for the oxidative hydrolysis process will have the Tafel-like behavior typically associated with charge transfer processes. Thus we assume a rate expression for cation formation of the form

$$i = k^{\circ}_{\text{ox}}(1 - \theta) \exp(BV) \quad [8]$$

where $B = \alpha F/RT$ is the Tafel coefficient.

To obtain an analytical expression for the corrosion current using either Eq. [7] or [8], we must first find an expression relating θ and V . Eliminating i from Eq. [7] and [8] and rearranging, we can write

$$V = \frac{1}{B} [-\beta\theta + \ln(k^{\circ}_{\text{dis}}/k^{\circ}_{\text{ox}}) + \ln(\theta/1 - \theta)] \quad [9]$$

The key feature of Eq. [9] is that for $\beta > 4$, there will be potentials at which more than one value of θ satisfies the equation. In other words, multiple steady-state solutions for $\theta(V)$ exist. This can be shown by examining the sign of the first derivative of Eq. [9] with respect to θ .

This is illustrated in Fig. 1, where we show $\theta(V)$ based on Eq. [9] for the case of $\beta = 6$. The sigmoidal behavior produces a potential region where three distinct values of θ satisfy Eq. [9]. This behavior is en-

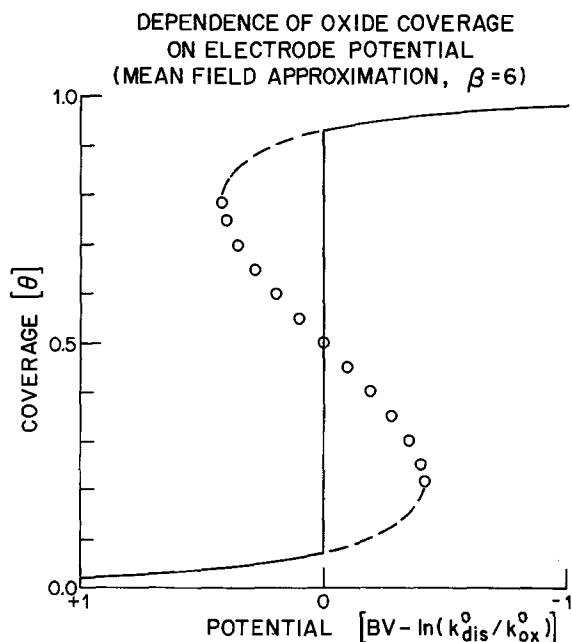

Fig. 1. Adsorbed cation coverage as a function of electrode potential, assuming a cation interaction parameter $\beta = 6$. (cf. Eq. [9]).

tirely analogous to a van der Waals loop (10), and represents the mean field approximation to a phase transition between isolated cations (dilute phase) and a continuous oxide layer (condensed phase). The vertical tie line passing through $\theta = 1/2$ represents the first order phase transition predicted by more exact statistical mechanical treatments. The dashed portions of the upper and lower branches that extend beyond the phase transition tie line represent excursions into the metastable regions of the condensed and dilute phase θ - V curves, respectively. Physically, these regions are accessible if a nucleation barrier for phase transformation is present, which prevents the condition of the cation layer from reversibly evolving along the phase transition tie line. The open circles represent the unstable region of the solution.

For larger values of β , the potential range of the multiple solution region increases. For smaller values of β , the range decreases, until multiplicity vanishes at $\beta = 4$. For $\beta < 4$, only a single-valued, nonsingular solution for $\theta(V)$ exists.

Examples of i - V curves calculated using these results for $\theta(V)$ are shown in Fig. 2. The parameters used in Eq. [7] and [8] are: $k^{\circ}_{\text{ox}} = 8 \times 10^{32}$ mA/cm²; $B = 57.6$ V⁻¹; and $k^{\circ}_{\text{dis}} = 1300$ mA/cm² (11). The interaction parameter, β , is varied between 0 and 6, in order to show the influence of attractive interactions (i.e., oxide formation) on the shape of the i - V curves. For reference, the asymptotic behavior limits (Tafel-like metal dissolution and constant rate oxide dissolution) are also shown.

For the extreme case of $\beta = 0$, no current maximum is observed. This illustrates that a simple two-step

Fig. 2. Current density-potential curves calculated for different values of the cation interaction parameter, $0 \leq \beta \leq 6$. Other rate parameters fixed: $k^{\circ}_{\text{ox}} = 8 \times 10^{32}$ mA/cm²; $B = 57.6$ V⁻¹; $k^{\circ}_{\text{dis}} = 1300$ mA/cm².

model based only on cation formation and uniform oxide dissolution (cf. Eq. [1] and [3] alone) cannot account for classic passivation behavior.

For $\beta = 2$, a current maximum is observed. For $\beta = 4$, which represents the critical value of the interaction constant in the mean field theory, the maximum value of the derivative of the current with respect to potential in the passivating region reaches infinity (at $\theta = \frac{1}{2}$).

For $\beta = 6$, the sigmoidal shape of the $\theta = V$ curve shown in Fig. 1 results in a multivalued analytic form for the i - V curve in the active-passive transition region. If the cation layer is fully equilibrated when the potential passes through this region, we would expect the i - V curve to follow the discontinuity represented by the horizontal tie line. If a nucleation process is required to convert between isolated cations and an oxide layer, then the i - V curve will follow the metastable branch dictated by the direction of the potential sweep. In the latter case, hysteresis would be expected around the active-passive transition.

Discussion

Clearly, the use of a two-step, variable rate constant model based on a mean field treatment is a gross approximation to the complex molecular behavior associated with the formation and destruction of the passive layer at a real metal surface. In particular, the assumption that the passive oxide layer can be modeled as a saturated monolayer of cations represents a serious restriction. Of equal concern is the use of a linear coverage dependence for the effective dissolution energy (cf. Eq. [5]), when in reality the value of E_d represents an average over a complicated distribution of step, ledge, and kink cation sites in the passive film. However, the most important feature of passive layer behavior is contained in the model, namely, the fact that the rate of cation dissolution must be treated as a function of cation (oxide) coverage.

With these cautions in mind, we proceed to examine the limiting behavior and major structural features of the i - V curves predicted using this model. Our goal is to relate these experimentally measurable features to the microscopic rate parameters for a given system.

Asymptomatic behavior.—Cathodic potentials.—At sufficiently negative values of the potential, θ will approach zero (cf. Fig. 1). As seen from Eq. [8], the observed current will approach the Tafel-like limit assumed for metal dissolution from an oxide-free surface

$$i_T = k_{ox} \exp(BV) \quad [10]$$

Anodic potentials.—At sufficiently positive potentials, θ will approach unity. As seen from Eq. [7], the observed current will approach the constant value characteristic of oxide dissolution in the passive region

$$i_p = k_{dis} \exp(-\beta) \quad [11]$$

We note that if i_p is known experimentally, then k_{dis} can be determined using this equation, provided that the value of β can be found independently (see below).

Structural features.—Maximum hysteresis.—The distinguishing feature of i - V curves in the active-passive transition region is the magnitude and shape of the current maximum. As noted in the description of Fig. 1 and 2, the branch of the analytic θ - V curve which the actual i - V curve will track is determined by the size of the nucleation barrier associated with the cation layer phase transition. We will first consider the situation resulting for the maximum barrier, in which case the i - V curves will extend into the metastable region all the way to the spinodal decomposition points.

Differential of Eq. [7] shows that the maximum current in this case occurs at $\theta_m = 1/\beta$. We can also see that within the context of the present model, a metal

surface will not show a maximum in its i - V curve unless $\beta > 1$. In other words, the latter condition represents the minimum necessary cation interaction energy to produce a passivating oxide layer.

We can find the relative amplitude of the current maximum by substituting θ_m back into Eq. [7]. The ratio of the maximum current, i_m , to the limiting current at potentials well into the passive region, i_p , is then

$$i_m/i_p = [\exp(\beta - 1)]/\beta \quad [12]$$

Thus a comparison of experimentally determined values of i_m and i_p will provide an estimate of β .

The potential at which the maximum current occurs, V_m , is found by substituting θ_m into Eq. [9]

$$V_m = \frac{1}{B} [\ln(k_{dis}^0/k_{ox}^0) - \ln(\beta - 1) - 1] \quad [13]$$

Thus k_{dis}^0 and β can be determined by solving any two of the Eq. [11]-[13] simultaneously. Comparison of the values obtained using alternative methods will provide a consistency check for the apparent accuracy of the model, since the experimental quantities i_p , i_m , and V_m are all independently determined.

The spinodal decomposition points of the metastable branches of the θ - V curve (Fig. 1) are located where the derivative of Eq. [9] with respect to θ vanishes. The coverages at these two points, θ^\pm , are given by

$$\theta^\pm = \frac{1}{2} \pm \sqrt{\frac{1}{4} - \frac{1}{\beta}} = \frac{1}{2} \pm \gamma \quad [14]$$

provided that $\beta \geq 4$.

The potential at each end point is found by substituting Eq. [14] into Eq. [9]. The potential range between the two points, ΔV , which corresponds to the maximum range that can be expected for a hysteresis loop, is then

$$\Delta V = \frac{1}{B} \left[2\beta\gamma - 2 \ln \left(\frac{\frac{1}{2} + \gamma}{\frac{1}{2} - \gamma} \right) \right] \quad [15]$$

Equilibrated phase transition.—For systems where there is no nucleation barrier for conversion between the dilute and condensed phases of the cation layer, there will be no hysteresis loop during a cyclic potential sweep. Instead, the i - V curve will track the phase transition tie line when passing through the active-passive transition region. The potential of this tie line, $V_{1/2}$, is given by

$$V_{1/2} = \frac{1}{\beta} \left[\ln(k_{dis}^0/k_{ox}^0) - \frac{\beta}{2} \right] \quad [16]$$

(cf. Eq. [9], with $\theta = \frac{1}{2}$). Thus, for materials which do not show hysteresis, Eq. [16] should be used instead of Eq. [13] for determining k_{dis}^0 and β from experimental results.

If the i - V curve tracks the equilibrium tie line, then we also note that the maximum current will not reach the value predicted by Eq. [12]. Instead, the maximum will occur at the intersection of the phase transition tie line and the high current low coverage branch of the i - V curve.

In this case, an exact analytic expression cannot be written for the maximum current in the absence of hysteresis, i_m^* . However, a reasonable approximation can be obtained by substituting $V_{1/2}$ from Eq. [16] into Eq. [8], and setting $\theta = 0$. This procedure will overestimate i_m^* by at most a factor of two, in the limiting case of $\beta = 4$. For values of $\beta > 4$, the approximation rapidly approaches the correct value, as seen either from Fig. 2 or Eq. [14] (note that $0 < \theta_m^* < \theta^-$). The equation relating i_m^* to i_p becomes

$$i_m^*/i_p = \exp(\beta/2) \quad [17]$$

Equation [17] should be used instead of Eq. [12] to estimate β for systems which do not show hysteresis.

Finally, we note that many real systems would be expected to show hysteresis behavior somewhere between the extremes of spinodal decomposition and equilibrated phase transition. Solution in this case will require knowledge of the nucleation barriers for the oxide layer phase transition, which generally is not available. However, one simplified case can be considered. If we assume that the coverage supersaturation at the nucleation threshold is the same for phase transitions in either direction, then comparison of Eq. [9] and [16] shows that $V_{1/2}$ is equal to the arithmetic average of the observed potential limits of the hysteresis loop, V_+ and V_-

$$V_{1/2} = (V_+ + V_-)/2 \quad [18]$$

Equation [18] provides a method to evaluate $V_{1/2}$ for systems which exhibit limited hysteresis. (Equation [18] is accurate in fact even for the limit of spinodal decomposition). Values of β and k_{dis}^0 can then be determined as above.

Summary

We have described a minimal parameter model which can reproduce the important features of the i - V curve in the active-passive transition region. The physical significance of each parameter in the model has been discussed, along with methods for determining the values of the parameters using experimental measurements. While the model is only an approximation to most real systems, we believe that it does provide a basis for proposing and evaluating more complicated passivation mechanisms. To this end, future work should be done both to assess the utility of the model for correlating experimental data and to theoretically examine approaches to loosening the restrictions imposed by the assumptions of the model.

Diffusion Controlled and Transient Photocurrents of Photo-Oxidation Reactions at Polycrystalline α - Fe_2O_3

M. Anderman* and John H. Kennedy*

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Steady-state photooxidation currents at polycrystalline α - Fe_2O_3 electrodes with low band bending were found to depend significantly on the reducing agents present in the electrolyte. Photooxidation of water at low band bending exhibited only transient character. Diffusion-controlled photocurrents for the photooxidation of I^- and $\text{Fe}(\text{CN})_6^{4-}$ in acidic solutions, and OH^- in unbuffered neutral solution were observed at an α - Fe_2O_3 RDE and could be fitted to the Levich equation. The steady-state and the transient photocurrents are analyzed and discussed in terms of cathodic back-reaction of intermediate products with conduction band surface forbidden electrons.

The semiconductor/electrolyte interface has been extensively studied in the last decade or so primarily because of its possible use for solar energy conversion. When an ideal semiconductor is brought into contact with a redox couple in solution, equilibration of the electrochemical potentials of the semiconductor and the redox couple will occur. If the electrochemical potential of the solution was initially more positive than that of an n-type semiconductor (the important case for solar energy conversion at n-type semiconductors), equilibration will result in the formation of a depletion layer inside the semiconductor with upward bending bands (1). This electric field will drive electron holes that may be generated by $>$ bandgap illumination toward the surface, and will drive photogenerated electrons toward the semiconductor bulk. Thus, one

can obtain a photopotential and a photocurrent between the illuminated semiconductor anode and a dark metallic cathode that is immersed in the same solution (1).

Under potentiostatic conditions and a reversible electrolyte couple the ideal model predicts: (i) onset of photocurrent will occur promptly following the onset of depletion layer formation, i.e., just anodic to the so-called flatband potential (V_{FB}); (ii) when a specific adsorption of the redox couple does not occur, the photocurrent should depend on the light intensity and on the semiconductor properties but should be independent of the redox couple; and (iii) no dark current is expected for a stable ideal semiconductor when the electrode potential is within the gap of the semiconductor.

The behavior of practical semiconductor anodes is usually less than ideal. Thus, (i) the onset of steady-

Key words: α - Fe_2O_3 photoanode, diffusion-controlled photocurrent, RDE photoanode, transient photocurrent.

state photocurrent often occurs a few hundred millivolts anodic to the observed V_{FB} ; (ii) in a few cases (2-4) it has been found that the photocurrent does depend upon the reduced species even when no shift of V_{FB} by specific adsorption could be detected; and (iii) dark current of various magnitude has frequently been observed in the forbidden potential zone.

Since these three deviations from ideality will usually result in a decrease of the optimal photoconversion efficiency, it is important to investigate them. We have extended our studies on polycrystalline α - Fe_2O_3 anodes in aqueous solution to the use of the rotating ring-disk electrode (RRDE). With it, the diffusion dependence of the photocurrent was studied and the oxidation products were analyzed. A light shutter to investigate transient currents has also been employed. It was found that not only may the redox species influence the photocurrent but that there exists a potential range in which water oxidation is completely deactivated by a coupled cathodic reaction, while the photooxidation of some reducing agents occurs under quantitative diffusion-limited conditions. The results are discussed in terms of a back-reaction of the water oxidation products with surface forbidden electrons.

Experimental

Polycrystalline α - Fe_2O_3 electrodes doped with 1 atom percent (a/o) SiC were prepared by sintering the appropriate pressed powder mixture at 1360°C for 14-20 hr as described earlier (5). Gold was sputtered on the back surface to form ohmic contact. To assemble the α - Fe_2O_3 electrode as a disk onto the Pine Instrument AFDTI36 Ring (demountable)-Disk Electrode Assembly, the following procedure was used. The electrode was contacted to a stainless steel pin with silver epoxy. The back surface was then insulated with black wax and a suitable Teflon cup was glued to the back surface using 5 min epoxy resin and Loctite 404 industrial adhesive. While it is generally desirable to polish a disk electrode for RRDE experiments, we found that polishing decreased the photoactivity of the surface probably by introducing surface defects. Thus, the flatness of the pellet surface was simply measured with a micrometer and only those electrodes that were perfectly perpendicular to the pin holder with deviations from flatness smaller than 50 μ m were used. After this check, the electrode and the Teflon back support were gently machined on the edge to the exact diameter of the RRDE disk (0.625 cm diam, 0.307 cm² area), leaving the Teflon cup a few micrometers oversize for a press fit. A small amount of Halocarbon 25-5S grease was applied around the electrode sides to ensure a good seal. The electrode was then pressed into the ring disk assembly, washed with acetone and deionized water, and was then ready for use. The ring electrode was platinum. The only problem encountered with this procedure was that sometimes the halocarbon grease seal had to be renewed after a few days of operation.

The electrochemical cell was a 200 ml all quartz cylinder covered with a Teflon lid. The cell included a SCE reference, Pt wire counterelectrode separated from the main compartment by fritted glass, and gas entry tubes. The light source was a 150W xenon lamp that delivered a light intensity of \sim 500 mW/cm² at the electrode surface. The light path included a shutter (1 in.), IR filter, reflecting mirror, and a 10 cm quartz lens. The light beam reached the electrode through the bottom of the cell, and hence, passed through \sim 8 cm of electrolyte solution.

The electrochemical instrumentation consisted of a Pine Instrument RDE-3 dual potentiostat in conjunction with X-Y recorder and a Tektronix 564B storage oscilloscope. A Pine Instrument ASR motor with rotation speeds of 0-3820 rpm (0-400 sec⁻¹) was used. The light shutter was Uniblitz 225L driven by a Uni-

blitz SD 122 electronic shutter drive unit that was pulsed by a Hewlett-Packard 3311A function generator. Opening time of the shutter was 2.0-2.5 msec.

The experiments in neutral solutions were carried out with a CO₂-free electrolyte. Cell resistance was \sim 100 Ω arising predominantly from the bulk resistance of the α - Fe_2O_3 electrode.

Results

Photocurrent-potential curves for a polycrystalline α - Fe_2O_3 electrode in 1M NaOH is given in Fig. 1. Curve 2 is the steady-state photocurrent as recorded at a scan rate of 10 mV/sec. Curve 1 shows the transient peak values that were taken pointwise with the oscilloscope at 50 mV intervals. The transient peak exhibited a first-order decay into the steady-state value with a lifetime of $<$ 2 msec. When the shutter was turned off, a cathodic transient peak of slightly lower magnitude and similar lifetime was observed, in agreement with earlier reports (6-8). The transient and the steady-state photocurrent converged into one curve about 800 mV past the onset of the transient photocurrent.

The V_{FB} of similar α - Fe_2O_3 electrodes, determined by Kennedy and Frese (9) from extrapolation of Mott-Schottky plots, was $-0.73V$ vs. SCE in 2M NaOH. However, in this work we have used a much simpler and satisfactory method to measure V_{FB} . The electrode potential was stepped from the onset of the steady-state photocurrent in the cathodic direction in intervals of 25-50 mV. At some point the anodic transient peak disappeared, and the electrode showed no photoeffect. If the electrode was stepped further in the cathodic direction, a small cathodic transient photoeffect was evident. The potential at which no photoeffect was observed is taken to be V_{FB} . Surprisingly, this simple method gave highly reproducible results. The experimental uncertainty for a specific electrode was $<$ 50 mV, and the variation among different samples was $<$ 100 mV. From this method, V_{FB} in 1M NaOH was $-0.8 \pm 0.1V$ vs. SCE, in good agreement with previous data (9-11).

In 1M HClO₄ with no added redox couple, the general picture was similar (curves 1 and 3 of Fig. 2). Anodic transient photoeffects started \sim 0.1V vs. SCE while steady-state photocurrent began only at \sim 0.5V vs. SCE. The two curves converged \sim 1V anodic to the onset of the transient photocurrent.

Addition of 0.1M NaCl to the 1M HClO₄ solution had no effect on the transient photocurrent. However, the steady-state photocurrent moved cathodically (curve 2 of Fig. 2) so that it was between the transient and the steady-state photocurrents of the chloride-

Fig. 1. Photocurrent-potential curves for a polycrystalline α - Fe_2O_3 electrode in 1M NaOH. 1, Transient photocurrent taken pointwise with an oscilloscope, and 2, steady-state photocurrent taken with a scan rate of 10 mV/sec. Electrode area = 0.307 cm².

Fig. 2. Photocurrent-potential curves for $\alpha\text{-Fe}_2\text{O}_3$ in 1M HClO_4 . 1, Transient photocurrent with no added redox species or in 0.1M NaCl or in 0.1M KBr. It is also the steady-state photocurrent-potential curve for 0.1M KBr/1M HClO_4 . 2, Steady-state curve for 0.1M NaCl/1M HClO_4 . 3, Steady-state curve for 1M HClO_4 (H_2O oxidation). 4, Steady-state and transient curve for 0.01M KI/1M HClO_4 uncorrected for light absorption by the colored solution.

free solution. The convergence of the transient and the steady-state photocurrents now occurred at a less anodic potential. The effect of bromide was even more pronounced. In fact, the transient and the steady-state photocurrents were essentially identical, except for a small difference near the onset potential, and they were also identical to the transient values for 0.1M NaCl and halide-free solutions. V_{FB} for all solutions as determined by the procedure described above was $0.1 \pm 0.1\text{V vs. SCE}$.

Curve 4 in Fig. 2 is the corresponding curve for a 0.01M KI/1M HClO_4 solution. It must be noted that the measured photocurrent was reduced due to absorption of light by the colored solution. In this case, no transient effect was seen. The onset of the photocurrent was around 0.05V vs. SCE , and the V_{FB} measurement gave $0.0 \pm 0.1\text{V vs. SCE}$. It appears from these results that I^- was the only species that affected V_{FB} by specific adsorption on the electrode surface.

Even here, the effect was rather small, only 50-100 mV. It is important to note that only transient effects that have a lifetime $\cong 2$ msec (the opening time of the shutter) could be detected. Dark current, observed $\sim 1.5\text{V vs. SCE}$, was only slightly affected by the addition of halide ions to the solution. Dark current was more dependent upon the specific electrode used.

Next, the dependence of the photocurrent on the rotation rate of the disk electrode for halide-containing solutions was measured. Figure 3 shows a photocurrent-potential curve at a rotation frequency of 196 sec^{-1} for $2.88 \times 10^{-4}\text{M KI/1M HClO}_4$ solution. It can be seen that the photocurrent was composed on two separate oxidation waves. The first one almost reached a plateau value that was dependent upon rotation speed (Fig. 3 inset) but was practically unchanged when the light intensity was reduced by a factor of two. The second oxidation wave started at the same potential at which the steady-state photooxidation of water was observed in the halide-free solution and exhibited the same general shape. Also, the dependence of the photocurrent on the rotation speed diminished as the electrode potential was scanned anodically from the plateau region. On the other hand, the dependence of the photocurrent upon the light intensity grew, reaching a linear dependence at 1.5V vs. SCE .

For a diffusion-limited current (I_{dl} , mA) at an RDE, Levich gives (12)

$$I_{dl} = 0.62nFAD^{2/3}\nu^{-1/6}\omega^{1/2}C_b \quad [1]$$

where n is the number of electrons transferred in the reaction, F is the Faraday constant, A is the electrode area (cm^2), D is the diffusion coefficient (cm^2/sec), ν is the kinematic viscosity (cm^2/sec), ω is the angular velocity (rad/sec), and C_b is the concentration of the diffusing species (M) in the bulk solution.

Thus for diffusion-limited current at an RDE, the current should depend on the square root of the rotation speed. Figure 4 is I_{dl} vs. $\omega^{1/2}$ for the photocurrent values at 0.45V vs. SCE taken from the curves shown in Fig. 3 (inset). An excellent straight line was obtained clearly indicating that the photocurrent was diffusion limited at that potential. The theoretical slope of the line in Fig. 4 can be calculated from Eq. [1] if the various factors are known. A value for D of $1.72 \times 10^{-5}\text{ cm}^2/\text{sec}$ for I^- (13), and $\nu = 10^{-2}\text{ cm}^2/\text{sec}$ were used. However, the value of n depends on the

Fig. 3. Photocurrent-potential curve for an $\alpha\text{-Fe}_2\text{O}_3$ electrode in $2.88 \times 10^{-4}\text{M KI/1M HClO}_4$. Fig. 4. Levich plot (I_{d1} vs. $\omega^{1/2}$) for the photocurrent values at 0.45V vs. SCE from the data shown in Fig. 3 (inset, broken line).

relative amounts of I_3^- and I_2 at the surface (14)

By using $K = 710 \text{ M}^{-1}$ (15) as the formation constant of I_3^- and taking into account the difference between the diffusion coefficient of I^- and I_2 (14), a value of $n = 0.87$ was calculated for these conditions. With these values inserted into Eq. [1]

$$\frac{dI_{d1}}{d\omega^{1/2}} = 6.7 \mu\text{A}\cdot\text{sec}^{1/2} \quad [4]$$

in reasonable agreement with the experimental slope of $6.1 \mu\text{A}\cdot\text{sec}^{1/2}$. The small difference may be attributed to adsorption of I_2 on the surface (16), which will change the average value of n . Adsorption of I^- is also the most likely explanation for the nonzero intercept seen in Fig. 4.

A detailed study of photooxidation competition at an $\alpha\text{-Fe}_2\text{O}_3$ photoanode using the ring electrode will be given in a separate publication (17). However, it can be noted here that the collection efficiency for I_2 at the ring approached 100% (of the theoretically expected value) up to 0.5V vs. SCE and declined sharply at higher potentials.

In a similar way, Br^- and Cl^- in acidic solution and all halides in neutral or moderately basic solution ($\text{pH} < 12.4$) exhibited photocurrents dependent upon the rotation speed in the potential region cathodic to the onset of steady-state photocurrent for the oxidation of water (OH^-). However, for these solutions, the photooxidation of water began before a diffusion-limited plateau current for X^- was achieved and no calculations as above could be made.

Figure 5 shows I-V curves for a $6 \times 10^{-4}\text{M}$ $\text{Fe}(\text{CN})_6^{4-}/1\text{M}$ HClO_4 solution at various rotation speeds. Figure 6 is a Levich plot for these data. As in the case of I^- , the photocurrent showed a diffusion-limited plateau current with an excellent fit to the Levich Eq. [1]. In this case, the photocurrent values were almost identical to the dark current values that were obtained at a Pt disk electrode of the same size in the same solution (curve 1 in Fig. 6). The diffusion coefficient for $\text{Fe}(\text{CN})_6^{4-}$ calculated from Eq. [1] using the slope of the line in Fig. 6 was $0.52 \times 10^{-5} \text{ cm}^2/\text{sec}$ and compared very well with the value of $0.50 \times 10^{-5} \text{ cm}^2/\text{sec}$ in 1M KCl reported by Jahn and Vielstich (18).

Figure 7 shows I-V curves for an $\alpha\text{-Fe}_2\text{O}_3$ electrode in an unbuffered $2 \times 10^{-4}\text{M}$ $\text{OH}^-/1\text{M}$ NaClO_4 solution at various rotation speeds. This measurement was

Fig. 5. Photocurrent-potential curves for an $\alpha\text{-Fe}_2\text{O}_3$ electrode in $6 \times 10^{-4}\text{M}$ $\text{Fe}(\text{CN})_6^{4-}/1\text{M}$ HClO_4 for the first oxidation wave at various rotation frequencies.

Fig. 6. I_{d1} vs. $\omega^{1/2}$ plots for $6 \times 10^{-4}\text{M}$ $\text{Fe}(\text{CN})_6^{4-}/1\text{M}$ HClO_4 . 1, Pt disk in the dark, 0.7V vs. SCE. 2 and 3, Two samples of $\alpha\text{-Fe}_2\text{O}_3$ disk electrodes with data taken at 0.5V vs. SCE.

carried out under N_2 or N_2/O_2 atmosphere to eliminate the influence of dissolved CO_2 on the pH. Also, a single compartment cell was used for these studies to maintain constant pH and this was verified experimentally.

As with I^- and $\text{Fe}(\text{CN})_6^{4-}$, the photocurrent in dilute base exhibited a diffusion-limited plateau region before it rose to what is apparently a second oxidation wave. A plot of Eq. [1] for photocurrent at 0.25V vs. SCE is given in Fig. 8. If the diffusing species is assumed to be OH^- and its concentration is used in Eq. [1], the calculated diffusion coefficient is 2×10^{-5}

Fig. 7. Photocurrent-potential curves for an $\alpha\text{-Fe}_2\text{O}_3$ electrode in an unbuffered $2 \times 10^{-4}\text{M OH}^-/\text{NaClO}_4$ solution at various rotation frequencies.

cm^2/sec . This value is significantly smaller than the typical reported values of $4.5\text{--}5.0 \times 10^{-5} \text{ cm}^2/\text{sec}$ (19). This experiment was repeated several times with varying OH^- concentration, supporting electrolyte, and electrode. In all cases, Levich plots were quite linear and I_{dl} depended linearly with $[\text{OH}^-]$ as predicted. At the same time, the slope was always about one-third of the calculated one.

Discussion

The results as shown in Fig. 1-8 and the additional data described above have shed some new light on the behavior of semiconductor photoanodes. It is the transient photocurrent at these electrodes that behaves as expected at an ideal semiconductor. The transient photocurrent turns on right at V_{FB} and it is independent of the redox couple in solution for a given V_{FB} . It depends linearly on the light intensity and is independent of the rotation speed. The transient photocurrent shifts 59 mV/pH (9) as does V_{FB} (1), while the shift of the steady-state photocurrent may be somewhat different (5). Thus, the transient photocurrent is controlled solely by solid-state processes.

The degree to which this is also true for the steady-state photocurrent depends on the nature of the charge transfer at the electrode surface.

Fig. 8. I' vs. $\omega^{1/2}$ plot for the data in Fig. 7 taken at 0.25V vs. SCE . Rotation frequencies: $12.25\text{--}100 \text{ sec}^{-1}$.

Thus, redox species with fast charge-transfer kinetics exhibit almost ideal behavior even for the steady-state photocurrent. This is the case for I^- and $\text{Fe}(\text{CN})_6^{4-}$. As the charge-transfer kinetics become less rapid, as for Cl^- and H_2O , the photocurrent no longer behaves ideally. Hardee and Bard (6) proposed cathodic dark current coupled to the anodic photocurrent as responsible for the transient effects they observed. Curran and Gissler (7) and, more recently, Iwanski *et al.* (8) have also studied these effects. Back-reaction of photooxidation products (or more likely, intermediates) with conduction band electrons via surface states is the probable cause of the several observations reported here. At very small band bending, just anodic to V_{FB} , electrons may still be accessible at the surface. Highly reactive photooxidized species, such as H_2O^+ , $\cdot\text{OH}$, $\text{Cl}\cdot$, *etc.*, are capable of capturing these electrons causing a cathodic current component equivalent to the anodic photocurrent component. This results in no net steady-state photocurrent. As the band bending increases, the availability of electrons at the surface decreases so that the cathodic current component also decreases. Therefore, the anodic steady-state photocurrent increases. Finally, at sufficiently large band bending no electrons are available to react at the surface and the cathodic current component disappears. At this potential, the steady-state photocurrent will converge with the transient photocurrent and will also be independent of the redox species present. The amount of band bending required to overcome the cathodic current component clearly depends on the affinity of the photooxidized species for electrons, and the observed order: H_2O^+ , $\cdot\text{OH}$, Cl^- , Br^- , I^- , $\text{Fe}(\text{CN})_6^{3-}$ is expected from electronegativity considerations.

A rather exceptional result that emphasizes the importance of the process described above is displayed in Fig. 3 and 5. Under conditions at which water is thermodynamically oxidizable by the photogenerated hole and is present in large excess at the surface, diffusion-controlled oxidation of I^- or $\text{Fe}(\text{CN})_6^{4-}$ with no oxidation of water was observed. Theoretical analysis of the influence of mass transfer and light flux on the photocurrent at photoelectrodes has recently been published by Bruckenstein and Miller (20).

We now turn to the results of Fig. 7 and 8. First it should be noted that the consumption of OH^- at the surface will cause the surface pH to drop. This, in turn, will change the adsorption equilibrium at the surface involving $\text{OH}^-/\text{H}_2\text{O}$ and will change V_{FB} (1). A less anodic V_{FB} means smaller band bending and a correspondingly smaller photocurrent. Thus, scanning of the potential in the plateau region ($0.1\text{--}0.3\text{V vs. SCE}$ in Fig. 7) hardly changes the band bending but mainly affects the $\text{OH}^-/\text{H}_2\text{O}$ adsorption equilibrium. When the surface pH drops to ~ 3.5 , the flux of H^+ (H_3O^+) away from the electrode surface becomes large enough to maintain a steady-state pH value at the surface. From that point, scanning the potential will increase the band bending and also the photocurrent. According to this model, the second oxidation wave corresponds to photocurrent at a surface pH of ~ 3.5 . The amount of OH^- depletion at the surface will depend on the normal diffusion-convection parameters, and hence, Levich behavior is expected.

An additional factor is that H_2O , which is a weaker nucleophile than OH^- , requires larger band bending to overcome back-reaction of intermediates. Thus, the first wave could be due to OH^- oxidation while the second wave is due to direct H_2O oxidation. From these experiments, there is no unambiguous way to distinguish between these two models.

Another observation needing discussion is the slope in Fig. 8. The good slopes observed for I^- and $\text{Fe}(\text{CN})_6^{4-}$ exclude the possibility of experimental error. However, the OH^- oxidation reaction is not a

one-step electron-transfer reaction, and the smaller slope is likely to be caused by the more complex kinetics.

Damjanovic (21) has summarized many of the possible paths for electrochemical O₂ evolution. Many of these paths can be generalized under the following reaction scheme (22)

where *S* stands for surface active site and *k* is the rate constant for the particular step. If reaction [5] occurs under diffusion-controlled conditions, its rate, *v*, will be

$$v_1 = K_D[\text{OH}^-] \quad [7]$$

where *K_D* is the appropriate diffusion factor which, in the case of an RDE, is

$$K_D = 0.62 AD^{2/3} \nu^{-1/6} \omega^{1/2} \quad [8]$$

The rate of the back-reaction, *v*₋₁, is

$$v_{-1} = k_{-1}[\text{SOH}] \quad [9]$$

where *k*₋₁ is a potential (band bending) dependent rate constant. The rate of reaction [6] will be

$$v_2 = k_2[\text{SOH}] \quad [10]$$

At a steady state, as is assumed for the case of an RDE

$$v_1 = v_{-1} + v_2 \quad [11]$$

Solving for the steady-state concentration of SOH one obtains

$$[\text{SOH}] = \frac{K_D[\text{OH}^-]}{k_2 + k_{-1}} \quad [12]$$

If reaction [6] includes the slow step, the current will be

$$\begin{aligned} I' &= nFv_2 = \frac{k_2}{k_2 + k_{-1}} FK_D[\text{OH}^-] \\ &= \frac{k_2}{k_2 + k_{-1}} 0.62 AFD^{2/3} \nu^{-1/6} \omega^{1/2} [\text{OH}^-] \quad [13] \end{aligned}$$

While the linear dependence upon [OH⁻] and ω^{1/2} is retained, the values of the pseudo diffusion-limited current, *I*'_{dl}, are reduced by a factor, *k*₂/(*k*₂ + *k*₋₁), due to the back-reaction of equation [5], i.e.

$$I'_{dl} = \frac{k_2}{k_2 + k_{-1}} I_{dl} \quad [14]$$

The fit between the derivation above and the previous results is straightforward. Reaction [5] in the forward direction is responsible for the transient photocurrent while in the backward direction is responsible for the cathodic transient. Reaction [6] is a measure of the steady-state photocurrent. Experimentally it was found that *k*₂/(*k*₂ + *k*₋₁) ≈ 0.3 so that the steady-state photocurrent occurs at a rate that is only one-third of the rate of the forward reaction [5], at that particular band bending.

While it is not possible to be more specific about the nature of the adsorbed intermediates, which in fact are not yet known even for metal electrodes, the gen-

eral scheme presented above fits all the experimental results reported in this work quite nicely.

Conclusions

The following have been observed and discussed for polycrystalline α-Fe₂O₃ photoanodes.

1. The transient photocurrent fits the ideal semiconductor/electrolyte interface model.

2. The availability of surface-forbidden electrons at the surface to react with highly active intermediates causes a decrease in the steady-state photocurrent at low band bending in the presence of redox species exhibiting slow charge-transfer kinetics.

3. Photoelectrochemical reactions that occur under diffusion control in aqueous solution have been established.

The extension of these observations to other non-ideal semiconductors is possible and should be investigated. TiO₂ and WO₃ have shown dependence of the photocurrent on redox species (2-4) and are likely candidates to exhibit similar behavior to that reported here for polycrystalline α-Fe₂O₃.

ABSTRACT

Basic electrochemical processes at GaAs, GaAsP, and GaAlAs electrodes were studied in H_2O_2 aqueous solutions at several pH values. An analytical automatic system, which directly plots gallium concentration vs. potential, allows the collection of information on corrosion processes. The approach of making continuous analysis of gallium ions, while dissolving the semiconductor at a preselected potential, was used in conjunction with impedance and ellipsometric measurements in order to study interfacial phenomena. On the basis of these results, a mechanism for chemical corrosion (etching) which involves electrons captured from semiconductor surface states by H_2O_2 was proposed. Anodic polarization can also induce corrosion by hole generation in the valence band or by avalanche breakdown. As expected, pH plays a fundamental role in the corrosion process through the solubility shift of the oxide layer. Further consideration is given to the effect of illumination, with special emphasis on p-type semiconductors, for which it can lead to an inhibition effect on corrosion via a current doubling mechanism. Finally, application of selective etching is described for GaAs, GaAlAs, and GaAsP hetero structures.

Selective etching has been the subject of a number of investigations of interest in connection with III-V semiconductor devices, heterojunction laser technology, and more general multilayer device technology (1, 2). For practical purposes, the dissolution is generally carried out by using redox etchants, without a thorough knowledge of the mechanisms leading to the selective corrosion phenomenon (3-6). The result is a semiempirical approach which is time consuming when a new specific problem is encountered.

Solar energy conversion has stimulated fundamental research in the field of semiconductor electrochemistry (7-9), and processes associated with semiconductor interfaces are now better understood. However, this knowledge is still very difficult to exploit directly for the investigation of redox systems that might be suitable for selective etching. From a practical point of view, it means that the corrosion behavior of a particular semiconductor has still to be explored in detail experimentally. To solve such problems, the choice of the perfect tool is not obvious. Since corrosion involves electron exchange through a solid-liquid interface, it follows that electrochemical tools seem to be the most appropriate. In the first instance, current-voltage curves are generally obtained. However, it has been observed in oxidizing media, and this point will be discussed at length later in this paper, that the anodic corrosion current of a n-type semiconductor in the dark is sometimes exactly compensated for by electrons captured by the etchant over a large potential range (2, 10-13). No information can be obtained about the corrosion rate for such situation from classical voltamperometry. This necessitates an alternative way of gaining further insight into the electrochemical behavior of semiconductors.

The rotating ring-disk electrode (RRDE), which has been largely used for semiconductor corrosion studies (see, for example, Ref. 14-17), does not perfectly suit our gas evolving etchant (H_2O_2). Direct sequential chemical analysis of corrosion products may give valuable information, especially since the gallium ion concentration vs. time can be converted into current voltage curves. Such a method would be tedious and time consuming unless a fast automatic system for

Ga analysis were available. Consequently, we have developed a method of investigation based on the use of an automatic colorimetric system. Gallium analysis is performed at the outlet of a three-electrode micro-electrochemical cell.

As shown later, this method, which can be adapted to redox couples other than the H_2O_2 used here, can lead to better knowledge of the dissolution process and thus can make the choice of selective etching criteria easier. In the future, this technique might be considered as a complementary tool for electrochemical studies involving, i.e., RRDE. In this study, impedance-electrode measurements and ellipsometry were also used in order to complete the information gained from the gallium concentration curves.

Experimental

Materials.—Unless otherwise specified, the III-V samples used in this study were (100) single crystals. n-Type gallium arsenide was Si-doped bulk material with donor density $N_D \sim 10^{18} \text{ cm}^{-3}$, n-type $\text{Ga}_{0.7}\text{Al}_{0.3}\text{As}$ (Si doped, $N_D \sim 2 \cdot 10^{17} \text{ cm}^{-3}$), and $\text{GaAs}_{0.6}\text{P}_{0.4}$ (Te doped, $N_D \sim 4 \cdot 10^{16} \text{ cm}^{-3}$) were vapor phase epitaxial layers grown on (100) GaAs substrate, with a typical thickness of 20 μm . Experiments on GaAs were performed after etching in $\text{H}_2\text{SO}_4/\text{H}_2\text{O}/\text{H}_2\text{O}_2$ (3:1:1) in order to remove the superficial damaged layer. The ohmic contacts were made using alloyed tin on the back of the GaAs substrate under N_2 or H_2/N_2 controlled atmosphere.

Apparatus.—The microelectrochemical cell with continuous electrolyte flow (4 ml min^{-1}) is shown Fig. 1. Its general design was drawn from Ref. (18) with some modifications. The electrode (0.2 cm^2) can be illuminated, via an optical fiber, with a 100W halogen lamp. In order to prevent thermal effects due to IR radiation, a filter (wavelength bandpass: 400-650 nm) and an absorption cell filled with water (2 cm thickness) were used.

Experiments were performed using a conventional potentiostatic system (Tacussel Solea S.A.). Successive preselected potentials were applied to the semiconductor electrode for 10 min while the electrolyte flow leaving the cell was analyzed. For each voltage, the static current was measured in order to get the corresponding current-voltage curves which, for simplicity, have been drawn as continuous lines in

* Electrochemical Society Active Member.

Key words: etching, semiconductor, H_2O_2 , photoelectrochemistry, corrosion mechanism, passivation, semiconductor technology, GaAs/GaAsP/GaAlAs.

Fig. 1. Plan of the microelectrochemical cell

the various figures. Between two consecutive steps, etching of the semiconductor surface was carried out with the help of the etchant solution described in the previous section and a bypass system. All potentials are expressed with respect to the saturated calomel electrode (SCE).

Electrolyte.—The choice of the electrolytes and redox system was dictated by experience, since citric acid and H_2O_2 are frequently used for GaAs etching as complexing electrolyte and oxidizing agent, respectively. Moreover, this mixed solution has good selectivity properties for GaAsP/GaAs heterostructures, since only the latter product dissolves. Given the poor buffer capability of citric acid, we also used a phosphate buffer in medium pH range. Experiments in highly acidic and alkaline media were also carried out by adding H_3PO_4 or NaOH to the solutions. In every case, and unless otherwise specified, a 0.1M concentration for electrolyte and 1% (33.3 ml of 30% H_2O_2 per liter) for H_2O_2 was chosen for experimental convenience. Sodium hydroxide was used for pH adjustments.

Gallium analysis.—At the outlet of the microelectrochemical cell, Ga was analyzed through a colorimetric automatic system (Auto Analyser II, Technicon). The measurement involved the following stages: (i) decomposition of excess H_2O_2 by hydroxylamine treatment; (ii) formation of a colored Ga-rhodamine complex; (iii) extraction of this complex by CCl_4 ; (iv) optical absorption measurements of the organic phase with a spectrophotometer (working wavelength 550 nm).

A calibration curve was drawn with standard solutions of gallium (the stock solution was prepared from high purity Ga metal dissolved in HCl) in the concentration range of interest ($0-50 \mu g ml^{-1}$). Under our experimental conditions, As and Al ions do not interfere in the Ga determination. Relative standard deviation of the calibration curve was 2%. For experiments involving GaAlAs material, a correction factor was used in order to take into account the presence of 30% of aluminum. Conversion of gallium concentrations into current was made by assuming a six-hole corrosion process (19). In order to distinguish clearly the current-voltage curves and the gallium concentration-voltage curves in the text and figure captions, we use $I = f(V)$ for the former and $I_{Ga} = f(V)$ for the latter.

Impedance and ellipsometric measurements.—Ellipsometric measurements were carried out with an automatic spectroellipsometer (20). In addition, capacitance measurements were performed with a potentiostatic system, using an ATNE lock-in amplifier and a Hewlett-Packard Model 3325-A function generator, which were controlled by an Apple II microcomputer. The GaAs electrode's area was $0.71 cm^2$. Unless otherwise specified measurements were made

Table I. Flatband potentials of n-type GaAs, $GaAs_{0.6}P_{0.4}$, and $Ga_{0.7}Al_{0.3}As$

at a frequency of 1 kHz. Flatband potentials of the freshly etched (called "clean" surface in the text, this term being further justified at the end of the next section) n-type semiconductors, obtained by extrapolation of Mott-Schottky plots calculated from a series equivalent circuit, at two pH's, are shown in Table I. The measured capacitances showed only a weak frequency dependence. The results were perfectly reproducible even after numerous voltage scans. These results are in good agreement with those of other authors (21, 22), except for those of GaAlAs (22). The reason for this discrepancy is not known. The pH dependence of the flatband is about 60 mV per pH unit, except for GaAsP (51 mV per pH unit).

Results and Discussion

n- and p-Type GaAs.—In order to have a better understanding of the mechanism by which a semiconductor like GaAs corrodes in H_2O_2 aqueous solution, bearing in mind that such corrosion might be used for selective etching of heterostructures, it is interesting to compare Fig. 2 and 3, which show the results obtained on n- and p-type GaAs in an acidic 1% H_2O_2 medium, at room temperature.

Fig. 2. $I = f(V)$ and $I_{Ga} = f(V)$ curves (see text) for n-type GaAs in 0.1M citric acid and 1% H_2O_2 . ---●--- I_{Ga} in the dark. ---○--- I_{Ga} under illumination. ——— $I = f(V)$ in the dark. ——— $I = f(V)$ under illumination.

Fig. 3. $I = f(V)$ and $I_{Ga} = f(V)$ curves for p-type GaAs in 0.1M citric acid and 1% H_2O_2 . Symbols are the same as used in Fig. 2.

With n-type GaAs, in the dark, on anodic scanning, we observe that corrosion begins at about $-1.0V$. The $I_{Ga} = f(V)$ curve thus exhibits a characteristic plateau before a sharp increase when the potential reaches $+0.5V$. As previously stated, the lack of faradaic current in a large range of potential where corrosion occurs (approximately -0.2 to $+0.4V$) should be noted. Under illumination, the corrosion is accelerated and a maximum appears in the $I_{Ga} = f(V)$ curve at about the same voltage as the photocurrent peak (see below). This corresponds to a passivation of the semiconductor.

With p-type GaAs in the dark, the results are comparable. Over a large range of potential (between -1.0 and $0.0V$), the corrosion rate remains constant and, as observed with n-type GaAs, this corrosion is not accompanied by a faradaic current.

The behaviors of these two kinds of materials differ strongly under illumination. With p-type, we observe that the corrosion does not increase with illumination, as it does for n-type GaAs; rather it vanishes when a cathodic photocurrent arises.

In order to explain this difference, we must consider the flatband values of these materials at this low pH ($-1.15V$ for n-type and $+0.15V$ for p-type, respectively) and the peculiar redox properties of H_2O_2 (23, 24). It is well known that H_2O_2 is a strong bifunctional oxidant whose two-step reduction involves an OH^\cdot radical intermediate. Two "microscopic" standard redox potentials correspond to these two successive steps, the values of which have been estimated by Memming to be widely separated from that of the global H_2O_2/OH^- system ($+1.54V$). According to Fig. 4, with p-type GaAs, hydrogen peroxide is capable of giving rise to a current doubling process (23, 24) where each photon induces a two-electron transfer across the interface. The capture of a photoexcited electron from the conduction band creates an OH^\cdot radical (which has empty levels of low energy) which is then able to inject a hole into the valence band of GaAs. The electric field within the depleted layer being directed towards the bulk semiconductor, the injected holes are driven in this direction. This prevents surface corrosion. This is the reason why no corrosion is observed under illumination with p-type GaAs. This current doubling on p-type GaAs has very recently been observed by Gerischer *et al.* (25). With n-type GaAs, current doubling is no longer possible, according to the direction of the electric field, which is now

Fig. 4. Energy diagram at pH 2 of the GaAs- H_2O_2 interface (24). This diagram supposes an equal concentration of all the redox species. The stationary concentration of OH^\cdot being small (24), the overlap of the conduction band and of H_2O_2 is probably much better than represented here.

directed towards the surface for this range of potential. Electrons are driven to the bulk, and holes to the surface, where they contribute to semiconductor dissolution while an anodic photocurrent appears (Fig. 2). This situation (increase of I_{Ga}) appears as soon as the electrode potential becomes positive of the flatband potential of the material.

The shapes of the curves of Fig. 2 and 3 are easy to interpret at high anodic and cathodic polarization.

With n-type GaAs in the dark (Fig. 2), the sharp increase of the corrosion at strong anodic polarization follows exactly the increase of the anodic current. It has been shown that this wave is an avalanche breakdown wave which depends on doping level and crystallographic defects of GaAs (26). The discrepancy observed between the breakdown voltage shown in Fig. 2 and 5, at the same pH, probably results from the

Fig. 5. Voltamperometric curves for n-type GaAs in the dark in 0.1M citric acid and several H_2O_2 concentrations. Voltage scanning rate: 100 mV min^{-1} .

batch origin of the GaAs substrate. For lower potentials, in the dark, the anodic breakdown current disappears while corrosion, as for p-type samples, decreases. The difference lies in the fact that for more negative potentials (less than $-0.3V$), a large cathodic wave arises and at the same time corrosion stops. It is logical to postulate that this corrosion suppression at low potential is a consequence of the electrolytic reduction of H_2O_2 at the interface by electrons from the conduction band, which accumulate when the electrode potential approaches its flatband value. This reduction of H_2O_2 at n-type GaAs electrode under cathodic polarization is indicated by the mass-diffusion limited waves of Fig. 5. The same explanation is given by Gerischer *et al.* for the observed chemical stability of n-type GaAs in Br_2 solution under cathodic polarization (12).

With p-type GaAs in the dark (Fig. 3), such a rapid reduction of H_2O_2 does not occur at the surface under cathodic bias, so the corrosion plateau remains flat even at $-1.0V$. For potentials more positive than $-0.2V$, the large anodic wave, which is accompanied by a strong corrosion, probably results from the hole accumulation in the valence band and from the resulting breaking of the chemical bonds of the semiconductor. Illumination has no influence here, because of the migration of the holes towards the bulk semiconductor.

The final point concerns how corrosion can occur in the dark, without electron transfer, in the intermediate range of potentials ($-0.5 < V < +0.5$ for n-type and $V < 0V$ for p-type).

Such corrosion can only be explained by a purely chemical process, *i.e.*, by an exactly compensated exchange of electric charges between the semiconductor, which is oxidized, and the oxidant, which is reduced. This process can be represented by the following schematic reaction

The nature of the resulting species depends on the pH and complexing power of the electrolyte. This is evidently the process by which chemical etching of the semiconductor proceeds at the rest potential.

The problem is thus to explain how such a reduction of H_2O_2 , at intermediate potential, can be initiated by high energy electrons (Fig. 4), since from the classical theory of electron transfer (7, 9, 10), these electrons can only be captured from the conduction band, whose electron concentration, for these two materials in the dark, is poor. In the absence of pinning of the Fermi level, the electron concentration increases as the potential of the semiconductor becomes more cathodic, but this increase is therefore not consistent with the observed voltage independence of chemical corrosion (see Fig. 3). Another explanation must be found.

It is well known that a high concentration of surface and interface states is always present at the surface of GaAs, especially near the middle of the bandgap (27, 28) and if the surface is oxygen covered (29, 30) as after etching by acidic H_2O_2 mixture (31). According to experiments conducted *in vacuo*, these electronic states often result from dangling bonds or a different band structure of surface atoms which have a high reactivity for the solvent (32). This is certainly the case for our highly reactive acid etched surfaces. If an electron from such a surface state (examples of which are drawn Fig. 4) is transferred to an adsorbed H_2O_2 molecule, it will lead to a short lived $OH\cdot$ radical, which is consequently attached to a surface atom with a weakened bond to the surface. This $OH\cdot$ radical is thus in a favorable situation to capture, directly, a second electron from the same atom, without the constraint of equality between donor and acceptor electronic states levels required by the faradaic transfer

through the Helmholtz layer. This leads to a still less strongly attached atom and to the progressive corrosion of the electrode.

This mechanism may explain why the chemical corrosion is potential independent and why it occurs in particular at the rest potential, *i.e.*, under the etching conditions, ($-0.075V$ for p-type and $-0.245V$ for n-type in our case).

Under illumination, for p-type material, electrons are available in the conduction band, which, by means of a current doubling mechanism, prevent the corrosion from continuing (Fig. 3). The current doubling phenomenon is thus more rapid than the chemical corrosion process. This is in agreement with the large photocathodic wave seen in Fig. 3. On the contrary, as previously stated, with n-type semiconductors, photoholes which appear in the valence-band contribute to corrosion by chemical bond breaking (Fig. 2).

This analysis shows that, in addition to anodic electrochemical corrosion resulting from hole accumulation in the valence band (p-type) or breakdown (n-type) and the photoelectrochemical corrosion by photoholes (n-type), simple chemical corrosion is another very important means of corrosion which probably does not only occur by hole injection into the valence band. Without any doubt, surface states play a very important role in the etching mechanism, and this fact is emphasized by the polishing or defect-revealing ability of this kind of etch.

Other semiconductors and pH effect.—Figures 6 and 7 show that in the same acidic corrosive medium, the behavior of GaAsP and GaAlAs can be explained using similar arguments. The values of the flatband potentials of these materials, which are slightly more negative than GaAs (Table I), support this argument. We observe that GaAsP (Fig. 6) exhibits a much lower chemical corrosion rate than the two other n-type materials (compare Fig. 2, 6, and 7).

An etchant is generally composed of an oxidant (here H_2O_2) and an acidic or basic solubilizing agent of the amphoteric oxide which grows at the surface of the semiconductor (33). Figure 8 shows that the etching rate (*i.e.*, the chemical corrosion at the rest potential) of GaAs in H_2O_2/H_3PO_4 mixtures at various pH's in the dark support this definition. The solubility of GaAs increases strongly in the regions of low and

Fig. 6. $I = f(V)$ and $I_{GaAsP} = f(V)$ curves for n-type GaAsP in H_3PO_4 0.1M and 1% H_2O_2 . Symbols are the same as used in Fig. 2.

Fig. 7. $i = f(V)$ and $i_{Ga} = f(V)$ curves for n-type GaAlAs in H_3PO_4 0.1M and 1% H_2O_2 . Symbols are the same as used in Fig. 2.

Fig. 8. Etching rate vs. pH curves in the dark of n-type GaAs in 1:2 H_2O_2 30% and H_3PO_4 2.4M mixture.

high pH when the solubility of the oxides of the different elements of which the semiconductor is composed are known to be large (34). Thus, etching of III-V semiconductors is only efficient at low and high pH and is slow at intermediate values when the low solubility of the oxide protects the material. The two other materials show curves similar to the curve of Fig. 8, except for the lower solubility of GaAsP, which has been already noted. In acidic or alkaline media, this poor etching rate of GaAsP offers selective properties for the removal of GaAs with respect to GaAsP layers in the GaAs/GaAsP heterostructure.

The effect of pH on the etching rate is clearly illustrated by the form of the curves of Fig. 9 obtained at pH 7. The chemical corrosion plateaus practically disappear, while the passivation peaks become very pronounced. Passivation, for these three materials, is very effective for voltages exceeding somewhat the passivation peaks.

On the other hand, at pH 13, Fig. 10-12 show that chemical dissolution is effective again and that the passivation becomes less pronounced.

In the absence of passivation, the corrosion rate is practically proportional to H_2O_2 concentration, as shown Fig. 10 and 12, in the cathodic range of potential (compare the values for i_{Ga} respectively with 1 and 0.5% of H_2O_2). When passivation occurs (as, for example, for GaAlAs and GaAs under illumination at 0.0V), oxide layer formation governs the dissolution process and proportionality with H_2O_2 concentration no longer holds.

All these observations are consistent with a corrosion mechanism which involves competition between the rates of oxide formation and dissolution. The second phenomenon prevails at low and high pH. However, it can also be noted that illumination sometimes reinforces passivation (see Fig. 2, 7, 10, and 12, for instance).

Passivation and oxide layer growth.—Spectroellipsometric and impedance measurements were carried out in order to reveal the effect of oxide growths on the dissolution phenomenon in H_2O_2 . n-Type GaAs was used exclusively for this study.

First, capacitance measurements and Mott-Schottky plots were obtained in citric and phosphoric 0.1M media at pH 2 and 7 without H_2O_2 and for "clean" surface n-GaAs. The data were taken at 1 and 10 kHz. From the Mott-Schottky plots of Fig. 13 we obtained donors densities (N_D) of about 7.1×10^{17} for 10 kHz and 1 kHz, which shows, as previously stated, a very

Fig. 9. $i_{Ga} = f(V)$ for n-type GaAs, GaAlAs, and GaAsP in H_3PO_4 0.1M and H_2O_2 1% at pH 7.

weak frequency dependence and a good agreement with the predicted values. No account was taken of

Fig. 10. $I = f(V)$ and $I_{Ga} = f(V)$ for n-type GaAs in H_3PO_4 0.1M and 1% H_2O_2 at pH 13. Symbols are the same as used in Fig. 2 except for 0.5% H_2O_2 solution.

Fig. 11. $I = f(V)$ and $I_{Ga} = f(V)$ for n-type GaAsP under the same conditions as Fig. 10.

surface roughness for the calculation of the doping level. The corresponding flatband potentials were frequency independent and compared favorably, allowing for the observed pH dependence with the values of Table I. Experimental values of these flatband potentials are identical for both solutions (citric and phosphoric), indicating that for a given sample in indifferent electrolyte this quantity is determined by the pH solely. Hence for practical convenience, further experiments were made in a phosphoric medium. The linearities over a large range of potentials of the Mott-Schottky plots (about 1.5V), as well as the perfect reproducibility of these plots even after numerous scans up to the highest voltage attained in capacitance measurements (deep depletion situation), show that the GaAs surface can be considered, from a practical point of view to be oxide free, even if such freshly etched surfaces cannot be considered as completely exempt of oxygen (31). It was impossible to detect the presence of oxide by ellipsometry on surfaces so prepared. This justifies our term "clean."

A second series of capacitance measurements were performed in a H_3PO_4 0.1M + H_2O_2 1% pH 7 medium. These results, which are not shown here, should be discussed in conjunction with the $I_{Ga} = f(V)$ curve for the n-GaAs of Fig. 9. Several points should be emphasized: (i) the range of potential where Mott-Schottky behavior was observed was very reduced compared to that in the previous media. (ii) The shape of the Mott-Schottky plots seemed to be very time dependent.

These two points clearly support the assumption that in such a medium and for the considered range of potential, changes in the GaAs surface occur in agreement with the observed corrosion and passivation of this material under these conditions.

Fig. 13. Mott-Schottky plots for "clean" (1) and oxidized (2) n-type GaAs in: a. H_3PO_4 0.1M at pH 7. b. H_3PO_4 0.1M + 1% H_2O_2 at pH 7. Frequency: 1 kHz.

In an attempt to explain such an evolution, further experiments were made on the basis of the $I_{\text{Ga}} = f(V)$ curve of Fig. 9.

First, a "clean" n-type GaAs electrode was held at -1.4V , i.e., on the cathodic side of the passivation peak, for more than 2h, the differential capacitance being periodically and automatically measured after a fast microcomputer monitored shift of the potential (less than 1s) to 0.0V. The measured capacitance at 0.0V remained perfectly constant and equal to that of the "clean" surface at the same voltage ($2 \cdot 10^{-7} \text{ F} \cdot \text{cm}^{-2}$ [see Fig. 13]) in all cases. The "new" smooth and polished surface appeared to be oxide free by ellipsometric measurements, as the "clean" surfaces were.

Second, a "clean" electrode was held at -0.75V , i.e., on the other side of the passivation peak. Capacitance measurements were performed for more than 10h in the same way as before. A fast increase followed by a slow continuous decrease of the capacitance was observed. Ellipsometric measurements proved the growth of an oxide layer which appeared to be linked with the change of the electrode capacitance.

Third, Mott-Schottky plots were obtained for such a deliberately oxidized sample in the different media: H_3PO_4 0.1M, pH 7 and H_3PO_4 0.1M + 1% H_2O_2 , pH 7. The results showed a good linearity for both solutions over a large range of potentials. This shows that the oxide evolution rate could be neglected during these experiments. Figure 13 shows that plots obtained in both media were identical, but were shifted towards positive potentials compared with the plots obtained for the "clean" sample in the first solution. It is worth noticing that such a phenomenon in a nonaqueous medium, probably due to a large potential drop across the oxide layer, has already been reported by Morisson *et al.* (27), as has been the lower slope for the oxidized sample compared with the "clean" one. We have no explanation for this phenomenon (note the two scales used in Fig. 13).

All these experiments clearly confirm that in H_2O_2 medium: (i) the decrease of the n-GaAs dissolution rate, above -1.1V (Fig. 9) is due to a passivation of the semiconductor caused by the growth of an oxide layer. (ii) the GaAs surface on the cathodic side of these passivation peaks can be considered oxide free.

Application: selective etching.—From a knowledge of the $I_{\text{Ga}} = f(V)$ curves it is possible to explore a new way of selective etching of the three III-V semiconductors considered here. Referring to the previous

sections concerning the behavior of these materials at pH 7 (when the passivation is very efficient) between -1.5 and -1.1V , GaAlAs is protected against corrosion by passivation, while GaAs dissolves. The same is observed for GaAsP between -1.3 and -1.1V . If the voltage of a heterostructure involving GaAs and GaAlAs, or GaAsP, is fixed within these ranges, dissolution of GaAs alone will occur. This selective process of dissolution involves both the choice of an applied voltage and the passivation phenomenon in oxidizing media. Usually these methods are used independently of each other, the latter being carried out at rest potential etching.

Preliminary experiments have been performed on a GaAs/GaAlAs heterostructure at -1.2V in a H_3PO_4 0.1M + 1% H_2O_2 aqueous solution at pH 7. Dissolution began from the GaAs surface. The approximate observed selectivity ratio (etching rate of GaAs upon etching rate of GaAlAs) was about 10, further experiments are needed for a better determination of this ratio.

It is worth noting that afterwards GaAlAs interface exhibits a smooth, mirrorlike surface. This is probably due to the fact that at this potential (-1.2V) the remaining oxide layer is thin and helps the polishing process by a diffusion mechanism. The quality of the surface after such selective attack appears to be one of the most important advantages of the method.

The same technique was applied to GaAs/GaAsP heterostructure. In this case, the nature of the surface is satisfactory enough for practical applications but the smoothness is not as marked as for GaAlAs. Therefore, for this last type of heterostructure there is no great advantage in using the technique with applied voltage, since, as already stated, selectivity is obtained directly in acid or alkaline media at the rest potential.

The experiments described above show that a precise knowledge of electrochemical behavior permits a rapid determination of possible selective etching procedures.

Conclusions

Using impedance and ellipsometric measurements, we have shown that a method based on direct analysis of corrosion products of the semiconductor under corrosion conditions leads to a better understanding of the corrosion mechanisms involved for the III-V compounds concerned in this study. The etching behavior of H_2O_2 appears to be controlled by an oxide

layer formation which depends to a great extent on the pH. From this result new experimental conditions may be established in order to solve practical problems concerning selective etching.

Acknowledgments

We are pleased to acknowledge that this work was supported by the French Direction des Recherches et Etudes Militaires (DRET) under contract no. 80-34-169-00-470-75-01. We would like to thank Dr. J. Joseph and Dr. A. Gagnaire for their useful contribution (ellipsometric measurements) and D. Richartz (RTC) for his technical assistance.

Catalytic Activity of Iron, Nickel, and Nickel-Phosphorus in Electroless Nickel Plating

J. Flis¹ and D. J. Duquette

Department of Materials Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The catalytic activity for electrooxidation of hypophosphite and electroless nickel plating on iron, nickel, and electrolessly plated nickel (with 2.2-2.9 weight percent (w/o) P) was investigated in an ammoniacal solution of pH 8.8 at 50°C by potential measurements and linear sweep voltammetry from -0.3V to 0.92V vs. SCE. Cathodic polarization of any of the substrates (in 0.1M H₂SO₄) before testing or permeation of hydrogen through iron foils during testing reduced the incubation time for electroless plating, increased anodic dissolution of the substrates in the passive region, and increased the hypophosphite electrooxidation on nickel and nickel-phosphorus at potentials of thermodynamic stability for nickel oxides or hydroxides. The nickel-phosphorus substrate exhibited significantly higher activity than pure nickel, in a similar manner to the effect of cathodic polarization. The effect of cathodic polarization and hydrogen is associated with the electrochemical reduction of surface oxides, whereas the higher activity of nickel-phosphorus deposits (as compared to that of pure nickel) is explained by the lower protectivity of surface oxides on these deposits.

Electroless nickel plating from hypophosphite solutions proceeds spontaneously on many metal surfaces (1-5), although the specifics of this process may be of a different nature. Some noble metals (palladium,

rhodium, nickel, cobalt, gold) possess an intrinsic catalytic ability to induce electrooxidation of hypophosphite, and electroless nickel plating; whereas some active metals become catalytic due to the deposition of nickel from a solution by a displacement reaction. The latter phenomenon has been shown for iron, aluminum, and beryllium (2), gallium and thallium (6), magnesium, zinc, and manganese. The

catalytic activity of copper has been shown to be strongly affected by surface oxides (7). The activation of copper or its alloys by anodic treatment (4) or by the addition of chloride ions to a given plating solution (8) is evidently associated with the removal of these surface oxides.

Nickel and iron induce spontaneous electroless plating of nickel, but the presence of surface oxides may considerably prolong incubation times and decrease the adhesion of the deposits to the substrates. Investigations by Gaigher and van Wyke (9) showed that contamination of a nickel substrate due to exposure to laboratory air resulted in a blocky discontinuous growth of nickel electrodeposits, in contrast to smooth monolayer-type growth for uncontaminated surfaces.

The catalytic activity of a nickel surface for dehydrogenation of hypophosphite diminishes with time (2, 3) in the absence of Ni^{2+} ions. However, it is sustained in the presence of these ions, even at concentrations as low as $2 \times 10^{-3}\text{M}$ (2). Gutzeit (2) indicated that the concentration of Ni^{2+} ions in the solution remains constant during a given experiment. Nevertheless, it seems that a small amount of deposition of electroless nickel is also possible, giving rise to the continuation of the catalytic activity.

Epifanova *et al.* (10) showed that the catalytic activity of electroless nickel for oxidation of hypophosphite was distinctly higher than that of pure nickel. This was explained in terms of the catalytic action of phosphorus. It is possible that the higher catalytic activity of nickel-phosphorus deposits when compared to that of nickel may also be due to other reasons, such as less vulnerability to oxide formation or other surface contamination, or to hydrogen absorbed by the deposits during plating. The effect of surface conditions on growth of the deposits was stressed by Cavallotti and Salvago (6). Inhibition of electroless plating and of hypophosphite electrooxidation by oxy-anions, oxides, or dissolved oxygen has been reported by several authors (7, 11-13).

Hydrogen has been shown to accelerate electroless plating, both by participation in the reduction of Ni^{2+} ions (1-3, 14), and also by reduction of surface oxides (13). On the other hand, hydrogen may diminish the catalytic activity of substrates, as it was observed for palladium (13).

The present work was undertaken in order to determine the effect of surface oxides and of hydrogen on the incubation time for electroless plating and on the catalytic activity for electrooxidation of hypophosphite on substrates of iron, nickel, and nickel-phosphorus.

Investigations were carried out in an ammoniacal hypophosphite solution, in which electroless plating produced nickel-phosphorus deposits with 2.2-2.9 w/o P (13). The catalytic activity and electrochemical behavior of the substrates were examined by potential measurements and linear sweep voltammetry.

Experimental

Tests were carried out on annealed Armco iron, 99.9% pure nickel, and preformed electroless nickel-phosphorus deposits containing 2.2-2.9 w/o P.

Specimens of Armco iron were electropolished in a solution of 940 ml acetic acid (glacial) + 60 ml perchloric acid, at 40-60V, while specimens of nickel were electropolished in a solution of 100 ml H_2SO_4 + 75 ml H_2O , at 5-6V; both at room temperature. Specimens were subsequently washed in distilled water, dried in air, and then masked with (MicroshieldTM) lacquer to obtain an uninsulated surface area of 1 cm^2 . The lacquer remained adherent and stable for periods of approximately 2 hr. Nickel-phosphorus deposits of $\sim 3 \mu\text{m}$ thickness were grown on electro-

polished nickel by immersion into a plating solution (cf. Table I) at 50°C for 30 min.

Specimens were examined under the following conditions: (i) electropolished (iron or nickel) or freshly deposited (nickel-phosphorus), tested within 1 hr after preparation. (ii) As (i), followed by cathodic polarization in 0.1M H_2SO_4 at a current density of $100 \text{ A} \cdot \text{m}^{-2}$ for 10 min and tested immediately after polarization and rinsing with distilled water. (iii) As (i), aged in air at 50°C for 28 hr. (iv) As (i), immersed into 0.1M NaOH at 25°C, for 30 min. (v) Electropolished iron with continuous permeation of hydrogen.

A schematic drawing of a specimen instrumented for hydrogen permeation is shown in Fig. 1. A 0.10 mm thick membrane of annealed Armco iron was glued to a glass tube which then was filled with 0.1M H_2SO_4 . The outer portion of the membrane served as the specimen's reaction surface. Permeation of hydrogen through this surface was achieved by cathodic polarization of the inner surface at a current density of $100 \text{ A} \cdot \text{m}^{-2}$. The rate of hydrogen permeation through Armco iron membranes was determined electrochemically (15) in separate experiments. In these experiments, the diffusion sides of the membranes were electroplated with palladium and the membranes were clamped between the two compartments of the electrolytic permeability cell. The diffusion compartment contained 0.02M NaOH with a reference electrode of $\text{Hg}/\text{HgO}/0.02\text{M NaOH}$. A typical current transient for hydrogen permeation during cathodic polarization of a membrane is shown in Fig. 2. No hydrogen gas bubbles were observed during the permeation experiments.

Specimens were examined in the solutions listed in Table I, prepared from reagent grade chemicals and distilled water. Sulfuric acid or, if necessary, NH_4OH , was added in amounts appropriate to adjust the pH of the solutions to 8.8. Measurements were carried out on stationary specimens at $50.0 \pm 0.5^\circ\text{C}$ in solutions deaerated by purging with pure nitrogen.

Measurements involved monitoring of open-circuit electrode potentials, and of linear sweep voltammograms. Potentials were measured against saturated calomel electrode (SCE) at 25°C via a Luggin capillary. Voltammetric measurements were performed using single cathodic sweeps at a rate of 1 mV/sec, beginning at -0.3V vs. SCE .

Results

Open-circuit potentials.—Changes of electrode potential for the substrates after immersion into electroless plating solutions are shown in Fig. 3 and 4. The rest potential of the electroless plating was approximately -0.87V (7, 13). The time required to reach this potential is defined as the incubation time and characterizes the ability of the substrates to become active for electroless plating.

appeared when specimens were cathodically polarized in 0.1M H_2SO_4 before testing. Permeation of hydrogen through iron membranes also diminished the extent of the potential arrest.

In the supporting solution (Table I), the rest potential of iron was approximately $-0.78V$. With a hypophosphite addition, the potential was nearly the same on an electropolished surface, but on cathodically polarized surfaces it shifted to approximately $-0.92V$, after a brief arrest at $-0.78V$.

The incubation time for plating on electropolished nickel (Fig. 4) was shorter than that for iron, and was also substantially diminished by cathodic prepolarization. Potential arrests were observed at approximately $-0.45V$.

On nickel-phosphorus deposits, the potential arrests observed at -0.45V were significantly shorter than those observed on nickel, indicating higher activity of these deposits for the initiation of electroless plating. In solutions without Ni^{2+} ions, potentials on nickel-phosphorus dropped to lower values than on nickel.

Voltammetric measurements.—Measurements were made in the supporting solution with and without the additives essential for plating (cf. Table I), by scanning the potential in the cathodic direction from -0.3 to -0.92V or lower. Potential scanning was initiated immediately upon immersion.

Voltammograms on electropolished and cathodically polarized iron are shown in Fig. 5 and 6. Electrooxidation of hypophosphite in the solution without Ni^{2+}

Fig. 5. Voltammograms for electropolished iron in the supporting solution with and without other components (cf. Table I), beginning at -0.30V . An arrow with "H" indicates the start of hydrogen permeation through an iron membrane. Below the discontinuities the current is cathodic, except where anodic current is denoted by $i+$.

Fig. 6. Voltammograms for iron after cathodic polarization in $0.1\text{M H}_2\text{SO}_4$, measured in the supporting solution with and without other components, beginning at -0.3V .

ions began at approximately -0.83 and -0.81V on electropolished and cathodically polarized iron, respectively. This was indicated by a deflection of the cathodic curves at these potentials, followed by the appearance of anodic current loops. In the solution containing Ni^{2+} ions, the electrooxidation of hypophosphite began at approximately -0.70V .

Permeation of hydrogen through the specimen's surface caused an increase in anodic current in the passive region, but did not affect the electrooxidation of hypophosphite. Cathodic polarization of specimens prior to testing also increased the anodic current in the passive region, without affecting the electrooxidation of hypophosphite (Fig. 6).

Voltammograms on nickel and nickel-phosphorus in various solutions are shown in Fig. 7-10. The curves were measured after cathodic polarization labeled "c.p." of specimens in $0.1\text{M H}_2\text{SO}_4$. These voltammograms show that the nickel-phosphorus deposits were significantly more active than pure nickel. The higher activity of the deposits was indicated by higher anodic currents at noble potentials in all solutions, by the occurrence of a peak at around -0.78V in the plating solution, and by a steeper rise in cathodic currents at approximately -0.75V in the supporting solution with Ni^{2+} ions.

As in the case for iron, cathodic polarization of nickel and nickel-phosphorus in $0.1\text{M H}_2\text{SO}_4$ before testing considerably increased anodic currents at noble potentials. At more active potentials, current increases were not significant. The effect of cathodic polarization was evident in essentially the same potential range for both materials.

Discontinuities in the voltammograms measured in the solutions without NaH_2PO_2 (Fig. 8 and 9) indicate mixed rest potentials. Currents measured noble to these potentials represent anodic dissolution of the substrates. The voltammograms show that the anodic dissolution rate of nickel-phosphorus was higher than that of nickel and that cathodic prepolarization increased the rate of dissolution of both substrates.

At potentials noble to -0.5V , anodic currents measured in the hypophosphite containing solutions (Fig. 7 and 10) were virtually identical to those measured in the hypophosphite-free solutions (Fig. 8 and 9)

Fig. 7. Voltammograms for nickel and nickel-phosphorus deposits in the plating solution, beginning at -0.3V . Curves denoted by "c.p." were measured after cathodic polarization in $0.1\text{M H}_2\text{SO}_4$.

Fig. 8. Voltammograms for nickel and nickel-phosphorus deposits in the supporting solution.

on each substrate. This suggests that at these potentials the measured current was associated primarily with anodic dissolution of the substrates, and that the electrooxidation of hypophosphite either did not take place or was negligible. An anodic current measured at more active potentials was evidently associated with electrooxidation of hypophosphite. This shows that the hypophosphite electrooxidation became significant at the potentials corresponding to rest potentials in the hypophosphite-free solutions. The higher anodic dissolution current corresponds to higher electrooxidation current near the corrosion potentials.

In the plating solution (Fig. 7) the electrooxidation current of hypophosphite, active to -0.75V , reached

Fig. 9. Voltammograms for nickel and nickel-phosphorus deposits in the supporting solution with added Ni^{2+} ions.

Fig. 10. Voltammograms for nickel and nickel-phosphorus deposits in the supporting solution with added NaH_2PO_2 .

higher values than in the solution without Ni^{2+} ions (Fig. 10). On nickel-phosphorus deposits, in the plating solution, the increase in the current active to -0.75V was greater than on pure nickel and showed a distinct peak at -0.78V . Nickel showed only a slight tendency to form a peak at this potential.

The increase in the electrooxidation current in the plating solution active to -0.75V coincided with the start of electrolytic deposition of nickel on the substrates. The latter can be seen from cathodic curves in the supporting solution with added Ni^{2+} ions (Fig. 9). The increased electrooxidation current in the plating solution thus results from electrolytic deposition of nickel on the substrates.

Discussion

Measurements of open-circuit potentials show that the incubation time for electroless nickel plating on the respective substrates decreased in the sequence: iron > nickel > nickel-phosphorus. Oxidation of specimens prior to immersion increased the incubation time, while cathodic polarization decreased it. On iron, the incubation time was also lowered by saturation of the surface with hydrogen as indicated by permeation plateaus.

The major part of the incubation times was associated with potential arrests in the range of -0.45V for nickel and of -0.5V for iron. Voltammograms in the supporting electrolyte showed that the potential arrest for iron was in the passive-active region, while that for nickel was approximately at the corrosion potential (Fig. 8). This suggests that these potential arrests are associated with oxide dissolution.

The decrease in incubation time resulting from cathodic prepolarization or by permeation of hydrogen can also be attributed mainly to the reduction of surface oxides. This is evidenced by higher anodic currents in the passive region on iron (Fig. 5 and 6), and also on nickel and nickel-phosphorus above their corrosion potentials (Fig. 8).

Cathodic polarization leads to the reduction of surface oxides and presumably saturates the specimen surfaces with hydrogen. This absorbed hydrogen may

contribute to reduction of oxides or hydroxides which form thereafter, especially upon immersion into the plating solution. Formation of oxides or hydroxides on the substrates in the plating solution can be surmised from the values of pH and of initial potentials, which indicate thermodynamic stability for oxides or hydroxides (16).

The voltammograms show that electrooxidation of hypophosphite started at potentials at which oxides should be reduced. On iron, this occurred at ca. -0.82V , which is approximately the equilibrium potential of the $\text{Fe}(\text{OH})_2/\text{Fe}$ reaction (16); while on nickel and nickel-phosphorus this occurred at approximately the corrosion potentials. At this potential, surface oxides should be reduced to a great extent, though not completely (17-19). The effects of hydrogen and of cathodic prepolarization on the initiation of plating and on the hypophosphite electrooxidation are associated with the reduction of surface oxides. The hypophosphite electrooxidation was not affected at more active potentials. Nor was the hypophosphite electrooxidation affected by evolution of hydrogen at ca. -0.7V , as has been reported for palladium (13).

The greater efficiency of the nickel-phosphorus substrate (compared to that of nickel) can also be explained in terms of surface oxides. Larger anodic dissolution currents on nickel-phosphorus than those on nickel indicate that the oxide layers on nickel-phosphorus were less protective, which may result from thinner, less stable, or discontinuous oxides. Thus, the incubation time for nickel-phosphorus was shorter and hypophosphite electrooxidation in the noble potential region was greater than are observed for nickel. At potentials active to -0.65V in the solution without Ni^{2+} ions, hypophosphite electrooxidation was essentially identical for nickel and for nickel-phosphorus. This indicates that the intrinsic catalytic activity of the two substrates is nearly the same. The difference in the activity occurs essentially because of the presence of surface oxides and can be attributed to the difference in the protective properties of the oxide layers on these substrates. The explanation of Epifanova *et al.* (10), which invokes a catalytic action of phosphorus in electroless deposits, does not seem to be appropriate for the present case. The surface of nickel-phosphorus deposits is probably less contaminated with residual oxides or other species at more negative potentials. This explains the steeper rise in the electrodeposition current of nickel at -0.75V on these deposits than on nickel (Fig. 9). It is suggested that faster electrodeposition of fresh nickel on nickel-phosphorus deposits from the plating solution is responsible for the higher electrooxidation current on these deposits below -0.75V (Fig. 7). The freshly electrodeposited nickel should possess high catalytic activity owing to low contamination of its surface.

Electrolytic deposition of nickel from a plating solution (active to -0.75V) enhanced the hypophosphite electrooxidation on nickel and nickel-phosphorus, whereas on iron it initiated the hypophosphite electrooxidation at approximately this potential (Fig. 5 and 6). In the solution without Ni^{2+} ions, the hypophosphite electrooxidation on iron began at -0.81V or below. This shows that for iron in the plating solution, electrolytic deposition of nickel occurs during the spontaneous potential shift, followed by electrooxidation of hypophosphite. This is in accord with the conclusion of Gutzeit (2).

Conclusions

Cathodic polarization of iron, nickel, and nickel-phosphorus in $0.1\text{M H}_2\text{SO}_4$ before testing considerably diminished incubation times for electroless nickel plating on these substrates. A similar effect was caused by permeation of hydrogen through the iron surface.

Potential scans from -0.3 to -0.92V vs. SCE showed that cathodic polarization and/or the presence of hydrogen in the substrates increased anodic dissolution of the substrates in the passive region, and increased the hypophosphite electrooxidation on nickel and nickel-phosphorus in the potential range of thermodynamic stability of nickel oxides or hydroxides.

The activating effect of cathodic polarization and hydrogen can be entirely ascribed to the reduction of surface oxides.

Nickel-phosphorus deposits showed lower incubation times for electroless plating of nickel, greater anodic dissolution in the passive region, and greater hypophosphite electrooxidation in the presence of oxides than those observed for nickel. This is attributed to lower protectiveness of surface oxides on these deposits.

Morphological Instability in Nonsteady Galvanostatic Electrodeposition

I. Effect of Surface Diffusion of Adatoms

Ryoichi Aogaki and Tohru Makino¹

Department of Chemistry, The Institute of Vocational Training, 1960, Aihara, Sagamihara, 229, Japan

ABSTRACT

In non-steady galvanostatic deposition without any surface diffusion, it has already been reported that the average size of crystals formed on an electrode surface decreases with deposition time since large number of crystal nuclei are successively generated due to high supersaturation of adatoms. However, when the crystal sizes become extremely small, it is necessary to consider the effect of the surface diffusion on crystal morphology. Therefore, we attempted to derive a degree of surface irregularity (dsi) equation including the surface diffusion to examine the time dependence of the maximum dis (dsi_{max}). It was found that the dsi_{max} value obtained here becomes smaller with time than that neglecting surface diffusion. The relation between the spatial wavelength (λ_{max}) corresponding to dsi_{max} and deposition time was obtained for the case where the surface diffusion cannot be disregarded, i.e., λ_{max} initially decreases, but approaches a certain constant value with time. Regarding λ_{max} as a measure of crystal size, it was obviously concluded that since the surface diffusion hinders the growth of crystal particles which develop from nuclei, the sizes do not decrease even after a long time passes. Moreover, as dsi_{max} is taken as a measure of increasing height of surface irregularity, it became clear that the surface diffusion also suppresses the growth rates of crystal peaks.

In galvanostatic deposition under diffusion control, owing to high supersaturation, a large number of crystal nuclei grow to form minute roundish particles without particular crystal faces. It has been pointed out that such growth is attributed to instability accompanied with the diffusion of depositing ions (1, 2, 9). Furthermore, a general expression for the variation of the surface morphology with increasing deposition time was derived for when the transition from thermodynamic equilibrium to nonequilibrium takes place (3). After drawing three-dimensional contour plotting obtained from the theory, the average particle size and standard deviation were calculated. The results were compared with statistical data obtained from SEM photographs by means of image analysis; both results were in good agreement (4).

According to this theory, as the bulk concentration decreases and the current density increases, the particle size decreases with time, and finally converges into zero (2). This is an extreme case, but to some extent such a prediction may be possible in a case of low concentration and high current density.

We attempted to improve the theory by introducing the effect of surface diffusion of adatoms. In order to make clear the mechanism of unstable growth, a thermodynamic condition was considered.

Theoretical

Diffusion of active ions in the electrolytic solution.—Following the concentration change of depositing ions near the electrode surface, which arises from sudden deposition, a nonsteady mass transfer occurs near the electrode. We assume that the solution is in a stationary state and contains a lot of supporting electrolyte so that the migration of the ions due to the presence of electric field can be neglected and there is no mass flow caused by fluid motion.

First, we consider a case where any fluctuations do not exist. Taking the electrode surface equal to the x-y plane, the concentration distribution in the present case has only one component in the z-direction perpendicular to the surface; i.e., the diffusion equation neglecting the terms of migration and mass flow (5)

$$\frac{\partial C^*(z, t)}{\partial t} = D \frac{\partial^2 C^*(z, t)}{\partial z^2} \quad [1]$$

¹ Present address: AHS Japan Company, 2-10-12, Akasaka, Minato-ku, 107, Japan.

Key words: unstable crystal growth, galvanostatic deposition, morphology.

is obtained, where $C^*(z, t)$ is the depositing ion concentration in nonfluctuated state, D is the diffusion coefficient, and t is deposition time. On the other hand, the fluctuation of the concentration, $c(x, y, z, t)$, imposed on this system can be written as follows (2)

$$\frac{\partial c(x, y, z, t)}{\partial t} = D \nabla^2 c(x, y, z, t) \quad [2]$$

where the migration and mass flow effects are also disregarded. Such fluctuation component is generally expressed by the superimposition of Fourier components, as long as they are sufficiently small compared with the nondisturbed component. Thus, a single component corresponding to a set of wave number, (k_x, k_y) as was shown in the preceding paper (2), is represented as follows

$$c_k(x, y, z, t) = c^0(z, t) \exp [i(k_x x + k_y y)] \quad [3]$$

where the subscript k means that the component corresponds to a single wave number, $k \equiv \sqrt{k_x^2 + k_y^2}$. Then substituting Eq. [3] into Eq. [2] under a quasi-steady condition

$$\left| \frac{\partial c^0(z, t)}{\partial t} \right| \ll |Dk^2 c^0(z, t)|$$

using the variable separation method, the general solution for $c^0(z, t)$ is obtained. It is

$$c^0(z, t) = (A_1 e^{-kz} + A_2 e^{kz}) \beta(t) \quad [4]$$

Here, A_1 and A_2 are arbitrary constants, and $\beta(t)$ is a function of the time. Because we should abandon a solution diverging in the bulk solution ($z \rightarrow \infty$), $A_2 = 0$ must be held. The following equation is derived

$$c^0(z, t) = A_1 e^{-kz} \beta(t) \quad [5]$$

[3] can be written as

$$c_k(x, y, z, t) = A_1 e^{-kz} \beta(t) e^{i(k_x x + k_y y)} \quad [3.1]$$

Thermodynamic condition accompanied with mass transfer.—In the electrolyte solution, the electrochemical potential of solute species, because of the electrode reaction, varies with location; consequently, the species transfer according to the inequalities of the potentials. This is a thermodynamical dissipative process. It is assumed that the species transfer in keeping local equilibrium (10). From this assumption, it can be

derived that the variation of the potential, Ψ , is equal to zero at all places of the electrolyte solution, and

$$\delta\Psi(x, y, z, t) = 0 \quad [6]$$

This relation is the necessary condition for $\Psi(x, y, z, t)$ to be minimum. If the temperature and pressure can be regarded as locally homogeneous, we can take $\Psi(x, y, z, t)$ as the electrochemical potential of active ionic species in the presence of a large amount of supporting electrolyte. Measuring the electrode potential, $V(x, y, z, t)$, at an arbitrary point of the solution with an electrode reversible to the active ions, if the potential in the bulk solution is taken as the standard, a relation is given in the form

$$\Psi(x, y, z, t) = n\mathbf{F}V(x, y, z, t) \quad [7]$$

Substituting [7] into [6], it follows that

$$\delta V(x, y, z, t) = 0 \quad [8]$$

However, the mass transport of the active ionic species induces the flow of electrolytic current in the solution. In the presence of a large amount of supporting electrolyte, the electrolytic current density is approximated (2) by

$$\vec{J}(x, y, z, t) = -\sigma \left[\nabla V(x, y, z, t) - \nabla H(x, y, z, t) - \frac{\Phi(x, y, t)}{n\mathbf{F}} \delta(z - Z) \right] \quad [9]$$

where σ is the electric conductivity of the bulk solution, $H(x, y, z, t)$ is the overpotential of the depositing ion, and $\Phi(x, y, t)$ is the surface potential arising from surface deformation. And $\delta(z - Z)$ is $\{0, 0, \delta(z - Z)\}$ where $\delta(z - Z)$ is the δ -function, and $z = Z$ is the equation of the electrode surface. Integrating Eq. [9] from a point (x, y, ∞) , of the bulk solution to a point, $(x, y, Z - 0)$, nearly inside the electrode, the equation

$$V(x, y, Z - 0, t) - V(z = \infty) = \frac{1}{\sigma} \int_{z=0}^{\infty} J_z(x, y, z, t) dz + H(x, y, Z, t) - H(z = \infty) - \frac{\Phi(x, y, t)}{n\mathbf{F}} \quad [10]$$

is obtained. Here, $V(z = \infty)$ and $H(z = \infty)$ are the electrode potential and concentration overpotential of the bulk solution, respectively, which take constant values. And $J_z(x, y, z, t) < 0$ is defined for cathodic deposition. Taking the variation of both sides of [10], the equation

$$\delta V(x, y, Z - 0, t) = \frac{1}{\sigma} \int_z^{\infty} j_z(x, y, z, t) dz + \eta(x, y, Z, t) - \frac{\phi(x, y, t)}{n\mathbf{F}} \quad [11]$$

is derived. Here, $j_z(x, y, z, t)$, $\eta(x, y, Z, t)$, and $\phi(x, y, t)$ are the fluctuation components of the electrolytic current in the z -direction, the concentration overpotential, and the surface potential, respectively. In terms of Eq. [8], Eq. [11] yields the following equation

$$\frac{1}{\sigma} \int_z^{\infty} j_z(x, y, z, t) dz + \eta(x, y, Z, t) - \frac{\phi(x, y, t)}{n\mathbf{F}} = 0 \quad [12]$$

Mass balance of adatoms at the electrode surface.—Active ionic species diffusing through the solution receive electrons to deposit as adatoms on the electrode surface. Then they move according to the difference of the chemical potential which changes with location, and is finally incorporated into the crystal lattice. The process mentioned above is schematically shown in Fig. 1. Conventionally, the interface between the double layer and the solution is denoted as $z =$

Fig. 1. Schematic diagram for the mass balance near the electrode. At the electrode surface, both the surface diffusion and nucleation simultaneously occur. Since the electron exchanging process is not rate determining, it is assumed that the adatoms are kept in equilibrium with the lattice atoms.

$Z + 0$ while the one between the double layer and the crystal lattice is as $z = Z - 0$. As shown in Fig. 1, the mass balance in the double layer is clearly written as follows

$$\frac{\partial C_{ad}(x, y, t)}{\partial t} + \nabla_{\perp} \cdot \vec{J}_{surf} = J_{flux}(z = Z + 0) - J_{flux}(z = Z - 0) \quad [13]$$

where C_{ad} is the surface concentration of the adatoms and $\nabla_{\perp} = (\partial/\partial x, \partial/\partial y)$. J_{surf} is the mass flux of the adatoms on the surface, namely

$$\vec{J}_{surf} = -D_{ad} \nabla_{\perp} C_{ad}(x, y, t) + b C_{ad}(x, y, t) \vec{f} \quad [14]$$

Here, D_{ad} is the diffusion coefficient of the adatom, and b is its mobility, which should satisfy the Einstein relation

$$b = \frac{D_{ad}}{RT} \quad [15]$$

\vec{f} is a motive force originated from the potential difference caused by surface deformation. Thus in the present case, the equation

$$\vec{f} = -\nabla_{\perp} \phi(x, y, t) \quad [16]$$

is derived (1). $J_{flux}(z = Z + 0)$ denotes the mass flux of the active ions going vertically into the double layer through the solution. The explicit form is represented by

$$J_{flux}(z = Z + 0) = D \{ \vec{n} \cdot \nabla C(x, y, z, t) \}_{z=Z+0} \quad [17]$$

where \vec{n} is a unit vector normal to the double layer surface. $J_{flux}(z = Z - 0)$ is the mass flux of the adatoms coming in and out of the interface between the double layer and the metal lattice. This process properly takes place at the active sites, such as kinks and steps.

As a result, the deposition continuously proceeds and the surface morphology changes with time. The variation can be described by

$$\frac{\partial Z(x, y, t)}{\partial t} = \Omega \left\{ \frac{\partial C_{ad}(x, y, t)}{\partial t} + J_{flux}(z = Z - 0) \right\} \quad [18]$$

Moreover, substituting Eq. [18] into Eq. [13], the rate equation of the surface height

$$\frac{1}{\Omega} \frac{\partial Z(x, y, t)}{\partial t} + \nabla_{\perp} \cdot \vec{J}_{\text{surf}} = J_{\text{flux}}(z = Z + 0) \quad [19]$$

is obtained, where Ω is the molar volume of metal.

In the present case, it is naturally assumed that the adatom concentration is equal to that in equilibrium between the adatoms and the lattice atoms.² Owing to the constant activity of lattice atom, the equilibrium adatom concentration, C_{ad}^* is concluded to be constant; i.e., independent of location. Thus, taking the variation of both sides of Eq. [19], it follows that

$$\frac{1}{\Omega} \frac{\partial \zeta(x, y, t)}{\partial t} = \frac{D_{\text{ad}}}{RT} C_{\text{ad}}^* \nabla_{\perp}^2 \phi(x, y, t) + D \left\{ \frac{\partial c(x, y, z, t)}{\partial z} \right\}_{z=Z} \quad [20]$$

where $\zeta(x, y, t)$ is the fluctuation component of the surface height.

Other relations.—The nondisturbed concentration of the active ionic species in the solution connected with an electrode has the relation

$$C^*(Z, t) = C^*(Z^*, t) \quad [21]$$

and the fluctuation component is expressed as

$$c(x, y, Z, t) = c(x, y, Z^*, t) + L(t)\zeta(x, y, t) \quad [22]$$

where Z^* is the average, nondisturbed height of the electrode surface, and $L(t)$ is the nondisturbed concentration gradient of the depositing ion, or

$$L(t) = \left\{ \frac{\partial C^*(z, t)}{\partial t} \right\}_{z=Z^*} \quad [23]$$

The concentration overpotential in the presence of a lot of supporting electrolyte is given in the form

$$H(x, y, z, t) = \frac{RT}{nF} \ln \left\{ \frac{C(x, y, z, t)}{C^*(z = \infty)} \right\} \quad [24]$$

where $C^*(z = \infty)$ is the constant concentration of active ions in the bulk of the solution. Taking the variation on both sides of [24], the equation

$$\eta(x, y, z, t) = \frac{RT}{nF} \frac{c(x, y, z, t)}{C^*(z, t)} \quad [25]$$

is obtained.

The fluctuation component of the electrolytic current has a well-known relation for the mass flux of depositing ion at an electrode surface, i.e.

$$\vec{n} \cdot \vec{j}(x, y, z, t) = -nFD\{\vec{n} \cdot \nabla c(x, y, z, t)\}_{z=Z} \quad [26]$$

Since the current density is conserved in the solution, the following conservative equation for current fluctuation is derived

$$\nabla \cdot \vec{j} = 0 \quad [27]$$

The increment of the surface potential due to surface deformation (11) is given as

$$\phi(x, y, t) = -\Omega\gamma \nabla_{\perp}^2 \zeta(x, y, t) \quad [28]$$

where γ is the surface energy of the electrode.

Derivation of dsi equation.—Before treating all the equations with regard to various fluctuations, we have to solve Eq. [1] for the case of galvanostatic dif-

fusion. Fortunately, this solution for surface concentration is the well-known Sand's equation (8)

$$C^*(z = Z^*) = C^*(z = \infty) + \frac{2J_z^*}{nF} \sqrt{\frac{t}{\pi D}} \quad [29]$$

As shown in the previous paper (2), as long as the fluctuation is small compared with the nondisturbed component, an arbitrary fluctuation can be decomposed into numerous Fourier components as well as the concentration fluctuation in Eq. [3]. The fluctuation of the surface irregularity is

$$\zeta_k(x, y, t) = \zeta^{\circ}(t) \exp[i(k_x x + k_y y)] \quad [30]$$

The current density fluctuation in the z-direction is

$$j_{zk}(x, y, z, t) = j_z^{\circ}(z, t) \exp[i(k_x x + k_y y)] \quad [31]$$

The fluctuation of the concentration overpotentials is

$$\eta_k(x, y, z, t) = \eta^{\circ}(z, t) \exp[i(k_x x + k_y y)] \quad [32]$$

whether or not this system is stable can be completely determined by examining the above components with a single set of wave numbers, (k_x, k_y) .

Substituting Eq. [3], [5], [29], [30], [31], and [32] into Eq. [12], [20], [22], [25], [26], and [28], respectively, and making the procedure similar to that in the preceding paper (2), the dsi equation is obtained as follows (see Appendix)

Step 1: $0 \leq t \leq t^*$

$$\begin{aligned} & \ln\{\zeta_k(x, y, t)/\zeta_k(x, y, 0)\} \\ &= -\frac{\sigma\Omega^2\gamma k^3 t}{(nF)^2} + \frac{\pi\sigma\Omega RTk}{2D(nF)^4 J_z^{*2}} (-nFJ_z^* + \Omega\gamma\sigma k^2) \\ & \cdot \left\{ \alpha \ln \left(\frac{\alpha}{\alpha + 2nFJ_z^* \sqrt{Dt/\pi}} \right) + 2nFJ_z^* \sqrt{Dt/\pi} \right\} \\ & \quad - \frac{D_{\text{ad}}C_{\text{ad}}^* \Omega^2 \gamma t}{RT} k^4 \quad [33] \end{aligned}$$

where $\alpha = D(nF)^2 C^*(z = \infty) + \sigma RT$, and t^* denotes the transition time when the surface concentration of the depositing ion falls to zero, or

$$t^* = \frac{\pi D(nF)^2 C^*(z = \infty)^2}{4J_z^{*2}} \quad [34]$$

Step 2: $t > t^*$

$$\begin{aligned} & \ln\{\zeta_k(x, y, t)/\zeta_k(x, y, 0)\} \\ &= -\frac{\pi\sigma\Omega^2 D\gamma C^*(z = \infty) k^3}{4J_z^{*2}} \\ & + \frac{\pi\sigma\Omega RTk}{2D(nF)^4 J_z^{*2}} (-nFJ_z^* + \Omega\gamma\sigma k^2) \\ & \cdot \left\{ \alpha \ln \left(\frac{\alpha}{\sigma RT} \right) - D(nF)^2 C^*(z = \infty) \right\} \\ & \quad - \frac{\Omega J_z^* k}{nF} (t - t^*) - \frac{D_{\text{ad}}C_{\text{ad}}^* \Omega^2 \gamma t}{RT} k^4 \quad [35] \end{aligned}$$

These results indicate that the surface diffusion term, $D_{\text{ad}}C_{\text{ad}}^* \Omega^2 \gamma k^4 t / RT$, simply adds to the dsi equations which were previously derived. Thus, the following approximated equations are obtained

$0 \leq t \leq t^*$

$$\begin{aligned} & \ln\{\zeta_k(x, y, t)/\zeta_k(x, y, 0)\}_{\text{app}} \\ &= \frac{\Omega t k}{nFRT} \left[-RTJ_z^* - \Omega\gamma k^2 \left\{ nFDC^*(z = \infty) \right. \right. \\ & \quad \left. \left. + \frac{4}{3} J_z^* \sqrt{\frac{Dt}{\pi}} \right\} \right] - \frac{D_{\text{ad}}C_{\text{ad}}^* \Omega^2 \gamma t}{RT} k^4 \quad [36] \end{aligned}$$

² According to the measurements by Bockris *et al.* (6, 7), the equilibrium concentration of adatoms at Ag electrode does not depend upon the bulk concentration of Ag ions and is likely to keep constant.

and

$t > t^*$

$\ln\{\xi_k(x, y, t)/\xi_k(x, y, 0)\}_{\text{app}}$

$$= \frac{\Omega k}{3nFRT} \left\{ -3RTJ_z^* t - nFD\Omega\gamma C^*(z = \infty)t^*k^2 \right\} - \frac{D_{\text{ad}}C_{\text{ad}}^*\Omega^2\gamma t}{RT} k^4 \quad [37]$$

Because the surface diffusion term always takes negative value and has the 4th power of wave number, it is concluded that the surface diffusion suppresses the unstable growth. Considering the relationship between the wave number and the wavelength ($\lambda = 2\pi/k$) it is predicted that the effect of the surface diffusion becomes significant with the decreasing crystal size.

Discussion

Occurrence of unstable growth.—From the dsi equations obtained, it is concluded that the dsi becomes positive for certain wave numbers only when the current density is negative, and that the dsi is negative for all wave numbers when the current density is positive. This means that the crystal growth becomes unstable only in cathodic deposition; i.e., the initial surface fluctuations in thermodynamic equilibrium develop with increasing time until the surface irregularities macroscopically emerge.

The process of the unstable growth is schematically explained in Fig. 2. In cathodic deposition, the concentration of the depositing ion increases with increasing distance from the electrode surface, so that the top parts of the surface fluctuation tend to protrude into higher concentration regions of the solution than the bottoms. Thus, the mass flux at the top becomes larger than the bottom. Moreover, the concentration in the neighborhood of the top parts is prevented from reducing by the following manner. The surface potential ($\phi[x, y, t]$) is positive at a convex part, where the fluctuation of the cathodic current density ($j_z[x, y, z, t]$) in the z -direction takes a negative value because the nonfluctuated cathodic current is defined negative and the mass transfer of ionic species is greater than that of concave parts. So, $\int_z^\infty j_z(x, y, z, t) dz < 0$ is obtained. From Eq. [12], at a convex portion

Fig. 2. Process of the occurrence of instability. In cathodic deposition, the concentration distribution of metal ions has a positive slope, so that the higher part (ξ_1) of the surface irregularity tends to protrude into higher concentration region than the lower part (ξ_2). The surface concentration of metal ion C_1 at ξ_1 becomes higher than C_2 at ξ_2 . The mass flux at ξ_1 increases more rapidly than at ξ_2 ; the higher the part, the more projects.

$$\eta(x, y, Z, t) = -\frac{1}{\sigma} \int_z^\infty j_z(x, y, z, t) dz + \frac{\phi(x, y, t)}{nF} > 0 \quad [38]$$

is derived. In other words, the concentration overpotential fluctuation, $\eta(x, y, Z, t)$ at a convex portion is positive. Therefore, using Eq. [25], the surface concentration fluctuation, $c(x, y, Z, t)$, at a top part is found to be positive, while $c(x, y, Z, t)$ at the bottom is negative. As a result, a convex part is always surrounded by higher concentration of the depositing ion than is a concave part. This effect is thought to support the unstable process mentioned above, so that the unstable growth proceeds.

Effect of the surface diffusion of adatoms.—Using the relationship obtained, dsi- λ curves were tentatively drawn (Fig. 3). The value of concentration C_{ad}^* , 8.0×10^{-6} mol/m², was obtained by averaging the experimental data of Bockris *et al.* (6, 7). It was found that every dsi- λ curve has a maximum value, dsi_{max}. It and the corresponding wavelength, λ_{max} , were plotted against the deposition time, as shown in Fig. 4 and 5.

In Fig. 4, it can be seen that as the deposition time elapses, due to the effect of the surface diffusion, the increasing rate of the dsi_{max} becomes slower than that in the case disregarding such effect. On the other hand, the surface diffusion affects the value of λ_{max} more drastically than that of dsi_{max}. Figure 5 indicates the result of a comparison of λ_{max} considering the effect of the surface diffusion with λ_{max} neglecting it. In the case where the surface diffusion is hindered, λ_{max} rapidly decreases with the deposition time. In such case, it can be expected that as time elapses, much more pronounced nucleation growth successively takes place, so that the average crystal dimension de-

Fig. 3. Fig. 4. Dependence of the maximum degree of surface irregularity (dsi_{max}) on the deposition time for various current densities at the bulk concentration of Ag ion. $C^*(z = \infty) = 56.8 \text{ mol m}^{-3}$; $\gamma = 1.0 \text{ Jm}^{-2}$. —: $D_{ad} = 2.2 \times 10^{-10} \text{ m}^2\text{s}^{-1}$; - - - -: $D_{ad} = 0.0 \text{ m}^2\text{s}^{-1}$. 1: $J_z^* = -50 \text{ Am}^{-2}$; 2: $J_z^* = -100 \text{ Am}^{-2}$; 3: $J_z^* = -300 \text{ Am}^{-2}$. Other data are the same as in Fig. 3.

Fig. 5. Dependence of the wavelength (λ_{max}) corresponding to dsi_{max} on the deposition time for various current densities at the bulk concentration of Ag ion. $C^*(z = \infty) = 56.8 \text{ mol m}^{-3}$; $\gamma = 1.0 \text{ Jm}^{-2}$. —: $D_{ad} = 2.2 \times 10^{-10} \text{ m}^2\text{s}^{-1}$; - - - -: $D_{ad} = 0.0 \text{ m}^2\text{s}^{-1}$. 1: $J_z^* = -50 \text{ Am}^{-2}$; 2: $J_z^* = -100 \text{ Am}^{-2}$; 3: $J_z^* = -300 \text{ Am}^{-2}$. Other data are the same as in Fig. 3.

creases without limit with time. The growth rates of the crystals increase violently with the increasing time.

This prediction seems insufficient, particularly for the case where λ_{max} starts to decrease to an infinitesimal value at a relatively early stage of the deposition; we have not observed such extremely small particles as were predicted. If we introduce the effect of the surface diffusion, λ_{max} indeed decreases at an early stage, but finally converges a certain finite value; obviously, such insufficiency as was mentioned above is improved.

This tendency becomes much clearer for the case of low bulk concentration and high current density. Figure 6 shows the time dependence of dsi_{max} in the case of flow concentration, and Fig. 7 represents the relationship between the deposition time and λ_{max} in the same case. As shown in Fig. 6, the surface diffusion

Fig. 6. Plots of the dsi_{max} vs. the deposition time for the galvanostatic Ag deposition on an Ag electrode at the bulk concentration of 5.68 mol m^{-3} . $\gamma = 1.0 \text{ Jm}^{-2}$. —: $D_{ad} = 2.2 \times 10^{-10} \text{ m}^2\text{s}^{-1}$; - - - -: $D_{ad} = 0.0 \text{ m}^2\text{s}^{-1}$. 1: $J_z^* = -50 \text{ Am}^{-2}$; 2: $J_z^* = -10 \text{ Am}^{-2}$. Other data are the same as in Fig. 3.

drastically hinders the increase of the dsi_{max} value. In Fig. 7, it is shown that λ_{max} vs. deposition time behaves much differently from that displayed in Fig. 5; from the early stage, it takes a constant value and decreases no more with time.

Fig. 7. Plots of λ_{max} vs. the deposition time for the galvanostatic Ag deposition on an Ag electrode at the bulk concentration of 5.68 mol m^{-3} . $\gamma = 1.0 \text{ Jm}^{-2}$. 1: $J_z^* = -50 \text{ Am}^{-2}$; 2: $J_z^* = -100 \text{ Am}^{-2}$; 3: $J_z^* = -300 \text{ Am}^{-2}$. Other data are the same as in Fig. 3.

Applying the conclusion obtained above to the actual system, it can be said that the particle sizes do not change after a long time passes. However, if the surface diffusion of adatoms is suppressed by some reasons, for example, the competitive adsorption of other species (which has an inhibiting effect for the metal adatoms), the theory disregarding the surface diffusion may still be important. In that case, nucleation growth may occur vigorously everywhere on the electrode surface.

Conclusion

Because of the large contribution of the surface diffusion of adatoms during galvanostatic deposition it can be proved that particle size decreases with deposition time into the infinitesimal dimension. After a certain period of time, the crystals formed on the electrode tend to keep their sizes constant. At the same time, the growth rate of the crystal is somewhat suppressed. However, when the surface diffusion of adatoms is blocked by the intense adsorption of other chemical species, the equations neglecting the surface diffusion are, as before, important to explain the rapid growth of minute crystal particles.

APPENDIX

On taking each variation of $\vec{J}(x, y, z, t)$, $V(x, y, z, t)$, $H(x, y, z, t)$, and $\Phi(x, y, t)$ in Eq. [9] and using Eq. [8], the following equation is obtained

$$\vec{j} = \nabla\eta(x, y, z, t) - \frac{\phi(x, y, t)}{nF} \delta(z - Z) \quad [\text{A-1}]$$

Substituting Eq. [A-1] into Eq. [27] in the solution, it follows that

$$\nabla^2\eta(x, y, z, t) = 0 \quad [\text{A-2}]$$

The fluctuations can be expressed in terms of their numberless Fourier components, so that Eq. [A-2] must also hold for $\eta_k(x, y, z, t)$ with a single set of wave numbers, k_x and k_y . Substituting Eq. [32] into Eq. [A-2], and adopting a boundary condition ($\eta_k[x, y, z, t] \rightarrow 0$ at $z \rightarrow \infty$), the solution of $\eta_k(x, y, z, t)$ is derived as

$$\eta_k(x, y, z, t) = B_1 e^{-kz} \xi(t) \exp[i(k_x x + k_y y)] \quad [\text{A-3}]$$

where $\xi(t)$ is an arbitrary function of t , and B_1 is an arbitrary constant. From Eq. [A-3], it is obvious that the z -component, $j_{zk}(x, y, z, t)$, has the following relationship with $\eta_k(x, y, z, t)$ in an electrolyte solution

$$j_{zk}(x, y, z, t) = \sigma \frac{\partial}{\partial z} \eta_k(x, y, z, t) \quad [\text{A-4}]$$

By means of Eq. [31], [A-3] and [A-4], $j_{zk}(x, y, z, t)$ is explicitly expressed as

$$j_{zk}(x, y, z, t) = -\sigma B_1 k e^{-kz} \xi(t) \exp[i(k_x x + k_y y)] \quad [\text{A-5}]$$

On the other hand, as far as the surface irregularity is small, normal unit vector (\vec{n}) of the surface can be approximated parallel to the z -axis, so that Eq. [26] can be rewritten as

$$j_{zk}(x, y, z, t) = -nFD \left\{ \frac{\partial c_k(x, y, z, t)}{\partial z} \right\} \text{ for } z = Z \quad [\text{A-6}]$$

Using Eq. [3], [A-3], and [A-6], current density fluctuation ($j_{zk}[x, y, z, t]$) has a relation with concentration fluctuation, ($c_k[x, y, z, t]$) at the electrode surface

$$j_{zk}(x, y, Z, t) = -nFDkc_k(x, y, Z, t) \quad [\text{A-7}]$$

A substitution of Eq. [22] into Eq. [25] yields the following equation

$$\eta_k(x, y, Z, t) = \frac{RT}{nF} \frac{c_k(x, y, Z^*, t) + L(t) \zeta_k(x, y, t)}{C^*(Z, t)} \quad [\text{A-8}]$$

From Eq. [28] and [32], the relation between ϕ_k and ζ_k is obtained

$$\zeta_k(x, y, t) = \Omega\gamma k^2 \phi_k(x, y, t) \quad [\text{A-9}]$$

where $\zeta_k(x, y, t)$ is surface potential with a single set of wave number. By means of Eq. [A-5] and [A-7], the equation

$$\int_Z^\infty j_{zk}(x, y, z, t) dz = nFDc_k(x, y, Z^*, t) \quad [\text{A-10}]$$

is derived. Substitution of Eq. [A-8], [A-9], and [A-10] into Eq. [12] yields the following equation

$$c_k(x, y, Z, t) = \frac{\sigma\{\Omega\gamma C^*(z = Z^*)k^2 - RTL(t)\}}{(nF)^2 DC^*(z = Z^*) + \sigma RT} \zeta_k(x, y, t) \quad [\text{A-11}]$$

Using Eq. [A-6] and [A-7], it follows that

$$\left\{ \frac{\partial c_k(x, y, z, t)}{\partial z} \right\}_{z=Z^*} = -kc_k(x, y, Z^*, t) \quad [\text{A-12}]$$

From Eq. [20], the following equation concerning the fluctuation components having a single set of wave number is obtained

$$\frac{1}{\Omega} \frac{\partial \zeta_k(x, y, t)}{\partial t} = \frac{D_{ad}}{RT} C_{ad}^* \nabla^2 \zeta_k(x, y, t) + D \left\{ \frac{\partial c_k(x, y, z, t)}{\partial z} \right\}_{z=Z^*} \quad [\text{A-13}]$$

Substituting Eq. [A-9], [A-11], and [A-12] into Eq. [A-13], one finally derives the dsi equation

$$\ln \{\zeta_k(x, y, t)/\zeta_k(x, y, 0)\} = \int_0^t f(k, t) dt \quad [\text{A-14}]$$

where

$$f(k, t) = \frac{\sigma\Omega Dk\{RTL(t) - \Omega\gamma C^*(z = Z^*)k^2\}}{(nF)^2 DC^*(z = Z^*) + \sigma RT} - \frac{D_{ad}C_{ad}^*\Omega^2\gamma}{RT} k^4 \quad [\text{A-15}]$$

Morphological Instability in Nonsteady Galvanostatic Electrodeposition

II. Experimental Demonstration of the Surface Diffusion Effect of Adatoms by Means of Image Analysis

Ryoichi Aogaki and Tohru Makino¹

Department of Chemistry, The Institute of Vocational Training, 1960, Aihara, Sagamihara, 229, Japan

ABSTRACT

In nonsteady galvanostatic deposition, where the surface diffusion of adatoms often plays an important role, the variations in surface morphology of electrodes during deposition was examined experimentally. When the surface diffusion can be ignored, as has been reported, nucleation growth caused by high supersaturation of adatoms at an electrode surface is so violent that the average crystal size becomes smaller with increasing deposition time. In extreme cases particle dimensions diverge into zero after long periods. A large discrepancy exists between the actual deposition and theoretical prediction. To deal with this difficulty, the introduction of surface diffusion is sufficient. Surface diffusion tends to suppress the development of the surface irregularities arising from nucleation growth, and consequently the average size of the crystals formed on the electrode increases somewhat with increasing deposition time. This was ascertained by several experiments concerning Ag deposition on Ag electrodes.

As shown in the previous paper (1), the surface diffusion of adatoms in galvanostatic deposition becomes

very important when the deposition occurs at low concentration and high current density. Under such conditions, electrodeposition theoretically allows the crystal sizes formed on electrode surface to decrease infinitely, since many crystal peaks continuously emerge through the nucleation because of the high

¹ Present address: AHS Japan Company, 2-10-12, Akasaka, Minato-ku, 107, Japan.

Key words: galvanostatic deposition, unstable crystal growth, morphology, image analysis.

supersaturation of adatoms. The surface diffusion seems to relieve such difficulty. In Ref. (1), it is predicted that the crystal size reaches a constant value after a certain deposition time elapses.

However, that prediction concerning the surface diffusion effect was derived from the behavior of $dsi-\lambda$ curves, not from the actually calculated crystal sizes, which are obtained only from three-dimensional contour plotting by means of computer graphics.

In the present paper, using the procedures of calculation obtained from another previous paper (2), we simulated the surface morphology in view of the surface-diffusion effect to obtain the crystal-size distribution. After a comparison of the results with experimental data given by image analysis of SEM photographs of electrodeposited surface, the effect of surface diffusion on crystal particle size was examined.

Experimental

Experiments were carried out for Ag deposition on Ag electrodes in a solution of $AgClO_4$ with a supporting electrolyte of $1M HClO_4$. The Ag electrodes were polycrystallines with $0.5 cm^2$ area, and they were 99.99% pure. They were chemically polished in a chromic acid/hydrochloric acid/nitric acid mixture, according to the Levinstein and Robinson method (9). Immediately after washing them several times in twice-distilled water with a supersonic washer, the polished planar electrode was set on an electrode cell and soaked in the electrolytic solution. The electrode cell was mainly composed of Teflon plates (see Fig. 1). So electrodes could be easily attached to the cell, they were inserted from the back of the cell using a screwed Teflon rod connected with a Pt wire. All the experiments were carried out in the stationary solution. Thus, the solution near the electrode surface was protected from any movement of the solution by the cylindrical wall part of a Teflon plate in front of the electrode. The Teflon plate and electrode were made to come closely into contact to inhibit the disturbance caused by the leakage of the solution through the gap between them. Then, the cell was immersed in the solution for the polished surface to face downward. This prevented the agitation of the solution from natural convection because the liquid containing a large amount of depositing ions was heavier than the dilute one. Consequently, potential-time curves under galvanostatic conditions were in good agreement with those predicted by the usual nonsteady diffusion equation (3).

The electrolytes used were $AgClO_4$ and $HClO_4$, both of reagent grade and made by Wako Pure Chemical Industries. The solutions were prepared with twice-

distilled water and they were deaerated before and after each experiment with bubbling nitrogen. Immediately after being deposited galvanostatically for a given period of time, the samples were again rinsed to be dried by N_2 gas. SEM photographs of the samples were then taken. From the photographs, the statistical properties of the crystal size, including the average diameter and standard deviation, were computed by means of a Toyo Ink Company, Luzex 500 Image Analyzer. The diameter of a crystal was defined as that of a circle equivalent to the area.

Calculations

The surface morphology was drawn in three-dimensional contour plotting, which was calculated in accordance with the procedures mentioned previously (2). Assuming a rectangular electrode surface divided into a mesh of 128×128 points, random numbers generated by computer were assigned to each point. Interpolation between neighboring mesh-point data yielded a matrix with 256×256 data points, which corresponded to the initial fluctuation ($\zeta[x, y, 0]$) of surface height arising from microscopic deposition and dissolution of metal.

The initial fluctuation ($\zeta[x, y, 0]$) exists in thermodynamic equilibrium between metal adatoms and ions near the electrode. When the ions are deposited on the surface by the application of a current galvanostatically, the electrode system transfers to a nonequilibrium state. Subsequently, the metal ions successively diffuse according to the electrode reaction. Initial microscopic surface fluctuations simultaneously develop to yield many macroscopic crystal peaks. This process can be expressed in the following equation of Fourier image functions

$$Z(k_x, k_y, t) = F(k_x, k_y, t) Z(k_x, k_y, 0) \quad [1]$$

where $Z(k_x, k_y, 0)$ and $Z(k_x, k_y, t)$ are the image functions of the initial surface fluctuation and the fluctuation at $t = t$, respectively. $F(k_x, k_y, t)$ is the transfer function concerning galvanostatic deposition. This is described by two different expressions of dsi which are given in Ref. (1).

$$t \leq t^*$$

$$F(k_x, k_y, t) = \exp \left[\frac{\Omega t k}{nFRT} \left\{ -RTJ_z^* - \Omega \gamma k^2 \left(nFDC^*(z = \infty) + \frac{4}{3} J_z^* \sqrt{\frac{Dt}{\pi}} \right) - \frac{D_{ad} C_{ad}^* \Omega^2 \gamma t}{RT} k^4 \right\} \right] \quad [2]$$

$$t^* < t$$

$$F(k_x, k_y, t) = \exp \left[\frac{\Omega k}{3nFRT} \left\{ -3RTJ_z^* t - nFD\Omega \gamma C^*(z = \infty) t^* k^2 \right\} - \frac{D_{ad} C_{ad}^* \Omega^2 \gamma t}{RT} k^4 \right] \quad [3]$$

where t^* denotes the transition time when the surface concentration of depositing ions falls to zero, or

$$t^* = \frac{\pi D (nF)^2 C^*(z = \infty)^2}{4J_z^{*2}} \quad [4]$$

All the notations of parameters in these equations are the same as in Ref. (1).

The initial surface fluctuation ($\zeta[x, y, 0]$) determined at the 256×256 data points was converted to its Fourier image function ($Z[k_x, k_y, 0]$) using two-dimensional Fourier transform for x - and y -coordinates. Describing the procedure mathematically

$$Z(k_x, k_y, 0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \zeta(x, y, 0) \exp[-i(k_x x + k_y y)] dx dy \quad [5]$$

is obtained. Then, the image function ($Z[k_x, k_y, t]$) at $t = t$ is computed by means of Eq. [1]. Finally, surface morphology at $t = t$ is given by the following Fourier inversion

$$\zeta(x, y, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} Z(k_x, k_y, t) \exp[i(k_x x + k_y y)] dk_x dk_y \quad [6]$$

From $\zeta(x, y, t)$, we know how the crystal peaks are distributed over the surface, which are defined as the parts above the root-mean-square height of $\zeta(x, y, t)$. Their average size and standard deviation can then be calculated. In these calculations, the surface diffusion coefficient and surface energy, which are unknown parameters, can be determined by curve fitting of the results to the experimental data.

Results and Discussion

Figure 2 is an SEM photograph of the minute crystal particles generated during galvanostatic deposition. Figure 3 represents the three-dimensional contour plotting of the surface morphology under the same conditions as in Fig. 2. Both figures have similar morphological features. Using the image analyzer, the crystal particles in Fig. 2 and 3 were converted into circles having areas equivalent to the particles. The diameters were defined as the crystal sizes. Figure 4 is a histogram of the crystal size distribution. It was obtained from the SEM photographs. From the surface morphology obtained theoretically, another histogram of crystal size distribution is given in Fig. 5. After confirming that the histograms had Gaussian distributions, the mean crystal sizes and standard deviations were obtained from both experiments and calculations.

At first, crystal size-time curves were experimentally obtained. Then, utilizing the surface diffusion coefficient and surface energy, which had already been determined by fitting the calculated data to observed ones, theoretical crystal size-time curves were calculated, where the average value of the data measured by Bockris *et al.* (4, 5) was used as the adatom concentration, *i.e.*, $C_{ad}^* = 8.0 \times 10^{-6} \text{ mol/m}^{-2}$. Figure 6 shows the results of the computation, where the diffusion coefficient determined is $D_{ad} = 1.6 \times 10^{-10} \text{ m}^2\text{s}^{-1}$, which is in good agreement with the value of $5.0 \times 10^{-10} \text{ m}^2\text{s}^{-1}$ predicted by Bockris *et al.* (8). In the figure, it is obvious that there is a large difference of the time dependence of crystal size as expected for the two cases, regardless of whether the surface diffusion is disregarded or not.

In the present case, the average size which is different from that in Ref. (7) increases to some extent

Deposition time is 3.0s, and current density is -100 Am^{-2} . The size of a crystal is defined as the diameter of a circle equivalent to its area.

Fig. 5. Theoretical crystal size distribution formed on an Ag electrode in galvanostatic diffusion-controlled deposition in a 56.8 mol m^{-3} Ag ionic solution. Deposition time is 5.0s, and current density is -100 Am^{-2} . Crystal size is defined as the diameter of a circle equivalent to a peak area in a three-dimensional contour line plotting. Other parameters used for calculation are the same as in Fig. 3.

Fig. 6. Crystal size distribution developed on an Ag electrode as a function of deposition time. Bulk concentration is 5.68 mol m^{-3} , and current density is -10 Am^{-2} . Solid dots represent the average values of crystal sizes, and the bars above and below the dots are upper and lower error limits. The numbered curves correspond to the two cases. Curve 1; $D_{ad}: 1.6 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Curve 2; $D_{ad}: 0.0 \text{ m}^2 \text{ s}^{-1}$. Other parameters used for calculation are; $D: 1.55 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$; $\gamma: 1.9 \times 10^{-2} \text{ J m}^{-2}$; $\Omega: 1.03 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}$; $\sigma: 1.7 \times 10^2 \text{ J m}^{-2}$; $C_{ad}^*: 8.0 \times 10^{-6} \text{ mol m}^{-2}$; $T: 300\text{K}$.

with increasing time. In Ref. (7) it was shown that the average size decreases with deposition time. This

was attributed to the high supersaturation of adatoms, which promotes the successive formation of a number of new crystal nuclei. In order to better examine the surface diffusion effect, another experiment and calculation were carried out (see Fig. 7). Ignoring the surface diffusion, we see that at the beginning, the average crystal size increases with increasing time, and after reaching a maximum value at a certain deposition time, it begins to decrease with time. This means that the crystal growth originated by nucleation has a certain induction time, which was predicted in Ref. (6). The presence of the induction time may be because the supersaturation of adatoms drastically increases after surface concentration falls to zero.

However, the surface diffusion of adatoms mitigates the nucleation growth because deposited adatoms rapidly move to other active sites, such as kinks and steps.

The effect of current density on crystal growth was examined. Figure 8 shows the results at a current density higher than in Fig. 6. The bulk concentration was the same as in Fig. 6, and the values of the surface diffusion coefficient (D_{ad}) and the surface energy

Fig. 7. Crystal size distribution developed on an Ag electrode as a function of deposition time. Bulk concentration is 56.8 mol m^{-3} , and current density is -100 Am^{-2} . Curve 1; $D_{ad}: 1.6 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Curve 2; $D_{ad}: 0.0 \text{ m}^2 \text{ s}^{-1}$. Other parameters used for calculation are the same as in Fig. 3.

Fig. 8. Crystal size distribution developed on an Ag electrode as a function of deposition time. Bulk concentration is 5.68 mol m^{-3} , and current density is -50 Am^{-2} . Curve 1; $D_{ad}: 1.6 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Curve 2; $D_{ad}: 0.0 \text{ m}^2 \text{ s}^{-1}$. Other parameters used for calculation are the same as in Fig. 6.

Fig. 9. Dependence of Ag crystal size distribution on the current density. Deposition time is 6.0s, and the bulk concentration of AgClO_4 in a 10^3 mol m^{-3} HClO_4 solution is 56.8 mol m^{-3} . Solid dots represent the average values of crystal sizes and, the bars above and below the dots are upper and lower error limits. The solid line is the theoretical average value and the dotted lines depict the theoretical upper and lower error limits. Fig. 10. Time variation in the height of the cross-sectional profile for the silver electrode surface at a given point ($y = 5.0 \text{ } \mu\text{m}$). Current density is -100 A m^{-2} , and bulk concentration is 56.8 mol m^{-3} . Other parameters are the same as in Fig. 9.

(γ) used for the calculations were also the same as in Fig. 6. The experimental values seem to agree well with the theoretical curves. This suggests that the electrode surface has values of D_{ad} and γ independent of the current density as long as the bulk concentration remains constant. In order to make sure of this fact, galvanostatic deposition with a constant bulk concentration was performed at various current densities. At the same time, the average size and its standard deviation of the crystals were calculated with the constant D_{ad} and γ which had already been obtained. As shown in Fig. 9, the experimental results are in good agreement with the theoretical computations. It can be concluded that in galvanostatic deposition, D_{ad} and γ depend only on the bulk concentration and not on the current density, and that the average size decreases with decreasing bulk concentration.

When surface diffusion does not contribute as much to crystal growth, many new crystal peaks emerge (7). This phenomenon was detected in profiles drawn by computer, such as appears in Fig. 10. It can be seen in Fig. 10 that the peaks do not develop vertically and that no new peaks protrude into the solution. This confirms that surface diffusion suppresses the development of the new crystals.

Conclusion

In galvanostatic deposition, the surface diffusion of adatoms becomes important at low bulk concentration and high current density, where the electrode surface has a tendency to form new crystal peaks with increasing time because of the high supersaturation of adatoms. If in this case the surface diffusion of the adatoms is hindered for some reason, the nucleation is likely to yield a number of small crystal peaks. Consequently, the average size of the crystal peaks decreases with increasing time. Also, it can be concluded that an induction period is needed for crystal formation arising from nucleation. At the beginning of deposition, supersaturation is not enough to generate new peaks due to nucleation, and so the peaks which have already existed grow to rather larger sizes. Minute new crystals start to grow when supersaturation reaches a sufficiently high value. The average particle size-deposition time curve, therefore, depicts one maximum value which seems to correspond to the induction time of nucleation. Surface diffusion suppresses such decreasing of the average size since it obstructs new nucleation growth.

In cases where surface diffusion is more active, new crystal growth caused by nucleation cannot be found in galvanostatic deposition. Both the calculation and experiment supported this prediction.

Nucleation and Growth of Electroless Nickel Deposits on Molybdenum Activated with Palladium

J. Flis¹ and D. J. Duquette

Rensselaer Polytechnic Institute, Materials Engineering Department, Troy, New York 12181

ABSTRACT

Early stages of electroless nickel plating from an ammoniacal hypophosphite solution of pH 8.8 at 50°C with palladium-activated Mo were investigated using TEM and SEM, potential measurements, and LSV. It was shown that activation of molybdenum in a PdCl₂/HCl solution resulted in the formation of palladium islands on the substrate. In the plating solution, the nickel deposition took place simultaneously, but it took place independently on the palladium islands and on the molybdenum substrate. It was concluded that the nickel deposition on the molybdenum substrate occurred upon a thin layer of nickel, electrolytically deposited during a spontaneous potential shift. The role of the palladium islands was to catalyze electrooxidation of hypophosphite and induce the potential shift. A potential arrest at -0.7V vs. SCE was observed on the palladium with a concomitant decrease in the oxidation rate of hypophosphite. This phenomenon was ascribed to competitive adsorption of hydrogen and possibly to poisoning of the palladium by a hydride (β -PdH). In systems of palladium with molybdenum and palladium with nickel, a synergistic effect of small amounts of one metal on the catalytic activity of the other was observed.

Electroless chemical deposition of nickel from aqueous solutions, described first by Brenner and Riddell in 1946-1947 (1), proceeds spontaneously only on some metals, such as nickel, cobalt, palladium, iron, aluminum, gold, and zinc. A few of these possess intrinsic catalytic activity, while others (*e.g.*, iron and aluminum) are believed to acquire catalytic activity after initial deposition of nickel. Nickel deposition can take place due to a displacement reaction in a plating bath (2) or by an electroplated nickel "strike."

A common method for activation of noncatalytic substrates involves immersion into HCl solutions of PdCl₂, RhCl₂, or SnCl₂. Marton and Schlesinger (3) used the SnCl₂-PdCl₂ treatment for obtaining small catalytic sites on dielectric substrates. They found that on the activated dielectric substrates the deposition of nickel starts only at certain specific sites and leads to the formation of islands. On nickel and palladium, nickel deposition is homogeneous and shows no island structure. The substrates investigated differed in their electron conductivity as well as in catalytic activity; dielectric substrates are nonconducting and nonactive; whereas nickel and palladium are conducting and highly active.

The objective of this work is to examine the nucleation and growth of nickel deposits on a nonactive metallic substrate of molybdenum after activation in a PdCl₂/HCl solution. Electroless nickel plating on molybdenum is described elsewhere (4-6). These investigations were carried out in order to determine the distribution of palladium on activated molybdenum substrates, and to examine the growth of nickel deposits on a heterogeneous surface of molybdenum and palladium.

The plating was carried out in an ammoniacal hypophosphite solution. Deposits were examined using transmission electron microscopy (TEM), scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS). The catalytic activity and electrochemical behavior of molybdenum with palladium

were evaluated on the basis of potential measurements and linear sweep voltammetry (LSV). These types of measurements are justified in view of the widely accepted opinion that electroless deposition involves a charge-transfer mechanism. Electrochemical measurements in studies of electroless deposition have been described by other investigators (7-14).

Experimental

The substrates examined were 99.7% molybdenum rolled sheet containing ~0.3% metallic impurities, and electrodeposited palladium.

The molybdenum was electropolished in a solution of 12.5% H₂SO₄ (by volume) in ethanol, rinsed with distilled water and methanol, and then masked with lacquer to obtain an uninsulated surface area of 1 cm². Thin foils for TEM were prepared by the double-jet electropolishing technique in a solution of 12.5% H₂SO₄ in methanol at -50°C. Activation was achieved by immersion into solutions of 1 g/l PdCl₂ = 1 ml/l concentrated HCl for chemical and structural analyses, or 0.2 g/l PdCl₂ + 0.2 ml/l HCl for electrochemical studies, for periods of 5-300s. This was followed by washing in distilled water and methanol. Molybdenum specimens for SEM and EDS examinations were activated by placing droplets of a PdCl₂/HCl solution on the surface.

Palladium substrates were obtained by Pd electrodeposition on pure copper from a solution of 0.8 g/l PdCl₂ · 2H₂O + 60 g/l NaOH. The electrodeposition was carried out at room temperature at a current density of 100 A/m² for 200s, producing palladium layers of approximately 1 μ m in thickness.

In some experiments, specimens were cathodically polarized in 0.1M H₂SO₄ at a current density of 100 A/m² for 600 sec prior to testing. Specimens were examined in the solutions listed in Table I. Sulfuric acid (98%) was added in amounts appropriate for adjusting the pH of the solutions to 8.8 (at 25°C). All measurements were carried out on stationary specimens at 50.0° ± 0.5°C (pH at 50°C was 8.3) in a 250 ml

Key words: electroless, nickel plating, molybdenum, palladium.

round-bottom flask provided with a reflux condenser, Luggin capillary, and a platinum wire as an auxiliary electrode. The solutions were deaerated by purging with pure nitrogen.

Electrochemical examinations involved (a) monitoring of open-circuit electrode potentials upon immersion of specimens into solutions, and (b) LSV measurements. Potentials were measured against saturated calomel electrode (SCE) at 25°C via a Luggin capillary. Voltammetric measurements were performed using single cathodic sweeps at a rate of 1 mV/s, beginning at -0.3V vs. SCE.

Uptake of hydrogen into the palladium substrates in the plating solution was determined by an electrochemical permeation method (15). Palladium was electrodeposited on a $50\ \mu\text{m}$ -thick membrane of Armco iron. The reverse (diffusive) side was electroplated with nickel from a Watt's solution at $100\ \text{A}/\text{m}^2$ for 100s. The diffusion compartment in the electrolytic permeability cell contained 0.02M NaOH, with a reference electrode of Hg/HgO/ 0.02M NaOH.

The growth rate of electroless deposits was determined gravimetrically on the platinum wire, which was electroplated with a nickel layer $\sim 0.2\ \mu\text{m}$ thick. (Deposited for 30 min after reaching a mixed potential of -0.87V .) The deposits were dissolved in concentrated HNO_3 and analyzed for phosphorus content by the molybdophosphoric acid method (16) with absorbance measurements being made at 380 nm.

Results

Open-circuit potential of molybdenum and palladium-activated molybdenum.—Changes of electrode potential of the substrates upon immersion into the plating solution are shown in Fig. 1. The rest potential was about -0.4V . Molybdenum alone did not fall below -0.5V , and no plating occurred on this substrate. Activation of molybdenum with palladium resulted in a potential shift to $\sim -0.87\text{V}$, (characteristic for the electroless plating in the solution examined). Two potential arrests tended to appear on the potential/time curves: the first at about -0.5V , and the second at about -0.7V . The former arrest decreased with increasing activation time (i.e., increasing amount of palladium deposited on the surface), whereas the latter increased with the activation time. Cathodic polarization of specimens prior to testing virtually eliminated both potential arrests.

Open-circuit potential of palladium.—Changes of the potential on palladium subjected to various surface treatments in different solutions are shown in Fig. 2. As in the case of palladium-activated molybdenum, the mixed potential of electroless deposition was about

Fig. 1. Open-circuit potential of molybdenum after immersion into the plating solution. Parameter is the time in seconds of palladium activation in the solution of $1\ \text{g}/\text{l}$ $\text{PdCl}_2 + 1\ \text{ml}/\text{l}$ HCl . Cathodic polarization prior to testing (cp) was carried out in 0.1M H_2SO_4 at $100\ \text{A}/\text{m}^2$ for 600s.

-0.87V . In the supporting solution with hypophosphite (no Ni^{2+} ions), the potential dropped to values of about -0.92V . A potential arrest at -0.7V was observed in both solutions. After the oxidizing surface treatments (aging in air or immersion into 0.1M NaOH), substrates showed an additional potential arrest at about -0.5V . Cathodic polarization prior to testing eliminated the arrest at -0.5V and substantially reduced the time of arrest at -0.7V . In the supporting solution (no hypophosphite or Ni^{2+} ions), the stationary potential was about -0.4V .

Growth rate and phosphorus content in the deposits.—At the mixed potential of -0.87V , the average growth rate of the deposits on nickel-covered platinum was $14 \pm 3\ \text{mg} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$. Assuming a density of the deposits of $7.85\ \text{kg}/\text{l}$ (17), this would correspond to an increase in thickness at a rate of $(1.8 \pm 0.4) \times 10^{-3}$

Fig. 2. Open-circuit potential of palladium upon immersion into various solutions after surface treatments as indicated at the curves.

$\mu\text{m} \cdot \text{s}^{-1}$. The deposits contained from 2.2 to 2.9 weight percent (w/o).

Voltammetric measurements.—To comply with the extent and direction of the open-circuit potential shifts (Fig. 1 and Fig. 2), the potential was scanned from -0.3V to -0.92V or below. Voltammograms for molybdenum, palladium-activated molybdenum, and palladium in the supporting solution with and without other components essential for plating (cf. Table I) are shown in Fig. 3, 4, and 5, respectively.

The polarization curves of molybdenum (Fig. 3) in the supporting solution and in the solution with sodium hypophosphite (NaH_2PO_2) were similar, indicating that hypophosphite did not undergo electro-oxidation on this substrate. However, the anodic current of elec-

Fig. 3. Voltammograms on molybdenum in the supporting solution without and with other components (see Table I), starting at -0.3V .

Fig. 4. Voltammograms on molybdenum and palladium-activated molybdenum in the supporting solution without and with other components, starting at 0.3V . Parameter is the time of activation in solution of $0.2\text{ g/l PdCl}_2 + 0.2\text{ ml/l HCl}$.

Fig. 5. Voltammograms on palladium in the supporting solution without and with other components.

tro-oxidation of hypophosphite appeared in the solution with NaH_2PO_2 and Ni^{2+} ions (plating solution). It started at the potential of nickel deposition, as seen from the curve for the solution with Ni^{2+} ions. Electro-oxidation of hypophosphite took place on a layer of nickel, electrolytically deposited on molybdenum during the potential scan (in Fig. 3 the potential of nickel deposition is shown as $E_{\text{Ni}^{2+}/\text{Ni}^0}$).

Cathodic polarization of specimens in $0.1\text{M H}_2\text{SO}_4$ prior to testing shifted the corrosion potential of molybdenum towards negative values, but did not affect electro-oxidation of hypophosphite.

Deposition of palladium significantly activated the molybdenum substrate both with respect to electro-oxidation of hypophosphite and its evolution of hydrogen (Fig. 4). Hydrogen evolution started at a potential of -0.65V , whereas electro-oxidation of hypophosphite took place over the entire potential range. Activation with palladium for a longer immersion time (30s) resulted in a decrease of anodic current and in the appearance of a distinct maximum in current at a potential of about -0.65V , as compared to the shorter immersion time (10s). Common for the immersion times of 10 and 30s was a maximum at about -0.82V . In the solution with NaH_2PO_2 (without Ni^{2+} ions), the anodic current decreased steadily with decreasing potential.

Voltammograms for palladium (Fig. 5) resembled those for the palladium-activated molybdenum. Cathodic polarization of palladium prior to testing increased the anodic current at the start of the potential scan and smoothed the curves, eliminating the maximum observed at -0.65V .

The voltammograms allow an interpretation of some of the features of the potential/time curves (Fig. 1, 2). The potential arrests at about -0.5V were associated with the corrosion potentials of the substrates (as indicated by discontinuities on the voltammograms), while the rest potential of -0.87V in the plating solution was the mixed potential of electrochemical processes involving oxidation and reduction of hypophosphite, evolution of hydrogen, and reduction of Ni^{2+} ions. In the absence of Ni^{2+} ions, the mixed potential was -0.92V .

The potential arrests on the palladium containing substrates at -0.7V may be associated with the decreasing anodic current for electro-oxidation of hypophosphite in this potential region (Fig. 4, 5). A rela-

relationship between the potential arrests and the decreasing current is also apparent from the effects of cathodic polarization, which reduces the potential arrests and also smoothes the voltammetric curves, eliminating the decrease in anodic current (Fig. 5).

The decrease in anodic current on palladium below about -0.65V appears to be associated with hydrogen, which begins to evolve at about this potential. This can be deduced from the voltammograms in the supporting solution, which show an increase of the cathodic current above -0.65V (Fig. 4, 5). There is also a relationship between the potential arrests at -0.7V and hydrogen evolution which can be deduced from a simultaneous measurement of the open-circuit potential and of hydrogen permeation (Fig. 6). Figure 6 shows that the potential arrest on palladium electrodeposited on an iron membrane began simultaneously with the permeation of hydrogen through the membrane. A rapid potential drop below about -0.78V was accompanied by a marked increase in the hydrogen permeation rate.

TEM examinations.—An electron micrograph of a molybdenum foil after activation in a PdCl_2/HCl solution is shown in Fig. 7. Palladium was deposited in small islands (black spots in the micrograph) between 0.01 and $0.1\ \mu\text{m}$ in diameter. The distribution of the palladium islands was random, and no correlation with dislocations or grain boundaries in the foil was observed. Large portions of the molybdenum surface remained free of palladium deposits.

Fig. 6. Open-circuit potential (E) of palladium electrodeposited on iron membrane and permeation (i_H) of hydrogen through the membrane upon exposure to the plating solution.

Fig. 7. Electron micrograph of a molybdenum foil after immersion into solution of $0.2\ \text{g/l PdCl}_2 + 0.2\ \text{ml/l HCl}$ for 10s. Black spots are deposits of palladium.

Figure 8 shows a palladium-activated foil of molybdenum after immersion in the plating solution until the open-circuit potential dropped to -0.80V . Upon attaining this potential, the foil was quickly withdrawn from the solution and rinsed with distilled water and methanol. The black spots shown in Fig. 8 are islands of palladium-nickel deposits as identified by electron diffraction. The micrograph shows that at the early stages of electroless nickel plating, the deposition of nickel is not confined to the palladium islands, but proceeds simultaneously on the entire molybdenum surface, without connection with the islands. Radial spreading of nickel deposits grown on the palladium islands was not observed.

SEM and EDS examinations.—SEM and EDS were used to examine more advanced stages of electroless nickel plating. In order to simulate the palladium islands, isolated droplets of the activating solution of $1.0\ \text{g/l PdCl}_2 + 1.0\ \text{ml/l HCl}$ were placed on molybdenum surface. Figure 9 shows an SEM micrograph of the molybdenum surface with a circular spot formed by a droplet of the activating solution. As determined by EDS, the white area in the center of the spot was a deposit of palladium, whereas the white flowerlike features were corrosion products containing oxygen and chlorides. The dark patches in the central area as well as the isolated white dots indicate that the palladium deposit on the molybdenum substrate was not uniform.

Specimens with the spots of palladium were in part masked with a lacquer and exposed to the plating solu-

Fig. 8. Electron micrograph of a palladium-activated molybdenum foil after immersion into the plating solution until open-circuit potential reached -0.80V . Black spots are deposits of palladium. Small gray circular patches are presumably deposits of nickel.

Fig. 9. SEM micrograph of a circular spot on molybdenum, formed by a droplet of activating solution of $1\ \text{g/l PdCl}_2 + 1\ \text{ml/l HCl}$. White diffused area in the center is deposited palladium. White flower-like features are corrosion products.

tion. The time of the plating was measured from the moment of attainment of an open-circuit potential of -0.80V and was varied from 8 to 40s.

An SEM micrograph of a partially masked specimen plated for 10s is shown in Fig. 10. A comparison of the masked and exposed areas indicates that deposition of nickel occurred both on the palladium-containing spots and on the surrounding molybdenum surface. The nickel deposit on the molybdenum surface was thinner than that on the palladium surface, and it differed in appearance.

This growth pattern continued for all of the times used. The nickel deposit on the molybdenum and palladium substrates after plating for 40s is shown in Fig. 11. The deposit on the molybdenum surface still remained thinner than that on the palladium surface. No indication of enlargement and coalescence of the nickel deposits growing on the palladium spots was ever observed.

As shown in Fig. 11, nickel deposition on the molybdenum surface after 40s was highly nonuniform. According to analysis by EDS, the dark stripes and patches indicated bare surface of molybdenum, with only a small amount of nickel.

Elemental analysis of the deposits grown on the molybdenum and palladium substrates also was performed by EDS. EDS spectra from molybdenum substrates (with and without palladium activation) after plating for various times are shown in Fig. 12. It can be seen that the energy peak of nickel in the region with palladium appeared sooner and was markedly higher than that of the molybdenum region without

Fig. 10. SEM micrograph of molybdenum substrate with circular spots formed by droplets of the activating solution, after plating of an unmasked area for 10s. Nickel plated areas are brighter than unplated ones. Arrow indicates a border between a masked area (to the left) and plated area (to the right).

Fig. 11. SEM micrograph of nickel deposit on (A) molybdenum region and (B) palladium-containing region after plating for 40s.

Fig. 12. EDS spectra from the molybdenum substrates with and without palladium after plating for 8, 10, and 40s. Arrows indicate peaks of palladium ($\text{Pd}_{L\alpha 1} = 2.838\text{ keV}$) and of nickel ($\text{Ni}_{K\alpha 1} = 7.477\text{ keV}$).

palladium. After plating for 40s, the nickel peak on molybdenum with palladium was about six times higher than the nickel peak on molybdenum itself.

The SEM and EDS examinations suggest that the rate of nickel deposition on palladium is considerably higher than that on molybdenum, both for the initial stage of a plating time of 8 or 10s (Fig. 10, 12) and also for its more advanced stage of 40s (Fig. 11, 12). Alternatively, there may be a delay in the initiation of plating. On the basis of the determined average rate of the nickel deposition ($1.8 \times 10^{-3} \mu\text{m} \cdot \text{s}^{-1}$), it can be estimated that after 10s of plating, the average thickness of the deposit was about 50 lattice parameters of nickel. This might lead to supposition that the effect of a substrate should disappear at about this thickness of nickel deposits. However, the deposits obviously were not continuous (note stripes in Fig. 11).

Discussion

These microscopic investigations have shown that electroless deposition of nickel on molybdenum around palladium spots proceeds simultaneously with and independently of the deposition on the palladium spots. Growth by coalescence of the deposits on palladium spots was not observed. The growth of nickel deposits on the molybdenum surface indicates that the catalytic activity of palladium spots is not restricted only to the spots themselves, but it is also transmitted to other noncatalytic areas of a metal substrate. It is suggested that this transmission occurs by an electrochemical effect of palladium, involving catalytic electro-oxidation of H_2PO_2^- with a resultant potential shift to negative direction and an accompanying electrolytic deposition of nickel.

As shown in the voltammetric curves (Fig. 3-5), hypophosphite undergoes electro-oxidation on palladium in the entire range of open-circuit potentials on the substrates examined. In the plating solution, this leads to a potential shift to -0.87V (Fig. 1, 2). If this potential shift occurs on molybdenum, then at about -0.78V nickel will start to deposit electrolytically and electro-oxidation of hypophosphite will follow on the deposited

nickel. This is apparent from Fig. 3, which shows a positive current of electro-oxidation of hypophosphite in the plating solution. Evidently, this is a consequence of the preceding nickel deposition on molybdenum. Growth of electroless nickel deposits on molybdenum around palladium islands can be regarded as a result of electrolytic deposition of nickel, which is a good catalyst for electroless plating. The electrolytic deposition of nickel under open-circuit conditions occurs during the spontaneous potential shift, when the potential falls below about -0.78V . This potential shift results from electro-oxidation of hypophosphite, which in turn is initiated by palladium areas. Electroless nickel deposition on molybdenum surfaces thus are a result of a secondary electrochemical effect of palladium, which provides nonactive molybdenum with a thin layer of active nickel.

Similarly, a preliminary deposition of nickel during the spontaneous potential shift also occurs on palladium. This suggestion is supported by the voltammograms in Fig. 4 and Fig. 5, which show that the anodic current of electro-oxidation of hypophosphite in the solution with Ni^{2+} ions increases with the decreasing potential (below about -0.75V) and reaches a maximum; whereas in the absence of Ni^{2+} ions, the current steadily decreases. The increase of the current in the solution with Ni^{2+} ions can be explained by electrolytic deposition of some amounts of nickel, which causes an enhancement of the catalytic activity of the palladium substrate.

Preliminary deposition of small amounts of nickel results in a discontinuous and porous layer constituting a heterogeneous surface of nickel and palladium. Thus, the enhancement of the catalytic activity of palladium occurred when both metals, palladium and nickel, were simultaneously present on the surface. This suggests a synergistic relationship between these two metals. This synergistic effect can also be observed for palladium with molybdenum. The voltammograms in Fig. 4 show that the anodic current of electro-oxidation of hypophosphite on palladium-activated molybdenum was higher after a short activation time (10s) than after a longer activation time (30s).

The synergistic effect of palladium and nickel in the electro-oxidation of hypophosphite may be responsible for the observation that the growth of electroless nickel deposits on palladium spots is faster than on the molybdenum surface (Fig. 10-12). If the electroless deposits were continuous and free of pores, the growth should be controlled by the catalytic activity of the deposits only and be the same on the palladium and molybdenum substrates. However, the growth rate does depend on the type of substrate. This can be ascribed to porosity of the deposits and to the effect of the substrate exposed through the pores. Alternatively, the faster growth of the electroless deposits on the palladium spots may be explained in terms of the mechanism proposed originally by Gorbunova and Nikofova (18) involving reduction of Ni^{2+} ions by hydrogen atoms

It is possible that the initiation of nickel deposition on the palladium spots is accelerated through the above reaction, for which an additional source of hydrogen can be hydrogen absorbed in the palladium. Subsequent growth would thus be supported by the co-deposition of both H and Ni. This effect of absorbed hydrogen on the rate of the electroless plating is not straightforward. Cathodic polarization considerably activates the substrates, diminishing the potential arrests at -0.5 and -0.7V (Fig. 1, 2). This could be due in part to absorbed hydrogen and also to the reduction of surface oxides.

On the other hand, there is an indication that hydrogen inhibited electro-oxidation of hypophosphite. This is indicated by the potential arrest on palladium at

about -0.7V (Fig. 1, 2) and the decreasing current of anodic oxidation of hypophosphite (Fig. 4, 5), which coincided with the start of hydrogen evolution at -0.65V (Fig. 4, 5) and its permeation through the metal (Fig. 6). The inhibiting effect of hydrogen may be due to its adsorption on the surface and possibly to the formation of palladium hydride $\beta\text{-PdH}$. Adsorption of hydrogen will be competitive to the adsorption of hypophosphite, and thus will decrease the adsorption and the oxidation rate of the latter. Competitive adsorption of hydrogen was suggested by Sazonova *et al.* (14) as being responsible for a decrease in adsorption of dimethylamine borane on platinum. Hydrogen may also form the hydride $\beta\text{-PdH}$ that can markedly diminish the catalytic activity of palladium (20, 21). It is noteworthy that the anodic current from the oxidation of hypophosphite in the absence of Ni^{2+} ions steadily decreased with potential (Fig. 4, 5), which may be attributed to the increasing amount of hydrogen adsorbed on and by palladium.

The geometrical pattern of discontinuities in the electroless nickel deposits on the palladium surface (Fig. 11) may have many explanations. Generally, it may be associated with high internal stresses and with poor adhesion of the deposits to the substrate. Adhesion of deposits is normally related to the binding and interfacial energies and also to the lattice parameter mismatch between deposit and substrate (22). In considering these factors, it is important to note that the molybdenum substrate is not really a bare metal, but is largely covered with oxides. According to potential-pH diagrams (23), under conditions of electroless nickel plating in the solution examined, an oxide of the MoO_2 type is possible and must be taken into account when adhesion of the electroless nickel deposits to molybdenum is being considered.

Conclusions

Electroless nickel deposition was examined on molybdenum which was activated with palladium by immersion into a PdCl_2/HCl solution. This procedure results in the formation of palladium islands on the molybdenum substrate. In the hypophosphite plating solution, the nickel deposition takes place on the palladium islands and on the molybdenum substrate simultaneously and independently. The deposition on the palladium islands appears to be considerably faster than that on the molybdenum substrate. On the basis of voltammetric measurements it is concluded that the electroless nickel deposition on the molybdenum substrate actually occurs upon a thin layer of nickel, which is electrolytically deposited during a spontaneous potential shift in the cathodic direction. The palladium islands act as catalysts for electro-oxidation of hypophosphite, which in turn causes the potential shift.

Voltammograms indicate that the anodic current associated with oxidation of hypophosphite on palladium is increased when small amounts of molybdenum or nickel are also present on the surface. This suggests that small amounts of one metal can exert a synergistic effect on the catalytic properties of another. This effect explains the observation that the growth of nickel deposits on molybdenum with palladium is more rapid than that on molybdenum alone under the same electrochemical conditions.

Cathodic polarization prior to plating results in substantial activation of the substrates. This activation can be attributed to removal of oxide layers rather than to an effect of absorbed hydrogen on the plating process.

Upon immersion of palladium into the plating solution a potential arrest is observed at about -0.7V . This potential arrest coincides with a decreasing electro-oxidation rate of hypophosphite and with the evolution of hydrogen. This phenomenon may be ascribed both to the competitive adsorption of hydrogen on the palladium surface, which may decrease the adsorption and the oxidation rates of hypophosphite, and to a decrease

in the catalytic activity of palladium, which may be due to the formation of β -PdH.

Cathode Characteristics of Organic Electron Acceptors for Lithium Batteries

Shin-ichi Tobishima, Jun-ichi Yamaki, and Akihiko Yamaji

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki-ken, 319-11, Japan

ABSTRACT

Discharge and charge characteristics of cathode-active materials for lithium batteries were studied. Electron acceptors of charge transfer complex with high electron affinity were examined as cathode-active materials because they were expected to have high cell voltage. These electron acceptors are 2,4,7-trinitro-9-fluorenone (TNF), 2,4,5,7-tetranitro-9-fluorenone, 7,7,8,8-tetracyanoquinodimethane, 9,10-phenanthrenequinone, and 13 other compounds. Among these compounds, TNF showed the highest discharge capacity (1050 A-hr/kg) and the highest energy density (2030 W-hr/kg). Cycle lives of TNF were 400 and 54 times at charge-discharge capacity of 100 of A-hr/kg (1.2 electron transfer per 1 mol TNF) and 200 A-hr/kg (2.4 electron transfer per 1 mol TNF), respectively. The cycle tests indicate reversibility of TNF up to two-electron transfer.

Lithium organic-electrolyte batteries are of great interest as power sources for electronic devices because of their high energy density. Characteristics of lithium batteries, such as discharge capacity, cell voltage, energy density, and rechargeability, are affected by the selection of cathode-active materials. In order to discover the best cathode-active materials, many materials have been examined over the last several years (1-3). Most of those compounds are inorganic compounds. However, N-halogen compounds (4) and pyromellitic dianhydride (5) are organic cathode-active materials. It was reported (6) that, theoretically, organic compounds had much higher electrochemical capacities than inorganic compounds. Furthermore, organic compounds, having high electron affinity, are expected to have high cell voltage.

In this work, 17 organic compounds, which are known as electron acceptors of charge transfer complex, are tested as cathode-active materials for lithium batteries. These electron acceptors were chosen for two reasons. First, many of these compounds have high

electron affinity. Second, there is a possibility that these compounds will react with lithium reversibly, at least for one electron transfer process (7). This could mean that these organic compounds can be used as rechargeable cathode-active materials.

Experimental

2,4,5,7-tetranitro-9-fluorenone and 7,7,8,8-tetracyanoquinodimethane were obtained from Aldrich Chemical Company. Other cathode-active materials were obtained from Tokyo Kasei Company.

A test cell was used to evaluate cathode-active material properties. It had a flat configuration, as shown in Fig. 1. The lithium electrode area was 3.14 cm². The cathode electrode area was 4.91 cm². Current density was calculated using the lithium electrode area. Cathode mixtures were prepared by mixing appropriate amounts of the active materials and acetylene black, obtained from Denkikagaku Kogyo Company. A carbon felt sheet (Nippon Carbon Company) was used to prevent direct reaction between the cathode-active

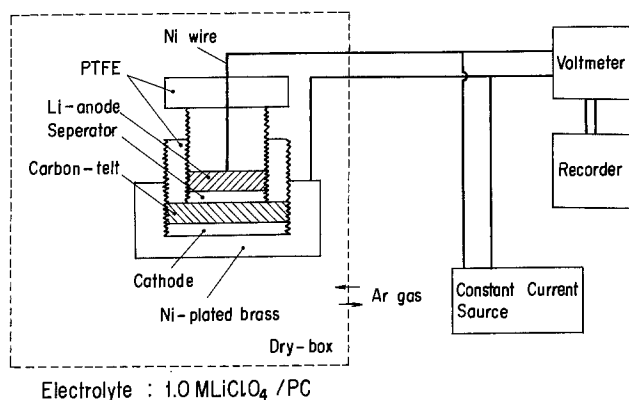

Fig. 1. Test cell configuration and measuring system

material and lithium metal. The electrolyte used was 1 or 1.25M LiClO_4 (Kanto Chemicals Company) solution in propylene carbonate (Tokyo Kasei Company). Water content was less than 200 ppm (Karl Fischer method). Porous polypropylene sheet (Polyplastic Company) was used as the separator. Lithium disk anodes were prepared by pressing in lithium wires (Merck Company). All cells were constructed and tested in a dry box filled with argon gas.

Results and Discussion

Discharge characteristics of organic electron acceptors coupled with lithium.—Organic electron acceptors used in this work are 2,4,7-trinitro-9-fluorenone (TNF), 7,7,8,8-tetracyanoquinodimethane (TCNQ), 9,10-phenanthrenequinone (PQ), 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ), and 13 other compounds, many of which are aromatic compounds. Figure 2 shows the chemical structure of TNF, PQ, TCNQ, and DDQ.

Lithium cells were discharged at a constant current of 1 mA (0.32 mA/cm^2). Figure 3 shows the relation between electron affinity (8) of organic electron acceptors used and the corresponding cell voltage measured at the initial flat part of discharge curves. Cell voltage was found to have the tendency to increase with increases in electron affinity.

Figure 4 shows discharge curves of TNF and 2,4,5,7-tetranitro-9-fluorenone (TENF). Figure 5 shows discharge curves of TCNQ, PQ, fluorenone, and fluorene. Most of the discharge curves showed two flat parts,

Fig. 2. Chemical structure of a: TNF; b: TCNQ; c: PQ; and d: DDQ.

Fig. 3. Fig. 4. Discharge curves of TNF and TENF at 1 mA

Fig. 5. Discharge curves of TCNQ, PQ, MAH, fluorenone, and fluorene at 1 mA.

which were followed by a gradually decreasing part. In cases of TNF and TENF, two flat parts were not clearly observed because the difference between voltages in the first part and in the second part was small (about 0.24V). The discharge capacity of the first part was a little higher than that of the second part. The discharge capacity of each part was nearly equal to that calculated on the basis of one electron transfer. It has been reported (9, 10, 11) that π -conjugated organic compounds are generally reduced through stepwise two-electron transfer in nonaqueous media.

Cathode mixture: active material 0.05g; AB 0.05g.

^a Values were based only on the cathode-active material weight and up to 1V.

^b Values were based on one-electron transfer per cathode 1 mol.

^c Values were based on two-electron transfer per cathode 1 mol.

^d Cathode mixture: TENF 0.03g; AB 0.1 g.

TNF: 2,4,7-trinitro-9-fluorenone; TENF: 2,4,5,7-tetranitro-9-fluorenone;

PQ: 9,10-phenanthrenequinone; TCNQ: 7,7,8,8-tetracyanoquinodimethane; MAH: maleic anhydride;

PDA: pyromellitic dianhydride; m-DNB: m-dinitrobenzene; TCNE: tetracyanoethylene;

DDQ: 2,3-dichloro-5,6-dicyanobenzoquinone.

These facts indicate that the cathode reactions, corresponding to the first and second plateau, are the production of radical anion and dianion, respectively. Details of the third reaction mechanism are not clear, but the reaction may be the opening of benzene rings and/or reaction of various functional groups, such as —CN, —NO₂, —Cl, and —Br, with lithium.

Table I summarizes the discharge characteristics of various organic electron acceptors used in these cells. Discharge capacity and energy density were calculated only on the basis of cathode materials. TNF showed the highest discharge capacity (1050 A-hr/kg) and the highest energy density (2030 W-hr/kg). TENF showed a 810 A-hr/kg discharge capacity and a 1590 W-hr/kg energy density.

From the discharge test results, it was found that TNF, TCNQ, and PQ showed high cell voltage, as well as high energy density. Other compounds, such as DDQ, bromanil, and chloranil, showed rather low energy density (see Table I). In the next section, more detailed cathode characteristics of TNF, TCNQ, and PQ are discussed.

2,4,7-trinitro-9-fluorenone (TNF; *m/o* 315.21; C₁₃H₅N₃O₇).—As mentioned earlier, TNF showed the highest discharge capacity (1050 A-hr/kg up to 1V at constant current of 1 mA). This value corresponded to about 12 Li mols per 1 mol TNF. The reason for this reaction mechanism is not perfectly clear, but one possible explanation is mentioned below. The initial TNF reaction seems to be the stepwise formation of radical anion and dianion, according to Eq. [1] and

[2]. This explanation is supported by the literature on cyclic voltammetry of TNF (11) and the reduction of aromatic nitro compounds (ArNO₂) in nonaqueous media (9, 12).

Although what further reduction mechanisms there might be is not clear, nitro function in the dianion seems to react electrochemically with lithium. The reduction of the dianion is supposed to occur, according to Eq. [3], as is the formation of nitroso function. This reaction is analogous to the reaction between aromatic nitro compounds and C₆H₅Li (12).

Assuming Eq. [1], [2], and [3], eight-electron transfer per mol TNF is possible. As a further reduced prod-

uct, $\text{Ar} >\text{NLi}$ and/or $\text{Ar} >\text{NOLi}$ is possible (12).

Discharge-capacity dependence on the acetylene black (AB) contents in cathode mixtures was measured galvanostatically at 1 mA for each cell, where AB contents varied from 0% to 91%. AB compositions and their effect on the discharge characteristics of TNF are summarized in Table II. Capacity and energy density increased with increasing AB contents and

Fig. 6. Discharge capacity dependence on current density, 1V cutoff, TNF/Li cell.

saturated at a maximum value near 1000 A-hr/kg and 200 W-hr/kg.

Since discharge capacity also depends on discharge-current density, the effect of current density on the discharge capacity of TNF was studied. A cathode mixture was made of 0.05g TNF and 0.05g AB. Results are shown in Fig. 6. Discharge capacity increased with decreasing discharge current and it attained a maximum value of about 1000 A-hr/kg at a current density of 1 mA/cm². These two experiments suggest that 100% discharge capacity for the TNF cathode is about 1000 A-hr/kg.

To examine the possibility of cycling TNF cathode material, a cycling test of TNF coupled with lithium was carried out at various charge-discharge capacities (from 50 A-hr/kg to 550 A-hr/kg). The results for charge-discharge capacity of 50 A-hr/kg are shown in Fig. 7. This value corresponded to 0.59 Li mols per 1 mol TNF. The numbers shown in Fig. 7 are cycle number. Cells were tested up to 700 times.

The charge-discharge test of the blank test cell, with a cathode containing only AB, was performed under the same conditions as in the TNF cell test. The charge-discharge capacity was 100 A-hr/kg and the current density was 0.32 mA/cm². The relationship between the minimum or maximum charge voltage and cycle number, together with the blank results, are summarized, in Fig. 8 and Fig. 9. Curves "a" and "b" in Fig. 8 show minimum discharge voltages of the TNF cell and the blank cell, respectively. Curves "a" and "b" in Fig. 9 show maximum TNF cell voltages and the blank cell, respectively. Minimum TNF cell voltage was 2.5V at the first cycle and becomes lower with increasing of cycle numbers. However, its value was 1.8V even at the 100th cycle. In cases of the blank test (curve "b" in Fig. 8), minimum voltage is about 1.2V from the first to the 35th cycle. Maximum charge voltage of the TNF cell (curve "a" in Fig. 9) shows a relatively constant value of 3.7V from the first to the 100th cycle. However, in the blank cell (curve "b" in Fig. 9), its value is more than 10V at the 45th cycle. From these results, it can be concluded that the TNF cathode reacts with lithium reversibly.

Table III summarizes the cycling test condition and the TNF cathode cycle life. Cycle life was expressed as a cycle number where discharge voltage was higher than 1V. Cycle numbers for 50 A-hr/kg and 100 A-hr/kg discharge capacities were 691 times and 400 times, respectively. However, in the case of 200 A-hr/kg, cycle number was 54 times. In case of more than 200 A-hr/kg, cycle life was rather low. Table III also indicates that TNF rechargeability becomes poor by reacting with three mols of lithium per one mol TNF.

The rechargeability of TNF coupled with lithium was observed for up to two lithium reactions for 1 mol TNF. This fact agrees with the results of cyclic voltammetry of TNF in nonaqueous solutions (11), which show the formation of reversible TNF dianion.

7,7,8,8-tetracyanoquinodimethane (TCNQ; *m/o* 204.19; C₁₂H₄N₄).—As mentioned earlier, the TCNQ cell

^b Cycle number, where discharge voltage is higher than 1V.

showed a discharge capacity of 300 A-hr/kg up to 1V. This value corresponds to 2.3 mol of Li per 1 mol TCNQ. The suspicion that there is a cathode reaction is supported by stepwise formation of the radical anion

(TCNQ⁻) and dianion (TCNQ²⁻), for the reasons mentioned below. TCNQ is known to react with at least 1 mol of Li per 1 mol TCNQ by the reaction involving n-C₄H₉Li (13). TCNQ⁻ (14) and TCNQ²⁻ (15) are reported as the reduction products of TCNQ. Polarographic results of TCNQ in nonaqueous solution (15), show two-step reduction mechanism. Cell voltages calculated from half-wave potential are about 3.2 and 2.7V, respectively. This fact agrees with the TCNQ discharge test result; i.e., the discharge curve showed two flat parts and decreasing third part, and cell voltage was 3.1V at the first flat part and 2.6V at the second flat part. Discharge capacity at the first flat part and the second flat part is near that calculated based on one-electron transfer at each flat part of discharge (0.89 e⁻ at the first and 0.79 e⁻ at the second).

In sum, the initial reaction seems to be the formation TCNQ⁻ and TCNQ²⁻. The third reaction mecha-

Fig. 10. Charge-discharge curves of TCNQ/Li cell at 200 A-hr/kg depth

nism is not clear, but the formation of LiCN may occur, because cell voltage at the third part of discharge is higher than that of the cathodic reaction of propylene carbonate with lithium (this value is reported as about 0.6V vs. Li (16)) or that of AB. Therefore, it was expected that TCNQ could be cycled up to two-electron transfer. A cycle test on TCNQ was carried out at 200 A-hr/kg charge-discharge capacity, which corresponds to 1.8 mols Li per 1 mol TCNQ.

Figure 10 shows the TCNQ cell charge-discharge curves. At the first cycle, both discharge and charge curves showed only two flat parts. With increasing cycle numbers, the discharge curve showed two flat parts and a third part, but the charge curve did not show a distinct third part. With increasing cycle numbers, utilization decreased at the first and the second flat parts, based on two-electron transfer. Utilizations of the first cycle, second cycle, third cycle, and fourth cycle were 1.58, 1.35, 1.16, and 1.02 e^- , respectively. The cycle number was 4, where discharge voltage was higher than 1V. So, the cathode reaction at the third part of the discharge is probably irreversible. One possible explanation for this fact is that third electrochemical reaction included the formation of insoluble and irreversible LiCN.

9,10-phenanthrenequinone (PQ; m/o 208.22; C₁₄H₈O₂).—As mentioned earlier, the PQ cell showed 310 A-hr/kg discharge capacity up to 1V. This value corresponded to 2.4 mol Li per 1 mol PQ, when the AB/PQ weight ratio was 1. We feel the cathode reaction is a

stepwise formation of $PQ^{\cdot-}$ and PQ^{2-} for the reasons mentioned below. Quinones are known to be reduced stepwisely by a two-electron transfer process (17). Radical anion and dianion are reported to be reduction products (17, 18). Polarographic results of PQ in nonaqueous solution (19) show a two-step reduction mechanism. Cell voltages, calculated from half-wave potential, are about 2.8 and 2.3V, respectively. This agrees with the discharge test results; i.e., the discharge curve showed two flat parts and a decreasing third part. Cell voltage is 2.7V at the first flat part and 2.2V at the second flat part of the discharge. The discharge capacity at the first and the second flat parts of discharge is near that calculated from one-electron transfer at each part (0.88 e^- at the first and 0.84 e^- at the second).

The initial PQ cathode reaction seems to be the formation of $PQ^{\cdot-}$ and PQ^{2-} . The third reaction mechanism is not clear, but the Li₂O formation may occur for the reasons mentioned in the TCNQ section.

The discharge capacity dependence on AB contents was measured galvanostatically at 1 mA. Results are shown in Fig. 11. Discharge capacity and energy density, based on PQ weight, increased with increasing AB contents and saturated to maximum values near 350 A-hr/kg and 750 W-hr/kg, respectively. From the results, it is found that the addition of 50 w/o or more than AB to PQ is necessary to achieve a good cathode efficiency.

Cycle tests of PQ were carried out at 200 A-hr/kg, which corresponded to 1.6 mols Li per 1 mol PQ. Figure 12 shows the result. The cycle number, where discharge voltage was higher than 1V, was only 2. The discharge voltage at the 5th cycle was 0.8V. The discharge curves showed two flat parts and a third part with increasing cycle numbers, but the charge curves did not show a distinct third part. This fact may be attributed to the formation of irreversible and insoluble Li₂O, as mentioned previously.

Conclusion

Cathode characteristics of organic electron acceptors for lithium batteries were examined. Based on the results, the following conclusions were reached.

1. Cell voltage is proportionally increased with increasing electron affinity of organic electron acceptors.

Fig. 11. Discharge capacity dependence of Li/PQ cell on AB contents, 1V cutoff.

Fig. 12. Charge-discharge curves of PQ/Li cell at 200 A-hr/kg depth

DDQ, TCNQ, bromanil, chloranil, and TNF show high cell voltage values of 3.4, 3.1, 3.0, 2.9, and 2.6V, respectively.

2. TNF shows the highest discharge capacity (1050 A-hr/kg) and the highest energy density (2030 W-hr/kg) of the materials examined for this work. TENF and PQ show energy density values of 1580 W-hr/kg and 710 W-hr/kg, respectively. However, the discharge capacities of DDQ, bromanil, and chloranil are rather low.

3. TNF rechargeability is good up to a capacity of two-electron transfer per 1 mol TNF. The cycle life of TNF at 100 A-hr/kg is 400 times and that at 50 A-hr/kg is about 700 times.

For lithium secondary batteries, TNF is a promising cathode-active material.

ABSTRACT

An electrochemical cell using a K₂CO₃ solid electrolyte has been employed as a gas probe to measure the equilibrium partial pressure of carbon dioxide in CO₂/synthetic air mixtures at 1 atm total pressure in the temperature range of 575-1025 K. Stable reversible emf's have been obtained in gas mixtures containing as little as 9 ppm CO₂ in air. The carbonate cell has also been used to measure the standard Gibbs energy change associated with the dissociation of calcium carbonate into calcium oxide and carbon dioxide in the temperature range of 725-975 K. The thermodynamic results are in good agreement with the published data from the literature, thus validating the use of K₂CO₃ as a CO₂ probe.

The use of solid-state galvanic cells as experimental tools for measuring thermodynamic properties of materials and gases is well established. One general category of solid electrolytes that has recently received attention in our laboratories is represented by the chemical formula A_nBX_m. Our efforts have been mainly devoted to the behavior of alkali sulfates in sulfur/oxygen atmospheres (1-3). For example, K₂SO₄, though entirely cation conducting, has been successfully employed as a solid electrolyte in measurements of the equilibrium partial pressures of SO₂ (and SO₃) in SO₂/O₂ gas mixtures in the temperature range of 873-1173 K. Stable reversible emf's have been obtained in SO₂/air gas mixtures containing as little as 0.1 ppm SO₂. K₂SO₄ has also been used to measure metal oxide-

sulfate thermodynamic equilibria in the Ni-NiSO₄, MgO-MgSO₄, and Mn₂O₃-MnSO₄ systems (4).

By comparison, the use of K₂CO₃ as a solid electrolyte for measuring the equilibrium partial pressure of CO₂ in gases has received little attention. Except for preliminary measurements obtained at 1000 K that have been included in a former publication (1) and in an internal report at IREQ (5), no systematic work has been published on the K₂CO₃(s)/CO₂(g), O₂(g), Pt electrode. The previously published results have shown that the following cell could be used at 1000 K to measure the equilibrium partial pressure of CO₂ in air

(working) (reference)

In the present investigation, this design was modified and the following cell used

* Electrochemical Society Active Member.

Key words: electrochemical cell, potassium carbonate, calcium carbonate, decomposition, carbon dioxide, probe, thermodynamics.

Fig. 1. Schematic representation of the K_2CO_3 concentration cell used in the present investigation

The Ag^+/Ag reference was replaced by a controlled CO_2/O_2 gas mixture, since the latter enables the partial pressure of CO_2 to be defined at different values. Also, Au electrodes were used, since it was observed that Pt tends to react with the K_2CO_3 solid electrolyte at high temperatures.

By analogy with the mechanism proposed by Salzano and Newman (6) for half-cells of the type Pt, SO_2 , O_2/SO_4^{2-} , it is assumed that the following reactions take place at each electrode

which lead to the overall electrode reaction

Therefore, the Nernst equation for the electromotive force of the carbonate cell is

$$E = \frac{RT}{2F} \ln \frac{P_{CO_2} P_{O_2}^{1/2}}{P'_{CO_2} P'_{O_2}^{1/2}} \quad [6]$$

By defining P'_{O_2} and P'_{CO_2} at the reference electrode, it is possible to deduce the value of P_{CO_2} at the working electrode from measurements of the cell emf if P_{O_2} is also known.

If the oxygen potential at both electrodes is that of air, i.e., $P_{O_2} = P'_{O_2} = 0.21$ atm, then Eq. [6] simplifies to

$$E = \frac{RT}{2F} \ln \frac{P_{CO_2}}{P'_{CO_2}} \quad [7]$$

For the case where P_{CO_2} at the working electrode is the product of dissociation of calcium carbonate, the following chemical reaction takes place in this electrode compartment

If the activities of CaO and $CaCO_3$ are unity, the standard Gibbs energy change of Eq. [8] is given by

$$\Delta G^\circ = -RT \ln P_{CO_2} \quad [9]$$

Hence, the emf measurements can be used to deduce the standard Gibbs energy change of $CaCO_3$ decomposition if the value of P_{O_2} at the working electrode is also known.

Experimental

The carbonate electrochemical cell used in the present investigation is schematically illustrated in Fig. 1. The cell design is similar to that described in an earlier publication on sulfate concentration cells (4). The cell contained two gas circulating electrodes and one metal oxide-carbonate-gas electrode. The emf given by Eq. [7] was measured between any two of the electrodes.

The 99.96% purity K_2CO_3 (see Table I) solid electrolyte pellet (1 cm diam \times 0.5 cm thick) was prepared by pressing K_2CO_3 powder at 4000 kg/cm² and then sintering at 1025 K for a period of 48 hr. Since K_2CO_3 is hygroscopic, precautions were taken to ensure that the humidity levels were kept at a minimum.

The gas circulating electrodes were CO_2 /air mixtures (9–12,000 ppm CO_2) flowing at controlled rates (40–500 ml/min measured at 298 K) over Au gauzes in contact with the electrolyte surface. The large gold-electrolyte contact surface promoted the electrode equilibria. In the case of CO_2 /air mixtures greater than 1000 ppm CO_2 , the mixtures were prepared by injecting an appropriate quantity of pure CO_2 measured with a gas syringe into plastic 10 liter Mylar bags already filled with synthetic air. The precision of the value of P_{CO_2} in the preparation of these mixtures was about 3%. Commercially analyzed gas mixtures stored in cylinders were used for CO_2 levels of less than 1000 ppm. For these cases the precision of the values of P_{CO_2} was of the order of 1%.

The calcium carbonate-oxide-gas electrode consisted of a 1 ml alumina crucible initially containing pure calcium carbonate (calcite) powder (see Table I). In order to prevent any reaction between the calcium and potassium carbonates, it was important to avoid physical contact between the powder and the electrolyte. An Au gauze connected to an Au wire was used as the electrode. The gold served to separate the

Table I. Principal impurities in K_2CO_3 and $CaCO_3$

powder mixture from the electrolyte as well as promote the electrode equilibria. The alumina crucible had a small hole (1 mm diam) in its wall and was exposed to air on the outside of the crucible. The hole was small enough so that only small amounts of CO₂ diffused out of the crucible, and the partial pressure of CO₂ inside was fixed by the calcium carbonate dissociation given by Eq. [9]. The hole was large enough to enable the air to slowly diffuse into the chamber so that when P_{CO₂} was small, the equilibrium partial pressure of O₂ was effectively 0.21 atm. A similar design has been successfully employed in the study of metal sulfate/oxide equilibria (4).

At high temperatures K₂CO₃ becomes ductile. A slight pressure applied to the housing (Fig. 1) caused a slight deformation of the pellet which resulted in gastight electrode compartments. In the case of the gas circulating electrodes, the seals were tested by connecting each compartment to a mercury manometer and changing the total pressure by 10 cm of mercury. The compartment was considered gastight if the meniscus in the manometer remained stable for at least 30 min.

The cell temperature was maintained at ± 1 K by use of a 45 cm horizontal Lindberg 940W furnace. The temperature was measured by two previously calibrated Chromel-Alumel-type K thermocouples placed on both sides of the electrolyte pellet, as shown in Fig. 1. The thermocouple emf signals were measured by a Keithley Model 191 multivoltmeter and showed the cell to be isothermal. The precision of the temperature measurements was estimated to be 1 K. All cell emf signals between the two circulating gas electrodes or between the circulating gas reference electrode and the carbonate-oxide-gas electrode were measured by a Tacussel Aries 20,000 high impedance (10¹⁴Ω) multivoltmeter. The thermocouple and cell emf's were also recorded on a two-pen SEFRAM chart recorder.

Results and Discussion

At the reference electrode, the equilibrium partial pressures of oxygen, carbon dioxide, and the other gaseous species at 1 atm total pressure and a fixed temperature can be calculated from the initial composition of the gas mixture prepared at 298 K. The results of the free energy minimization calculation performed at the F*A*C*T thermodynamic data treatment center (7) are shown in Table II, where the equilibrium partial pressures of the principal species have been calculated at 1025 K from an initial gas mixture of P_{CO₂} = 12,000 ppm in air. It is clear from Table II that CO₂, O₂, and N₂ are the prominent stable gaseous species, and that P'_{O₂} effectively remains at 0.21 atm, since the initial concentration of CO₂ is dilute. However, at much higher concentrations of CO₂ and for higher temperatures it is evident that P'_{O₂} would no longer be 0.21 atm. In such cases, the simplified Nernst relation given by Eq. [7] would no longer be valid. Instead, it would then be necessary to measure P'_{O₂} and use this equilibrium value in the expanded Nernst Eq. [6]. This, however, was not necessary in the present study, since P_{CO₂} = 12,000

ppm and T = 1025 K were the maximum concentration and temperature employed.

Circulating gas electrode emf's.—In Fig. 2 are plotted the experimental emf results in the temperature range 525–1025 K for measurements made between the circulating gas electrodes for two series of experiments corresponding to two concentrations of CO₂ in synthetic air at the reference electrode. In the first series, measurements were made with the reference electrode fixed at 1,099 ppm CO₂, and the working electrode varied from 90.9 to 12,000 ppm CO₂. In the second series, the reference electrode was 948 ppm CO₂, and the working electrode 9.1 ppm CO₂. Measurements were made after increasing or decreasing temperatures as shown, and in all cases the flow rate of the gas in each electrode was 200 ml/min (measured at 298 K) at a total pressure of 1.0 atm. During the course of the experiments the solid electrolyte pellet was often examined and replaced. No discoloration or contamination of the pellet was ever detected.

The solid lines in Fig. 2 correspond to the theoretical values obtained from the simplified Nernst relationship of Eq. [7]. The agreement between the theoretical and measured values is good, except for the case where the concentration of CO₂ is 9.1 ppm. The theoretical values are also compared in Table III with the linear expression of emf as a function of T obtained from a least square regression analysis of the results. EMF data are often extrapolated down to 0 K in order to determine enthalpy values. The nonzero values of "a" in Table III calculated from the experimental data illustrate the weakness of such extrapolations.

In Fig. 3 are plotted, at selected temperatures, the measured emf (obtained from the regression analysis of Table III) as a function of P_{CO₂} for the case of 1099 ppm CO₂ at the reference electrode. The solid lines in this figure correspond to the theoretical values of Eq. [7].

From Fig. 2-3 and Table III it can be seen that in most cases there is good agreement between the measured and theoretical values, particularly when the concentrations of CO₂ at the two electrodes are similar. During the course of the experiments the electrodes were often short-circuited for several seconds, and the time required to return to a stable emf was recorded. It was noted that the response time for stable emf's varied from less than 1 sec to several minutes, depending upon the cell temperature and

2,000	1099	-3.23	0.029	0.64	0	0.026
3,500	1099	-4.54	0.057	0.47	0	0.050
5,500	1099	7.21	0.060	0.55	0	0.069
8,500	1099	14.87	0.071	0.50	0	0.088
12,000	1099	7.39	0.095	1.06	0	0.103

concentration of CO₂ at the working electrode. The response time was longest at low temperatures and/or low concentrations of CO₂. The results were rejected in those cases where the emf did not return to its previous value or when stable values were difficult to obtain. For the case where the concentration of CO₂ at the working electrode was 9.1 ppm, it became increasingly difficult to obtain stable values at the lower temperatures. It was impossible to obtain a stable emf below 575 K even after 1 hr regardless of the concentration of CO₂.

Although the upper temperature limit was set at 1025 K, there appears to be no reason why reversible emf's could not be obtained up to the melting point of K₂CO₃ (1174 K). However, the electrolyte pellet may become too soft to support the cell housing (Fig. 1) at such temperatures.

In Fig. 4 are plotted the measurements of the emf at 923 K as a function of flow rate of gas (measured at 298 K) in the working electrode. The concentrations of CO₂ were fixed at 2000 and 1099 ppm in the working and reference electrodes, respectively. The flow rate in the reference electrode was maintained at 200 ml/min. It was found that the measured emf was independent of flow rate in the range 100-400 ml/min. Using the same temperature and gas mixtures, and a flow rate of 200 ml/min in both circulating electrodes, an experimental run which lasted 40 days was carried out. At all times the difference between the measured and the theoretical emf (23.80 mV) was never greater than 1.5 mV. This confirmed the stability of the Au supporting electrodes.

Decomposition of CaCO₃.—In Fig. 5 are plotted 31 emf measurements made between the calcium carbonate-oxide-gas electrode and the circulating gas reference electrode containing a concentration of 1050 ppm CO₂ in air flowing at 200 ml/min through the gas compartment. Measurements were made after both

increasing and decreasing temperatures. Figure 5 summarizes the results of four different experimental runs using different samples of K₂CO₃ electrolyte and CaCO₃ powder. Examination of the cell at the end of each run showed that the electrolyte remained uncontaminated and that the calcium carbonate had not completely dissociated.

Stable emf's were obtained in the temperature range 725-975 K. Measurements made outside this range were rejected. At temperatures much higher than 975 K, the dissociation partial pressure of CO₂ becomes so large that the partial pressure of O₂ defined by air diffusing into the crucible can no longer be approximated at 0.21 atm, and so Eq. [7] is no longer valid. At 725 K, the dissociation partial pressure of CO₂ is approximately 10⁻⁵ atm; below this temperature it becomes too small to be measured. This is the same limit of CO₂ detection that was observed using the synthetic CO₂/air mixtures described previously.

Assuming a temperature independent enthalpy and entropy of dissociation of calcium carbonate, a linear least squares regression analysis of the measurements leads to the following expression for the temperature dependence of the standard Gibbs energy change of Eq. [9]

$$\Delta G^\circ = 169.55 - 0.1443 T \text{ kJ } (T = 725-975 \text{ K}) \quad [10]$$

(standard deviation = 0.41 kJ)

Fig. 6. Comparison of the data for the standard Gibbs energy change of the reaction; $\text{CaCO}_3(\text{s}) = \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$.

This computed free-energy expression is compared with the data published in the literature in Fig. 6 and in Table IV. The results are in very good agreement with the data of Hill and Winter (8), who measured the total pressure of dissociation in the same temperature range as the present study. The difference between the results of the present study and the data of Hills (9) and Baker (10), which were obtained at higher temperatures, can be attributed to the effect of the small temperature dependence of the enthalpy and entropy of the reaction.

Error analysis.—There are several factors which can cause errors in the measured P_{CO_2} . As well as errors in preparing the reference gas mixture and measuring the cell temperature and emf, errors can be created by impurities in the gas mixtures.

Theoretical calculations using the F*A*C*T thermodynamic data treatment center (7), show that trace impurities of SO₂ and Cl₂ and even H₂O can have catastrophic effects upon the K₂CO₃ electrolyte due to the formation of K₂SO₄, KCl, and KOH.

Stable emf's are most difficult to obtain at low concentrations of CO₂ and low temperatures, particularly when there is a large difference in CO₂ concentration (and hence large emf) between the two electrode compartments.

The error in the measured concentration of CO₂ with respect to the error in the measured emf (ΔE), at a given temperature can be derived from Eq. [7] and is given by

$$\% \text{ error} = \left(1 - \exp \left[\frac{2F\Delta E}{RT} \right] \right) \times 100 \quad [11]$$

Table IV. Comparison of thermodynamic data for the reaction*

Source	ΔH° (kJ)	ΔS° (J/K)	Temp (K)
Hill and Winter (8)	168.41	143.9	722-1177
Baker (10)	161.34	137.2	1175-1483
Hills (9)	163.64	138.5	973-1173
Present study	169.55	144.3	725-975

* Reaction: $\text{CaCO}_3(\text{s}) = \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$.

In the case of the results of the circulating gas electrode, assuming a precision of 1.5 mV in the measured emf's for concentrations of CO₂ > 100 ppm, it follows from Eq. [11] that at 873 K there will be a maximum error of 3.9% in the measured P_{CO_2} at these concentrations. This error decreases with increasing temperature.

With respect to the measurements of the CaCO₃ decomposition, if we assume an error of ± 1 K in the value of the temperature, and an improbable error of 2 mV in the measured emf, it follows from Eq. [7] that overall precision in the measured Gibbs energy will be in the order of 500J. This value compares favorably with the experimental standard deviation of 0.41 kJ.

Summary

The equilibrium partial pressure of carbon dioxide in CO₂/synthetic air mixtures has been successfully measured by an electrochemical concentration cell using K₂CO₃ as a solid electrolyte in the temperature range 575-1025 K. Reversible emf's were obtained for mixtures containing as little as 9 ppm CO₂ in air. The cell response was less than 1 sec at high concentrations of CO₂ at high temperatures. An error analysis indicated a precision of 3-4% of the value of CO₂ for concentrations above approximately 100 ppm CO₂. The cell was used to measure the thermodynamic properties of calcium carbonate dissociation in the temperature range 725-975 K. By a least squares analysis applied to the results, the following free energy expression was calculated

$$\Delta G^\circ = 169.55 - 0.1443T \text{ kJ} \quad (T = 725-975 \text{ K}) \quad [10]$$

with a standard deviation = 0.41 kJ. An error analysis indicated a precision of 500J. The measured change in Gibbs energy is in good agreement with the published data from the literature, thus validating the use of K₂CO₃ as a CO₂ probe.

Determination of Activity Coefficients for KCl at Elevated Temperatures

W. F. Bogaerts* and A. A. Van Haute

Leuven University (K. U. Leuven), Institute for Industrial Chemistry de Croylaan 2, B-3030 Leuven (Heverlee), Belgium

ABSTRACT

A real breakthrough in high temperature-high pressure electrochemical measurements will depend on the availability of precision reference electrode systems, which in turn require an accurate knowledge of activity coefficients of the reference electrolyte solution. The paper summarizes available literature and evaluates different approximating equations. It also derives a new calculation method, which is applied on KCl electrolytes and which seems to provide very accurate results for activity coefficients at temperatures up to 300°C. Reliable data have been derived for KCl concentrations up to about 4 molal.

The Ag/AgCl/KCl reference electrode system is frequently used in high temperature-high pressure electrochemical measurements. In order to calculate the Nernstian response of the system as a function of temperature, activity coefficients at each temperature must be known. Unfortunately, literature data on high temperature activity coefficients are rather scarce, particularly on KCl electrolytes.

An array of useful experimental results for simple aqueous solutions at elevated temperatures is listed in Table I (γ_{\pm} : mean molal ionic activity coefficient; ϕ : molal osmotic coefficient).

As can be seen in Table I, a complete set of activity data for NaCl is readily available for temperatures up to 300°C (8, 9, 11-13). Data for the KCl-H₂O system, however, are not, except for some recently published, isolated data in the 200°-250°C range (40). In spite of the general observation that the individual ionic character of the different alkali metal halides (and probably most 1:1 electrolytes) is much less pronounced at high temperatures (14, 15), there is a considerable difference between the activity coefficients for NaCl and KCl at room temperature (e.g., for 1m NaCl and KCl at 25°C, $\gamma_{\pm} = 0.657$ and 0.604, respectively). This indicates that the NaCl data cannot be directly applied to the KCl system over the whole temperature range, as has been done in some earlier electrochemical investigations at moderately high temperatures.

Existing Equations

Different ways have been suggested in the literature to derive approximate KCl activity coefficients from available data on other systems or from values at lower temperatures.

Based on lower temperature observations, Danielson (23) and Seys (24, 25) assumed that $(\partial \ln \gamma_{\pm} / \partial T)_m$ is the same for NaCl and KCl solutions. By combining this expression with the least squares fit cubic function of $\ln \gamma_{\pm}$ vs. T given by Gardner (8) for NaCl solutions, and fitting the equation to the activity coefficient value of 1m KCl at 25°C, Danielson obtained for 1 molal KCl solution

$$\ln \gamma_{\pm}(T) = 2.113 - 0.0213T + [0.5897 \times 10^{-4}]T^2 - [0.568 \times 10^{-7}]T^3 \quad [1]$$

where T is in degrees Kelvin.

Following the same procedure, similar expressions may be derived for other concentrations

$$\begin{aligned} 0.5\text{m KCl: } \ln \gamma_{\pm}(T) &= 2.005 - 0.0196T \\ &+ [0.5325 \times 10^{-4}]T^2 - [0.501 \times 10^{-7}]T^3 \quad [2] \end{aligned}$$

* Electrochemical Society Active Member.
Key words: electrolyte, electrode, emf.

$$\begin{aligned} 2.0\text{ m KCl: } \ln \gamma_{\pm}(T) &= 1.597 - 0.0181T \\ &+ [0.5266 \times 10^{-4}]T^2 - [0.543 \times 10^{-7}]T^3 \quad [3] \end{aligned}$$

$$\begin{aligned} 3.0\text{m KCl: } \ln \gamma_{\pm}(T) &= 0.884 - 0.0127T \\ &+ [0.3999 \times 10^{-4}]T^2 - [0.459 \times 10^{-7}]T^3 \quad [4] \end{aligned}$$

Seys (24, 25) has used a graphic extrapolation method, based on the same principle, for estimating mean ionic activity coefficients of 0.01N-0.1N KCl solutions at elevated temperatures. Although the basic equation of these methods can hardly be assumed to be exact at each temperature, fairly good approximations may be expected at elevated temperatures and rather low concentrations.

Another approximate calculation technique has been derived by Cobble (26)

$$\log \gamma_{\pm}(T) = \log \gamma_{\pm}(25^{\circ}\text{C}) - [I^{1/2}/(1 + I^{1/2})] \cdot [A\gamma^T - A\gamma^{25^{\circ}\text{C}}] \quad [5]$$

which may be obtained by using an extended form of the Debye-Hückel equation (Guggenheim equation)

† Data reported on (NaCl), KCl, LiCl, CsCl, Na₂SO₄, BaCl₂, MgSO₄, and UO₂SO₄.

$$\log \gamma^{\pm} = -A\gamma^T \cdot |z_+ \cdot z_-| \cdot [I^{1/2}/(1 + I^{1/2})] \\ + 2[\nu_+ \cdot \nu_-/\nu] \cdot B_{(m)} \cdot m \quad [6]$$

and assuming that the concentration dependent parameter $B_{(m)}$, which varies from solute to solute, is independent of the temperature. $A\gamma^T$ is given as

$$A\gamma^T = [2\pi N_{APW}/2.303]^{1/2} \cdot [e^2/\epsilon kT]^{3/2} \quad [7]$$

Values of $A\gamma^T$ taken from Cobble (26) and Silvester and Pitzer (36), are given for different temperatures in Table II. These data are preferred over those of Cohen (37) or Dobson (27), since the former are based on a fitting of more literature data.

The assumption that $B_{(m)}$ is independent of temperature has been proven to be incorrect (9, 12, 27), and deviations from the predicted behavior (Eq. [5]) may be expected. The usefulness of the method has been tested by Macdonald (28) for low concentrations of HCl and HBr (0.001, 0.01, and 0.1m). Additional tests for higher concentrations and for NaCl solutions are shown in Fig. 1 and 2.

The differences between calculated and measured activity coefficients are rather small at lower temperatures and/or low concentrations. For the NaCl-H₂O system, Eq. [5] gives values which are too low in the lower temperature range and too high at the higher temperatures (> approximately 250°C). Deviations increase with increasing concentration.

Dobson (27), using a Guggenheim-type expression for $\log \gamma^{\pm}$ with two terms

$$\log \gamma^{\pm} = [-z^2 \cdot A\gamma^T \cdot I^{1/2}/(1 + I^{1/2})] \\ + B \cdot I + C \cdot I^{3/2} \quad [8]$$

and trying to take into account the temperature dependence of these correction terms (cf. B of Eq. [6]), gives the following equation for the mean ionic activity coefficient of KCl

$$\log \gamma^{\pm}(T) = -[A\gamma^T \cdot I^{1/2}/(1 + I^{1/2})] \\ + [-0.134964 + 0.599323 \times 10^{-3} \times T] \cdot I \\ + [0.052002 - 0.20659 \times 10^{-3} \times T] \cdot I^{3/2} \quad [9]$$

An analogous expression is given for HCl

$$\log \gamma^{\pm}(T) = -[A\gamma^T \cdot I^{1/2}/(1 + I^{1/2})] \\ + [0.232448 - 0.2172 \times 10^{-3} \times T] \cdot I \\ + [0.40129 - 0.16861 \times 10^{-3} \times T] \cdot I^{3/2} \quad [10]$$

Equation [9] and [10] were said to represent activity coefficients up to at least 5m and 150°C.

The validity of these equations for estimating activity coefficients at elevated temperatures has been tested in Fig. 1 and Tables III and IV. Up to about 0.1m, Eq. [10]

be some doubt about the usefulness of Eq. [9], especially for temperatures higher than 150°C. This is indicated in Table III and IV. KCl activity coefficients larger than the ones which have been estimated for NaCl are calculated by means of Eq. [9] at the elevated temperatures.

Development of More Reliable Data

Another method, which might provide more reliable results in our case (but which implies the availability of some osmotic data) is similar to the idea suggested by Lindsay *et al.* (14).

Experimental osmotic coefficient data are correlated by a general equation of the form

$$\phi = 1 - DH(\beta, m) + Bm + Cm^2 + \dots \quad [11]$$

which is related through the Gibbs-Duhem relation

$$\phi(T, m) = 1 + \frac{1}{m} \int_0^m m \cdot d \cdot \ln \gamma_{\pm}(T, m) \quad [12a]$$

or

$$\phi(T, m) = 1 + \ln \gamma_{\pm}(T, m) - \frac{1}{m} \int_0^m \ln \gamma_{\pm}(T, m) \cdot dm \quad [12b]$$

to an extended form of Debye-Hückel equation with both a linear and a quadratic correction term

$$\ln \gamma_{\pm} = -[\alpha m^{1/2}/(1 + \beta m^{1/2})] + 2Bm + 1.5Cm^2 \quad [13]$$

The coefficients β (which contains the ion-size parameter), B , and C are adjustable temperature dependent parameters. $DH(\beta, m)$ is the Debye-Hückel term, given by

$$DH(\beta, m) = [\alpha/\beta^3 \cdot m] ([1 + \beta m^{1/2}] - 2 \ln [1 + \beta m^{1/2}] - [1 + \beta m^{1/2}]^{-1}) \quad [14]$$

where α is the Debye-Hückel limiting slope ($\alpha = A\gamma^T \cdot \ln 10$).

Up to 1m, the experimental NaCl osmotic coefficients could best be represented by putting $C = 0$ in Eq. [11] (14)

$$\phi = 1 - DH(\beta, m) + Bm \quad [15]$$

According to Fig. 3, it seems reasonable that the KCl osmotic coefficients can also be described by a similar equation.

Additionally, if the β parameters can be assumed to be equal for NaCl and KCl,¹ then

$$\phi_{\text{NaCl}} - \phi_{\text{KCl}} = [B_{\text{NaCl}} - B_{\text{KCl}}] \cdot m \quad [16]$$

It follows that

¹ This is not unreasonable, since ion size parameters for NaCl and KCl may be expected to be nearly equal (35). A value of $\beta = 1.5$ is typical. Even if the best fitting β_{KCl} is slightly different from β_{NaCl} , we can assume a coefficient β'_{KCl} which is equal to β_{NaCl} . Differences, introduced by using this new β'_{KCl} value, may be cancelled by a modified value for B_{KCl} .

Fig. 3. Temperature dependence of osmotic coefficients of 1m alkali metal chlorides and HCl. Compilation of data from different sources: ● Ref. (15); ○ Ref. (4); ⊙ Ref. (29); ⊚ Ref. (30); ⊠ Ref. (20); ▲ Ref. (31); △ Ref. (16-18); ▼ Ref. (32); ▽ Ref. (33); ■ Ref. (41); □ Ref. (34).

$$\ln [\gamma_{\pm \text{NaCl}} / \gamma_{\pm \text{KCl}}] = 2[B_{\text{NaCl}} - B_{\text{KCl}}] \cdot m \quad [17]$$

Values of ΔB ($\equiv B_{\text{NaCl}} - B_{\text{KCl}}$) may be directly estimated from the plots of ϕ vs. temperature for the 1 molal solutions (Fig. 3). The corresponding values of $(\phi_{\text{NaCl}} - \phi_{\text{KCl}})$, $\gamma_{\pm \text{NaCl}} / \gamma_{\pm \text{KCl}}$, and $\gamma_{\pm \text{KCl}}$ are shown in Table III. Extrapolation errors may be expected to be lower than ca. 1%.

The same procedure can be followed at other concentrations. However, since less osmotic coefficient data are available at these concentrations (Table I), many data must be extrapolated, and the expected accuracy will be smaller.

A test for the accuracy of the method is shown in Table IV. Remarkably good agreement is obtained between the activity coefficients calculated by means of the present method and values and tabulated in standard texts. Extremely close agreement is also obtained with the experimental data of Holmes and Mesmer at 225° and 250°C (40).

It may be concluded that the above method seems to provide very reliable results for calculating high temperature activity data. However, sufficient osmotic data must be available. Up to about 150°C, these may be provided by results of Soldano *et al.* (16-18). At more elevated temperatures, only sporadic results are available (14, 38, 40), and extrapolations and interpolations are necessary. Data obtained from the other equations might provide additional results (cf. Table III).

The final results of the calculations based on Eq. [17] are presented in Fig. 4. Some experimental data points and results obtained by other equations are also shown.

Conclusions

Available activity coefficients for different solutions at elevated temperatures have been summarized in Table I. Sufficient data for KCl solutions, which are of particular interest for high temperature electrochemical measurements, are not present; at least not up to temperatures of about 300°C, which are especially impor-

tant for a number of power generating or cooling systems.

Different ways suggested in the literature for deriving approximate KCl activity coefficients from available data on other electrolytes or from values at lower temperatures have been evaluated. None seems to be completely satisfying, and a new calculation method has been derived. The latter is based on the knowledge of activity data for NaCl and a limited number of osmotic coefficients or KCl solutions at elevated temperatures. Reliable data for KCl activity coefficients have been calculated in this way for temperatures up to 300°C and concentrations up to about 4 molal (Fig. 4). If additional osmotic data for KCl at higher concentrations become available—such as those of Holmes and Mesmer at 225° and 250°C—extensions are easily possible and more precise activity coefficients can be obtained at higher concentrations.

Comparison of data for NaCl and KCl clearly shows that a substitution of KCl activity coefficients by NaCl values, as has been done in most of the earlier electrochemical corrosion studies at elevated temperatures, can lead to imprecise or erroneous conclusions, especially at lower or intermediate temperatures and at moderate or higher solute concentrations.

Anodic Iridium Oxide Films

XPS-Studies of Oxidation State Changes and O₂-Evolution

R. Kötz, H. Neff, and S. Stucki

Brown Boveri Research Center, 5405 Baden, Switzerland

ABSTRACT

The anodic oxidation of iridium and O₂ evolution on iridium oxide films in 1N H₂SO₄ has been investigated using x-ray photoelectron spectroscopy. The binding energy of the O 1s level decreases with anodic polarization of the electrode while the relative amount of oxygen compared to iridium remains constant. The XPS results are consistent with a model of subsequent deprotonation of the anodic iridium oxide upon anodic polarization. A reaction path for O₂ evolution and corrosion on iridium oxide is proposed. Valence band spectra of the oxide surfaces confirm the proposed model.

Iridium oxide films have attracted much attention recently for two reasons. First, these films exhibit high electrocatalytic activity for the anodic oxygen evolution (1, 2). Second, the anodic iridium oxide films show a pronounced electrochromic effect (3).

The electrocatalytic properties of iridium oxide films for the O₂ evolution reaction in acid electrolytes are excellent. They are only exceeded by those of the ruthenium oxide. Both materials, however, suffer from substantial corrosion during O₂ evolution at high current densities. The favored anode catalyst for water electrolysis in acid electrolytes turns out to be a mixed oxide of ruthenium and iridium (4).

In order to gain a further understanding of the O₂ evolution mechanism on the mixed oxides, we have investigated the anodic behavior of the single components. Recently, we proposed a model for the O₂ evolution reaction and corrosion on ruthenium oxides, based mainly on XPS results (5). O₂ evolution and corrosion on ruthenium starts from a surface site with Ru in the hexavalent state. After two consecutive deprotonation steps, oxygen is released from RuO₄.

In the present study, we have applied x-ray photoelectron spectroscopy (XPS) in order to determine changes in the composition of the iridium oxide electrode surface leading to the O₂ evolution reaction. On a metallic iridium electrode, oxygen evolution is preceded by the formation of a thin oxide layer. This was demonstrated by Mozota and Conway using voltammetry (6) and recently in our laboratory with the aid of XPS (7). The thickness of this oxide layer can be increased substantially by periodic potential cycling. Oxide layers grown by potential cycling exhibit an

electrochromic effect, which results from a reversible redox reaction of the iridium in the bulk of the film. Because of the electrochromic effect, which might be useful for display applications, the charge storage mechanism in iridium oxides has been investigated extensively (3, 8-11). McIntyre *et al.* (8) have demonstrated that the electrochromism is due to a cation-insertion mechanism. In an aqueous electrolyte, the charge arising from the oxidation or reduction of the film is compensated by a transfer of protons between the bulk of the film and the electrolyte. The stoichiometry of the transferred proton is either H⁺ or H₃O⁺. It is, however, not clear whether the above mechanism, which has been proved with a mildly surface-insensitive technique (Rutherford backscattering spectroscopy), holds also for the surface of the oxide where O₂ evolution should take place. In addition, it has to be examined whether an analogous mechanism with proton transfer can be formulated for the oxygen evolution reaction.

XPS has been used effectively as a surface-sensitive technique in several studies of electrochemically modified electrode surfaces (12). Although there are still some questions as to what extent the electrochemical interface is preserved upon emersion and transfer to the vacuum chamber, the successful correlation of XPS results and electrochemical parameters demonstrates the usefulness of this *ex situ* method for electrode surface analysis (13).

Experimental

The XPS measurements were performed in a Kratos ES 300 electron spectrometer using non-monochromatized AlK_α radiation. The overall spectral resolution was 1.2 eV, and the measured binding energies were

calibrated against the Au $4f_{7/2}$ line at 84.0 eV. The photoelectrons were detected at normal emission.

The electrochemical experiments were performed in 1N H_2SO_4 using the standard three-electrode potentiostatic arrangement. All potentials are quoted with respect to the saturated calomel electrode (SCE). The anodic iridium oxide films were grown by periodically stepping the potential of a metallic iridium working electrode between $-0.25 V_{SCE}$ and $+1.30 V_{SCE}$ with a step frequency of 1 Hz.

The iridium electrodes were prepared as thin films by rf sputtering from an iridium target (4N) onto glass substrates. Iridium oxide films were also prepared by reactive sputtering of iridium in an Ar atmosphere with an O_2 partial pressure of 10^{-3} Torr (2).

Before any sequence of electrochemical measurements, the iridium samples were Ar ion sputtered until no oxygen or carbon was detectable by XPS. The electrodes were removed from the electrolyte under potential control and immediately transferred to the electron spectrometer using a fast insertion lock.

Results

In Fig. 1, voltammograms are shown for a metallic iridium electrode and an anodic iridium-oxide film obtained by potential cycling. The charge storage capacity of the oxide is clearly reflected by the considerable broadening of the voltammogram above $0.5 V_{SCE}$. At more cathodic potentials, the measured current is comparable to that of the clean metal surface. The wave at $0.7 V_{SCE}$ for the iridium oxide is accompanied by a coloration of the film from clear to dark blue in an anodic potential scan. Similar curves have been measured and discussed before by several authors (8-11).

The oxide formed on an iridium metal electrode due to one anodic scan up to $1.3 V_{SCE}$ appears to have properties comparable to those of the thick anodic oxide. The pronounced waves in the voltammogram of the oxide at $0.7 V_{SCE}$ and at $1.15 V_{SCE}$ are also indicated in the cathodic potential scan of the iridium metal electrode at $0.75 V_{SCE}$ and $1.1 V_{SCE}$, respectively.

XPS results of anodic iridium oxide films are displayed in Fig. 2. The anodic films were grown to a moderate thickness by potential cycling and removed

Fig. 2. X-ray photoelectron spectra of Ir $4f_{5/2,7/2}$ and O $1s$ levels of an anodic iridium oxide film exposed to 1N H_2SO_4 at different potentials (15 min).

from the electrochemical cell at the respective potentials. The position of the Ir $4f$ bands is found to be independent of the electrode potential. Compared to the Ir $4f_{7/2}$ binding energy of 60.9 eV for the metal (14), the Ir $4f$ levels of the anodic oxide shift to a higher binding energy by 1.5 eV, indicating a surface layer with Ir in a higher oxidation state.

A more pronounced dependence on the electrode potential was observed for the O $1s$ level (Fig. 2). At 0.0V, where the oxide is bleached, the O $1s$ binding energy is 531.2 eV. Upon anodic polarization, the O $1s$ level shifts to lower binding energies of 530.5 eV and 529.8 eV, at $0.9 V_{SCE}$ and $1.25 V_{SCE}$, respectively. If the potential is kept at $1.5 V_{SCE}$, where O_2 evolution occurs and the anodic oxide starts to corrode, the O $1s$ level shifts back to 530.4 eV (not shown in Fig. 2, but see Table I). In addition to the shift in binding energy, a significant broadening of the O $1s$ structure is noticed. The FWHM value increases from 2.1 eV at $0.0 V_{SCE}$ to 2.9 eV and 3.2 eV at $0.9 V_{SCE}$ and $1.25 V_{SCE}$, respectively.

The thermal stability of the surface species formed at different electrode potentials was tested by varying the temperature of the substrate in the vacuum chamber. Figure 3 shows the O $1s$ - and Ir $4f_{7/2}$ -level positions as a function of temperature. While the O $1s$ binding energies differ significantly at room temperature for the various electrode potentials, a common binding energy is reached at $230^\circ C$ ($E_B = 530.5 \pm 0.2$ eV). The oxide species formed at $0.9 V_{SCE}$ appears to be the most stable configuration. In contrast to the O $1s$ levels, the Ir $4f_{7/2}$ levels shift to lower binding energies independent of the electrode potentials. The decrease in Ir $4f_{7/2}$ binding energy is probably due to dehydration or decomposition of the anodic oxide.

In order to provide complementary information about the electronic properties of the oxide surfaces,

Fig. 3. Binding energies of the O 1s and Ir 4f_{7/2} levels as a function of substrate temperature.

XP spectra were recorded of the valence band region. In Fig. 4, the spectra of the clean polycrystalline iridium surface and of the oxides after polarization at 0.0V and 1.25V are plotted. The spectrum of the clean surface exhibits the broad, rather structureless 5d-

Fig. 4. X-ray photoelectron spectra of the valence band region of clean iridium and anodic iridium oxide films polarized at 0.0 V_{SCE} and 1.25 V_{SCE}. AlK_α excitation, normal emission.

band of Ir, extending to about 8 eV below the Fermi level (15). After electrochemical oxide formation, O 2s emission is evidenced at 24.3 eV and 22.5 eV. The strong maximum right below the Fermi level for both polarizations can be attributed to the *t*_{2g} band of the respective compound, assuming octahedrally coordinated iridium (16). At 0.0V, this band is located at 2.5 eV with virtually zero electron density at the Fermi level, while at 1.25V, the center of the *t*_{2g} emission shifts to 1.8 eV, giving rise to a nonzero electron density at *E*_F. In addition, a pronounced drop in emission intensity from the *t*_{2g} band is noticeable upon anodic polarization.

The emission characteristics in the O 2p energy region are also dependent on the electrode potential. The maximum at 7.0 eV in the spectrum for the electrode polarized at 0.0V changes to a broad plateau between 4.0 eV and 8.0 eV.

Discussion and Conclusions

Several mechanisms have been suggested for the charge storage process in iridium oxide films (8 and references therein), the majority of which assume a change in the Ir valence state from III to IV across the wave at 0.7 V_{SCE} of the voltammogram. Our XPS results for the Ir 4f binding energy, which was found to be potential independent (Fig. 2), do not contradict this assumption. However, a definite correlation of the experimental binding energy of the Ir 4f level with an oxidation state of III or IV cannot be made from available data. A binding energy of 62.4 eV might be interpreted as iridium being in a trivalent state or as a hydrated iridium dioxide with iridium in the tetravalent state. For IrCl₃, a Ir 4f binding energy of 62.6 eV has been found by Folkesson (17). On the other hand, the Ir 4f level at 61.9 eV (16) for the iridium dioxide might be shifted to higher binding energies as a consequence of hydration. This has been observed before for ruthenium oxide films (5, 18). The relatively shallow minimum between the two spin-split Ir 4f levels for the electrodes polarized at 0.9V and 1.25V (Fig. 2) may indicate the presence of higher oxides. A similarly unsatisfactory situation with respect to the interpretation of Ir 4f binding energies of iridium oxide films was encountered by Kim *et al.* (14). Therefore, the following discussion of the XPS data will be restricted to the O 1s level.

According to the oxide path (19) for the oxygen evolution reaction and to the models which have been suggested for the charge storage mechanism, there are three oxygen species, which may contribute to the intensity of the O 1s core level: (i) oxide, (ii) hydroxide, and (iii) water. The binding energies of these species on Ir were established from the following data (see Table II). For single-crystalline IrO₂, the O 1s binding energy was determined to be 529.8 eV (16). In our laboratory, we found a binding energy of 529.6 eV for polycrystalline IrO₂. Chemisorbed oxygen on Ir exhibits a binding energy of 529.8 (20). For hydroxides

of nickel (21) and iron (22, 23), a somewhat higher binding energy of 531.5 eV has been reported. A binding energy around 531 eV has been measured for hydroxyl species adsorbed on metals (24-26). We have found a binding energy of 533.1 eV for water adsorbed on Ir. This is in agreement with several other investigations of different metals (24-26).

Assuming that only these three species, with approximate binding energies of 529.6 eV (oxide), 531.0 eV (hydroxide), and 533.1 eV (water), contribute to the XPS spectra, we have deconvoluted the measured O 1s bands. It is evident in Fig. 5 that the contribution of hydroxide species to the overall O 1s signal decreases with anodic polarization. Simultaneously, the photoemission intensity originating from O 1s levels of oxide species increases. The shift of the O 1s level to lower binding energies at anodic potentials can thus be understood as a consequence of decreased OH contribution and increased oxide intensity. At a potential of 0.0V, only hydroxide is found on the surface of the anodic oxide layer. Further information about the chemical composition of the electrode surface can be gained from an analysis of the relative intensity of the O 1s and Ir 4f_{7/2} levels. Taking into account a relative scattering cross section of 0.86 for Ir 4f and 0.338 for O 1s (27), and an analyzer sensitivity proportional to the kinetic energies (FRR mode), we find a constant oxygen/iridium ratio of 3.0 ± 0.2 for all three polarizations. These results demonstrate that upon anodic polarization the total amount of oxygen species stays constant, while the contribution of oxide species grows at the expense of hydroxide species.

Based on the above findings, we propose a mechanism for anodic processes on iridium which is sketched in Fig. 6. Starting from Ir(OH)₃, a deprotonation step leads to the formation of IrO(OH)₂ with Ir in the tetravalent state. As indicated in Fig. 6, this first deprotonation step is connected with the coloration of the oxide film. After two additional deprotonation steps, IrO₃ is formed, with Ir in the hexavalent state, where oxy-

Fig. 5. Deconvoluted O 1s levels of anodic iridium oxide films at different potentials.

Fig. 6. Model for charge storage and oxygen evolution on iridium electrodes.

gen is split off. Simultaneous uptake of one water molecule leads back to tetravalent iridium as the starting position for the cycle. Alternatively, IrO₃ may corrode into the electrolyte as IrO₄²⁻ ion (28). A similar mechanism has been suggested recently for O₂ evolution on Ru (5).

In order to decide whether the anodic charge storage process occurring in the bulk of the oxide holds also for the oxide surface, the first step of our proposed mechanism in Fig. 6 (Ir(OH)₃ → IrO(OH)₂) should be compared with known models describing the bulk reaction. Gottesfeld and Srinivasan suggested a model based on ellipsometry results which is in complete agreement with our findings (9). According to the redox reaction

with $n = 3$ and $x = 1$, a proton is ejected from the oxide film upon coloration. A similar model was proposed by Michell *et al.* (10). These authors, however, found a transfer of two electrons for the bleaching mechanism ($n = 2$, $x = 2$ in Eq. [1]), which might be due to the wide potential step ($-0.2 \text{ V}_{\text{SCE}}$ to $1.25 \text{ V}_{\text{SCE}}$). For a potential step this wide, our model also suggests the transfer of two electrons according to $n = 3$ and $x = 2$

The second step (see Fig. 6), however, does not change the color of the oxide layer and is connected with the wave at $1.15 \text{ V}_{\text{SCE}}$ of the voltammetry curve.

The absence of significant amounts of H₂O in the spectra of the O 1s level and the potential-independent O/Ir ratios indicate that free H₃O⁺ ions, liberating one H⁺, are the external proton source or sink during the redox reactions. Water, bound to the solid and serving as "vehicle" for the proton, would give rise to an increase in O/Ir ratio upon bleaching. This has been suggested by McIntyre (8) and Burke and Whelan (11). If only free protons are considered, the mechanism based on RBS measurements suggested by McIntyre (8) predicts also a constant O/Ir ratio. The constant O/Ir ratio at the oxide surface is in discord with the OH⁻ insertion mechanism proposed by Beni *et al.* (29) for the bulk of the oxide. Obviously, at the immediate surface of the oxide, protons are readily available from the bulk electrolyte, according to the Grothuss mechanism, without strong interaction of

H₂O with the surface. It is, however, possible that water bound to the surface evaporates or dissociates after emersion under UHV conditions.

With respect to O₂ evolution, it is obvious that the proton ejection step can be applied consecutively in order to provide the amount of electrons required to liberate oxygen from IrO₃. Although relatively stable in alkaline electrolytes, IrO₃ decomposes readily in dilute sulfuric acid with simultaneous O₂ evolution (30). Further oxidation of iridium to an oxidation state higher than the hexavalent state is very unlikely, because the existence of such a species has not been established. Therefore, our model is consistent with the known electrochemical oxide path (19), if Ir in the tetravalent state is assumed to be the surface site. As has been discussed before for ruthenium (5), the species representing the starting position of the O₂ evolution cycle has to have a relative stability on the respective substrate in order to prevent heavy corrosion. The thermodynamic stability of iridium compounds with Ir in the tetravalent state is well known and was confirmed by our results (Fig. 3) for the species involved in anodic oxidation. It can be shown by voltammetry that on Ir, as well as on polycrystalline or amorphous IrO₂, a film is generated during O₂ evolution with properties similar to those of anodic iridium oxide. We assume, therefore, that our model for O₂ evolution and corrosion holds not only for thick anodic iridium oxide films, but also for IrO₂ and Ir anodes.

The valence band spectra (Fig. 4) corroborate our interpretation of the core-level data. The change in valence state from Ir(III) to Ir(V), which did not show up as a chemical shift in the core level spectra, gives rise to the reduction of emission intensity of the t_{2g} band. Upon anodic polarization, more electrons per iridium atom are needed to fill the O 2p shell. Despite its higher total population of electrons in the iridium d-band (t_{2g}), the hydroxide at 0.0 V_{SCE} has a much lower density of occupied states near the Fermi level. This result is consistent with the rather low electronic conductivity found for bleached anodic iridium oxide film in electrochemical experiments. At potentials cathodic of 0.25 V_{SCE}, electrode reactions like H adsorption or underpotential deposition of Cu or Ag (31) take place only at the metal/oxide interface.

At a potential of 1.25V, the valence band spectrum is in good agreement with published data for IrO₂, with emission from M-O σ and M-O π orbitals at 7.9 eV and 5.7 eV (16, 32). In addition, the position of the t_{2g} band at 1.8 eV indicates that oxide species dominate at 1.25 V_{SCE}. At 0.0 V_{SCE}, the O 2p region is characterized by a strong band at 7.0 eV with a weak shoulder at 10 eV. We attribute the band at 7.0 eV to the M-O π band, while that at 10 eV is likely to have OH σ-bonding character (22, 33, 34). Thus, the spectrum at 0.0 V_{SCE} is dominated by hydroxyl species. The above assignment, which appears to be rather ambitious in view of the low resolution of our XPS valence-band data, was confirmed by UPS measurements on the same samples using He II excitation with a much better resolution and signal-to-noise ratio. The UP spectra revealed bands at 2.5 eV (t_{2g}), 6.5 eV (M-O π) and 10.3 eV (O-H σ) for the sample polarized at 0.0V and 1.8 eV (t_{2g}) and 5.3 eV (M-O π) and 8.0 eV (M-O σ) for 1.25 V_{SCE} polarization (35).

In conclusion, we have demonstrated with the aid of XPS that oxygen evolution on anodic iridium oxide is preceded by consecutive deprotonation steps during the anodic potential scan. Upon deprotonation, the relative amount of oxygen is constant while the O 1s binding energy decreases. The shift in O 1s binding energy is due to a transition from oxygen bound as hydroxide to oxygen bound as oxide.

The first of these deprotonation steps goes together with the known electrochromic effect in anodic iridium oxides. Upon coloration, the stoichiometry at the immediate oxide surface changes from Ir(OH)₃ to

IrO(OH)₂. Oxygen evolution starts from the latter species along the known electrochemical oxide path.

ABSTRACT

Highly insulating red HgI_2 shows a very small quantum yield for both anodic and cathodic polarization. This is due to the poor charge separation made by an insufficient electric field strength in the wide space-charge layer characteristic of lightly doped materials. Quantum efficiencies exceeding 50% can be obtained for anodic polarization, however, through the artificial generation of a space-charge layer. In this approach, use is being made of the photoconductivity of HgI_2 . Illuminating the sample with light of wavelengths close to the bandgap of 2.1 eV at 300 K, leads—in conjunction with the trapping processes occurring in HgI_2 —to a potential distribution similar to an n-doped semiconductor. We discuss the dependence of the spacial and temporal buildup of this potential distribution on the external parameters such as the illumination intensities, wavelengths, and bias. Included is a discussion of the corrosion mechanisms of HgI_2 .

Red (tetragonal) mercuric iodide has been experiencing continued interest throughout this century. Beginning with investigations of its photoconductivity (1) and its exciton structure (2), emphasis has shifted toward the application of HgI_2 as a nuclear detector and spectrometer (3).

Tetragonal HgI_2 has a bandgap of 2.1 eV at room temperature and exhibits a very high resistivity (1)—typically $10^{13} \Omega\text{cm}$ —despite a remarkable amount of elemental impurities (4, 5). Insulating materials have not been commonly used for photoelectrochemical studies so far because of the lack of efficient separation of the electron-hole pairs created within the penetration depth of suprabandgap light. The separation of charge carriers usually (except in extremely thin crystals) requires a strong electric field such as is present in the depletion region at the interface between an electrolyte and a suitably doped and biased semiconductor. Recently, however, it has been shown that a potential distribution reminiscent of that of a doped semiconductor can be obtained by illuminating the investigated insulator with two light sources simultaneously (6). In this new approach, the appropriate doping for the formation of a depletion layer at the interface is achieved by making use of the photoconductivity of the crystal; i.e., one of the two light sources provides radiation which is only weakly absorbed and hence produces (mobile and fixed) charge carriers throughout the bulk of the sample. Under suitable conditions the quantum yield for nonpenetrating (suprabandgap) radiation of the second light source is thus increased dramatically.

Double-beam experiments have been reported in a number of previous publications (7). They usually deal with relatively highly doped semiconductors, however, and the change of the potential distribution in them is of a different nature than that reported here. One exception is an article on the surface-photovoltage diffusion-length measurement in amorphous silicon (8).

Key words: photoconductivity, photodoping, potential distribution.

In this paper we present a study of the photoelectrochemical properties of red HgI_2 , as well as its corrosion behavior. We use the techniques mentioned above.

Experimental Procedures

Crystal growth and characterization.—The single crystals used in this work were grown by static sublimation from prepurified material. A detailed discussion of the growth and characterization processes has already been published (4). Here we want to stress the relatively high degree of perfection and conventional purity of these crystals. We are supported by the following: (i) low etch-pit concentration ($<10^3/\text{cm}^2$) of the as-grown crystal faces; (ii) lack of striations common to the usually applied temperature oscillation growth methods (9); (iii) annealing at 75° in iodine atmosphere of the single-crystal plates ($\approx 5 \times 5 \text{ mm}$, 2 mm thick) used in this investigation. These plates were cleaved from the as-grown crystals and etched in an alcoholic solution of KI before annealing.

Compared with HgI_2 from other laboratories, the purity of our crystals is high (5). However, spark-source mass spectrographic analysis revealed that our crystals contained several thousand ppm of hydrocarbon impurities. This led to the suggestion that our HgI_2 -crystals were actually clathrates or intercalates of the layer structure (4). The influence of this effect on the measured physical properties is presently not known.

Electrode preparation.—Like many workers before, we used carbon contacts in order to avoid a chemical reaction with the HgI_2 . The crystals were mounted on a brass rod surrounded by a piece of Teflon tubing. Before embedding the electrode in silicone rubber, the crystals were usually thinned down to an appropriate thickness of $\approx 0.1\text{--}0.2 \text{ mm}$ by peeling off successive layers with a self-adhesive tape. In order to remove any surface damage, the electrodes were etched in 1M KI for up to 1 min. By this method a perfectly smooth and shiny surface was obtained.

Electrolyte.—The support electrolyte used in all the experiments was 0.5M K_2SO_4 in triple-distilled water,

in which HgI_2 is stable in the dark. $\text{Fe}^{2+}/\text{Fe}^{3+}$ did not affect the stability in the dark, nor did it suppress photocorrosion at all. The only way to substantially reduce the degradation of the electrode surface by the anodic photocorrosion (described in more detail below) was found to be the use of a solution containing the complex HgI_4^{2-} ($2 \times 10^{-2} - 0.1\text{M}$). The solution was prepared by adding one mol fraction of HgCl_2 to the support electrolyte in addition to about four mol fractions of KI, the exact amount being chosen in a way that led to a small amount of precipitated red HgI_2 ; the solution was saturated with HgI_2 .

Experimental setup.—In the electrochemical cell, a platinum wire served as the counterelectrode, and a saturated calomel electrode served as the reference. Instead of a potentiostat, an ordinary power supply was used which allowed the application of voltages up to 70V between the counterelectrode and the working electrode. The working electrode was grounded via the measuring resistor (100Ω – $1\text{M}\Omega$, depending on the current to be measured).

Steady-state measurements.—The photocurrent spectra and the current-potential curves were obtained by chopping the monochromatized beam of a high pressure xenon lamp at $\approx 15\text{ Hz}$, and recording the corresponding voltages across the measuring resistor with a PAR lock-in amplifier. As will be described below, the quantum efficiency for monochromatic light was very low unless the electrode was illuminated in addition with a long-wavelength light source. This was achieved by filtering the light from a tungsten-filament lamp through 8 cm of triple-distilled water and a Schott filter with an absorption edge just below that of HgI_2 (OG 590 or RG 610). The intensity of this broad-band light was varied either by operating the lamp at 12V or 6V or by inserting a neutral-density filter into the beam. We did not measure the absolute intensity of this light source. The room temperature optical properties (reflection and absorption) were measured by standard techniques.

Time-dependent properties.—These were obtained with essentially the same setup except that both light sources could be chopped either simultaneously or interchangeably and at different frequencies. The signals were recorded by means of a signal averager.

Results

Steady-State Photocurrent Measurements

We observed a pronounced asymmetry between anodic and cathodic polarization of the electrode. Numerous other workers have reported analogous observations in photoconductivity measurements. The photoresponse was restricted to a small region at or near the negative electrode (1). This corresponds to the anodic polarization in our photoelectrochemical experiments, since in them the crystal-front surfaces were at the lower potential. In Fig. 1 the photocurrent-potential curves for an anodically polarized electrode in $0.5\text{M K}_2\text{SO}_4 + 0.1\text{M HgI}_4^{2-}$ illuminated with strongly absorbed light of $\lambda = 550\text{ nm}$ and with sub-bandgap radiation of different intensities (given in arbitrary units) are shown. The filter used for the sub-bandgap illumination was OG 590. If the additional broad band light source is operated at high enough intensity (i.e., at 12V, with no neutral-density filters introduced into the beam), then the current-potential curves and the associated quantum efficiency are the same for Schott filters RG 610 and OG 590. Using filters with a higher or lower lying cutoff leads to lower quantum efficiencies.

The intensity of the monochromatic light beam was $\approx 180\ \mu\text{W}/\text{cm}^2$. The most pronounced feature of Fig. 1 is the steep rise of the photocurrent at small potentials for high-intensity sub-bandgap radiation (top curve). This indicates the formation of a barrier region

Fig. 1. Photocurrent-potential curves at an HgI_2 electrode in $0.5\text{M K}_2\text{SO}_4 + 0.1\text{M HgI}_4^{2-}$. The electrode is illuminated by a chopped monochromatic light source ($\lambda = 550\text{ nm}$, intensity $\approx 180\ \mu\text{W}/\text{cm}^2$) and by steady-state sub-bandgap light (tungsten lamp, filtered through H_2O and Schott glass OG 590). The intensity of the latter is highest for the top curve O (100% in relative units), and decreases steadily for the other curves (curve \star : 14%; $+$: 2.3%; $\#$: 0.65%; \times : monochromatic illumination only).

at the electrode surface. For monochromatic illumination alone ($\lambda = 550\text{ nm}$), the photocurrent-potential curve nearly coincides with the potential axis (bottom curve in Fig. 1). The photocurrent is smaller by about two orders of magnitude ($\approx 0.3\ \mu\text{A}/\text{cm}^2$ at 50 V_{SCE}).

All measurements in Fig. 1 were performed by applying a voltage of 70V first and then recording the photocurrent as a function of decreasing cell voltage. Before any change of the intensity of the sub-bandgap radiation, the initial voltage of 70V was reapplied. After a waiting period, the associated value for the photocurrent was found to be equal to the original one (hence ruling out a serious degradation of the surface). The waiting period became longer the smaller the intensity of the sub-bandgap light.

Other time-dependent effects were observed at low voltages. After any change of voltage, the photocurrent slowly decreased for several minutes. This transient effect became more pronounced at lower sub-bandgap intensities. For the top curve in Fig. 1, the effect was observed below $\approx 0.5\text{ V}_{\text{SCE}}$ only, for the bottom curve below 10 V_{SCE} .

The linearity of the photocurrent with the monochromatic light intensity depends strongly on the intensity of the additional sub-bandgap light source (Fig. 2). In Fig. 2, curves a, b, and c represent the photocurrent (electrode potential 60 V_{SCE}) as a function of intensity. The full curves in this double log-plot correspond to a linear relationship (slope = 1). The additional light source was operated at 12V with OG 590 (curve a), at 12V with RG 610 (curve b), and at 6V with RG 610 and an additional neutral density filter of 0.1% transmittance (curve c).

For the sake of clarity, only the curves showing the most pronounced behavior have been displayed in Fig. 2. At $\lambda = 600\text{ nm}$ (curve b) the linearity is not influenced at all by changes of the intensity of the second light source. The opposite is true at 550 nm: for high intensity sub-bandgap illumination (curve a), deviations from the linear relationship occur around $1\text{ mW}/\text{cm}^2$. On decreasing the intensity of the long wavelength light source, these deviations occur at lower and lower intensities until for curve c there is no linear relationship in the entire investigated range. In fact, the photocurrent is even partly quenched in this case, as can be seen by reducing the intensity of the monochromatic beam to the lowest value of 180

Fig. 2. Dependence of the photocurrent on the intensity of the monochromatic illumination. Electrode potential 60 V_{SCE}, electrolyte 0.5M K₂SO₄ + 2 × 10⁻²M HgI₄²⁻. Curves a (λ = 550 nm) and b (λ = 600 nm) correspond to intense illumination with sub-bandgap light (curve a: tungsten lamp 12V, filter OG 590; curve b: 12V, RG 610). For curve c (λ = 550 nm) the intensity of the long-wavelength radiation was much smaller (tungsten lamp 6V, filtered with RG 610 and 0.1% neutral-density filter). The full curves have a slope of 1; they correspond to a linear relationship.

μW/cm² (see tip of the arrow in Fig. 2). The original value of the photocurrent at this intensity can be restored by illuminating the sample with long wavelength light of higher intensity (e.g., as in curve a) for several minutes.

Figure 3 shows the quantum efficiencies (uncorrected for reflection losses) of an HgI₂ electrode in 0.5M K₂SO₄ + 0.1M HgI₄²⁻ for anodic (curves a and c) and cathodic (curve b) polarization.

For curves a and b, the electrode was illuminated by monochromatic light only. In both cases the response was limited to a narrow spectral region around the onset of the interband absorption (insert Fig. 3). The anodic photocurrent changed drastically upon illumination of the electrode with a second lamp (curve c) providing sub-bandgap radiation (Schott filter RG 610). For the low monochromatic light intensity used in this measurement (approximately 50 μW/cm² on average), the apparent quantum efficiency remained at around 50% in the spectral range between 450 nm and 570 nm. Taking into account the reflection losses at the surface (R ≈ 20% at 550 nm) leads to a corrected quantum efficiency larger than 60%. For cathodic polarization, however, the quantum efficiency was not altered by the additional illumination of the electrode. Hence, the mentioned asymmetry between anodic and cathodic polarization became even much more pronounced when the electrode was illuminated with the second light source. An additional, even more dramatic manifestation of this asymmetry was found in the frequent breakdowns encountered in the cathodic case (under illumination), sometimes at voltages as low as 1V. No breakdowns happened for the anodic polarization up to the highest applied voltage (70V).

Photocorrosion

Anodic photocorrosion.—Mercury is already in its highest oxidation state (2+) in HgI₂. It is clearly the iodide which is oxidized in an anodic reaction. The electrode was photocorroded in 0.5M K₂SO₄ for a time sufficient to yield 10⁻⁴M I₂ if iodide were oxidized to I₂ according to

No elemental iodine could be detected, however, by the very sensitive iodo-starch reaction. We have to con-

clude that iodide is oxidized to a higher oxidation state. The reaction can be tentatively formulated as

Since IO₃⁻ is a strong oxidizing agent, it should be able to oxidize I⁻ to I₂ in an acidic solution. After adding a few drops of HCl and KI solution to the electrolyte, the iodo-starch reaction indeed indicated the presence of I₂.

Optical examination of the electrode surface revealed clear signs of photocorrosion even for intensities as low as 50 μW/cm² and after a few minutes of exposure. This was accompanied by a marked decrease of the photocurrent at wavelengths below 560 nm. Addition of Fe²⁺ (up to 0.1M) did not result in any visible reduction of the photocorrosion. The introduction of the solution containing the HgI₄²⁻ complex (see preparation of the electrolyte) did, however, result in a visibly slower rate of deterioration of the surface, at least at low intensities. The oxidation of adsorbed HgI₄²⁻ to iodate represents a competing reaction that could lead to slower photocorrosion. The photocurrent was indeed stable for a much longer time (several hours at low intensities) with this electrolyte.

Cathodic polarization.—Cathodic photodecomposition of HgI₂ might in principle lead to the reduction of Hg²⁺ to either Hg⁺ or Hg⁰. After illumination of the electrode with filtered white light (OG 590, for which the photocurrent at -0.7 V_{SCE} was 0.3 μA) for 2h, a yellow layer was observed on top of the electrode. This reaction product was light sensitive and assumed a grayish coloration upon illumination with white light. Since it does not seem to be soluble in KI (which Hg₂I₂ would be) the reaction product probably consists of Hg₂SO₄. The most likely reaction mechanism is thus

Transient Effects

In order to shed some light on the role played by the additional long-wavelength light source, particularly with regard to the time-dependent effects already mentioned above, we decided to look at the time dependence of the photocurrent signal itself. In the first experiment the sample was illuminated with monochromatic light (λ = 550 nm) only. The long-wavelength illumination was then switched on. In order to be able to distinguish between the two contributions to the photocurrent, the monochromatic beam was chopped with 1.5 Hz. In Fig. 4 two such sets of measurements are displayed (upper curves: total photocurrent; lower curves: photocurrent due to the sub-bandgap illumination alone). Both were taken on the same electrode. The middle curves (#) show the behavior of the virgin electrode (never before illuminated), while the others (*) were taken after the electrode had been illuminated several times. The most striking feature of all these curves is the extremely slow rise of the photocurrent associated with the monochromatic radiation (given by the difference of the total photocurrent and the sub-bandgap contribution in Fig. 4). Moreover, this risetime diminishes when the electrode has been illuminated for some time before the experiment (top curve in Fig. 4). By contrast, the initial risetime of the photocurrent due to the sub-bandgap illumination is always fast (we have no explanation for the hump seen in the lower of the [#] curves in Fig. 4). The decay time after switching off the sub-bandgap radiation is nothing on the scale of Fig. 4 both for the total and for the photocurrent due to the penetrating radiation alone (examine also Fig. 5 for this point).

Fig. 3. Quantum efficiency with monochromatic illumination alone ($50 \mu\text{W}/\text{cm}^2$) for anodic (a) and cathodic (b) polarization and with additional long-wavelength illumination (c, anodic polarization). The insert shows the absorption coefficient around the onset of the inter-band transition. The electrolyte was $0.5\text{M K}_2\text{SO}_4 + 2 \times 10^{-2}\text{M Hgl}_4^{2-}$, electrode potential 20V_{SCE} .

Since the risetime observed in Fig. 4 depend so strongly on the history of a sample and because of the considerable variation from sample to sample, our dis-

Fig. 4. Time dependence of the photocurrent signal ($\lambda = 550 \text{nm}$) after switching on the sub-bandgap radiation (at $t = 0\text{s}$). Electrode potential 20V_{SCE} ; electrolyte $0.5\text{M K}_2\text{SO}_4 + 2 \times 10^{-2}\text{M Hgl}_4^{2-}$. The lower curves show the photocurrent due to the sub-bandgap radiation alone, the upper ones the total photocurrent. #: virgin electrode which was never illuminated before; *: same electrode after having been illuminated for several minutes.

cussion will be limited to the qualitative features of these experiments. The important result pertaining to Fig. 4 is that the risetime of the photocurrent after the initial application of the long-wavelength radiation is much longer than the decay time after shutting it off. Those two times may be expected to be of a different physical origin.

The situation is quite different once the sample has been irradiated for some time with sub-bandgap light

Fig. 5. a: Photocurrent signal for chopped monochromatic illumination ($\lambda = 550 \text{nm}$, $\nu = 100 \text{Hz}$) and continuous sub-bandgap radiation with electrode potential 10V_{SCE} ; b: photocurrent signal for continuous monochromatic ($\lambda = 550 \text{nm}$) and chopped (100Hz) sub-bandgap illumination with electrode potential 10V_{SCE} (full curve) and 20V_{SCE} (dashed curve). Same electrolyte as in Fig. 4.

(i.e., after reaching the saturation region in Fig. 4). The risetime then decreases dramatically. This is shown in Fig. 5 where the monochromatic light beam has been chopped at 100 Hz for continuous illumination by the sub-bandgap source (Fig. 5a) and vice versa (Fig. 5b). A comparison of Fig. 5a and Fig. 5b shows that the amplitude of the modulation of the photocurrent is practically the same in both cases. Hence, the risetime of the photocurrent associated with the onset of the sub-bandgap illumination is now of the same order of magnitude as the decay time after entering the dark phase (Fig. 5b). The risetime observed here must thus be due to a different mechanism than that one seen in Fig. 4.

Figure 5b also shows that in the dark phase of the sub-bandgap radiation (with monochromatic illumination), the photocurrent does not decay to zero (the photocurrent for monochromatic radiation alone, i.e., with no second lamp present at all, would be much smaller on this scale. See also Fig. 1). This becomes more pronounced the higher the electrode potential, as can be seen in Fig. 5b. Here the full curve is for a potential of 10 V_{SCE} and the dashed one for 20 V_{SCE}.

Discussion

Before we enter the discussion of the experimental results presented above, we should like to summarize the main points again:

1. The photocurrent response of HgI₂ to monochromatic light alone is limited to a narrow spectral region near the absorption edge.

2. For anodic polarization, the quantum efficiency is increased drastically for wavelengths below 570 nm when the electrode is illuminated in addition to sub-bandgap light of high enough intensity. The cathodic photocurrent, however, is little affected.

3. For a high enough intensity of the sub-bandgap illumination, the photocurrent due to the monochromatic light saturates at relatively low voltages, indicating the formation of a depletion region near the electrode surface.

4. The photocurrent varies linearly with the intensity of short-wave ($\lambda \leq 560$ nm) monochromatic radiation only for as long as the intensity of the additional light is high enough. If it is not, the response to the short-wavelength radiation may be quenched.

5. The improvement of quantum efficiency after switching on the sub-bandgap light source is a very slow process. It takes up to tens of minutes for low intensities of the sub-bandgap illumination. This risetime is fastest for high sub-bandgap intensities and high voltages.

6. Once the space-charge configuration leading to high quantum efficiency has been established by prolonged illumination with sub-bandgap light, and after a (short) dark phase of the latter (in which the current decays almost to zero), the rise of the photocurrent is faster by several orders of magnitude upon renewed illumination of the electrode (the monochromatic source being on continuously).

Most of the phenomena described above have been observed at relatively high electrode potentials (≥ 3 V_{SCE}, with the exception of the current-potential curves). Thus, the kinetics of the charge transfer at the HgI₂/electrolyte interface may be expected to be of minor importance for our discussion. We have to deal with the solid-state properties of HgI₂ exclusively. Our main task is of course to explain the mechanism for the drastic increase of the quantum efficiency brought about by the illumination of an anodically polarized electrode with a second light source providing broad-band long-wavelength radiation with a cutoff close to the absorption edge of HgI₂ (in the following, this is called penetrating radiation). The high absorption coefficient ($K \approx 10^4$ cm⁻¹ at $\lambda = 550$ nm (10)) leads to a very short penetration depth

for wavelengths beyond the absorption edge. In case of a linear potential distribution within the sample, the electric field strength would be below 10⁴ V/cm even for the highest applied voltage of 70V and the thinnest crystals (≈ 0.1 mm). This would clearly be insufficient for efficient carrier separation, especially in view of the rather small hole mobility encountered in these compounds (3, 11). In fact, if we assume such a linear potential distribution in the dark, it is easy to see that illuminating the electrode with light of a short penetration depth could influence this potential distribution in a way detrimental to carrier separation. Due to their higher mobility, the electrons diffuse faster toward the back contact than toward the holes. The electric field generated by the resulting charge distribution is thus opposed to the external field (the electrode being polarized anodically). The total electric field in the generation region is therefore definitely too weak. This situation is pictured in Fig. 6a; which shows the electric potential for anodic polarization in the dark (curve 1) and under illumination by monochromatic light only ($\lambda < 570$ nm, curve 2). The corresponding band diagram is shown in Fig. 6b. The experimental results provide compelling evidence for a profound change of the potential distribution upon the simultaneous illumination of the electrode by penetrating radiation. The effective range of wavelengths of this additional light is confined to a rather narrow spectral region near the onset of the absorption in HgI₂. In other words, in order to be efficacious, the long wavelength photons must be able to cause inter-band transitions and hence produce additional mobile carriers of both signs in the bulk of the electrode. Sub-

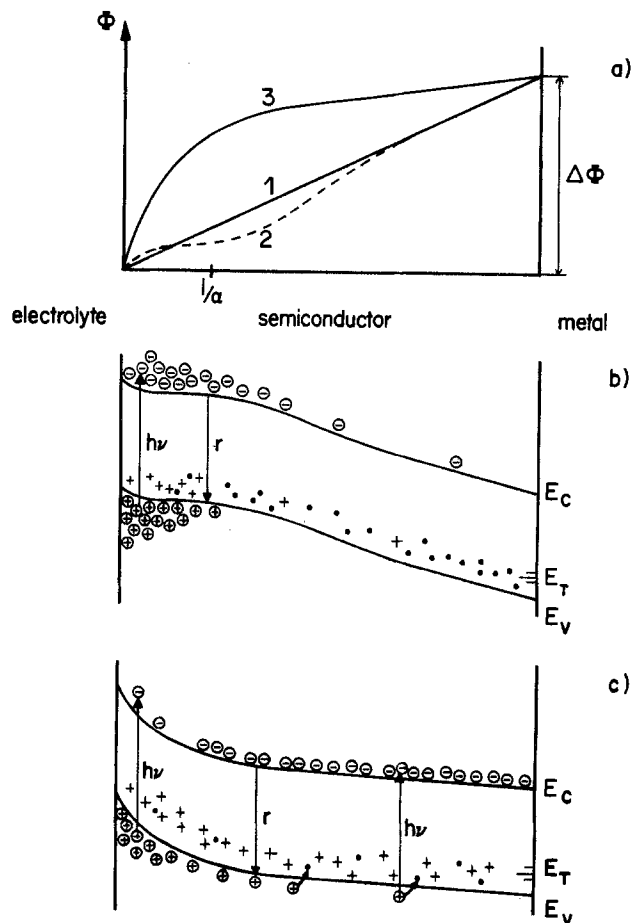

Fig. 6. a: Approximate potential distribution in an anodically biased ($\Delta\Phi$) HgI₂ electrode in the dark (1), for monochromatic (suprabandgap) illumination alone (2), and for additional continuous illumination with sub-bandgap photons (3). b: Band diagram corresponding to illumination mode 2. The dots in the figure represent empty hole traps. c: Band diagram for illumination mode 3.

sequently, the holes become trapped in the bulk, so that the steady-state photocurrent is mainly carried by electrons. (There is a marked difference in mobilities for electrons [$\approx 100 \text{ cm}^2/\text{Vs}$] and holes ($\approx 4 \text{ cm}^2/\text{Vs}$), as has been shown by many authors (3, 11).

Hence the irradiation of the sample with penetrating radiation leads to a shift of the electron Fermi level from a value near the middle of the bandgap towards the conduction band. The insulator is thus transformed into an effective n-type semiconductor with a carrier concentration depending on the intensity of the penetrating radiation. The trapped holes play the role of the positively charged donors in an ordinary semiconductor. (Curve 3 of Fig. 6a shows qualitatively the potential distribution for this situation, and Fig. 6c shows the corresponding band diagram [both again for anodic polarization].)

With this picture in mind, we see that the asymmetry between cathodic and anodic polarization immediately becomes apparent. In the cathodic case, both the increased recombination rate due to the accumulation of electrons at the surface and the poor mobility of the holes lead to a negligible photocurrent for nonpenetrating (i.e., short wavelength) radiation. In the anodic case, however, the electric field in the depletion region (Fig. 6c) will be able to separate the charge carriers produced by the nonpenetrating radiation. This will happen only if the ratio between the barrier's height and width is high enough. The barrier height and width are controlled not only by the applied voltage, but also by the intensity of the long-wavelength radiation, since the latter controls the doping level. In the depletion approximation, the barrier width depends on the inverse square root of the doping concentration. We are now able to explain the nonlinear intensity dependence of the photocurrent for nonpenetrating radiation (Fig. 2), and for low-level penetrating radiation. Only if the intensity of the latter is made high enough, so a depletion region forms, does one get a linear relationship over an appreciable range of intensities. Under the same conditions, the saturation at low potentials (Fig. 1) and the high quantum efficiency follow suit.

Without a more detailed investigation (by other means) of the trapping processes occurring in our HgI_2 crystals, it does not seem appropriate to construct an artificial trapping model which might explain the time dependence of the photocurrent shown in Fig. 4 and 5.

It is, however, possible to give some qualitative arguments on the basis of the available experimental evidence. Figure 4 suggests a very slow buildup of the space-charge layer under sub-bandgap illumination which could result from the slow filling of deep hole traps. The latter might then be expected to be sufficiently long lived so that once they have been gen-

erated, the response is governed by other processes which may very well be much faster (Fig. 5b). For a detailed discussion of these phenomena, the recombination mechanisms and eventual electron trapping will have to be taken into account.

Conclusions

We have shown that red HgI_2 , which is a material with an extremely high resistivity, can be optically doped so that photoelectrochemical investigations become feasible. A model has been proposed in which holes generated throughout the bulk by weakly absorbed long-wavelength light are trapped and so act as ionized donors and convert the insulator into an effective n-type semiconductor. This greatly affects the potential distribution near the electrolyte interface. The much-improved carrier separation leads to a pronounced enhancement of the otherwise poor quantum yield up to values above 50% over a wide spectral range.

The dependence of the steady-state photocurrent on applied potential and light intensity and the observed transient effects are in agreement with the model mentioned above.

Acknowledgments

Many valuable discussions with Dr. B. Bressel and Dr. M. Piechotka are gratefully acknowledged. We thank Ms. M. Lübke and Mr. J. Müller for their technical help in some of the experiments and the NEFF for financial support.

Hydrodynamic Studies on a Vertical Electrolyzer with Gas Evolution under Forced Circulation

F. Hine,* M. Yasuda,* Y. Ogata, and K. Hara
Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

The electrical resistance of the gas-solution mixture and the hydrodynamic pressure drop in a vertical cell operated under forced circulation of the electrolytic solution were measured. They strongly depended on the electrode configuration and the cell geometry, especially in narrow channels. One must be careful designing electrolyzers with gas evolution, otherwise the cell voltage increases extensively. Relationships among the electrical resistivity, the gas void fraction, the flow rate or the Reynolds number, the friction factor, and others are obtained.

The electrolyte conductivity in electrolyzers decreases when the solution contains gas bubbles, resulting in high cell voltage. The flow of the gas-solution mixture in a vertical cell depends on the configuration of the electrolyzer and is classified into three types: blocked convection, natural circulation, and forced circulation (1). Of these, blocked convection is undesirable, especially in narrow channels since separation of gas bubbles from the two-phase mixture is difficult. Electrolyte circulates by gas lift when a downcomer is provided, which is a common feature of water electrolyzers and chlor-alkali cells. The gas voidage in the electrolysis zone, and hence the ohmic voltage drop, are decreased by natural circulation in this case. The gas voidage can be further reduced by forced circulation, however, it is rarely used because a circulation pump is required. Most experiments described here were conducted under forced circulation to clarify the hydrodynamic behavior of the vertical cell with gas evolution since the analysis of natural circulation of electrolyte was somewhat complicated. The results obtained are, of course, applicable to cells under natural circulation when appropriate assumptions and/or modifications are used.

The anolyte and/or catholyte of the membrane-type chlorine cell are circulated between their compartments and respective reservoirs to maintain the solution composition and temperature. Also, the current efficiency is improved somewhat by solution circulation, probably due to reduced concentrations of NaCl and NaOH near the membrane in both sides.

Generally speaking, the interelectrode gap or the distance between the electrode and the separator must be small for reducing the IR drop and cell voltage. But good design is important otherwise the gas voidage in the narrow channel increases, resulting in large IR drop.

Nonflat plate electrodes such as perforated plate, mesh, and expanded metal can release electrolytic gas bubbles in the space in the rear of the electrode (2, 3), but these electrodes result in friction loss of solution flow.

This work deals with the hydrodynamic behavior of a vertical cell equipped with gas evolving electrodes of various kinds and the voltage characteristics of these systems.

Experimental Procedure

The flow sheet is illustrated in Fig. 1. The electrolyte 0.2N NaOH, was pumped into the bottom part of cell through the flowmeter, and was sent back to a 30 liter reservoir where the solution temperature was controlled by both an electric heater (1 kW) and a cooling water coil.

* Electrochemical Society Active Member.

Key words: bubble effects, electrolyte conductivity, flat plate electrode, forced circulation, friction factor, gas void fraction, mesh electrode, pressure drop, vertical cell.

A vertical PVC pipe (19 mm inner diam and 64 cm long), equipped with two platinized Pt foil electrodes of 23 mm length and 3 mm width, was located above the test cell to determine the conductance of the two-phase mixture and hence, the gas void fraction at the cell top (ϵ_T). The relationship between the gas voidage and the conductance was calibrated prior to the measurement.

The returned solution was reserved in the cushion tank during the conductivity measurement to avoid any disturbance of the leakage current from the electrolyzer. Gas was purged out from the cushion tank and the reservoir.

Two Luggin-Haber probes were positioned at the center of the electrolyzer to evaluate the gas voidage (ϵ_C) at the point from the solution IR drop perpendicular to the electrodes. One probe protruded 1-5 mm, depending on the electrode spacing, from the flat plate counterelectrode, and another Luggin was located just at the electrode surface.

The pressure drop between the top and the bottom of the electrolyzer was measured by a manometer connected with the pressure taps located at the respective points. The distance between two taps was 90 cm, but the pressure drop presented in the text was on the basis of 1m in distance.

The electrolyzer, made of Lucite resin, is shown in Fig. 2. The flat plate counterelectrode and the flat plate test electrode were made of a Type 304 stainless

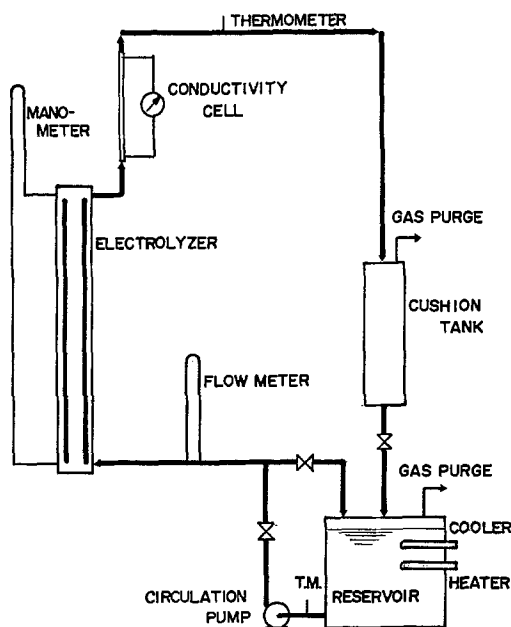

Fig. 1. Flow sheet

Fig. 2. Electrolytic cell (A and B) and expanded metal (C)

steel sheet (100 cm long, 9 cm wide, and 2 mm thick). A heavy copper bus bar was bonded at the end of the steel plate longitudinally to avoid voltage drop in the electrode hardware. These electrodes were clamped together with a plastic spacer, and hence, the working area was 96 cm long and 3 cm wide.

The electrode gap was varied in the range 1-20 mm with various spacers. The width of the space in the back of the nonflat plate electrode was also varied with the spacers in the range 2.5-7.0 mm (see Fig. 2B).

The nonflat plate electrodes include the mesh electrodes (ME) and the expanded metal electrodes (EX). The perforated plate electrode was also employed as reference. A mesh, 96 cm long and 3 cm wide, was soldered to the window frame (100 cm long and 9 cm wide) to fabricate the mesh electrode. Some examples of the meshes and expanded metals tested are listed in Table I. These materials were made of Type 304 stainless steel with some exceptions, due to availability in the market. Generally, the test electrode was used as cathode, and the counterelectrode as anode.

Caustic soda solution (0.2N NaOH) was electrolyzed. The operating temperature was 50°C. The physico-chemical properties of the electrolytic solution at 50°C are as follows

$$\text{Specific resistance} = 16.4 \Omega \text{ cm}$$

$$\text{Viscosity} = 0.006101 \text{ g/cm sec}$$

$$\text{Density} = 1.0215 \text{ g/cm}^3$$

During electrolysis, hydrogen and oxygen evolved at the cathode and the anode, respectively, and mixed together because there was no separator between two electrodes. Thus, $\frac{1}{2}$ mol H₂ and $\frac{1}{4}$ mol O₂ were evolved for 1F. These gas bubbles cover the electrode surface and the overvoltage increases. On the other hand, the electrolyte resistance is increased by dispersion of bubbles. However, the surface coverage is small since the solution flow diverts gas bubbles from the electrode in a vertical cell.

The electrolytic current was varied in the range 0-100A. The average current density was 34.7 A/dm² at 100A of total current for a flat plate electrode.

The flow rate of solution was varied from 30 to 300 cm³/sec. The interelectrode gap was a simple flow channel when a flat plate was used as the test electrode. On the other hand, the electrolytic solution could pass through the nonflat plate electrode to the back space, and hence, the actual flow rate in the electrolysis zone decreased.

Results and Discussion

Flat plate electrode.—The terminal voltage of the cell equipped with the flat plate electrode decreased with increase in the flow rate, especially at high currents, and approached asymptotes as illustrated in Fig. 3A. At high flow rates, the terminal voltage was almost linear with electrolytic current since the gas voidage was small even at large currents (Fig. 3B). The cell voltage increased rapidly with an increase in

Fig. 3. Cell voltage as a function of the solution flow rate (A), the electrolytic current (B), and the electrode gap (C). Electrode = flat plate. (A) Electrode gap = 2.5 mm. (B and C) Solution flow rate = 40 cm³/sec.

the electrode gap, especially for a small gap (Fig. 3C) because of the distribution of bubbles across the electrode gap in a wide channel; that is, most of the bubbles are crowded next to the electrode, and only solution flows in the center of the channel, while bubbles are uniformly distributed in a narrow channel. It differs from the results obtained under natural circulation and blocked convection (1, 2), where the cell voltage rises greatly when the electrode spacing becomes small because of large gas voidage.

Figure 4A shows examples of the solution resistivity and the gas voidage as functions of the flow rate. The gas void fraction (ϵ) is represented by Eq. [1]

$$\epsilon = \frac{Q_G}{Q_G + sQ_S} \quad [1]$$

Generally, the slip ratio (s) for the gas-solution mixture in electrolytic cells is considered to be unity (4, 5). Also, the electrical resistivity of the two-phase mixture (ρ) is a function of ϵ such as

$$\frac{\rho}{\rho_0} = \frac{1 + 0.5\epsilon}{1 - \epsilon} \quad \text{Maxwell} \quad [2]$$

and

$$\frac{\rho}{\rho_0} = (1 - \epsilon)^{-1.5} \quad \text{Bruggeman} \quad [3]$$

Although many have discussed the accuracy of these equations (6), no significant difference is found in the range $\epsilon < 0.3$ (7-10). The gas void fraction on the right side in Fig. 4A was calculated from Eq. [2].

Table II shows the voltage balance of the cell with a flat plate electrode. At low currents, the solution IR drop was only one tenth of the cell voltage when the solution flow rate was large. On the other hand, it becomes the largest component of the terminal voltage at large amperages and small flow rates because the reduced resistivity (ρ/ρ_0) increases with an increase in the amperage and a decrease in the flow rate. The resistivity ρ is almost independent of the interelectrode gap since the gas voidage is a function of the amperage or the gas evolution rate and the solution flow rate (see Eq. [1]).

The potential drop, $E_d + \Sigma\eta$, in Table IIB is 0.15V larger than that of Table IIA, probably due to a small deviation of the position of the Luggin probe and the electrode gap during fabrication of the cell. Deviation of the distance by 0.1 mm causes a voltage drop of 60 mV at 35 A/dm², for example.

The pressure drop vs. flow rate curve is almost independent of the electrolytic current at flow rates more than 100 cm³/sec as shown in Fig. 5 because the gas void fraction is almost negligible even at large

amperages. At low flow rates, the pressure drop became negative, depending on the amperage, due to gas lift. It suggests circulation of the two-phase flow in a closed loop in the cell. The flow pattern in a cell with a perforated electrode is illustrated in Fig. 1 in the previous paper (2). Contribution of such complicated flow to the reduction of the gas void fraction in the interelectrode gap was small. Therefore, an appropriate design of the cell, especially the down-comer or the back space, is important if one seeks to decrease the gas voidage by means of natural circulation.

The pressure drop in the cell equipped with an expanded metal electrode is significantly large compared to the flat plate electrode, due to turbulence of the solution flow, as illustrated by the dotted line in Fig. 5.

Thorpe *et al.* proposed the frictional pressure drop multiplier (Ψ) as follows (5)

$$\Psi = \frac{\Delta P_T}{\Delta P_S} \quad [4]$$

Vogt introduced a coefficient K , which is a function of ϵ (10)

$$\frac{dP_T}{dx} = K \frac{dP_S}{dx} \quad [5]$$

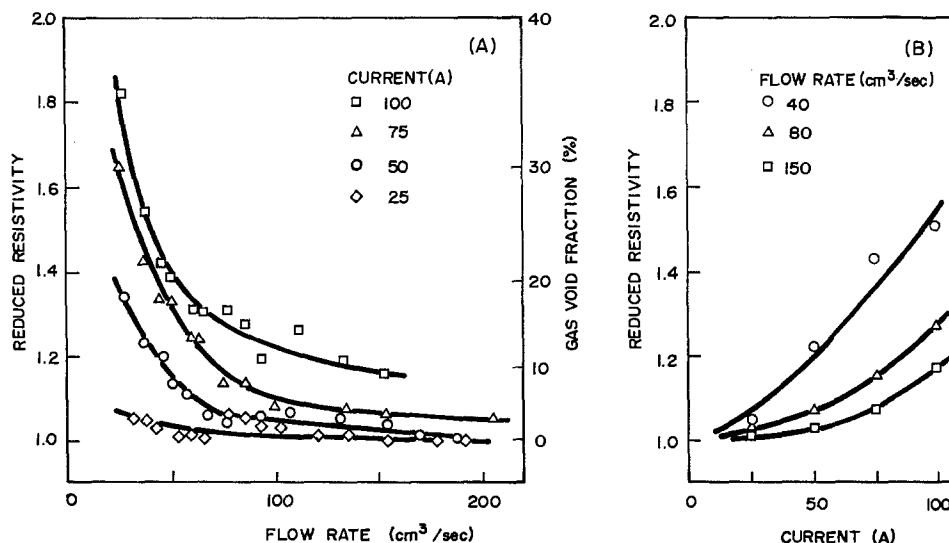

Fig. 4. Reduced resistivity (ρ/ρ_0) as a function of the solution flow rate (A) and the electrolytic current (B). Electrode = flat plate; electrode gap = 2.5 mm.

Fig. 5. Pressure drop vs. solution flow rate curves. Electrode = flat plate; electrode gap = 5.1 mm.

$$K = \frac{1}{1 - \epsilon} \frac{f_T}{f_S} = \frac{(1 + \epsilon)^n}{1 - \epsilon} \quad [6]$$

where n is an exponent depending on the flow velocity, e.g., $n = 1$ for laminar flow and $n = 0$ for fully developed turbulent flow. Correlation between Ψ and K is as follows

$$\Psi = \int_0^H K \frac{dx}{H} \quad [7]$$

For fully developed turbulent flow, Vogt obtained Eq. [8]

$$\Psi = \frac{1 - 0.5\epsilon_T}{1 - \epsilon_T} \quad [8]$$

The multiplier Ψ evaluated with the experimental results was a function of the gas void fraction and the electrode gap, as shown in Fig. 6, a power law, Eq. [9], fit the data better than Eq. [8]

$$\Psi = \left(\frac{1 - 0.5\epsilon_T}{1 - \epsilon_T} \right)^m \quad [9]$$

$$m = 840d + 0.5 \quad [10]$$

If $n = 0.25$, we obtain

$$\Psi = \left(\int_0^H \frac{[1 + \epsilon_T(x/H)]^{0.25} dH}{1 - \epsilon_T(x/H)} \right)^m \quad [11]$$

Fig. 6. Frictional pressure drop multiplier (Ψ) vs. gas void fraction at the cell top. Electrode = flat plate.

$$m' = 750d + 0.8$$

[12]

This equation is too complicated for practical use, and it gives almost the same results as Eq. [9]. Although a simple form of Ψ can be found (11), it deviates significantly from experiments.

Because the frictional pressure drop multiplier depends on the geometry of the flow channel, as shown by Eq. [9] and [11], further work is required.

Nonflat plate electrodes.—Most of the mesh electrodes tested showed high voltages compared to the flat plate electrode as shown in Fig. 7. The voltage with the expanded metal electrode was almost the same as with the flat plate electrode, and a few materials such as ME-4 were preferable.

The cell voltage was almost independent of the mesh size when the back space was small, but the voltage of the cell having a large back space increased as the mesh became lighter because the two-phase mixture could not escape from the electrolysis zone to the back space. That is, the actual flow rate in the electrolysis zone becomes small at a given flow rate when the back space is large, resulting in large gas voidage.

If the back space was too large and the mesh was so tight the two-phase mixtures could not penetrate it, the cell voltage rose greatly as the interelectrode gap decreased, just as the voltage of narrow cells having a pair of the flat plate electrodes was high (1). The current distribution near the nonflat plate electrode causes a large solution IR drop, especially in the narrow channel. Both oxygen and hydrogen overvoltages on the nonflat plate electrode are high because of reduction of the electrode area, which also causes high cell voltage.

The reduced resistivity at the cell top and at the center of the cell are shown in Fig. 8. The resistivity of the two-phase flow at the cell top is of course independent of the electrode configuration, but is only a function of the gas void fraction (Fig. 8A).

On the other hand, the resistivity of the two-phase system in the electrolysis zone depends greatly on the electrode configuration, as shown in Fig. 8B. Note that the resistivity in the electrolysis zone is significantly larger than at the cell top when a badly designed electrode is employed, suggesting very large gas voidage in the electrolysis zone in comparison with that in the back space. The expanded metal electrodes, both EX-1 and EX-2 in this figure, can release electrolytic gases to the back side, resulting in low gas voidage and cell voltage.

In the previous paper (9), assumptions of a linear distribution of a population of gas bubbles along the vertical flat plate electrode and also uniform distribution perpendicular to the electrode, agreed with the

Fig. 7. Cell voltage vs. solution flow rate curves. Electrode = nonflat plate; electrode gap = 1.1 mm; back space = 7.0 mm; electrolytic current = 100A.

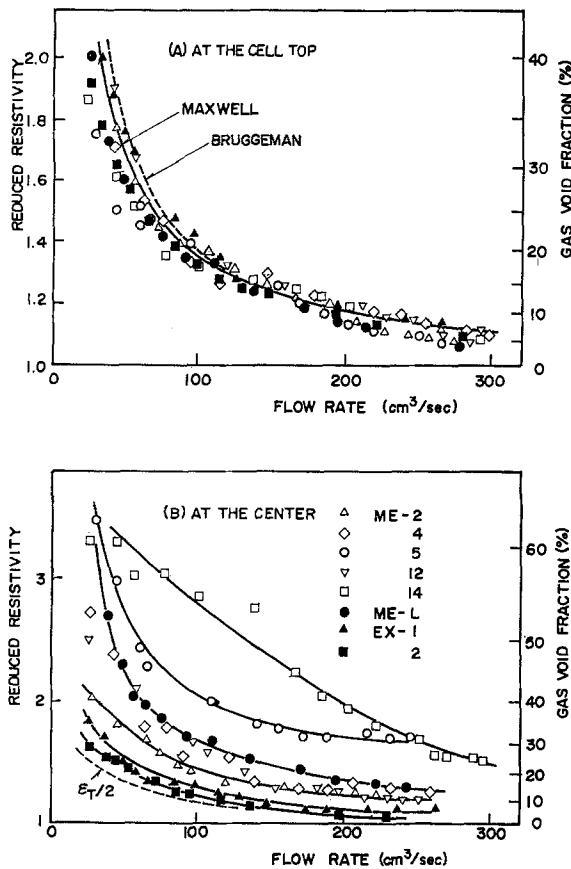

Fig. 8. Reduced resistivity (ρ/ρ_0) vs. solution flow rate curves at the cell top (A) and at the center (B). Electrode = nonflat plate; electrode gap = 1.1 mm; back space = 7.0 mm; electrolytic current = 100A.

experiment. An estimated gas void fraction with an assumption of $\epsilon_c = \epsilon_T/2$ is illustrated by the dotted line in Fig. 8B. All of the experimental data with the mesh electrodes are significantly larger than the dotted line.

Although a large portion of electrolytic gas bubbles can escape from the electrolysis zone to the back side through the mesh, the interelectrode space is still crowded with a swarm of gas bubbles, and its gas voidage is greater than that in the back space and also that with a simple assumption: $\epsilon_c = \epsilon_T/2$.

The cell geometry such as the ratio of the electrode spacing (d) to the depth of the back space (d_B) is also an important factor of ρ/ρ_0 and ϵ , as shown in Fig. 9, for example. A straight line in the figure shows $\epsilon_c = \epsilon_T/2$. The gas voidage in the electrolysis zone is almost equal to that in the back space if the ratio d/d_B is large. On the other hand, a narrow space between two electrodes was crowded with a swarm of gas bubbles and the gas void fraction increased greatly because most of the solution passed through the back space (Fig. 9A). The gas voidage in the cell equipped with EX-1, for example, was almost uniformly perpendicular to the electrode since the electrode permitted the gas bubbles to escape (Fig. 9B).

Since a mesh in the flow behaves as a turbulent promoter, the pressure drop of the channel is increased by its insertion, as shown in Fig. 10 (also see Fig. 6). The pressure drop in the channel with ME-5 was very large since this mesh was composed of thick wires. The expanded metal showed a large pressure drop due to its configuration. Two meshes, ME-12 and ME-14, showed a relatively small resistance to the two-phase flow since these meshes were fabricated with thin wires and tight. The pressure drop is, of course, a function of the cell geometry as well.

Fig. 9. Gas void fraction at the cell top and at the center.

Fig. 10. Pressure drop vs. flow rate curves in the single-phase flow (zero current). Electrode = nonflat plate; electrode gap = 1.1 mm; back space = 2.5 mm.

The pressure drop (ΔP_S) is represented as follows

$$\Delta P_S = 4f \frac{u_s^2}{2g_c} \frac{H}{D_e} \quad [13]$$

where the equivalent diameter of the flow channel is roughly shown by Eq. [14]

$$D_e = \frac{2w(d + d_B + t)}{w + d + d_B + t} \quad [14]$$

The friction factor is a function of the Reynolds number Re and the slope of the logarithmic plots of f vs. Re are almost independent of the inserts, as shown in Fig. 11. Consequently, we have an equation

$$f = f_1 Re^{-0.126} \quad (400 < Re < 2000) \quad [15]$$

where f_1 is the standard friction factor at $Re = 1$, and is a function of the insert.

The pressure drop vs. flow rate curves were almost independent of the rate of gas evolution even at large currents, except at low flow rates, smaller than 50 cm³/sec, where the pressure drop became negative due to the gas lift.

Fig. 11. Friction factor vs. Reynolds number in the single-phase flow. Electrode = nonflat plate; electrode gap = 1.1 mm; back space = 2.5 mm.

The frictional pressure drop multiplier in the channel equipped with a mesh electrode agrees well with Eq. [9], as shown in Fig. 12, and the exponent m varies linearly with the cell geometry ($d + d_B$), as shown in Fig. 13.

Conclusion

The cell voltage decreased with increasing flow rate since the gas void fraction decreased. The voltage of the narrow channel equipped with a pair of the flat plate electrodes was low when the flow rate of electrolyte was large enough.

The terminal voltage of the cell equipped with the nonflat plate electrode was rather high compared to that with the flat plate electrode. Therefore, careful selection of the electrode material and appropriate design of the cell equipped with the nonflat plate electrode are of great importance since the cell voltage is sensitive to the bubble effects.

The mesh electrodes of ca. 50% open yielded the lowest cell voltage. Tight meshes woven with heavy wire retard gas bubbles passing through. However, the overvoltage and the electric resistance of these electrodes, and hence the cell voltage, are relatively low.

Fig. 12. Frictional pressure drop multiplier (Ψ) vs. gas void fraction at the cell top. Electrode = ME-2; electrode gap = 1.1 mm; back space = 7.0 mm.

Fig. 13. Component m vs. cell size ($d + d_B$)

The expanded metal electrode permits gas bubbles to escape and contributes to the reduction of the cell voltage even at low flow rates.

The logarithmic plots of the friction factor vs. the Reynolds number was linear, and the slope was independent of the electrode configuration. The standard friction factor f_1 depends on the type of electrode.

The friction loss with the mesh electrode woven with thin wires less than 0.6 mm in diam was small. The friction loss with heavy wire mesh was large. Cold rolling enabled the reduction of the hydraulic resistance of mesh, whereas the open area was decreased.

The frictional pressure drop multiplier Ψ was related to the gas void fraction with a simple equation. Consequently, these factors are useful for designing a vertical cell equipped with either a flat plate electrode or a nonflat plate electrode operated under forced circulation of electrolytic solution. The experimental results are also applicable for a cell operated under natural circulation.

Conductivity of Anodic Silver Chloride during Formation

Theodore R. Beck* and David E. Rice

Electrochemical Technology Corporation, Seattle, Washington 98107

ABSTRACT

Silver electrodes were anodized in KCl, NaCl, LiCl, and HCl solutions of concentration greater than 4N. High field conduction was exhibited by the growing AgCl film during the anodizing process at current densities greater than 1 mA/cm². The high field barrier film reverts to a porous high conductivity film at applied potentials greater than 20V or when the anodizing current is interrupted or briefly reversed.

Anodic silver chloride films for Ag/AgCl reference electrodes are commonly formed in 0.05N KCl or 0.1-1N HCl at current densities of 0.4-10 mA/cm² (1). Under these conditions, porous anodic films form with specific conductivities that are 10-100 times (1-4) that of bulk AgCl. The conductivities of these films increase with the concentration and conductivity of the electrolyte in which they are measured, indicating a predominance of pore conduction.

The present work deals with formation of anodic AgCl films in concentrated (4-15N) solutions of KCl, NaCl, LiCl, and HCl. For these electrolytes, there is a region of current densities in which AgCl films exhibit high field conduction, *i.e.*, exponential relation of current density to potential, during the anodizing process. There is no systematic relation of the film conductivity to solution conductivity for the high field films, indicating a bulk film effect. This region is illustrated in Fig. 1. The high field conduction region occurs at concentrations well above common usage for anodizing silver for reference electrodes, which may account for it not being previously observed and studied.

Experimental

Anodizing experiments were conducted with silver disk or rectangular electrodes imbedded flush in epoxy resin insulation. Silver from three sources was used: 99.999% pure bead (Cominco), an unknown but high purity rod, and 99.9% pure wire. The respective dimensions of the silver electrodes were: $d = 1.8 \text{ mm}$, $A = 2.5 \text{ mm}^2$, length = 2 mm; $1.6 \times 3.2 \text{ mm}$ rectangle, $A = 5.0 \text{ mm}^2$, length = 25 mm; $d = 0.75 \text{ mm}$, $A = 0.44 \text{ mm}^2$, length = 25 mm. Pretreatment was sanding with no. 600 silicon carbide paper and rubbing with a cotton swab under the electrolyte solutions. Solutions were made from ACS specification chemicals and distilled water.

A Princeton Applied Research 173 potentiostat was used for the constant current experiments with a platinum counterelectrode. The silver electrodes were mounted in the anode facing up position so that events could be observed under a 60 \times binocular microscope.

* Electrochemical Society Active Member.

Key words: films, electrode, current density, transients.

Potential transients of the silver electrodes were measured in respect to a saturated calomel electrode. Slow low current density transients were recorded on a strip chart recorder, and fast high-current density transients were recorded on a storage oscilloscope. All experiments were carried out at room temperature, $21^\circ \pm 2^\circ\text{C}$.

Results and Discussion

Constant current experiments.—A typical potential transient at constant current is shown in Fig. 2. Five distinct regions of potential were observed over most of the range of current densities for high field conduction shown in Fig. 1, although at the higher current densities the regions A and B were indistinct. In region A, the potential at low current densities was close to that of the reversible Ag/AgCl couple. The silver surface color gradually turns brown during the period of region A, and at the end of region A, a wave of different texture is seen moving from the edges to the center of the electrode. No visible change is seen in region B. At the beginning of region C, small gas

Fig. 2. Typical potential transient at constant current. Time scale is approximately 100s down to 0.1s depending on current density from 10^{-3} to 10 A/cm 2 .

bubbles sprout from the surface. Starch-iodide paper touched to the removed electrode turned blue, indicating that the bubbles were chlorine. During region C, a whitish haze appears over the surface and increases with time of anodizing.

Region D is a nearly linear rise in potential with time. No visible change occurs on the surface other than a decrease in the gas evolution rate. The slope of the region D curve increases with current density. As region E is approached, occasional spikes of decreasing potential occur. The frequency increases with time and in region E the spikes become a continuous band. Zones of intense agitation and evolution of microbubbles are seen to move around the electrode surface during region E. The potential of region E is nearly independent of current density.

The only reasonable phenomenon that could cause such a large increase in potential in region D is increase in AgCl film resistance due to thickening with time. The AgCl thickness for a dense film would vary with time as

$$l = \frac{iM}{zF\rho} (\tau - \tau_1) \quad [1]$$

and the conductivity is defined by

$$\kappa = \frac{il}{\Delta\phi} \quad [2]$$

A constant slope in region D shows that AgCl conductivity is constant at constant current density, and it can be readily shown that

$$\kappa = \frac{Mi^2}{zF\rho(d\phi/d\tau)} \quad [3]$$

The value of $M/zF\rho$ is 2.67×10^{-4} cm 3 /C for AgCl.

Values of κ calculated from Eq. [3] and experimental data for three concentrations of chloride solutions are given in Fig. 3. Because of the high solubility of LiCl, a wide range of concentrations was possible with LiCl. Current density was based on geometric area; no correction was made for surface roughness. Within experimental error, no difference was observed in conductivities for the three electrodes with purities from 3-9 to 5-9.

Conductivity is seen to vary as the first power of current density in Fig. 3. A linear relationship of conductivity to current density in Fig. 3 is consistent with high field conduction

$$i = i_0 \exp\left(\frac{\beta\Delta\phi}{l}\right) \quad [4]$$

for which the integral conductivity, Eq. [2], is

$$\kappa = \beta i / \ln(i/i_0) \quad [5]$$

The term $\ln(i/i_0)$ varies slowly with current density as discussed further on. The higher measured conduc-

Fig. 3. Calculated conductivities of AgCl during anodizing in chloride solutions at constant current (region D, Fig. 2) compared to literature data for conductivity of AgCl after formation in lower concentration chloride.

tivities in the 6N and 15N LiCl solutions are not explained at this time.

The vertical bar at the lower end of the line for each concentration in Fig. 3 indicates the current density below which region D of Fig. 2 is not observed. These are the values plotted in Fig. 1. At lower current densities the region C is extended and becomes noisy or the potential goes into violent fluctuations. Some published conductivities for preformed AgCl from the common usage region of Fig. 1 are given in Fig. 3 for comparison.

The theoretical value of β based on an ion hopping model (5) is

$$\beta_{\text{Theor}} = \frac{\alpha z F a}{RT} \quad [6]$$

For $\alpha = 0.5$ and the hop distance, a , equal to the sum of ionic diameters of Ag $^+$ and Cl $^-$, $2(1.26 + 1.81) = 6.14$ Å (6), the value of β_{Theor} at 294 K is 1.2×10^{-6} cm/V. The experimental values in Fig. 3 ($\beta = \kappa \ln(i/i_0)$ at $i = 1$ A/cm 2) are 2-4 times this value, which may be attributed in part to the term $\ln(i/i_0)$ and in part to surface roughness.

The true current density should be smaller by the roughness factor, γ , and the true conductivity calculated by means of Eq. [3] should be smaller by a factor of γ^2 . The result in Fig. 3 is that the plotted experimental conductivity is high by a factor of γ . Birss and Wright (7) observed a roughness factor of 2-4 by EDL capacitance measurements for silver surfaces polished with up to 1200 grade emery paper. In our experiments, some electropolishing is to be expected under the growing AgCl films.

Superimposed triangular wave.—To confirm that the growing AgCl films conduct by the high field mechanism, fast transient experiments were conducted during film growth in region D. A 10 Hz triangular current wave of amplitude $\pm 1.1 i_1$ was superimposed for a second or less on the steady anodizing current i_1 at certain potentials, ϕ_1 . Current-voltage curves were displayed on the storage oscilloscope. Results of a set of experiments in saturated LiCl are shown in Fig. 4. The curves are clean and reproducible at a frequency around 10 Hz, whereas lower frequencies disturbed the anodizing current for too long a time and high frequencies gave hysteresis loops. The curves go smoothly through the origin and give negative potentials at negative current densities; the Ag/AgCl reversible potential is essentially equal to the SCE

Fig. 4. Potential-current density transients for 10 Hz triangular current density wave superimposed on the steady $i_1 = 0.01 \text{ A/cm}^2$ at various potentials. ϕ_1 , in region D (Fig. 2), saturated LiCl, 5 mm^2 electrode.

potential within the accuracy of the scale of Fig. 4. Increase in the amplitude of the triangular current density wave in the negative direction gave a sharp decrease in magnitude of the potential (higher conductivity), which, however, recovered to the Fig. 4 displayed potentials on the positive sweep. This sharp decrease in potential (increase in conductivity) for a large negative current density sweep and recovery of potential suggests incipient pore or crack formation and healing.

Data from Fig. 4 are plotted semilogarithmically in Fig. 5 in accordance with the high field equation. The curves become linear at the high current density ends but deviate at the low current density ends. Extrapolation of the linear region to zero potential in Fig. 5 gives $i_0 = 0.0022 \pm 0.0005 \text{ A/cm}^2$ in the high field equation. Since the curves in Fig. 4 go linearly through the origin and are logarithmic in Fig. 5 at higher current densities, the hyperbolic sine function was fit to the data.

$$i = 2i_0 \sinh\left(\frac{\beta \Delta \phi}{l}\right) \quad [7]$$

The inverse function

$$\sinh^{-1}\left(\frac{i}{2i_0}\right) = \frac{\beta}{l} \Delta \phi \quad [8]$$

was used to replot data from Fig. 4 with $i_0 = 0.0022$

Fig. 5. Replot of Fig. 4 curves on semilogarithmic coordinates

Fig. 6. Replot of Fig. 4 curves in accordance with hyperbolic sine function. ϕ_1 is the quasi steady-state potential at which the triangular wave is superimposed. $i_0 = 0.0022 \text{ A/cm}^2$, $i_1 = 0.01 \text{ A/cm}^2$.

A/cm^2 . As shown in Fig. 6, the data plot as straight lines using Eq. [8]. Conductivity of anodically forming silver chloride appears to follow a function analogous to the Butler-Volmer equation of electrochemical kinetics.

Discussion.—The slopes of the lines in Fig. 6 can be used to calculate the parameter, l/β

$$\frac{l}{\beta} = \frac{d\phi}{d \sinh^{-1}\left(\frac{i}{2i_0}\right)} \quad [9]$$

The value of l at each potential, ϕ_1 , can be determined from Eq. [1] if τ_1 is defined. The value of τ_1 was determined from the zero potential intercept of the plot of the slopes of the curves in Fig. 6 vs. time from τ_0 (Fig. 2). The value of $\tau_1 = 53 \text{ sec}$ found corresponds approximately to τ_1 shown in Fig. 2. In other words, it appears that most of the current density in regions A, B, and C builds porous AgCl and generates chlorine, rather than contributing to the barrier layer.

Values of i_0 for experiments over a range of anodizing current densities, i_1 , for which measurements were feasible are plotted in Fig. 7. The linear least squares fit to these data in logarithmic coordinates gives

$$i_0 = 0.089 i_1^{0.81} \quad [10]$$

for $0.003 < i_1 < 0.06 \text{ A/cm}^2$.

Fig. 7. Relation of i_0 to i_1

The value of i_0 is not constant, but varies as the 0.81 power of the base applied current density, i_1 . Assuming Eq. [10] to apply over the whole range of the experiments, $0.001 < i_1 < 10$ A/cm², the value of $\ln(i_1/i_0)$ in Eq. [5] for steady-state anodizations varies from 1.11 to 2.86.

The extrapolated current density at which $i_1 = i_0$, and below which low field or ohmic conduction would always be expected, is $i_1 = i_0 = 3.0 \times 10^{-6}$ A/cm², a value outside of the possible range of the present experiments. The low field conductivity from Eq. [7] would be

$$\kappa_\Omega = 2i_0\beta \quad [11]$$

The extrapolated lower limit i_0 and $\beta = 5 \times 10^{-6}$ cm/V from Fig. 3 in Eq. [11] give $\kappa_\Omega = (2)(3 \times 10^{-6})(5 \times 10^{-6}) = 3.0 \times 10^{-11}$ S · cm⁻¹. This value is in approximate agreement with the intrinsic conductivity from the paper by Corish and Jacobs (8), extrapolated to a temperature of 298 K. These results indicate that the conductivity of silver chloride at the high current densities ($>10^{-3}$ A/cm²) reported herein are due to the intrinsic conductivity of AgCl rather than extrinsic conductivity from impurities which give a value of about 10^{-7} S · cm⁻¹ (8, 9) for 5-9 purity silver chloride and 3×10^{-6} S · cm⁻¹ (8) for 3-9 AgCl. These literature conductivities were measured at small current densities with impedance bridges. Impurities in the silver electrodes would be expected to be divalent and less noble than silver and be oxidized into the silver chloride as ionic impurities.

Interruption of the current during the anodizing process in region D of Fig. 2 for periods of seconds or more followed by reapplying the current results in a restart through regions A to D. The periods of regions A, B, and C are shorter and the initial slope in region D steeper to the potential at which the current was interrupted compared to the first curve. The slope then becomes the same as the first curve. These data suggest that pores or cracks form in the barrier film when the current is interrupted and heal when the current is turned on again.

The noise and erratic potentials in region C at low current densities also indicate an instability and opening of pores or cracks. The rapid decrease in the absolute value of the negative potential (increased conductivity) at negative current densities in the superimposed triangular current density wave (Fig. 4 type experiment) also indicates opening of pores. The time for the conductivity to increase at negative current density in the negative sweep was observed to be about 20 msec. Even more rapid cracking and healing is noted in Fig. 4 for the thicker films. The time for the shortest excursions in potential (conductivity increase) is less than a line width in Fig. 4, ~ 0.2 msec.

The noise and the potential plateau in region E, Fig. 2, also suggest a continuous widespread fracture and healing process in the AgCl film. The accompanying intense agitation by microbubbles of chlorine is also consistent with Cl⁻ discharge at high overpotential at the base of cracks in the AgCl layer. The existence of region E suggests that the thicker AgCl layer is under considerable mechanical strain. Since the potential of region E is nearly independent of current density in the region $10^{-3} < i < 10$ A/cm² for a given electrolyte, the AgCl film thickness in region E is nearly independent of current density. The thickness is

$$l_E = \beta \Delta \phi_E / \ln(i/i_0) \quad [12]$$

from Eq. [5] and [2]. The barrier AgCl film thickness in region E is therefore about $l_E = (5 \times 10^{-6} \text{ cm/V})(20\text{V}) = 1 \times 10^{-4}$ cm or on the order of one micrometer, neglecting $\ln(i/i_0)$.

Bro and Marincic (10) observed a potential-time dependence like that in Fig. 2 on galvanostatic charging of silver in 2M ZnCl₂, 0.5M NaClO₄ solution at

0.15 A/cm² but did not try to explain it. They attributed their plateau at 30V to Joule heating of their thin electrodes and onset of boiling. A much smaller temperature rise is expected for the relatively more massive silver electrode used in the majority of the present experiments in which the 5 mm² rod was 25 mm long. The heat generated in the growing AgCl film from τ_1 to τ_E in Fig. 2 is

$$Q_g = \int_{\tau_1}^{\tau_E} i \phi d\tau \quad [13]$$

Substitution of $i d\tau$ from Eq. [3] and [5] into Eq. [13], assuming $\phi = 0$ at $\tau = \tau_1$ and neglecting $\ln(i/i_0)$ gives

$$Q_g = \frac{\beta z F \rho}{M} \int_0^{\phi_E} \phi d\phi = \frac{\beta z F \rho \phi_E^2}{2M} \quad [14]$$

The heat generated in an AgCl film in region D, irrespective of current density, is approximately

$$Q_g = \frac{(5 \times 10^{-6})(20^2)}{(2)(2.67 \times 10^{-4})} = 3.75 \text{ J/cm}^2 \quad [15]$$

The sensible heat that can be absorbed by the silver rod is

$$Q_s = \rho_s l_s C_p \Delta T \quad \text{J/cm}^2 \quad [16]$$

If all of the heat generated is absorbed by the silver rod, the temperature rise is

$$\Delta T = \frac{3.75}{\rho_s l_s C_p} \quad [17]$$

Handbook values of silver density and specific heat (10) and $l = 2.5$ cm give

$$\Delta T = (3.75)/(10.5)(2.5)(0.234) = 0.61^\circ\text{C} \quad [18]$$

The time constant for heat flow into the silver rod is

$$\tau = \frac{l^2}{(k_s/\rho_s C_p)} \quad [19]$$

which for handbook data (10) for silver gives

$$\tau = (2.5)^2(10.5)(0.234)/4.19 = 3.7 \text{ sec} \quad [20]$$

All experiments at current densities < 0.1 A/cm² had $(\tau_E - \tau_1) > 3.7$ sec so that temperature rise would have been of no consequence. At 10 A/cm², the value of $(\tau_E - \tau_0)$ (Fig. 2) is about 0.03 sec and $(\tau_1 - \tau_0)$ is small at this current density. This value gives a heat conduction length of 0.2 cm from Eq. [19]. The temperature rise of this length in Eq. [17] gives $\Delta T = 7.6^\circ\text{C}$ so that temperature rise should not have caused a significant error in any of the experiments with the silver rod or for the 5-9 Ag electrode which had about 0.2 cm length in the epoxy resin. The temperature rise should actually be smaller than these calculated values due to conduction of heat to the epoxy resin surrounding the silver anodes and to transport of heat to the electrolyte solution. The temperature rise at the worst case by conduction within the AgCl barrier layer at 20V is calculated to be less than 0.5°C at 10 A/cm² using a typical handbook value of conductivity for alkali halide salts of ~ 50 mW · cm⁻¹ · K⁻¹ (6).

A question is whether chloride ion can be transported from solution to the silver chloride surface fast enough during the anodizing process. This question can be answered by comparing the time $(\tau_E - \tau_0)$ in Fig. 2 to the time to deplete Cl⁻ at the surface according to Sand's equation

$$i_- = \frac{\frac{1}{2}z_-FC_- \sqrt{\frac{\pi D_-}{\tau}}}{(1 - t_-)} \quad [21]$$

Experimental values of τ_E vs. i in Fig. 8 are compared to Eq. [21] for $C_- = 6 \times 10^{-3}$ mol/cm³, $D_- = 1 \times 10^{-5}$ cm²/sec, and $t_- = 0.6$. Results in Fig. 8 show that chloride ion depletion is not a limiting factor in reaching region E in 6N Cl⁻ solutions.

Fig. 8. Comparison of time to reach region E to time for Cl^- ion depletion (Eq. [21]) as a function of current density in $6N \text{ Cl}^-$.

Events in regions A, B, and C of Fig. 2 may now be speculated upon. Region A is probably dissolution of silver ion to form a supersaturated solution of AgCl which precipitates AgCl particles at the end of region A as observed for other metals and their salts (12, 13). Region B may be the filling in of further AgCl between the first particles by the mechanism of AgCl^{n-n+1} complex formation and transport described by Katan, Szpak, and Bennion (14). As the voids between particles fill in, the actual current density and overpotential rise at the end of region B until chloride ion discharges at the silver surface to form Cl_2 . The voids continue to fill during region C until virtually complete coverage by AgCl at the metal surface, and then the high field conduction process can start. There is apparently a competition between filling the voids and cracking of the existing AgCl layer. High chloride ion concentration which promotes AgCl^{n-n+1} formation, and high current densities, favor the void filling process over the cracking process and thus, the formation of the barrier AgCl film.

Formation of a barrier layer film has been reported by Birss and Wright (15) for silver in $1N \text{ NaI}$ solution at a current density of about 0.2 A/cm^2 . They did not observe the barrier type AgI effect in $0.1N \text{ NaI}$. These observations are in accord with the relative solubilities of the silver halide complexes in chloride and iodide solution. Figure 1 shows that the boundary chloride concentration at a current density of 0.2 A/cm^2 is about $5N$. The solubility of AgCl in $5N$ chloride is about $10^{-2}N$ (15). Silver iodide has this solubility in $0.9N$ iodide (16), which is between the concentrations forming and not forming barrier-type AgI of Birss and Wright (15). Their conductivity of AgI at 0.2 A/cm^2 of 8.7×10^{-5} is about two orders of magnitude larger than the corresponding value for AgCl in Fig. 3.

Conclusions

The following conclusions are made concerning anodic formation of silver chloride in concentrated chloride solutions.

1. A barrier layer film of AgCl exhibiting high field conduction forms at high current densities in KCl, NaCl, LiCl, and HCl solutions at concentrations greater than $4N$.

2. A superimposed triangular current density on the anodizing current density, i_1 , gives a response that can be fit by the expression

$$i = 2i_0 \sinh \left(\frac{\beta \Delta \phi}{l} \right)$$

in which $\beta \cong 5 \times 10^{-6} \text{ cm/V}$ and i_0 is a function of the base current density, i_1 .

3. The barrier film reverts to a porous condition at $\Delta \phi > 20V$ or when the anodizing current is interrupted or briefly reversed.

ABSTRACT

Seebeck coefficient and electrical conductivity are measured at 1300 K vs. oxygen partial pressure in the p_{O_2} range between $2.12 \cdot 10^4$ -23 Pa. Comparative analysis of both parameters indicates that the mobility term for electron holes in undoped CoO is changing vs. oxide composition. Its average value is: $\mu_h = 0.33 \pm 0.03 \text{ cm}^2 \text{ V}^{-1} \text{ sec}^{-1}$. Singly ionized cation vacancies were established as predominant defects for undoped CoO and doubly ionized cation vacancies for CoO-Cr₂O₃ solid solutions. No simple relationship is observed between the concentration of Cr incorporated into CoO and the generated hole concentration as predicted by the controlled valency theory. In contrast to this theory, the experimental data indicate a strong decrease of the Fermi energy E_F vs. Cr concentration for CoO-Cr₂O₃ solid solutions. Accordingly, significant interaction between point defects in Cr-doped CoO crystal is postulated. The application of the Debye-Huckel theory for strong electrolytes allows for the calculation of E_F which is in an agreement with experimental results. The defect equilibrium constants are calculated for formation of singly and doubly ionized cation vacancies in CoO at 1300 K

$$K_v' = [V_{Co}'] [h'] f_h' f_v' p_{O_2}^{-1/2} = 6.3 \pm 2.0 \cdot 10^{-8} [\text{Pa}^{-1/2}]$$

and

$$K_v'' = [V_{Co}''] [h']^2 f_v'' f_h^2 p_{O_2}^{-1/2} = 1.2 \pm 0.5 \cdot 10^{-11} [\text{Pa}^{-1/2}]$$

The electrical conductivity method is frequently used in studies of structural properties of ionic crystals (1-3). The interest in this method is generated because of its high sensitivity to defect structure. In these studies, it is generally considered that electrical conductivity is proportional to concentration of electronic carriers generated during ionization of crystal point defects. This requires an assumption that the mobilities of electronic carriers are independent of their concentration and thus, of crystal composition. This is usually accepted for oxides exhibiting lower concentration of defects. However, if an increasing concentration of defects leads to their mutual interactions, the mobility term is changing. Then the correct interpretation of electrical conductivity data should involve independent discussion of both concentration and mobility.

The effect of changing mobility of electronic carriers vs. crystal composition is not significant in the interpretation of thermoelectric power data which enables one to directly calculate the concentration of electronic carriers in the crystal. Furthermore, comparative studies of both electrical conductivity and thermoelectric power enable determination of the mobility term.

The purpose of the present work is to perform comparative studies of both electrical conductivity and Seebeck effect for an oxide crystal as a function of its composition. Both undoped CoO and CoO-Cr₂O₃ solid solutions were chosen as model systems.

Properties of undoped CoO were the subject of numerous studies (4-9). Recent works strongly indicate that electrostatic interactions between point defects are rather important. The interactions producing a marked deviation from the ideal point defect theory were observed by Chen, and Mason (10) who studied Seebeck effect vs. p_{O_2} . Morin and Dieckmann (11) have also found variations of chemical diffusion coefficient vs. crystal composition that is considered in terms of defect interactions. Although different observations were reported elsewhere (9), there has been a gradual

Key words: Seebeck effect, electrical conductivity, nonstoichiometry, Fermi energy, thermopower, cobaltous oxide, point defect interactions.

accumulation of data indicating that the deviation from ideality must be taken into account for undoped CoO, especially at higher activity close to CoO-Co₃O₄ phase boundary and at lower temperatures (10). One may expect that these interactions should have an effect on the mobility of electronic carriers as well. Comparative study of both electrical conductivity and Seebeck effect is a possible quantitative approach of solving this question.

Cr-doped CoO is even a better object for studies of defect interactions since in this case, the concentration of defects may be easily controlled within the solubility region of the CoO-Cr₂O₃ system, which amounts to 1 atomic percent (a/o) at 1000°C (12).

Definition of Terms

The electrical conductivity of a predominantly p-type semiconductor may be expressed as

$$\sigma = B \mu_h [h'] e \quad [1]$$

where: B is the constant value involving sample geometry in cm^{-1} , μ_h is the mobility of electron holes in $\text{cm}^2 \cdot \text{V}^{-1} \cdot \text{sec}^{-1}$, $[h']$ is the concentration of electron holes in cm^{-3} , and e is the elementary charge in C. For a metal deficient oxide Me_{1-y}O , lattice electroneutrality requires the correlation between the concentrations of quasifree holes and cation vacancies as predominant lattice defects

$$[h'] = 2[V''_{Me}] + [V'_{Me}] \quad [2]$$

where V'_{Me} and V''_{Me} are singly and doubly ionized cation vacancies, respectively.

At lower temperatures, formation of neutral vacancies V^x_{Me} should also be taken into account.

Depending on temperature and crystal composition, the following three limiting cases may be considered

$$[V^x_{Me}] \gg [V'_{Me}] + [V''_{Me}] \quad [3]$$

$$[V'_{Me}] \gg [V^x_{Me}] + [V''_{Me}] \quad [4]$$

$$[V''_{Me}] \gg [V^x_{Me}] + [V'_{Me}] \quad [5]$$

where

$$[V^x_{Me}] + [V'_{Me}] + [V''_{Me}] = y$$

Accordingly, assuming application of the mass action law to defects in crystal, the following relationships may be written for the concentration of predominant defects as a function of T and p_{O_2} when the crystal is in equilibrium with p_{O_2} in the gas phase

$$[V_{Me}^x] = \text{const. } p_{O_2}^{1/2} \exp\left(-\frac{\Delta H_f}{RT}\right) \quad [3a]$$

$$[V_{Me}'] = [h\cdot] = \text{const. } p_{O_2}^{1/4} \exp\left[-\frac{\frac{1}{2}\Delta H_f}{RT}\right] \quad [4a]$$

$$[V_{Me}''] = \frac{1}{2} [h\cdot] = \text{const. } p_{O_2}^{1/6} \exp\left[-\frac{\frac{1}{3}\Delta H_f}{RT}\right] \quad [5a]$$

Generally for ionized defects we may write

$$[V_{Me}^{z\cdot}] = \frac{1}{z} [h\cdot] = \text{const. } p_{O_2}^{1/n} \exp\left[-\frac{\frac{2}{n}\Delta H_f}{RT}\right] \quad [6]$$

where constant involves the entropy term, ΔH_f is formation enthalpy of defects in crystal, and z is ionization degree of cation vacancies which may be related to n

$$n = 2(z + 1) \quad [6a]$$

When trivalent cations F^{3+} are substituted into the lattice exhibiting a deficit of metal $Me_{1-y}O$

and assuming that $[h\cdot] \ll [V_{Me}'']$, the lattice electro-neutrality condition acquires the simple form

$$[V_{Me}'] = \frac{1}{2} [F_{Me}'] \quad [8]$$

Then application of the mass action law leads to the relation

$$[V_{Me}''] = \text{const. } p_{O_2}^{1/4} \exp\left[-\frac{\frac{1}{2}\Delta H_f}{RT}\right] \quad [9]$$

In both thermal and chemical equilibrium $1/n$ in Eq. [6] may be expressed as

$$\left\{ \frac{1}{n} = \frac{\partial \ln [h\cdot]}{\partial \ln p_{O_2}} \right\}_{T=\text{const.}} \quad [10]$$

Assuming that $\mu_{h\cdot}$ is independent of crystal composition, we obtain by combination of Eq. [1] and [10]

$$\left\{ \frac{1}{n} = \frac{\partial \ln \sigma}{\partial \ln p_{O_2}} \right\}_{T=\text{const.}} \quad [11]$$

Determination of thermoelectric power α enables one to calculate the Fermi energy of crystal E_F and, therefore, the concentration of electronic carriers, independently of a knowledge of the mobility term $\mu_{h\cdot}$, which is rather difficult to determine. For p-type semiconductors, α is intercorrelated with E_F and thus with $[h\cdot]$ according to the relation

$$\alpha = \frac{k}{e} \left(\frac{E_F}{kT} + \frac{S_V}{k} \right) \quad [12]$$

where: E_F is the Fermi energy, S_V is the parameter referring to vibrational entropy associated with the polaron environment, and k is the Boltzmann constant ($8.6173 \cdot 10^{-5} \text{ eV} \cdot \text{K}^{-1}$). Taking into account the Fermi-Dirac statistics

$$\left\{ \frac{[h\cdot]}{N_{h\cdot}} = \{1 + \exp(E_F/kT)\}^{-1} \right\} \quad [13]$$

where $N_{h\cdot}$ is density of states, Eq. [12] assumes the form

$$\alpha = \frac{k}{e} \ln \frac{N_{h\cdot} - [h\cdot]}{[h\cdot]} + \frac{S_V}{k} \quad [14]$$

Assuming $N_{h\cdot} \gg [h\cdot]$, the simple Maxwell-Boltzmann statistics may be applied. Consequently

$$\alpha = \frac{k}{e} \ln \frac{N_{h\cdot}}{[h\cdot]} + \frac{S_V}{k} \quad [15]$$

Assuming $E_F \gg kT$, Eq. [13] assumes the form

$$E_F = kT \ln \frac{N_{h\cdot}}{[h\cdot]} \quad [16]$$

Assuming S_V is independent of crystal composition, the combination of Eq. [11] and [15] leads to the expression

$$\left\{ \frac{1}{n} = -\frac{\partial \alpha}{\ln p_{O_2}} \cdot \frac{k}{e} \right\}_{T=\text{const.}} \quad [17]$$

A difference in the value of $1/n$ calculated according to Eq. [11] on one hand, and [17] on the other, results in the mobility term $\mu_{h\cdot}$, which may vary with composition. Combining Eq. [1] and [15], we obtain the expression which enables one to calculate the mobility term

$$\ln \mu_{h\cdot} = \ln \sigma + \frac{e\alpha}{k} - \frac{S_V}{k} - \ln B - \ln N_{h\cdot} - \ln e \quad [18]$$

Experimental

The preparations were obtained by annealing of co-precipitated mixtures of both cobalt and chromium hydroxides at 1270 K for 5 hr. The preparation procedure, determination of Cr concentration, and spectral analysis of impurities are described elsewhere (12). The measuring setup for Seebeck effect and electrical conductivity is shown in Fig. 1. The CoO sample in the form of a pellet was placed between the two Pt measuring electrodes [Fig. 1 (3)]. The temperature gradient across the pellet was achieved by two heating elements [Fig. 1 (10)] located on both sides of the pellet. The measuring setup was placed inside the aluminum tube [Fig. 1 (6)]. The required oxygen activity in the chamber was achieved by Ar-O₂ mixture flowing through the measuring tube. Before taking the measurements, the sample was standardized by heating at 1300 K in air and in argon until a constant value of electrical conductivity in the two consecutive runs was reached.

The Seebeck voltage ΔV was measured for six to eight different temperature gradients. The Seebeck coefficient α was calculated from slopes of ΔV vs. ΔT dependences

$$\alpha = \frac{\partial V}{\partial T} \cong \frac{\Delta V}{\Delta T} \quad [19]$$

The electrical conductivity was measured by the classical four-probe method for five different voltages ranging between 0.5-5V (3).

Results and Discussion

Undoped CoO.—The obtained experimental data as well as the calculated values of α at p_{O_2} ranging from $2.12 \cdot 10^4$ to 23 Pa and $T = 1300$ K are listed in Table I and illustrated in Fig. 2. The following relationships may be written for σ and α vs. p_{O_2} , respectively

$$\ln \sigma = 1.74 + 0.258 \ln p_{O_2} \quad [20]$$

$$\alpha_{\text{exp}} = 0.352 - 0.0205 \ln p_{O_2} \quad [20a]$$

Therefore, we obtain for n , respectively

Fig. 1. Measuring setup for Seebeck effect and electrical conductivity. (1) Gas inlet, (2) gas outlet, (3) measuring Pt electrodes, (4) thermocouples PtRh10-Pt, (5) oxygen gauge CoO, (6) aludum tube, (7) Pyrex joints, (8) Pt wires sealed through Pyrex glass, (9) furnace, (10) microheaters.

$$n = 3.88 \pm 0.12 \quad [21]$$

$$n = 4.20 \pm 0.24 \quad [21a]$$

Both Eq. [20] and [21] indicate that singly ionized cation vacancies predominate in CoO for the conditions under study. Therefore, the following equilibrium should be considered

for which the equilibrium constant is

$$K_{V'} = [V'_{\text{Co}}][h]p_{\text{O}_2}^{-1/2} \quad [23]$$

Therefore, we assume the condition [4] and Eq. [4a] for calculation of $[V'_{\text{Co}}]$ in undoped CoO. Appropriately, the electroneutrality condition of the lattice Eq. [2] may be reduced to the form

$$[V'_{\text{Co}}] = [h] \quad [24]$$

Combining Eq. [15] and [23], we may calculate the entropy term

$$\frac{S_V}{k} = \frac{1}{2} \left\{ \ln K_{V'} + \frac{1}{2} \ln p_{\text{O}_2} \right\} + \frac{e\alpha}{k} - \ln N_{h'} \quad [25]$$

Assuming full ionization of cation vacancies in CoO, ($N_{h'} = 1$) and also taking $K_{V'}$ after Kofstad (1)

$$K_{V'} = 10^{-2} \exp(-13,000/RT)$$

Equation [25] leads to

$$\frac{S_V}{k} = -0.868 \pm 0.080$$

This value is close to that determined for the wustite phase by Seltzer and Hed (2) ($S_V/k = -0.89$).

According to the theory of small polarons, S_V may be evaluated as (13)

$$\frac{S_V}{k} = \beta E_m/kT \quad [26]$$

where E_m = activation energy of mobility, and

$$\beta \leq 1$$

According to Fisher and Tannhauser (4), S_V for CoO is close to zero around $p_{\text{O}_2} = 1$ Pa and increases at very low p_{O_2} values. Generally, the component of α resulting from S_V in Eq. [15] remains within $10 \mu\text{V K}^{-1}$ (14).

Table I. Determined values of α_{exp} and $\ln \sigma$ as well as calculated α_{calc} for undoped CoO

$\ln p_{\text{O}_2}$ [p_{O_2} in Pa]	α_{exp} [$\text{mV} \cdot \text{K}^{-1}$]	α_{calc} [$\text{mV} \cdot \text{K}^{-1}$]	$\ln \sigma$ [σ in Ω^{-1}]
9.97	0.391	0.374	1.294
8.67	0.412	0.402	0.983
8.12	0.415	0.414	0.889
7.26	0.434	0.432	0.710
7.19	0.425	0.434	0.685
3.16	0.527	0.521	-0.452

Thus, for CoO it is negligible. Generally, it seems that for semiconductors for which conduction occurs according to a "hopping mechanism" and also for smaller deviations from stoichiometry, this assumption seems to be valid. If this is assumed, Eq. [25] leads to

$$N_{h'} = 0.43 \pm 0.03$$

This value seems reasonable if a significant concentration of defects is taken into account, as is the case for CoO where the defects in crystal cannot be considered as an ideal solution (10, 11).

Accordingly, assuming $S_V = 0$ and $N_{h'} = 0.43$, we may calculate α from Eq. [15] (see Table I). As it results from the above consideration, both presented assumptions (*i.e.*, $N_{h'} = 1$, $S_V/k = 0.868$ or $N_{h'} = 0.43$, $S_V = 0$) provide a satisfactory agreement with the experiment. However, the second possibility is more consistent with the theory of thermoelectric phenomena in crystals. Therefore, in the considerations below we assume that $S_V = 0$ and $N_{h'} = 0.43$. A good agreement between experimental α_{exp} and calculated α_{calc} values is observed. The inverse of oxygen exponent n (Eq. [6]), computed from both σ and α , is close to 4,

Fig. 2. $\ln \sigma$ and α vs. $\ln p_{\text{O}_2}$ for undoped CoO at 1300 K ($B = 3.7 \text{ cm}^{-1}$).

Table II. Parameter n in Eq. [8] reported in literature

No.	Authors	n	p_{O_2} range (Pa)	T (K)	Experimental method
1.	Fisher and Tannhauser (4)	1/3.8-1/4.3 1/5.7-1/6.1	10^5 – 10^{-1} 10^{-1} – 10^{-7}	1190-1620	electrical conductivity
2.	Morin (6, 7)	1/4	10^5 – 10^2	1270	electrotransport
3.	Mrowec and Przybylski (15)	1/4.0-1/3.4	$6.7 \cdot 10^4$ – 66.7	1570	volumetry
4.	Carter and Richardson (11)	1/3.4	$5.6 \cdot 10^2$ – 10^5	1420	gravimetry
5.	Chowdhry and Coble (9)	1/3.8-1/4.2	10^4 – 10^5	1170-1310	electrical conductivity

which is in agreement with singly ionized cation vacancies as major type of defects as postulated in the literature at higher p_{O_2} (4, 5). Table II summarizes some data of n for CoO (4, 6, 7, 15, 16).

The observed difference in n determined in the present work from σ on one side (3.88) and from α on the other (4.20) is beyond experimental error. In determination of n , we usually assume that $\mu_{h^{\cdot}}$ is constant vs. oxide composition (1, 3). However, this assumption is not obvious for CoO. Therefore, assuming that $n = 4.20$, determined from α , is correct, Eq. [18] was applied to calculate the mobility term $\mu_{h^{\cdot}}$ which is listed in Table III. Its average value in the p_{O_2} range under study yields $\mu_{h^{\cdot}} = 0.329 \text{ cm}^2 \text{ V}^{-1} \text{ sec}^{-1}$. This value is in good agreement with that given by Fisher and Tannhauser (4) ($\mu_{h^{\cdot}} = 0.4 \text{ cm}^2 \text{ V}^{-1} \text{ sec}^{-1}$). However, in contrast to literature reports (8, 17), the present work indicates that $\mu_{h^{\cdot}}$ for CoO varies with p_{O_2} vs. crystal composition.

CoO-Cr₂O₃ solid solutions.—Crystals of three different concentrations of chromium were prepared containing 0.048, 0.49, and 0.90 a/o Cr. These concentrations are well below the solubility limit of Cr in CoO which amounts 1 a/o (12).

Figure 3 illustrates, as example, the dependence of both $\ln \sigma$ and α vs. $\ln p_{O_2}$ at 1300 K for $[\text{Cr}] = 0.048$ a/o. The parameters n determined from both σ (n_{σ}) and α (n_{α}) are shown in Table IV. As can be seen, both sets of data are close to four, which is in agreement with the substitutional mechanism of Cr incorporation into CoO

where the electroneutrality condition requires

$$[\text{Cr}'_{\text{Co}}] = 2[V''_{\text{Co}}] \quad [28]$$

The experimental values of Fermi energy (E_F)_{exp} were determined from Eq. [12]. Curve 1 in Fig. 4 illustrates (E_F)_{exp} vs. $[\text{Cr}'_{\text{Co}}]$ at $p_{O_2} = 2.12 \cdot 10^4$ Pa. As seen, (E_F)_{exp} initially slightly increases by 0.03 eV and then sharply

Table III. Mobility of electron holes $\mu_{h^{\cdot}}$ calculated from Eq. [1] and [18] ($B = 3.75 \text{ cm}^{-1}$)

$\ln p_{O_2}$ (p_{O_2} in Pa)	$\mu_{h^{\cdot}}$ ($\text{cm}^2 \text{ V}^{-1} \text{ sec}^{-1}$)
9.97	0.367
8.67	0.343
8.12	0.323
7.26	0.337
7.19	0.296
3.16	0.310
Avg. 0.329 ± 0.025	

Table IV. Parameter n determined from σ (n_{σ}) and α (n_{α}) for CoO-Cr₂O₃ solid solutions at $T = 1300$ K

No.	Cr concentration (a/o)	n_{σ}	n_{α}
1.	—	3.88 ± 0.12	4.20 ± 0.24
2.	0.048	4.14 ± 0.07	4.25 ± 0.36
3.	0.49	4.60 ± 0.20	4.52 ± 0.21
4.	0.90	3.83 ± 0.12	4.37 ± 0.38

decreases by 0.11 eV, relative to the value for undoped CoO. This final decrease of (E_F)_{exp} is in apparent contradiction with the controlled valency theory. According to this theory, the formation of donor centers causes an increase in E_F .

Assuming doubly ionized cation vacancies V''_{Co} as predominant defects in CoO-Cr₂O₃ solid solutions, the following equilibrium should also be taken into account.

for which the equilibrium constant is

$$K_{V''} = [V''_{\text{Co}}][h^{\cdot}]^2 p_{O_2}^{-1/2} \quad [30]$$

Considering the condition Eq. [28], we obtain for $[h^{\cdot}]$

$$[h^{\cdot}] = p_{O_2}^{1/4} (2K_{V''})^{1/2} [\text{Cr}'_{\text{Co}}]^{-1/2} \quad [31]$$

Assuming that for CoO $S_V = 0$, and considering Eq. [16] and [31] we may express E_F vs. $[\text{Cr}'_{\text{Co}}]$

$$E_F = \frac{kT}{2} \ln [\text{Cr}'_{\text{Co}}] - \frac{kT}{2} \left\{ \ln 2K_{V''} + \frac{1}{2} \ln p_{O_2} \right\} + kT \ln N_{h^{\cdot}} \quad [32]$$

Equation [32] enables one to calculate theoretical changes of E_F vs. $[\text{Cr}'_{\text{Co}}]$. For calculations, we assume that for undoped CoO the concentration of impurities

Fig. 3. $\ln \sigma$ and α vs. $\ln p_{O_2}$ for CoO + 0.048 a/o Cr at 1300 K

Fig. 4. Fermi energy E_F plotted vs. $[CrCo]$. (1) Experimental data, (2) calculated relative changes of E_F using concentrations of defects, (3) theoretical dependence E_F vs. $CrCo$ calculated using defect activities.

forming donor centers equals 0.01 a/o (12). This value was substituted in Eq. [32] instead of $[CrCo]$ for the undoped sample of CoO. The calculations lead to relative changes of E_F vs. $[CrCo]$ which is illustrated by curve 2 in Fig. 4. The observed increase of ΔE_F is consistent with the generally acknowledged classical considerations resulting from the ideal point defect theory. As seen, however, there is a considerable discrepancy between the theoretical dependence and experimental results. The discrepancy indicates that the generally assumed defect structure model of CoO considering isolated point defects is not satisfactory. The model should involve interactions between defects as has been already considered (10, 11). These interactions are not negligible for undoped CoO and become considerable for Cr-doped CoO.

Equation [23] and [30] as well as corresponding electroneutrality conditions Eq [24] and [28], involving isolated point defects, enable one to calculate defect concentrations for undoped CoO (Fig. 5) and Cr-doped CoO (Fig. 6, 7). Formation of aggregates of four vacancies was postulated by Catlow and Stoneham (18) for CoO as well as for NiO and MnO. Formation of defect complexes was also considered by Perkins and Rapp (19) for NiO-Cr₂O₃ solid solutions. The picture is even more complicated if cation interstitials are involved, as it has been postulated by Stiglich *et al.* (20) and by Mrowec *et al.* (15). Although the discussion on the defect structure model for CoO is still open, the results presented in this work indicate that the simple classical model involving unassociated point defects is not satisfactory. Therefore, in the considerations presented below, activities of defects are used instead of concentrations and the Debye-Hückel theory is applied to calculate appropriate equilibrium constants and resulting Fermi energy changes.

Fig. 5. Concentration of defects in undoped CoO at 1300 K

Fig. 6. Concentration of defects in Cr-doped CoO (0.048 at.% Cr) at 1300 K.

Considering activities, Eq. [23] and [30] assume the following forms

$$K^*_{v'} = \frac{[V'Co][h] \cdot f_h \cdot f_{v'}}{p_{O_2}^{1/2}} \quad [33]$$

$$K^*_{v''} = \frac{[V''Co][h]^2 \cdot f_h^2 \cdot f_{v''}}{p_{O_2}^{1/2}} \quad [34]$$

The Debye-Hückel theory for strong electrolytes was applied to calculate the activity coefficients

Fig. 7. Concentration of defects in Cr-doped CoO (0.49 a/o Cr) at 1300 K.

$$\ln f_i = -\frac{1}{2\epsilon} \cdot \frac{z_i^2 e^2 N_A}{RT} \cdot \frac{H}{1+a} \quad [35]$$

where ϵ is the dielectric constant of the solvent, z_i is the charge of the ion, N_A is Avogadro's number, a is the distance between ions, and

$$H = \sqrt{\frac{4\pi e^2}{kT} \sum_{i=1}^n N_i z_i^2} \quad [36]$$

where N_i is the number of ions in cm^3 and the other parameters have their traditional meaning. For calculations, it has been assumed that $\epsilon = 12.9$ (21) and

$$a = \frac{a_0}{\sqrt{2}} = 3.01 \cdot 10^{-8} \text{ cm}$$

where a_0 is the lattice parameter equal to 0.426 nm (4.26Å) (4). In calculations of ionic force

$$I = \frac{1}{2} \sum_{i=1}^n N_i z_i^2 \quad [37]$$

the following defects were considered: $h\cdot$, V'_{Co} , V''_{Co} , and $\text{Cr}\cdot_{\text{Co}}$. Therefore, considering appropriate simple electroneutrality conditions [24] and [28], we obtain

$$I = [h\cdot] \quad [38]$$

for undoped CoO and

$$I = \frac{1}{2} \{2[h\cdot] + 3[\text{Cr}\cdot_{\text{Co}}]\} \quad [39]$$

for CoO-Cr₂O₃ solid solutions.

As results from Eq. [35]

$$f_{h\cdot} = f_{V'} = f_{\text{Cr}\cdot} = f \quad [40]$$

and

$$f_{V''} = f^4 \quad [41]$$

The calculated values of activity coefficients as well as equilibrium constants are listed in Table V and VI for

undoped CoO and Cr-doped CoO samples. As can be seen, the equilibrium constants, $K^{*V'}$ and $K^{*V''}$ calculated from activities, show significantly smaller changes compared to those calculated from concentrations, except in the case of $K_{V''}$ data for the CoO sample containing the smallest concentration of Cr (0.048 a/o). As one can expect in this case, the simple electroneutrality condition [28] is not valid. Therefore, the average values of the equilibrium constants were calculated for positions 5-11 (Table VI). Accordingly, the general electroneutrality condition involving both singly and doubly ionized cation vacancies should be applied

$$[V'_{\text{Co}}] + 2[V''_{\text{Co}}] = [h\cdot] + [\text{Cr}\cdot_{\text{Co}}] \quad [42]$$

Taking into account Eq. [33], [34], [40], and [41], we obtain

$$f^6 [h\cdot]^2 [h\cdot] + [\text{Cr}\cdot_{\text{Co}}] - K^{*V'} p_{\text{O}_2}^{1/2} [h\cdot] f^4 - 2K^{*V''} p_{\text{O}_2}^{1/2} = 0 \quad [43]$$

Values of $[h\cdot]$ were calculated from Eq. [43] for a given $K_{V'}$ and $K_{V''}$. The successive approximations method was applied for calculations of consistent values $[h\cdot]$ and f . Thus, determined values of $[h\cdot]$ served to calculate E_F vs. $[\text{Cr}\cdot_{\text{Co}}]$ from Eq. [16]. This dependence, which is illustrated by curve 3 in Fig. 4, shows a satisfactory agreement with experimental data, again with the exception of the case where the concentration of chromium is the smallest.

Conclusions

Comparative studies of electrical conductivity and of Seebeck effect enables one to determine the mobility of electron holes. The mobility term is changing vs. oxide composition which is an indication of defect interactions in undoped CoO.

The results presented here indicate that the simple defect model involving unassociated point defects is not adequate to describe defect structure of Cr-doped CoO.

Photoelectrochemistry of WSe₂ Electrodes

Comparison of Stepped and Smooth Surfaces

H. J. Lewerenz,^{*1} H. Gerischer,^{*} and M. Lübke

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Faradayweg 4-6, D-1000 Berlin 33, Germany

ABSTRACT

Smooth and stepped surfaces of n-WSe₂ have very different properties for adsorption and charge transfer. Adsorption of OH⁻ and I⁻ is strong at stepped surfaces, but not observable at smooth surfaces. This is apparent in flatband potential measurements. Photocurrent voltage curves indicate in the steady state slow charge transfer rates with all redox couples. This leads to an inversion at smooth parts of the surface, while the high recombination rate at steps prevents accumulation and makes them a sink for holes. I⁻ reacts faster than other redox couples with holes, and catalyzes further hole transfer. The presence of I₂ in the solution modifies the surface chemically, and the blocking character of the contact is lost.

Low susceptibility to photocorrosion has advanced the use of layered compound transition metal dichalcogenides in liquid-junction solar cells. Considerable stability and solar conversion efficiencies have been reported (1-5). This stability against photocorrosion, particularly for photoanodes, has been attributed to phototransitions involving quasi-intrametallic d-bands. These leave M-X bonds largely unaffected (1, 2). This, however, can only be expected for perfect Van der Waals planes. From growth process, the materials are known to exhibit a varying number of steps, which have been discovered to act as recombination centers and to limit conversion efficiencies. They also enhance photocorrosion (6-7).

For fundamental investigations, the morphological surface anisotropy of MX₂ (M = W, Mo; X = S, Se) electrodes provides the opportunity to study two distinctly different types of surfaces *in situ*. At steps, strong covalent bonds can be formed with components of the ambient, but the smooth surfaces are mainly interacting via weak Van der Waals bonding with the environment.

At steps, the chemical interaction with electrolyte species is considerably stronger and introduces a variety of reaction possibilities. Adsorption (or chemisorption) can occur. This affects the surface-state energy and density distribution. Examples of this will be given in this paper.

The general coexistence of smooth and stepped regions, whose relative areas vary for each crystal and depend on the surface preparation, makes it impossible to prepare reproducible electrode surfaces. One can only demonstrate the general trend by comparing samples with large differences in surface perfection with respect to their electrochemical behavior. We report here such results obtained with WSe₂ crystals. The well-known effectiveness of the I₃⁻/I⁻ redox couple for high charge transfer rates and reduction of corrosion (8, 9) deserves investigation, particularly of its microscopic interaction with stepped and smooth surfaces. An understanding of the role of steps and other surface imperfections on the photoredox reactions and photocorrosion is important for an understanding of limits and possible improvements of liquid-junction solar cells made with these materials.

Experimental

The n-WSe₂ crystals used were grown by standard chemical transport reaction (10). Smooth and structured crystals were selected from the same batch upon visual inspection with a light microscope. Ohmic contacts were made with Hg-In amalgam, followed by Ag-epoxy (Epoxy Prod. 40773) making contact to a copper rod, which was then encapsulated with insulating epoxy (Scotchcast 3M No. 4). Experiments were performed with a standard three-electrode potentiostatic arrangement using a Pt counterelectrode and a saturated calomel electrode (SCE) as reference electrode. All potentials are referred to SCE. All current potential curves were measured with rotating electrodes. Solutions were made from triple-distilled water

and analytical-grade chemicals. The differential capacitance has been measured by standard techniques at 800 Hz. Illumination was provided by a 100W tungsten-iodine lamp with 5 mW/cm².

Results

The opportunity to monitor the interaction of electrolyte species with a semiconductor surface is provided by capacitance measurements. Corresponding flatband potentials (U_{FB}), extrapolated from Mott-Schottky plots, allow the determination of the semiconductor band-edge positions.

Figure 1 shows the influence of I^- concentration on the flatband potential of a smooth and two stepped WSe₂ electrodes. For the smooth sample, very little dependence is noted, but the stepped samples have a much more negative U_{FB} and show a further cathodic shift when the I^- concentration is changed from $10^{-4}M$ to $10^{-1}M$. Because of high Faradaic currents, U_{FB} could not be determined for I^- concentration higher than $10^{-2}M$ at the stepped-III anode with the highest surface imperfection. Figure 2 shows the influence of pH on the flatband potential of smooth and two highly structured WSe₂ electrodes (stepped I and stepped II) in three supporting electrolytes. For the smooth sample, no measurable dependence of flatband potential on OH^- concentration is found. The stepped samples show pronounced changes with pH in K_2SO_4 and KCl but not in KI . Changes are largest in K_2SO_4 . For $pH < 1$, the value of U_{FB} of a stepped sample is almost identical to that of a smooth electrode. The overall change in flatband potential between pH 1 and 11 is $\Delta U_{FB} = -0.25V$. At the steepest part of the curve around $pH = 5$, the slope dU_{FB}/dpH reaches 46 mV/pH. For a solution with 1M Cl^- , U_{FB} at this particular stepped electrode is shifted at pH 1 towards more negative values than the smooth sample, but approaches the values in K_2SO_4 for $pH > 7$. In 1M KBr , U_{FB} is shifted somewhat more cathodically at pH 1, and in 1M KI the shift of U_{FB} reaches 200 mV. The influence of pH was no longer detectable in 1M KI solution within the error limits of our measurements.

The influence of the surface structure of WSe₂ on photocurrent voltage curves for two different redox

Fig. 1. Flatband potentials of smooth and stepped WSe₂ electrodes in dependence on the KI -concentration. Electrolytes: 1M KCl , pH 6. Flatband from Mott-Schottky plots at 800 Hz.

Fig. 2. pH dependence of the flatband potentials of smooth and stepped WSe₂ electrodes with different anions: 0.5M K_2SO_4 , 1M KCl , 1M KI .

electrolytes is displayed in Fig. 3. In I^- , the smooth surface shows a photocurrent onset at $-0.2V$, and a relatively steep increase and saturation at $+0.8V$. The stepped sample shows a delayed onset in photocurrent and a considerably smaller slope of the $I-V$ curve. It does not reach saturation upon polarizing to $+1.1V$. The behavior of these electrodes in $Fe(CN)_6^{4-}$ is considerably worse with respect to the photocurrent voltage characteristics. Although the onset of the photocurrent coincides for the smooth electrode for both electrolytes, the raise with potential is much lower for $Fe(CN)_6^{4-}$ than for I^- . The photocurrent of the stepped electrode in $K_4Fe(CN)_6$ is further reduced, and is approximately 1/6 of the current of the smooth electrode in KI at 1.0V. Also indicated in Fig. 13 are the respective dark currents for the smooth and the

Fig. 3. Photocurrent voltage curves at smooth and stepped WSe₂ electrodes with different concentrations of $K_4Fe(CN)_6$ or KI in 1M KCl , pH 6.

stepped sample. It is shown that the anodic dark currents increase with surface imperfection.

The influence of I^- on the photocurrents was further examined by changing the I^- concentration and monitoring the I-V curves on stepped and smooth samples (Fig. 4). It is noted that upon increasing the I^- concentration on a stepped sample up to $10^{-3}M$ KI, no distinct difference in photoresponse compared to the base line in KCl is found. A substantial increase in current and shift to more negative bias, however, is observed for $10^{-1}M$ KI and much more so if the concentration is increased to $5.5M$. On the smooth electrode, a deviation from the curve recorded in KCl is already found for $10^{-3}M$ KI. This improves further upon increased I^- concentration. The steepness of the photocurrent voltage curve on the smooth electrode is considerably higher, and the photocurrent reaches the saturation region at much less positive bias.

A very drastic change of the surface chemistry occurs if I_3^- is present in the electrolyte. Electrodes with a large number of steps lose their blocking character in the potential range above 0V (SCE) in the dark, and their current voltage curves pass the open-circuit potential linearly. This potential approaches the redox potential of the electrolyte.

Figure 5 shows the potential dependence of the currents passing in the dark the contact between an iodine and iodide containing electrolyte and n-WSe₂ samples with four different surface morphologies. The currents increase with surface distortion. They are very small for the smoothest electrode and largest for the edge of a crystal exposed to solution.

Discussion

Influence of surface morphology.—The results are evidence of the influence of surface structure on the photoelectrochemical behavior of layered semiconductors, and the exceptional role of the I^-/I_3^- redox couple in the charge transfer reactions at the WSe₂ electrolyte interface. This is similar to experience with

Fig. 4. Photocurrent voltage curves for stepped WSe₂ and smooth WSe₂ electrode with different KI-concentrations in 1M KCl. Both crystals are from the same growth batch.

Fig. 5. Current-potential curves for 4 WSe₂ samples with different surface structures in solution of 1M KCl + $10^{-2}M$ KI + $1.5 \times 10^{-3}M$ KI₃. a = very smooth (as grown), b = relatively smooth, c = stepped, d = edge of a crystal (surface || \vec{c}).

MoSe₂ electrodes (11). The s-p bonding orbitals between metal and chalcogene atoms are located below the d_{z²} orbitals, which form the uppermost valence band (12). The d_{z²} orbitals are shielded by the Se layers from interaction with the ambient. W atoms at steps and other surface defects can interact strongly with components of the electrolyte because the d orbitals of the W atom there are not shielded against external reactants. These unsaturated bonds of the W atoms can overlap with electronic orbitals of components of the electrolyte and form new chemical bonds, particularly those with nucleophilic reactants, like OH⁻ and the halide ions. Chemical modification of such surface sites will introduce surface or interface states in the semiconductor-energy gap which act as recombination centers. The poor solar-cell performance of stepped WSe₂ electrodes has mainly been attributed to this effect (13, 14).

Our experiments show that this interaction occurs already in the dark and leads to the negative shift of the flatband potential for electrodes with stepped surfaces, since the adsorption of negative charge on the surface leaves behind a positive counter charge in the solution at a distance of the Helmholtz double-layer dimension (Fig. 1, 2). The size of this shift depends necessarily on the number of surface sites where such an interaction is possible. Saturation of the reactive sites is approached at high concentrations of the interacting species in the electrolyte. On the most stepped surface with a large excess of such sites in Fig. 1, a flatband-potential shift of 59 mV per concentration decade is approached. Figure 2 displays the relative

binding of SO_4^{2-} , Cl^- and I^- with respect to OH^- at steps. SO_4^{2-} appears to have negligible interaction, but I^- is much more strongly bound than OH^- and occupies all the accessible chemisorption sites. Therefore, the pH has little effect on U_{FB} in the presence of a high concentration of KI. Cl^- and Br^- do not interact as well as OH^- . Quantitative relations are difficult to obtain because of the limited control and reproducibility of surface preparation.

Smooth surfaces.—Photocurrents in the presence of redox systems increase only very slowly with positive bias. The reason for the delayed onset of the photocurrents relative to the position of the flatband potentials and the sluggish increase with bias could be a shift of the band-edge position. This comes about because of the charging of surface states, which can capture holes and accumulate positive charge to a sufficiently large amount. Since the missing voltage drop of the space charge layer would in this case appear in the Helmholtz double layer, a high number of surface states would be needed. The inertness to adsorption of these planes makes it difficult to assume this for a smooth Van der Waals plane. Fermi-level pinning appears, therefore, insufficient as an explanation for the photocurrent-voltage characteristics of the smooth electrodes.

A more plausible explanation is the assumption that the electron transfer rate is slow, and leads to an accumulation of holes underneath the interface. This explanation has been discussed by Reichmann (15), and Albery *et al.* (16). In this case, an inversion layer is formed as was indicated already for MoSe₂ electrodes by capacity- and surface-conductivity measurements under illumination (17).

The formation of an inversion layer will also affect the position of the bandedges to some extent. The additional electric charge in an inversion layer can create a considerably increased field strength at the surface, which extends through the Helmholtz double layer.

The additional voltage drop in the Helmholtz double layer due to this effect cannot, however, be as large as that generated by a high concentration of charged surface states, but this effect will nonetheless contribute to the slow increase of the photocurrents with bias.

Stepped surfaces.—At the surfaces with a large number of steps, surface recombination is enhanced considerably. There is also some evidence that dislocations or other structural defects are concentrated in the bulk near steps and increase the rate of recombination in this region of the bulk (14). This leads to a very inhomogeneous concentration distribution of holes in the space charge layer. We can assume that holes are consumed much faster by recombination at steps and in the surrounding bulk than at smooth parts of the surface. The result is that the concentration of holes around steps is much lower than at the smooth parts, and a large concentration gradient between smooth-surface areas and steps will exist. This causes a preferential transport of holes to the steps, as displayed in Fig. 6. The higher hole mobility parallel to the layers will further contribute to the increased drift of holes to steps on the surface.

If the flatband potential is shifted at the stepped electrodes to more negative values by the adsorption of anions which can be oxidized by holes, such as I^- ions, the consumption of this negative surface charge can reverse the shift of U_{FB} , as was observed for adsorbed S^{2-} on CdS (18). This is, however, unlikely for solutions with very high I^- concentration, because the adsorption of I^- is a fast reaction, and with a large excess of iodide the generated iodine will quickly be desorbed by complexation with I^- ions. It must be mentioned that accumulation of positive charge in surface states at steps also contributes to the slow increase of the photocurrent with applied voltage. This comes about by an increase of the voltage drop in the Helmholtz double layer and a corresponding shift of the bandedges to more positive potentials. The predom-

Fig. 6. Schematic representation of the motion of photogenerated minority carriers near the edge of a step. Hole-concentration profiles parallel and perpendicular to the \vec{z} -axis are also indicated.

inant effect of the steps, however, seems to be the increase of the recombination rate.

The specificity of the iodide redox reaction.—In the absence of specific adsorption, the interaction between the holes and the ions in solution will be very weak due to the small overlap between the d_{z^2} orbitals and the highest occupied orbital of the redox species. Consequently, the charge transfer rate is low. These unfavorable conditions are less important for iodide for two reasons. First, its solvation shell is more weakly bound, and the ion itself may be able to approach the surface closer than other redox ions. Second, the iodine atom as the reaction product appears to interact more vigorously even with the smooth surface. This will affect the transition state in which electron transfer occurs and reduce the activation barrier for hole transfer. The adsorbed I atoms will further catalyze the electron transfer from I^- ions to holes and enhance the formation of the I_2 molecule in the second step of this redox reaction. However, one still needs a very high concentration of I^- to make the electron transfer reaction at the WSe_2 surface so fast that the surface concentration of holes is drastically reduced at the smooth electrodes and the flux of minority carriers to the surface can approach its limiting value (cf. Fig. 4).

At the stepped electrodes, the I^- ions are adsorbed and can react with holes easily. However, this enhanced charge transfer rate has to compete with the increased rate of recombination. The catalytic effect of adsorbed I atoms on the rate of hole transfer to other I^- ions can obviously not fully compensate for the increased losses by recombination. The overall result is still a slower increase of the photocurrent with the bias applied than at the smooth surfaces.

If iodine is present in the electrolyte, the surface seems to change completely in chemical character, at least around steps and other defects. A layer with a high concentration of surface states is formed. The layer catalyzes electron transfer to and from the conduction band to an extent that dark currents passing continuously the abscissa close to the equilibrium po-

tential of the redox system become possible (cf. Fig. 5). The chemical nature of this surface modification remains to be determined.

Technical Notes

Graphite Fiber as a Positive Electrode of Rechargeable Lithium Cells

Yoshiharu Matsuda,* Masayuki Morita, and Hidenori Katsuma

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwa-dai, Ube, Yamaguchi, Japan

Graphite compounds have gained interest as possible positive electrodes for rechargeable lithium cells. Their charge-discharge characteristics have been studied in organic electrolytic solutions such as sulfolane (1), dimethylsulfoxide (2, 3), and propylene carbonate (4, 5). The charge-discharge reactions of graphite positives are believed to involve the intercalation-deintercalation process shown in Eq. [1]

* Electrochemical Society Active Member.

Key words: lithium cell, graphite fiber, rechargeability, anion intercalation.

where n is an integer and A^- denotes an anion (2-5). Cell performance is dependent on the variety of the graphite. Bennion *et al.* (2) and Ohzuku *et al.* (5) presented some high-efficiency charge-discharge cycles using pyrolytic graphite positives. It is held that the edge face (parallel plane to the c -axis of the crystal) of the graphite structure is effective for the intercalation reaction (4). This note presents the use of carbon (graphite) fibers with surfaces consisting mainly of the edge face of the graphite. The charge-discharge behavior of the graphite fiber electrode was studied in propylene carbonate (PC) solutions of $LiClO_4$, $LiBF_4$, and $LiPF_6$. The results are discussed from the standpoint of the structure change.

Experimental

A felt of graphite fiber (Nihon Carbon Company, Limited, GF-25A) was used as the test electrode. It was characterized by x-ray diffraction analysis and scanning electron microscopy (SEM). The felt was cut into disks of 12.5 mm diameter (average weight; 0.038g), and then mounted on a Teflon holder with a Pt current-collector. The apparent surface area exposed to the solution was 0.5 cm².

The solvent PC was purified and dehydrated by the usual methods, as described elsewhere (6, 7). The electrolytic salts (LiClO₄, LiBF₄, and LiPF₆) were extra-pure grade. They were used after drying under reduced pressure for 24 hr or more (7). The concentration of the electrolyte was 1.0 mol dm⁻³. The water contents of the solution were less than 80 mg dm⁻³.

The charge-discharge characteristics were investigated using a half-cell test with an excess of the electrolytic solution (about 100 cm³). A beaker-type cell with a Pt counterelectrode (16 mm × 28 mm) was used. A SCE was used as the reference electrode. The electrode potential is reported against the Li/Li⁺ couple. The potential of the Li/Li⁺ vs. SCE was directly determined by separate experiments. It was -3.0V. The felt electrode was charged at a constant current of 0.1 mA (0.02 A dm⁻²) for 60 min. Discharging was done without a break at the same current density until the electrode potential was 3.0V (vs. Li/Li⁺). The charge-discharge cycle was repeated at least six times. These electrochemical measurements were carried out under a dry N₂ atmosphere at 298 K.

Results and Discussion

Figure 1 shows SEM photographs of the graphite fiber before its electrochemical use. The maximum length of the fiber was about 3 mm, and the average diameter was 10-15 μm. The x-ray diffraction pattern of the graphite fiber is shown in Fig. 2. This indicates that the (100) plane of the graphite structure, as well as the (002) or (004) plane, is highly developed

Fig. 1. SEM photographs of the graphite fiber

Fig. 2. X-ray diffraction pattern of the graphite fiber electrode

in the fiber. Thus the plane parallel to the c-axis (so-called edge face) of the graphite crystal is preferentially exposed at the surface of the fiber.

The charge-discharge curves of a graphite fiber electrode are shown in Fig. 3, where the charge (or discharge) time of 60 min corresponds to a capacity of 24 C g⁻¹. The charging potentials remained almost constant after the first 30 min, and the curves scarcely varied with increasing cycle numbers. During discharge, potential plateaus, which might be attributable to the deintercalation of the anion, were observed. These results are similar to those in dimethylsulfite solution, as reported by Deshpande and Bennion (3). There is no evidence for intercalation *per se*, but the data would be consistent with the formation of a graphitic acid salt as reported in works on aqueous solutions (8, 9). The coulombic capacities (A-hr discharged) tended to increase with continued cycling. The variation in the x-ray diffraction pattern of the fiber was investigated during the charge-discharge process. The intensity of each diffraction peak fell off with repeated cycling; though shifts in the diffraction angles were not observed. This indicates a decreasing crystallinity of the graphite with cycling. The increase in the coulombic capacity with repeated cycling is probably related to the lowered degree of crystallinity. On the other hand, the coulombic effi-

Fig. 3. Charge-discharge curves of the graphite fiber electrode. A: in 1.0 mol dm⁻³ LiClO₄; B: in 1.0 mol dm⁻³ LiBF₄; C: in 1.0 mol dm⁻³ LiPF₆.

Fig. 4. SEM photographs of the graphite fiber after 6 charge-discharge cycles. A: in $1.0 \text{ mol dm}^{-3} \text{ LiClO}_4$; B: in $1.0 \text{ mol dm}^{-3} \text{ LiPF}_6$.

ciency of the charge-discharge cycle (A-hr discharged/A-hr charged) increased in the order of $\text{ClO}_4^- < \text{BF}_4^- < \text{PF}_6^-$. Such differences in the efficiency could result from the difference in the extent of intercalation during the charge. Purity of the salt is probably not a main factor in the cycle efficiency because the impurity contents were low (e.g., $< 1\%$ in LiPF_6 and $< 0.1\%$ in LiBF_4) even in the solution

prepared. The cycle efficiency would depend on the kind of anion to be intercalated, though the reason for the difference in the reactivity was not clarified in the present work.

There was little change in the appearance of the fiber electrode after the charge-discharge cycles, although the results of x-ray diffraction analysis showed a decrease of graphite structure in the fiber. Figure 4 shows SEM photographs of the graphite fiber after the sixth discharge in the LiClO_4 and LiPF_6 solutions. There was little change in shape of the fiber except for some roughness of the surface. This should be an important feature for the electrode of secondary cells, and it suggests that such fiber electrodes abounding with the edge face of the crystal are favorable for practical use. However, further attempts should be made to improve charge-discharge efficiency, and the long-term characteristics of the cycling should also be investigated for realizing a practical rechargeable cell.

Repassivation Behavior of Two Glassy Alloys in Sulfuric Acid with and without Chloride Ions

Ronald B. Diegle,^{*,1} and David M. Lineman²

Battelle Columbus Laboratories, Columbus, Ohio 43201

The excellent corrosion resistance of certain Cr-containing glassy alloys has been attributed to the presence of very protective passive films, particularly hydrated chromium oxyhydroxide (1, 2). The degree of enrichment of Cr^{3+} in such films can be greater than that in films formed on crystalline stainless steels containing comparable levels of alloyed Cr. P in the glassy structure greatly facilitates enrichment of Cr^{3+} into the passive film (1, 3, 4); analysis of repassivation transients (2, 5, 6) has suggested that P accelerates dissolution of the unfiled alloys, and that this intensified dissolution promotes the formation of passive films

that are highly enriched in Cr^{3+} . The work reported here was undertaken to analyze the repassivation behavior of certain glassy alloys as influenced by the metalloids P, B, and Si, and by chloride ion in solution.

Experimental

Compositions of the alloys that were used are given in Table I. The alloys designated 2826A and Si/B were glassy, and they were procured from Allied Chemical Corporation and prepared at Battelle, respectively; both were made by the melt spinning process. The T316 stainless steel was procured from a commercial vendor and it was included so that repassivation behavior of the glassy alloys could be compared with that of a crystalline Cr-containing stainless steel. Current transients were generated by scratching specimens that were potentiostated relative to a satu-

Table I. Compositions of alloys

Alloy	Composition, atomic percent ^a							
	Fe	Ni	Cr	Mn	Mo	P	B	Si
2826A	32	36	14	—	—	12	6	—
Si/B	32	36	14	—	—	—	12	6
T316	65	11	18	2.0	1.4	0.0	—	2.0

^a Compositions of 2826A and T316 were quoted by suppliers and Si/B was analyzed at Battelle.

rated calomel electrode (SCE) in 1N H₂SO₄, with or without addition of 1N NaCl. Scratching was performed with a spring driven sapphire stylus (7), and the transients were recorded on a waveform recorder (Physical Data Model 514A). This recorder could sample the signal at intervals as short as 0.5 μsec, and thus it was more than adequate for resolving current-time behavior in the 10⁻³-1 sec range. The alloy electrodes were first abraded with 600 grit SiC paper to create a standard surface finish, then rinsed with acetone, air dried, and mounted to a Teflon holder prior to scratching. The average scratch area for each type of alloy was determined after several scratch events by means of a high power optical microscope equipped with a filar eyepiece. The scratches were approximated as being rectangular in cross section and sufficiently shallow that the area of the inside walls of the scratch could be ignored. Several areas were measured and then averaged for use in calculating current densities. (Only the scratch area, not the total exposed electrode area, was used to calculate current density.)

Results

Potentials in the passive range of polarization behavior were selected for the scratching experiments so that well-developed passive films would form on the scratched areas. Anodic polarization curves for the three alloys are shown in Fig. 1 for 1N H₂SO₄. T316 steel was polarized to 0.20V (SCE), which was in the passive potential region in both 1N H₂SO₄ and 1N H₂SO₄ + 1N NaCl. A potential further into the passive region was selected for the two glassy alloys, namely, 0.60V (SCE); however, because this value exceeded the critical pitting potential of the Si/B alloy in 1N H₂SO₄ + 1N NaCl, a potential of 0.20V (SCE) was used for the Si/B alloy in Cl-containing 1N H₂SO₄. It was not considered critical to use the same potential for all three alloys because neither the passive film compositions nor the current passed should depend strongly on the applied potential over this potential range.

Shown in Fig. 2 are typical current density-time plots measured at passive potentials. Two distinct regions are evident. In region 1, the current density decreased linearly with a slope of about -1 sec⁻¹. After about

Fig. 1. Polarization curves obtained in deaerated 1N H₂SO₄ at room temperature. Scan rate = 1 mV/sec.

Fig. 2. Typical anodic current transients obtained in 1N H₂SO₄. $i_b \approx 4 \cdot 10^{-5}$, $4 \cdot 10^{-5}$, and $2 \cdot 10^{-4}$ A/cm² for 2826A, Si/B, and T316, respectively.

700-1000 msec had elapsed, the current density decreased at a slower rate, denoting region 2 behavior. The current density-time relationship was of the form

$$(i - i_b) = (i_p - i_b) 10^{st} \quad [1]$$

in which i is current density, i_p is the peak current density measured, i_b is the background or steady-state current density, s is the slope of the data in either region 1 or 2, and t is the time after i_p occurred. This equation was integrated between appropriate limits to calculate the charge density passed in region 1, Q_1 , and in region 2, Q_2 . Repassivation parameters are presented in Table II, and they are the mean values from, typically, three replicate experiments for each alloy. The effect on repassivation of adding 1N NaCl to the electrolyte is shown in Fig. 3. The two stage semilogarithmic current decay still occurred, but the dissolution current was substantially increased for the Si/B alloy. Repassivation parameters measured in the presence of NaCl are presented in Table III.

Discussion

Hashimoto *et al.* (6) measured repassivation transients on glassy Fe-10Cr-13B-7X alloys in 0.1N H₂SO₄, where X = Si, B, or P. They showed that P caused the most rapid current decay after abrasion, and Si the least rapid, although they did not analyze quantita-

tively the kinetics of current decay. Reference to Fig. 2 shows that the repassivation rate for the Si/B alloy was somewhat faster than that of 2826A, and thus our results regarding the influence of metalloids are somewhat at variance with these workers. However, the presence of chloride ion markedly differentiated the effects of P from Si in promoting rapid repassivation, as evident in Fig. 3 and Table III.

It is interesting to compare the Q_1 values to the charge required to form one monolayer of passive film. As a first approximation and to simplify the calculation, it was assumed that the only cation present in the film was Cr^{3+} . This was not strictly true, yet under some conditions the cationic fraction of Cr, relative to Fe, Ni, and other cations, can indeed be large, especially at potentials well cathodic to transpassive behavior (2, 4). Second, the film composition was taken to be $CrO(OH) \cdot H_2O$ because $CrO_x(OH)_{3-2x} \cdot nH_2O$ has been postulated, based on extensive XPS analysis, to comprise a substantial proportion of the passive film on glassy Cr-containing alloys exhibiting high corrosion resistance (1, 2); for this calculation x was taken to be 1. An estimate of the monolayer equivalent charge density (MEQ) was made for a film of the above composition with a density of 3 g/cm 3 and thickness of 0.3 nm.

The calculated charge density is 0.34 mC/cm 2 , in agreement with the lower range of 0.4-0.7 mC/cm 2 calculated by Frankenthal for Fe-24Cr (8). However, if the film is pure $CrO(OH) \cdot H_2O$ and selective dissolution of Cr from the alloy does not occur, then Fe and Ni must be dissolved into solution; this dissolution would increase the total measured charge to 1.4 mC/cm 2 , provided that P and B (in 2826A, e.g.) are not oxidized. [Both elemental and oxidized P have been found in the passive film on a glassy alloy (9).] If all of the P and B are oxidized to P^{5+} and B^{3+} , then the MEQ is increased further to 2.0 mC/cm 2 . These calculated values of 1.4-2.0 mC/cm 2 are less than the experimental values of 2.8-4.1 mC/cm 2 in Table II. Although the agreement is reasonable given the uncertainties in scratch area and film composition, the larger experimental values suggest that a portion of the measured Q_1 charge represents alloy dissolution in addition to repassivation. [Growth to more than one monolayer is ruled out because region 1 obeys semilogarithmic

growth kinetics, which is expected for monolayer film formation when metal dissolution is rate controlling (10).] The MEQ's for T316 and Si/B alloys are, respectively, 1.3 and 1.5 mC/cm 2 . They are also less than the Q_1 values in Table II, again suggesting that some alloy dissolution accompanied repassivation.

The effect of chloride addition to the electrolyte was to intensify dissolution during repassivation of T316 and especially Si/B, as reflected by increases in $i_p - i_b$ and Q_1 . The effect was very pronounced for Si/B, as shown in Table III. Addition of chloride did not, however, greatly alter the rate of repassivation, s_1 .

Concerning region 2, it was observed that if current density were plotted vs. time on log-log coordinates (not shown), the curves became linear at the time in which region 2 behavior was established in semi-log plots, i.e., about 700-1000 msec. The linearity is suggestive of a high field oxide growth mechanism, although the variable slopes in this work precluded unequivocal identification of a recognized growth rate law. Note that the Q_2 values in Table III are equivalent to about one additional monolayer of $CrO(OH) \cdot H_2O$ except for the Si/B alloy; it is not known why this value is so small. The addition of 1N NaCl to the H_2SO_4 moderately increased Q_2 for T316 steel and profoundly increased Q_2 for the Si/B alloy.

The repassivation behavior of the two glassy alloys and T316 steel is similar in form, as evident by the two stage semilogarithmic current decay in Fig. 2 and 3. The inclusion of T316 steel in this study was not intended to imply that it is a compositional analog to the glassy alloys; rather, it was included as being representative of Cr-containing crystalline stainless steels; and therefore, this similarity in current decay was unexpected. The presence of chloride ion had little effect on repassivation of 2826A, whereas it increased the region 1 dissolution, Q_1 , of T316. This difference in Q_1 presumably resulted from the ability of 2826A to incorporate Cr^{3+} at relatively high cationic concentrations into the passive film, as demonstrated by the XPS work of Hashimoto and co-workers (11). However, Cr in the glassy alloy structure is not a sufficient condition for excellent passivity, as evident from the large amount of dissolution accompanying repassivation of the Si/B alloy in chloride-containing H_2SO_4 . The combination of 14% Cr, 12% P, and 6% B showed a considerably faster repassivation rate than 14% Cr, 12% B, 6% Si in chloride-containing 1N H_2SO_4 , but unexpectedly and for yet unknown reasons the reverse is true in 1N H_2SO_4 without chloride ions. In both of these environments, the behavior of 2826A was only slightly faster than T316 steel. As expected, the repassivation rates were slower and required more dissolution to accomplish repassivation in the chloride-containing environment than in the environment without chlorides. The excellent chemical stability of 2826A supports the contention (3) that a synergism exists between Cr and P in glassy alloys, and that P can greatly increase the ability of Cr to confer passivity in very corrosive electrolytes.

The Determination of Ammonia in Copper Pyrophosphate Plating Solution

Thomas M. Tam* and John S. Zevely

Lockheed Missiles and Space Company, Process Control Engineering, Sunnyvale, California 94086

Copper pyrophosphate solutions are commonly used for plating through-holes in printed circuit boards. Precise monitoring and control of several of the solution constituents is essential for achieving a good quality copper deposit. Recently, a cyclic voltammetric (CV) stripping technique has been shown to provide a measure for the concentration of effective brightener (1) and nitrite, NO_2^- (2), in this solution. We have found that the CV technique can also be used to monitor the concentration of ammonia, NH_3 , in the solution.

Ammonium hydroxide or ammonia gas is added to the solution to produce a more uniform and lustrous deposit and to improve anode corrosion during electroplating. Excess ammonia can cause the formation of cuprous oxide which can hinder the adhesion of the copper deposit to the circuit board (3). For this reason, ammonia in the solution needs to be controlled. The desired range of total ammonia in the solution is 0.06-0.18M.

Experimental

Equipment.—The CV experiments described herein were performed using a platinum working electrode, platinum auxiliary, and Ag/AgCl reference electrodes. The apparatus has been described elsewhere (2). No routine maintenance of the electrodes was required after initial setup.

The pH of the solutions was measured using an Altex (gel-filled) combination pH electrode. The electrode was calibrated against pH 10 and 7 buffer solutions. An Orion Ammonia electrode was used to measure ammonia in the solutions. The electrode was prepared according to the manufacturer's procedure for measuring the ammonia content of solutions with salt content above 1M, and was calibrated using 1M potassium pyrophosphate solutions which contained known amounts of NH_4NO_3 . These pyrophosphate solutions had ionic strengths ($\mu = 10$) similar to those of the copper pyrophosphate solutions used in this study. The pH of the pyrophosphate solutions was adjusted to 12 to ensure that NH_3 was the major species in solution. The membrane of the electrode was replaced when it became discolored or when stable readings could not be achieved. This occurred after 1-2 days of extensive use. It was necessary to recalibrate the electrode after about 2 hr of use. The concentrations of NH_3 in the test solutions were determined by using the calibration curve.

* Electrochemical Society Active Member.

Key words: analysis, electrode, voltammetry.

The pH and ammonia electrodes were connected to an Orion Model 901 Ionalyzer, which gives a digital read out.

Solution.—The copper pyrophosphate solutions used were prepared by dissolving copper pyrophosphate ($\text{Cu}_2\text{P}_2\text{O}_7 \cdot 3\text{H}_2\text{O}$) and potassium pyrophosphate ($\text{K}_4\text{P}_2\text{O}_7$) in deionized water. Pure pyrophosphate solutions were prepared with $\text{K}_4\text{P}_2\text{O}_7$ only. The pH of the solutions was adjusted with concentrated potassium hydroxide or nitric acid.

Ammonium nitrate (NH_4NO_3) was added to copper pyrophosphate solutions to vary the amount of NH_3 in the solutions. The loss of NH_3 was kept to a minimum by making the measurements within 15 min after the solutions were prepared.

Current determinations at -0.26V (Fig. 1).—The current at -0.26V is due to ammonia (see Results and Discussion) and significant background current (i_b). This i_b is difficult to reproduce. To correct for it, the following procedure was used: A straight line was drawn from -0.125 to -0.425V assuming that the i_b increases linearly in this region. The difference in cur-

¹ All voltages reported herein are with respect to the Ag/AgCl electrode.

Fig. 1. Variation of cathodic peaks of copper pyrophosphate solutions with respect to NH_4NO_3 . Experimental conditions, see Fig. 2, pH = 8.80. $[\text{NH}_4\text{NO}_3] = 0.0\text{M}$ (A); 0.056M (B); 0.088M (C); 0.153M (D).

rent between the total current and i_b at $-0.26V$ is due to ammonia.

Results and Discussion

Ogden and Tench have reported the stripping cyclic voltammogram of copper pyrophosphate solutions (1). They observed a small oxidation peak at $0.2V$ and the corresponding reduction peak at $-0.3V$. We have found that when NH_3 is not present in the copper solution, a similar cathodic peak is observed between -0.15 and $0.0V$ (Fig. 2). This peak is due to reduction of platinum oxide (4).

When ammonia is added to the solution, a peak at $-0.26V$ is observed (Fig. 1). As the pH of the solution is adjusted above 8.8, an additional peak at $-0.38V$ is observed.

The characteristics of these peaks are as follows:

1. $-0.15-0.0V$ peak: this peak exists both in pyrophosphate and copper pyrophosphate solutions. The position of the peak is pH dependent (Fig. 2), and the intensity of the peak is inversely proportional to the amount of NH_4NO_3 added.

2. $-0.26V$ peak: this peak exists only when NH_4NO_3 is added to copper pyrophosphate solutions. Its intensity is directly proportional to the amount of NH_4NO_3 added. Also, as the NH_4NO_3 concentration is maintained constant, and the pH is changed from 8.0 to 9.0, the intensity of the peak increases.

3. $-0.38V$ peak: this peak shows up only in copper pyrophosphate solution when the pH is adjusted above 8.8 (Fig. 2).

These results are consistent with the interpretation that NH_3 , OH^- , and copper pyrophosphate ions are the active species that cause the changes of these peaks. The main concern of this study is the characterization of the peak at $-0.26V$. To accomplish this, the relation between NH_3 and copper pyrophosphate complexes was first investigated.

An Orion Ammonia electrode was used to measure the activity of NH_3 in two sets of solutions. The solutions in Set A are copper pyrophosphate solutions, and those in Set B are pyrophosphate solutions. Both solutions contained various amounts of NH_4NO_3 . The data shown in Table I are explained in terms of the dissociation of NH_4^+

where a_{NH_3} and a_{H^+} are the activities of NH_3 and H^+ measured by the ammonia and pH electrodes, respectively. The Qa term is the equilibrium quotient as defined. Notice the a_{NH_3} values in both sets with a comparable amount of NH_4NO_3 added to them, are quite similar. In addition, Qa in both cases is not significantly different and is constant.

The major chemical species in the copper solutions are: $[Cu(P_2O_7)_2^{6-}] = 0.35M$ and $[P_2O_7^{4-}] = 0.27M$. The equilibrium between copper (II) mono- and di-

Fig. 2. Variation of cathodic peaks of copper pyrophosphate solutions with respect to pH. $[Cu(P_2O_7)_2^{6-}] = 0.35M$. pH = 8.00 (A); 8.82 (B); 9.14 (C); 9.50 (D). Sweep rate = 40 mV/sec; rotation speed = 3000 rpm; temperature = $25^\circ \pm 1^\circ C$.

pyrophosphate complexes in the pH range of about 8-9 is shown in Eq. [2]

A treatment of this equilibrium (5) permits the evaluation of the concentration of $CuP_2O_7^{2-}$ ions. Its concentration is calculated to be approximately $10^{-4}M$. If either copper species will complex with NH_3 , their concentration in solution should be enough to affect the a_{NH_3} measured (Table I). The dissociation quotient Qa , also would not be a constant value as reported. If therefore can be concluded that the $Cu(P_2O_7)_2^{6-}$ and $CuP_2O_7^{2-}$ do not form significant amounts of copper ammonia complexes. The changes in current density of the peak at $-0.26V$ measured from the cyclic voltammograms correlate with changes in the a_{NH_3} . This relationship is shown in Fig. 3. When the $Cu(P_2O_7)_2^{6-}$ concentration is varied between 0.31-0.41M the intensity of the peak remains constant. (These are the control limits for our production baths.) We have stated that the $-0.26V$ peak exists only when both copper and NH_3 are present in solution. However, the copper species do not complex with ammonia. We therefore assign this peak to the reduction of copper on a platinum surface with NH_3 adsorbed on it

The peak at $-0.38V$ can be assigned to the reduction of Cu^{2+} on a platinum surface with OH^- adsorbed on it. No quantitative data however has been obtained regarding this peak.

Peak assignment.—The overall assignments of the anodic and cathodic peaks on the cyclic voltammogram of the copper pyrophosphate solution are as follows (Fig. 4): (A) oxidation of NO_2^- and organic impurities (7); (B) reduction of platinum, (C) reduction of $Cu(P_2O_7)_2^{6-}$ on Pt- NH_3 surface; (D) reduction of $Cu(P_2O_7)_2^{6-}$ on Pt- OH^- surface; (E) reduction of $Cu(P_2O_7)_2^{6-}$ on Pt-Cu surface; (F) oxidation of Cu^0 .

Conclusions

It has been shown that the CV technique can be used to monitor the concentration of effective brightener (1), the buildup of nitrite (2), and organic impurities (7) in copper pyrophosphate plating solutions. In this study, we have identified a cathodic peak at -0.26V due to the presence of NH_3 . The current of the peak is proportional to the α_{NH_3} in the solution. The CV unit is not as sensitive (minimum limit $\sim 1 \times 10^{-4}\text{M}$, NH_3) as the Orion Ammonia electrode (minimum detection limit $\sim 10^{-6}\text{M}$, NH_3). It is, however, a much more durable system. The concentration range of the ammonia in the copper pyrophosphate bath is well above the limit of the unit.

From the equilibrium study, we found that under these experimental conditions, less than 2% of the

NH_4^+ dissociates to give NH_3 . There is no evidence to show that NH_3 forms complexes with the copper species present. This result was somewhat surprising. The most likely function of ammonia is to modify the surface that copper is plated on (6).

Composition and Crystallinity of Electroless Nickel

Kazuyuki Sugita and Nobuo Ueno

Department of Image Science and Technology, Faculty of Engineering, Chiba University, Chiba, Japan 260

In the literature dealing with the deposition product of electroless nickel, several studies have been focused on the evaluation of properties, such as coercivity (1, 2), electrical resistivity (3, 4), and mechanical strength (5), and their correlation to phosphorus or boron content in the deposit, degree of crystallinity, and size or orientation of grains. It is known that the composition and structure of the deposit, in turn, depend on the substrate for deposition (1, 2), method of activation or acceleration (3, 6), type of plating bath (ligand or buffer system and reducing agent) (1-3), and plating conditions including concentration of each component, pH of plating bath, bath temperature, and plating duration (1, 5, 7, 8).

For the nickel deposited from the plating solutions, in which NaH_2PO_2 is employed as the reducing agent, it was reported that the deposit was a Ni-P binary alloy (2, 5, 7). As-plated nickel deposited from acidic solution had a higher phosphorus content and was

Key words: alloy, analysis, deposition, ESCA.

amorphous, while the nickel from alkaline solution had a lower phosphorus content and was crystalline (5, 7). On the other hand, Schwartz and Mallory have found that two Ni-P alloys containing approximately the same amount of phosphorus exhibited different magnetic behavior even after heat-treatment, if they were prepared from different solutions (2). The initial structure of nickel film as-plated from electroless solution is generally considered to be metastable, but it is transformed to a more stable state by aging or heat-treatment. The structure and property of aged deposits should have the correlation with the composition, if they are thoroughly heat-treated to attain to the most stable state which is determined by the phosphorus content. The result suggests that the structure of electroless nickel may not be determined only by the phosphorus content.

The purpose of this study is to analyze composition and crystallinity of the nickel deposits simultaneously and to find out what factors other than phosphorus

content govern the structure and property of the Ni-P alloy.

Experimental

Specimen preparation.—The substrate was the poly-(4,4'-bisphenylene ether pyromellitimido) film Torey 25KA, which was preliminarily activated with palladium for electroless plating. Other chemicals used in this study were of extra pure grade. The substrates were immersed in the electroless solution for nickel deposition. The formulation of electroless solutions and plating conditions are listed in Table I.

The nickel deposited above pH 10.7 at 60°C was metallic film tinged with black, while the deposits below pH 10.2 at 60°C and those below pH 10.4 at 52°C were lustrous silver. The rate of deposition showed a maximum at pH 10.2-10.5 when the bath temperature was kept constant, and pH was changed as a parameter in the range from 8.5 to 10.7. The maximum rate of deposition at 60°C was calculated to be 0.34 μ /min at pH 10.2, assuming that the density of the deposit equals that of pure nickel. The rate is very close to the value at 70°-75°C reported in the literature (2).

The nickel deposited on the polyimido film was scraped off and used as the sample for x-ray diffraction measurement and elemental analysis.

Composition of electroless deposits.—Nickel and phosphorus contents were measured first by chemical analysis: the nickel was determined by the dimethylglyoxime method (9), and the phosphorus was by the ammonium molybdophosphate method (10). The detailed procedure in the literature was modified until reproducible values were obtained: when nickel metal and phosphorus pentaoxide of extra pure grade chemicals were employed as the standard, the observed values coincided to the theoretical within relative errors of ± 4 and $\pm 2\%$, respectively.

Then, some of the nickel deposits on the polyimido film were analyzed with a VG Scientific ESCA Lab-5 Spectrometer which uses $AlK\alpha$ line as the x-ray source before and after argon ion etching.

X-ray diffraction.—X-ray reflection from the nickel deposits was measured with a Rigakudenki Diffractometer using $FeK\alpha$ or $CuK\alpha$ line.

Electron transmission microscopy and diffraction.—Clean substrates of glass, on which copper film was preliminarily vacuum-evaporated, were immersed in the electroless nickel solution and the plating was initiated by contacting with an aluminum wire for an instant (7). At the completion of a plating run, the copper substrate was stripped from the deposits in an aqueous solution of chromic acid (500 g/liter) and sulfuric acid (50 g/liter) (8). A Japan Electron Optics JEM-T6S and a Hitachi HU-11D electron microscopes were used for the measurements. The former was operated at 60 kV and the latter at 75 kV.

Results and Discussion

Composition of nickel deposits.—Nickel and phosphorus contents in the nickel, which was deposited from the plating solutions of various pH are illustrated in Fig. 1. It was found that the deposits contained a few weight percent of phosphorus and, besides nickel and phosphorus, a few weight percent of other compo-

nent(s). The amount of impurities, phosphorus and other component(s), was smaller in the range of pH 9.5-10.5 than in the range of pH 8.5-9.0. Correlation between composition of the deposits and concentration of the reducing agent, NaH_2PO_2 , was studied and is shown in Fig. 2. The amount of impurities was depressed by lowering concentration of NaH_2PO_2 . It is found that the phosphorus and other component(s) incorporated in the nickel deposit can be controlled by concentration of NaH_2PO_2 as well as pH of the plating solution.

The deposits from plating solutions of pH 9.0 and 10.0 were taken as an example with higher content of impurities (designated as Deposit-9, hereafter) and another with lower content of impurities (designated as Deposit-10, hereafter), respectively. They were studied by ESCA. The normalized spectra are shown in Fig. 3 and the peak intensities are in Table II. The first spectrum was run on the surface of the nickel deposit film without argon ion etching, and the second and the third ones were after argon ion etching down to depths of 5 and 20Å, respectively. The etched depth was estimated by the sputter yield of the iron film. The N_{1s} peak due to the substrate of polyimido was not detected, until the nickel film was etched about 100Å deep.

At the surface of the nickel films, P_{2p} and O_{1s} peaks, as well as Ni_{2p} peak due to nonmetallic nickel, were observed for both Deposit-9 and Deposit-10. By the way, the peaks around 860 eV of binding energy are the satellite ones. At a depth of 5 or 20Å, Ni_{2p} peak due to nonmetallic nickel was still intense for Deposit-

Fig. 2. Nickel and phosphorus contents in deposits from plating bath of various NaH_2PO_2 conc [pH 10.0, 55°C]; dotted area: other component(s) than Ni and P.

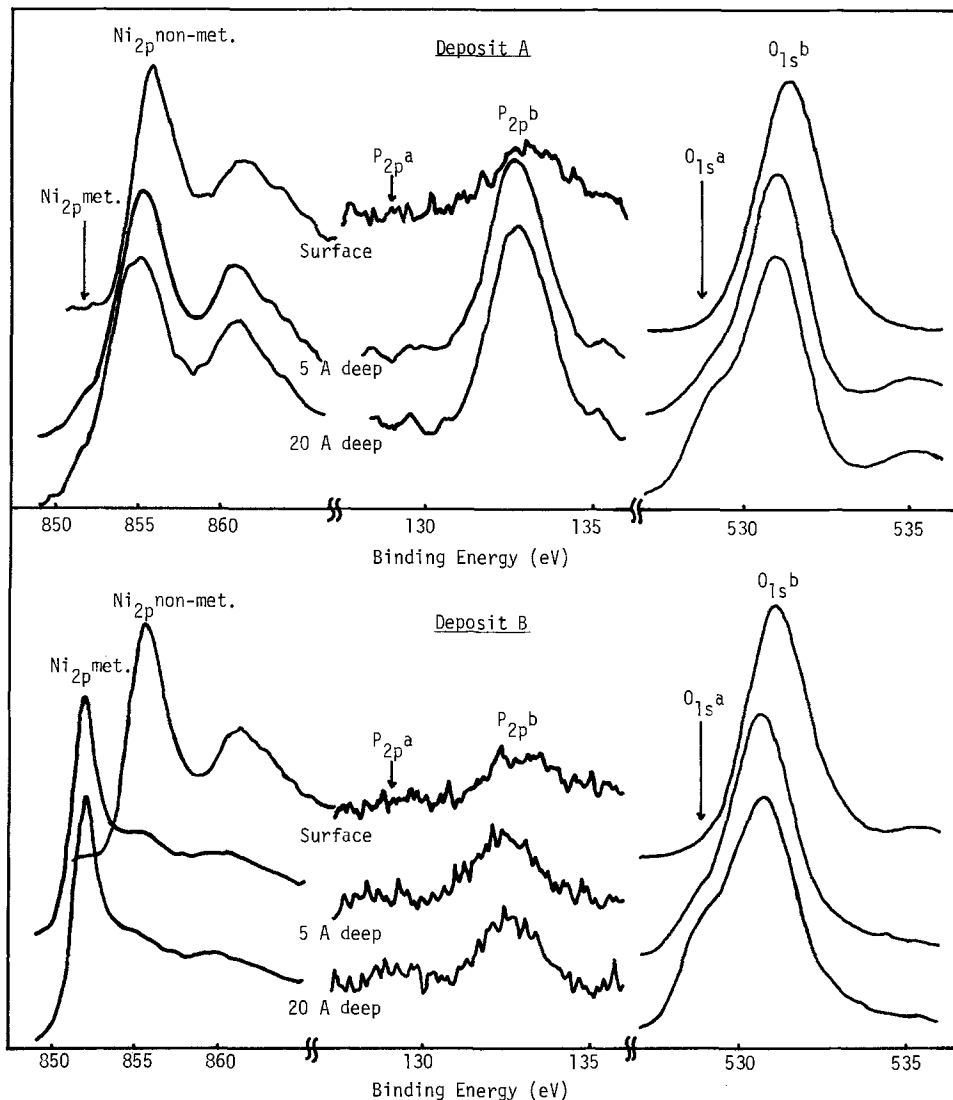

Fig. 3. Normalized ESCA spectra of nickel deposit film [NaH_2PO_2 conc: 25 g/liter, 55°C]; upper: Deposit-9 from plating bath of pH 9.0, lower: Deposit-10 from plating bath of pH 10.0.

9, while Ni_{2p} peak due to metallic nickel became dominant for Deposit-10. P_{2p} and O_{1s} peaks at a depth of 5 or 20 Å were as intense as those at the surface in the case of Deposit-9. The intensity of P_{2p} and O_{1s} peaks at a depth of 5 or 20 Å was much smaller than that at the surface in the case of Deposit-10. The peak intensities were consistent with the results of chemical analysis: intense for Deposit-9 (P; 6.3%, others; 7.2%), but weak for Deposit-10 (P; 3.2%, others; 2.0%).

The results indicate that metallic nickel is contained in Deposit-10, while most of Deposit-9 is composed of nonmetallic nickel. Shift of binding energy of 3-4.5 eV cannot be ascribed to the difference between crystalline and amorphous states, but indicates different valence states of nickel, metallic and nonmetallic. Then, it is considered that Deposit-9 with higher impurity content is nonmetallic or intermetallic compound. Moreover, it is confirmed that oxygen is contained, more or less, in the nickel deposit, and that the deposit is not a Ni-P binary alloy but ternary or quaternary, since hydrogen is difficult to be detected by this method.

Crystallinity of nickel deposits.—The crystallinity was investigated both by x-ray diffraction and by electron transmission diffraction. The former reveals the value averaged over many nickel grains, while the latter examines the value of a comparatively narrow area.

An influence of the substrate on the crystallinity of the deposits was suggested (2). In our study, x-ray diffraction was observed on the nickel deposit on the

polyimido film, and electron diffraction was on the deposit on the copper. The coincidence of the results by x-ray diffraction with those by electron diffraction indicates that the crystallinity of the deposit did not depend on the substrate in this system.

Graham *et al.* studied effects of variation in phosphorus content of electroless nickel deposited from alkaline-chloride-citrate and acid-sulfate baths, and established that increase of phosphorus content brings about decrease of crystallinity and that an abrupt change in the structure occurs at phosphorus content of about 7% (5). Chow *et al.* demonstrated that nickel film deposited from an alkaline-citrate bath assumes a crystalline structure when the solution is strongly alkaline (pH 10 or above) (7).

In this study, it was found that the nickel deposits from the pyrophosphate bath were crystalline above pH 9.4 when the concentration of NaH_2PO_2 was kept constant at 25 g/liter, or below 35 g/liter of NaH_2PO_2 concentration when pH was kept constant at 10.0. The deposit from the plating solution containing 15 g/liter of NaH_2PO_2 at pH 10.0 was as highly crystalline as the nickel which was vacuum-evaporated. When these results of crystallinity are considered together with those of composition mentioned above, it is concluded that decrease of crystallinity is caused by increase of oxygen (or oxygen and hydrogen) content(s) as well as increase of phosphorus content, and that amorphous nickel is composed of nonmetallic compound. The nickel deposits, which contained less than 4 weight percent (w/o) of phosphorus and more than 92 w/o of nickel, were crystalline and metallic.

Table II. Peak intensity of ESCA spectrum

Sample	Peak B.E. (eV) Depth	Ni _{2p}		P _{2p}		O _{1s}	
		metallic 851.80-851.95	nonmet. 854.95-856.35	a 128.70-129.55	b 132.40-133.10	a 528.60-528.95	b 530.55-531.25

	5	4707 (89)	5304 (100)	14	76 (1.4)	173	1767 (33)
	20	6448 (86)	7539 (100)	18	85 (1.1)	503	1853 (25)

* The number in parentheses indicates intensity relative to Ni_{2p} peak.

** Deposit-9 and Deposit-10 are those from plating bath of pH 9.0 and pH 10, respectively.

Impurity in nickel deposits.—Considerable amount of oxygen was directly detected by ESCA with Deposit-9 even after the surface layer of nickel oxide was etched away by argon ion bombardment. The oxygen incorporated in Deposit-10 was not negligible, either. Then, the impurity was found to be composed of phosphorus and oxygen (or phosphorus, oxygen, and hydrogen).

Since both the phosphorus component and the other components(s) increased as the concentration of NaH₂PO₂ increased, it should be reasonable to consider that they came from the hypophosphite ion. Therefore, the results suggest the possibility that the nickel deposit may contain, besides nickel phosphide, nickel phosphite as an impurity which was formed by oxidation of hypophosphite. The reactions which take place in the plating bath, including the side reactions, can be expressed by the following equations

where, Eq. [1] is the main reaction of the electroless deposition which gives metallic nickel (4).

In conclusion, the nickel film deposited from the ammoniacal pyrophosphate bath is not merely a Ni-P binary alloy, but contains oxygen (or oxygen and hydrogen). The crystallinity has a close relation to the amount of the impurities. The as-plated nickel can be

kept as metallic and highly crystalline as the vacuum-evaporated one by controlling pH and concentration of the reducing agent. On the contrary, electroless deposition of amorphous nickel, which is composed of non-metallic compound, is also possible.

Acknowledgment

The authors wish to thank Dr. Kozo Tsunoyama and Miss Takako Hane of Research Laboratories, Kawasaki Steel Corporation for their valuable assistance in the ESCA experiments. Thanks are also to Mrs. Kieko Harada for her helpful suggestions, and to Messrs. Yoshitomo Nabeoka, Shinya Maruyama, Masato Nagasawa, Hiroshi Ito, Masahiro Onuma, and Yasunori Doi for their contribution to this research.

Tungsten Etching in CF_4 and SF_6 Discharges

C. C. Tang* and D. W. Hess*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Plasma etching characteristics of tungsten films are studied in CF_4 and in SF_6 discharges. The etch rates are investigated as a function of electrode temperature, oxygen and hydrogen additions, system pressure, and RF power. Relative fluorine atom concentrations are determined by optical emission spectroscopy. Results indicate that tungsten etching is primarily controlled by fluorine atoms generated in the discharge in CF_4 plasmas or when oxygen is added to the etch gases. In pure SF_6 , SF_x species may play an important role in the etch process. Hydrogen additions scavenge fluorine atoms and generate residues which inhibit etching.

Due to the fine line geometries required for very large scale integration (VLSI), intense interest has developed in RF glow discharge etching of metal films. Since aluminum and its alloys are widely used for interconnections in integrated circuits, much of the work in plasma etching of metals has centered around these materials. However, as the need for lower resistivity and improved contact barriers arises, refractory metals such as tungsten receive increasing attention. Thus, an understanding of the chemistry of plasma-enhanced etching of these materials is necessary.

Tungsten plasma etching has been performed both in barrel and in parallel plate reactors. The primary gases used have been CF_4 and CF_4/O_2 mixtures (1, 2) although reactive ion etching (RIE) of tungsten in SF_6 has also been reported (3). It is believed that fluorine atoms formed by electron impact dissociation of fluorine containing molecules react with the tungsten surface to form tungsten hexafluoride as the final etch product. There are no reports concerning the use of chlorinated gases to etch tungsten. Most likely this is due to the lower volatility of tungsten chlorides (WCl_5 , bp 275.6°C; WCl_6 , bp 346.7°C) compared to tungsten hexafluoride (WF_6 , bp 17.5°C).

Maeda *et al.* (1) etched tungsten with pure CF_4 in a barrel reactor at 13.56 MHz. They reported that there was no etch rate dependence on temperature or on etch time. In addition, it was found that the etch rate and the fluorine atom emission intensities both decreased with increasing pressure. They conclude that the etching of tungsten was limited by the supply of active species. Kumar *et al.* (2) reported the etching of tungsten using 4% O_2 in CF_4 in an electrodeless chamber. The etch rate increased with RF power sub-linearly.

Wolfe *et al.* (3) reported the reactive ion etching of tungsten using SF_6/O_2 mixtures at a pressure of 10 mtorr. The etch rate of tungsten decreased monotonically with the addition of oxygen. At an SF_6/O_2 flow ratio of 5.7, the etch rate of tungsten increased with pressure from 80 nm/min at 5 mtorr to 200 nm/min at 30 mtorr.

This paper presents the results of a study initiated to investigate the plasma-enhanced etching of tungsten films. The effect of substrate temperature, RF

power, gas pressure, and oxygen and hydrogen additions to CF_4 and SF_6 etch gases are studied in a parallel plate plasma etching system. Optical emission spectroscopy is used as a diagnostic tool to determine relative fluorine atom concentrations in the etching atmospheres.

Experimental Procedures

Unless otherwise noted, the tungsten films were obtained via plasma-enhanced deposition from WF_6 and H_2 (4). The depositions were carried out at an electrode temperature of 350°C, and RF frequency of 4.5 MHz, an H_2/WF_6 ratio of 3, a pressure of 200 mtorr, and a power density of 0.12 W/cm². Sputtered films were deposited in a Perkin Elmer Randex sputtering system at 20 mtorr and 0.55 W/cm². The tungsten films used for etching studies were typically 0.4 μm thick, deposited onto borosilicate glass substrates. In all cases, the surface area of tungsten etched was 6.5 cm².

Plasma etching was performed in a 14 in diam stainless steel radial flow reactor with 7 in diam stainless steel electrodes. The samples were positioned on the lower grounded electrode, which was separated from the upper powered electrode by a distance of 2 in. The lower electrode was heated resistively by a ring heater affixed to the underside of the electrode. Since no cooling capabilities were available in this particular reactor, the minimum electrode temperature utilized for the present study was 60°C. This temperature allowed etch times greater than 15 min to be used without any detectable increase in electrode temperature as measured by a shielded chromel-constantan thermocouple.

The pumping system consisted of a 50 cfm corrosion resistant mechanical vacuum pump with a liquid nitrogen cold trap positioned between the pump and the etch chamber. The pressure was altered by throttling the pump at a fixed flow rate. A capacitance manometer was used to determine chamber pressure.

The etch gases used in this study were CF_4 (99.7%) and SF_6 (99.99%) obtained from Matheson Gas Products. No further purification was attempted. Oxygen (99.99%) was obtained from a liquid source, and was passed through a Matheson no. 451 purifier before being mixed with CF_4 or SF_6 . The flow rates of individual gases were controlled by Tylan mass flow controllers, and the gases were mixed prior to entering the etch chamber. Etch rates were determined gravimetrically

* Electrochemical Society Active Member.

by weighing samples before and after specific etch times.

In order to separately evaluate the effect of various plasma parameters on tungsten etch rates and fluorine atom densities, a set of standard etch conditions was established. The conditions used were; 50W (0.2 W/cm²), at 4.5 MHz, 200 mtorr pressure, 60°C electrode temperature, total flow rate of 75 sccm, 60°C electrode temperature, total flow rate of 75 sccm, and gas mixtures of 10% O₂ in either CF₄ or SF₆.

Optical emission studies were performed using a Plasmatherm (Model PSS-2) Plasma Scan Emission Monitoring System. The monochromator was positioned at a 4 in diam quartz window to monitor emission intensities. Relative fluorine atom densities were determined by using argon (2% of the feed gas) as a tracer or "actinometer," and recording emission intensities of Ar (750.4 nm) and F (703.7 nm) as a function of plasma parameters (5). No change in F atom emission intensity was observed for Ar additions up to 4%.

Results and Discussion

The etch depth of tungsten films in SF₆/O₂ or in CF₄/O₂ plasmas increases linearly with etch time. Further, when this linear relationship is extrapolated, the line passes through the origin, indicating that no lag time or initiation period exists at the start of tungsten etching. Such results are in sharp contrast to those observed during aluminum etching, wherein an induction period is typically observed (6). The cause of this difference in etch behavior is due to the fact that the native tungsten oxide does not present a barrier to plasma etching, whereas native aluminum oxide does. Aluminum forms strong bonds with oxygen. However, tungsten forms an unstable oxide (volatile above 800°C). A second consideration with regard to the observed etch differences between tungsten and aluminum relates to the heats of formation of the compounds involved in the two chemical systems. The heat of formation of the etch product WF₆ (-421 kcal/mol) is much higher than those of the oxides (WO₂, -136 kcal/mol; W₂O₅, -169 kcal/mol; WO₃, -201 kcal/mol), whereas the heat of formation of AlCl₃ (-140 kcal/mol) is considerably lower than aluminum oxide (-398 kcal/mol). These thermodynamic data are consistent with the observations that ion bombardment is needed to assist native aluminum oxide removal, while ion bombardment is not necessary for tungsten oxide etching. Indeed, tungsten can be etched in a barrel reactor with an etch tunnel that isolates the wafers from energetic ion bombardment (1).

Temperature dependence of etch rates.—Arrhenius plots of the etch rate of tungsten in 90% SF₆/10% O₂ and in 90% CF₄/10% O₂ plasmas are shown in Fig. 1. The apparent activation energy for both etching reactions is 0.2 eV/mol. The agreement of activation energies for tungsten etching in CF₄ and in SF₆ plasmas suggests that the active etchant species and the reaction mechanism may be the same for both etch gases. The higher etch rates observed with SF₆ over CF₄ plasmas are apparently due to the higher fluorine atom concentrations in SF₆ plasmas (see optical emission studies described below).

The temperature dependence of tungsten etching observed in the present study disagrees with the results of Maeda *et al.* (1). Maeda used pure CF₄ to etch tungsten in a barrel reactor. They reported that the etch rate did not depend upon substrate temperature between 25° and 320°C. Differences in these two studies are probably due to the variation in fluorine atom concentration between CF₄ and CF₄/O₂ plasmas. Clearly, a much lower concentration of fluorine atoms is present in CF₄ relative to CF₄/O₂ plasmas (see below). Since fluorine atoms appear to be the primary etchant for tungsten in these discharges, the discrepancies between this study and that of Maeda suggest

Fig. 1. Arrhenius plots of tungsten etch rate in CF₄/O₂ and SF₆/O₂ discharges.

basic differences in the rate-controlling steps for CF₄ vs. CF₄/O₂ plasmas.

In pure CF₄ discharges, the etch rate is most likely limited by reactant supply. That is, the generation of active species in the plasma, which is independent of temperature, is rate limiting. Further, fluorocarbon radicals generated in pure CF₄ plasmas may polymerize and deposit on tungsten surfaces. The removal of these polymers or residues on tungsten surfaces must be considered in the etching mechanism. However, the addition of oxygen greatly increases the supply of fluorine atoms. Consequently, the reactant supply is no longer rate limiting; instead, a surface reaction step becomes rate limiting in CF₄/O₂ plasma etching of tungsten. In addition, oxidation of fluorocarbon radicals precludes the deposition of fluorocarbon polymers.

Oxygen additions.—The effect of oxygen additions to CF₄ on the relative fluorine atom density and on the tungsten etch rate is shown in Fig. 2. Although both fluorine atom density and etch rate go through a maximum, the peak etch rate does not coincide with the maximum fluorine atom density. Such trends are identical to those observed in the CF₄/O₂ plasma etching of silicon (7, 8). These results also substantiate the claim that fluorine atoms are the primary etchant for tungsten in CF₄/O₂ discharges. As in the case of silicon etching (7), oxygen additions to CF₄ enhance the production of fluorine atoms and reduce carbon containing residues, thereby increasing the tungsten etch rate. Further, since fluorine and oxygen atoms compete for surface adsorption sites, a non-coincidence of the tungsten etch rate and the maximum fluorine atom concentration results, exactly analogous to that observed in silicon etching (7).

If direct electron impact excitation from the ground state to the emitting state is the dominant excitation process, then (5) the optical emission intensity, I_x , is given by $I_x = CN_x[X]$, where C is a constant, $[X]$ is the ground state concentration of species, X , and $N_x = k_x n_e$ is the excitation efficiency, a product of the rate

Fig. 2. Etch rate of tungsten and relative fluorine atom density as a function of oxygen concentration in CF_4 plasmas.

constant for direct excitation (k_x) and the electron density (n_e). The normalized excitation efficiency observed for argon atoms in this study is shown as a function of oxygen addition in Fig. 3. For comparison, these efficiencies are also given for results reported in Ref. (5) and (8). In all cases, the excitation efficiency decreases as the oxygen concentration increases. However, results reported in this study and in Ref. (8) are essentially the same, while the data from Ref. (5)

Fig. 3. Comparison of excitation efficiency as a function of oxygen concentration in CF_4 .

shows a more rapid initial drop in excitation efficiency with oxygen content. In large part, the nonconstant pressure conditions in the study of Ref. (5) (36 mtorr at 0% O_2 , 44 mtorr at 20%, 37 mtorr at 66% O_2) may be the cause of this difference.

The observed decrease in the excitation efficiency of Ar and F atoms suggests that the enhanced fluorine atom concentration caused by oxygen addition cannot be due to an increase in the dissociation rate of CF_4 [threshold energy for CF_4 dissociation and argon excitation energy are quite similar, 12 and 13.5 eV (3), respectively]. Thus, the enhanced fluorine atom density due to oxygen additions must be a result of reactions between oxygen atoms and radicals formed by the dissociation of CF_4 . Oxygen reacts with CF_x radicals to liberate fluorine atoms, thus minimizing CF_x and F recombination. Indeed, many reaction schemes are possible and these have been discussed previously (7).

Tungsten etch rates and relative fluorine atom concentrations in SF_6 plasmas are shown as a function of oxygen content in Fig. 4. Again, the maximum observed in the fluorine atom density is consistent with that displayed by CF_4/O_2 plasmas and is in agreement with results reported for silicon etching in SF_6/O_2 plasmas (9, 10). In a manner identical to CF_4/O_2 mixtures, enhanced fluorine atom production via oxygen additions to SF_6 can be explained by reaction of oxygen with SF_x radicals. Possible reaction schemes for SF_6/O_2 plasmas are discussed in Ref. (9).

The maximum etch rate shown in Fig. 4 occurs with a pure SF_6 discharge, which is in agreement with results reported on reactive ion etching of tungsten in SF_6/O_2 discharges as a function of oxygen addition (3). However, the maximum fluorine atom density which is four times higher than in a pure SF_6 discharge, occurs at 30% oxygen. Clearly, competitive adsorption between oxygen and fluorine atoms on a tungsten surface cannot explain the maximum etch rate at such low fluorine atom concentrations.

It is expected that the primary free radicals generated in SF_6 plasmas are SF_5 and SF_3 (11). When SF_5 and SF_3 migrate to the tungsten surface, they can undergo dissociative chemisorption to form F, SF_4 , and SF_2 . Thus, in addition to electron impact dissociation of SF_6 , another source of fluorine atoms is available. Therefore, if such dissociative chemisorption occurs, SF_x radicals may play an important role in

Fig. 4. Etch rate and relative fluorine atom density as a function of oxygen concentration in SF_6 plasmas.

tungsten etching in pure SF_6 discharges. Further support for these conclusions arises from the observation that the apparent activation energy for tungsten etching in a pure SF_6 discharge is 0.07 eV/mol. However, stable oxyfluorides form in SF_6/O_2 plasmas (9), so that fluorine atoms may be the important etchant species in the presence of even small concentrations of oxygen. Currently, the reasons for the striking differences between the etch behavior of silicon and tungsten in pure SF_6 vs. SF_6/O_2 plasmas are unclear; nevertheless, in light of the above results, the differences are probably related to variations in surface chemistry between these two film materials.

Sulfur hexafluoride has a higher F/S ratio and weaker sulfur-fluorine bonds than the corresponding F/C ratio and carbon-fluorine bonds in CF_4 . As a result, a higher fluorine concentration exists in SF_6/O_2 discharges. This explains the higher tungsten etch rate in SF_6/O_2 than in CF_4/O_2 discharges. In addition, sulfur forms compounds that are more volatile than similar carbon compounds. This is consistent with the fact that no sulfur or sulfur compounds are detected by Auger analyses after tungsten etching in pure SF_6 discharges. Therefore, residues may not be a great concern in these plasmas.

Hydrogen additions.—Hydrogen additions to CF_4 decrease the fluorine atom concentration dramatically due to the formation of relatively stable HF. Indeed, the emission intensity of fluorine (703.7 nm) quenches to zero after 10% hydrogen is added to CF_4 . No etching is observed and the weight of the sample increases as a result of a film being deposited on the tungsten surface. A postetch Auger spectrum of the tungsten surface shows W, C, O, and F. Apparently, a fluorocarbon film with tungsten incorporation forms from simultaneous tungsten etching and plasma polymerization. These results are similar to previous reports of simultaneous aluminum etching and chlorocarbon film formation (12). In the present study, hydrogen atoms are efficient scavengers of fluorine atoms causing an increase in the concentration of gas phase fluorocarbon unsaturates which are precursors to polymer formation. When the polymer film completely covers the tungsten surface, the film inhibits the etching of tungsten. Such observations are in agreement with silicon etching studies using CF_4/H_2 mixtures (13).

The addition of hydrogen to SF_6 discharges significantly decreases the tungsten etch rate. The rate falls from 80 to 25 nm/min with 10% H_2 added to SF_6 . However, the relative fluorine atom density is higher with 10% hydrogen addition than with pure SF_6 discharges. The reasons for such observations are unknown, but the results again suggest that SF_x radicals may be important in the etching of tungsten. Of course, the decreased etch rate due to hydrogen additions also results from competitive chemisorption on the tungsten surface between hydrogen and fluorine atoms or SF_x radicals.

Although Auger analysis did not detect sulfur on the tungsten surface during etching in SF_6/O_2 plasmas, a yellow deposit was observed on the base plate of the reactor. Auger confirmed that this deposit was sulfur. Apparently ion bombardment of the wafer combined with the slightly elevated electrode temperatures in this study, assist sulfur removal from the tungsten surface, thereby precluding deposition on the film.

Pressure dependence.—The dependence of the etch rate of tungsten and of the relative fluorine atom density on the reactor pressure are illustrated in Fig. 5 and 6 for CF_4/O_2 and SF_6/O_2 , respectively. Clearly, the etch rate and the relative fluorine atom density vary greatly with pressure in CF_4/O_2 and SF_6/O_2 plasmas; however, the functional relationship of etch rate with pressure in CF_4/O_2 and SF_6/O_2 is quite dif-

Fig. 5. Etch rate and relative fluorine atom density as a function of pressure in a 90% $\text{CF}_4/10\% \text{O}_2$ discharge.

Fig. 6. Etch rate and relative fluorine atom density as a function of pressure in a 90% $\text{SF}_6/10\% \text{O}_2$ discharge.

ferent. As shown in Fig. 5, the etch rate and the relative fluorine atom density in CF_4/O_2 both increase linearly with pressure in the range of 100–500 mtorr. Unlike CF_4/O_2 , the etch rate and the relative fluorine atom density in SF_6/O_2 plasmas increase with pressure and exhibit a maximum at 200 mtorr as indicated in Fig. 6. Above 200 mtorr, the etch rate and the relative fluorine density both decrease as the pressure increases.

The results of Fig. 5 and 6 can be explained by considering plasma energetics. As the total pressure increases, the ion energy drops; thus, the etch process will become more dependent upon a mechanism involving neutral reactive species. Therefore, the pressure dependence of the etch rate should be dominated by the relative abundance of neutral etchant species. As shown in Fig. 5 and 6, the functional relationship between the etch rate and the relative fluorine density and the pressure dependence in their respective plasmas are quite similar. Again, this indicates that the active etchant for tungsten is fluorine atoms.

An investigation of the excitation efficiencies of argon in both CF_4/O_2 and in SF_6/O_2 plasmas, indicate that the efficiencies decrease monotonically with increasing pressure. Although the electron density increases with pressure, the average electron energy, which is principally a function of the ratio of the electric field to the pressure (E/P), decreases with increasing pressure (14). The formation of excited argon species generally involves electrons with energies > 13.5 eV. This corresponds to electrons in the high energy tail of the electron energy distribution function. Naturally, the energies of these electrons are extremely sensitive to pressure variation.

Several factors are involved in the effect of pressure on fluorine atom density. (i) The collision rate of gas molecules with electrons will increase as pressure increases, thereby altering the generation rate of fluorine atoms; (ii) the electron energy decreases with a pressure increase which decreases the generation rate of fluorine atoms; and (iii) the fluorine atom residence time will increase with pressure, thereby increasing the fluorine atom density. These phenomena have opposing effects on fluorine atom density. As a result, the fluorine atom density reaches a maximum at a certain pressure which depends on the chemical system.

Comparison of the dependence of the fluorine atom density on pressure in CF_4 and in SF_6 discharges (Fig. 5 and 6) suggests that the electron energy in SF_6 plasmas is more sensitive to pressure variation than in CF_4 plasmas. Such conclusions are confirmed by measurement of the excitation efficiency of argon in these two plasma atmospheres. The normalized excitation efficiency in SF_6 discharges decreases much faster with pressure increases than in CF_4 discharges.

For comparison to the PECVD results, the etch rate of sputtered tungsten films was determined as a function of pressure. The dependence of etch rate on CF_4/O_2 pressure was identical to that shown in Fig. 5. However, the sputtered films etched at a rate 15% lower than the PECVD films. This result is probably due to the higher density of sputtered (19 g/cm^2) vs. PECVD (16.8 g/cm^3) films.

RF power.—Both the electron density and the average electron energy increase with RF power; thus, the rate of ionization, excitation, and dissociation of gas phase molecules increases. As a result, both the excitation efficiency and the relative fluorine atom density should increase with RF power in CF_4/O_2 and in SF_6/O_2 discharges. As shown in Fig. 7, this is the trend observed for SF_6/O_2 discharges. The identical situation is noted for CF_4/O_2 plasmas, except that the etch rates are lower than those observed for SF_6/O_2 by approximately a factor of 2.5. Clearly, this result is due to the lowered fluorine atom density in CF_4/O_2 compared to SF_6/O_2 plasmas.

Summary

Tungsten films can be etched in CF_4 and in SF_6 discharges. Unlike certain other metal films, the native oxide on tungsten does not inhibit etching. Therefore, reproducible and controllable etch rates can be routinely achieved in CF_4/O_2 and in SF_6/O_2 plasmas.

The etch rate of tungsten is strongly dependent upon oxygen additions. A maximum etch rate is observed

Fig. 7. Etch rate and relative fluorine atom density as a function of RF power in a 90% $\text{SF}_6/10\%$ O_2 discharge.

in 90% $\text{CF}_4/10\%$ O_2 plasmas, which is analogous to the trend observed in silicon etching in CF_4/O_2 discharges. With SF_6 , oxygen additions decrease the etch rate even though the fluorine atom density reaches a maximum at 30% O_2 . Such results suggest that SF_x radicals may play an important role in pure SF_6 plasma etching of tungsten. The increased etch rate observed in SF_6/O_2 compared to CF_4/O_2 discharges is due to the higher fluorine atom density in SF_6 plasmas. This fact, coupled with the observation that the apparent activation energy is identical for tungsten etching (between 60° and 160°C) in CF_4/O_2 and in SF_6/O_2 plasmas, indicates that fluorine atoms are the primary etchant in these atmospheres, and that the same reaction mechanism is probably operative in both discharges. With 90% $\text{CF}_4/10\%$ O_2 or 90% $\text{SF}_6/10\%$ O_2 plasmas, increases in RF power increase tungsten etch rates.

Hydrogen additions to CF_4 and to SF_6 result in a scavenging of fluorine atoms, thereby decreasing the overall etch rate, and generating residues of carbon or sulfur. However, Auger results suggest that sulfur is easily sputtered from the wafer during etching in SF_6 plasmas.

Deviation from Stoichiometry of Boron Monophosphide

C. J. Kim* and K. Shono**

Sophia University, Faculty of Science and Technology, Kioicho-7, Chiyoda-ku, Tokyo 102, Japan

ABSTRACT

The deviation from stoichiometry of boron monophosphide (BP) was controlled by heat-treatment. The BP of n-type conductivity was caused by anti-site phosphorus or by phosphorus vacancy. The BP of p-type conductivity was caused by anti-site boron or by boron vacancy.

Boron monophosphide (BP) is one of the III-V compound semiconductors. It is well known that BP grows on Si substrate by the thermal reaction of B_2H_6 and PH_3 in H_2 (1). Two possible causes of the donor or the acceptor in the BP have been reported (2). This work shows that the excess or lack of boron or phosphorus determines the conduction type and resistivity of the BP.

Experimental Procedure

The experimental apparatus for the growth of BP on Si substrate has already been reported (3). n-Type BP (100) was grown at $950^\circ C$, and p-type BP (100) at $1080^\circ C$ on the Si (100) substrate. Characteristic crystalline imperfections such as {111} twins, {211} twins, and {111} planar defects, exist at early growth of BP less than 300\AA thick (4). However, the half-order streak pattern observed by reflection electron diffraction (RED) from the surface of the 500\AA -thick BP shows a BP (100)-c (2×2) surface structure (5).

The BP compound decomposes easily when exposed in hydrogen at temperatures greater than $900^\circ C$. After the epitaxial growth of the BP, the BP surface was covered to 500\AA with Si_3N_4 deposited at $680^\circ C$ by the thermal reaction of SiH_4 and NH_3 in N_2 . Then, the sample was heated in N_2 . After the heat-treatment, the Si_3N_4 was removed by etching in hydrofluoric acid. The BP is chemically stable and cannot be attacked. The conduction type of the BP was determined by measuring thermoelectric power. The resistivity of the BP was measured with the four-point probe method or by measuring the ohmic current through the BP. The BP was removed by plasma etching in a mixture of CF_4 (98%) and O_2 (2%) or by a selective removing method (6). By measuring the sheet resistance and junction depth of the diffusion layer formed in the Si substrate during the heat-treatment, the amount of boron or phosphorus diffused from the as-grown BP was determined. The complementary error function profile was assumed.

Experimental Results

Resistivity of as-grown BP.—n-BP (100) can be grown on Si (100) at $950^\circ C$, and p-BP (100) at $1080^\circ C$. The flow rate of PH_3 and B_2H_6 has to be varied according to the growth temperature. The resistivity can be measured by the four-point probe method for n-BP grown on a highly doped p-Si substrate and for p-BP grown on a highly doped n-Si substrate by assuming p-n junction isolation. The resistivity obtained is

10^{-2} - 10^{-3} Ω -cm for both as-grown n- and as-grown p-BP.

Conduction type and resistivity of BP after heat-treatment.—After as-grown n- or p-BP covered with Si_3N_4 is heated in N_2 , a resistor with two Al electrodes, as shown in the inset of Fig. 1, is made to measure the resistivity of the BP. A diffusion layer is formed in the Si substrate having the same type of conductivity as the BP. The results are summarized in Fig. 1 for as-grown n-BP, and in Fig. 2 for as-grown p-BP.

The as-grown n-BP shows a high resistivity for 8 min of heat-treatment at $1200^\circ C$ and for 30 min at $1100^\circ C$. For longer heat-treatment times, it changes to p-BP. The resistivity of the p-BP decreases to as low as 10^{-2} Ω -cm as the heat-treatment time increases. The treatment temperature of $1050^\circ C$ is a characteristic one, where the resistivity is over 10^{10} Ω -cm for the heat-treatment time of more than 2 h. The conduction type cannot be determined by the

Fig. 1. Resistivity and conduction type of BP as a function of heat-treatment time. Starting n-BP was grown at $950^\circ C$. Inserts (a) and (b) are cross-sectional views of samples for the measurement of current-voltage characteristics through BP, after (a) the phosphorus diffusion layer is formed from n-BP in the Si substrate and (b) the boron diffusion layer is formed from p-BP over the phosphorus diffusion layer.

Key words: stoichiometry, BP, heat-treatment.

Fig. 2. Resistivity and conduction type of BP as a function of heat-treatment time. Starting p-BP was grown at 1080°C.

conventional thermoelectric power method. At 1000°C, the n-BP does not change its conduction type, and its resistivity increases gradually as the heat-treatment time is increased.

For the as-grown p-BP of Fig. 2, no change of the conduction type can be observed. However, for 1200° and 1100°C, a peak was observed in the resistivity. For treatment time greater than 8 min at 1200°C and for 30 min at 1100°C, the resistivity decreased as the heat-treatment time increased. The final value of the resistivity is less than 10^{-2} Ω -cm. At 1050°C, a resistivity of more than 10^{10} Ω -cm was obtained for the heat-treatment time of more than 3 h, and the conduction type could not be measured by the conventional thermoelectric power method. At 1000°C, the type of conductivity did not change from p-type for heat-treatment time of more than 10 h.

By the heat-treatment at 1100°C for 30 min on the as-grown p-BP, p-BP acquires a resistivity of 150 Ω -cm. When given subsequent heat-treatment at 1000°C for several hours, a conversion of the conduction type from p-BP to n-BP was observed.

Diffusion layer formed in Si substrate.—It was found that n-BP acts as a source diffusing phosphorus into the Si substrate and that p-BP diffuses boron into the Si substrate. If a p-Si substrate is employed for the growth of n-BP, and an n-Si substrate is employed for the growth of p-BP, diffusion layers are found in the Si substrate.

Representative results for as-grown n-BP for heat-treatment at 1100°C are shown in Fig. 3. For a heat-treatment time of less than 30 min, an n-type diffusion layer was formed in the Si substrate. The junction depth (x_j) increases in proportion to the square root of the heat-treatment time (t), and the sheet resistance (R_s) decreases in proportion to the square root of t . After 30 min, a p-type diffusion layer appeared on the n-type diffusion layer. Its junction depth (x_{jB}) seems to increase linearly with the increase of the heat-treatment time. The sheet resistance R_{sB} decreases steeply in comparison with that of R_s .

Discussion

Total amount of phosphorus or boron in as-grown BP.—The resistivity of as-grown n- or p-BP in the range from 10^{-2} to 10^{-3} Ω -cm gives a carrier concentration of 10^{20} – 10^{21} cm^{-3} when assuming an electron or hole mobility of about $15 \text{ cm}^2/\text{V} \cdot \text{s}$ (7). As-grown

Fig. 3. Junction depth (x_j) and sheet resistance (R_s) of phosphorus or boron-diffusion layer formed in Si substrate. The heat-treatment temperature was 1100°C.

n-BP acts as a diffusion source of phosphorus, which forms an n-type diffusion layer in the Si substrate. A double donor of anti-site phosphorus is a cause of as-grown n-BP (2). As-grown p-BP acts as a diffusion source of boron, which forms a p-type diffusion layer in Si substrate. A double acceptor of anti-site boron is a cause of as-grown p-BP. The excess amount of phosphorus or boron contained in the as-grown BP is estimated to be in the range of 10^{15} to 10^{16} cm^{-2} for the BP thickness of 500Å employed in the experiment.

Total amount of phosphorus or boron diffused into the Si substrate.—From the sheet resistance (R_{sP}) and the junction depth (x_{jP}) given in Fig. 3, the phosphorus surface concentration (C_{SP}) can be obtained by applying Irvin's curve (8). As shown in Fig. 4, C_{SP} is constant at about 5.0×10^{19} cm^{-3} . The total amount of phosphorus (Q_P) diffused into the Si substrate, which is almost in proportion to the square root of t , reaches about 2×10^{15} cm^{-2} . After 25 min of heat-treatment, Q_P reaches a saturation point. The diffusion coefficient of phosphorus (D_P) can be estimated to be: $D_P = 5.5 \times 10^{-13}$ cm^2/s . This value is almost the same

Fig. 4. Surface concentration and total amount of phosphorus and boron diffused into Si substrate from the BP. The heat-treatment temperature was 1100°C.

as the well-known phosphorus diffusion coefficient at 1100°C (9).

The boron surface concentration (C_{SB}) and the total amount of boron (Q_B) diffused over the phosphorus diffusion layer are also obtained. A simple calculation employing t gives the result of Fig. 4. C_{SB} is a constant of about $5.3 \times 10^{19} \text{ cm}^{-3}$, a value larger than that for phosphorus. Q_B seems to increase linearly with t . However, by employing the actual time of boron diffusion, which is given as $(t - 25)$ min for 1100°C, the total amount of boron (Q_B') shown in Fig. 4 becomes in proportion to the square root of t .

Qualitative characteristics of BP according to the heat-treatment are summarized in Fig. 5. At heat-treatment temperatures greater than 1050°C, the as-grown n-BP finally changes to p-BP. By observing the diffusion layer formed in the Si substrate, it was confirmed that the n-BP acted as a phosphorus diffusion source ("1" in Fig. 5) and that the p-BP as a boron diffusion source ("3" in Fig. 5). The total amount of phosphorus for 8 min at 1200°C, for 25 min at 1100°C, and for 120 min at 1050°C is almost the same as the same level as the excess amount of phosphorus contained in the as-grown n-BP (i.e., about $2.5 \times 10^{15} \text{ cm}^{-2}$). Boron diffusion can be explained as due to a boron vacancy formation after stoichiometric composition. The amount of boron vacancy in p-BP was ascertained to be almost equal to the total amount of boron diffused into the Si substrate over the n-type diffusion layer.

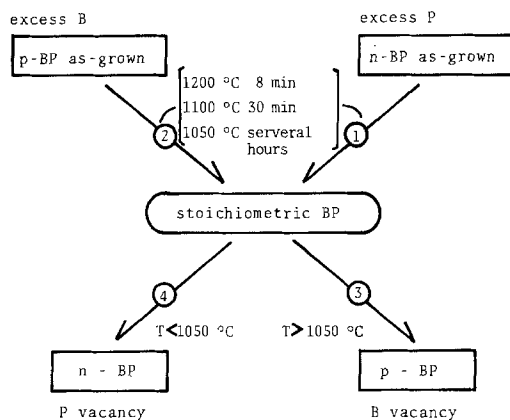

Fig. 5. Qualitative characteristics of BP due to the heat-treatment.

For as-grown p-BP, with the heat-treatment greater than 1050°C, as-grown p-BP keeps the p-type conductivity. The first boron diffusion into the Si substrate from p-BP ("2" in Fig. 5) comes from the excess boron on regular phosphorus sites, and the second one ("3" in Fig. 5) comes from a boron on the regular lattice sites, resulting in a boron-vacancy formation.

A phosphorus-vacancy formation ("4" in Fig. 5) can also be expected. It was confirmed that the stoichiometric BP after a preliminary heat-treatment for 30 min at 1100°C of as-grown n- or p-BP finally changed to n-BP after several hours of heat-treatment at 1000°C. In this case, the analysis of the phosphorus diffusion layer was difficult, because C_{SP} is lower than C_{SB} , and the total amount of phosphorus is too small for diffusion temperatures less than 1050°C.

Conclusion

The deviation of BP from stoichiometry determines its conduction type. The type obtained is determined by heat-treatment after the BP surface was covered with Si_3N_4 . n-BP is given by anti-site phosphorus or phosphorus vacancy, and p-BP is given by anti-site boron or boron vacancy.

A Method of Forming Contacts Between Two Conducting Layers Separated by a Dielectric

E. R. Sirkin* and I. A. Blech**

Xerox Corporation Palo Alto Research Center, Palo Alto, California 94304

ABSTRACT

A technique for vertically interconnecting two conducting layers separated by an insulator is described. The technique offers advantages over present methods, including complete step coverage over vertical via walls and a planarized surface. In addition, this technique can be extended easily to form multiconductor-insulator interconnects. Moreover, as device dimensions are reduced to the micron and submicron level, the planarization and therefore the interconnection will improve. The method will have applications in integrated electronics and perhaps integrated optics and other semiconductor devices.

Integrated circuits contain several electrically conducting layers such as the silicon itself, polycrystalline silicon, and one or more layers of metallization. The conductors are separated by dielectric layers which are preferentially etched to make interlayer contacts. The interlayer contacts are traditionally made by etching holes (vias) in the dielectric prior to the deposition of the top conductor. The disadvantages of this method are: (i) incomplete metal coverage over the via sidewall, and (ii) creation of a nonplanar structure.

The present paper describes a procedure which overcomes both disadvantages using a planarization technique. A similar technique has been suggested previously (1).

Interconnect Technique

The planarization consists of six basic steps.

First, deposition of a thick conductor layer having a thickness at least equal to the sum of the standard first-level conductor and the insulator thicknesses.

Second, formation of pillars on the first conductor (rather than vias) by etching part of the thick conductor (Fig. 1a).

Third, definition of the first-level conductor (Fig. 1b).

Fourth, deposition of a thick insulator layer.

Fifth, application of a viscous thick layer (e.g., photoresist) to a thickness greater than the pillar height in a manner which results in a planar surface (Fig. 1c).

Sixth, etchback of the thick viscous and insulator layers at similar rates (thereby exposing the top of the conducting pillars [Fig. 1d]).

Seventh, formation of the top conductor (Fig. 1e).

Experimental

Starting materials consisted of polished 3 in 20-50 Ω -cm $\langle 100 \rangle$ p-type Si wafers with 75 nm of thermally grown SiO_2 . Deposition of the first conductor, 1300 nm Al, was accomplished in a Balzers Model 450 PM Magnetron Sputterer. Shipley Microposit 1400-26 positive photoresist was spun over the metal surface and exposed using a reticle opposite in polarity to that of a standard via pattern. The photoresist was developed and the aluminum wet etched to form pillars 750 nm high (Fig. 1a). Next, the first-level metal mask was defined, and the metal etched (Fig. 1b). The resulting structure, as seen in Fig. 2, a scanning electron micrograph (SEM micrograph), shows 750 nm-high pillars extending from the remaining aluminum film, which is 550 nm thick.

The insulating layer, a 4% by weight phosphorous-doped SiO_2 film, was deposited at 400°C to a thickness of 850 nm in a low temperature chemical vapor depo-

sition (CVD) system. This thickness is somewhat less than that prescribed according to Fig. 1c. As a consequence, after planarization the metal pillars were coplanar with the SiO_2 surface over the bottom metal film, but not with the SiO_2 surface over the field regions of the wafer. This technique, however, can be easily extended so as to produce truly planar surfaces by depositing a thicker dielectric (as illustrated in Fig. 1). Measurements made using a Tencor Alphastep profilometer showed that the metal step heights were reproduced after SiO_2 deposition, thereby indicating good conformal coverage. Shipley 1400-33 Microposit photoresist was spun over the insulating SiO_2 layer using a Machine Technology, Incorporated Omnichuck at a spin speed of 2840 rpm. To ensure good uniformity, the resist was dispensed while the wafer spun at ~ 90 rpm. Hexamethyldisilazane was also applied prior to the resist to ensure good adhesion. The wafer was then baked at 180°C for 30 min. Duplication of this procedure on a test wafer without the SiO_2 and metal layers indicated a photoresist index of refraction of 1.65 and a thickness of 2240 nm. A photoresist thickness

Key words: etching, contacts, integrated circuits.

Fig. 2. SEM micrograph of the etched first conductor showing the pillar interconnects.

of 2240 nm, as measured in the field, on wafers with etched-metal structures was verified with a Nanometrics Nanospec. Measurements on the Tencor Profilometer indicated that the step height of 750 nm resulting from the metal pillars was reduced to 50 nm. Thus, the metal steps were planarized.

The metal pillars were exposed by etching back the resist and SiO_2 layers above the pillars. This was accomplished in an Applied Materials AME 8110 Reactive Ion Etcher. By varying the $\text{CHF}_3:\text{O}_2$ gas ratio while maintaining all other etch parameters, constant etch-rate curves were generated for the SiO_2 and the planarizing photoresist (Fig. 3). Etch conditions were chosen so that the oxide and photoresist etched at the same rate. As a consequence, the planar resist surface profile is transferred into the oxide surface. A similar planarization approach was previously described by Adams and Capio (2). Figure 4, an SEM micrograph, shows the etched back structure with the pillar-top surface exposed. Calculations indicated that for the etch cycle used, the final photoresist thickness over the SiO_2 layer in the field should be 530 nm. The measured thickness was 512 nm, verifying that the etch performance was consistent with predictions. This resist layer was next stripped in an asher.

Prior to depositing the second conducting layer, the surface of the wafer was exposed to an RF backscatterer in the magnetron sputterer in order to remove the native oxide on top of the conducting pillars. Without breaking vacuum, a thin layer 100 nm of Ti-10%W alloy followed by 1000 nm of Al-2%Cu were sputtered on the wafer. The only purpose for depositing the TiW was to provide an etch stop in case the wafer had to be stripped and etched further in the Reactive Ion Etcher.

The top metal layer was defined by wet etching both the Al-2%Cu and TiW layers. The completed structure, consisting of interconnected first- to second-level metal stitchthroughs, is shown in Fig. 5. A cross section of the interconnecting structure showing the bottom-level metal, the interconnecting pillar, the insulating oxide film, and the top-level metal is shown in Fig. 6. The first-level metal and field regions are uniformly covered by the deposited oxide ensuring electrical insulation between the two conducting layers. The utility of the planarization technique is demonstrated by the pillar structure, which does not suffer from step coverage problems normally encountered in via etching followed by metal deposition. Moreover, the plasma-etched insulating oxide surface, over the first-level metal, is coplanar with the top surface of the pillar.

Fig. 3. Etch rates of 4% p-doped SiO_2 and planarizing photoresist as a function of O_2 gas concentration.

Fig. 4. SEM micrograph of planarized SiO_2 surface with pillar interconnect exposed.

This enhances step coverage and photolithographic definition in subsequent processing steps. The top-pillar surface is clearly in direct physical contact with the top-level metal.

Results

Electrical probe measurements were taken in order to ensure that contacts were made between the first and second conducting layers by the interconnecting pillars and wherever there were no pillars that the two conducting films were electrically isolated. The

Fig. 5. SEM micrograph of the completed interconnect structure on a stitchthrough test pattern.

pattern used to test electrical continuity between the two metal layers was a standard stitchthrough pattern consisting of 108 rows of 20 contacts per row. Each contact size was $2 \times 2 \mu\text{m}$ (area = $4 \mu\text{m}^2$). A standard overlapping meander structure with 3600 crossovers was used to test electrical isolation.

The first- and second-level metal widths were $4 \mu\text{m}$. Testing of these structures on a wafer processed according to the procedure given in the previous section did not result in a positive continuity test. However,

Fig. 6. SEM micrograph of a cross section through a pillar interconnect.

after the wafer was given a standard sintering treatment (450°C for 30 min in a reducing atmosphere of 15% N_2 and 85% H_2) contact was made and showed that all of the 2160 contacts in the stitchthrough were electrically conducting. The measured resistance was 500Ω , indicating a resistance of 0.25Ω per contact. Allowing 0.18Ω for the metallization, the net contact resistance is 0.07Ω per contact (or $\sim 3 \times 10^{-9} \Omega\text{-cm}^2$ specific contact resistivity). On the same die, the meander structures showed electrical isolation up to 15V dc.

Conclusions

A technique for interconnecting two conducting layers separated by an insulating film has been demonstrated. The technique does not suffer from step coverage problems encountered in standard via-interconnect fabrication. The surface of the intermediate insulating film is coplanar with top of the interconnecting metal (pillars), and provides a smooth surface for the second-level metallization. This technology can be readily extended to multilevel (>2) interconnects.

Chemical Etching of GaAs

Sadao Adachi and Kunishige Oe

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo 180, Japan

ABSTRACT

A new HCl:CH₃COOH:K₂Cr₂O₇ system which is particularly suitable for use in etching solutions of GaAs crystals has been developed. This system can be classified into two individual regions, A and B, according to etching characteristics. The solutions in region A are light orange in color, while those in region B are dark brown. The rate-limiting process is the reaction rate limited in region A, and the diffusion limited in region B. This system, especially in Region A, provides high-quality etched surfaces without any undesirable roughness or etch pits. Etching rates for (001) GaAs vary from 0.01 to 1 μm/min, depending on the component proportion of the solutions and/or on the normal K₂Cr₂O₇ aqueous solution. Ordinary mesa-shaped structures have been formed on etching stripes in (001) GaAs parallel to the [110] and $\bar{1}\bar{1}0$ directions. The system does not erode photoresists, and so is attractive for a variety of GaAs device applications.

Chemical etching is one of the most commonly employed techniques in the semiconductor device and materials science fields. A number of investigators have reported on the etching characteristics of GaAs crystals (1). Recently, we have studied the preferential etching characteristics of GaAs in solutions of various etchant systems (HCl, HNO₃, HBr, etc.) and have demonstrated geometrically etched profiles produced in the (001) planes of GaAs by employing these etchant systems (2). Important factors determining the choice of an etchant are, generally, the etching rates for the materials in question, the degree of surface quality, the solution chemical aggressiveness toward photoresist masks, and the desired etching profile for the relevant purpose.

The most commonly used etchants for GaAs are various compositions of Br₂-CH₃OH, H₂SO₄-H₂O₂-H₂O, and NH₄OH(NaOH)-H₂O₂-H₂O (1). These solutions, however, tend to erode photoresist masks such as AZ-1350J, and often provide little degree of reproducibility of etched-depth control. In the fabrication of GaAs electron devices, e.g., field effect transistors (FET's), the thickness of the active layer must be controlled with sufficient accuracy. Various depth profiles (impurity concentration, mobility, etc.) must be exactly measured by using etch removing techniques to characterize various kinds of devices based on such material properties.

In this paper, a new etching solution composed of HCl, CH₃COOH, and K₂Cr₂O₇ aqueous solution is developed for the etching of GaAs. This system can be classified into two regions (A and B), according to the etching characteristics. Region A is the chemical-reaction rate-limited process, while region B is the diffusion-limited one. This solution does not erode photoresists such as AZ-1350J, and gives high-quality etched surfaces. Etching rates for (001) GaAs vary from 0.01 to 1 μm/min, depending on the component proportion of the solutions and/or on the normal K₂Cr₂O₇ aqueous solution. Such features are attractive for a variety of GaAs device applications.

Experimental

The GaAs single crystals employed were Si-doped, n-type with carrier densities in the region of 10¹⁸ cm⁻³. Studies were also performed on Cr-doped, semi insulating GaAs crystals, and it was found that the etching rates were not affected by conductivities of the wafers. All the wafers used were of (001) surface orientation with an uncertainty of one degree or less. After being mirror-like finished, degreased, and rinsed in deionized water, they were chemically etched in an H₂SO₄:H₂O₂:H₂O = 3:1:1 solution for 1 min at 80°C.

Key words: GaAs, chemical etching, etching rate, etching profile.

The etching solution was prepared by mixing HCl, CH₃COOH, and K₂Cr₂O₇ aqueous solution. The chemicals used were all of reagent grade. They were as follows: HCl (12N), CH₃COOH (17N), K₂Cr₂O₇ (purity ≅ 99.8%), and H₂O (deionized water). The composition dependence of the etching rate was measured by changing the proportions of these etching solutions. A large quantity of solution was prepared to prevent the etching temperature from rising and the etching solution composition from varying during the experiments. Etching was carried out in a temperature-regulated water vessel without illumination and stirring. The etching solution temperature was varied between 5° and 60° ± 0.5°C. The etchant was freshly mixed prior to each experiment.

Etching studies were performed for the etching selected regions of (001) surface GaAs through windows in AZ-1350J photoresist mask. The desired geometries, in this case the window width of 30 μm, were defined by standard photolithography techniques (3). After etching, removing the AZ-1350J mask, and rinsing in deionized water, the etched depths were measured from a step height between the etched and unetched surfaces using an interference microscope. Etching profiles were also observed on the (110) and $\bar{1}\bar{1}0$ planes perpendicular to the wafer surface under an optical microscope.

Etching Rate

The purpose of this section is to present accurate data of the etching rate as a function of composition proportion in the HCl:CH₃COOH:(1N-K₂Cr₂O₇) system. The etching kinetics will be mentioned in detail in the next section. The dependence of the etching rate on composition *m* of the etchant HCl:CH₃COOH:(1N-K₂Cr₂O₇) = *m*:1:1 by volume ratio (hereafter referred to as HCl-*m*11) for (001) GaAs at 20°C is shown in Fig. 1. The K₂Cr₂O₇ solution was prepared by dissolving 14.7g K₂Cr₂O₇ in deionized water (100 cm⁻³). The data show that the etching rate increases with increasing *m* in the lower *m*-value region and is nearly constant in the higher *m*-value region (*m* ≅ 2.0). For *m*-values lower than 1.5, the etchants are transparent and light orange in color. The etchants with *m* ≅ 1.5, on the other hand, are dark brown in color. The etchants, especially in the region of *m* < 1.5, provide high quality etch-pit free GaAs surfaces.

Figure 2 shows the dependence of the etching rate on composition *n* of the etchant HCl:CH₃COOH:(1N-K₂Cr₂O₇) = 1:*n*:1 by volume ratio (HCK-1*n*1) for (001) GaAs at 20°C. As clearly seen in the figure, the etching rates decrease gradually with increasing *n*. In this case, the etchants are transparent and light orange in color within our experimental range. An etched-surface quality is also very good within our measured *n*-value range.

Fig. 1. The dependence of the etching rate on composition m of the etchant $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = m:1:1$ (HCK-m11) for (001) GaAs at 20°C .

Fig. 2. The dependence of the etching rate on composition n of the etchant $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 1:n:1$ (HCK-1n1) for (001) GaAs at 20°C .

The dependence of the etching rate on composition l of the etchant $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 1:1:l$ by volume ratio (HCK-11l) for (001) GaAs at 20°C is shown in Fig. 3. The etching rate increases with increasing l , peaking at $l \approx 0.7$ ($\approx 0.49 \mu\text{m}/\text{min}$), and then decreases with increasing l . The etchants are dark brown in color for the l -values lower than 0.55, and light orange in the region of $l \approx 0.55$. The etchants also provide high-quality etch-pit free GaAs surfaces within our experimental range.

The etchants, such as $\text{HCl}:\text{CH}_3\text{COOH}$ and $\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)$ mixtures do not etch GaAs, but the $\text{HCl}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)$ mixture etches GaAs sufficiently. Figure 4 shows the etching rate as a function of the solution of $(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)/\text{HCl}$ by volume ratio for (001) GaAs at 20°C . It can be seen that the etching rate is proportional to this ratio in the lower ratio

Fig. 3. The dependence of the etching rate on composition l of the etchant $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 1:1:l$ (HCK-11l) for (001) GaAs at 20°C .

Fig. 4. The dependence of the etching rate on volume ratio of the $(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)/\text{HCl}$ etchant for (001) GaAs at 20°C .

region, showing a maximum at $(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)/\text{HCl} \approx 0.7$, and then decreases gradually with increasing ratio. The etched-surface quality is good within our experimental range.

Dissolution Process

We showed in Fig. 1-4 accurate experimental data of the etching rate as a function of composition proportion in the $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)$ system. It was found that the etchants' being light orange in color provide good reproducible etching rates and high-quality etched surfaces, their being dark brown does not. In this section, we shall investigate in detail the dissolution mechanism of this system on GaAs of (001) surface orientation.

Figure 5 shows the triangular coordinate system that was used to represent the composition of the $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)$ system. Each vertex corresponds to 100% of one of the constituents. This figure presents the composition of the etchant by volume of the constituents. Shown in the figure are lines

Fig. 5. Constant etching rate curves for (001) GaAs in the system $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7)$, at 20°C . The numbers represent etching rates in $\mu\text{m}/\text{min}$.

of constant etching rate with its increment of $0.1 \mu\text{m}/\text{min}$, plotted as a result of a large number of individual determinations. The triangular diagram can be divided into two individual regions, A and B. A corresponds to the light orange solution and B to the dark brown solution. The boundary between the regions A and B is given by the dashed line. As shall be shown, these regions exhibit different etching characteristics.

The etched depth as a function of time for (001) GaAs in the light orange (HCK-111) and dark brown solution (HCK-511) is shown in Fig. 6. The data were taken at 20°C . The stirring effect was examined for

Fig. 6. Relation between etched depth and etching time for (001) GaAs in the solutions of $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 1:1:1$ (HCK-111) and $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 5:1:1$ (HCK-511) at 20°C .

these solutions by stirring the samples by hand. As clearly seen in the figure, the etched depths were found to have a nearly linear dependence on etching time for both the solutions with and without stirring. It is noted that the light orange solution did not show a clear stirring effect, as the dark brown solution did.

Figure 7 shows the temperature dependence of the etching rate in the light orange (HCK-111) and dark brown (HCK-511) solutions. The etching rates were found to increase exponentially with increasing etchant temperature in each etchant. The activation energies were determined to be 11.6 kcal/mol for the HCK-111 and 4.6 kcal/mol for the HCK-511 etchant.

It is well known that the dissolution process is either reaction-rate limited or diffusion limited (4-6). The reaction-rate limited process is a function of the chemical reaction rate, while the diffusion-limited process depends on the transport of etchant molecules by diffusion. The former process has a linear dependence of the etched depth d on etching time t , i.e., $d \propto t^{1.0}$, while the latter process has in general a relation of $d \propto t^{0.5}$. The diffusion-limited process usually has lower activation energy than the reaction-rate limited process, and is therefore relatively insensitive to temperature variations. In fact, Iida and Ito (7) have studied the etching characteristics of (001) GaAs in the $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ system and obtained activation energies of $6-8 \text{ kcal/mol}$ in high H_2SO_4 solutions (diffusion limited) and $8-11 \text{ kcal/mol}$ in low H_2SO_4 solutions (reaction-rate limited). Moreover, the diffusion-limited process shows notable stirring effect on the etching rate; the reaction-rate limited process does not. From these considerations, one can conclude that the light orange and dark brown solutions are due to the chemical-reaction rate-limited and diffusion-limited etching processes, respectively.

Figure 8 shows the etching rate as a function of normal k ($k\text{N}-\text{K}_2\text{Cr}_2\text{O}_7$) in the $\text{HCl}:\text{CH}_3\text{COOH}:(k\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 1:1:1$ solution taken at 20°C . The etching rate increases with increasing normal k in the region up to $k \approx 0.2$, and then saturates with k in the region higher than 0.2 . In the low- k region ($k \leq 0.2$), the dependence of the etching rate R on k can be expressed exactly by $R \propto k^{1.0}$. For the k -value lower than 0.2 , the etchants are dark brown in color (diffusion-limited process). The etchants with $k > 0.2$, on the other hand, are light orange (reaction-rate limited process).

The microscopic etching mechanisms under consideration are thought to be very complex, since the dependence of the etching rates for (001) GaAs on the etchant-component proportions does not have simple linear relations; it indicates complicated behavior (see Fig. 1-4). Thus, at present, we cannot formulate

Fig. 7. Temperature dependence of the etching rate in the solutions of $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 1:1:1$ (open circles) and $\text{HCl}:\text{CH}_3\text{COOH}:(1\text{N}-\text{K}_2\text{Cr}_2\text{O}_7) = 5:1:1$ (filled circles).

Fig. 8. Etching rates as a function of normal k ($kN\text{-}K_2Cr_2O_7$) in the solution of $HCl:CH_3COOH:(kN\text{-}K_2Cr_2O_7) = 1:1:1$ for (001) GaAs at $20^\circ C$.

rate equations of dissolution processes for GaAs by taking into account the etchant-component proportions. However, one can expect from a phenomenological aspect the following etching kinetics. The chemical reaction in the light orange solutions may be formally represented by the equations

The $Cr_2O_7^{2-}$ ion provides the light orange color, and its oxidation action would oxidize GaAs. The oxidized products can, then, be easily dissolved by HCl. As can be seen in Fig. 5, CH_3COOH acts only as a diluent for these kinetics. The rate-limiting process is thought to be the surface reaction, such as oxidation of GaAs and dissolution of oxidized products. The case for the dark brown solutions should essentially be the same as for the light orange. The dark brown color would arise from various kinds of chromates. The rate-limiting process, however, is the diffusion of oxidizing agents. One can also point out that the $K_2Cr_2O_7$ aqueous solution in this system contributes to produce etch-pit free, high-quality surfaces and, moreover, to increase the etching rates of (001) GaAs with increasing its normal, k (see Fig. 8).

Etching Profile

Etching profiles are examined by cleaving the (001) GaAs wafer in orthogonal directions along the (110) and $(\bar{1}10)$ planes. The profiles of (001) GaAs etched through AZ-1350J mask in the HCK-111 (light orange) solution are shown in Fig. 9a. It is clear from the figure that the profiles change in shape with a crystallographic rotation of 90° about the [001] axis and that they exhibit clear crystal habits. The etching profile of the (110) cleavage plane exhibits the ordinary mesa-shaped plane forming an angle of about 70° with respect to the (001) surface plane. The profile of the $(\bar{1}10)$ cleavage plane also indicates the inclined plane whose side forms an angle of about 35° with respect to the (001) surface plane. The etch-revealed plane forming an angle of about 70° with respect to the (001) surface plane, observed on the (110) cleavage plane, corresponds to the $\{2\bar{2}1\}$ crystallographic plane. The $\{2\bar{2}1\}$ plane, in principle, forms an angle of 70.5° with respect to the (001) surface plane. The inclined plane forming an angle of about 35° with respect to the (001) surface plane, observed on the $(\bar{1}10)$ cleavage plane, corresponds to the $\{112\}$ crystallographic plane. This plane, in principle, forms an angle of 35.3° with respect to the (001) surface plane.

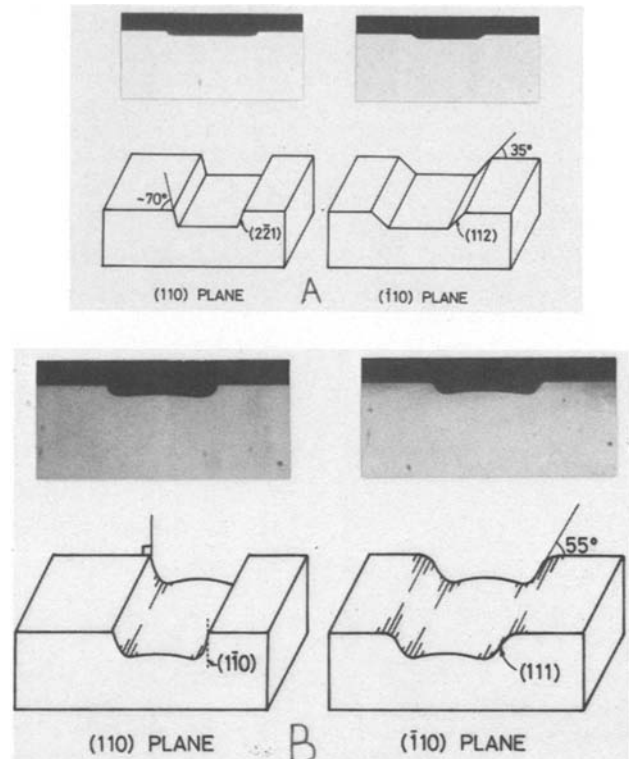

Fig. 9. A: etching profiles of (001) GaAs etched in the solution of $HCl:CH_3COOH:(1N\text{-}K_2Cr_2O_7) = 1:1:1$ at $20^\circ C$. B: etching profiles of (001) GaAs etched in the solution of $HCl:CH_3COOH:(1N\text{-}K_2Cr_2O_7) = 5:1:1$ at $20^\circ C$.

The etching profiles of (001) GaAs etched through AZ-1350J mask in the HCK-511 (dark brown) solution are shown in Fig. 9b. This solution provides the ordinary mesa-shaped structures with roundish tails at the etched bottoms for both the (110) and $(\bar{1}10)$ cleavage planes. The profiles, however, do not exhibit clear crystal habit. The tangents of the etch-revealed walls form angles of 90° and 55° with respect to the (001) surface planes for the (110) and $(\bar{1}10)$ cleavage planes, respectively.

It is known (7) that the reaction-rate limited etchant usually produces a flat-etched bottom, but the diffusion-limited one provides a roundish tail near the frame of the window, similar to the present results (see Fig. 9a and b). We have found that all the light orange solutions studied produce the flat-etched bottoms and that all the dark brown solutions provide the roundish tails at the etched bottoms.

Conclusion

A new etching solution composed of HCl, CH_3COOH , and $K_2Cr_2O_7$ aqueous solution has been developed for the etching of GaAs. This system can be classified into two individual regions, A and B, according to the etching characteristics. The solutions in Region A are light orange in color, while those in Region B are dark brown in color. The rate-limiting process is determined to be the reaction-rate limited in Region A and the diffusion-limited in Region B. This system does not erode photoresists such as AZ-1350J, and provides high-quality etched surfaces without any undesirable roughness or etch pits. Etching rates for (001) GaAs vary from 0.01 to $1 \mu m/min$, depending on the component proportion of the solutions. The rates increase linearly with increasing the normal $K_2Cr_2O_7$ aqueous solution in the low normal region ($\leq 0.2N$) and then saturate in the higher normal region. This system, especially in Region A, has reproducible etching rates and is thereby useful for GaAs device processing. The etching profiles are also

examined by cleaving the wafer in orthogonal directions along the (110) and ($\bar{1}\bar{1}0$) planes. Ordinary mesa-shaped structures have been formed on etching stripes in (001) GaAs with shiny flat-etched bottoms in the solutions of Region A, and with roundish tails at the etched bottoms in the solutions of Region B.

Chromium and Manganese Redistribution in Semi-insulating GaAs

M. Oshima, K. Watanabe, and S. Miyazawa

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino, Tokyo 180, Japan

ABSTRACT

Cr and Mn redistribution in various semi-insulating GaAs substrates annealed with or without encapsulation have been investigated quantitatively using secondary ion mass spectrometry (SIMS) and photoluminescence (PL). Mn was incorporated into Cr-depleted sites (Ga vacancies). Cr out-diffusion can be explained by simple diffusion theory having critical Cr depletion concentration under which no Cr depletion and Mn accumulation occur. While stress-enhanced diffusion takes place without Mn incorporation in capped annealing, a large Cr out-diffused area appears in the case of capless (face-to-face) annealing of high-dose implanted GaAs. This may be attributed to defects and surface dissociation.

Semi-insulating GaAs substrates provide active layers for high-speed GaAs IC devices after ion implantation and annealing processes. However, it has been reported that these substrates, usually doped with Cr, are thermally unstable, and show type conversion during heat-treatment. These phenomena (1-3) are reportedly due to Cr out-diffusion and Mn accumulation at the surface, where Mn serves as shallow acceptors. However, the relationship between Cr depletion and Mn accumulation has not been quantitatively discussed yet.

This paper aims at a better understanding of this relationship during various kinds of heat-treatment. Cr and Mn redistribution are discussed in terms of SIMS depth profiles from their dependence on annealing time, ambient gases, annealing temperature, Cr concentration in substrates, capping films, and ion implantation. Redistribution mechanisms are also discussed.

Experimental

Semi-insulating, Cr-doped wafers used in this study were of (100) orientation and grown by the horizontal Bridgeman technique (HB) and the liquid encapsulation Czochralski (LEC) method. Their initial preparation was the same as that reported by Watanabe *et al.* (4). Annealing was performed at 700°-900°C. The ambient gas was H₂ purified by a Pd diffuser. In the case of As₄/H₂, the mixture gas was supplied by H₂ passing through a GaAs chunk strainer held at the annealing temperature. Therefore, the As₄ atmosphere was not the same as controlled atmosphere technique (CAT). The estimated arsenic partial pressure is lower than 5×10^{-4} torr at 800°C (5). Ion implantation of Cr was done at room temperature at 300 keV with a dose of 10^{13} - 10^{15} cm⁻². Sputtered SiO₂ and plasma CVD Si₃N₄ films were used as capping layers.

An ion microanalyzer with O₂ primary ion bombardment was used to obtain the Cr, Mn, and other impurity depth profiles. Calibration of atomic concentration was established using standards prepared by ion

implantation. The Cr detection limit was examined using an epitaxially grown undoped GaAs film grown on GaAs substrate. The minimum detectable concentration of Cr was 5×10^{14} cm⁻³. Talystep was employed to measure the resultant crater depth. While an area of 250 μm square was sputtered, secondary ions were collected from the 60 μm-diam central area. The depth resolution was checked using a 8600Å Mo film on a Si substrate. From the width of the interface $\Delta d/d$ (the depth resolution) was found to be 8.7%, mainly due to knock-on effects and sputter redeposition.

Photoluminescence measurements were carried out at 4.2 K with the sample immersed in liquid He, using an Ar laser as the excitation source.

Redistribution Resulting from Capless Annealing

Figure 1a and 1b show Cr and Mn depth profiles for samples annealed in two different furnaces at 800°C for 1h in H₂ flow without capping layers. Both samples were from the same wafer. There is a remarkable difference in the amount of accumulated Mn, while the Cr profiles look alike. This is one of the reasons why we believe the Mn mainly originates from the ambient gas, presumably from heaters through the quartz tube.

A second reason is the large amount of accumulated Mn in the depleted region. If all the Mn concentrated at the surface is to have come from the bulk material, then it must have diffused distances of up to 100 times the thickness of this surface region. In order to estimate the diffusion length of Mn in GaAs at 800°C for 1h, we employed the diffusion coefficient with As reported by Sze (6). It comes to only about 2 μm at most, which is too small to account for the Mn accumulation.

A third reason is that when the sample was annealed again after polishing off about 10 μm from the surface, similar depth profiles of Cr and Mn were obtained. While Klein *et al.* (2) reported that Mn began to be depleted by the sequential heating and removal of Mn which diffused to the surface, we observed almost the same Mn accumulation after the heat/polish cycle.

Key words: SIMS, GaAs depth analysis, annealing redistribution.

Fig. 1. Cr and Mn redistribution of GaAs substrates annealed in two different furnaces at 800°C for 1h in H₂ without encapsulation

Figure 2 shows PL spectra of the sample used in Fig. 1a. Peak A is reportedly carbon-related (carbon shallow acceptors), and peak B is due to Mn occupying Ga vacancies (7). Peaks at 1.375 and 1.34 eV are attributable to peak B's LO phonon replica and its 2 LO phonon replica, respectively. Interestingly, after being incorporated into the GaAs, Mn diffuses into the Cr-depleted region and occupies Ga vacancies dur-

ing H₂ annealing, although the diffusion coefficient of Mn is reportedly larger than that of Cr.

In order to understand the redistribution mechanism, the dependence of the Cr-depletion depth on annealing time was investigated. Figure 3 shows the depth of the Cr out-diffused region, which is defined as the depth where the Cr concentration becomes 84% of the original value, as a function of annealing time. Here, 84% is the value of $\text{erf}(x/2\sqrt{Dt})$, when the x is equal to $2\sqrt{Dt}$. Open circles indicate H₂ ambient gas, and open squares (8) As₄/H₂ (H₂ flow with a GaAs strainer). Estimated values were calculated using the reported Cr diffusion coefficient (9) and the first term ($\text{erf}[x/2\sqrt{Dt}]$) of the equation reported by Smith *et al.* (10). Although the rough estimation (solid line) shows slightly higher values than experimental results, it is evident that the diffusion process is dominant in Cr redistribution, judging from the proportionality of

Fig. 2. GaAs photoluminescence spectra at 4.2 K. Sample is the same as Fig. 1a.

Fig. 3. Cr depleted depth as a function of annealing time. Samples are annealed at 800°C in H₂ (circles) and in As₄/H₂ (squares) without encapsulation. Solid line indicates the estimated value from the reported Cr diffusion coefficient in GaAs.

the depletion depth to \sqrt{t} . The discrepancy between estimation and experiment might be attributed to surface reactions forming volatile Cr compounds.

Kasahara *et al.* (11) reported that Cr redistribution is controlled by the partial pressure of arsenic during annealing, since the interfacial conductance decreases with high arsenic partial pressure. However, our results show no significant difference in Cr out-diffusion under various ambient gases up to annealing time of 1h. This is probably because our atmosphere of As_4/H_2 did not reach the sufficient arsenic pressure to prevent the loss of As and dissociation of GaAs.

Next, we investigated the dependence of Cr and Mn redistribution on the original substrate Cr concentration. Figure 4 shows Cr depth profiles in GaAs substrates with three different Cr concentrations. Curves (a) and (b) are for Cr-doped HB crystals, and curve (c) is for undoped LEC. Annealing was performed at 800°C for 1h in H_2 . While (a) and (b) show Cr depletion, (c) shows no change in the Cr profile. Mn accumulated in Cr-depleted regions. As a result, there was almost no Mn accumulation in the case of (c).

These results suggest two important points. First, there might be a minimum or critical Cr concentration for Cr depletion. The level is about $5 \times 10^{15} \text{ cm}^{-3}$, which is in good agreement with other authors' results (12, 13). Therefore, no Cr depletion takes place for Cr content substrates lower than that critical level. This critical concentration shows no dependence on annealing temperature. This suggests that it might not be due to thermal equilibrium considerations. More detailed work should be done.

Second, Mn was incorporated mainly into Cr-depleted sites. Zucca (14) reported that Mn diffusivity is large under a condition of V_{Ga} population excess. Sze (6) reported a dependence of the Mn diffusion coefficient on the presence or absence of As in the ambient gas, which in turn would strongly effect the number of As vacancies in the lattice. The precise role of Ga and As vacancies in the redistribution of Cr and Mn is still the subject of active discussion.

Fig. 4. Cr depth profiles as a function of Cr concentration in GaAs. (a) and (b) indicate HB Cr-doped substrates, and (c) LEC. Annealing was performed at 800°C for 1h without encapsulation. Mn profiles, which are not shown here, are located only in the Cr-depleted region.

Redistribution Resulting from Cr Ion Implantation

Cr ion-implanted samples were annealed to investigate their Cr-depletion behavior. Figure 5a, 5b, and 5c show Cr-implanted GaAs substrates with 10^{13} , 10^{14} , and 10^{15} cm^{-2} doses at 300 keV, respectively. In Fig. 5a, most of the implanted Cr on interstitial sites out-diffused, and Mn accumulation took place to the same degree as in the unimplanted samples, indicating that the Cr on Ga site was also depleted. In this case, the accumulation of Cr at the surface and the bump located around $R_p + \Delta R_p$ reported by Simondet *et al.* (15) were not observed. In Fig. 5b, Cr also out-diffused toward the surface and piled up with the surface concentration exceeding the solid solubility limit in GaAs ($2-3 \times 10^{17} \text{ cm}^{-3}$).

When the dose exceeded the amorphous limit, a large area of Cr depletion appeared, extending to the same depth as the region of Mn accumulation, as shown in Fig. 5c. The Cr depth profile does not look like the error function as predicted by simple diffusion theory. This may be due to the existence of a critical Cr concentration which limits the minimum Cr level. Even taking into account the amorphous area that would be caused by the dosage and the energy used, this region of enhanced Cr out-diffusion seems to be too deep. In the sample annealed at 850°C, Cr depletion extended to a depth of 9 μm . This result is quite different from that (see Fig. 5) reported by Simondet *et al.* (15). Their sample was annealed at 772°C for 15 min, after an implantation of $3 \times 10^{14} \text{ Cr cm}^{-2}$ at 190 keV.

We consider this enhancement of Cr out-diffusion to be mainly due to surface dissociation, while Magee *et al.* (16) reported that out-diffusion was enhanced by defects created by implantation. The sample in Fig. 5c showed considerable surface roughness compared to lower dosed samples, which may have been caused by surface thermal dissociation. Figure 6a shows an SIMS secondary ion image of $^{69}\text{Ga}^+$, and Fig. 6b an image taken by a Nomarski interference microscope. Although an $^{75}\text{As}^+$ ion image could not be obtained because of the low ionization yield of As (about 3 orders of magnitude lower than Ga), As^+ depth profiles show that the surface region of this highly dosed sample was more As deficient than the other samples. We consider this surface roughness to be due to Ga droplets (several microns diameter) resulting from in-stensate surface dissociation, which might be enhanced by the recrystallization of the amorphized region.

The difference between our results and those reported by Simondet *et al.* can be attributed to this surface morphological change. Udagawa *et al.* (17) reported that the agreement between calculations of Cr depletion profiles and experimental results were poor when samples were annealed for long times. This discrepancy was reportedly caused by the slightly matte surface, indicating the initiation of thermal dissociation. Further investigation will be needed to discover the cause of this surface morphological change.

Redistribution Resulting from Capped Annealing

Finally, in order to compare these results with capped annealing, SIMS analysis was performed on GaAs substrates capped with 3000Å SiO_2 or 1600Å Si_3N_4 films. Here, appropriate electron bombardment during depth profiling was employed to prevent charging up.

Figure 7a and 7b show As, Cr, and Mn depth profiles of GaAs. These samples were annealed in H_2 for 1h at 800°C. The As^+ pile up at the interface might be attributed to the well-known SIMS interface effect. When these samples were analyzed after removal of these films using $HF + H_2O$ solution, Cr showed the same profiles as before with a completely flat As^+ profile, and no Mn was detected in either case. The amount of Cr piled up at the surface proved to be equal

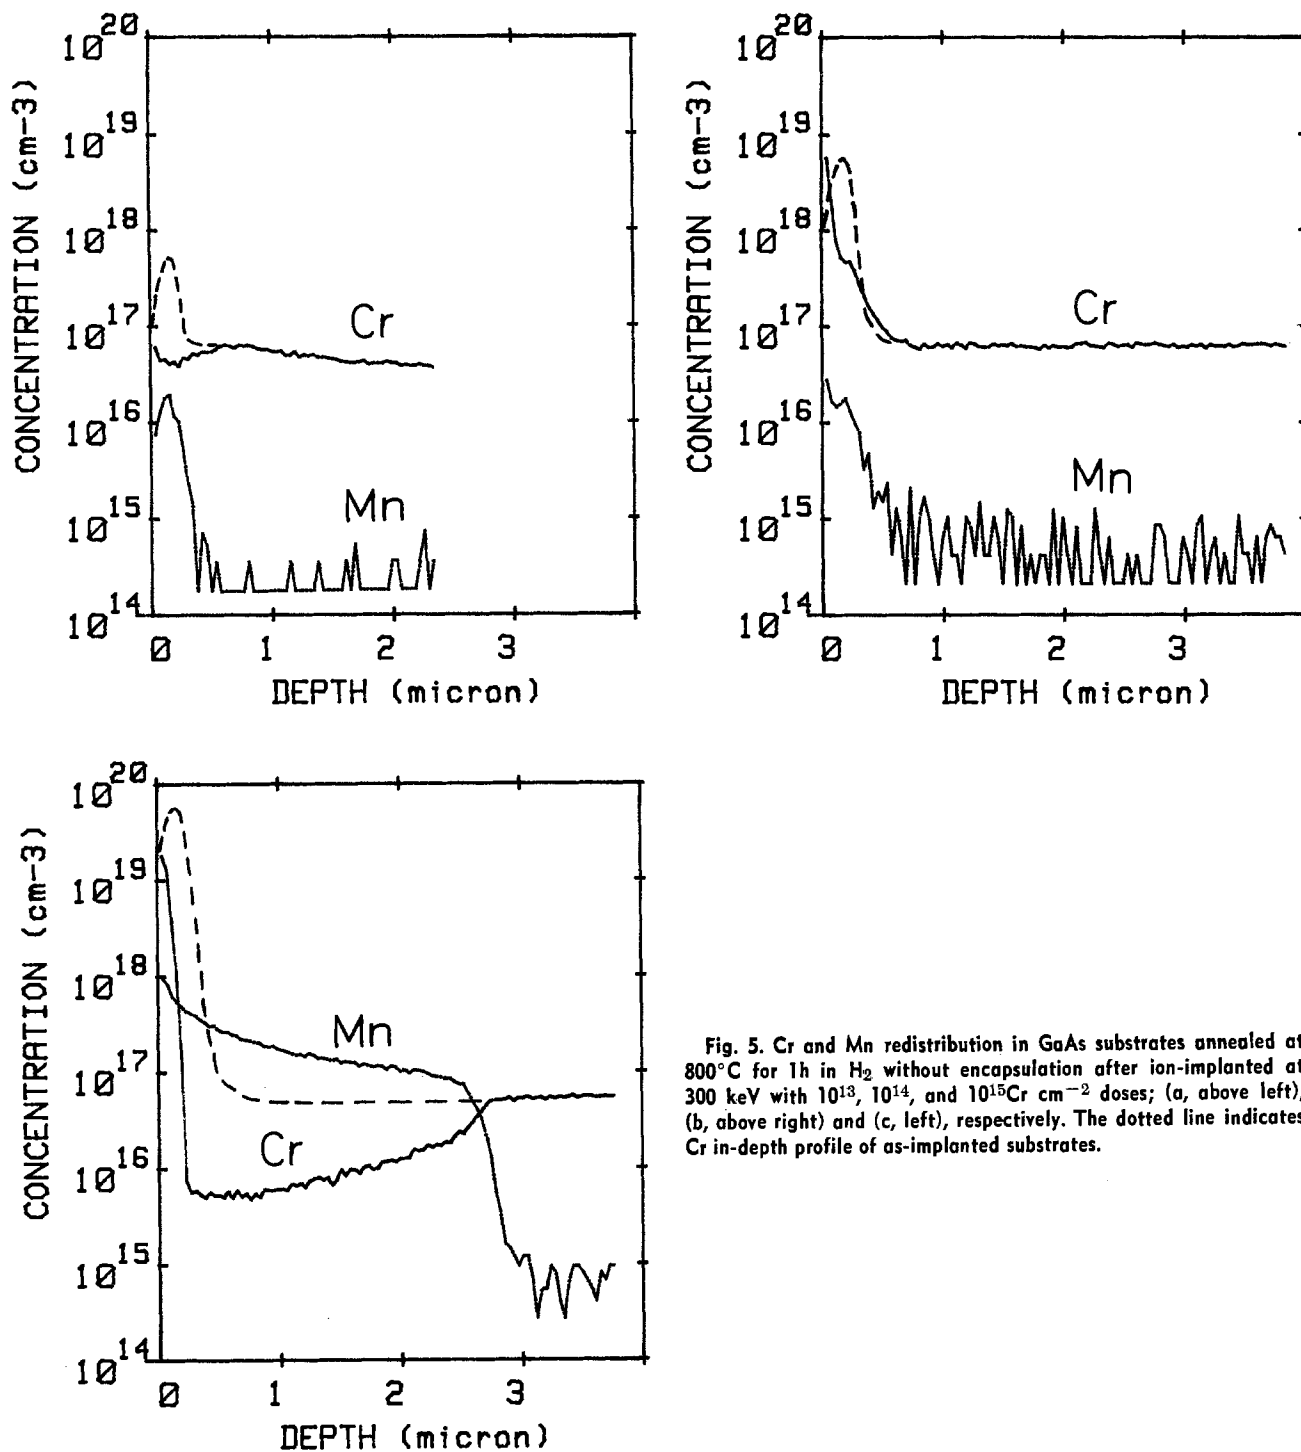

Fig. 5. Cr and Mn redistribution in GaAs substrates annealed at 800°C for 1h in H₂ without encapsulation after ion-implanted at 300 keV with 10^{13} , 10^{14} , and 10^{15} Cr cm⁻² doses; (a, above left), (b, above right) and (c, left), respectively. The dotted line indicates Cr in-depth profile of as-implanted substrates.

to that depleted from the bulk, within an uncertainty of 20%, indicating that Cr does not out-diffuse into capping films even when annealed at 800°C. In addition, these films were found to prevent Mn invasion from the ambient gas into the GaAs.

Note that the Cr and Mn ion intensity observed in the capping layers is anomalously high. Actually, the Cr and Mn concentrations are very low, but the ion intensities are greatly enhanced in the capping layers by SIMS matrix element effects. This was experimentally verified by SIMS on Si₃N₄ films which had undergone the same Cr implantation.

Since the Cr-depleted regions were about 4 times as deep as those observed in capless annealing, the stress field caused by capping layers is thought to enhance Cr out-diffusion. This strain field could arise from thermal mismatch between the capping film and the GaAs.

As was the case for capless annealing, a critical Cr concentration for Cr depletion was observed. (In both

cases, the substrate Cr concentration was well below the solid solubility limit.) Figure 8 shows the Cr depth profiles of GaAs subjected to capped annealing at 800°C in H₂. While curve A shows Cr depletion, the Cr profile (B) (18) is not changed by annealing. Therefore, it can be said that substrates with a Cr concentration lower than the critical level (about 5×10^{15} cm⁻³) do not suffer Cr depletion in capped annealing. Although the mechanism by which this critical Cr concentration for depletion occurs is not clear at present, it is probably not due to thermal equilibrium considerations, since the critical Cr concentration does not depend on annealing temperature.

The Cr depletion depth is plotted in Fig. 9 as a function of $1/T$ (annealing temperature). The solid line indicates the estimated value from simple diffusion theory. Here we used $D = 4.3 \times 10^3 \exp(-3.4/kT)$ (7). The circles indicate capless annealing, the triangles ion-implantation (with a 10^{15} cm⁻² dose), and the squares capped annealing. There have been many

Fig. 6. $^{69}\text{Ga}^+$ secondary ion image by SIMS (a), and photograph by Nomarski differential interference microscope (b). Sample is the same as Fig. 5c. In this case, SIMS spatial resolution was about $1\ \mu\text{m}$, which was verified using $1\ \mu\text{m}$ line and space patterns fabricated by electron beam exposure system and reactive sputter etching. $^{75}\text{As}^+$ ion image could not be observed because of its weak ionization yield.

different diffusion coefficients for Cr in GaAs values reported. Sato (21) reported $1.6 \times 10^{-12}\ \text{cm}^2/\text{s}$ at 800°C , determined by an analysis of the conductive layer thickness resulting from capped annealing of Cr-doped GaAs. Wilson *et al.* (22) reported $D_{800^\circ\text{C}}$ to be $6.7 \times 10^{-12}\ \text{cm}^2/\text{s}$ from a depth analysis of Cr in Cr-doped GaAs with an epitaxially grown GaAs layer. This is large compared to other values. Kasahara *et al.* (11)

reported $D = 6.3 \times 10^5 \exp(-3.4/kT)$ using the diffusion equation with the interfacial conductance (23). Judging from Fig. 4 by Kasahara, the pre-exponential term might be 6.3×10^3 , which fixes $D_{800^\circ\text{C}}$ at $6 \times 10^{-13}\ \text{cm}^2/\text{s}$. Simondet *et al.* reported $D = 2 \times 10^{-14}\ \text{cm}^2/\text{s}$ at 772°C from a "crude calculation" using SIMS depth profiles of Cr in-diffusion in implanted and annealed GaAs. This seems too small, if defect-enhanced diffu-

Fig. 7. As, Cr, and Mn depth profiles of GaAs substrates capped with 3000\AA SiO_2 (a, left) and 1600\AA Si_3N_4 (b, right) films. Annealing was performed at 800°C for 1h in H_2 . Electron bombardment was employed during analysis for preventing charging-up.

Fig. 8. Cr depth profiles of GaAs substrates with different Cr concentration. Samples (A,B) were annealed at 800°C for 1h in H₂ with 3000Å SiO₂ films for encapsulation. SIMS analysis was performed after removal of capping films. In the case of B, no Cr depletion was observed.

sion caused by ion implantation is taken into account. Therefore, the value given in Ref. 7 is adopted in this work.

From this graph (Fig. 9), three important results can be pointed out. First, capless annealing causes Cr depletion, which can be explained by simple diffusion theory in both HB and LEC crystals. However, in annealing at 750°C, Cr depletion and Mn accumulation are limited only to a shallow region. Kasahara *et al.* (11) reported that almost no Cr out-diffusion was observed after annealing at 700°C. At these low temperatures, the surface reaction necessary to allow Cr to evaporate might be the rate-determining process for Cr depletion. In the case of capped annealing a deep depleted region was observed even for 700°C annealing. This may be because no surface reaction is necessary.

The second point to note is the enhancement of Cr out-diffusion by ion implantation-induced defects. Deveaud *et al.* (24) reported that implanted (600 keV) Cr diffuses rapidly when annealed at 800°C ($D_{800-C} > 10^{-12}$ cm²/s). Since our result at 800°C roughly corresponds to $D = 5 \times 10^{-12}$ cm²/s, it is clear that defects by ion implantation definitely act to enhance Cr out-diffusion. Perhaps the large activation energy (about 5 eV) is due to surface dissociation reactions in addition to defect-enhanced diffusion.

Finally, in capless annealing, Cr depletion is enhanced with an activation energy similar to that observed after capless annealing.

Conclusions

Cr and Mn redistribution during heat-treatment has been investigated using SIMS and PL. Mn was found to be incorporated mainly from the ambient gas into Cr-depleted sites. Cr out-diffusion can be explained by simple diffusion theory, except for low-temperature annealing, where surface reaction effects might dominate behavior. Cr out-diffusion is strongly enhanced in samples undergoing capped annealing or high-dose

ion implantation. This enhancement is attributed to stress fields in the former case, and defects and surface dissociation in the latter. There exists a critical Cr concentration for Cr depletion. GaAs substrates with lower Cr content than this do not exhibit Cr depletion regardless of whether they have undergone capless or capped annealing.

Acknowledgments

The authors wish to express their sincere thanks to M. Yamaguchi, S. Hattori, M. Ohmori, and Y. Imamura for their discussion and support during the course of this work. One of the authors (K. W.) thanks Y. Matsuoka for his discussion. Thanks are also due to S. Nojima for providing us with the GaAs substrates.

Electrochemical Deposition of Photosensitive CdTe and ZnTe on Tellurium

Hendrik J. Gerritsen¹

Institut für Angewandte Physik der Universität Karlsruhe, Karlsruhe, Germany

ABSTRACT

Two methods to prepare Cd and Zn telluride layers electrochemically on a Te electrode situated in 0.1M CdSO₄ electrolyte are described. Crystalline, photoelectrochemical, and spectral sensitivity properties of the layers are described. The simplicity of the preparational methods and the various interesting semiconductor and photochemical properties of the resulting telluride layers lend themselves well to instructional purposes.

A great many electrochemical deposition methods for cadmium and bismuth chalcogenides have been reported in the literature. CdS and Bi₂S₃ have been formed by anodic deposition on Cd and Bi, respectively, in S²⁻ containing aqueous electrolyte (1, 2, 3). While large photo quantum efficiency was reported for Bi₂S₃ (4), layers of CdSe similarly prepared were less satisfactory because of their thinness (5).

Cathodic coprecipitation of photosensitive cadmium selenide and telluride layers on a variety of substrates from aqueous solution containing CdSO₄ and SeO₂ or TeO₂ has been reported (6, 7, 8). This method has more recently been extended to nonaqueous electrolytes as well (9, 10).

What will be described in this paper is the electrochemical deposition of cadmium and zinc telluride on a tellurium electrode as substrate in 0.1M CdSO₄ electrolyte. Two different modes of operation were studied. In one, called Method I, no bias was applied between the electrodes, in the other, Method II, the tellurium electrode was biased strongly positively. The crystalline and photoelectrical properties of layers prepared by these two methods are described and compared with each other. Causes for the differences are discussed.

Experimental

A tellurium rod and a cadmium strip were hung in a 0.1M solution of cadmium sulfate in water and connected with each other via a 20 kΩ variable resistor and a microamp meter (see Fig. 1). A high impedance voltmeter was connected across the two electrodes, and N₂ could be bubbled through the electrolyte. A variable external potential (V) was applied in some of the experiments.

To prepare ZnTe, a metal zinc strip and a 0.1M ZnSO₄ solution were used instead. Contact to the cadmium or zinc metal was made by spotwelding a Pt wire to one side of the 0.5 × 5 cm metal foil 0.05 cm thick.

Te was also contacted with Pt wire, usually by sending an electrical current through the wire and pressing the red glowing platinum wire into the Te rod. Some experiments were performed starting from small chunks of Te, which were melted under a slow stream of dry nitrogen in a Pyrex mold. In that case, the contacting wire (platinum or standard tinned copper wire) was placed with the Te in the mold and became embedded into the molten Te. The heat of a Bunsen burner (450°C) sufficed to melt the tellurium. The mold was covered with a lid to minimize contact with the air and because Te tends to sublime and its

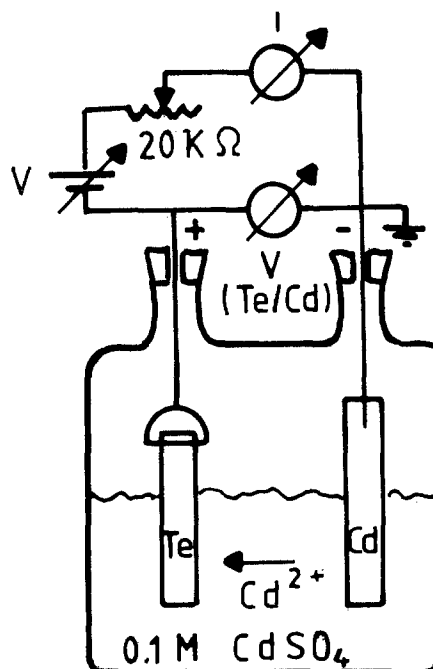

Fig. 1. Basic setup to grow and measure CdTe and ZnTe layers

Key words: cadmium, photocurrent, polycrystalline deposit, preparation, telluride, zinc.

vapors are poisonous. The tellurium rod could be lifted easily out of the mold since Te shrinks upon cooling.

The Cd and Zn used were 99.97% pure; the Te was 99.99% pure. The electrodes were degreased with acetone, and the metals further cleaned by immersion in diluted HCl and rinsing in distilled water. The tellurium was cleaned by immersion and stirring in 5% (by volume) Br₂ in methanol for 10 min, followed by more stirring in the solution which was gradually diluted with methanol, ending up with pure methanol. After this treatment the polycrystallinity of the Te surface was clearly visible to the eye.

Method I

Cadmium.—In this very simple method, the cadmium and tellurium in the 0.1M CdSO₄ solution form a battery. The open voltage of this battery is about 0.63V, although one Te electrode that had been freshly etched for a long time (1h in 5% bromo methanol) gave 0.85V. Measurements of the potential of the Cd and Te vs. a saturated calomel reference electrode in the 0.1M solution gave -0.69V for the Cd. This was in fair agreement with the calculated value of -0.66V. For the Te, it varied from -0.06V to +0.16V depending on the degree of etching previously given.

The current that flows when one connects the Cd and Te via a 20 kΩ resistor corresponds to a flow of Cd²⁺ onto the Te followed by formation of CdTe. In minutes, the initially large current decays to a fraction of a milliamp, and the variable resistor is reduced to zero. In most of the experiments N₂ was bubbled through the electrolyte at a slow rate, but in the few experiments where this was omitted and the electrolyte exposed to the open ambient air, the resultant films were not noticeably different. Almost all the experiments on film growth were performed in the dark for reasons that will soon become apparent.

The progress of film formation was followed by visual observation, by measurement of the short-circuit photocurrent of the layer upon brief illumination, and by measurement of the open-circuit photovoltage. A 6 mW HeNe laser with wavelength of emission at 633 nm was the illumination; it illuminated the telluride layer in the cadmium sulfate solution.

Initially the color of the CdTe layer forming on the silvery Te substrate was golden, and the short-circuit current, observed on the μA meter, did not change much upon illumination. After 4h of growth the short-circuited dark current of +4 μA (flowing externally from the Te to the Cd) increased to +5 μA upon laser illumination. As a function of time of film growth, a color mosaic develops of gold, red, blue, and purple areas, the dark current decreases steadily, and the photocurrent increases. The size of the color domains appears to be similar to that of the polycrystalline areas previously observed on the Te substrate, that is, from 1 to 10 mm². After 70h of growth, the photocurrent of the purple areas is typically +180 μA, and that of the golden-bronze areas is only +50 μA, while the open-circuit voltage was 290 mV. The time of appearance of the color mosaic did depend on the previous etch given to the Te; a Te electrode that had been given a long etch developed the colors after only 24h. Film growth after one week was very slow, but a small current kept flowing, the color mosaic assumes deeper colors, and the photosensitivity increases still slowly in time. A tellurium electrode made by melting Te chunks in a Pyrex form and placing them in the electrolyte in air (no N₂ used) and short-circuited with the Cd electrode behaved in a manner similar to that of the polycrystalline Te rod; it was very sensitive to daylight.

It should be mentioned that no growth occurred on a piece of tellurium which was left for two weeks in the solution and was not externally connected with the cadmium electrode.

Zinc.—Less effort was expended to grow ZnTe by this method than was spent on CdTe. It appeared that

Method II worked better for zinc telluride than Method I. The battery Zn/0.1M ZnSO₄/Te has an initial voltage of 1.2V. After shortening via a 20 kΩ resistor for two days in open air, the dark current was still rather large, +20 μA. With laser light this current increased to +23 μA. The layer had a gold/bronze color with indication of a mosaic structure in the shades of gold, similar to, but much less colorful, than that observed in the CdTe layer.

Method II

This method was discovered accidentally when an attempt was made to reverse the flow of positive metal ions by biasing the Te electrode positively with respect to the metal electrode. While a fair degree of electrocleaning was obtained by applying a bias of about +0.9V (Te w.r.t. Cd) and drawing a small reversed current for typically one day, a very different behavior was observed when a large reverse current was maintained.

Layers with optimal photosensitivity were obtained by maintaining a current flow of -5 mA going from Te to the metal in the liquid for about 10 min. This requires a bias increased gradually from +1.3 to 4.5V. The resultant layers were shiny black, with some indication of colors in the CdTe layer. Exclusion of air by bubbling through of N₂ appears not to make much difference.

Results and Discussion

Current-voltage measurements.—The measurement setup was identical to that used to grow the layers, as in Fig. 1. Keithley Instruments Electrometers 610C or 602 (battery operated) were used for the electrical measurements, while the light intensity of the HeNe laser was measured with a photometer/radiometer system, EG&G Model 450.

Figure 2 shows the results of a CdTe and a ZnTe layer. The CdTe was grown with Method I (though CdTe layers grown with Method II have a similar i-V characteristic); the ZnTe was grown with Method II. A rectifying barrier between 0 and +0.5V is evident in both. A positive current is defined as a current that flows in the same direction as the current in the short-circuited, unbiased battery that is in the liquid from the metal towards the tellurium. In the metal-tellurium battery, the Te has the positive potential w.r.t. the metal. Therefore, the potential will be chosen as that of the Te w.r.t. the metal. When the Te, covered with the telluride layer, is biased negatively, the photo-effects are at their largest, but also a very large dark current begins to flow. This was identified in the Cd system as the reduction of Cd²⁺ at the CdTe layer, forming Cd dendrites along crystallite boundaries and along edges. The right side of the i-V characteristic shows blocking, but above +0.5V, current begins to flow, again leading to formation of the telluride by Method II.

An explanation of the general features of these curves must include the semiconductor properties of the telluride layer and the nature of the electrolyte, in which the positive metal ions play a special role. If one assumes that p-type metal tellurides are formed, which cover themselves with an n-type inversion layer at the electrolyte interface, one has an explanation for the direction of the short-circuited photocurrent, which is carried in the liquid by Cd²⁺ and is discharged at the CdTe layer by the photoelectrons present at the interface. Application of a positive bias blocks that photocurrent. However, one has a problem understanding the dark current behavior. If the p-n junction is as postulated, then forward current should flow when the CdTe (and thus the Te) is given a positive bias, while blocking is expected for Te at negative potential. A possible explanation for the phenomenon shown in Fig. 2 is that for negative bias, the metal ions discharge on the telluride, and the charge transfer takes place by tunneling through the very thin n-layer. In the positive bias direction, electrolysis of the electrolyte would

Fig. 2. C-V characteristics of CdTe and ZnTe layers

have to take place to provide the necessary carriers and charge transfer. It seems plausible that this requires voltages above +0.5V.

In order to obtain additional confirmation regarding this explanation, experiments were done with 2 mm-thick melt-grown polycrystalline crystals of p-CdTe and of n-CdSe, grown by a modified Bridgman technique, as shown in Fig. 3 and 4. Except for the difference in slope, caused by the rather large (15 kΩ) resistance of the melt-grown CdTe, Fig. 3 is in all essential points identical with Fig. 2. In contrast, in the low resistivity in n-CdSe one sees the reversal of the direction of photocurrent, as expected, and also the extreme blocking (both semiconductor and electrolyte are blocking) and large forward current. A similar characteristic was observed when the same n-CdSe disk was placed in a 1M polysulfide solution, a common electrolyte for this material (Fig. 5). Since there was now a photocurrent at zero bias, this electrolyte could be used as a photovoltaic cell, while it could not be so used in the CdSO₄ solution.

Two attempts were made to grow n-type CdTe on Te. These attempts were inspired by the results obtained in the cathodic codeposition method (8), in which additions of small quantities of In₂(SO₄)₃ changed the p-type into n-type material. Layers grown from 0.1M CdSO₄, to which in one experiment was added 0.001M In₂(SO₄)₃, and in a second experiment 0.01M InCl₃, by both Methods I and II, came out as p-type with characteristics not much different from undoped layers. Perhaps the fact that the layers are grown on Te, which is a p-dopant for CdTe, explains this negative result.

Light damage and recovery.—This effect was studied in CdTe layers and consists of the following observation: when the layer is illuminated by a light beam, the

closed-circuit photocurrent rises rapidly, comes to a standstill and then decreases. The speed of decrease depends on the intensity. At the same time, one observes a whitish-gray spot on the layer. After several hours in the dark, the spot disappears, and the layer recovers. The study of this effect was important for two reasons: first, to assure that the photomeasurements done on the layers could be performed under conditions (short pulses of low intensity light) where the effect was absent; second, the curious dark recovery held out some possible hope for semiconductor systems in which light damage occurs.

Quantitatively, the 6 mW laser beam illuminating one of the sensitive, purple areas on a CdTe film grown for one week by Method I gave a 200 μA short-circuit photocurrent, which decayed to 100 μA in 45s, leaving a gray white spot of 3 mm diam. Leaving the cell short-circuited in the dark results in the shrinking and final disappearing of the spot after about 8h while the photocurrent is back at 200 μA . If one disconnects the short between the Cd and Te, recovery occurs after about 2½h. Chemical analysis determines that the spot consists of Cd metal, as is to be expected. As soon as photocurrent flows in this system, cadmium plates out on the CdTe. However, the recovery occurs because the cadmium spot acts as the electrode of a Cd/Te battery which forms CdTe probably by Cd movement along the layer and inward. If one keeps the Te and Cd electrodes connected, the spot experiences competition from the Cd^{2+} flow of the latter and is expected to disappear slower than when the Te and Cd electrodes are disconnected. This form of recovery will of course proceed slower and slower the thicker and longer the telluride layer has grown. It would be interesting to see if a slightly negative bias of the CdTe w.r.t. the Cd electrode might make the spot grow by selective Cd plating. Such an effect would be similar to chemical development in photography and might improve the sensitivity of this layer, which is presently about 500 mJ/cm^2 for clearly visible spots. The spectral range and reversibility makes this simple system of some potential interest as photographic material for study of near IR lasers.

For comparison, light damage experiments were performed on the 2 mm-thick melt-grown polycrystalline p-CdTe sample in the same setup. There too, the light created cadmium at the surface, but recovery did not occur. A clean Te rod was placed in the solution and externally connected to the CdTe sample which had the Cd spot. In the course of several minutes most of the Cd had migrated off from the CdTe sample and onto the Te rod.

Photovoltaic characteristics.—A CdTe layer grown for 1 week by Method I was used in the configuration of Fig. 1. It was illuminated by a spread-out 5 mW laser beam, and the i/V plot was obtained by varying the load resistance from 0 to 20 k Ω . The experiment was done in a time short compared to the time it takes the Cd layer formed to reduce the photocurrent. The result is shown in Fig. 6a and compared with the characteristics of the 2 mm-thick, low-ohmic, polycrystalline n-CdSe in a solution of polysulfide consisting of 1M each of NaOH, Na_2S , and S with Pt as counter-electrode. The p-CdTe layer had an efficiency of 0.2%; the best efficiency measured for a similar layer has been 0.4%. In comparison, the p-CdTe polycrystalline crystal of 2 mm thickness showed a 0.55V open-circuit voltage and a photovoltaic efficiency of 16% at low light levels where the resistive voltage drop across the crystal does not limit the current or the measured efficiency appreciably.

Spectroscopic characteristic.—Figure 7 shows the spectral characteristics measured for the two type CdTe layers discussed in the text and a polycrystalline CdTe disk. The values on the ordinate represent the short-circuit photocurrent in a cell consisting of the CdTe

Fig. 6. Photovoltaic characteristics: (a) electrodeposited CdTe on Te, (b) polycrystalline n-CdSe in polysulfide solution.

layer on Te (or the CdTe disk), a Cd electrode, and 0.1M CdSO_4 electrolyte. The monochromator used was a prism-type Zeiss M4G11 which was illuminated with a 50W tungsten/halogen lamp and calibrated with a photometer/radiometer system EG&G Model 450. The room temperature bandgap of single-crystal CdTe is about 1.5 eV, corresponding to 826 nm. Of interest is the rather steep rise in photocurrent with decreasing wavelength for both the melt-grown CdTe and the layer grown by Method I, while the photocurrent in the layer grown by Method II rises slowly and does not seem to reach its plateau at 500 nm.

A similar difference between single crystals (steep rise) and electrodeposited layers (gradual) has also been reported for CdSe (11), and for CdS (12). The explanation for the observations in Fig. 7 would then be that the electrodeposited p-CdTe layer grown

Fig. 7. Spectral sensitivity of polycrystalline CdTe (\square); CdTe layer grown on Te without bias (Method I) (∇); CdTe layer grown with positive bias on Te (Method II) (\circ).

by Method II contains such a high density of acceptors ($>10^{18} \text{ cm}^{-3}$) that the space charge region is thin compared to the penetration depth of the light. Going towards shorter wavelengths decreases this penetration depth and produces more photocurrent in the space-charge region. It is significant that the CdTe layers prepared by Method I behave like melt-grown polycrystalline CdTe. ZnTe prepared by Method II was also measured (Fig. 8) and behaved similarly to the CdTe grown by Method II, with the exception that its bandgap is wider. That layer too seems to contain a high density of acceptors.

Mechanism of layer formation.—Method I is straightforward; the Cd/CdSO₄/Te battery operates by migration of Cd²⁺ from the Cd to the Te electrode, discharge of the Cd²⁺ to Cd, and subsequent formation of CdTe. Cd requires some time to diffuse through this layer to recombine with Te, as demonstrated by the gradual disappearance of a light-damage Cd spot at the surface of the layer. The growth speed of a single-crystal CdTe domain seems dependent upon the crystal domain orientation of the Te substrate, as evidenced by the difference of interference colors in the color mosaic.

Method II involves most likely a positive tellurate ion, perhaps injected into the solution as HTeO₂⁺ (13 and 8) that combines with Cd²⁺ from the solution and settles down on the Te electrode as CdTe. The resultant free positive charge presumably oxidizes water to O₂, though the exact mechanism has not been studied.

Crystalline and mechanical properties of the layers.—The layers of CdTe grown by Method I attach themselves very strongly to the Te substrate. Their lively colors are due to a combination of interference and absorption effects and indicate: (i) their thickness is of the order of 0.1 to 0.2 μm; (ii) the domains of area 1-10 mm² are single crystals. Well-defined Laue back-

Fig. 8. Spectral sensitivity of electrodeposited ZnTe on Te

scattering spots of the CdTe layers showed that the various differently colored areas correspond to various single- or twin-crystal orientations.

The layers grown by Method II are black in appearance and attach well, but not as strongly to the tellurium as the layers grown slowly by Method I. There were no single-crystal lines observable in the Laue pattern of these layers. Chemical analysis and photo response indicate that both layers are metal telluride, but the stoichiometry has not been determined.

Conclusions

Two electrochemical deposition methods for the preparation of CdTe and ZnTe have been described. The layers have interesting properties in particular that single-crystal domain telluride layers can be prepared electrochemically. The many photoelectrochemical effects observable in this simple system make it attractive for educational purposes as well, particularly since the toxicity aspects (cadmium sulfate solution) are not especially hard to control.

ABSTRACT

High resolution, low temperature photoluminescence spectra of manganese-doped willemite ($\text{Zn}_2\text{SiO}_4\text{:Mn}$) single crystals have been measured. "Hot" bands on the zero-phonon lines of the ${}^4\text{T}_1$ excited state of $\text{Mn}_{\text{Zn}}^{2+}$ on inequivalent sites are observed at low Mn concentration between 4 K and 29 K. Their appearance is attributed to vibronic (Ham) quenching of the first-order spin-orbit interaction in the ${}^4\text{T}_1$ excited state, by analogy with known properties of $\text{Mn}_{\text{Zn}}^{2+}$ in ZnS and ZnSe. At higher Mn concentration, additional lines appear which are assigned to Mn pair centers involving substitution on nearest neighbor Zn sites. Electron microprobe analysis shows that the segregation coefficient of Mn incorporation in the crystal increases as the Mn concentration in the melt increases. This is indicative of pairwise incorporation during growth, and consistent with the optical detection of Mn pairs in the crystals at higher Mn concentrations. The measured luminescence decay times depend on both Mn concentration and temperature of the crystals, due to thermally activated energy transfer between Mn centers.

Manganese-doped willemite finds practical application as a green-emitting phosphor in both fluorescent lamp and display devices (1). In the particular case of cathode ray tube devices, the basic $\text{Zn}_2\text{SiO}_4\text{:Mn}$ system (designated P1) (2) is typically employed in high luminance applications, and when co-doped with arsenic (designated P39) (2) it is used as an anti-flicker phosphor for information display. The luminescence in all these phosphor applications is that of the divalent Mn^{2+} ion substituted on Zn sites (3). Optimization of phosphor efficiency and lifetime, two important practical quantities, depends critically on the details of impurity incorporation in the willemite lattice (4). In this paper, we report a high resolution spectroscopic study of Mn incorporation in willemite, together with measurements of luminescence lifetime as a function of both Mn concentration and temperature.

The willemite lattice has two inequivalent Zn sites, both having four nearest neighbor oxygen ions in a slightly distorted tetrahedral (T_d) configuration (5, 6). Two inequivalent Zn tetrahedra and one Si tetrahedron alternate in chains parallel to the c-axis; these chains are linked on a threefold screw axis in such a way that neighboring inequivalent Zn tetrahedra form pairs by sharing corners, the pair axes lying approximately parallel or perpendicular to the crystal c-axis. Nearest neighbor cation interactions between ions on Zn sites therefore occur between the inequivalent Zn sites. Luminescence is assigned to transitions between the spin-orbit components of the ${}^4\text{T}_1$ excited state and the ${}^6\text{A}_1$ ground state of Mn^{2+} in T_d coordination (7). EPR studies (8) originally showed that Mn could be incorporated on both Zn sites. Low temperature photoluminescence spectra (9-12) excited by broad band, high-energy radiation revealed two zero phonon lines (ZPL's) which were attributed (12) to $\text{Mn}_{\text{Zn}}^{2+}$ ions on the two inequivalent Zn sites, designated A and B sites. The sharp ZPL's were reported (12) at 2.455 eV (504.6 nm) for the Mn_A centers and 2.404 eV (515.3 nm) for the Mn_B centers, and confirmed by Fern and Chang (13). The energy difference was suggested to be consistent with the difference in crystal field strength estimated from differences in Zn—O bond lengths at the two sites. However, the spectral resolution achievable in these earlier studies was limited by the use of polycrystalline material. In particular, the line broadening observed at high Mn concentrations (12) precluded the observation of impurity interaction effects at higher doping levels.

For the present study, single crystals of Zn_2SiO_4 including both Mn and As impurities have been used

(14). Preparation of the material in single crystal form allows better control of impurity incorporation and offers the possibility of improved spectral resolution through reduction of inhomogeneous line broadening. Selective excitation of the Mn_A and Mn_B centers has been achieved using various lines from an Ar^+ laser, allowing spectral isolation of luminescence from the lower energy Mn_B centers for the first time. The Ar^+ laser lines at 501.7 and 514.4 nm provide near-resonant excitation of the Mn_A and Mn_B centers, respectively, and under this condition of near-resonance additional fine structure has been observed at low temperature in the region of the ZPL's. The experimental procedures employed in this study are outlined in the section on experimental techniques, and the results reported in the results section. The significance of these results is discussed more fully later, and comparisons are made with the properties of $\text{Mn}_{\text{Zn}}^{2+}$ in ZnS and ZnSe, where analogous effects of Mn impurity concentration and temperature on the optical spectra have been reported.

Experimental Techniques

Single crystals of Zn_2SiO_4 in the form of hexagonal prisms several millimeters in size were grown between 1300° and 960°C by the slow cooling (1°C/hr) of molten solutions of composition $5\text{Zn}_2\text{SiO}_4 + 3\text{Pb}_2\text{ZnSi}_2\text{O}_7$. Mn and As impurities were introduced as MnF_2 and As_2O_5 , respectively. Crystal compositions were determined with an Applied Research Laboratory's Scanning Electron Microprobe Quantometer, using the characteristic MnK_α , AsL_α , and PbM_α lines for low level impurities and Mn° , GaAs , and Pb° as reference materials. Arsenic is incorporated into the willemite crystals to a lesser degree than Mn, the segregation coefficient for As being more than an order of magnitude lower than that for Mn. Little, if any, Pb is soluble in willemite grown in this way. Further discussion of the crystal growth and analysis procedures is given in Ref. (14).

High resolution, low temperature PL spectra were measured using a Spex 1402 0.75m double monochromator and cooled RCA C31034A (GaAs) phototube, with excitation by selected lines from the Ar^+ laser. The samples were mounted in a variable-temperature cryostat. Luminescence decay times were measured between 5-300 K using a mechanical shutter in the laser beam. In order to improve signal/noise ratio in the decay curves when a narrow bandpass in the detection monochromator was used, signals from repeated pulses were added using a Nicolet 1174 signal averager.

Results

Chemical analysis and buoyancy density measurements have indicated a nonstoichiometric crystal for-

* Electrochemical Society Active Member.

mula $Zn_{1.96}Si_{1.04}O_{4.04}$ for the willemite lattice (14). The results of 14 separate microprobe analyses on Mn-doped crystals show that the number of Mn atoms per formula unit incorporated in the willemite crystal (denoted $[Mn]_x$) is not a simple linear function of the mol fraction of MnF_2 in the growth melt (denoted $[Mn]_m$). The data points are plotted in Fig. 1, and the line represents a least squares fit giving the relationship

$$[Mn]_x \cong 75[Mn]_m^2 + 0.6[Mn]_m + 0.0007 \quad [1]$$

This equation has been used to estimate the Mn concentration in crystals used in the spectroscopic measurements for which no microprobe analyses were available. The results are shown in Table I. The fractional substitution of Mn for Zn in the willemite lattice is then approximately equal to $[Mn]_x/1.96$, allowing for the nonstoichiometry of the crystal formula.

Figure 2 shows the low temperature Mn^{2+} luminescence spectra excited by different lines of the Ar^+ laser. The two ZPL's, attributed to the high energy (Mn_A) and low energy (Mn_B) sites, are clearly seen. The relative intensities of these two ZPL's vary with excitation energy, even for relatively high-energy and nonresonant excitation using laser lines at 473 and 458 nm. This variation presumably reflects differences in the absorption spectra of Mn^{2+} ions on the inequivalent Zn sites. The laser line at 514.5 nm (2.41 eV) is at too low an energy to excite luminescence from the Mn_A centers, and the lowest curve in Fig. 2 therefore represents the emission spectra from Mn_B centers alone. This is the first time that luminescence from the two inequivalent Mn centers in willemite has been clearly separated, and the technique reveals the vibronic sideband associated with the Mn_B site without interference from sidebands of the higher energy Mn_A site which are otherwise present.

Figure 3 shows the luminescence spectrum excited at 458 nm at a series of temperatures between 4.2 and 29 K. These spectra were measured with a lower resolution detection monochromator, but the resolution is adequate to show that the ZPL's for both Mn_A and Mn_B sites have the "hot" components which appear as shoulders ~ 1 meV to high energy of the main lines as the temperature is increased. The effect is illustrated with better resolution for the Mn_B center in Fig. 4; the upper figure shows the temperature dependence for a crystal of low Mn concentration ($\sim 0.3\%$ Mn substituted for Zn), and the lower figure for a high Mn concentration ($\sim 3\%$ Mn). The dependence of lineshape on temperature and the appearance of the hot band 1.2 meV above the main line are most marked for the sample with lower Mn concentration.

Fig. 1. A plot of the number of Mn atoms per formula unit of willemite vs. the number of mols of MnF_2 in the growth melt. Each melt contained 0.433 mols Zn. The data points represent 14 independent microprobe analyses. The fitted line is described by Eq. [1].

Fig. 2. Low temperature photoluminescence spectra of a Zn_2SiO_4 :Mn crystal excited by different lines of an Ar^+ laser. The laser line at 514 nm falls between the ZPL's for Mn_A and Mn_B centers, allowing isolation of luminescence from Mn_B centers.

Stevens and Vink (12) noted that higher concentrations of Mn impurity ($> 1\%$) produced spectra in which the ZPL's for both Mn_A and Mn_B centers were less well resolved. However, this broadening is not simply the result of decreasing crystal perfection, and near-resonant excitation of the two centers reveals additional fine structure in the region of the ZPL's. Near-resonant excitation of the Mn_A centers is achieved with the 501.7 nm (2.47 eV) Ar^+ line, the 5 K ZPL luminescence for a series of crystals with increasing Mn concentration being shown in Fig. 5. solid arrows indicate the peak energy of the single ZPL observed at low temperature for crystals with low Mn concentration. As the Mn doping level increases additional lines appear, mainly to higher energy (indicated by broken arrows), and steadily increase in intensity until they constitute the major features for crystal 2228A. Similar near-resonant excitation of the Mn_B centers is achieved with the 514.5 nm (2.41 eV) Ar^+ line, the corresponding ZPL luminescence being illustrated in Fig. 6. Again the low Mn concentration crystals show a single ZPL at low temperature with additional lines increasing in intensity as the Mn doping level increases. However, for these Mn_B centers the major new lines appear at lower energy than the ZPL observed at low Mn concentration. The observation of single ZPL's for Mn_A and Mn_B centers at low concentration can be attributed to the dominance of isolated Mn_{Zn}^{2+} impurities at low doping levels. The appearance of additional ZPL's which increase in intensity with increasing Mn concentration is characteristic of Mn-Mn pair interactions. As discussed in the following section, the fact that the barycenter of the Mn_A luminescence shifts to higher energy, while that of the Mn_B luminescence shifts to lower energy, with increasing Mn concentration suggests that the dominant interaction involves nearest neighbor Mn_A - Mn_B pairs in the willemite lattice. It can also be seen from Fig. 5 and 6 that whereas the changes in lineshape correlate strongly with changes in Mn doping level, there is no evidence for spectral features correlating with the As concentration which could be attributed to interaction between Mn_{Zn}^{2+} and the As impurity.

The decay curves for the Mn_A and Mn_B centers at various temperatures were separately measured using near-resonant excitation, with the detection monochromator tuned at the appropriate ZPL energy. The

Fig. 4. High resolution photoluminescence spectra of the ZPL region for Mn_A centers at different temperatures: (a) low Mn concentration and (b) high Mn concentration. The "hot" band in (a) is ~ 1.2 meV above the ZPL (cf. Fig. 3).

decays were in general not simple exponentials; the time to decay to $1/e$ of the initial intensity ($t_{1/e}$) for a series of crystals is given in Table II for the Mn_A centers and in Table III for the Mn_B centers. At low temperature the Mn_B decay is independent of Mn concentration. However, the decay time decreases as the temperature increases, the effect being more significant at high doping levels. Only small differences in decay time were observed at low temperature for crystal 2228A when the detection monochromator was set on the peak of ZPL's attributed to single Mn_B centers and to Mn_A - Mn_B pairs. The decay of the Mn_A centers, on the other hand, is measurably different for high and low Mn concentrations, but the change with temperature is smaller than for the Mn_B luminescence. The decay times observed at ~ 5 K for low Mn concentrations are in good agreement with values reported by Stevels and Vink (12), viz., 12 ms and 15 ms for Mn_A and Mn_B sites, respectively, at 1.6 K.

Discussion

Figure 1 demonstrates that the relationship between Mn incorporation in a crystal and the melt concentration includes both linear and quadratic terms. A quadratic dependence is indicative of Mn pairing during growth, as shown by the following argument. Since the substitution of Mn^{2+} for Zn^{2+} in the lattice maintains charge neutrality, and assuming that activities are proportional to concentration in the melt and crystal (i.e., approximately ideal behavior), the thermodynamics of Mn incorporation can be described by the law of mass action as follows. If $[V_{Zn}]$ and $[MnMn]_x$ are the zinc vacancy and Mn-pair concentrations in the growing crystal, then the incorporation of Mn as single ions is given by

Fig. 5. High resolution photoluminescence spectra of the ZPL region for Mn_A centers for crystals with varying Mn concentration. The solid arrows indicate the ZPL energy at low Mn concentration, due to single ions. The broken arrows indicate lines appearing at high Mn concentration and attributed to pairs. $[Mn/Zn]_m$ and $[As/Si]_m$ indicate the molar ratios of Mn/Zn and As/Si in the growth melt, respectively. The estimated Mn concentration in each crystal is given in Table I.

$$\frac{[Mn]_x^s}{[Mn]_m[V_{Zn}]} = K_s(T) \quad [3]$$

and as Mn-Mn pairs by

$$2[Mn]_m + 2[V_{Zn}] \rightleftharpoons [MnMn]_x \quad [4]$$

$$\frac{[MnMn]_x}{[Mn]_m^2[V_{Zn}]^2} = K_p(T) \quad [5]$$

The concentration of Mn incorporated in the crystals in the form of pairs is

$$[Mn]_x^p = 2[MnMn]_x \quad [6]$$

The total Mn concentration in the crystal is then given by

$$[Mn]_x = [Mn]_x^p + [Mn]_x^s = \{2K_p(T)[V_{Zn}]^2 + K_s(T)[V_{Zn}]\} [Mn]_m \quad [7]$$

The quadratic term only appears for pairing during the growth process, which must be energetically favored in order to be significant. The high resolution optical spectra provide evidence for dominant nearest neighbor Mn_A - Mn_B pair formation in the crystals at higher Mn concentrations. It may therefore be the case that strain energy associated with incorporation of Mn in willemite is minimized if two Mn ions substitute simultaneously in neighboring inequivalent zinc sites rather than as separated, isolated ions. Further work to establish the dependence of pairing on growth temperature and on zinc vacancy concentration is required to provide more insight into the mechanism of Mn incorporation.

The observation of "hot" bands in luminescence 1.2 meV ($\sim 10 \text{ cm}^{-1}$) to high energy of the ZPL's for both Mn_A and Mn_B single-ion centers in willemite is entirely analogous to the luminescence of Mn_{Zn}^{2+} in ZnS and ZnSe (15, 16). There, "hot" bands are found $\sim 10 \text{ cm}^{-1}$ and $\sim 11.5 \text{ cm}^{-1}$, respectively, above the lowest ZPL for the Mn ions in T_d symmetry, i.e., substitutional on cubic zinc sites. In addition, luminescence excitation spectra (15, 17) for ZnS:Mn and ZnSe:Mn reveal that the "hot" band arises from a second ZPL lying above the lowest energy line. Con-

sideration of first-order spin-orbit coupling in the 4T_1 excited state of Mn^{2+} in T_d symmetry predicts the following order of components (7): $\Gamma_6 < \Gamma_8(3/2) < \Gamma_7, \Gamma_8(5/2)$, using standard notation (18). The observation of only two ZPL's has been attributed to a complete vibronic quenching of the first-order spin-orbit coupling by strong coupling to a phonon mode of e-symmetry (the Ham effect) (15, 17). The second-order spin-orbit coupling is not quenched by the vibronic coupling, resulting in assignment of the two lines as transitions to the doubly degenerate levels represented as (15)

$$(i) \quad |\Gamma_7\rangle \text{ and } (3/\sqrt{10})|\Gamma_8(3/2)\rangle \\ - 1/\sqrt{10}|\Gamma_8(5/2)\rangle \quad (\text{lower energy})$$

$$(ii) \quad |\Gamma_6\rangle \text{ and } (1/\sqrt{10})|\Gamma_8(3/2)\rangle \\ + 3/\sqrt{10}|\Gamma_8(5/2)\rangle \quad (\text{higher energy})$$

This assignment is supported in the case of ZnS:Mn and ZnSe:Mn by analysis of Zeeman and uniaxial stress data (15, 17). The separation of the two components depends on second-order spin-orbit interactions summed over all multiplets of the d^5 configuration which differ by not more than one electron from the configuration of the 4T_1 state. A similar assignment must be supposed for the two lines in Fig. 4(a), although it is remarkable that almost identical behavior should be observed for Mn^{2+} in Zn_2SiO_4 when the crystal field parameters and the phonon spectrum are very different from the zincblende semiconductors ZnS (16, 18).

Mn pairs have also been observed in ZnS (16, 19), with antiferromagnetic spin coupling producing additional luminescence lines to low energy of the ZPL for isolated Mn_{Zn}^{2+} centers. In the case of ZnS, pairing occurs between Mn ions on equivalent sites. However, for willemite the nearest neighbor interactions involve the inequivalent Zn sites, with the possibility of Zn_A - Zn_B pairs having axes approximately parallel or perpendicular to the crystal c-axis. The most appropriate model for the Mn-Mn interaction in an ionic compound like willemite is likely to be multipolar (20), the leading term being the dipole-dipole coupling in the T_d symmetry field, with electron exchange small. The interaction between nearest neighbor inequivalent Mn_A - Mn_B centers is then best described as a second-order Davydov interaction between non-degenerate transition dipoles on the two centers, which are mixed via the crystal potential. The effect can be illustrated schematically by a simple perturbation argument. Denoting the ground state wavefunctions of isolated Mn_A and Mn_B centers as $|\phi_A\rangle$, $|\phi_B\rangle$, and using primes for the excited states (taken to be nondegenerate for simplicity), the zero-order wavefunctions for the ground and lower excited states of a nearest neighbor pair are given by the products

$$\psi_g = |\phi_A\rangle |\phi_B\rangle \quad [8]$$

$$\psi_{e^A} = |\phi_A'\rangle |\phi_B\rangle \quad [9]$$

$$\psi_{e^B} = |\phi_A\rangle |\phi_B'\rangle \quad [10]$$

The Hamiltonian for the pair is of the form

$$\mathcal{H} = \mathcal{H}_A + \mathcal{H}_B + \mathcal{H}_{AB} \quad [11]$$

where \mathcal{H}_A , \mathcal{H}_B are the Hamiltonians for the isolated Mn centers, and \mathcal{H}_{AB} represents the pair interaction, which is assumed small. Using perturbation theory, and retaining only the second-order terms involving the excited states, the energies of the pair states are

$$E_g = E_A^0 + E_B^0 + \langle \phi_A \phi_B | \mathcal{H}_{AB} | \phi_A \phi_B \rangle \quad [12]$$

$$E_{e^A} = E_A' + E_B^0 + \langle \phi_A' \phi_B | \mathcal{H}_{AB} | \phi_A' \phi_B \rangle + \frac{E_{AB}^2}{\Delta} \quad [13]$$

$$E_{e^B} = E_A^0 + E_B' + \langle \phi_A \phi_B' | \mathcal{H}_{AB} | \phi_A \phi_B' \rangle - \frac{E_{AB}^2}{\Delta} \quad [14]$$

where E_A^0 , E_B^0 and E_A' , E_B' are the energies of ground and excited states for isolated Mn_A and Mn_B centers, and

$$E_{AB}^2 = |\langle \phi_A' \phi_B | \mathcal{H}_{AB} | \phi_A \phi_B' \rangle|^2 \quad [15]$$

$$\Delta = (E_A' - E_A^0) - (E_B' - E_B^0) \quad [16]$$

The transition to the higher excited pair state therefore occurs at an energy

$$(E_{e^A} - E_g) = (E_A' - E_A^0) + D_A + \frac{E_{AB}^2}{\Delta} \quad [17]$$

where

$$D_A = \langle \phi_A' \phi_B | \mathcal{H}_{AB} | \phi_A' \phi_B \rangle \\ - \langle \phi_A \phi_B | \mathcal{H}_{AB} | \phi_A \phi_B \rangle \quad [18]$$

and $(E_A' - E_A^0)$ is the transition energy at an isolated Mn_A center. The transition to the lower pair state occurs at an energy

$$(E_{e^B} - E_g) = (E_B' - E_B^0) + D_B - \frac{E_{AB}^2}{\Delta} \quad [19]$$

where

$$D_B = \langle \phi_A \phi_B' | \mathcal{H}_{AB} | \phi_A \phi_B' \rangle \\ - \langle \phi_A \phi_B | \mathcal{H}_{AB} | \phi_A \phi_B \rangle \quad [20]$$

and $(E_B' - E_B^0)$ is the transition energy at an isolated Mn_B center. The net effect of the Mn_A - Mn_B pairwise interaction is, therefore, to produce shifts (δE^A , δE^B) in the transition energies compared with the isolated centers, where

$$\delta E^A = D_A + \frac{E_{AB}^2}{\Delta} \quad [21]$$

$$\delta E^B = D_B - \frac{E_{AB}^2}{\Delta} \quad [22]$$

If the differential first-order terms D_A , D_B are small, the second-order interaction predicts an upward shift in energy for transitions at the Mn_A center in the pair, and a downward shift for transitions at the Mn_B center. This is the sense of the barycenter shifts illustrated in Fig. 5 and 6, and it is for this reason that we propose a dominant nearest neighbor Mn_A - Mn_B pairing to explain the changes in lineshape observed at higher Mn doping levels. The appearance of extra lines in addition to the barycenter shifts for the pairs can be accounted for in terms of the known degeneracy of the Mn_A and Mn_B excited states (discussed in the previous paragraph), and the possibility of forming inequivalent pairs of different symmetry. However, no detailed treatment of the pair fine structure will be attempted here.

The antiferromagnetic spin coupling between nearest neighbor Mn_{Zn}^{2+} ions on equivalent sites in ZnS produces a low temperature, pair luminescence decay time approximately an order of magnitude faster than that for single ions (19). The corresponding ZPL for the spin-coupled pair is shifted ~ 15 meV to low energy (19). However, the predominantly second-order interaction between inequivalent nearest neighbor sites in willemite gives pair line shifts which are much smaller, ~ 1 meV. This weakening of the pair interaction, combined with spectral overlap resulting from larger linewidths, may explain why no significant difference in decay time at low temperature was observed in willemite when the detection monochromator was tuned to lines attributed to pairs and to single ions. Nevertheless, the luminescence decay for both Mn_A and Mn_B sites becomes faster as tempera-

ture increases. Tables II and III show that the effect is greater as the Mn concentration increases, i.e., as the Mn inter-center energy transfer becomes more facile, indicating a thermally activated energy transfer to centers with larger recombination rates. Preliminary measurements (21) on a number of crystals suggest that the luminescence efficiency at room temperature does not decrease markedly at higher Mn doping levels. The decrease in decay time at higher Mn concentrations therefore probably does not reflect a "concentration-quenching" (20) at nonradiative centers in the crystals, but rather an energy transfer to complex centers involving Mn^{2+} ions with faster radiative rates. The probability of exciting such centers is presumed larger at higher temperatures and higher Mn concentration due to the increased rate of inter-center energy transfer in the crystal. The sensitivity of the Mn_A decay rate to the Mn concentration even at low temperature (Table II) may indicate a significant nonthermal component in energy transfer from the higher energy Mn_A centers to Mn_B centers. Further efficiency measurements are required to confirm the possible usefulness of variations in Mn concentration for control of decay time in phosphors based on the $Zn_2SiO_4:Mn$ system.

Archival Life of Tellurium-Based Materials for Optical Recording

G. M. Blom* and D. Y. Lou

Philips Laboratories, Briarcliff Manor, New York 10510

ABSTRACT

The archival life of digital optical recording air-sandwich disks is described in this paper. The optically sensitive materials are tellurium-based alloys, and the substrates are polymethylmethacrylate. Various techniques such as reflection, transmission, signal-to-noise ratio, and bit-error rate measurements are used to characterize degradation. It is demonstrated that bit-error rate measurements are by far the most sensitive. It is shown that elemental tellurium, when stored under normal office conditions, has an archival life of at least several years when the optical disk is in the form of an air-sandwich disk. Tellurium alloys fabricated into an air-sandwich disk have a projected archival life of at least ten years. The projections are based on bit-error rate measurements on air-sandwich disks stored under accelerated degradation conditions for periods of several years. Storage conditions which allow condensation of water vapor must be avoided. Experiments with disks having trilayers and containing the normally excellent tellurium alloys show rapid degradation. Such degradation is believed to result from electrochemical corrosion.

Digital optical recording (DOR) is a new technology which has been proven on a pilot production scale to be capable of storing large amounts of data (1-9). Large area and volumetric densities have been achieved. Densities as high as 10^{11} bits per 12 in diam disk and up to 5×10^{11} bits per surface of a 16 in diam disk have been demonstrated. The thickness of a two-sided air-sandwich disk and its protective cartridge is about 1 cm. Hence, densities per area and volume are significantly enhanced compared to current

magnetic recording technology. It seems likely that commercial products will be introduced in the near future in an office environment and as data processing peripherals. In either case, media are required on which the information is stored.

The three parameters most important for a successful optical recording media are archival life, resolution, and sensitivity (10). Several materials such as organic dyes (4), tellurium and other metal trilayers (11-12), amorphous materials (13), magneto-optical materials (6), textured surfaces (14), silicides (15), and, of course, tellurium-based alloys (9) have been investi-

* Electrochemical Society Active Member.
Key words: films, optics, corrosion, failure.

gated by many researchers. Most of these materials have shown to have adequate performance characteristics as far as resolution and sensitivity are concerned. This is especially true as long as the highest storage densities are not required. Currently, tellurium alloys are the only group of materials on which sufficient data have been collected concerning archival life. It will be shown that archival life with these alloys is excellent. It was shown previously (16) that the archival life of air-sandwich disks with elemental tellurium was several weeks when stored under accelerating conditions. The magnitude of the acceleration factor was unknown at that time.

In this paper, we will discuss the various criteria which are commonly used for measuring archival lives of optical recording media. It will be demonstrated that the bit-error rate (BER) is a much more sensitive parameter than other commonly measured parameters, such as reflectivity, transmission, and signal-to-noise ratio (SNR). Nevertheless, the other parameters are useful for initial screening new materials for their archival quality in optical recording technology. Subsequently, various storage conditions and their possible influence on the archival life of the optical disk will be discussed. This will also uncover information regarding conditions and precautions which must be adhered to and taken for storage of these disks under normal operating conditions. The storage conditions are not arbitrarily selected: they take into consideration that the DOR disk is packaged in the well-known air-sandwich disk. We will describe the air-sandwich disk that uses polymethylmethacrylate (PMMA) substrates in some detail and elaborate on its features.

Air-Sandwich Disk

The air-sandwich disk, shown schematically in Fig. 1, consists of two PMMA substrates each coated with a 30 nm layer of elemental tellurium or a tellurium alloy. Sometimes a polymer or acrylic subbing layer is applied on the substrates prior to metal deposition. Many subbing layers have a detrimental effect on disk archival life. The data reported here refer to disks without subbing layers. The two individual disks are separated by spacers at the inner and outer radii of the information band. Typically, the information band is between 70 and 145 mm radius for a 300 mm diam disk. The inner spacer is usually PMMA, which is bonded with transfer adhesive to the two individual disks. An alternative method uses a hot-melt adhesive that also serves as a spacer. The width of this spacer extends from the inner radius of the disk, i.e., 35-55 mm. The outer spacer of the air-sandwich disk is either an adhesive open-cell foam strip, 5 mm wide, or 3 mm of hot melt followed by a 2 mm acrylic adhesive for added strength. All spacers are 1 mm thick. Of course, metal film is deposited on the inside surfaces of the air-sandwich disk.

The advantages of the air-sandwich structure are that the sensitive material is protected from environmental effects such as dust and operator handling, as well as

Fig. 1. Schematic diagram of air-sandwich disk

that any particles and smudges, such as fingerprints, are out of focus as a result of the substrate thickness being 1-1.2 mm. Because the tellurium is inside the structure, the operators are protected from the possible harmful effects of tellurium. Also, one has a two-sided disk.

The tellurium alloys are made by mixing the appropriate elements, sealing them in a quartz ampul, and heating the ampul at a temperature of about 600°C. The alloy is vacuum deposited by flash evaporation on the PMMA substrate, which is maintained at room temperature. The average evaporation rate is 0.1 nm/s.

We find it essential to use air-sandwich disks for archival testing, because testing of single disks is complicated by the lack of protection of the metal film from the environment. The air-sandwich structure was found to be necessary for continuous optimum performance. Alternative protective structures for the sensitive media can be devised, however, we find the air-sandwich disk structure simple to fabricate as well as easy to operate, and it attains excellent archival life properties.

Measured Parameters

To obtain information concerning the archival properties of an optical recording medium, possible changes of optical parameters as a function of time must be measured. Optical reflection and transmission are often chosen for measurement. They are useful for initial screening, since they help ascertain if a new material has any potential as an optical recording medium. These two parameters can be measured without performing optical recording. We found, as is shown in Fig. 2, that consistent optical transmission is a prerequisite for good archival life, but by no means is it sufficient. The optical reflection, measured at 488 nm, of our tellurium alloy is typically 44%, while the transmission is typically 7%. The uniformity of these parameters within the disk and between disks is $\pm 10\%$ relative, corresponding to a thickness variation of ± 2 nm.

Another parameter for determining archival life of DOR disks is the signal-to-noise ratio (SNR). Of course, this requires that actual recording must be

Fig. 2. Comparison of various media parameters, such as BER, signal-to-second harmonic (S/SH), signal-to-noise ratio (S/N), and optical transmission (T) as a function of storage time, indicating that BER is the most sensitive parameter.

performed. Sometimes video information is recorded off the air, and the SNR is measured over a 4.2 MHz bandwidth. However, for digital optical recording, one must recognize that translation from SNR to bit-error rates is not necessarily straightforward. We have measured the SNR of digital information (at 4.2 MHz bandwidth) and, as shown in Fig. 2, it was found to be a prerequisite for good archival life. However, the fact that SNR remains unchanged does not necessarily imply that the digital recording medium is stable. Similarly, we have measured the signal-to-second harmonic ratio and found a comparable behavior as for the SNR.

The parameter which we find must be measured for determining archival life properties of optical recording media is the bit-error rate. In all cases the presented data apply to the uncorrected or raw BER. The uncorrected BER provides true disk characterization. Upon applying error correction codes, the combination of the disk BER and the correcting electronics results in a corrected BER. It will be shown later that with uncorrected BER's of 10^{-4} corrected BER's of better than 10^{-9} can be obtained.

In Fig. 2 we have plotted the BER as a function of time for an air-sandwich disk coated with 30 nm of elemental tellurium. Also plotted are SNR, optical transmission, and signal-to-second harmonic ratio (S/SH) for this same disk. It can be seen that the BER catastrophically increased after about 2 weeks storage at a temperature of 45°C and a relative humidity of 95%, while the other three parameters shown in Fig. 2 were still unchanged even after 3 weeks. This demonstrates that the BER must be directly measured in determining the archival life of DOR media.

The reason for the above-mentioned observation is that transmission and reflection measurements are macroscopic parameters. The areas involved in these measurements are typically large compared to the spot size used for actual recording. While the SNR and S/SH ratios require actual recording, the measured values represent an average of a microscopic parameter over a large area. Hence, changes in the 10^{-4} range cannot be measured. The BER, however, is a bit-by-bit comparison of the recorded information, and it simply counts the number of times that a bit does not correspond to what was recorded. BER is a microscopic measurement. Therefore, it is sensitive to levels much lower than 10^{-4} , as when we observed BER's of 10^{-7} . Consequently, we will use BER to determine archival life of our media.

Storage Conditions

In order to generate meaningful archival data, one must specify the storage conditions for the DOR air-sandwich disks. One expects to specify test conditions which accelerate the degradation phenomena in a specific, well-known way. This assumes that one knows the temperature dependence of the chemical reactions responsible for degradation, e.g., an exponential relation with temperature. In the case of semiconductors this is generally a safe assumption. For DOR air-sandwich disks with tellurium alloys as the sensitive media this is not necessarily the case. It is expected that elevated temperatures and elevated relative humidities accelerate the degradation reactions. Since we are operating with PMMA substrates, a practical upper temperature for these tests is approximately 45°C. At higher temperatures, the PMMA deforms irreversibly. Consequently, one of the storage conditions which was selected is 45°C and 95% relative humidity (RH). Another storage condition is room ambient, which is an average temperature of 22°C and an average RH of 50%. In order to differentiate between the influence of elevated temperature and increased RH, another storage condition is 45°C and 50% RH. A cyclic storage condition where the temperature was changed between

25° and 45°C with 8h cycles, ramps of 2h, and a constant RH between 90 and 95% was also used. As expected, no degradation of the recording media was observed when stored at 0°C. Hence, as far as media testing is concerned, we have four different storage conditions: (i) 45°C and 95% RH, (ii) room ambient, (iii) 45°C and 50% RH, and (iv) cyclic. Temperatures around 0°C were used to test the strength of the seal. Many adhesives work well at room temperature and higher, but becomes brittle at freezing temperatures. Thus, low temperature tests were performed on blank disks to select the proper sealing technology.

Archival Life

Miller modulated pseudorandom bit patterns were recorded on air-sandwich disks and in some cases on single, open disks. The recorder had a He-Ne laser, a data rate of 2 Mbit/sec, and a spot size of 0.8 μm FWHM. The spot was focused through the PMMA substrate onto the elemental tellurium or the tellurium alloy. When measuring the average BER, a band of about 1 cm wide was recorded with the bit pattern generated and compared by an HP 8088A. In other measurements, the recording consisted of a single track of data divided into 32 sectors, each with protection bits, clock-synchronization bits, etc. Bit by bit comparisons were made. BER values, as well as various statistical information about the error distributions, could be obtained.

Typical BER results for medium-quality single open disks coated with 30 nm of elemental tellurium are shown in Fig. 3. Clean room (class 100) ambient storage conditions are designated by the open circles, and the 45°C/95% RH storage conditions are depicted by the triangles. For single open disks stored at 45°C/95% RH, catastrophic degradation occurs after 2 days. However, storing such disks under clean room ambient conditions, we observed that even after 2 yr they still had an unchanged BER. While we do not suggest using such open single disks these results show that elemental tellurium, when properly stored, is a good DOR medium.

BER data on air-sandwich disks coated with 30 nm of elemental tellurium are shown in Fig. 4. Room

Fig. 3. Degradation characteristics of a single open disk coated with 30 nm elemental tellurium.

Fig. 4. Degradation characteristics of an air-sandwich disk coated with 30 nm elemental tellurium.

ambient and 45°C/95% RH are the storage conditions. Again these are typical results. Storing at the accelerated conditions shows that catastrophic degradation occurs after about 2.5 weeks. Comparing the 45°C/95% RH data in Fig. 3 and 4 indicates that nearly an order of magnitude is gained in storage time for an air-sandwich configuration compared with a single open disk. As would be expected from the data shown in Fig. 3, it is seen in Fig. 4 that room ambient storage shows no change in BER data after 2 yr. Dividing the storage times to catastrophic degradation obtained from Fig. 4 results in an acceleration factor greater than 45. Again we confirm here that elemental tellurium as a medium is far better, as we have often claimed, especially if used in combination with the air-sandwich disk configuration.

Alloying of selenium in the tellurium results in a significant improvement for the archival life of DOR disks. The data shown in Fig. 5 and 6 are BER data as a function of storage time for single open disks and air-sandwich disks containing 30 nm of the tellurium-selenium alloy. For single open disks stored at 45°C/95% RH and recorded with pseudorandom data, catastrophic degradation occurs after 3 weeks. This is approximately one order of magnitude longer than with elemental tellurium; significant improvement is obtained. Storing an air-sandwich disk at the accelerated conditions of 45°C/95% RH shows that even after nearly 2 yr no change has occurred in the BER; and an improvement of at least 30 is obtained. Figure 6 also shows the data for room ambient storage and the single open disk for comparison.

While the average BER is a simple and useful description of disk performance, the possibility of applying error correcting codes to the recovered data means that we also need information about the statistical distribution of the errors. Figure 7 shows such a distribution. It was measured over about 10^9 bits, and is the distribution of the lengths of burst errors detected on a typical medium-quality disk. Most of the errors are randomly occurring single-bit errors. Relatively simple error correcting algorithms are readily available, and have been used in recordings with BER's of better than 10^{-9} .

Fig. 6. Normalized BER as a function of storage time for tellurium alloy coated disks stored under various conditions.

Discussion

Improvements in storage times between air-sandwich disks and single open disks of 10 and 30 were established for disks containing elemental tellurium and Te-Se alloys, respectively. These improvements are attributed to two possible factors. One is that the air-sandwich structure protects the metal film from immediate exposure to water vapor and chemical pollutants in the air. The other is that the air-sandwich protects the metal film from dust. Dust probably contains metal particles, for which it has been established that corrosion is enhanced significantly when contacted by the Te or Te-Se film in the presence of water vapor. The electrochemical potential difference between a metal particle and the sensitive film is believed to be a major factor for this rapid degradation. Since the air-sandwich disks are fabricated in a class 100 clean room, the air-sandwich disks are like miniature clean rooms themselves. Single open disks stored in a dust-free (class 100 clean room) condition show an archival life of at least 20 months.

From the acceleration factors stated earlier, up to at least 45, one can conclude that the air-sandwich disks

Fig. 7. Bit error distribution of a typical disk

containing the Te-Se alloy have an archival life of at least 20 yr and possibly as high as 75 yr under normal ambient conditions. The uncorrected or raw BER data, being in the 10^{-5} to 10^{-4} range, together with the BER distribution data (Fig. 7) and the application of error correcting codes, show that our data demonstrate that sufficient archival life exists for our DOR medium. In magnetic recording, BER's of at least 10^{-8} are required for sufficient archival life; however, this pertains to measurements after at least sector rewrites and is therefore not equivalent to our uncorrected BER. As stated earlier, correcting algorithms have been used to obtain BER's of better than 10^{-9} . Sufficient archival life is often specified as 10 yr under normal storage and operating conditions as are currently used in data storage operations. Thus, we conclude that our DOR medium is superior to the current archival medium, *i.e.*, magnetic tape. For comparison,

we tested a magnetic tape at the $45^{\circ}\text{C}/95\%$ RH conditions. It was observed that the data was unretrievable after a few days of storage.

From our measurements, we can conclude that the storage conditions of $45^{\circ}\text{C}/95\%$ RH indeed accelerate the degradation for elemental tellurium and for tellurium alloys on single open disks and most likely also for air-sandwich disks with the alloy. However, from the limited data at $45^{\circ}\text{C}/50\%$ RH, where no degradation was observed after more than a year of storage, and from the earlier shown data, we cannot draw conclusions concerning the degradation mechanism itself. Also, the cyclic storage conditions for which we have not shown data because of redundancy indicate that this environment gives the same BER data as a function of time as the $45^{\circ}\text{C}/95\%$ RH conditions. Possibly, longer storage times would allow such differentiation. Our main objective is to demonstrate that a tellurium alloy is an excellent DOR medium for storage times of up to 10 yr.

Measurements of shelf-life of optical recording disks coated with elemental tellurium have been reported earlier (17). In these measurements, the recording sensitivity was measured as a function of storage time. It was shown that high-humidity storage conditions degrade the films rapidly; this agrees with our archival data.

In addition to the single-layer films deposited on the PMMA substrates, we have also looked at the application of this alloy in a trilayer or bilayer configuration. Figure 8 is an optical micrograph of what happens to a bilayer consisting of 100 nm of aluminum covered with about 20 nm of our tellurium alloy upon storage for a few days at $45^{\circ}\text{C}/95\%$ RH. Large corroded areas are observed. While the original BER was about 10^{-4} , the data could not be retrieved after this storage time. We believe that such degradation results when two different metals are in contact with each other, or, in the case of the trilayer, separated by a dielectric several tens of nm thick. As is well known in metallurgy, an electrochemical potential difference is set up in such a structure. In the presence of any water vapor, a corrosion process can be activated. This can either oxidize the mirror, *i.e.*, the aluminum, or the sensitive medium, *i.e.*, the tellurium alloy. This corrosion process proceeds much faster than the simple oxidation degradation occurring with single tellurium alloy films in air-sandwich disks. It is likely to be a mechanism similar to the corrosion/degradation process observed in single open disks when stored at $45^{\circ}\text{C}/95\%$ RH.

Fig. 8. Photograph of a bilayer disk containing the tellurium alloy showing severe degradation. Degradation is believed to result from electrochemical corrosion.

The fact that the PMMA substrates which we have used in this study are very permeable to water vapor, and to a lesser degree to other possible pollutants, apparently plays no major role. Degradation is no problem. The only condition which we found must be adhered to is that condensation of water vapor must be prevented. This is easy to accomplish even for storage at 45°C/95% RH. One simply must not put the disk after removal from the environmental chamber directly onto a cold table. No condensation was observed when the disks were left in ambient conditions after removal from the environmental chambers. In fact, the permeability of PMMA to water vapor is an advantage. From separate experiments we concluded that the equilibrium water vapor pressure inside the air-sandwich disk is established in approximately 10 min. This certainly helps to prevent condensation of water vapor, since the equilibrium water vapor pressure is obtained very rapidly.

Conclusion

Tellurium alloys deposited on PMMA substrates and fabricated into air-sandwich disks have proven to have an archival life, when stored at 45°C and 95% relative humidity, of at least 2 yr. From our data on elemental tellurium we conclude that the acceleration factor is at least 10, and possibly as much as 45. Hence, an archival life for the air-sandwich disk with the alloy can safely be extrapolated to an archival life of at least 10 yr when the disks are stored and used in normal computer room environments. This shows a significant improvement over magnetic tape, the current medium for long-term storage.

ABSTRACT

Very adhesive poly (3-methyl-thiophene) and poly (3,4-dimethyl-thiophene) films were photoelectrochemically grown on platinum-plated n-GaAs electrodes. The stability of poly (3-methyl-thiophene)-coated photoanodes is dependent on the nature of the counterion used during the synthesis of the polymer. Best results were obtained with SO_3CF_3^- . No film peeling was observed after a 17 h run in a $\text{Fe}(\text{CN})_6^{4-/3-}$ aqueous solution under 30 mW/cm² tungsten lamp illumination. This is attributed to the greater density and smaller porosity of the polymer grown with this counterion. However, corrosion of the photoanode occurred, because of the reduction of the polymer to its neutral form where its conductivity is drastically lowered. Reduction of the polymer film was also observed with poly(3,4-dimethyl-thiophene), but a comparison between the absorption spectra of electrochemically and chemically reduced polymers suggests that the electrochemical reduction is not complete. This can account for the lack of photocorrosion of GaAs after a 4 h run in a $\text{Fe}(\text{CN})_6^{4-/3-}$ electrolyte. The use of more oxidizing redox couples prevented the reduction of the polymer film, but led to a rapid photodissolution of the electrode.

The development of semiconductor-based photoelectrochemical (PEC) solar cells is mainly limited by the problem of photodegradation of small bandgap electrodes. A good stabilization of GaAs has been obtained by adding selenide to the electrolyte (1-3). More recently, polymer coatings have been employed to protect semiconductor photoelectrodes. One of the most reported polymers is polypyrrole, which has been

shown to be a good conducting electrochemically synthesized organic polymer on Au or Pt electrodes (4). Long term stabilization (up to 450h) has been reported on polypyrrole-protected n-Si in various aqueous solutions (5-7). Protection of n-GaAs by polymer coating seems to be a more difficult task. The reported stabilities in aqueous solution are 10-20 min with polypyrrole (8) and 2h with polystyrene pendant $\text{Ru}(\text{bpy})_3^{2+}$ complex (9). It has been shown recently that other conducting organic polymers of the same group as polypyrrole can be electrochemically gener-

Key words: photoelectrode stabilization, conducting polymer, gallium arsenide.

ated, e.g., polythiophene and polyfuran (10). In this paper, we show that very adhesive films of poly(3-methyl-thiophene) and poly(3,4-dimethyl-thiophene), hereafter called PMeT and PMe₂T, can be photoelectrochemically grafted on platinum-plated n-GaAs. The protection of the electrodes is shown to be dependent on the nature of the counterion. Corrosion or passivation of the GaAs surface may occur, depending on the counterion and the monomer. An attempt is made to explain the lack of long-term stabilization of n-GaAs by means of conducting organic polymers.

Experimental

Electrodes were prepared from (100) and (111) n-GaAs wafers purchased from RTC-Caen (France). The doping level ranged from 1.5 to 2.5 × 10¹⁶ cm⁻³. Ohmic contacts were made by evaporating Au-Ge alloy and annealing at 400°C under N₂ atmosphere. A copper wire was attached to the back contact with silver epoxy cement. The wafers were then mounted on glass tubes with Torr Seal (Varian) resin. The active surface was polished with 1 μm diamond paste and etched in 5% bromine-methanol for 5-10s. It was then rinsed thoroughly with ethanol.

The platinum electroplating was carried out in the dark under -0.6 to -0.7 V/SCE cathodic polarization in an aqueous solution of (NH₄)₂PtCl₆ and LiClO₄. Electrodeposition of polymers was performed under tungsten illumination (ca. 30 mW/cm²) in acetonitrile solutions containing 0.1M supporting salt and 1M distilled 3-methyl or 3,4 dimethyl-thiophene. The supporting electrolyte was LiClO₄, Bu₄NBF₄, or Bu₄NSO₃CF₃. The quantity of deposited Pt, as well as the polymer film thickness, were followed by using a digital coulometer. Interferometric measurements that were carried out on platinum electrodes showed a linear variation of the thickness of electrodeposited PMeT films as a function of the charge, with a slope of 10 Å/mC × cm⁻². This value was used for determining the film thickness on platinized GaAs. The stability of protected n-GaAs photoanodes was tested by measuring the short-circuit current vs. time of an illuminated cell with a load resistance of 1Ω. Electrolytes were prepared with reagent-grade chemicals and distilled water. Stability tests were performed in two different redox solutions: (i) 0.1M K₃Fe(CN)₆ and 0.1M K₄Fe(CN)₆ in 0.1M KCl (pH = 7.3), and (ii) 0.1M FeCl₂ and 0.1M FeCl₃ in 0.1M HCl (pH = 1.0). I⁻/I₃⁻ and Br⁻/Br₂ aqueous solutions were prepared as follows: 1M KI, 0.1M I₂, 0.2M KCl and 0.2M KBr, 0.02M Br₂, 0.1M KCl. Illumination was obtained with a tungsten lamp and was roughly estimated as 30 mW/cm² with no correction for absorption by the solution and polymer film.

Results

Table I gives the polymerization-onset potentials of pyrrole and thiophene derivatives on Pt and illuminated platinum-plated n-GaAs electrodes. Attempts to grow polythiophene derivative films on naked GaAs led to very inhomogeneous films, probably because corrosion competes with polymerization at the potentials used. No improvement was obtained by etching the electrode in 1:1 H₂SO₄/H₂O₂ solution, or by ruthenium pretreatment (1). Very adhesive films could be grown on platinum-plated GaAs electrodes. The best results were obtained with a charge of 10 mC/cm², corresponding to a thickness of about 20Å of platinum. Scanning electron micrographs of a platinized electrode showed that Pt films are not continuous and tend to leave uncovered islands. However, continuous polymer films could be grown on such pretreated electrodes.

Linear sweep cyclic voltammograms of PMeT-covered Pt and illuminated platinized-GaAs electrodes are shown in Fig. 1. It must be pointed out that the oxidation peak is observed on GaAs only under illumination, whereas the reduction peak can also be obtained in dark. The 0.6V cathodic shift of the peaks is similar to the one observed on the polymerization onset potentials.

The adhesion of polymer films was checked by applying a piece of adhesive tape on the electrode and peeling it off. No removal of the polymer film was obtained for both PMeT and PMe₂T.

The corrosion behavior of a naked GaAs electrode in an aqueous solution depends on the pH of the electrolyte (11, 12). At neutral pH (electrolyte i), both As₂O₃ and Ga₂O₃ are stable, and GaAs is rapidly covered with an oxide layer, leading to a sharp decrease of the photocurrent, as shown by the dashed curve in Fig. 2. In acidic electrolyte (ii), Ga₂O₃ is completely soluble, and a continuous dissolution of the electrode is observed, without any decrease of the photocurrent. Platinization did not change the corrosion behavior of GaAs, probably because of the discontinuous character of the electrodeposited Pt films.

The evolution of the photocurrent with time in electrolyte i is shown in Fig. 2, 3, and 4 for different polymer films. The rapid decrease occurring within the first minute is associated with an electrochemical reduction of the film to its neutral form. This reduction is evidenced by the change of color from dark blue to red for PMeT, and from dark blue to pale blue for PMe₂T films. It has also been verified by measuring the rest potential of the electrode in an acetonitrile solution of the supporting salt. The film could then be reoxidized to its conducting form. The rapid decrease of the photocurrent can then be attributed to the increase of the ohmic resistance of the polymer film, as will be discussed in the following section.

Figure 2 corresponds to a PMeT-BF₄⁻ film. It is worth noting the increase of the photocurrent during the first hour. During the course of the experiment, a white insoluble deposit appeared on the surface, which gradually covered the electrode, leading to a decrease of the photocurrent. The experiment was interrupted after 3h and the electrode was rinsed in distilled water and blown dry. The deposit appeared as little pellets of oxide that have grown over the polymer film. This latter was still covering the whole electrode surface. After removing the oxide pellets, polymer film corrosion pits could be seen on the electrode. The j-v characteristic measured before the stability test is shown in the inset of Fig. 2. The values for the parameters of the corresponding power curve are the following. Short-circuit current density: 5.7 mA/cm². Open-circuit voltage: 0.54V. Fill factor: 0.50. The power efficiency at 30 mW/cm² is thus 5%. An efficiency of 10.5% has been reported for polypyrrole-coated n-GaAs in methanol (8). Attempts to obtain power curves for uncoated GaAs failed because of the rapid passivation of the electrode.

Similar behavior was observed with PMeT-ClO₄⁻ films, with a photocurrent maximum occurring after only 15 min.

The photocurrent vs. time behavior of a PMeT-SO₃CF₃⁻ film covered electrode is shown in Fig. 3. No deposit appeared over the film after 17h. We observed a slow decay of the photocurrent, which can

3,4-Me ₂ Thiophene	1.3	0.7

Fig. 1. Cyclic voltammogram of PMeT-BF_4^- on platinum and illuminated platinized-n-GaAs electrodes. Illumination by a tungsten lamp at 30 mW/cm^2 . Scan rate: 50 mV/s .

Fig. 2. Short-circuit current vs. time for a bare (---) and PMeT-BF_4^- -coated platinized (—) n-GaAs photoanode, in aqueous $0.1 \text{ M K}_3\text{Fe(CN)}_6$, $\text{K}_4\text{Fe(CN)}_6$, KCl solution. The polymer layer is 1000 \AA thick. Illumination by a tungsten lamp at about 30 mW/cm^2 . A voltammetric curve for the protected electrode is shown in the inset (scan rate: 200 mV/s).

Fig. 3. Same as Fig. 2 for a $\text{GaAs/Pt/PMeT-SO}_3\text{CF}_3^-$ electrode. Film thickness: 1000 \AA .

be attributed to the passivation of the semiconductor. Some corrosion pits were visible at the electrode surface after removing the polymer film.

The best protection was obtained with $\text{PMe}_2\text{T-SO}_3\text{CF}_3^-$ films, as shown in Fig. 4. No deposits on the film or corrosion pits on the electrode were observed after a 4h run under tungsten lamp illumination.

Experiments in solution *ii* led to similar results with all the polymer films. After about 1h under illumination, the film cracked and peeled off the electrode. Dissolution of GaAs occurred during the course of the experiment.

Finally, Fig. 5 shows the correlation between the equilibrium redox potential and the open-circuit voltage (V_{oc}) for a GaAs/Pt/PMeT photoanode. V_{oc} was taken as the difference between the onset of the photocurrent and the redox potential. The linear variation

observed has also been reported for other GaAs/polymer PEC cells (8, 9), and suggests the absence of Fermi level pinning, at least within the voltage range $0.2\text{--}0.8 \text{ V/SCE}$.

Discussion

The lack of long-term stabilization of polymer-coated n-GaAs in aqueous solutions originates from film peeling that occurs after 10–20 min with polypyrrole (8), and 2h for polystyrene $\text{Ru}(\text{bpy})_3^{2+}$ complex (9). With PMeT and PMe_2T , one of the most remarkable features is that film peeling only occurs after a significant corrosion of the photoanode. This is particularly evident in solution *ii*, where the GaAs dissolution is not prevented by the polymer, and where the film peels off the electrode only after a substantial corrosion of the electrode. Moreover, a $\text{PMeT-SO}_3\text{CF}_3^-$ -coated electrode could be run for 17h in solution *i* without any film peeling.

The explanations can be given for the corrosion of polythiophene protected electrodes; first, the reduc-

Fig. 4. Same as Fig. 2 for a GaAs/Pt/PMe₂T-SO₃CF₃⁻ electrode. Film thickness: 750Å.

tion of the film to its neutral (semiconducting) form, and second, the porosity of the film.¹

The porosity of the polymer is clearly shown by the growth of oxide pellets over the film with PMeT-BF₄⁻ and PMeT-ClO₄⁻ in electrolyte *i*. This feature cannot be explained without assuming that Ga or As ions are able to get through the polymer to the electrolyte. The porosity of PMeT films seems to be dependent on the nature of the counterion used for the electrochemical synthesis, since no oxide growth was observed with SO₃CF₃⁻. This is clearly shown by the scanning electron micrographs of reduced PMeT films, grown on platinum electrodes shown in Fig. 6, which reveal

¹One of the referees suggested that the photocurrent bump in Fig. 2 and 4 could be due to a light filtering effect originating from a decrease of the polymer absorption (see Fig. 7) as it is reduced. This can be discarded, since the reduction occurs within the first minute of the stability test, whereas the photocurrent increase is a much longer process.

a much higher degree of porosity of films originally grown with ClO₄⁻ counterion. The more space filling character of SO₃CF₃⁻ films could be attributed to a better match between the sizes of the thiophene mole-

cule and the counterion. Studies of PMeT grown on Pt substrates have shown a higher density of the polymer with SO_3CF_3^- counterion, which could be explained by a smaller distance between the polymer chains (13).

Reduction of the polymer film occurred in both electrolytes *i* and *ii*. It is shown by the rapid photocurrent drop that takes place within the first minute of the experiment. The reduction was clearly evidenced by putting back the electrode in an acetonitrile solution where the PMeT film could be reoxidized as described in the previous section. A probable explanation of the polymer reduction is a positive shift of the redox peaks of PMeT from their position in acetonitrile; a shift of ca. 0.35V has been observed on Pt/ PMeT electrodes (14). Corrosion of the photoanode could then occur, because the photocarriers are not drained rapidly enough towards the electrolyte through the polymer film. The polymer reduction can also account for the low power efficiency (5%) observed on PMeT -coated GaAs photoanodes.

The reduction of the polymer induces a change of its color and absorption spectrum. A complete dedoping can be obtained chemically in ammonia. This gives red PMeT and yellow PMe_2T . The red color is also obtained on electrochemically reduced PMeT . Furthermore, elemental microanalysis showed a doping level of 0.005% for chemically reduced and 0.010% for electrochemically reduced (at -0.2V/SCE) poly-3-methylthiophene. For comparison, the doping level of the conducting form is about 30%. The corresponding conductivities are $30 (\Omega \times \text{cm})^{-1}$ for the oxidized form and $10^{-7} (\Omega \times \text{cm})^{-1}$ for the reduced form (these values were measured on pressed pellets). Then, the PMeT -coated electrodes are worked with a neutral (quasi-insulating) protective film; this explains the corrosion observed in electrolyte *i*.

The pale blue color of reduced- PMe_2T films indicates that the reduction of this film is only partial. Absorption spectra of oxidized and reduced- PMe_2T films are shown in Fig. 7. These spectra were measured on PMe_2T films grafted on semitransparent Pt electrodes. A complete electrochemical reduction of the film, leading to an absorption spectrum similar to the one measured on chemically reduced PMe_2T , is only obtained at a highly reducing potential (-4V/SCE). The polymer film reported in Fig. 4 is then only partly dedoped. This explains the smaller value of the initial

photocurrent drop, and can account for the better stability of a PMe_2T -coated GaAs photoanode.

The reduction of the polymer film could be prevented by using a more oxidizing redox couple. A trial has then been performed with a Br^-/Br_2 aqueous solution. The experiment led to a rapid corrosion of the photoanode with the formation of white insoluble Ga and As bromide. However, the blue color of the PMeT film proves that it has stayed in its conducting form. The open-circuit voltage measured in this redox couple is surprisingly high: 1.20V , approaching the bandgap of GaAs (1.42eV). It can be compared to the value reported by Noufi *et al.* on polypyrrole-coated GaAs (8): 1.37V in $\text{Fe}(\text{CN})_6^{4-/\text{Fe}(\text{CN})_6^{3-}}$, NaOH aqueous solution. It must be noted that the values reported in Fig. 5 cannot be related to corrosion, since they have been measured at open circuit, with no net current flowing through the electrode.

Conclusion

Electrodeposition of PMeT and PMe_2T films on GaAs seems to be more difficult than on polypyrrole. Pre-deposition of platinum was necessary in order to obtain homogeneous films. However, very adhesive films were grown. They resist to the adhesive-tape peel test, and still adhered to the electrode even when corrosion evolved. The protection against photocorrosion is only partial, because of the porosity of the film and its reduction to its neutral form. Long-term stabilization could be reached if a compromise is found between the nonreduction of the polymer film, which requires a higher oxidizing redox couple, and the enhanced corrosion of GaAs with such a couple.

ABSTRACT

The effect of reactive ion etching on silicon surfaces with NF_3 diluted with argon and nitrogen was studied. Similar to the pure NF_3 case, the Schottky barrier height was increased for p-Si and decreased for n-Si. This barrier modification was most effective at ~10% NF_3 , while the silicon-etch rate was reduced by an order of magnitude, as compared to pure NF_3 . The degree of ion bombardment, as inferred from substrate dc bias, reached a maximum at ~20% NF_3 for argon-diluted cases, but increased monotonically from pure NF_3 to pure N_2 for nitrogen-diluted cases. Optical emission spectra indicated that atomic fluorine concentration decreases with increasing diluent content for both plasmas, with molecular nitrogen being the major product detected.

Reactive ion etching (RIE) is becoming a commonly used processing technique in patterning high-resolution structures in integrated circuits, because it combines the high selectivity of plasma etching with the anisotropy of sputter etching. Various thin film materials have been etched under a wide range of conditions (1). However, the surface properties of silicon after RIE have not been investigated in detail. In prior works, fluorocarbons were usually used, and several structural (TEM and RHEED) and electrical measurements (MOS retention time, DLTS) were performed on the etched surfaces (2-5). Also of relevance are two previous studies using low-energy ion beams to simulate the damages created during plasma etching, one using argon (6), and another using chlorine and fluorine as well as argon (7). All these studies indicated that plasma-induced damages result in changes in Schottky barriers and carrier lifetime, but high-temperature annealing can at least partially eliminate these changes. Our interests in studying the phenomenon of RIE-related damages are in its applications for controllably modifying Schottky barrier heights. An alternative technique towards this end is low-energy implantation of dopant atoms (8, 9).

In this paper, an examination of silicon surfaces after RIE with NF_3 -based plasmas by Schottky-diode characteristics and secondary ion mass spectrometry (SIMS) is reported. The discharge characteristics were monitored *in situ* with optical emission spectroscopy and substrate dc voltage measurements; they too are reported herein.

Experimental Procedure

The RIE was performed in a commercial, parallel-plate-type reactor (Plasmatherm PK 1241). p-Type, (111)-oriented and n-type, (100)-oriented, silicon

Key words: discharge, diodes, surfaces, spectra.

wafers with a resistivity of 1-4 Ω -cm were cleaned in the usual manner prior to loading into the reactor. They were then etched with 50-200W of RF power. The dc bias developed on the RF electrode was monitored, but the plasma potential was not directly measured. The conditions used for the RIE were: gas flow rate of 5-10 sccm, pressure of 60-90 mtorr, substrate temperature of 40°C, etching time of 10 min, and electrode spacing of ~5 cm. An automated optical spectrometer scanning between 200 and 800 nm was used to analyze the plasma emission spectrum. After RIE and a standard cleaning cycle with $\text{H}_2\text{O}_2/\text{H}_2\text{SO}_4$, hot nitric acid, and HF dip, gold dots (1 mm diam and 2000Å thick) were e-beam evaporated using shadow masks. Back ohmic contacts were formed by evaporating ~1 μm of Al. (The back side of the n-type wafers were implanted with phosphorus at $1 \times 10^{15}/\text{cm}^2$ and then activated before RIE and Al deposition.) On some samples, Al was used to check the effect of the Schottky metal. SIMS was performed with a Cameca IMS 3-f ion microscope with a cesium primary beam of impact energy of 17 keV and negative ion sampling.

Results

Previously, we have reported that RIE with pure NF_3 leads to a gradual increase in Schottky barrier in p-Si and a decrease in n-Si with increasing applied RF power up to 200W (10). After RIE, the silicon surface was examined with SIMS to determine the composition of the surface layers. A marked increase in fluorine (M/e of 19) was found; its integrated intensity is shown in Fig. 1 as a function of applied RF power. It was also determined that fluorine was present only up to ~500Å. Other species, such as SiN^- and AlO^- , were also found to be significantly higher on the etched surfaces, but no systematic dependences on RF power were seen. The origins of the nitrogen and aluminum species are attributed to NF_3 , and reactor electrodes

and chamber walls, respectively.

For 100% NF_3 plasmas, the optical emission intensities of atomic fluorine and molecular nitrogen, as well as the substrate dc bias, increases with increasing RF power (Fig. 2). This increase is due to the enhanced dissociation of the NF_3 molecules. However, the substrate bias decreases rapidly at higher pressures, while the optical emission intensities of both

F and N_2 increase slightly, as shown in Fig. 3.

One of the major limitations of using pure NF_3 plasma for Schottky barrier tailoring is its extremely fast silicon etch rate (11, 12). It has been previously demonstrated that inert gases can be used as diluents in reducing poly-Si and $MoSi_2$ etch rates (12). Under the present conditions used for RIE, pure NF_3 plasmas etched crystalline silicon quickly (~ 5000 Å/min), but diluting to only 10-20% with argon or nitrogen reduced the etch rate by about an order of magnitude. Figure 4 illustrates this trend for the case of 200W and 60 mtorr at 40°C. Also shown is the etch rate of a positive photoresist (AZ1470) which hardly changes with dilution.

In general, the Schottky barriers were modified in these diluted plasmas in a way similar to those obtained with NF_3 alone. The I-V characteristic of an unetched Au/n-Si device is shown in Fig. 5, together

tics of Au/n-Si samples etched in nitrogen-diluted NF_3 plasmas. A similar decreasing trend in barrier height can also be observed. Figure 7 and 8 show the I-V behavior of gold/p-silicon diodes exposed to NF_3/Ar and NF_3/N_2 plasmas, respectively. An increase in barrier height was seen with decreasing NF_3 percentage when compared to the unetched sample.

By measuring log current *vs.* voltage under forward and reverse biasing conditions, the Schottky barrier height and ideality factor can also be deduced. These two parameters are shown in Fig. 9 as a function of gas composition of both Ar- and N_2 -diluted plasmas for the Au/n-Si devices. A larger barrier-height change is accompanied by a greater deviation from unity of the ideality factor. For the p-Si devices, large values of n (1.3-1.5) were obtained. Similar characteristics were observed for devices with aluminum for the Schottky metal.

Substrate dc bias can be used to infer the degree of ion bombardment during RIE. Generally, it is higher during silicon etching than in an unloaded chamber. Also, different variations in this voltage were observed, dependent on whether argon or nitrogen was used for dilution. When the plasma becomes less NF_3 rich with argon addition, the voltage increases up to $\sim 20\%$ of NF_3 . Further dilution leads to a gradual drop until pure argon is reached (Fig. 10a). A monotonic increase has been observed with increasing nitrogen content, and the maximum occurs at pure N_2 (Fig. 10b). Despite the different trends described, the dc biases for these two types of plasmas at the composition of most interests (10-20% NF_3) only differs slightly.

When the gas composition varies, there are substantial changes in concentrations of constituent atoms and molecules. These changes were monitored with optical emission spectroscopy for reactor under empty and silicon-loaded conditions. In these plasmas, the major spectral lines have been attributed to atomic fluorine (703.7 nm), argon (706.7 nm), and molecular nitrogen (297.7 nm). While the most intense N_2 line is at 337.1 nm, we have chosen to monitor the 297.7-nm line because its intensity range is closer to those of argon and fluorine. Spectral lines that may be traceable to atomic nitrogen, F_2 or NF_x ($x = 1, 2, 3$) were not identified.

In general, atomic fluorine concentration (as inferred from line intensity) decreases with increasing

dilution. Since atomic fluorine is believed to be the species responsible for silicon etching in fluorine-based plasmas (13), the decrease in silicon with decreasing NF_3 percentage can be explained by the decrease in reactant concentration. The presence of a silicon wafer on the cathode ($\sim 10\%$ area coverage) drastically reduces the 703.7-nm line intensity (by $\sim 70\%$). As shown in Fig. 11, for either an empty or silicon-loaded reactor, the decrease in fluorine emission varies linearly with decreasing NF_3 percentage, except at the extremes of the composition range. Furthermore, there is little difference between the Ar- and N_2 -diluted cases (Fig. 11a *vs.* b), indicating that nitrogen does not significantly suppress fluorine generation. However, such a correlation was not observed for NF_3 diluted with He in a dc hollow-cathode reactor (14). The reason is probably because of the difference in diluent nature (helium *vs.* argon and nitrogen) and in reactor configuration. While the variation of the other constituents (mostly argon and/or nitrogen) is monotonic for argon-diluted NF_3 , it is not for the N_2 -diluted ones (Fig. 12 and 13). As expected, the molecular nitrogen intensity increases with increasing nitrogen content, but at $\sim 10\%$ NF_3 it reaches a local minimum, probably due to other competing reactions involving fluorine and nitrogen atoms. Furthermore, it can be noted that in the NF_3/Ar case, the steep decrease in argon line intensity also occurs at low NF_3 percentage. In contrast to fluorine, loading the reactor with silicon only changes the levels of argon and nitrogen slightly, confirming their inert chemical nature in the etching reactions.

When only inert gases (argon and nitrogen) were used for RIE, the Schottky barrier change is very much dependent on reactor background-gas levels and chamber conditioning. Hence, they cannot be used reliably for the Schottky barrier modification. The exact nature of the damage has not been studied here, but it has been proposed (7) that it is a complex formed by a defect with a halogen atom.

Summary

Reactive ion etching of silicon surfaces with NF_3 diluted with nitrogen and argon have been shown to result in Schottky barrier shifts similar to those obtained with pure NF_3 . However, while NF_3 plasma

etched silicon at a relatively high rate, the diluted plasmas only etched silicon at much reduced rates (about 10% of that in NF_3). The degree of ion bombardment upon argon and nitrogen addition follows different trends, reaching a maximum at 80% Ar dilution. Optical emission spectra showed that fluorine concentration increases with increasing NF_3 percentage. Molecular nitrogen is the major reaction product detected.

(100) Silicon Etch-Rate Dependence on Boron Concentration in Ethylenediamine-Pyrocatechol-Water Solutions

N. F. Raley,* Y. Sugiyama,¹ and T. Van Duzer

Department of Electrical Engineering and Computer Sciences and the Electronics Research Laboratory, University of California, Berkeley, California 94720

ABSTRACT

The (100) silicon etch-rate dependence on boron concentration in ethylenediamine-pyrocatechol-water (EPW) solutions at 110°C has been measured by successive etching of boron-diffused silicon. The etch rate begins to decrease near 10^{19}cm^{-3} and decreases approximately as the fourth power of doping over three orders of magnitude in etch rate. The etch-rate ratio between heavily and lightly doped silicon appears insensitive to pyrazine concentration from 0.01 to 6.0g/liter E, oxygen exposure of the etch solution, and light. The etch-rate decrease is sensitive to hole concentration and not to atomic concentration of boron or stress. The etch-rate dependence may be explained by assuming that the hydrogen-evolution cathodic half-reaction of the oxidation-reduction reaction is the rate-determining step. The reason for the etch-rate decrease as the hole concentration increases is given in terms of increased Auger recombination of large numbers of electrons chemically produced at the silicon surface during etching. Excellent agreement with experiment is obtained. Similarities of this etch system and the phenomenon of silicon staining are discussed in terms of oxidation-reduction reactions. Application to control of thickness and uniformity of boron-doped silicon membranes is discussed.

Boron-doped silicon membranes have been fabricated using ethylenediamine-pyrocatechol-water (EPW) etching solutions for a variety of purposes: as thin substrates to reduce backscattering in electron (1) or ion beam lithography (2), to reduce scattering of transmitted radiation in x-ray lithography (3), as thin highly doped barriers for Josephson junctions or super-Schottky diodes (4), as ink-jet nozzles (5), and for the fabrication of micromechanical beams used in accelerometers (6, 7). In almost all cases, boron diffusions are used to stop the EPW-etchant attack on silicon. Thus far, there has been very little work reported on the etch-rate dependence on boron or on the basic etchant system itself. Finne and Klein (8) first reported the etchant but did not find any etch-rate dependence up to $8 \times 10^{17}\text{cm}^{-3}$ boron. It was reported later that the etchant stopped at $7 \times 10^{19}\text{cm}^{-3}$ (9), but there was no detailed measurement of the transition region. Reisman *et al.* (10) discovered the effect of pyrazine and oxygen-induced benzoquinone catalysts on the etch rate for lightly doped silicon in EPW solutions. This is important, since the pyrazine and quinone concentration in commercially available ethylenediamine and pyrocatechol, respectively, varies from lot to lot. They briefly report the etch-rate dependence on boron in bulk silicon wafers at two levels of heavy doping for high pyrazine/low benzoquinone etch solutions and find the etch rate to be small but finite in the 10^{20}cm^{-3} range. Seidel and Csepregi (11) reported a stronger etch-rate dependence on doping in epitaxial layers than that reported by Reisman *et al.* They used a similar etch solution, except with somewhat lower pyrazine concentration and unknown benzoquinone content. Initial experiments in our laboratory had indicated an etch rate approximately an order of magnitude smaller than that obtained by Reisman *et al.*, although still non-zero. There has been no indication in the literature of the effect of pyrazine or benzoquinone on the heavy doping etch rate or etch-rate measurements on diffused layers. Also, there has been no report on the mechanism of the decrease of etch rate for EPW solutions. As a consequence of the scarcity of data, membrane formation has been a trial and error process.

The purpose of the present investigation is to study the etch-rate dependence on boron concentration in

diffused layers, as this is the most common method of dopant introduction in the fabrication of silicon membranes. The effect of catalyst concentration and the dependence of the etch rate on light are also analyzed. Possible mechanisms for the etch-rate decrease with doping are considered, and oxidation-reduction reactions are proposed to explain the observations. Design curves are calculated using the etch-rate dependence and the diffusion profile employed in this study as an aid in the determination of etching time needed in order to obtain desired membrane thickness and/or uniformity. The principles used here can be applied to any known concentration profile.

Experimental

The starting wafers used in this study were 51-76 mm diam, nominal (100) orientation ($\sim \pm 1^\circ$), 1-10 $\Omega\text{-cm}$, 300 μm thick, and polished on one side. The wafers were of p-type conductivity in most cases. However, no difference was observed in etching with n-type wafers.

Sample preparation.—Two different methods of etch-rate measurement were used, as shown in Fig. 1. In the method shown in Fig. 1a, etching was done from the most heavily doped side of the wafer in such a way as to make a measurable step. In the method shown in Fig. 1b, etching was done from the more lightly doped side of a thick membrane (4), and the remaining membrane thickness was measured by observing the minimum energy for transmission of an electron beam.

We will describe first the fabrication procedure for the etch-step method shown in Fig. 1a. The wafers were first degreased in trichloroethylene, acetone, and methyl alcohol and then rinsed in deionized water and dried in nitrogen gas. Following a 5s dip in buffered HF ($\text{NH}_4\text{F}:\text{HF} = 5:1$), the wafers were cleaned for 10 min in $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2 = 4:1$ solution. Final cleaning was done in RCA-1 solution ($\text{NH}_4\text{OH}:\text{H}_2\text{O}_2:\text{H}_2\text{O} = 1:1:5$) for 15 min at 75°C. Oxide on the wafers was then removed in buffered HF. The wafer was rinsed, dried, and immediately loaded lying horizontally on a quartz boat in the boron predeposition furnace. The gas flows were 210 cm^3/min of 1000 ppm $\text{B}_2\text{H}_6/\text{Ar}$, 13 cm^3/min O_2 , in a carrier gas of 1.3 liter/min N_2 and were set 30 min prior to wafer loading. The temperature was measured using a Chromel-Alumel thermocouple connected to an Omega 199 thermocouple meter with an accuracy of $\pm 2^\circ\text{C}$. The diffusion was performed at 950°C for 45 min.

Key words: anisotropic silicon etching, silicon membranes, boron concentration profiles.

Fig. 1. Sample geometries used to study successively etched silicon: (a) direct etch-step method; (b) electron-transmission method. The thickness of the oxide layers is in the range 2000-5000Å in both cases. In method (b), the thickness and area of the thick membrane are 1.5 μm and 100 μm × 100 μm; the thickness and area of the thin membrane are ~0.3 μm and 10 μm × 10 μm.

The ~1000Å thick boron glass formed on the wafer was removed by dilute HF (HF:H₂O = 1:20) for 1 min in the dark. The etching was done in the dark to prevent stain formation on the heavily doped p-type silicon surface, which occurs especially in dilute HF solutions in bright light (12). No stains were observed, especially after a subsequent RCA-1 clean designed to remove them. In order to remove the SiB phase layer (~50Å) under the glass, a wet oxidation at 800°C for 15 min was performed, which grew ~200Å oxide. The phase layer was removed because it has properties different from boron-doped silicon and knowledge of its etching properties were not desired in this study.

After BHF etching of the phase layer oxide, sputtered SiO₂ or evaporated SiO was deposited as an etchant mask. In the first experiments, SiO₂ sputtering was performed at a base pressure of ~10⁻⁶ torr in 8 mtorr Ar:O₂ = 4:1 gas at ~1.4 W/cm² power density for 3h, giving about 6000Å. However, this process was found to cause sputter damage, as evidenced by sheet resistance increases of 10-20% after sputtering, indicating that the electrically active concentration profile had been altered (refer to Results section). In order to avoid damage, 1500Å SiO layers deposited at 15Å/s in 10⁻⁶ torr vacuum were used instead, with no measurable sheet-resistance change. The wafers were then scribed into 5/8 in. × 1/2 in. rectangles. Wax was applied along one edge (~1/8 in. wide) and baked until hard; the mask layer was subsequently etched in BHF in the dark. After wax removal and cleaning, the wafers were ready for silicon etching.

The fabrication scheme for the electron-beam-transmission method shown in Fig. 1b was somewhat more involved (4). First, a silicon wafer was anisotropically etched to about 1-5 μm thickness over ~100 × 100 μm area. Thermal oxide (~2000Å) was grown on both sides of the wafer and stripped off the etched side. The p⁺ diffusion/wet oxidation as described above was performed. The bottom window (~10 × 10 μm) in thermal oxide was opened using conventional electron-beam lithography techniques. Then, SiO₂ or SiO was deposited as before on top as an etchant mask but was not patterned. This scheme allowed etch rate measurement of the diffusion profile at lower concentration (~5 × 10¹⁹ cm⁻³) without the need for prolonged etching of the highly doped (~1.5 × 10²⁰ cm⁻³) surface region.

Silicon etching.—The silicon etching apparatus is shown in Fig. 2. Nitrogen is bubbled into the solution through a quartz diffuser at 160 cm³/min in order to minimize the oxidation of the solution and to provide stirring. Cool water is circulated in the upper jacket in order to condense evaporated solution vapor onto the walls. It is then fed back into the solution through a teflon valve. The solution level does not change over many hours of etching. The temperature is monitored by a thermometer placed in the etch bath and is maintained at 110° ± 1°C. The wafers are held in place by the removable quartz holder.

The chemical proportions of the etchant used were 17 ml E: 3g P: 8 ml W. The ethylenediamine was made by J. T. Baker and the pyrocatechol was made by MCB Company. The pyrazine concentration in a particular batch of ethylenediamine was measured by ultraviolet absorption at 3150Å wavelength with a Carey 219 spectrophotometer using a volumetric technique. It was initially desired to keep the pyrazine concentration low in the etch rate experiments in order to minimize its effect. It was discovered later, however, that high pyrazine levels did not seem to significantly effect the etch-rate ratio between heavy and light doping.

The silicon etchings were performed about 1h after the solution was mixed in order to allow stabilization of the solution temperature and gas-flow rate. The color of the etch solution at this time was pale amber; the color darkened slightly after many hours of etching but never assumed the deep-red coloration which is characteristic of EPW-etch solutions substantially exposed to air. Both heavily and lightly doped wafers were etched at the same time in order to best characterize the etch-rate ratio. After loading of the wafers in the quartz holder, a 5s BHF dip followed by 30s running DI rinse was done to remove the native oxide and rinse off HF. The wafers were immediately inserted into the silicon etch without drying in order to prevent reformation of the native oxide. At this point, the silicon surface was always hydrophobic. After silicon etching, the wafers were first rinsed in running DI water for 15s to remove most of the silicon etchant. This was followed by a 5s BHF and a 30s final DI water rinse. The silicon surface was again hydrophobic. After residual organic removal steps and a subsequent BHF dip, the silicon steps were measured and the etch process repeated. All etchings were performed under yellow lighting except where otherwise noted.

Measurement accuracies.—The etch-step method shown in Fig. 1a was used for most of the measurements of heavy doping etch rate. The etched-silicon step was measured indirectly as the difference of the total step (oxide and silicon) and the oxide thickness.

Fig. 2. Schematic diagram of the silicon etching apparatus with reflux column. The wafers are loaded through the top of the beaker. The condensate is fed back into the etch solution.

The total step was measured using a Tencor α -step depth profiler. Oxide thickness was measured using a Gaertner L119 ellipsometer. The total step and oxide thickness were in the 2000-5000Å range. The difference between the measurements of the depth profiler and the ellipsometer on a 4700Å thermal-oxide calibration standard was $\sim 100\text{Å}$; the measurement uncertainties were ± 50 and $\pm 5\text{Å}$, respectively. We estimate a worst case error in etch depth of $\sim 150\text{Å}$. However, the oxide mask was removed from time to time on some samples and the silicon steps (about 400-1000Å) were measured directly, using only the depth profiler, as a check against the indirect method. In most cases, the indirect steps measured were in agreement with the more accurate direct measurements. For the direct method, the difference between the α -step and ellipsometer on a 770Å oxide standard was very small (30Å); the depth profiler measurement uncertainty was also reduced to $\pm 20\text{Å}$. Thus, the worst case accuracy in etch steps in these experiments is 50Å out of 400Å minimum etch steps (less than 15%).

In the second method, the silicon thickness after etching was determined by finding the maximum electron-beam voltage at which the transmitted beam current was zero. Thickness was then calculated using appropriate electron-range formulas, taking into account the thickness of the oxide mask (13). The details of this thickness-measurement technique will be published elsewhere. It is sufficient to say that the uncertainty using this technique is, at worst, $\pm 100\text{Å}$ out of typical 1000Å silicon thickness etched (about $\pm 10\%$).

The light-doping etch rate was measured using the first method on bulk silicon, without the diffused layer, with 5000Å thermal or sputtered SiO_2 as the mask. Typical etch steps measured were 3-30 μm with about $\pm 10\%$ error. Approximately $\pm 5\%$ of this error is attributable to variation of the etch rate over the etching time due to solution oxygenation (refer to Results section).

Concentration profile.—The atomic concentration of boron in both damage-free and sputter-damaged profiles was determined by secondary ion mass spectrometry (SIMS) using a CAMECA Model IMS-3f with a negative oxygen ion as the sputtering ion to enhance yield. The ion beam was scanned over a 400 μm area on a control chip from the same diffused wafer used in the silicon etching experiments at a beam energy of ~ 5 kV, ~ 1 μA current at $\sim 10^{-8}$ torr chamber pressure. The sputter etch rate was ~ 500 Å/min. As boron naturally occurs as B10 and B11 isotopes, both singly charged B10 and B11 ions were monitored, and their contributions added to obtain the total boron concentration. The accuracy in boron concentration is generally quoted as being in the ± 10 -20% range or less, depending on the accuracy of the measurement of a B11 ion implanted calibration standard and the physical and chemical similarity between sample and standard. As discussed in the Results section, the accuracy for our profiles is $\sim \pm 5\%$, which is probably due to our relatively simple analytical situation. The depth scale accuracy is determined by the accuracy in measurement of the final sputtered crater depth ($\sim \pm 5\%$) and the linearity of etch depth with time ($\sim \pm 5\%$). The total depth scale error, then, is $\sim \pm 10\%$.

Spreading resistance measurements were also performed using Solid State Measurements Model ASR-100 as a check of the electrical profile. The bevel angle used was $\sim 0.25^\circ$ and the probe step increment ~ 3.0 μm , giving a profile depth increment of 150Å. The probe spacing used was 20 μm with a probe weight of 5.0g.

Profile sheet resistance measurements were made using a standard four-point probe technique with 0.67 mm probe spacing in order to compare to calculated sheet resistance. A Keithley Model 225 current source

provided 1 mA current and separate Keithley Model 169 multimeters monitored the probe current and voltage. The worst case accuracy in measured sheet resistance was $\sim \pm 5\%$. The measured sheet resistance variation over a 25×25 mm area for a given diffusion run was $\pm 0.5\%$. It was $\pm 4.0\%$ from run to run.

The profile in the surface region of sputter-damaged samples was investigated using the incremental sheet resistance (ISR) technique (14) using the method illustrated in Fig. 1a to successively etch silicon. Even though finiteness of the sample size ($\frac{1}{2}$ in. \times $\frac{1}{2}$ in.) was taken into account, it was relatively unimportant as the sample-size correction factor was approximately 0.96. As a direct consequence, the electrical shunting effect of the nearby unetched heavily doped region under the oxide mask was unmeasurable for the maximum etched depth encountered in these experiments ($\sim 1000\text{Å}$), as was confirmed by measured values of sheet resistance for samples with and without this region present.

Oxygen, pyrazine, and light effects.—The surface of a boron-diffused wafer ($\sim 1.2 \times 10^{20}$ cm^{-3}) and a bulk wafer ($\sim 1.6 \times 10^{19}$ cm^{-3}) were etched at various levels of solution oxygenation using the method shown in Fig. 1a with an SiO_2 mask. Some etching experiments were performed in an open beaker in order to further expose the etch solution to oxygen. These experiments were done at low pyrazine concentration (~ 0.01 g/liter E) in order to isolate the effect of oxygen. The etch rate at the surface of the boron-diffused wafer was also measured at high pyrazine levels (~ 6 g/liter E) and in various light intensities ranging from etching in the dark to etching under illumination of a 650W lamp held 6 in. from the etch solution.

Results

Etch solution characterization.—The absorbance at 3150Å wavelength of typical ethylenediamine used to determine the etch-rate dependence on boron concentration is plotted in Fig. 3 as a function of pyrazine concentration added. The absorbance is given by

$$\text{abs} = \log_{10} (I_i/I_t) \quad [1]$$

where I_i is the transmitted intensity through an empty reference quartz cell and I_t is the transmitted intensity through an identical quartz cell filled with ethylenediamine. According to Beer's law (15), $I_i/I_t = 10^{\alpha c l}$ where α is the absorption coefficient per unit concen-

Fig. 3. Absorbance of typical ethylenediamine as a function of added pyrazine at 3150Å wavelength. Cell path length is 1 cm. The data are described by this equation: absorbance = 9.79 (pyrazine added) + 0.16. Original pyrazine concentration determined here is 0.016 g/liter E.

tration of absorbent in a nonabsorbing medium, c is the concentration of absorbent, and l is the cell path length. In this case

$$\text{abs} = alc \quad [2]$$

and

$$d(\text{abs})/dc = al \quad [3]$$

assuming that the absorption coefficient α is a constant and independent of concentration c . In our case, pyrazine is the absorbent and ethylenediamine is the non-absorbing medium. Referring to Fig. 3, if we assume that the absorbance is zero for pyrazine-free ethylenediamine, then the original pyrazine concentration is approximately 0.016 g/liter E. The slope $d(\text{abs})/dc$ for our 1 cm cell was determined to be $9.79 \text{ (g/liter)}^{-1}$. The slope obtained by Reisman *et al.* (10) for a 0.1 mm path length, when corrected to 1 cm path length using Eq. [3], gives $10.3 \text{ (g/liter)}^{-1}$, in good agreement with our result.

The typical etch rate for lightly doped silicon as a function of time after solution mixing is shown in Fig. 4. Note that the initial etch rate is $27.5 \mu\text{m/h}$. Assuming that the activation energy of 8.4 kcal/mol (10) is independent of pyrazine concentration c_p to values as low as 0.01 g/liter E, then

$$\log ER_{110\text{-C}} = 1.694 + 0.134 \log c_p \quad [4]$$

which gives $c_p = 0.013 \text{ g/liter E}$, in good agreement with the measured result of 0.016 g/liter E, using ultraviolet absorption. Note that the etch rate in Fig. 4 increases gradually as a function of time. An "oxygen-enhancement factor" F_{O_2} is defined as

$$F_{O_2} = ER_0(t)/ER_0(0) \quad [5]$$

for low pyrazine solutions used here. It is a measure of solution oxygenation. The enhancement factor ranged from 1.07 to 1.72. In other experiments performed in open beakers, values as large as 2.92 were obtained. We believe this is because of exposure of the solution to oxygen due to backstreaming from the etch beaker top or to oxygen impurity in the nitrogen bubbling gas. We also believe this exposure is responsible for the slight change in etch-solution coloration after many hours of etching. Reisman *et al.* (10) have seen a similar effect when oxygen is bubbled into an etch solution initially free of oxygen. However, they observed more drastic change in solution color from pale amber to deep red. As mentioned before, the color change in our samples was not drastic. This is most likely due to the difference in levels of oxygen exposure.

Fig. 4. Typical light doping (1-10 $\Omega\text{-cm}$) etch rate (ER_0) as a function of time after mixing. The solution proportions are 17 ml E: 3g P: 8 ml W and 0.016 g/liter E pyrazine. The etch temperature is 110°C . The oxygen enhancement factor F_{O_2} is the ratio of etch rate at time (t) to initial etch rate.

In general, we have not observed haze due to low pyrazine concentration on the lightly doped or heavily doped silicon surfaces, as was seen by Reisman *et al.* Haze was observed on only one occasion with a 10^{19} cm^{-3} doped wafer.

Concentration profiles.—The SIMS and spreading resistance results for the profile used for the etch-rate dependence are shown in Fig. 5a. The SIMS profile is only accurate past the first 150Å; the corresponding time is required for the sputter-etch rate to stabilize because of the layer of native oxide (16). The depth at which the etch rate became stable was verified to be $\sim 150\text{Å}$ by observing the point at which the B⁺10 and B⁺11 ion current ratios with respect to total ion current were within a few percent of their steady-state values. The fact that the proportions of B10 and B11 were 23% and 77%, respectively, which is close to the proportions in naturally occurring boron (20% and 80%) (17), is a good indication that the calibration factors for B10 and B11 ions are the same and that there is negligible interference from Si^{2+} 30 ion in the B10 signal.

Fig. 5. Hole concentration as a function of depth. (a, top) un-damaged samples. — SIMS. --- spreading resistance. The concentration reduction from the surface to $\sim 350\text{Å}$ is due to the boron segregation effect. (b, bottom) sputter-damaged samples: ● incremental sheet resistance. --- spreading resistance. — resultant profile. Concentrations (○) derived from etch-rate data in the damaged region using Eq. [10] show good agreement with profile.

There is a concentration reduction from the surface to approximately 350Å depth due to segregation of boron into the oxide during the 800°C wet oxidation step. The extrapolated concentration value at the surface, neglecting the segregation effect, is $\sim 1.5 \times 10^{20} \text{ cm}^{-3}$, which is very close to the expected solid solubility of boron in silicon at the diffusion temperature (18). Furthermore, since the boron concentration in our profile is always less than the expected solid solubility, the existence of electrically inactive boron caused by boron precipitation is unlikely.

The sheet resistance ρ_s of an arbitrary doping profile $N_B(x)$ is

$$\rho_s = \frac{1}{\int_0^\infty [1/\rho(x)] dx} \quad [6]$$

where the resistivity $\rho(x) = 1/qp(x)\mu(x)$, q is the electronic charge, and the hole concentration $p(x)$ and mobility $\mu(x)$ are some functions of $N_B(x)$. The sheet resistance calculated for the SIMS profile using precise values for resistivity as a function of unprecipitated boron concentration (19) is very close to the measured value, as seen in Table I. This value is not very sensitive to the first 150Å, assuming that the concentration is $\sim 10^{20} \text{ cm}^{-3}$, so the fact that the profile is not well known there does not appreciably affect the result. Note also that since the measurement uncertainty in sheet resistance is $\pm 5\%$ and that the integrated doping profile gives the measured sheet resistance result, the doping uncertainty in this case is closer to $\pm 5\%$ than $\pm 10\text{-}20\%$.

The solid-solubility concentration and integrated-sheet resistance results allow us to conclude that the doping profile is correct and boron precipitation unlikely. In addition, since differences between boron concentration and hole concentration due to deionization effects are not observed at high concentrations (19), we have plotted the SIMS result as hole concentration in Fig. 5a.

Comparison of the spreading resistance profile to the SIMS profile indicates that the profile shapes are in qualitative agreement. However, the calculated sheet resistance for the spreading resistance profile does not give quantitative agreement with the measured sheet resistance value, as seen in Table I. For this reason and the fact that the interpretation of raw data is more straightforward in SIMS analysis, the concentration values used here are those determined from the SIMS profile.

The profiles for those samples that were sputter damaged are shown in Fig. 5b. The SIMS profile was the same as that for undamaged samples, indicating that boron was not displaced and that the SIMS sputter etch rate was unaffected by the damage. The electrically active concentration for depths less than 625Å was determined by the incremental sheet resistance technique assuming a bulk mobility value of 53 cm^2/sec (19). The concentration in this depth range is less than the boron concentration determined by SIMS. This is consistent with the idea that the sputter damage creates donor traps at energy levels within the silicon-forbidden gap, which compensate the boron

acceptors (20, 21). We believe that there is no damage past 625Å, however, so that the profile there is identical to the SIMS profile. This supposition is supported by the fact that a maximum in electrical concentration as obtained from spreading resistance data and a minimum in silicon etch rate were found to occur at approximately 600Å depth. The calculated sheet resistance for the resultant profile is very close to the measured value, as seen in Table I. It should be noted that the donor traps cause $\sim 50\%$ max increase in ionized scattering centers relative to the ionized boron impurity; however, this increase should have negligible effect on the hole mobility used to determine the hole concentration in the damaged region, since the hole mobility is relatively independent of the scattering center concentration for concentrations in the $\sim 10^{20} \text{ cm}^{-3}$ range (19). The interest in the damaged samples derives from the fact that the effects of boron and hole concentration on the etch rate can thereby be isolated, as we see below.

Etch-rate dependence on hole concentration.—The successive etching aspect of the experiment made it possible to express the etch-rate data as etch-time integrals between position x and a common fixed reference point $x_r > x$ in the concentration profile as

$$t_{\text{etch}} = \int_x^{x_r} dx/ER_p(x) \quad [7]$$

where $ER_p(x)$ is the concentration-dependent etch rate, and t_{etch} is the time required to etch from x to x_r . If we multiply Eq. [7] by the light-doping etch rate ER_0 and define the etch-rate ratio $ERR(x) = ER_p(x)/ER_0$, then

$$G(x) = ER_0 t_{\text{etch}} = \int_x^{x_r} dx/ERR(x) \quad [8]$$

or

$$ERR(x) = -\frac{1}{dG(x)/dx} \quad [9]$$

We use the etch-rate ratio so as to be able to compare etch-rate results obtained under different levels of etch solution oxygenation with different light doping etch rates.

A good fit to the data is $\ln G(x) = -ax + b$, where $a = 26.01$ and $b = 5.365$ with $G(x)$ in microns, and x is the distance from the surface in microns. In this case, $ERR(x) = 1/aG(x)$. The etch-rate ratio so determined as a function of position was then transformed to a function of hole concentration using the SIMS profile in Fig. 5a. The data were then fit to a straight line on a log-log scale using the least squares method as

$$ERR(p) = 2.8 \times 10^{-3} p^{-4.3} \quad [10]$$

which is valid for concentrations in the range from $\sim 3.0 \times 10^{19} \text{ cm}^{-3}$ to $1.28 \times 10^{20} \text{ cm}^{-3}$.

This result is plotted in Fig. 6 along with assorted etch-rate ratios measured on bulk wafers. Note that the etch-rate ratio begins to decrease at approximately 10^{19} cm^{-3} . The etch-rate ratio found by Reisman *et al.* (10) for bulk wafers using 6 g/liter E pyrazine-etch solutions is shown in Fig. 6 for comparison. Approximately $\pm 10\%$ etch-rate variation for concentrations less than 10^{19} cm^{-3} is observed and is most likely due to differences in misorientation of the different wafers from true (100) orientation, as observed by Finne and Klein for wafers of nominal (111) orientation (8). Finally, one can see using Eq. [10] that the etch-rate ratio for the practical maximum boron concentration in silicon is $\sim 1.4 \times 10^{-4}$ for $2.0 \times 10^{20} \text{ cm}^{-3}$ boron doping. This corresponds to less than 1 Å/min for a typical light doping etch rate of 25 $\mu\text{m}/\text{h}$.

Important secondary results can be derived from consideration of the etch-rate data obtained for sputter-damaged samples. In the damaged region, the etch-

Table I. Comparison of measured sheet-resistance values to calculated sheet-resistance values based on profiles obtained using various methods (SIMS, ISR, spreading resistance). Results for undamaged and sputter-damaged samples are shown.

Sample	Profile sheet resistance ρ_s (Ω/\square)		
	Measured	Calculated	
		SIMS/ISR	Spreading resistance
Undamaged	41.5	41.6	54.0
Sputter-damaged	45.3	45.2	61.0

rate ratio was significantly larger and hole concentration smaller than the ratio and concentration observed before damage, respectively; however, the boron concentration remained unchanged. This result indicates that the etch-rate ratio depends directly on the concentration of holes and not on the concentration of boron. Furthermore, for a given etch-rate ratio at a given depth, the effective hole concentration was calculated using Eq. [10] and plotted in Fig. 5b in the damaged region from the surface to 600Å depth. There is good agreement between the calculated points and the hole concentration profile obtained using the incremental sheet resistance method. This result indicates that the only effect of the sputter damage on the etch-rate ratio is to reduce the hole concentration through boron compensation so that Eq. [10] is still valid. This conclusion is in agreement with the observation that the heavy doping etch rate increases significantly as a result of sputter damage, whereas the light doping etch rate does not change appreciably compared to etch rates of undamaged samples.

Oxygen enhancement effects.—The effect of the oxygen enhancement factor (F_{O_2}) on the etch-rate ratio is shown in Fig. 7. We will consider data at a negligibly low (~ 0.01 g/liter E) level of pyrazine, so that the effects of pyrazine as an additional variable are eliminated. For high boron concentrations ($\sim 1.2 \times 10^{20}$ cm $^{-3}$), it appears that the etch-rate ratio is nearly independent of F_{O_2} for values of 1.20-2.32. This covers most of the range of factors (1.07-1.74) encountered in the experiments used to determine the etch-ratio dependence on hole concentration. Similarly, for lower boron concentrations ($\sim 1.6 \times 10^{19}$ cm $^{-3}$), the etch-rate ratio is seen to be independent over the 1.10-2.77 measured range. Due to the small oxygenation effect ($\sim 20\%$) on the etch-rate ratio compared to the doping effect, correction of the data presented in Fig. 6 to the oxygen-free condition was deemed unnecessary.

Pyrazine effects.—The effect of high pyrazine level on the etch-rate ratio is shown in Fig. 7, at high boron

Fig. 7. Etch-rate ratio as a function of oxygen enhancement factor for various hole and pyrazine concentrations. \circ ~ 0.01 g/liter E. \bullet 6 g/liter E.

concentrations only. First, note that the etch-rate ratio is relatively independent of F_{O_2} from 1.04 to 2.92 at 6 g/liter E pyrazine concentration. The etch-rate ratio of 10^{-3} ($\pm 25\%$) is very close to that for ~ 0.01 g/liter E pyrazine. Consequently, at any value of F_{O_2} , the etch-rate ratio is relatively independent of pyrazine level.

One must be aware that when a fresh etch solution of large pyrazine content (~ 6 g/liter E) is oxygenated, the light doping etch rate actually decreases with increasing oxygen until a minimum is reached, and then increases monotonically. Therefore, for initial oxygenation times, $F_{O_2} < 1.0$, this makes it difficult to compare high pyrazine-etch rate results to etch-rate results obtained with low pyrazine-etch solutions at the same oxygen level where $F_{O_2} > 1.0$. Furthermore, it is possible to infer two different oxygen levels from the same F_{O_2} factor due to the nonmonotonic dependence of etch rate on oxygen level. To avoid these difficulties, we define the oxygen factor for high pyrazine-etch solutions to be the value that would have been obtained at the oxygenation time of interest if the pyrazine concentration were approximately zero (in our case, ~ 0.01 g/liter E). This assumes identical oxygenation conditions and that the presence of pyrazine does not affect the oxygenation of the solution (production of benzoquinone). In this way, over a wide range of pyrazine concentration, comparison of etch-rate results is facilitated and the oxygen factor truly reflects the extent of solution oxygenation.

Light effects.—The etch-rate ratio for the diffused surface was independent of incident light in the range studied for low pyrazine levels and $F_{O_2} > 1.4$. The value of light doping etch rate was also independent of light, as has been observed by Reisman *et al.* (10), since the etch rate followed a continuous oxygen-enhancement curve independent of light conditions. No difference was observed between white and yellow light. The approximate light intensity incident on the etching apparatus ranged from 0 to 0.44 W/cm 2 (650W Sunn gun with 3400 K filament temperature). No measurements of etch solution absorption were made in the visible region (4000-7000Å). However, we believe that not more than $\sim 50\%$ of the light incident on our etch apparatus is absorbed by the solution before reaching the wafers. Otherwise, one would not be able to see the wafers in the etch bath as easily as is now possible. This conclusion agrees with the absorption measurements made by Reisman *et al.* (10) where little absorption was found in the visible region. Therefore, the maximum light intensity incident on the wafers was ~ 0.22 W/cm 2 .

Discussion

Any proposed etch mechanism must explain the critical concentration at which the etch-rate ratio decreases, the -4.3 power-law dependence on hole concentration, and the insensitivity of the etch-rate ratio to oxygen, pyrazine, and light. One mechanism could be the formation, at high boron concentrations, of slowly etched SiB_4 precipitates, whose rate of formation is proportional to the fourth power of boron doping. However, as the boron doping in the experiments conducted here is less than the solid-solubility concentration, boron should not precipitate. In addition, we have shown that the boron doping is completely electrically active; that would not be the case for higher resistivity precipitates (22).

A second mechanism could be that the decrease in etch rate is caused by an increase in boron-induced stress. The etch-ratio dependence on hole concentration would be replaced by a similar dependence on tensile stress, since tensile stress is directly proportional to boron doping in the heavily doped region (23), and the boron is assumed to be electrically active. This mechanism would explain the critical concentration level, since the concentration at which measurable tensile stress is developed for boron in silicon ($\sim 10^{19} \text{ cm}^{-3}$) (23) is close to the concentration at which the etch-rate ratio decreases. However, the reason for the fourth power dependence is not obvious. To explain the etch-rate increase in damaged samples, it might be supposed that the argon-sputter damage relieves tensile stress in the damaged region. This is conceivable, since any implanted argon atoms would tend to expand the silicon lattice due to their larger atomic diameter and offset the contraction caused by the smaller diameter boron atoms. However, it is necessary to explain the fact that the etch-rate ratio in the damaged region also depends on hole concentration in the same way as in undamaged regions. This requires that the net tensile stress in the damaged region has the same dependence on net hole concentration as boron-induced stress on boron doping (the net hole concentration is given by the difference between the boron concentration and compensating donor-trap concentration). This situation seems unlikely, as the process of stress creation in the damaged and undamaged cases is quite different. In the undamaged case, the tensile stress simply increases in direct proportion to the hole concentration, which depends on the number of boron atoms on substitutional lattice sites. In the sputter-damaged case, it is supposed that dechanneled argon atoms displace silicon atoms to interstitial sites to create divancies (21) which act as the donor traps previously mentioned. The stress in this situation, however, depends on the relative position of the displaced silicon atoms, the implanted argon atoms, the original boron atoms (all of which can be on substitutional or interstitial sites), and the divancies. The situation is further complicated by argon damage and atom depth distributions, which are not necessarily the same. This makes it possible that trap concentration has little causal relation to the argon concentration at a given depth. Since the embedded argon atoms would be a main source of stress relief, the relation between net hole concentration and net tensile stress at a given depth is indirect, unlike the direct dependence in the undamaged case.

To test the stress hypothesis further, lightly doped p-type wafers were stressed in a cantilever-beam fashion with one end fixed and the other end deflected to provide the desired stress. The maximum stress level at the fixed end was calculated from elementary beam mechanics (24) to be $9.8 \times 10^8 \text{ dynes/cm}^2$ for a strain of 7.5×10^{-4} , which corresponds to $\sim 1.4 \times 10^{20} \text{ cm}^{-3}$ boron-doped silicon with no applied stress (23). The etch rate was measured using the etch-step method in Fig. 1a with thermal SiO_2 masks and with

the silicon beam in tension and compression. No etch-rate decrease was observed at various positions along the beam compared to the unstressed condition. Even though the stress levels required to simulate BO_3 molecules (25) formed in the silicon lattice may be somewhat larger than those used here for boron, it seems reasonable to conclude that stress is not a factor.

Nevertheless, a variation of the stress mechanism has been proposed by Palik *et al.* to account for the etch-rate decrease in KOH-etch solutions (25). They propose that the boron-induced strain in the silicon lattice at high doping levels promotes the formation of a slowly etched surface layer. However, one must exercise caution in applying their results to our experiments. Their investigation utilizes a different etch solution (KOH and water) at a lower etch temperature (25°C) with no complexing agent. Even for KOH solutions at a higher etch temperature (60°C), the etch-rate dependence on boron concentration is different from that obtained for EPW solutions (11). It is also well known that the magnitude and orientation dependence of etch rate of lightly doped silicon in KOH solutions (26) is different from that in EPW solutions (8). Consequently, the rate-determining reaction may be different for the two solutions, even though the main solution constituents believed to be responsible for etching (OH^- and H_2O) are the same. Furthermore, one would expect that, as a result of sputter damage and the consequent increase in defect concentration, the surface layer proposed by Palik *et al.* (25) would be more likely to form and decrease the etch rate. This is contrary to our observations. Finally, we obtain excellent agreement between experiment and the theory based on a mechanism different from strain-induced formation of surface layers which we now develop.

It is now clear that any proposed mechanism for the etch-rate decrease must incorporate the fact that the etch-rate ratio depends on the hole concentration. It is well known that free electrons and/or holes are often involved in the chemical reactions that take place in the etching of semiconductors (27, 28). Finne and Klein (8) proposed that the reactions involved in EPW etching of silicon were ionization of the ethylenediamine base in solution, oxidation-reduction of the silicon surface forming hydrous silica and hydrogen, and complexing of the hydrous silica to a complex pyrocatecholate. Since the ionization step occurs very rapidly and the complexing step does not normally limit the etch rate (8), the rate-determining step for the total reaction must be either the oxidation or reduction reaction. We propose that the rate-determining step for the etching of both heavily and lightly doped silicon is the reduction reaction. The proposed oxidation-reduction reactions are: for oxidation

and for reduction

which is followed by

where e^+ signifies a hole, e^- an electron, and (surf) indicates that the corresponding chemical reactant is attached to the silicon surface. The values of the coefficients m and k are such that $0 < m < 4$ and $0 < k < 4$, since the oxidation state of silicon is four. The overall reduction reaction is then

Combining Eq. [11] and [13], the net oxidation-reduction reaction is

which is the same as that proposed by Finne and Klein except for the addition of free carriers. Note that the net numbers of electrons and holes in Eq. [14] are equal in order to maintain charge neutrality. The reactions in Eq. [11] and [12] are similar to those proposed by Turner (29) for germanium. Here, the monolayer of hydroxide maintained at the silicon surface is indicated by $\text{Si}(\text{OH})_2(\text{surf})$. The reactions are different from those of Turner in three ways: (i) the $\text{Si}(\text{OH})_2^{2+}$ at the surface is converted into $\text{Si}(\text{OH})_6^-$, which dissolves in solution; (ii) the silicon hydride decomposes in the presence of water to evolve two mols of hydrogen gas (30) and to regenerate the hydroxide monolayer; and (iii) the number of holes and electrons involved are generalized. The first two differences are necessary in order for the reactions to agree with the observations of Finne and Klein; the third difference is to facilitate comparisons. In anode/cathode experiments on germanium, Turner (29) found $m \sim 2$ and $k \sim 4$; we also believe that $k \sim 4$, which fits our etch-rate dependence results (Fig. 6), but that $m \sim 0$. This is explained in the recombination model section.

It is important to note that if Eq. [13] is the etch-rate determining step and the reverse reaction is negligible, then the total etch rate is proportional to the production rate of hydrous silica and hydrogen. This production rate is, in turn, proportional to the product of the deficient reactant concentrations. Assuming in Eq. [13] that the electrons needed are deficient for heavily doped boron surfaces, then the etch rate is

$$ER(p) \propto n^k = n^4 \quad [15]$$

where n is the free-electron concentration at the silicon surface being etched. For lightly doped surfaces, the electron concentration is not deficient. This fixes the etch rate at a value corresponding to some electron concentration n_0 , where n_0 is the electron concentration below which the etch-rate ratio is 1.0. Therefore, the etch-rate ratio is

$$ERR(p) = (n/n_0)^4 \quad [16]$$

valid for p such that $ERR(p) \leq 1.0$. Note that even though a fourth power dependence of reaction rate on concentration is uncommon, it has also been observed in the formation of donor states in heat-treated silicon (31). Finally, even though the oxidation-reduction reaction product $\text{Si}(\text{OH})_6^-$ proposed by Finne and Klein appears in Eq. [14], it has not been experimentally verified in EPW solution to our knowledge. This may be because $\text{Si}(\text{OH})_6^-$ is very quickly converted into a complex pyrocatecholate (8) and therefore not easily observable. An alternative choice of reaction product is $\text{SiO}_2(\text{OH})_2^-$ as determined by Palik *et al.* for silicon etching in KOH solution (32) (Eq. [13] would then require two mols of water instead of four in order to remain balanced). However, the important point here is that the fourth power dependence is still valid as it derives from the fact that four electrons are needed to reduce hydrogen to form the silicon hydride surface layer and is independent of the particular silicon-etch product which goes into solution.

Recombination model.—The source of the electron concentration n and its dependence on the boron doping must now be determined. It is unlikely that the source of electrons is the semiconductor near the surface, as the electron concentration at the point of

etch-rate decrease ($\sim 10^5 \text{ cm}^{-3}$) is too low to explain the fact that the etch rate is independent of light. The approximate electron concentration induced by light of the intensity used is $\sim 10^{15} \text{ cm}^{-3}$, and it seems improbable that diffusion away from the surface or recombination would prevent greater than 10^5 cm^{-3} effective concentration due to light from reaching the surface. Electron supply from the semiconductor bulk is not important, since there appears to be no etch-rate difference for diffusions into p or n substrates.

We propose, then, that the supply of electrons is generated by the chemical reaction at the semiconductor surface and not provided by the semiconductor near the surface or in the bulk. Specifically, the oxidation reaction in Eq. [11] generates electrons which can be used in the reduction reaction in Eq. [13]. This explains our choice for $m \sim 0$ in Eq. [11] with $k \sim 4$; four electrons must be chemically generated in Eq. [11] to satisfy the four electrons needed in Eq. [13]. Otherwise, electron sources other than chemical generation would be required in order for the net oxidation-reduction reaction in Eq. [14] to proceed, which we have shown to be unlikely. The idea that free carriers are generated at silicon surfaces during chemical etching is not a new one; it was proposed by Turner (28) to explain results obtained using the HF-HNO_3 system to etch silicon. For example, if the chemical generation rate of electrons is greater than the generation rate due to light, the mechanism of electron supply through chemical generation would explain the fact that light has no noticeable effect on the etch rate in the range studied.

One can calculate the relative magnitudes of the chemical and light generation rates. From the known etch rate of (100) silicon in EPW solution and knowledge of silicon bond density and lattice constant, it is found that $\sim 10^{17} \text{ e/cm}^2 \text{ s}$ are needed to etch silicon at its maximum rate; these are presumably supplied chemically. In order to calculate the electron generation rate due to light, we assume that only those electrons generated within a specific distance from the surface can participate in the etch reaction. It will be shown later that this distance is $\sim 100 \text{ \AA}$. Assuming a light intensity of 0.22 W/cm^2 corresponding to the maximum intensity used in these experiments, the useful electron generation rate due to light is then $\sim 8 \times 10^{15} \text{ e/cm}^2 \text{ s}$, more than an order of magnitude smaller than the chemical generation rate.

Assuming that the electron supply is predominantly generated chemically with negligible contribution from the semiconductor, we propose that the etch-rate decrease is due to fewer electrons recombining at the surface, since the enhanced recombination of electrons near the surface increases with boron doping. In this model, the electron concentration generated by the oxidation reaction in Eq. [11] is independent of surface hole concentration, and the electrons are injected into the semiconductor to a distance L_{eff} from the surface, which is probably about 100 \AA . The tendency for these injected electrons to recombine at the surface and participate in the reduction reaction in Eq. [13] increases as the time taken to reach the surface from the injection distance L_{eff} decreases. The time taken to reach the surface is L_{eff}/s_0 where s_0 is the surface recombination velocity. Similarly, the tendency for these electrons to recombine in the semiconductor en route to the surface is proportional to the inverse of the electron lifetime τ_n . Therefore, the concentration of electrons n recombining at the surface is

$$n = \left[\frac{s_0/L_{\text{eff}}}{s_0/L_{\text{eff}} + 1/\tau_n} \right] n_0 \quad [17]$$

where n_0 is the maximum concentration of electrons recombining at the surface. It has been reasonably assumed that since the injection distance L_{eff} is suffi-

ciently close to the surface, the electron velocity at any depth from the surface to L_{eff} is well approximated by the surface velocity s_0 . When the electron lifetime is large compared to the transit time, $n = n_0$ and the etch rate is the light doping etch rate. Substituting Eq. [17] into Eq. [16] and rearranging, the etch-rate ratio is

$$ERR = \left[\frac{1}{1 + L_{\text{eff}}/s_0\tau_n} \right]^4 \quad [18]$$

In layers heavily doped with boron in approximately $10 \mu\text{s}$ lifetime intrinsic silicon material and free of diffusion-induced defects, the lifetime τ_n is dominated by Auger recombination and given by K/p^2 , where p is the hole concentration and $K = 8.33 \times 10^{30} \text{ cm}^{-6} \cdot \text{s}$ (33, 34). Inserting this expression into Eq. [18], we obtain

$$ERR(p) = \left[\frac{1}{1 + (p/p_c)^2} \right]^4 \quad [19]$$

where

$$p_c = (s_0K/L_{\text{eff}})^{1/2} \quad [20]$$

If we fit Eq. [19] at $p = 10^{20} \text{ cm}^{-3}$ where $ERR = 2.8 \times 10^{-3}$, then $p_c = 5.5 \times 10^{19} \text{ cm}^{-3}$. Equation [19] is plotted for this value of p_c in Fig. 6; the agreement with experiment is very good. Using Eq. [20], $s_0/L_{\text{eff}} = 3.63 \times 10^8 \text{ s}^{-1}$. We assume that the surface recombination velocity s_0 is determined by the monolayer of hydroxide maintained at the silicon surface during etching. For reasonable values of capture cross section $\sigma \sim 10^{-15} \text{ cm}^2$, thermal velocity $v_{\text{th}} \sim (3kT/m)^{1/2} \sim 1.32 \times 10^7 \text{ cm/s}$, and trap density $N_t \sim 10^{10} \text{ cm}^{-2}$ representative of thin oxide layers on silicon (35), $s_0 \sim 1.32 \times 10^2 \text{ cm/s}$ and $L_{\text{eff}} \sim 36\text{\AA}$. This indicates that the doping profile is sampled over a very small depth and that the concentration being etched can be considered constant and equal to the surface concentration, as has been tacitly assumed in all the etching experiments. Note that we have assumed a one-dimensional path for the injected electrons. In reality, the silicon surface is composed of local, adjacent oxidation and reduction sites, and the injected electrons travel a curved two-dimensional path from an oxidation site surface through the semiconductor to an adjacent reduction site surface. The distance L_{eff} can then be seen to be somewhat larger than the average oxidation-reduction site separation.

Pyrazine and oxygen effects.—The independence of etch-rate ratio from pyrazine and oxygen content seen in our experiments can be explained by considering their effect on the etch-rate determining step. It has been shown in the model presented here that the reduction half-reaction in Eq. [13] is the etch-rate determining step over the range of contaminant levels studied. We propose that the effect of pyrazine and oxygen is to increase the rate of the oxidation-reduction reaction in Eq. [14] without affecting the complexing step; this, in turn, means that these contaminants increase the rate of the reduction half-reaction. This can be seen from the following argument. Reisman *et al.* (10) reported that in the case of pyrazine additions to the etch bath there was a tendency for residues to form on the silicon surfaces unless additional pyrocatechol was added. They concluded that pyrazine increases the rate of the oxidation-reduction reaction, and residues form if the complexing step becomes the rate-determining step because of a lack of pyrocatechol. Reisman *et al.* also reported that "B" etch (18.8 ml E: 3g P: 6 ml W, presumably with no pyrazine) that has been oxygenated increases the overall etch rate, but no residues are formed. The "B" etch has nearly the same composition as that used by Finne and Klein, in which the complexing step is saturated for the amount of pyrocatechol used. The pyrazine content in the latter was $\sim 1.1 \text{ g/liter E}$;

therefore, the complexing step was surely saturated for $\sim 0 \text{ g/liter E}$ in "B" etch, and the only way oxygen could increase the etch rate would be to increase the oxidation-reduction reaction.

Therefore, as pyrazine and/or oxygen levels increase, it may be possible to increase the rate of the reduction reaction so that it is larger than the complexing step. In this case, the reduction reaction will no longer be the rate-determining step, and Eq. [15] will be invalid. In addition, residues will appear if the complexing step becomes the rate-determining step. However, Eq. [15] has been found to be in good agreement with our experiments, and residues were not observed. Therefore, we believe that the light and heavy doping etch-rate determining step remained the reduction reaction over the range of pyrazine and oxygen levels considered here so that the etch-rate ratio was independent of these contaminants.

Different rate-determining steps for light and heavy doping etching may explain the fact that Reisman *et al.* observed an etch-rate ratio at a hole concentration of $1.2 \times 10^{20} \text{ cm}^{-3}$ more than an order of magnitude higher than observed here, using high pyrazine "B" etch (refer to Fig. 6). A possible scenario of etch-rate increase due to pyrazine would be as follows. Suppose the high pyrazine level increased the rate of the reduction reaction by a factor of ten with respect to the rate with low pyrazine level. For initial etch-rate ratios less than 0.1, the reduction reaction would still be the rate-determining step for the heavy doping etch rate since the dopant limiting effect is dominant. However, the rate-determining step of the light doping etch rate may be changed to the complexing step. This is plausible, since Reisman *et al.* did observe residue formation. The rate of the complexing step would be less than that of the reduction reaction; suppose that the effective light doping etch rate increases by a factor of two. In this case, the etch ratio would increase by a factor of five due to pyrazine. If this analysis is valid, then the etch ratio may not be independent of pyrazine for levels above 6 g/liter E . The fact that their experiments were conducted on bulk wafers should not be an important difference according to the model presented here. However, if the resistivity of their wafers was $0.002 \Omega\text{-cm}$ instead of $0.001 \Omega\text{-cm}$, there would be good agreement with our results.

Silicon staining correlation.—Finally, the correlation between the etch-ratio decrease and the silicon staining phenomenon (12, 36, 37) is further evidence for the proposed oxidation-reduction reactions. Both effects are predominant for heavily boron-doped (100) silicon for concentrations greater than $\sim 10^{19} \text{ cm}^{-3}$. For high boron concentration, the common silicon stain compounds SiH_x , SiO_y , or SiH_xO_y , where $1.0 < x < 2.0$ and $1.0 < y < 2.0$, can be formed if any of the reactants in the stain reaction are of insufficient concentration to allow the reaction to go to completion. This is correlated to the observed decrease in etch rate because of insufficient electron concentration. The reduction reaction in Eq. [12a] could be the stain reaction since the possibility of the formation of silicon hydride exists. Furthermore, in a way analogous to that by which insufficient oxidizing agent can cause staining (12), it is possible that it is also caused by electron concentration deficiency.

For heavy n-type doping less than $8 \times 10^{19} \text{ cm}^{-3}$, the etch rate is found to decrease only slightly (10), which correlates with the fact that the stain phenomenon occurs to a lesser extent than with heavy boron doping. In the heavy n-type doping case, the rate-determining step may be the oxidation reaction Eq. [11]. From arguments similar to those used in the case of heavy p-type doping, any holes needed in the oxidation reaction are assumed to be chemically generated. However, the onset of near-surface recombina-

tion of these holes should occur at considerably higher n-type doping (as opposed to p-type doping) because the surface recombination velocity s_0 for holes is larger than that for electrons. This is because the hole traps are likely to be associated with surface $(OH)^-$ ions whereas the electron traps are associated with surface H^+ ions (38); since there are more larger $(OH)^-$ ions near the surface in basic solution than smaller H^+ ions, the trap density and capture cross section are correspondingly larger for holes than for electrons. In addition, the dependence of etch rate on n-type doping should be slight, since $m \sim 0$ in Eq. [11]. These may be the reasons that the etch rate is only slightly dependent on heavy n-type doping in the range studied. Similarly, little or no silicon hydride stain would be formed, since the reduction reaction (Eq. [12a]) would go further to completion than with p-type material due to the large electron concentration with n-type doping; also, little or no silicon hydroxide stain would be formed in the oxidation reaction (Eq. [11]) because the hole-reactant concentration should be only slightly deficient based on the slight decrease in etch rate.

The previous discussion might seem to indicate that the stain would always form at high boron dopings in the etch-ratio experiments. However, the silicon hydride stain is removed easily in alkaline solutions with $pH > 9$ (36). As the pH of the EPW solution was measured to be about 10 and may actually be as high as 11, one can be sure that silicon etching was not impeded by a surface layer of stain residue.

Applications

For applications, it is useful to be able to calculate the resultant membrane thickness for a given concentration profile and etch conditions; this can be done using Eq. [8] and Eq. [10] and numerical integration. For an initial silicon thickness x_i , the final membrane thickness x_f can be plotted as a function of the product of light doping (1-10 Ω -cm) etch rate and etch time. This calculation was done for $x_i = 1 \mu m$ and $5 \mu m$ for the SIMS profile in Fig. 5a and is shown in Fig. 8. For known $x_i = 1 \mu m$ and light doping etch rate $ER_0 \sim 60 \mu m/h$ (measured prior to membrane etching), the etch time is determined to be approximately 20 min to obtain a 1000 \AA -thick membrane. These curves can be easily extended to larger initial thicknesses by calculating the additional light doping etch time needed to etch to the thicknesses that appear in Fig. 8. Note that the membrane can be etched away entirely in about 2h for $ER_0 \sim 60 \mu m/h$ due to the finite etch rate even at high doping. Note

Fig. 8. Final membrane thickness x_f as a function of product of light doping etch rate and etch time with initial silicon thickness x_i as parameter. The SIMS concentration profile used is shown in Fig. 5a.

also for a variation in x_i of 1-5 μm , the uniformity in final thickness is $\sim 50\text{\AA}$ out of 500 \AA or $\pm 5\%$.

This point is elaborated in Fig. 9. The variable t_{crit} is the time needed to etch from the thinnest region of the sample to the position x_{crit} at which the boron concentration equals p_{crit} . The quantity p_{crit} is the hole concentration at which the etch rate has reduced to 90% of its maximum value; referring to Fig. 5a and Fig. 6, $p_{crit} \sim 1.3 \times 10^{19} \text{ cm}^{-3}$ at $x_{crit} \sim 3500\text{\AA}$. The variable Δx is the initial thickness variation of the sample and is set for purposes here from 0.1 to 10 μm in Fig. 9. Note that $\Delta x = 4 \mu m$ represents the thickness variation shown in Fig. 8. Final membrane thickness variation is the ratio of maximum thickness difference over the sample to the thickness at the thinnest region, which gives worst case results. The results differ by only a few percent if normalized to the average membrane thickness.

Note that the uniformity for our particular profile is best near 50 μm on the abscissa. Note also that $\Delta x = 10 \mu m$ corresponds to etching thick bulk wafers with typical $\pm 5 \mu m$ thickness variation over the wafer diameter, giving $\sim 16\%$ min. final membrane variation. On the other hand, $\Delta x = 0.1 \mu m$ can correspond to the double-etch scheme as described by Huang and Van Duzer (4), where less than 0.2% variation over the wafer can be expected. In addition, the thickness variation over individual membranes in these two cases can be considerably less than the variations stated over the whole wafer because of the smaller etching area and corresponding smaller value of Δx . Finally, large-area membranes ($\sim 0.9 \text{ cm} \times 0.9 \text{ cm}$) were found by Rutherford backscattering to have approximately 7% thickness variation (39). Assuming 10 μm initial thickness variation over a 51 mm diam wafer, then $\Delta x \sim 2 \mu m$ over each of these large-area membranes. Using the stated etch conditions (39) of 50 $\mu m/h$ light doping etch rate and assuming a minimum etch time of 1h with 25 μm initial silicon thickness, $ER_0 \times (\text{etch time} - t_{crit}) \sim 50(1-25/50) \mu m \sim 25 \mu m$. The thickness variation calculated in Fig. 9 is $\sim 4\%$, in reasonable agreement with the observed result. An exact comparison is not possible, since these diffusions were performed at 1050°C for 15 min and the calculation applies for a 950°C, 45 min diffusion.

A secondary application of the etch-rate dependence is to the measurement of electrically active surface concentration in heavily doped boron layers for concentrations in the range $\sim 0.5-1.5 \times 10^{20} \text{ cm}^{-3}$, pro-

Fig. 9. Membrane thickness variation as a function of product of light doping etch rate and etch time after the critical concentration p_{crit} is reached where $p_{crit} = 1.3 \times 10^{19} \text{ cm}^{-3}$. The parameter is the initial thickness variation Δx . The etched sample (insert) is shown at a total etch time equal to t_{crit} . The SIMS concentration profile used is shown in Fig. 5a so that $x_{crit} \sim 3500\text{\AA}$.

vided that the profile variation at the surface is not too large. Analytical techniques such as SIMS and spreading resistance profiling often give questionable results at the surface ($\sim 100\text{\AA}$) because of physical limitations. This was the case for the profile in Fig. 5a, where the surface concentration was determined instead by etch rate to be $\sim 1.1 \times 10^{20} \text{ cm}^{-3}$.

Conclusions

The etch-ratio dependence of (100) silicon in EPW solutions for high boron doping has been found to decrease at $\sim 10^{19} \text{ cm}^{-3}$ and follows a -4.3 power law dependence on doping over three orders of magnitude of etch-rate ratio. The etch rate is determined by the hole concentration and not by stress due to substitutional boron.

The etch-rate ratio appears independent of solution oxygenation and pyrazine content in the ranges studied, since the reduction reaction rate-determining step is unchanged as a function of these contaminants. The etch-rate ratio is independent of light intensity in the range studied, since the number of electrons generated by light that participate in the etch reaction is far smaller than the number of electrons generated by the chemical etching reaction at the silicon surface. Furthermore, the independence of etch-rate ratio from light intensity has been shown to indicate that the number of electrons generated chemically is large compared to the equilibrium electron concentration.

An etching model has been proposed in which the electrons injected into the semiconductor by the oxidation reaction return to and recombine at the surface and thereby participate in the reduction reaction. It is proposed that the etch-rate decrease with increased hole concentration is due to insufficient electrons recombining at the surface because of enhanced Auger recombination in the semiconductor. An equation for the etch-rate ratio which assumes that the reduction reaction is the rate-determining step is derived and gives excellent agreement with experiment. The oxidation-reduction reactions proposed can also explain the correlations between the dependence of the etch-rate ratio on heavy boron doping and the silicon staining phenomenon.

Design curves for membrane fabrication are presented as a guide in the calculation of etch time needed to obtain desired membrane thickness. It is shown that the final membrane thickness variation over a wafer can be as small as 0.2%, depending on the etch conditions, the initial thickness difference over the sample, and the doping profile. The etch-rate ratio can also be used to determine the hole concentration at heavily boron-doped silicon surfaces.

Acknowledgments

This work was supported in part by AFOSR (JSEP) F49620-79-C-0178. The authors would like to acknowledge the help of C. Evans for the SIMS measurement, D. Dickey for the spreading resistance profiles, J. Kiely and A. Waterhouse for the ultraviolet absorption measurements, and D. McDaniel, D. Rogers, and R. Hamilton for their technical assistance. One of us (N. Raley) appreciates the stimulating discussions with R. Ruby and C. Drowley and the encouragement and support provided by R. Frustino throughout the course of this work.

Low Resistance Contacts for Lead-Sulfide-Selenide Diode Lasers

D. E. Swets and C. R. Harrington

General Motors Research Laboratories, Physics Department, Warren, Michigan 48090-9055

ABSTRACT

Cryogenically cooled lead-sulfide-selenide ($\text{PbS}_{1-x}\text{Se}_x$) diode lasers have been used in vehicle exhaust gas measurements. Diodes with a continuous wave (cw) operating temperature above 95 K would permit cooling with a small microminiature refrigerator. This would greatly enhance the possibility of practical applications. One important factor that prevents higher operating temperatures is the heat generated at the electrical connections to the diode (produced at the contact resistance, R_c). Reproducible low R_c was not obtained for PbS and $\text{PbS}_{1-x}\text{Se}_x$ of low x compositions by the contact formation technology developed for PbSnTe and $\text{PbS}_{1-x}\text{Se}_x$ of high x . A new method, in which the crystal surfaces are electrolytically etched (in HBr) followed by a nitric acid rinse, has resulted in a low R_c for all $\text{PbS}_{1-x}\text{Se}_x$ compositions.

Operation of $\text{PbS}_{1-x}\text{Se}_x$ diode lasers at temperatures above 95 K is desirable for various practical applications. One factor that limits the operating temperature is the ohmic heat (I^2R_c) generated at the metal-semiconductor interface when a current (I) is passed through a contact resistance (R_c). For higher temperature of operation, R_c should be as low as possible.

The contact formation procedure developed for $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ crystals resulted in low R_c routinely (1). When that fabrication procedure was applied to $\text{PbS}_{1-x}\text{Se}_x$ crystals, R_c was low for PbSe, but very high for PbS. A high p-type carrier concentration is necessary for a low R_c . This is more difficult to achieve and maintain in PbS than in PbSe, due to the nature of their respective pressure-temperature-composition phase diagrams. Results on mixed composition crystals with $x = 0.18, 0.38,$ and 0.60 were inconsistent.

An attempt was made to determine which processing step, or steps, were responsible for the high R_c . Careful examination of the various steps suggested the following. (i) The most likely cause of the large differences in R_c is the etching step. (ii) Improper crystal handling (lapping, polishing, etc.), plating, and mounting can cause poor R_c . This, however, is true for all crystal compositions and was not the cause of the difference in R_c results between PbS and PbSe. (iii) It was also determined by tests with n-type and p-type samples (rather than p-n junction diodes) that low R_c was easily achieved on clean untreated n-type PbS (i.e., facets or cleaved surfaces). Low R_c was not achieved on similar p-type surfaces without etching.

Experimental

Low resistance contacts to PbSnTe and PbSe crystals can be formed by squirting a stream of concentrated HBr over lapped p-type surfaces and then rinsing in a stream of deionized water. Concentrated HBr was also used on PbS by Ralston *et al.* (2), who reported low R_c (10 m Ω at 15 K) for their diodes. We were unable to reproduce their results. Tests were devised to determine any differences between HBr etching of PbSe and PbS. One such test was made to verify a suspected difference in etch rate.

Similar sized crystals of PbTe, PbSe, and PbS were weighed and then immersed in HBr for 3 min and rinsed. The etch rate was determined by the loss of weight during the etch. Table I shows the etch rate for PbS to be much greater than for PbSe or PbTe. The high etch rate was related to the R_c for PbS, but the mechanism was not known. (See Discussion.)

Electrolytic etching of $\text{PbS}_{1-x}\text{Se}_x$, with HBr as the electrolyte, was studied as an alternative to mechanical lapping and polishing, and also for stripe geometry applications. Etching with the sample as the anode and a platinum cathode produces a red or yellow "film"

on the sample (depending on composition). This film can be removed by a reverse polarity etch or by a nitric acid rinse. This procedure resulted not only in good material removal, but also in low R_c . The electrolytic etch-nitric acid rinse (E-N) method was optimized and found to give consistently low R_c on both PbS and PbSe. The best results were obtained when the electrolyte was one part HBr, one part H_2O for PbSe (1:1) and 1:3 for PbS.

The current density was held at 20 mA/cm². The voltage was typically between 50 and 100 mV depending on electrolyte concentration, crystal size, and crystal composition. Sample area was $\sim 7 \times 10^{-4}$ cm². Under these conditions the etch rate was ~ 2 $\mu\text{m}/\text{min}$. Both the electrolyte and the HNO_3 rinse were at room temperature.

The following comparison was made between the HBr squirt etch method and the E-N method: several as-cleaved n-type PbS and PbSe crystals were converted to p-type by annealing at 700°C with a p-type source. The crystals were then etched by one of three methods: HBr-squirt, HNO_3 alone (dipped in a beaker), or the E-N method. In all cases, the samples were rinsed in deionized H_2O after etching. All other processing steps were similar for all samples. Electroplated layers of gold, palladium, gold, and indium (in that order) formed the contacts (3). The samples were tested for R_c at 77 K. The results (shown in Fig. 1) illustrate the lower R_c (17 m Ω) obtained on PbS with the E-N method compared to the HBr squirt method (3 Ω). Also, the E-N method is superior to the HNO_3 alone, i.e., the electrolysis improves the R_c .

The results of a similar test on PbSe are given in Fig. 2. The E-N method was superior in this case also. A third study of R_c on PbS as a function of hole concentration is shown in Fig. 3. In this test, all the crystals were etched using the E-N method, but had different hole concentrations due to annealing at temperatures of 900°, 700°, and 400°C. The results illustrate that even with electrolytic etching, R_c will be high when the hole concentration is too low. (The 400°C anneal resulted in a carrier concentration of $\sim 10^{18}/\text{cm}^3$.) This result was expected, but is included to illustrate the importance of achieving as high of a hole concentration as possible on the PbS crystal surface.

Discussion

Auger surface analysis showed that both PbSe and PbS have similar trace amounts of Br and O, regardless of how they were etched (each etched by the squirt or E-N methods). It is evident that the residue cannot

Table I. Etch rate comparison

Material	HBr etch rate (mg/min)
PbS	23.0
PbSe	0.37
PbTe	0.10

¹ Auger analysis of the film on PbSe showed it to be $\sim 100\text{\AA}$ thick and contain excess bromine and oxygen. The chemical and physical properties of the film suggest the compound SeOBr_2 or $\text{PbOSe}_2\text{Br}_2$.

Fig. 1. *i*-*V* curves of p-type PbS etched by three methods

Fig. 3. *i*-*V* curves of E-N etched PbS annealed at various temperatures to show effect of hole concentration.

Fig. 2. *i*-*V* curves of p-type PbSe etched by three methods

account for the difference in R_c by different etching methods. SEM studies showed a considerable surface texture difference between squirt and E-N etched samples, especially on PbS (see Fig. 4). The E-N method produces a coarse textured high surface area on PbS, whereas the squirt method polishes PbS and leaves the surface relatively smooth. In Fig. 4a, the original surface had been lapped, yet squirt etching made it smoother.

In the case of PbSe, the slower etch rate of the squirt method preserves the coarse texture produced by prior lapping, i.e., there is no polishing effect. The E-N method also produces a coarse texture, but the difference between squirt and E-N etching is not as pro-

Fig. 4. (a, top) PbS surface after HBr squirt etch. SEM photos at 85 and 850 \times . (b, bottom) PbS surface after E-N etch. SEM photos at 85 and 850 \times .

nounced. It is then hypothesized that the key to achieving low R_c is the ability to achieve and maintain a coarse surface texture and that in the case of PbS, such a surface can be formed during electrolyte etching in HBr. Furthermore, this texture is maintained during subsequent etching in HNO_3 . Simply dipping a PbS crystal in HNO_3 also produces a rough texture but results in a somewhat higher and less ohmic R_c . We were not able to show by Auger analysis any evidence of selective etching which might make the surface metal rich and improve bonding to the metal layers.

The present result is consistent with an earlier finding that coarse surface texture is required for making stable low resistance contacts to $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ (4). The E-N method developed in this study has enabled us to produce coarse textured surfaces on crystals (such as PbS) that have a high etch rate in HBr solutions.

Summary

The following statements summarize our findings:

1. The hydrobromic acid squirt etching method developed for making low resistance contacts to PbSnTe and high x $\text{PbS}_{1-x}\text{Se}_x$ does not work reproducibly for $\text{PbS}_{1-x}\text{Se}_x$ of low x .

2. Electrolytic hydrobromic acid etching, followed by a nitric acid rinse, gives low R_c for $\text{PbS}_{1-x}\text{Se}_x$ of all compositions.

3. High R_c was related to a low carrier concentration in some PbS crystals.

4. Studies with Auger spectroscopy showed that poor R_c was probably not due to an insulating film or residue from the etching.

5. Scanning electron microscope studies showed that HBr squirt etching polishes PbS and results in a low surface area texture. The electrolytic etch results in a high surface area texture. This difference in texture may explain the differences in ohmic contact resistance observed, but more study is needed to determine the nature of the surfaces after etching and their reactions with the contact material.

ABSTRACT

A new method to determine depth profiles for carrier concentration in semiconductor has been developed using infrared ellipsometry. The method is based on theoretical calculations which have shown that a carrier profile can be sensitively described by its infrared ellipsometric parameters as function of the incident angle. Through measuring ellipsometric parameters and performing computer analysis, carrier profiles for shallow-doped samples made by arsenic ion implantation were nondestructively determined. The results are in good agreement with those from the conventional anodization stripping method.

The depth profile of the carrier concentration in silicon is a fundamental parameter for determining device characteristics. Thus, measurement of carrier concentration profiles is inevitable for semiconductor process technologies. However, conventional measuring methods, *e.g.*, the anodization stripping (1) or capacitance methods (2), are destructive, and are so laborious that they have been obstacles to the development of LSI technologies.

Several workers have performed optical measurements of carrier concentrations in silicon. Rawlins (3) measured the resistivity of epitaxial layer by the infrared attenuated reflection method. Jastrzebski *et al.* (4) determined the lateral changes of carrier concentrations in silicon wafers by measuring CO_2 laser transmittance. In their papers, the depth profiles were assumed to be homogeneous. Abe and Kato (5) and Wagner and Schafer (6) tried to measure carrier concentration depth profiles by infrared reflectance and transmittance spectroscopy (2.5–20 μm). Since reflectance or transmittance measurements are not so accurate, it has proven difficult to accurately determine the depth profiles with these methods.

In the present paper, we show a new measuring method which makes it possible to nondestructively determine depth profiles in less than 15 min using infrared ellipsometry.

In the present paper, we show a new measuring method which makes it possible to nondestructively determine depth profiles in less than 15 min using infrared ellipsometry.

Principle

Our new method is based on ellipsometry. When linearly polarized light is incident to a sample surface with incident angle θ , reflected light is generally elliptically polarized, as shown in Fig. 1. Mathematically, this transformation can be described as follows. If electric vectors of the incident (reflected) light are decomposed into the *s*- and *p*-polarized waves (E_s and E_p [E'_s and E'_p]) then they are connected in the manner

$$\begin{pmatrix} E'_s \\ E'_p \end{pmatrix} = \begin{pmatrix} R_s \exp(i\phi_s) & 0 \\ 0 & R_p \exp(i\phi_p) \end{pmatrix} \begin{pmatrix} E_s \\ E_p \end{pmatrix} \quad [1]$$

Key words: semiconductor, infrared, ellipsometry.

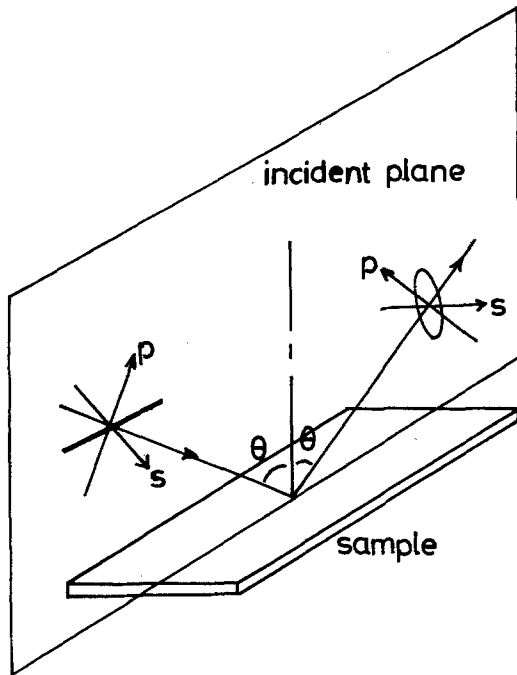

Fig. 1. Reflection ellipsometry. Incident linearly polarized light, with incident angle θ , is generally transformed into elliptically polarized light after reflection from the sample surface. Electric fields associated with incident and reflected light are decomposed into s- and p-axes, which are defined as those perpendicular and parallel to the incident plane, respectively.

where $R_s(R_p)$ and $\phi_s(\phi_p)$ are changes in the amplitude and phase for the s- or p-polarized wave after reflection. Ellipsometry determines the Δ and ψ , which are defined as

$$\Delta = \phi_p - \phi_s \text{ and } \tan \psi = R_p/R_s \quad [2]$$

These ellipsometric parameters are determined through the Maxwell equations (7)

$$\text{rot}\mathbf{E} = i(\omega/c)\mathbf{H} \text{ and } \text{rot}\mathbf{H} = -i(\omega/c)\epsilon(\omega)\mathbf{E} \quad [3]$$

Here, ω is the angular frequency of the incident light, and $\epsilon(\omega)$ is the dielectric function of the sample and is used to describe the electrical or optical properties of the sample. In this way, we can investigate the sample properties by ellipsometry.

The dielectric function for a doped semiconductor (8) is

$$\epsilon(\omega) = \epsilon_\infty - \frac{4\pi N e^2}{m^* \omega^2} \frac{1}{1 + i/\omega\tau} + \epsilon_b(\omega) \quad [4]$$

where ϵ_∞ is the dielectric constant of a nondoped sample. The second term is due to intraband transitions and is directly proportional to free electron or hole concentration, i.e., carrier concentration, N . Here m^* is the carrier effective mass, e is the electron charge, and τ is the carrier relaxation time. The third term concerns real interband transitions and can be neglected if we use infrared light.

In the case of silicon, $\epsilon_b(\omega)$ can be neglected if we use an infrared light with wavelength longer than 1.09 μm , and m^* is 0.27 m_0 (m_0 : electron rest mass) for n-type doping (9). The used τ value is 1×10^{-14} sec, which approximately corresponds to the value at the electron concentration of $5 \times 10^{19} \text{ cm}^{-3}$.

From now on, we will fix ω at the value corresponding to a CO_2 laser with 10.6 μm wavelength, and instead of a dielectric function we will use the optical constants defined by

$$\sqrt{\epsilon} = n + ik \quad [5]$$

Here, n is the refractive index, and k is the extinction coefficient.

Figure 2 shows the infrared optical structure of the sample. The first layer is impurity doped, and in this

Fig. 2. The optical model of impurity doped semiconductor wafer. The first layer is inhomogeneous with the optical constant distributions $n(z)$ and $k(z)$. The second layer is a homogeneous thick substrate with homogeneous optical constants.

layer carriers are usually distributed as shown. The second layer is the substrate, and in this layer carrier concentration is homogeneous. The corresponding optical constants are calculated by Eq. [4] and Eq. [5]. Once these optical constants are determined, the ellipsometric parameters Δ and ψ can be calculated by solving the Maxwell equations. In this calculation, it was necessary to get rid of the interference effect in the thick transparent substrate (10).

Figure 3 shows an example of calculated Δ and ψ values. In this example, carrier profiles are assumed to be Gaussian distributions with three widths (W) and incident angles are changed from 0 to 85 degrees. This calculation indicates that each carrier distribution corresponds to each (Δ, ψ) locus when the incident angle changes continuously. In fact, the one-to-one correspondence can be proven for the box-type profiles. The proof is shown in the Appendix.

Generally, for each carrier profile $[N(z)]$ the optical constant distribution is uniquely determined by the equation

$$n(z) + ik(z) = \left[\epsilon_\infty - \frac{4\pi N(z) e^2}{m^* \omega^2} \frac{1}{1 + i/\omega\tau} \right]^{1/2} \quad [6]$$

If we consider the n - k plane and the third axis z (depth), each carrier profile is uniquely transformed into the spatial curve shown in Fig. 4a. Considering the Δ - ψ plane and the third axis θ (incident angle), spatial curve a corresponds to spatial curve b . Although an exact mathematical proof of the one-to-one correspondence between these two spatial curves has not been arrived at, we have concluded that this correspondence is correct from computer experiments.

This one-to-one correspondence means that it is possible to construct the carrier profile from the experimental (Δ, ψ) values for various incident angles.

Fig. 3. Calculated Δ - ψ curves. Carrier profiles are assumed to be Gaussian distributions, $N(Z) = N_0 \exp(-Z^2/W^2)$, where $N_0 = 6 \times 10^{19} \text{ cm}^{-3}$ and $W = 0.18, 0.36, \text{ and } 0.54 \text{ }\mu\text{m}$. The substrate is a non-doped silicon wafer with a $100 \text{ }\mu\text{m}$ thickness. Incident angles are changed from 0 to 85 degrees and the symbols are marked every five degrees for each line.

Experiments and Analysis

Figure 5 shows a schematic diagram of our carrier profiler. The light source is a CO₂ laser. The CO₂ laser beam is linearly polarized by the metal grid polarizer and impinges upon the silicon wafer with incident angle θ . The reflected light becomes elliptically polarized, and Δ and ψ for this ellipse are determined by the rotating analyzer method (11). The apparatus are all controlled by a minicomputer, and the ellipsometric parameters Δ and ψ for each incident angle θ are obtained automatically. The obtained (Δ, ψ) values are input to a large computer to determine the carrier profile, as will be shown later.

An example of some experimental results is shown in Fig. 6. The sample for this experiment was made by arsenic ion implantation at an energy of 40 keV and a dose of $5 \times 10^{15} \text{ cm}^{-2}$, followed by isothermal annealing at 1000°C for 40 min. We chose four incident angles (65°, 69°, 73°, and 77°) near the Brewster angle, because Δ is usually very sensitive to the sample properties near this angle.

In order to determine the carrier profile from these data we introduced an appropriate carrier profile model for ion implanted samples as shown in Fig. 7. This profile model has four adjustable parameters: N_0 , P , W_1 , and W_2 . By adjusting these parameters, a wide

Fig. 4. General relation between carrier profile and Δ - ψ curve. a: Each carrier profile uniquely corresponds to the spatial curve in n - k - z space. b: The spatial curve in (a) corresponds to the spatial curve in Δ - ψ - θ space.

range of carrier profiles can be included in this model. Using a large computer, these four parameters were optimized for the calculated (Δ, ψ) values to fit the experimental ones. The moving range of the four parameters were $10^{17} \leq N_0 \leq 5 \times 10^{20} \text{ cm}^{-3}$, $0 \leq P \leq 3 \text{ }\mu\text{m}$, $0 \leq W_1 \leq 10 \text{ }\mu\text{m}$, and $0 \leq W_2 \leq 3 \text{ }\mu\text{m}$. The optimized values were $N_0 = 1.3 \times 10^{20} \text{ cm}^{-3}$, $P = 0.23 \text{ }\mu\text{m}$, $W_1 = 5.0 \text{ }\mu\text{m}$, and $W_2 = 0.098 \text{ }\mu\text{m}$. Results are shown in Fig. 6. The theoretical Δ - ψ curve is shown as a solid line.

The discrepancy between the theoretical and experimental values in Fig. 6 is attributed to the following reasons. (i) There exists some experimental errors in the ellipsometric measurements. In our experimental apparatus, we estimate these errors at about three degrees for both Δ and ψ . (ii) The true carrier profile may not be exactly described by the profile model shown in Fig. 7.

Fig. 5. Schematic diagram of the carrier profiler

Fig. 6. Experimental results and how they fit the theoretical values. The (+) symbols represent the experimental (Δ, ψ) points for the selected incident angles. The (x) symbols represent the theoretical (Δ, ψ) points. Each is connected with its corresponding experimental points by a broken line. The solid line shows the (Δ, ψ) locus when θ continuously changes from 65 to 77 degrees.

Figure 8 shows the carrier profile of the sample. The solid line represents the carrier corresponding to the theoretical Δ - ψ curve. The (+) symbols represent the carrier profile determined by the conventional anodization stripping method. Both are in good agreement.

Fig. 7. Carrier profile model. The profile is assumed to be Gaussian: $N(Z) = N_0 \exp[-(Z - P)^2/W_1^2]$ for $Z \leq P$ and $N_0 \exp[-(Z - P)^2/W_2^2]$ for $Z > P$. Here, N_0 is the peak carrier concentration, P is the peak depth, W_1 and W_2 are the two widths of the Gaussian distributions.

Fig. 8. Carrier profile. The solid line shows the carrier profile determined by our method, and the (+) symbols show the profile determined by the conventional destructive method.

Conclusions

The features of our method are outlined in Table I and compared with those for conventional methods. Comparison is made with respect to measurable range, resolution, and turnaround time. The measurable range and the resolution of our method were estimated by assuming the experimental errors to be one degree for both Δ and ψ .

The weak point in our method is the minimum detectable density, i.e., 10^{17} cm^{-3} . This limit is deduced from Eq. [4]; the dielectric function becomes insensitive to the carrier density when the ratio of the plasma frequency to the incident light frequency ($[4\pi N e^2 / \epsilon_0 m^*]^{1/2}$) becomes small. This ratio is ~ 0.01 for CO_2 laser wavelength and the carrier density of 10^{17} cm^{-3} . However, the difficulty can be avoided if

Fig. 9. A box-type profile. The first layer is a homogeneously doped layer with carrier concentration N and thickness d . The second layer is substrate with carrier concentration N_0 .

we use a longer wavelength. For example, if we use a light source with a wavelength of $30 \mu\text{m}$, then the minimum detectable density goes down to 10^{16} cm^{-3} .

In summary, our method is superior to conventional methods, and will become an efficient tool for developing LSI technologies.

APPENDIX

Let us show the one-to-one correspondence between the Δ - ψ curve and the carrier profile in the case of the box-type profile as shown in Fig. A-1. For a proof, we introduce complex variable $\rho = \tan\psi \exp(i\Delta)$ instead of Δ and ψ . For the box profiles, ρ can be described (12) as

$$\rho = \frac{D + Ex + Fx^2}{A + Bx + Cx^3} \quad \text{[A-1]}$$

where

$$x = \exp \left[i \frac{4\pi d}{\lambda} (\epsilon - \sin^2\theta)^{1/2} \right] \quad \text{[A-2]}$$

λ is the incident light wavelength, θ is the incident angle, and d and ϵ are, respectively, the depth and the dielectric constant of the first layer with carrier concentration N . In Eq. [A-1], $A, B, C, D, E,$ and F are the functions of $\lambda, \theta, N,$ and N_0 (carrier concentration of the substrate).

Each box profile is represented by one point in the N - d plane. This point is transformed into the point in the complex ρ -plane through Eq. [A-1] and [A-2]. Mathematically, ellipsometry defines a mapping from the N - d plane to the ρ -plane.

Let us consider the properties of this mapping. Any region of the N - d plane can be covered by the lines parallel to the d -axis as shown in Fig. A-2a. These lines are transformed into the x -plane through Eq. [A-2]. Figure A-2b shows three examples of this mapping. General properties are as follows: all $d = 0$ points in the N - d plane correspond to the $(1, 0)$ point in the x -plane, and as d increases along with the line, the x -locus makes a spiral curve converging on the $(0, 0)$ point in the limit $d \rightarrow \infty$. For small N , the x -locus is like a circle, and as N becomes larger, the x -locus spirals inward.

Since N is constant on each line, $A, B, C, D, E,$ and F in Eq. [A-1] are constants on each line. Thus, ρ is a rational function of x ; that is, Eq. [A-1] represents a conformal mapping from the x -plane to the ρ -plane, as illustrated in Fig. A-2c. This means that the one-to-one correspondence between the x - and ρ -loci is fulfilled unless $\rho'(x) = 0$ ($'$ means the derivative about

Fig. 10. Mapping by ellipsometry. a: any region of the N - d plane is covered by the lines like 1, 2, and 3. b: schematic diagram of x -loci corresponding to the lines 1, 2, and 3. c: conformal mapping from x -plane to ρ -plane.

x). Generally, there exist three x -points that satisfy $\rho'(x) = 0$. However, we can always select an incident angle to avoid $\rho'(x) = 0$. Thus, one-to-one correspond-

Table I. Features of respective carrier profile measurement methods

		Measurable range		Resolution		Turnaround time	Remarks
		Density (cm^{-3})	Depth (μm)	Depth (μm)	Area (mm^2)		
Conventional method	Anodization stripping method	$10^{19.5} \times 10^{20}$	0-10	~ 0.05	~ 10	4-5 hr	Destructive
	Capacitance method	$10^{15}-10^{18}$	0.2-10	~ 0.01	~ 1	4-5 hr	Destructive
Our method	Polarization of reflected light	$10^{17.5} \times 10^{20}$	0-10	≤ 0.01	≤ 1	≤ 15 min	Noncontact and nondestructive

ence between x - and ρ -points can be concluded. Moreover, if there is no crossing between the x -loci, the

one-to-one correspondence between N - d and ρ -points is fulfilled.

If the range of the N - d plane becomes larger, the crossing between two x -loci occurs as shown in Fig. A-3. In this example, two points, (N_1, d_1) and (N_2, d_2) are transformed into the same point in the x -plane. However, even in this case, it is possible to discriminate between (N_1, d_1) and (N_2, d_2) by measuring the ellipsometric parameters at the two incident angles.

Let us introduce z (depth) and θ (incident angle) as the third axes in the N - d and ρ -planes, respectively. All the box-type carrier profiles are represented by the straight lines in the N - d - z space, and these lines have the one-to-one correspondence to the curves in the ρ - θ space.

The Effects of Substrate Oxygen Content and Preannealing on the Properties of Silicon Epitaxial Layers

Motorola, Incorporated, Semiconductor Research and Development Laboratories, Phoenix, Arizona 85008

ABSTRACT

A study was carried out to evaluate whether the quality of Si epitaxial layers could improve if they were deposited on substrates intrinsically gettered through thermal annealing. Three different two-step procedures were used to preanneal the substrates prior to deposition. Optical microscopy revealed the presence of defect-free (denuded) zones at the surfaces of preannealed substrates only when the initial concentrations of interstitial oxygen in the substrates were $>1.5 \times 10^{18}$ atoms cm^{-3} , and if the high temperature step of the preannealing was carried out in a nonoxygen ambient. While the density of oxidation-induced stacking faults in the epitaxial layers showed no such dependence, the minority carrier generation lifetimes in the layers were strongly dependent on the oxygen content and thermal history of the substrates. Layers deposited on preannealed substrates of high initial oxygen content exhibited the greatest lifetimes. It is believed that oxygen precipitates and related defects, when present in a substrate, getter metallic impurities introduced during processing away from the epitaxial layer and thus improve lifetimes. Such gettering appeared to be most effective when the substrates had both surface denuded zones and high densities of bulk defects.

During the past several years, there has been an extensive amount of research in the area of intrinsic gettering in Si (1). Currently, the majority of the Si material used for electronic device fabrication is grown by the Czochralski (Cz) technique, and the incorporation of oxygen in the Si during Cz growth is well known. The general idea behind intrinsic gettering is to make use of selective thermal annealing to cause the grown-in oxygen to precipitate in the bulk region of a wafer and to out-diffuse from the surface regions, resulting in the formation of defect-free surface regions. Devices subsequently fabricated in such defect-free regions have been reported to exhibit better yield and/or performance (2, 3). This is because of the higher degree of crystallographic perfection of the surface region, and the gettering ability of the precipitates and related defects in the bulk to suppress structural defect formation and reduce contamination by impurities in the surface region of the wafer (4, 5).

The majority of studies on intrinsic gettering to date, however, has been focused on bulk wafers. Relatively little work has been published about the effects of intrinsic gettering on the quality of epitaxial layers. There have been reports on the suppression of epitaxial stacking fault formation by reducing the nucleation sites for these stacking faults through the gettering action of SiO_2 precipitates formed in the substrates (6, 7). It has also been reported that minority carrier generation lifetimes in epitaxial layers can be improved by using as substrates high oxygen content wafers that have been intrinsically gettered prior to deposition (8). Thus it appears that epitaxial layer quality can be improved if through successful intrinsic gettering the substrate provides a defect-free surface region (the so-called denuded zone) to form a good epi/substrate interface, and bulk defects to act as sinks for contaminating impurities.

Recently, however, it has been reported (9) that a high temperature anneal as used in the earlier studies (2, 4, 8) can no longer consistently induce the intrinsic gettering effect in the higher quality Si wafers currently available. The reason suggested is that as crystal growth techniques improved, wafers nowadays contain smaller and fewer grown-in nuclei for the formation of oxygen precipitates and related defects (9, 10). Consequently, a single high temperature anneal may not always induce the higher density of bulk defects necessary for effective intrinsic gettering. Instead, two-step

annealing procedures must be used (9-11). Here the low temperature annealing step creates nuclei and causes grown-in nuclei to grow in size. On the other hand, the high temperature step causes dissolution of nuclei and out-diffusion near the wafer surfaces as well as the growth of oxygen precipitates and related defects in the bulk. Two-step annealing procedures can much more consistently result in the formation of surface denuded zones and a high density of bulk defects. So far, there apparently has been only one published report on the deposition of epitaxial Si on substrates in which denuded zones have been formed and the reduction of epitaxial microdefects achieved by two-step annealing (12). In this paper, we report our findings on the effects of various two-step substrate preannealing procedures on the structural and electrical properties of epitaxial layers subsequently deposited on those substrates.

Experimental Procedures

The substrates used in the present study were dislocation-free, p-type (B-doped, ~ 60 - $110 \Omega\text{-cm}$), 76 mm diam Cz wafers of (100) orientation. All the wafers were from the same ingot, which was treated, in accordance with common manufacturing practices, with a donor thermal anneal at 650°C for 1.5h prior to processing. The interstitial oxygen and substitutional carbon concentrations in these wafers were determined by measuring the room temperature infrared (IR) absorption at wavelengths around $9 \mu\text{m}$ (13) and $16 \mu\text{m}$ (14), respectively, and using the appropriate scaling factor to multiply the absorption coefficient, α . In the case of substitutional carbon, its concentration (C_{sub}) is given by the relation (C_{sub}) = $1.1 \times 10^{17} \alpha$ atoms cm^{-3} (ASTM F123-74). The concentration of interstitial oxygen (O_{int}) is given by the relation (O_{int}) = $4.81 \times 10^{17} \alpha$ atoms cm^{-3} (ASTM F121-79). The initial (i.e., prior to any two-step annealing) concentration of interstitial oxygen, (O_{int})_i, in each wafer was determined, and the range was from 8.48×10^{17} to 2.03×10^{18} atoms cm^{-3} . The initial values of (C_{sub}) in these wafers were low, ranging from 4×10^{16} atoms cm^{-3} in those from the tang end of the ingot to not detectable ($<1 \times 10^{16}$ atoms cm^{-3}) in those from the seed end. All the concentration data described in this paper were obtained from IR absorption measurements made using a Perkin-Elmer 180 double-beam spectrophotometer. During the course of the study, IR absorption in some wafers was also measured using a Nicolet 170 SX Fourier Transform IR spectrophotometer. The two different techniques gave values of (O_{int}) with ex-

Key words: epitaxial silicon, intrinsic gettering, minority carrier generation lifetime.

cellent agreement. All wafers were scribe marked for identification.

The wafers were then divided into four groups. After being cleaned, each of the first three groups was heat-treated using a different two-step preannealing procedure. The wafers in the fourth group were set aside as controls and were not annealed. The three different preannealing procedures used were: (i) a low/high anneal consisting of 16h at 800°C in N₂ followed by 18h at 1050°C in O₂ (Procedure 1), (ii) a low/high anneal consisting of 16h at 650°C in N₂ followed by 4h at 1050°C, all in N₂ (Procedure 2), and (iii) a high/low anneal consisting of 4h at 1050°C in N₂ followed by 64h at 650°C in O₂ (Procedure 3). According to published results and studies in our laboratory (10, 15, 16), these procedures have been found to cause the formation of bulk precipitates and denuded zones in wafers with high (O_{int})_i. On completion of the anneals, surface oxides were stripped off using HF and the final concentration of interstitial oxygen, (O_{int})_f, in each wafer was determined from IR absorption measurements as described above.

Next, epitaxial deposition was made on all four groups of wafers. After being cleaned, the wafers were loaded onto an Applied Materials AMC 7600 reactor. Then approximately 0.1-2.0 μm of Si was removed from the surface of each substrate by *in situ* HCl etching at approximately 1160°-1200°C. Finally, approximately 10-15 μm of p-type (B-doped, ~1 Ω-cm) epitaxial layers were deposited at 1150°-1160°C, using SiCl₄ as the Si source, and at a rate of approximately 0.65-1.0 μm min⁻¹.

After deposition of the epitaxial layers, each of the four groups of wafers was divided into two lots. One lot was wet oxidized for the evaluation of oxidation-induced stacking faults (OISF), and the other lot set aside for electrical characterization. The wafers were thus divided into a total of eight different lots. The wet oxidation procedure consisted of: (i) ramp up from 650° to 1050°C in N₂ + 1% O₂, (ii) 2h at 1050°C in H₂ + O₂ (torch used, plus 2% HCl added for the last 45 min), and (iii) ramp down from 1050° to 650°C in N₂. The surface oxide layers (~7000Å) formed on each of the wafer so oxidized were then stripped off with HF, and the wafer was cleaved into two halves such that the cleavage plane was (110) oriented. Cleaved halves were then immersed for 1 min in a Secco etch (17) which has an etch rate of ~1.5 μm min⁻¹. Structural defects thus delineated were observed using optical microscopy. The OISF density in the epitaxial layer was measured at four points that lay in a straight line parallel and close to the cleaved edge. Two of the points were 38 mm apart and equidistant from the center of the cleaved edge. The other two were 56 mm apart and also equidistant from the center of the cleaved edge. The cleavage plane was examined to determine if a denuded zone was present in the substrate. Wafers from four of the eight lots were so studied.

MOS capacitors were fabricated onto the surfaces of the epitaxial layers of the other four lots of wafers set aside for electrical characterization. The fabrication procedure basically consisted of: (i) growing ~1000Å of gate oxide at 1050°C on the epitaxial layer surface, (ii) an ion implantation of B (using an energy of 50 keV and a dosage of 10¹⁵ ions cm⁻²) into the back side of the substrate to facilitate the making of ohmic contacts, (iii) a postimplantation anneal at 900°C in N₂ for 0.5h, (iv) a front-side deposition of ~10,000Å of Al, (v) photolithographic patterning and etching to form capacitors (26 mils diam) and guard rings (separated from the capacitor by a 0.2 mil gap), and (vi) an anneal at 465°C in forming gas for 0.5h. Using these capacitors, measurements of capacitance and current transients were made after the capacitors were pulsed into deep depletion. The epitaxial minority carrier generation lifetime (τ) was deduced from these measurements

using calculations based on the Zerbst method (18, 19) with τ being determined from the slope of a curve which is a plot of the measured generation current *vs.* the normalized depletion depth. The measurement system consisted of a Princeton Applied Research 410 C-V plotter and a Keithley 619 electrometer/multimeter, controlled by a Hewlett Packard 85 desktop computer system, and a probe station. Measurements were made inside a dark enclosure at either room temperature or 40°C. Due to the time consuming nature of each measurement, only four or five capacitors per wafer were sampled. These capacitors were located typically at four points lying on the two orthogonal diameters of the wafer with each point approximately 20 mm from the wafer center. In some cases the capacitor at the wafer center was also used for the measurement.

Results and Discussion

Oxygen precipitation and denuded zone formation.—The reduction of (O_{int}), defined as $\Delta(O_{int}) = (O_{int})_i - (O_{int})_f$, that had occurred in the substrate wafers due to preannealing Procedures 1-3 are shown in Fig. 1, as a function of (O_{int})_i. The data indicated that the magnitude of $\Delta(O_{int})$ depended strongly on (O_{int})_i. In the cases where Procedures 2 and 3 were used (see Fig. 1b and 1c, respectively), $\Delta(O_{int})$ became significant (>1 × 10¹⁷ atoms cm⁻³) once (O_{int})_i exceeded approximately 1.4-1.5 × 10¹⁸ atoms cm⁻³. Furthermore, for substrates with (O_{int})_i > 1.9 × 10¹⁸ atoms cm⁻³, preannealing with Procedure 2 clearly resulted in higher values of $\Delta(O_{int})$ than those obtained using Procedure 3. However, as shown by Fig. 1a, preannealing with

Fig. 1. Reduction in the interstitial oxygen concentration [$\Delta(O_{int})$] as a function of the initial concentration of interstitial oxygen [(O_{int})_i] in substrates: (A) preannealed using Procedure 1 (◆), (B): preannealed using Procedure 2 (■), (C): preannealed using Procedure 3 (●).

Procedure 1 resulted in even higher $\Delta(O_{\text{int}})$, at least when $(O_{\text{int}})_i > 1.5 \times 10^{18}$ atoms cm^{-3} . It is generally agreed that some outdiffusion of oxygen from the surface regions of a wafer occurs during the high temperature annealing. If the amount of interstitial oxygen so lost from a substrate during two-step annealing is neglected, $\Delta(O_{\text{int}})$ is then indicative of the amount of interstitial oxygen that has precipitated due to the pre-annealing procedure.

Data gathered by observing the Secco-etched (110) cleavage planes of the wet-oxidized wafers tend to support this (see Table I). Substrates that had $(O_{\text{int}})_i > 1.5 \times 10^{18}$ atoms cm^{-3} and were preannealed using Procedures 1-3 exhibited a high density of defects. On the other hand, substrates with $(O_{\text{int}})_i < 1.5 \times 10^{18}$ atoms cm^{-3} had been preannealed using Procedures 2 and 3, but these substrates showed very little, if any, defects. When present, the density of these defects increased with increasing $\Delta(O_{\text{int}})$, as can be seen in Fig. 2. While it is apparent that Procedures 1-3 all caused the formation of oxygen precipitates and related defects in the substrates, no denuded zones were observed in those substrates preannealed using Procedure 1 (see Fig. 2d). Conversely, denuded zones with thicknesses of 20-40 μm were found in all the substrates with $(O_{\text{int}})_i > 1.5 \times 10^{18}$ atoms cm^{-3} and preannealing using Procedure 2 (see Fig. 2c) or Procedure 3 (see Fig. 2a and 2b). In the substrates that were not preannealed (controls), no defects could be seen when their cleavage planes were observed under the optical microscope, irrespective of $(O_{\text{int}})_i$.

The absence of denuded zones in substrates preannealed using Procedure 1 led to the speculation that because the high temperature (1050°C) step was carried out in an O_2 ambient the out-diffusion of dissolved oxygen from the surface regions of the substrates was retarded. Subsequent split-lot experiments in which wafers were annealed using Procedure 1 with the 1050°C step being carried out in either a N_2 or O_2 ambient were performed. Denuded zones were observed in wafers annealed with the 1050°C step carried out in a N_2 ambient. However, the thicknesses of these denuded zones were much thinner ($< 10 \mu\text{m}$) than those obtained using Procedures 2 and 3. Again, no denuded zones were found in wafers annealed with the 1050°C step carried out in an O_2 ambient. These evaluations were carried out immediately after the two-step annealing and not after epitaxial deposition as in the original experiments. Thus the possibility that the *in situ* epi etch-back (of $\sim 2 \mu\text{m}$) removed a very thin denuded zone can be ruled out. Furthermore, a dry oxidation of 18h at 1050°C will only consume about 3500Å of Si, an amount that is insignificant in the consideration for denuded zone formation.

It is possible that after 16h at 800°C, relatively large-sized precipitates and/or nuclei form near wafer surfaces, and the subsequent step at 1050°C becomes less effective in causing their dissolution and out-diffusion in order to form denuded zones. Carrying out the 1050°C step in O_2 makes this even less effective. The experimental results discussed so far do indicate that $(O_{\text{int}})_i$, the annealing sequence (high/low vs. low/

(D): preannealed using Procedure 1. $(O_{\text{int}})_i$ and $\Delta(O_{\text{int}})$ for each substrate are given beneath the corresponding micrograph.

high), and the annealing ambient are among the factors that influence the way in which oxygen precipitation occurs.

Oxidation induced stacking faults in the epitaxial layers.—The structural characteristics of the epitaxial layers were examined after wet oxidation and Secco etching. The OISF density in the layers deposited on substrates that were preannealed using Procedures 2 and 3 as well as on substrates that were not preannealed (controls) are shown in Fig. 3, as a function of $(O_{\text{int}})_i$ in the substrates. Each data point represents the averaged density, and the spread between the maximum and minimum densities observed is also indicated.

The data do not indicate a strong correlation between OISF density and $(O_{\text{int}})_i$. Densities in general were lowest in epitaxial layers deposited on substrates preannealed using Procedure 2 (see Fig. 3b) and highest in layers deposited on control substrates, especially for those with high values of $(O_{\text{int}})_i$ (see Fig. 3a). It appears that while successful intrinsic gettering through the use of two-step annealing greatly reduces the OISF density on the surfaces of wafers (10, 16), the effect is less pronounced in epitaxial layers deposited on such two-step annealed substrates.

Finally, while the highest OISF densities shown in Fig. 3 were $< 800 \text{ cm}^{-2}$, densities in layers deposited on substrates preannealed using Procedure 1 were $> 10^4 \text{ cm}^{-2}$. It is known that dislocation loops are generated at oxygen precipitates (5). The heavy precipitation that had occurred throughout these substrates after preannealing with Procedure 1 (with no denuded zones formed) most likely resulted in a high density of dislocations at the substrate surfaces. These dislocations in turn gave rise to defective epi/substrate

Table I. Oxygen precipitation in the substrates as observed on Secco-etched (110) cleavage planes

Substrate preanneal procedure	Initial substrate oxygen concentration (cm^{-3})	
	$< 1.5 \times 10^{18}$	$> 1.5 \times 10^{18}$
800°/1050°C (Procedure 1)	No precipitation	Precipitation
650°/1050°C (Procedure 2)		No denuded zone
1050°/650°C (Procedure 3)	No precipitation	Precipitation with denuded zone
None (Control)		No precipitation

Fig. 3. Oxidation induced stacking fault (OISF) density in epitaxial layers as a function of $(O_{\text{int}})_i$ in substrates. (A): not preannealed (\circ). (B): preannealed using Procedure 2 (\blacksquare). (C): preannealed using Procedure 3 (\bullet).

interfaces on the subsequent deposition of the epitaxial layers, and allowed dislocations to propagate through the growing layers. The presence of these dislocations in the epitaxial layers created a large number of centers to nucleate OISF on the subsequent oxidation of Fig. 2d. The significantly higher OISF density in these layers compared to those observed in the other three lots of wafers (*i.e.*, $>10^4$ vs. $<800 \text{ cm}^{-2}$) is indicative of poorer structural quality. This is reflected in the electrical properties of these layers, as will be described below.

Minority carrier generation lifetime in the epitaxial layers.—Figure 4 shows τ in the epitaxial layers as a function of $(O_{\text{int}})_i$ in the substrates. Each data point corresponds to the averaged lifetime, and the spread between the maximum and minimum values of τ determined is also shown. The response time of the experimental setup limited the lowest measurable value of τ to $0.1 \mu\text{s}$. Epitaxial layers with $\tau < 0.1 \mu\text{s}$ are indicated by arrows (see lower left portion of Fig. 4); solid arrowheads indicate that the substrates had been preannealed using Procedures 2 or 3, and open arrowheads indicate control substrates.

First we will discuss the values of τ in layers deposited on substrates preannealed using Procedure 1 (as indicated by the symbol \blacklozenge and all located in the lower right portion of Fig. 4). In this group, the values of τ were low (typically $< 1 \mu\text{s}$), a fact that is not unexpected in view of the poor structural quality of these epitaxial layers (OISF density $> 10^4 \text{ cm}^{-2}$). The rest of the data in Fig. 4 show the following trends (see Table II for a summary). (i) For the epitaxial layers deposited on substrates with $(O_{\text{int}})_i < 1.2 \times 10^{18}$ atoms cm^{-3} , the values of τ were below the measure-

Fig. 4. Minority carrier generation lifetime (τ) in epitaxial layers as a function of $(O_{\text{int}})_i$ in substrates. Layers with $\tau < 0.1 \mu\text{s}$ are indicated by arrows, with solid arrowheads for substrates preannealed using Procedure 2 or 3 and open arrowheads for control substrates. All other symbol designations are the same as in Fig. 1 and Fig. 3.

ment limit of $0.1 \mu\text{s}$, irrespective of whether the substrate had been annealed. (ii) In cases where the substrates had $(O_{\text{int}})_i$ in the range of ~ 1.2 - 1.5×10^{18} atoms cm^{-3} , the values of τ in layers deposited on substrates preannealed using Procedures 2 and 3 (indicated by the symbols \blacksquare and \bullet , respectively, in Fig. 4) increased from ~ 1 to $\sim 10 \mu\text{s}$ as $(O_{\text{int}})_i$ increased. τ in layers deposited on control substrates remained $< 0.1 \mu\text{s}$. (iii) When the substrates had $(O_{\text{int}})_i > 1.5 \times 10^{18}$ atoms cm^{-3} , the values of τ in layers deposited on substrates preannealed using Procedures 2 and 3 increased to as high as $80 \mu\text{s}$ and averaged around 20 - $40 \mu\text{s}$, with no strong dependence on $(O_{\text{int}})_i$. The lifetimes in layers deposited on control substrates were now measurable, but their values were typically a factor of 2-3 lower than those in layers deposited on preannealed substrates with comparable $(O_{\text{int}})_i$. (iv) For substrates with $(O_{\text{int}})_i$ in the range of $\sim 1.2 \times 10^{18}$ to 2.0×10^{18} atoms cm^{-3} , τ in a layer deposited on a substrate preannealed using Procedure 2 was always slightly higher than that in a layer deposited on a substrate with comparable $(O_{\text{int}})_i$ but preannealed using Procedure 3.

Table II. Minority carrier generation lifetimes in epitaxial layers deposited on preannealed (using Procedures 2 and 3) and control (not preannealed) substrates

Initial substrate oxygen concentration (cm^{-3})	Epitaxial minority carrier generation lifetime (μs)	
	Preannealed substrate	Control substrate
$< 1.2 \times 10^{18}$	< 0.1	< 0.1
1.2 - 1.5×10^{18}	~ 1 - 10	< 0.1
$> 1.5 \times 10^{18}$	~ 20 - 40	~ 5 - 15

The lifetime data for epitaxial layers deposited on substrates preannealed using either Procedure 2 or 3 can be explained if defects in the bulk regions of these substrates had given rise to gettering effects in the cases where $(O_{\text{int}})_i$ was high. As mentioned earlier, it had already been determined that either Procedure 2 or 3 could create denuded zones and bulk defects in substrates with $(O_{\text{int}})_i > 1.5 \times 10^{18}$ atoms cm^{-3} . Intrinsic gettering effects would thus be expected to be highest in such substrates; values of τ in the layers deposited on such substrates indeed were consistently the highest. As $(O_{\text{int}})_i$ in the substrates gradually decreased below $\sim 1.5 \times 10^{18}$ atoms cm^{-3} , corresponding decreases in $\Delta(O_{\text{int}})$, together with the absence of bulk defects and denuded zones, had been observed. Gettering effects would be expected to diminish as well, and values of τ did drop from ~ 10 to ~ 1 μs as $(O_{\text{int}})_i$ in the substrates decreased from ~ 1.5 to $\sim 1.2 \times 10^{18}$ atoms cm^{-3} . It was not possible to determine if this trend continued when $(O_{\text{int}})_i$ in the substrates was $< 1.2 \times 10^{18}$ atoms cm^{-3} , since values of τ in layers deposited on such substrates were below 0.1 μs . It is not unreasonable to expect τ to eventually level off at a lower limit of < 0.1 μs when $(O_{\text{int}})_i$ in the substrates were so low that no gettering effect whatsoever was induced through preannealing.

As for the cause of the degradation in τ and the nature of the gettering mechanism, there does not appear to be a direct correlation to OISF densities in the epitaxial layers. Whereas the difference in values of τ were large (< 0.1 μs vs. > 10 μs), there were no significant differences in OISF densities between the layers deposited on substrates of varying $(O_{\text{int}})_i$ values and preannealed using Procedures 2 and 3 (see Fig. 3b and 3c). Furthermore, even the highest densities in these cases (which tended to be found in layers deposited on preannealed substrates with low $(O_{\text{int}})_i$; this class of layers had $\tau < 0.1$ μs) were much lower than the OISF densities in layers deposited on substrates preannealed using Procedure 1 (< 500 vs. $> 10^4$ cm^{-2}). Nevertheless, this latter class of layers still had $\tau > 0.1$ μs consistently.

However, it has been reported that OISF-related degradation in electrical properties was observed only when the stacking faults were decorated with impurities (20, 21). It has also been reported that metallic impurities such as Fe, Cr, Ni, Cu, and Au could often be introduced as contaminants during epitaxial processing (22, 23). It has been shown that intrinsic gettering as induced by two-step annealing has the ability to make use of bulk defects to getter heavy metals such as Cu away from the surface denuded zone (24). It is possible that in the present study impurities and/or impurity-decorated stacking faults in the epitaxial layer had a strong influence on τ . Preannealing of substrates with low $(O_{\text{int}})_i$ did not result in the formation of bulk precipitates and related defects, and thus no sinks were provided to getter metallic impurities out of the epitaxial layers. As $(O_{\text{int}})_i$ in the preannealed substrates increased, the gettering effect began to come into play, with maximum effectiveness being achieved in substrates with high $(O_{\text{int}})_i$ where both denuded zones and bulk defects were formed. In the substrates preannealed using Procedure 1, bulk defects were present, but the gettering effectiveness was probably reduced because of the absence of denuded zones.

In fact, the proposed model could explain all the τ data except for those in layers deposited on control substrates with high $(O_{\text{int}})_i$. Even though no bulk defects were observed in these substrates under the optical microscope (and none were expected since these substrates were not preannealed), the values of τ in the layers deposited on these substrates were substantially higher than those in layers deposited on control substrates with low $(O_{\text{int}})_i$. This phenomenon has been

observed previously (8). It is possible that in control substrates microprecipitates of oxygen too small in size to be detected using optical microscopy, but still possessing a certain degree of gettering ability, exist. These microprecipitates are believed to be present in the as-grown Si crystal and can act as nuclei for further precipitation on receiving subsequent thermal annealing. The growth or dissolution of these microprecipitates is dependent on $(O_{\text{int}})_i$ and the temperature of the subsequent anneal (25). For a given value of $(O_{\text{int}})_i$, there is at each temperature a critical size above which a microprecipitate will grow and below which it will shrink or dissolve. In the control substrates with low $(O_{\text{int}})_i$, it is possible that these microprecipitates were smaller than the critical size at the high temperature experienced during epitaxial processing, and the microprecipitates would dissolve. The critical size is smaller, though, for the same temperature in the control substrates with high $(O_{\text{int}})_i$. Thus the microprecipitates in these substrates would not shrink or dissolve and might possibly provide some ability to getter metallic impurities, though not as effectively as high $(O_{\text{int}})_i$ substrates preannealed using Procedure 2 or 3. Further work is necessary to get a better understanding of the mechanisms involved in control substrates with high $(O_{\text{int}})_i$.

Finally, it should be mentioned that while lifetime is strongly dependent on measurement technique and resistivity of the material (26), as well as on the thermal processing the material has received (23), it is not directly related to the oxygen content of the material. The lifetimes of material grown by the float-zone technique can be very high, even though such material contains much less oxygen than Cz material. However, the results of the present study do indicate that oxygen precipitates and related defects, when present in the bulk region of a wafer, getter impurities away from the wafer surfaces and so remove the lifetime degrading effects of the impurities. Since oxygen precipitation depends on the oxygen concentration of the material, lifetime is thus indirectly related to oxygen content.

Summary

Silicon epitaxial layers have been deposited on preannealed (prior to deposition) and control (not preannealed) substrates with initial concentrations of interstitial oxygen ranging from $8\text{--}20 \times 10^{17}$ atoms cm^{-3} . All the substrates were wafers taken from the same ingot of Si to eliminate variations that could possibly arise due to different thermal histories during crystal growth. Three different two-step preannealing procedures were used, including high/low and low/high temperature anneals in different ambients. The degrees of oxygen precipitation due to the preannealing were monitored. Surface denuded zones free of precipitates and related defects, as observed using optical microscopy, were found in preannealed substrates only when their initial concentrations of interstitial oxygen were $> 1.5 \times 10^{18}$ atoms cm^{-3} and when the high temperature step of the preannealing was carried out in a nonoxygen ambient.

Minority carrier generation lifetimes (determined using measurements of capacitance relaxation time) in the epitaxial layers deposited on substrates with low initial oxygen concentrations ($\lesssim 1.2 \times 10^{18}$ atoms cm^{-3}) were below the measurement limit of 0.1 μs , irrespective of whether the substrates had been preannealed or not. The lifetimes of layers deposited on control substrates with high initial oxygen concentrations averaged ~ 10 μs . Lifetimes in layers deposited on preannealed substrates with high initial oxygen concentrations averaged another factor of 2-3 higher (and reached as high as 80 μs) if the substrates had surface denuded zones. In both cases, high initial oxygen concentration meant $> 1.5 \times 10^{18}$ atoms cm^{-3} .

It is believed that oxygen precipitates and related defects, when present in the substrate, getter metallic impurities introduced during processing away from the epitaxial layer and thus improve lifetimes. Such gettering appeared to be most effective when the substrates had both surface denuded zones and high densities of bulk defects. Of the three different two-step substrate preannealing procedures used, the low/high procedure of 16h at 650°C/4h at 1050°C (all in N₂) appeared to provide somewhat better gettering (in terms of generally lower densities of oxidation induced stacking faults and higher lifetimes in the epitaxial layers) than the high/low procedure of 4h at 1050°C in N₂/64h at 650°C in O₂.

Characteristics of Sputter-Deposited Mo Films

Masamitsu Suzuki and Kazuyoshi Asai

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, Tokyo, Japan

ABSTRACT

Plasma etching characteristics and electrical resistivities for sputtered Mo films on GaAs substrates were studied. The plasma etching rate of the films depends largely on deposition rate. High etching rates and electrical resistivities are obtained by lowering deposition rates. Anisotropies both in the side etching rates and electrical resistivities are found in intermittently deposited Mo films resulted from rotating the substrate holding table. It is concluded from SEM, x-ray, and Auger analyses that the principal factors dominating these film characteristics are the anisotropically grown grains caused by oblique incident-angle deposition and oxygen adsorption in grain boundaries of the Mo films.

Molybdenum films have been used in Si MOS LSI's as gates and interconnections (1, 2, 3) because of their thermal stability (4), low resistivity (5), and plasma etching availability (6). The authors have proposed using Mo films as the self-aligned submicron Schottky gates for GaAs IC's (7).

In this paper, detailed studies on the plasma etching characteristics and the electrical resistivities of sputtered Mo film deposited on GaAs substrates are described. Mo films were prepared by sputter deposition for good adhesion on GaAs substrates. As for Mo film patterning, a CF₄ + 5% O₂ plasma etching technique was adopted because of its superior etching controllability over wet etching.

It was found that the resistivity and etching rate of Mo film largely decrease with an increasing sputter

deposition rate. Lateral anisotropic characteristics were also found in the films deposited by intermittent deposition (ID). These resulted from rotating the substrate holding table in our film deposition setup, shown in Fig. 1.

To explain these facts, the structure of the sputtered Mo films and the effect of O₂ absorption were studied.

Experimental

Molybdenum films were deposited on semi-insulating (100) GaAs wafers with planar magnetron sputtering equipment. A diagram showing the substrate holding table and the sputter target is presented in Fig. 1. The Mo target was located off the rotating axis of the substrate holding table, and was 65 mm above the sample zone. The table rotated at speeds between 0 and 6 rpm. Target and table diameters were 10 cm

Key words: films, metals, integrated circuits, etching.

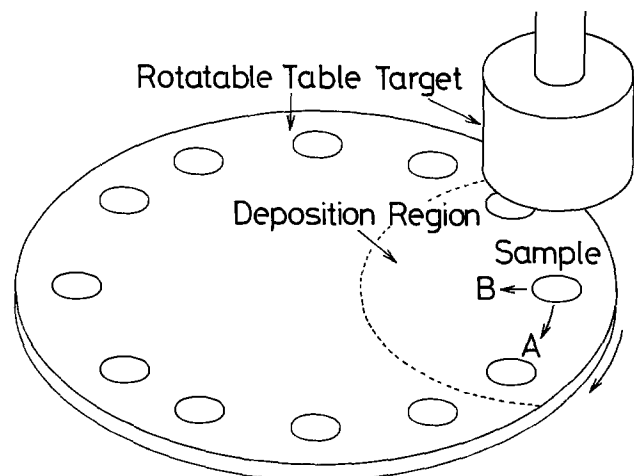

Fig. 1. A bird's eye view of planar magnetron sputter deposition equipment.

and 35 cm, respectively. The depositing area was 3 times larger than the Mo target, that is, about 30 cm diam. Argon pressure during film deposition was set at 4×10^{-3} torr. RF or dc power was applied to the target. The thickness of the Mo films prepared was about $0.3 \mu\text{m}$.

When the table was rotated during deposition, Mo film was deposited intermittently on the substrate, because the substrate repeatedly passes the deposition region (ID Mo). When the table was stationary and the substrate was fixed under the target, Mo was deposited on the substrate surface continuously (CD Mo). To clarify further explanations, axes A and B are defined with respect to the table rotating and radial directions, respectively, as shown in Fig. 1.

The Mo films were etched by $\text{CF}_4 + 5\% \text{O}_2$ plasma in a barrel-type etcher with an Al etch tunnel. Etching pressure and power were 0.3 torr and 50W, respectively. Under these conditions, GaAs substrates were not etched. The amounts of the Mo etched in both depth and side directions were measured by Talystep and SEM, respectively. Using Mo stripes $3 \mu\text{m}$ wide and $832 \mu\text{m}$ long, which were delineated by ion milling, Mo film resistivities were measured in the A and B directions. Molybdenum film structures were examined by SEM and x-ray diffraction. Oxygen absorption was measured by Auger electron spectroscopy.

Results

Plasma etching characteristics.—Molybdenum film etching rates vs. sputter deposition rates are shown in Fig. 2. Table I lists the sample preparation conditions used throughout this study. In the case of ID films, deposition rates indicate average deposition rates defined by a ratio of the film thickness to the total deposition time including nondepositing intervals. The ID cases are shown on the left of the dashed division line in Fig. 2; the CD cases are shown on the right. From these results, the following characteristics can be stated: (i) vertical depth etching is faster than side etching in all cases; (ii) in the case of ID Mo films, side etching in direction B is faster than in direction A;

Table I. Sample preparation conditions

No.	Sputter power	Deposition mode	Table rotation speed	Deposition rate
1	dc 150W	Intermittent deposition (ID)	6 rpm	123 A/min
2	RF 500W			145 A/min
3	dc 335W			245 A/min
4	dc 720W			442 A/min
5	dc 150W	Continuous deposition (CD)	0 rpm	700 A/min
6	RF 500W			870 A/min
7	dc 335W			1400 A/min

Fig. 2. Relation between etching rates and sputter deposition rates for sputtered Mo films. The deposition rate for the ID Mo films indicates the average deposition rate defined by the ratio of film thickness to total deposition time. Etching rates for CD Mo films are on the right of the dashed division line; etching rates for ID Mo films are on the left. A and B indicate side etching rates in the directions A and B, respectively. For sample preparation conditions, see Table I.

(iii) both vertical and side etching rates decrease rapidly with increasing sputter-deposition rates and are independent of RF and dc power sources.

It may be noted that the etching characteristics are discontinuous between the ID and the CD cases. When parameters a , b , and c are defined as: $a = (\text{vertical etching rate})/(\text{side etching rate along A direction})$; $b = (\text{vertical etching rate})/(\text{side etching rate along B direction})$; $c = a/b$, the differences on the etching properties are represented by these parameters. Here, $a = 6.9$, $b = 5.2$, $c = 1.3$ for the ID cases, and $a = b = 2.2$, $c = 1$ for the CD cases. This suggests an abrupt change in Mo film structure between the ID and CD Mo films.

Different edge shapes between ID and CD line patterns delineated by plasma etching also were observed by SEM, as shown in Fig. 3. In the ID Mo films, edge shape is anisotropic. That is, the line edge parallel to direction A shows many deep notches (Fig. 3a), and the line edge parallel to B is smoother (Fig. 3b). In the CD Mo films, the line edge has neither anisotropic shapes nor notches (Fig. 3c).

Another difference between etching characteristics for these two mode films was observed in SEM photographs shown in Fig. 4. In the case of ID Mo films, isolated columnar crystal grains were observed in a slightly etched film (Fig. 4a). In the case of CD Mo film, such columnar grains are not seen in a slightly etched film; the film seems to be uniformly etched (Fig. 4b).

These observations about the pattern edge shapes and the slightly etched surfaces suggest that ID Mo films have some irregular grain structure while CD Mo films have uniform grain structure.

Electrical resistivity.—Figure 5 shows resistivities for both ID and CD Mo films as a function of the sputter deposition rates. The resistivities for the ID Mo films show anisotropies similar to the side etching rates as presented with two separate curves on the left of the dashed division line in the figure. The resistivities for the CD Mo films are shown on the right of the dashed division line. From Fig. 5, it is also clear

that for both CD and ID cases film resistivity decreases with increasing film deposition rate.

Fig. 3. SEM photographs of pattern edge shapes for Mo films etched with a photoresist masking. The photoresist has been removed. (a) and (b) are pattern edges parallel to directions A and B for the same intermittently deposited Mo film, respectively; (c) is the pattern edge of the continuously deposited Mo film. Sample preparation conditions: (a) and (b) ID, RF 500W, 6 rpm, 145 Å/min; (c) CD, dc 335W, 1400 Å/min.

Fig. 4. SEM photographs of Mo films' slightly etched surfaces. (a) Intermittently deposited Mo film, (b) continuously deposited Mo film. Sample preparation conditions: (a) ID, dc 335W, 6 rpm, 245 Å/min; (b) CD, dc 335W, 1400 Å/min.

Fig. 5. Electrical resistivities vs. sputter deposition rates. r_A and r_B are resistivity values in directions A and B, respectively. Resistivities of the continuously deposited Mo films are isotropic. For sample preparation conditions, see Table I.

Discussion

Structural anisotropy of Mo films.—To investigate the cause of the anisotropies observed in side etching rates and electrical resistivities of the ID Mo films, more precise analyses were performed. First, x-ray diffraction was measured. A clear and large intensity peak of x-ray diffracted by (110) crystal planes of Mo and small peaks diffracted by other crystal planes such as (211) were observed for all Mo films studied. Figure 6 shows intensity ratios $I_{(211)}/I_{(110)}$ vs. sputter deposition rate. The CD Mo films are better ordered in the (110) direction, while the ID Mo films include many (211) directed grains (the fully disordered value of $I_{(211)}/I_{(110)}$ is 0.39 from ASTM).

The table rotation was first suspected to cause these anisotropies. Figure 7 shows plots of resistivities r_A , r_B and the ratio of r_A/r_B vs. rotation speed. The results show that the table rotation speed does not affect the anisotropies. Consequently, another possible cause of the anisotropy, the oblique angle between the incident Mo particles and the substrate surface, was investigated.

Experiments to investigate the oblique angle deposition effect were set up, as shown in the inset in Fig. 8. In the experiment, the substrates were tilted from

Fig. 6. Ratios of $I_{(211)}$ to $I_{(110)}$ vs. sputter deposition rates, where $I_{(211)}$ and $I_{(110)}$ are diffracted x-ray intensities from (211) and (110) crystal plane of molybdenum, respectively. For sample preparation conditions, see Table I.

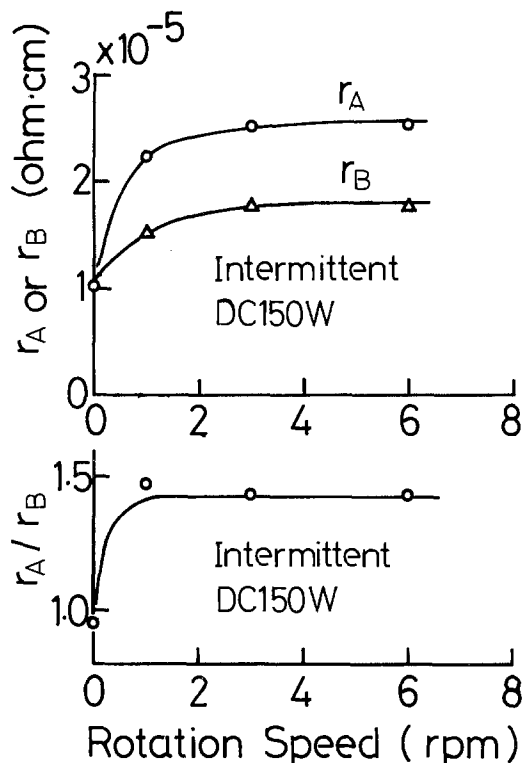

Fig. 7. Dependences of intermittently deposited Mo film resistivities r_A and r_B and ratio r_A/r_B on table rotation speed. Sample preparation condition: ID, dc 150W, 123 Å/min.

Fig. 8. Anisotropic resistivities of Mo films continuously deposited on a tilted GaAs substrate. Plot shows r_A/r_B vs. tilting angle θ . The directions A and B are the same as in Fig. 1, at 0 degrees. Sample preparation condition: CD, dc 335W.

0 to 80 degrees, and Mo was deposited with CD mode. The resistivities r_A and r_B of the Mo films were measured along the slope direction A and the direction B perpendicular to the direction A, respectively. They are plotted vs. tilting angle in Fig. 8. The marked anisotropy can be seen. The ratio r_A/r_B increases prominently with the tilt angle increase.

This anisotropy was found to be induced by structural anisotropy of the film. Figure 9 shows SEM photographs of the 70° tilt-angle deposited Mo film.

Fig. 9. SEM observations for anisotropic film structure of a tilt-angle deposited Mo film. Tilt angle is 70° . (a) Cross section parallel to direction A, (b) surface of the as-deposited film observed from deposition direction, (c) the Mo film surface etched for 5s, observed from the deposition direction. Sample preparation condition: same as in Fig. 8.

Columnar crystal grains growing toward the depositing direction are seen in Fig. 9a, which shows a cross section along the A direction. The photographs in Fig. 9b and 9c are viewed from the vertical direction of the film surface. Figure 9b shows an as-deposited surface and Fig. 9c shows a surface etched by plasma for 5s. The anisotropic grain structure is clearly observed. The grains have a tendency to grow faster in the B direction and slower in the A direction, resulting in a platelet-like grain. This platelet-like grain shape causes anisotropy in resistivity of the tilt-angle deposited Mo film. Furthermore, fast grain boundary etching is evident in Fig. 9c, which shows a deep grain boundary, which resulted after only 5s of plasma etching, and grains isolated from each other. The notched edges shown in Fig. 3 also related well with these anisotropic grain shapes.

In the real film deposition, when the divergent projection of the sputtered Mo particles is taken into account, as illustrated in Fig. 10, the substrates on the rotating table were subjected to the tilted state repeatedly. Consequently, oblique deposition can be reasonably viewed as the cause of the anisotropy of the intermittently deposited films.

Oxygen enhanced etching at Mo grain boundaries.— It has been reported (5) that EB-evaporated Mo film consists of columnar crystal grains, and that its electrical resistivity is affected strongly by oxygen content in grain boundaries. It is felt that sputtered Mo films also include oxygen in grain boundaries, and that the percentage of oxygen affects their resistivities. ID Mo films are expected to contain more oxygen than CD Mo films because of oxygen absorption during nondeposition intervals. This speculation is consistent with larger resistivities for ID Mo films as shown in Fig. 5. Furthermore, the additional oxygen absorption in ID cases is confirmed by AES analysis. Figure 11 shows Auger profile data on O_2 contents for an ID Mo film. The depth profile of O_2 is wavelike. The wavelength for the O_2 signal just coincides with sputter deposited film thickness/rotation. The peaks of the profile indi-

Fig. 11. Auger profile data on O_2 contents of the intermittently deposited Mo film. Sample preparation condition: ID, dc 720W, 6 rpm, 442 Å/min.

cate the presence of the additionally absorbed oxygen in the ID Mo film.

In order to verify the oxygen-enhanced etching phenomenon, oxygen annealed Mo films were prepared and etched. Figure 12 shows etching amounts vs. etching time for the CD Mo films, in their as-deposited state, annealed at 460°C for 3 min each in N_2 or H_2 atmosphere (line 1), and annealed in O_2 atmosphere (line 2). The CD Mo films annealed in N_2 or H_2 atmosphere exhibit the same etching rate as that of the as-deposited sample. However, for the CD Mo films annealed in O_2 atmosphere, a surface layer $\cong 1000\text{Å}$ thick was etched with the same rate (5200 Å/min) as that of the ID films. These results seem to support the possibility that oxygen absorbed in the grain boundaries of Mo film during the deposition periods accelerates the CF_4 plasma etching rate, especially in the ID Mo films.

Conclusions

Plasma etching and electrical resistivity characteristics for sputtered Mo films were studied. Both etching rate and resistivity depend largely on deposition rate. Anisotropies in both characteristics, which were

observed in the intermittently deposited Mo films, are the results of the oblique incident-angle deposition and the oxygen absorption at grain boundaries.

ABSTRACT

The optimum condition for Sb diffusion into silicon using a silicon wafer lapped with Al_2O_3 powder and a sapphire wafer as an auxiliary wafer has been determined. To obtain higher Sb concentrations—as high as the solid solubility of Sb into silicon—the Sb_2O_3 vaporized source concentration has to be kept over 0.4 mol percent (m/o) during diffusion. A nonoxidizing atmosphere and a small distance between the diffusion and auxiliary wafers are desirable. Although sheet conductance obtained by utilizing a lapped silicon wafer depends on the number of uses it has, that obtained by the sapphire wafer is independent of use number. When Al_2O_3 is present on the diffusion wafer beforehand, the diffusion concentration increase is similar to that with the auxiliary wafers with Al_2O_3 on their surface. The process presented here has no effect on phosphorus impurity diffusion. The solubility change of elemental Sb in the multicomponent glass film grown on the diffusion wafer is presented to explain the higher Sb concentration when Al_2O_3 is present.

In bipolar IC fabrication, Sb-buried layers are more effective than As-buried layers for lowering auto-doping from the buried layer during epitaxial growth (1). However, two problems remain in conventional Sb-diffusion processes. One is diffusion-induced defects such as erosions (2, 3), which hinder normal epitaxial growth and decrease device yield. The other is difficulty in obtaining high carrier concentrations at the surface of the diffused layer (4). Although SbCl_3 and $\text{Sb}(\text{C}_2\text{H}_5\text{O})_3$ have been proposed as dopant sources to avoid the former problem, the latter problem has yet to be resolved (5).

Recently, a new Sb-diffusion technique that avoids both these problems has been presented (6-8). This new technique uses auxiliary silicon wafers lapped with Al_2O_3 powder. Diffusion wafers in this method are set face to face with auxiliary wafers in an open-tube system using Sb_2O_3 . The behavior of the new diffusion process has already been investigated, and it has been confirmed that the effect of the auxiliary wafer on Sb diffusion was due to the presence of the Al_2O_3 on its wafer surface (9).

However, the effects of the auxiliary wafer and diffusion conditions have not yet been explained. These conditions include dopant-source concentration, diffusion atmosphere, diffusion temperature, and so on. This work describes optimum conditions and the diffusion mechanism for this new diffusion technique.

Experimental Procedures

Sample preparation.—Diffusion silicon wafers employed in this study were Czochralski-grown (CZ) (100) oriented, p-type with a resistivity of 10-30 Ω -cm. Four different types of auxiliary wafers were prepared. Auxiliary wafers in the first group were silicon wafers polished with no. 1200-1500 Al_2O_3 . Those in the second, third, and fourth groups were wafers deposited with chemical vapor deposition (CVD) Al_2O_3 film (about 50-100 nm thick), wafers implanted with a dose of 1×10^{15} Al^+ ions/ cm^2 at 47 keV, and sapphire single-crystal wafers.

When auxiliary wafers of the first group were utilized, the sheet conductance (σ_s) of the diffusion wafer depended on the number of uses of the auxiliary wafers. Therefore, the wafers of these groups were changed every experiment unless specifically designated.

Key words: glass, solubility, mass spectroscopy.

Diffusion was performed through a two-zone furnace system, as shown in Fig. 1. Dry nitrogen was used as a carrier gas. To investigate σ_s dependence on an oxidizing atmosphere, a little dry oxygen gas was mixed into the nitrogen gas. In the first furnace zone, Sb_2O_3 powder was charged in a Pt boat and heated to either 750° or 800°C. In the second, diffusion and auxiliary wafers were set on a fused-silica holder at 1025°-1200°C. The distance d between the diffusion and auxiliary wafers was varied from 2 to 32 mm to determine the influence of d on σ_s .

To evaluate the applicability of our process to impurities other than Sb, phosphorus diffusion was carried out with liquid-source POCl_3 . The source liquid was maintained at 20°C. A large flow (3000 cm^3/min) of nitrogen was sent through the diffusion tube. During impurity deposition, a low flow (150 cm^3/min) of nitrogen was bubbled through the POCl_3 . A low flow of oxygen (50 cm^3/min) was mixed in to facilitate POCl_3 decomposition into P_2O_5 .

Sample analysis.—Concentration profiles of Sb in the diffusion wafers were obtained by a differential conductivity method (10). Sheet resistance (ρ_s) of the diffusion layer was measured with a four-point probe after the glass was etched away. The σ_s is obtained from the reciprocal of this ρ_s measurement. The concentration of Sb in the glass layer grown on the diffusion wafer was measured by ion microanalyzer (IMA). These

Fig. 1. Experimental apparatus. Diffusion was mainly executed at the condition of 2 mm for distance (d) between the diffusion and auxiliary wafers.

samples for IMA were sputter etched using 13 keV O^+ ions at a rate of about 6 nm/min. The glass thickness grown on the samples was measured by ellipsometry.

Results

Influence of dopant-source concentration.—The diffusion of Sb was carried out using both the new and conventional processes at Sb_2O_3 dopant-source concentrations in the carrier gas in the range of 0.1–1.0 m/o. In this new process, the silicon wafers polished with No. 1200–1500 Al_2O_3 were used for the auxiliary wafers. The glass layer grown on the diffusion wafers was measured by IMA. The relative intensity of ^{122}Sb in the layer is shown in Fig. 2. This intensity directly corresponds to its concentration. Accordingly, it becomes evident that glass concentration using conventional technique is proportionate to dopant-source concentration. However, the glass concentration in the new process varies at approximately the square of the dopant-source concentration. This suggests that the Sb glass-formation mechanism obtained by the new process differs entirely from that obtained by conventional processes.

The Rutherford backscattering (RBS) spectra for the diffusion wafer at 0.65 m/o of source concentration has already been reported (6). Sb yield in a glass layer obtained by this technique was about 10% of that obtained by conventional techniques. At the same source concentration in Fig. 2, it could be confirmed that the Sb concentration in a glass layer using the new technique is also about 10% of that obtained by the conventional one.

The thickness of the glass layer observed under dopant conditions similar to Fig. 2 is given in Fig. 3. In the glass layer, oxygen is formed by the reaction

Generally, the glass thickness is proportionate to the oxygen concentration. Therefore, if the chemical equilibrium Eq. [2] is formed

$$\frac{(O)(Sb_2O_5)(Sb)^2}{(Sb_2O_3)^2} = K \quad [2]$$

where K is equilibrium constant, the thickness is proportionate to the square root of Sb_2O_3 source concentration. This agrees with the experimental data of conventional method. However, although the thickness

Fig. 2. Normalized ^{122}Sb intensity in the glass layer grown on the diffusion wafer vs. Sb_2O_3 source concentration. \circ and \bullet indicate the intensity obtained by the new and conventional processes, respectively.

Fig. 3. Glass film thickness dependence on Sb_2O_3 source concentration.

obtained by the new process is proportionate to source concentration, this may be because the $(Sb)^2$ term of Eq. [2] is close to constant in the presence of Al_2O_3 in the glass layer on the diffusion wafer (9).

The relation of diffusion wafer σ_s and Sb_2O_3 source concentration are shown in Fig. 4. The σ_s using the new process strongly depends on source concentration. At a source concentration of less than 0.2 m/o, the technique has a negative effect on high concentration Sb diffusion. This is because σ_s 's obtained by the new process are lower than those obtained by a conventional one.

σ_s 's obtained by conventional processes are independent of those in the range 0.1–0.4 m/o, and slightly increase in the region over 0.4 m/o.

The reason σ_s in the new process rapidly decreased at source concentrations below 0.2 m/o is important in understanding the diffusion mechanism obtained from the new technique.

Diffusion under variant source concentrations.—The diffusion process described above was carried out at a constant-source concentration for the entire diffusion time. Here, to determine the dependence of diffusion behavior on time, this source concentration was controlled as shown in Fig. 5a.

The resultant surface concentration C_0 and carrier concentration profiles of the Sb diffusion layer are shown in Fig. 5b and Fig. 6. Distribution results labeled 15 min, 30 min, and 60 min in Fig. 6 correspond to diffusion time. The C_0 obtained by conventional processes is nearly constant during diffusion time. How-

Fig. 4. Relation between σ_s and Sb_2O_3 source concentration

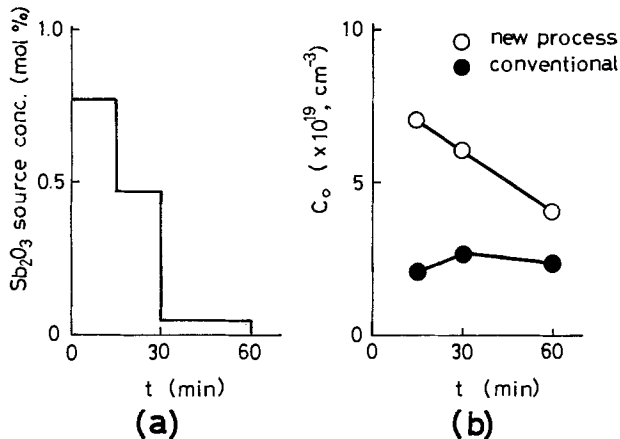

Fig. 5. Sb_2O_3 source concentration vs. diffusion time (a), and surface concentration C_o obtained by these source conditions (b).

Fig. 6. Carrier concentration profiles obtained by the new (Δ , \circ , \square) and conventional (\blacktriangle , \bullet , \blacksquare) processes.

ever, the C_o in our process at 15, 30, and 60 min of diffusion time was 7.0×10^{19} , 6.0×10^{19} , and 4.0×10^{19} cm $^{-3}$, respectively. Large decreases in C_o occurred between 30 and 60 min. These correspond to the decrease of Sb_2O_3 source concentration from 0.47 to 0.05 m/o. Thus, it provides that diffusion in the new process is very sensitive to dopant-source concentration. Both constant-source concentration through the diffusion time and its being above 0.4 m/o are necessary for our process.

This may mean that the interface condition between the glass layer and silicon substrate with the new technique is affected by Sb_2O_3 concentration in the

gas phase. However, that obtained by conventional methods is stable and similar to the results shown in Fig. 4.

Effect of oxygen in the carrier gas.—An effect of oxidizing atmosphere is shown in Fig. 7. Even when the $O_2/(N_2 + O_2)$ ratio is changed to 0, 1, 2, and 4%, results obtained by conventional processes are approximately 14.9 m(Ω/\square) $^{-1}$ in all cases and hardly change. In contrast, σ_s obtained by the new process become 40.0, 31.3, 26.3, and 16.7 m(Ω/\square) $^{-1}$ at the respective ratios, and gradually decrease as the O_2 content increases.

A previous paper (9) reported that comparison of the Sb concentration at the silicon surface C_o with the Sb concentration at glass-silicon interface C_r for elemental Sb produced good results. Therefore, it was concluded that carrier concentration in silicon depended on the concentration of elemental Sb at the glass-silicon interface. From this point of view, it can be assumed that the C_r levels obtained by the new process decrease as oxygen increases. The reason for the C_r decrease is not clear. However, in our process there is no doubt that something effective for high-concentration Sb diffusion onto the diffusion wafer depends on several diffusion conditions.

Here the C_r of the conventional process cannot be high in comparison with that obtained by the new process, because the C_o obtained by the former process is lower than that obtained by the latter process, as shown in Fig. 6. On the contrary, the Sb concentration in the glass layer on the diffusion wafer in the conventional process is higher than that in the new process, as shown in Fig. 2. Thus, it should be considered that the Sb concentrations in glass layer are no relation to the C_r . The factors which determine the C_r will be described in another section.

Dependence on the diffusion temperature.—Let σ_s^p and σ_s^c be defined as the sheet conductance obtained by the new process and by conventional processes, respectively (6). The value $\sigma_s^p - \sigma_s^c$ should reveal the effect on Sb diffusion obtained by the new technique.

The relationship between vicinity distance d and the $\sigma_s^p - \sigma_s^c$ with diffusion temperature as a parameter is given in Fig. 8. Here, σ_s^c are 23, 3.1, 0.78, and 0.25 m(Ω/\square) $^{-1}$ at diffusion temperatures of 1200°, 1100°, 1050°, and 1025°C, respectively.

Fig. 7. Effect of oxygen content in nitrogen carrier gas on diffusion.

Fig. 8. The $(\sigma_s^p - \sigma_s^c)$ vs. d with diffusion temperature (1025°-1200°C) as a parameter. The σ_s^p and σ_s^c show σ_s obtained by the new and conventional techniques.

As distance d between the diffusion and auxiliary wafers becomes smaller, $\sigma_s^p - \sigma_s^c$ of the wafer increases remarkably. When distance d is about 6-8 mm or greater, the effect of the auxiliary wafer decreases drastically, and σ_s^p attained becomes identical to σ_s^c realized by conventional methods.

From the dependence of $\sigma_s^p - \sigma_s^c$ on diffusion temperature, it is known that distance d which is effective in our process decreases with diffusion temperature. The relation between $\sigma_s^p - \sigma_s^c$ and d in Fig. 8 is represented by

$$(\sigma_s^p - \sigma_s^c) = \sigma_{s0} \exp(-d/\lambda') \quad [3]$$

where σ_{s0} and λ' are functions of diffusion temperature and source concentration. σ_{s0} and λ' correspond to the increase in Sb amount created by the effect of the auxiliary wafer and mean free distance of the material diffused from the auxiliary wafer surface to the diffusion one.

The λ' values obtained from Fig. 8 are 4.3, 3.6, 1.9, and 1.05 mm for diffusion temperatures 1200°, 1100°, 1050°, and 1025°C, respectively. λ' should correspond to the diffusion length of activated species emitted from the surface of auxiliary wafer. The species are perhaps Al-Sb complex oxide.

Dependence upon distance d at various source concentrations.—At a source concentration under 0.2 m/o,

diffusion using the new technique has a negative effect on high-concentration Sb diffusion, as seen in Fig. 4. The d in that diffusion was 2 mm and smaller than λ' at 1200°C, as shown in Fig. 9. If d is larger than λ' , it is expected that σ_s attained with this new condition will differ from those attained with the former one. Therefore, the relationship between σ_s and d with source concentration as parameters were examined. The result is shown in Fig. 10. At a 0.17 m/o source concentration, σ_s obtained by the new process is also lower than that obtained by conventional processes. However, σ_s increases with d , and σ_s with a d of 32 mm is nearly equal to that obtained for the conventional processes.

In high and low source concentrations, the effects of the new process vary drastically as d decreases.

Comparison between Al_2O_3 -lapped wafer and sapphire.—When silicon wafers are lapped with no. 1200-1500 Al_2O_3 as the auxiliary wafer, σ_s of the diffusion wafer depends on the number of uses of the auxiliary wafer. Therefore, these wafers were changed every experiment. To clarify the role of the auxiliary wafer in the diffusion runs, these wafers were not changed; they were used sequentially.

Variation of σ_s obtained with these polished silicon wafers is shown in Fig. 11 by \circ . In this figure, the σ_s variation obtained with the sapphire single-crystal wafers as an auxiliary wafer is denoted by Δ . Compared with σ_s obtained by Si and sapphire wafers, it becomes clear that in practical use the latter auxiliary wafer is more useful than the former. Therefore, the result shows that Al_2O_3 is effective for Sb diffusion.

With the decrease of σ_s obtained by sequential use of the Al_2O_3 lapped wafer, it is assumed that the Al_2O_3 on the surface of the auxiliary wafer is diffused out during the diffusion procedure (9). Hence, the Al_2O_3 concentration reached on the diffusion wafer is lower than that which could contribute to higher concentra-

Fig. 9. Dependence of mean free distance λ' of the material out-diffused from the surface of the auxiliary wafer on diffusion temperature T .

Fig. 10. σ_s dependence on d for the new process

Fig. 11. Comparison of diffusion using Al_2O_3 -lapped wafer (\circ) and sapphire (\triangle) as auxiliary wafers.

tion Sb diffusion in the diffusion wafer, as shown in Fig. 11.

Diffusion in the auxiliary wafer itself.—The dependence of σ_s on the four different types of auxiliary wafers is shown in Table I. In this table, "Diffusion wafers" indicates that σ_s was measured for diffusion wafers utilizing four different types of auxiliary wafers, and "Auxiliary wafers themselves" shows that the σ_s was measured for the auxiliary wafer (CVD- Al_2O_3 , Al^+ implantation).

Since σ_s of "Diffusion wafers" are higher (46.08 – $54.95 \text{ m}[\Omega/\square]^{-1}$) than those obtained by conventional method ($16.64 \text{ m}[\Omega/\square]^{-1}$), it becomes apparent that all these auxiliary wafers bring desirable results. Such results confirm that the effect of the auxiliary wafer on Sb diffusion is due to Al_2O_3 presence on its surface (9), as seen in Fig. 11.

However, the σ_s of "Auxiliary wafers themselves" should be noted. The σ_s for " Al^+ implantation" is $40.82 \text{ m}(\Omega/\square)^{-1}$, and suitably high as compared with that obtained by conventional methods. Therefore, it is shown that the effect of Al (probably from the Al_2O_3 because of changes occurring during prethermal treatment for diffusion) presented on the diffusion wafer itself beforehand is similar to that of auxiliary wafers, which have Al_2O_3 on their surfaces. The σ_s for "CVD- Al_2O_3 " ($29.85 \text{ m}(\Omega/\square)^{-1}$) is not so large as those obtained by conventional methods. This takes in consideration the fact that CVD- Al_2O_3 film (about 50–100 nm thick) on the wafer acts as a diffusion mask during the initial period of diffusion.

Phosphorus diffusion using auxiliary wafers.—It is expected that the new process using auxiliary wafers may be useful in impurity diffusions other than Sb. However, the new process has no appreciable effect on diffusion with a phosphorus oxychloride (POCl_3) source, as is shown in Table II. This shows that the new process is useful for limited impurities. These are difficult to diffuse in a surface concentration as high as the

Table I. Sheet conductance (σ_s) obtained by the new and conventional techniques. In the new technique four different types of auxiliary wafers were used. Diffusion temperature, diffusion time, and distance (d) were 1200°C , 45 min, and 4 mm, respectively

solid solubility (12). Our phosphorus diffusions were executed at high concentration conditions as described, in the section on experimental procedure. Further investigation will be necessary at the lower flow ($<150 \text{ cm}^3/\text{min}$) condition of nitrogen bubbled through the POCl_3 .

Discussion

It was confirmed that σ_s obtained by the new technique rapidly decreased at dopant-source concentrations below 0.2 m/o, and became lower as compared with that obtained by the conventional technique (Fig. 4). However, in such low dopant-source concentrations, if d between the diffusion and auxiliary wafers was increased, σ_s obtained by our technique was increased to as much as that by the conventional technique, as seen in Fig. 10. Furthermore, the diffusion of the new process was dependent upon several diffusion conditions.

To obtain high concentrations of Sb diffusion with our process, source concentrations have to be kept as high as 0.4 m/o throughout the diffusion procedure. The σ_s obtained by the new process gradually decreased as O_2 content increased. However, continuous presence of Al_2O_3 on the auxiliary wafer was necessary for higher concentration diffusion. Results described above are too complex to discuss briefly. A similar phenomenon is not seen anywhere but in our reports (6, 9).

Here, the effects of elemental Sb can be assumed. Elemental Sb is created on the auxiliary wafer using Al_2O_3 and is emitted toward the diffusion wafer. When Sb diffusion is carried out at 1200°C for 30 min in a 0.65 m/o source concentration, the thickness of the glass layer obtained by conventional techniques ($\sim 71 \text{ nm}$) is roughly similar to that obtained by the new technique ($\sim 56 \text{ nm}$).

This glass should be produced according to a chemical reaction such as

If the glass layer is assumed to be twice that of the Sb atomic radii (1.45\AA), the layer obtained by our technique is 193 layers. Because the Sb atom concentration is $3.3 \times 10^{22} \text{ atoms/cm}^3$, the amount of elemental Sb per layer is about $1.0 \times 10^{15} \text{ atoms/cm}^2$. Therefore, the total formation amount of elemental Sb in the glass layer is high ($\sim 10^{17} \text{ cm}^{-2}$) and similar to that obtained by the conventional method. Consequently, it is difficult to justify that such high concentrations of elemental Sb at the interface are affected by the amounts of elemental Sb emitted from the auxiliary wafer. Another model is necessary.

For the above reasons, it is important for understanding our diffusion mechanism to know why surface concentrations obtained by conventional techniques are lower than those obtained by the new technique.

A large quantity of Al, probably Al_2O_3 , was detected in the glass layer grown in the diffusion utilizing an auxiliary wafer (9). The Al_2O_3 is transferred from the auxiliary wafer. This Al_2O_3 transfer is supported by the described results (Fig. 11).

At present, considerations, such as that the solid solubility of elemental Sb in the glass layer depends on the amount of Al_2O_3 present in the layer, most

naturally explain the diffusion mechanism obtained by the new process.

Here, the chemical reaction and transfer path of elemental Sb are as shown in Fig. 12.

When a Sb_2O_3 source is supplied, Sb_2O_3 reacts with the Al_2O_3 on the surface of the auxiliary wafer and produces $(\text{Al-Sb})\text{O}_x$.

The $(\text{Al-Sb})\text{O}_x$ is diffused toward the diffusion wafer by gas phase diffusion.

However, Sb_2O_3 reacts with Si (diffusion wafer) and produces SiO_2 and elemental Sb, as is seen in Eq. [4]. The SiO_2 forms a glass layer.

Elemental Sb is divided into four components. First is the component diffused into Si (Sb_A in Fig. 12). The second is that in glass (Sb_B). The third and fourth are those that diffused out into the gas phase (Sb_C), and that diffused into auxiliary wafers (Sb_D), respectively.

Thus, either by decreasing distance d (Fig. 8) or by increasing Sb_2O_3 source concentration (Fig. 4), the $(\text{Al-Sb})\text{O}_x$ amounts reached on the glass layer increase. Therefore, the elemental Sb concentration at the glass-silicon interface grows as the effect of the new process reveals.

At a low Sb_2O_3 source concentration, the Sb_2O_3 concentration in the glass layer becomes smaller. Therefore, elemental Sb concentration drops drastically (Fig. 4).

At a low Sb_2O_3 source concentration and at a small distance between the diffusion and auxiliary wafers, σ decreases more as compared to the conventional process, because Sb_2O_3 source is consumed by the auxiliary wafer (Fig. 10).

According to these considerations, the key in interpreting the diffusion mechanism may be the solubility change of elemental Sb in the multicomponent glass (SiO_2 , Al_2O_3 , Sb_2O_3 , and elemental Sb). However, to support this diffusion model, the effective concentrations of Sb_2O_3 and Al_2O_3 in the glass layer on the surface of the diffusion wafer will have to be revealed.

The optimum diffusion conditions for higher Sb concentration using the new process are shown in Fig. 13. The optimum conditions are the region divided by the definite concentration of the host (Sb_2O_3) and the assisting impurity concentration (Al_2O_3). At lower concentrations of both Sb_2O_3 and Al_2O_3 , the surface concentration of Sb diffusion obtained by the new process is lower than that obtained by the conventional one (Fig. 4, 10). When the host source and the assisting concentration increase, the surface concentration of the diffusion wafer increases to as high as the solid solubility of Sb in silicon. However, when these concentrations increase more, two problems result. One is

Fig. 12. Assumption of chemical reaction and transfer path of elemental Sb in the new diffusion process.

Fig. 13. Conception of optimum diffusion conditions for higher Sb concentration.

surface defects, such as surface erosion (2). The other is contamination by the assisting Al_2O_3 impurity.

Furthermore, in the diffusion described (6, 9), the only usable material is Al_2O_3 . However, it is expected that some other material might also prove usable, as shown in Fig. 13. Such details can be clarified in further investigations.

Conclusion

The optimum conditions for higher Sb diffusion into silicon with auxiliary wafers were clarified. The following results were obtained from the new diffusion process: 1. To obtain higher Sb concentration diffusion using an auxiliary wafer, Sb_2O_3 source concentration in a nitrogen carrier gas has to be kept as high as 0.4 m/o during the entire diffusion process.

2. When a very small amount of oxygen is mixed into the nitrogen carrier gas, the sheet conductance obtained by the new process decreased.

3. Both high Sb_2O_3 source concentration and a small distance between the diffusion and auxiliary wafers are effective in the new process.

4. Although the sheet conductance obtained by utilizing an Al_2O_3 -lapped wafer depends on the number of uses, that obtained by a sapphire wafer is independent of the number of uses.

5. When Al_2O_3 is present on the diffusion wafer beforehand, the effect of Al_2O_3 on Sb diffusion is almost the same as that of auxiliary wafers having Al_2O_3 on their surface.

6. The new process has no effect on phosphorus diffusion.

7. To explain diffusion behavior, solubility change of elemental Sb in the multicomponent glass is discussed.

A Scanning Auger Electron Spectroscopic Study of Particulate Defects in Metallurgical-Grade Silicon

J. H. Thomas III,* R. V. D'Aiello, and P. H. Robinson*

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Metallurgical-grade silicon, used as a substrate material for low-cost epitaxial solar cells, purified by the heat-exchange method leaves some metallic particulate residue in the purified ingots. Scanning Auger electron spectroscopy has been used to elementally identify the particulate residue exposed in sections from purified ingots. Particle composition (V, Ti, Ni, Fe, Al, and C rich silicon) was found to be position sensitive within an ingot and to depend on the source of MG feedstock.

An alternate low-cost method of producing silicon solar cells uses commercial metallurgical-grade silicon as a substrate material (1). Various methods have been described to improve the quality of this silicon

such as the heat-exchange method (HEM) (1). In these studies (1), it was shown that residue contamination in the substrate produces defects in the epitaxial silicon layer and results in a lower cell yield. The composition, nature, and distribution of defects or impurities within a refined ingot is important to the characterization of the refining process as well as

understanding the contamination of the epitaxial silicon layer.

Small beam Auger electron spectroscopy has been applied with considerable success to the characterization of solar cell materials (2-7). The general methodology of application is well established. However, surface studies using this technique must be viewed with caution, especially on topographically rough surfaces such as those encountered in this work (7). In this paper, results of an Auger electron spectroscopic study of defects in HEM refined metallurgical-grade silicon are presented. The elemental composition and compositional variations of particulate defects were studied with respect to their position in the ingot.

Sample Preparation

The details of silicon refinement using HEM are described elsewhere (1, 8). Ingots of Hanna Mining Company feedstock (8) (Ingot 015) and Silicon Smelters, Limited, South Africa feedstock (8) (Ingot 020) silicon were refined by double solidification using the heat-exchange method. Slabs were sliced from the top, middle, and bottom of the ingots to study the distribution of particles in the resolidified material.

The slabs of silicon were polish-etched in an HF:HNO₃(1:6) etchant (8). The silicon immediately surrounding defects near the surface of a slab etched faster than the "bulk" silicon, leaving a pit and exposing the surface of the defect at the bottom of the pit. Pits and defects vary from ~10 to 500 μm in diameter. Some defects are larger since they occur along

extensive grain boundaries. A total of six samples (top, middle, and bottom of Ingot 015 and Ingot 020) were studied by Auger electron spectroscopy.

Instrumental Approach

Scanning Auger microprobe (SAM) studies were performed using a Physical Electronics Industries Model 545 system equipped with a Physical Electronics Industries Model 20-015 rastered ion gun for sputter microsectioning samples in depth. This system maintains a base pressure of less than 3×10^{-10} torr. Sputtering was performed by backfilling the vacuum system to a static pressure of 5×10^{-5} torr argon. Argon sputter rates were about 50 $\text{\AA}/\text{min}$ (relative to Ta₂O₅) at 2 keV ion energy. Auger measurements and video display were performed at an electron beam potential of 3 keV using an electron beam current to give a beam size of about 10 μm FWHM. Spectra were obtained using processed modulation to the CMA in the derivative mode. Micrographs were obtained by measuring the sample absorbed current. Auger elemental maps were made by adjusting the spectrometer to a given elemental peak and using this analog signal to Z-modulate the monitor oscilloscope with raster position. Most mappings were obtained at a lock-in time constant with 20 ms and required 1 min per frame. Elemental line scans were obtained by scanning the electron beam in the X direction with Y = 0 (midpoint of the micrograph) and displaying the Auger intensity as Y modulation on the oscilloscope.

Metallic Defects

Figure 1 shows a typical defect from Ingot 015 (top) taken in the absorbed current mode at 60 \times ($E_e = 3$ keV). At this magnification, not much detail is observed. The defect appears as a mound (~100 μm diam) at the bottom of a shallow etch pit. Because of the intrinsic 5-10 μm resolution of this instrument, higher magnification does not yield any further detail. The majority of the defects studied were similar in appearance at this resolution. The electron beam size was sufficiently small so that the beam could be centered on the defect and Auger analysis performed at this point.

The crater region was sputter cleaned for 10 min removing about 500 \AA of material (relative to the sputter rate of Ta₂O₅) and an Auger spectrum of the defect was obtained. This spectrum is shown in Fig. 1 below the micrograph of the defect. The spectrum is displayed from 0 to 1000 eV for the lower trace and from 1000 to 2000 eV for the upper trace. The lower trace shows the elements Si, Fe, Ni, Ti, V, O, and Ar, and the upper trace shows Si and Al. This spectrum is qualitatively representative of most of the Auger spectra taken in this study. Two points must be made: (i) all the defects studied contain silicon as a major constituent and (ii) argon is observed as a result of implantation due to sputtering at 2 keV and will henceforth be ignored. Sputtering sequentially removes carbon contamination revealing an oxygen-rich surface. The most significant peaks aside from Si were Fe and Ni. Al, Ti, and V are observed under the oxide layer that measures perhaps 100 \AA thick. Further sputtering does not significantly change the spectrum as shown.

Semiquantitative analysis was performed by measuring the peak-to-peak signal intensities and applying tabulated elemental sensitivity factors as described in Ref. (9). This procedure yields a normalized surface composition of Si (50%), Al (16%), Fe (29%), Ni (2.5%), V (1.5%), Ti (1%), and O (1%) at a depth of 500 \AA . Data are accurate to within a factor of $\pm 30\%$. Therefore, the major constituents of this typical defect are Fe and Al in addition to Si. It is possible that conditions are favorable for silicide formation and the defect represents a combination of Fe_xSi compounds. This procedure is useful to determine qualitatively an ordering of elemental composition for a given signal strength. Unfortunately, true quantitative analysis is not possi-

Fig. 3. Ingot 015. Auger elemental line scans are shown for Fe, Ni, Al, and V at 300X. Lines are taken at the midpoint of the 300X micrograph (Fig. 2).

Fig. 4. Ingot 015 (top). (A) Micrograph of another defect (60X). (B) Same defect at (150X). (C) Fe line scan showing two prominent peaks [dots on micrograph (B)] due to topography. (D) Silicon Auger elemental map showing topographically enhanced features. Note the substrate is silicon.

ble due to surface topography effects that dominate the Auger signal intensity (10), in this case, of extremely rough defects at the bottom of etch pits. In addition, quantitative analysis requires a detailed knowledge of many other factors, e.g., preferential sputtering. This is beyond the scope of this study.

Figure 2 shows an absorbed current micrograph of the same defect at 300X. Immediately below the micrograph is shown the corresponding Fe Auger map. The Fe map was obtained by using the 702 eV LMM Fe transition (the most intense peak in the derivative spectrum). The most intense portion of the Fe map

Fig. 5. Ingot 020. Auger spectrum of a carbide-like defect after sputtering 20 min.

may correspond to a peak in Fe concentration. The Fe peak does not correspond exactly to the "geometric" center, but lies slightly to the right-hand side of the observed defect. The dark regions in the map may correspond to lower Fe but not necessarily zero Fe due to the reduction in sensitivity at the small time constants required to perform an analog map.

By plotting the Auger peak amplitude as a function of X position (Y is centered on the micrograph), a more quantitative evaluation of the elemental concentration gradient can be obtained. Figure 3 summarizes line scans for Fe (702 eV), Ni (856 eV), Al (1389 eV), and V (470 eV) for this defect. All the elements shown have similar distributions across the defect and reach a maximum concentration near the center of the defect region. This distribution is representative of many of the defects studied. In performing Auger analysis of defects, it is therefore necessary to characterize the position (X, Y) where the electron beam is placed.

Topographic Effects

Some defects show considerable concentration variation across the sputtered cross section. An example of this behavior is shown in Fig. 4. Two absorbed-current micrographs are shown at 60 and 150 \times . Even with the poor resolution of the electron beam, surface details are readily observed. To demonstrate the effects of topography on the apparent elemental composition of the defect, a Si (91 eV) elemental map and an Fe (702 eV) elemental line scan at 150 \times are included. The Si map shows features similar to the micrograph. Since the substrate is Si, the bright regions of the map are due to topographically enhanced Si detection or electron emission and probably represent an overall change in the electron yield in this region. Auger spectra show that Si is actually less concentrated in this defect region. The Fe line scan is equally dramatic, showing two peaks in Fe concentration. The Fe concentration peaks occur at the black dots on the 150 \times micrograph. Again, Auger spectra show that in fact the low Fe concentration region between the peaks correlates with an overall reduction in detected current (electron yield). Although topography tends to reduce the apparent usefulness of the mapping technique, elemental intensity correlations with micrograph features aid in the understanding of the chemical composition of the defects.

Carbide/Oxide Defects

Most of the defects studied contain heavy elements: Fe, Ni, V, Ti, etc. There are a few defects that appear

similar in physical structure ($\sim 100 \mu\text{m}$ diam at the bottom of an etch pit) but contain no detectable heavy elements. A sample Auger spectrum from a defect in Ingot 020 (bottom) is shown in Fig. 5. Auger peaks are observed for Si, C, O, and Ar after sputtering the surface for ~ 10 min. Using the peak-to-peak amplitudes with appropriate elemental sensitivity factors (9), the Si to C ratio is found to be 2. This indicates that Si is in the form of a carbide, Si_2C . Figure 6 shows a 300 \times

micrograph and a corresponding carbon elemental map. Carbon is peaked in the center of the defect region.

Defect Compositional Gradients

To characterize and summarize defect compositional variations from Ingots 015 and 020, Auger spectra were obtained after sputtering each defect ~10 min. Peaks were observed for Si and Al, Fe, Ni, V, Ti, O, C, and S and varied with ingot and position within the ingot. Amplitudes varied with the type of defect, heavy metal, or carbide. The electron beam was positioned with the aid of the micrographs and subsequent elemental mapping information. An assessment of the amplitudes of the observed Auger peaks was used to qualitatively rank the ingots corresponding elemental concentration as large, medium, or small. These data were used to generate Fig. 7 and 8 which summarize the elemental composition of 20 defects studied from the two ingots. Detected elements are listed in the left column. The position of the sample in the ingot and the defect number are listed horizontally; each column represents the qualitative magnitude of the elemental concentration; the largest circle corresponds to the largest in rank and the smallest to the smallest in rank. In this way, the defect elemental composition can be viewed as a function of position in the ingot.

Although only four defects at most were studied at each ingot position, trends are readily observed from Fig. 7 and 8. In Ingot 015, most of the defects studied contain heavy elements (Fe, etc.). No carbide-type defects were observed within the sample of nine defects studied. Heavy element concentration, that is, the number of heavy elements incorporated in the defects, appears to be more concentrated at the ingot top. Fe-rich defects or Al-rich defects occur at the bottom. Also, O and S are more prevalent at the bottom of this ingot. V was not detected at the bottom. In comparison,

defects in Ingot 020 are Fe-rich throughout but a significant number of carbide-rich defects are also observed in the middle and bottom. In general, Ingot 020 contains fewer metallic elements, excluding Fe, than does Ingot 015. The gradient in the ingot is for heavy metal containing defects or particles to be concentrated at the ingot top and the lighter oxide/carbide type defects to be concentrated toward the bottom of the ingot.

Conclusions

Particulate defects in metallurgical-grade silicon are easily observed by Auger electron spectroscopy using a modest spatial resolution. Ion microsectioning by sputter profiling shows that the defects are composed of silicon alloyed or compounded with metals (Fe, Ni, Ti, V, and Al), as observed in some earlier studies of similar material (11), and carbon or oxygen to form carbides or oxides (12). Depth profiling the particles shows that the surface is oxide-rich and the bulk (>500Å) is relatively uniform in composition. Defect composition is position-dependent within a given ingot with light element-rich defects concentrated at the bottom and heavier element-rich defects concentrated at the top. This distribution is not consistent with what is expected or observed in studies (11) by other methods. Considerable differences in composition were noted for defects from Ingot 015 as compared with Ingot 020. This is due to the differences in impurities found in the raw feedstock materials used in forming the silicon ingots. In general, this study has demonstrated the utility of scanning Auger electron spectroscopy as applied to defect characterization in metallurgical grade silicon. It is also shown that impurities detected by bulk analysis methods (8) segregate as silicide-like particles during solidification.

ABSTRACT

In order to increase the conductivity of polysilicon lines used in polysilicon VLSI technology, silicides (e.g., WSi_2 , MoSi_2 , and TaSi_2) are presently being considered as overlays on the polysilicon lines. One advantage of a polysilicon/silicide structure is that, presumably, it is an oxidizable, self-passivating structure. Under certain oxidation conditions similar to those employed in polysilicon FET processing, voids may develop in the polysilicon layer and/or undesirable oxides lacking structural integrity may develop on the silicide surface. The oxidation mechanisms governing these phenomena are herein discussed.

As semiconductor device dimensions continue to decrease, the need to enhance the conductivity of doped polysilicon interconnections and gate electrodes in VLSI circuits becomes increasingly acute. Refractory metal silicides (e.g., TiSi_2 , WSi_2 , MoSi_2 , and TaSi_3) are presently being considered as overlays to, or replacement for, polysilicon lines as a means of increasing the conductivity of these lines while still retaining an oxidizable structure for self-passivation (1). This structure, consisting of a metal silicide layer directly on top of a polysilicon film, is referred to as the "polycide" structure while the word "silicide" refers only to the metal silicide layer on top of the polysilicon film.

The kinetics of the oxidation of the polysilicon/silicide (polycide) structure have been previously reported (2, 3). It has been found that atoms from the underlying polysilicon layer diffuse through the silicide film to the top silicide surface, where the silicon is oxidized, while the silicide layer itself is not oxidized. We have found (4) that, under certain oxidizing conditions, voids may form in the polysilicon layer and/or undesirable oxides which lack structural integrity may grow on the top surface of the silicide layer.

Geipel, *et al.* (5) have reported extensively on the microstructural, processing, and MOS characteristics of the polycide films. The purpose of this present article is to elaborate on the oxidation characteristics of the polycide structure and, in particular, to specify the conditions under which the aforementioned oxidation phenomena take place.

Experimental Procedure

In order to fully investigate the oxidation characteristics of the polycide structure, various silicon/silicide structures were formed. The standard procedure for forming the polycide structure consists of first depositing 400 nm of *in situ* phosphorus-doped polysilicon on 45 nm of thermal oxide grown on a $\langle 100 \rangle$ p-type silicon substrate. A 350 nm layer of WSi_2 is then coevaporated on top of the polysilicon layer in a dual *e*-beam evaporator. The entire structure is then annealed at 1000°C (1273 K) for 30 min in an inert ambient in order to homogenize and to lower the resistivity of the WSi_2 layer. The blanket polycide structure is then patterned by CF_4/O_2 plasma etching, using photoresist as an etch mask. The patterned polycide film is subsequently subjected to a dry-wet-dry oxidation process at 1000°C (1273 K) so as to form about 240 nm of oxide on top of the WSi_2 layer and a substantial oxide

layer along the edges of the patterned polycide structure.

In order to elucidate the polycide oxidation characteristics and the ensuing results, two slightly different structures were also formed and investigated. In one case, the polysilicon layer was deposited by *e*-beam evaporation of intrinsic silicon onto the thermal oxide which was immediately followed by the coevaporation of the WSi_2 layer. Thus, the intrinsic polysilicon and the WSi_2 layers were deposited sequentially in the same *e*-beam evaporator without breaking the evaporator vacuum between the deposition of the two layers. The resulting structure is similar to that of the usual polycide structure except that the polysilicon layer is intrinsic (undoped) instead of being doped with phosphorus. Some of the resulting blanket films were subsequently annealed and oxidized, while other films were annealed, patterned, and then oxidized.

A second structure was also formed which started with 45 nm of thermal oxide grown on a $\langle 100 \rangle$ p-type silicon wafer. The oxide was patterned to form 2 μm wide openings down to the substrate. A layer of WSi_2 was then coevaporated onto the oxide pattern and annealed at 1000°C (1273 K) in an inert atmosphere. This procedure resulted in regions of WSi_2 on top of 45 nm of oxide (regions A) and regions of WSi_2 on top of bare silicon (regions B), as illustrated in Fig. 1. This structure was then subjected to a dry-wet-dry oxidation cycle which resulted in the growth of 500 nm of oxide over both regions A and B.

Results and Discussion

Voids.—We have observed that the oxidation of the polysilicon/ WSi_2 structure under the aforementioned conditions results in the formation of voids in the polysilicon layer, as indicated in Fig. 2. In the patterned polycide structure, the voids form first and are largest near the edges of the patterned polycide structure. Smaller voids are generally observed away from the patterned edges. The voids range in size from a few tens of nanometers to over a micron in diame-

Fig. 1. Patterned oxide structure with WSi_2 coevaporated over the entire structure.

Key words: tungsten, tungsten silicide, silicide, polycide, refractory materials.

Fig. 2. Large voids are observed in the polysilicon layer of an oxidized polysilicon/ WSi_2 blanket structure.

ter. The smaller voids are bounded by the polysilicon/ WSi_2 interface whereas the larger voids span the entire thickness of the polysilicon film.

Crowder and Zirinsky (3) have shown that the oxidation mechanism of a polysilicon/ WSi_2 structure involves the diffusion of silicon atoms from the polysilicon layer to the top surface of the silicide film where the silicon is oxidized. Throughout the oxidation process, the silicide film remains relatively inert. The presence of voids in the polysilicon layer in the present experiments apparently results from a net flux of silicon atoms from this layer with an insufficient counterflux of other atoms.

The nonuniform distribution of the voids in the polysilicon layer and their variation in size indicates that vacancy supersaturation and nucleation occur at preferred sites. One possible cause of this effect is the presence of a silicon diffusion barrier, such as a polysilicon native oxide, at the polysilicon/silicide interface. This diffusion barrier would inherently have attendant weak points or pinholes through which the silicon could easily diffuse. Hence, these points would become sites for void nucleation and growth.

In order to ascertain if a polysilicon native oxide was present, and acting as at least a partial diffusion barrier, a layer of intrinsic silicon and a film of WSi_2 were sequentially deposited in an *e*-beam evaporator without breaking the evaporator vacuum of 5×10^{-6} torr between depositions. In this manner, the presence of a polysilicon native oxide was minimized, if not totally eliminated. Oxidation of blanket films produced in this manner resulted in no voids in the polysilicon layer. Thus, pinholes in the polysilicon native oxide contribute to the formation of large discrete voids in the polysilicon layer. (Although the *e*-beam evaporated polysilicon also differs from the conventional doped CVD polysilicon in that the latter has a high concentration of phosphorus, later experiments show that phosphorus is unrelated to void formation.)

In order to gain a more quantitative understanding of the factors contributing to the void formation, the pinholes in the polysilicon native oxide were simulated by $2 \mu\text{m}$ wide strips deliberately etched into a thermally grown oxide on a silicon wafer. (See Fig. 1.) Since the native oxide thickness on a bare, lightly doped single-crystal silicon wafer is believed to be thinner than that on heavily doped polysilicon, the presence of any native oxide on the silicon wafer in the etched spaces may be assumed not to inhibit the diffusion of silicon from the substrate. (Indeed, the experimental results support this assumption.) After deposition and annealing of the WSi_2 film on the patterned oxide, the wafer was oxidized and a uniformly thick 500 nm oxide was grown over both regions A (WSi_2 on oxide) and B (WSi_2 on the silicon substrate). Where a $2 \mu\text{m}$ wide B region lies between two $2 \mu\text{m}$

wide A regions or between a $2 \mu\text{m}$ and a $30 \mu\text{m}$ wide A region, voids do not form in the silicon substrate in the B regions (see Fig. 3). However, voids are observed exclusively in the silicon substrate in those B regions which separate two $30 \mu\text{m}$ wide A regions, as shown in Fig. 4.

Two things are immediately evident from Fig. 3 and 4. First, the role of phosphorus in void formation is excluded since the voids also form in the lightly boron-doped substrate, in a similar fashion to the voids which form in the phosphorus-doped polysilicon layer. Second, the micrographs clearly show the consumption of silicon atoms from the wafer, where the silicon diffusion is uninhibited. The consumption of silicon atoms either results in the movement of the WSi_2/Si interface (Fig. 3) or in the formation of voids (Fig. 4).

The relative area ratios of the silicon source (B regions) to the silicon drain (A regions) contributes to the formation of voids in the silicon substrate during oxidation. If A_A and A_B are the respective areas of regions A and B, and if $A_A/A_B = 15/2 = 7.5$, as in the case of Fig. 3, then voids do not form in the underlying silicon. Rather, the WSi_2 layer moves towards the silicon substrate in the opposite direction of the silicon flux. If $A_A/A_B = 30/2 = 15$, then voids will form in the silicon substrate, as observed in Fig. 4. These results indicate that the formation of voids in the polycide structure is dependent upon the local area fraction of the pinholes in the polysilicon native oxide. If the ratio of the oxidized area to the (polysilicon native oxide) pinhole area is large, then there is a high flux of silicon atoms through the pinhole. This results

Fig. 3. A cross-sectional view of alternating regions A ($\text{WSi}_2/\text{SiO}_2/\text{Si}$ substrate) and B (WSi_2/Si substrate). A uniformly thick oxide layer has grown over both structures. No voids are observed at the WSi_2/Si substrate interface. The A region at the left is $30 \mu\text{m}$ wide.

Fig. 4. A similar cross section to that in Fig. 3, except that the area ratio of region A to region B is much greater than 1. Large voids have formed in the silicon substrate in region B which is adjacent to two $30 \mu\text{m}$ wide A regions.

in a supersaturation of vacancies at the pinhole and subsequent void formation.

Based on the findings of Crowder and Zirinsky (3), it had been anticipated that the WSi_2 film would migrate toward the substrate during the oxidation process and thus provide the necessary flux of atoms to counter the flux of silicon atoms supplying the oxidation reaction. This is the case in Fig. 3, where A_A/A_B is small. In the case where voids form, however, the movement of the WSi_2 layer toward the substrate is almost nonexistent, so as not to be sufficient to offset the flux of silicon atoms from the polysilicon layer. Consequently, there is a net flux of vacancies from the free surface to the polysilicon layer.

This phenomenon of vacancy flux to counter an atomic flux is similar to the Kirkendall effect, after the work of Smigelskas and Kirkendall (7). If the excess vacancy concentration or vacancy supersaturation becomes great enough, vacancies will condense to form voids. Based on classical nucleation theory, Seitz (8) and Barnes and Mazey (9) concluded that homogeneous nucleation of voids by the accumulation of individual vacancies is improbable. However, if the vacancies condense on relatively large defects, i.e., by heterogeneous nucleation, the required supersaturation for void nucleation may be considerably less than that for homogeneous nucleation. In particular, Resnick and Seigle (10) and Balluffi (11) have concluded that the vacancy supersaturation need only be on the order of one percent for heterogeneous nucleation of voids. The observation that the smaller voids are bounded by the polysilicon/silicide interface implies that this interface acts as the nucleation site for the voids.

The predominance of voids at the edges of the patterned polycide structures results from the fact that the polysilicon layer in these regions must supply silicon for the oxidation of both the top polycide surface and the side of the patterned structure. Hence, the critical supersaturation for void formation occurs first at the edges of the patterned polycide structure and later within the interior of the pattern.

Once a void nucleates, it continues to grow and to act as a sink for vacancies, and as a source for silicon atoms. This feature of voids results from the void/polysilicon surface acting as a high diffusivity path for the silicon atoms from the interior of the polysilicon layer up to the polysilicon/silicide interface. Vignes and Badia (12) demonstrated in the Fe-Ni system that the presence of voids results in an abnormal increase in the interdiffusion coefficient. Therefore, the presence of voids enhances rather than inhibits the kinetics of the diffusing specie(s).

Once the silicon atoms from the polysilicon layer reach the silicide layer, they are capable of rapid lateral diffusion. Hence, the oxide on the silicide surface is of a uniform thickness despite a nonuniform distribution of voids in the polysilicon layer. From our oxide pattern in Fig. 1, it is apparent that the lateral silicon diffusion in WSi_2 is rapid enough to assure uniform oxide growth to a lateral range of at least 15 μm during oxidation. The high lateral diffusivity is apparently oxidation-induced where a lateral vacancy flux exists.

In order to analyze the factors contributing to the formation of voids, the diagram in Fig. 5 shows the basic structure involved in the potential formation of voids. Area A represents the total oxidized area that is supplied by the diffusion of silicon atoms from the WSi_2/Si interface of area a . A differential volume of $dV = a \cdot d$ is constructed just below this interface in order to monitor the atomic fluxes. The thickness, d , of this differential volume may be chosen to be sufficiently small so that the atomic and vacancy concentrations may be regarded as constant within this volume. Also, the atomic/vacancy diffusion through the

Fig. 5. Schematic of the patterned oxide structure with coevaporated WSi_2 after oxidation. The appropriate diffusive fluxes are also shown.

perimeter of this volume may be assumed to be negligible.

Consider three major atomic fluxes, \vec{J}_{Si} , \vec{J}_{WSi_2} , and \vec{J}'_{Si} , associated with this volume, dV . \vec{J}_{Si} is the flux of silicon atoms from dV to the oxidizing interface, \vec{J}_{WSi_2} is the flux of silicide molecules into dV , and \vec{J}'_{Si} is the flux of silicon atoms from the bulk silicon to dV by self-diffusion from the substrate.

In nonsteady-state conditions, the net atomic flux of atoms or molecules into dV will be negative due to a loss of silicon atoms. In order to conserve space or lattice sites within dV , there must be a counterflux of vacancies, \vec{J}_V , into dV , presumably from the oxidizing free surface. Therefore

$$\vec{J}_V + \vec{J}_{Si} + \vec{J}_{WSi_2} + \vec{J}'_{Si} = 0 \quad [1]$$

From Fick's second law, the relationship between \vec{J}_V and the vacancy concentration is

$$\nabla \cdot \vec{J}_V = - \frac{\partial N_V}{\partial t} \quad [2]$$

By applying Gauss's theorem to dV

$$\vec{J}_{V1} \cdot S_1 - \vec{J}_{V2} \cdot S_2 = - \int \left(\frac{\partial N_V}{\partial t} \right) dV - \frac{\partial}{\partial t} \int N_V dV \quad [3]$$

where \vec{J}_{V1} and \vec{J}_{V2} are the vacancy fluxes at the top and bottom surfaces of dV , respectively. Since areas S_1 and S_2 are both equal to area a , and since N_V is assumed to be constant throughout dV , Eq. [3] becomes

$$(\vec{J}_{V1} - \vec{J}_{V2})a = - \frac{\partial N_V(a \cdot d)}{\partial t} \quad [4a]$$

or

$$\vec{J}_{V1} - \vec{J}_{V2} = - d \frac{\partial N_V}{\partial t} \quad [4b]$$

At the top surface of dV , $\vec{J}'_{Si} = 0$; therefore, from Eq. [1]

$$\vec{J}_{V1} = - (\vec{J}_{Si} - \vec{J}_{WSi_2}) \quad [5]$$

where proper sign considerations have been taken. At the bottom surface of dV , $\vec{J}_{WSi_2} = \vec{J}_{Si} = 0$ or

$$\vec{J}_{V2} = - \vec{J}'_{Si} \quad [6]$$

Substituting Eq. [5] and [6] into Eq. [4], we get

$$\vec{J}_{Si} - \vec{J}_{WSi_2} - \vec{J}'_{Si} = d \left(\frac{\partial N_V}{\partial t} \right) \quad [7]$$

\vec{J}_{Si} is the flux of silicon atoms to be oxidized and it may be expressed as

$$\vec{J}_{\text{Si}} = \frac{\rho}{M} \frac{A}{a} \frac{dl}{dt} \quad [8]$$

where ρ is the density and M is the molecular weight of SiO_2 formed over area A on top of the silicide film. The variable l is the top oxide layer thickness and dl/dt is the oxidation rate.

Although no explicit expressions can be written for \vec{J}_{WSi} and \vec{J}'_{Si} , they are both driven by the vacancy concentration in dV . Therefore, to a first-order approximation

$$\vec{J}_{\text{WSi}} + \vec{J}'_{\text{Si}} = \alpha N_V \quad [9]$$

where α is a proportionality constant, assumed to depend only on temperature. Substituting Eq. [8] and [9] into Eq. [7], we arrive at the expression

$$\frac{\partial N_V}{\partial t} = \frac{\rho}{M} \frac{A}{a} \frac{dl}{dt} - \frac{\alpha N_V}{d} \quad [10]$$

In order to solve Eq. [10], we assume at $t = 0$ that the vacancy concentration is $N_V(0)$ and, afterward, a constant oxidation rate $dl/dt = r$ is maintained. It is easy to show then that

$$N_V(t) = \frac{\rho}{M} \frac{A}{a} \frac{r}{\alpha} \left[1 - \exp\left(-\frac{\alpha}{d} \cdot t\right) \right] + N_V(0) \exp\left(-\frac{\alpha t}{d}\right) \quad [11]$$

Equation [11] describes the change of vacancy concentration at the silicon surface immediately below the WSi_2 layer. For times $t \gg d/\alpha$, the exponential terms become negligible, and a steady-state value of N_V is reached, namely

$$N_V = \frac{\rho}{M} \frac{A}{a} \frac{r}{\alpha} \quad [12]$$

The steady-state value of N_V is proportional to the oxidation rate r and to the area ratio A/a . In practice, the oxidation rate does change with time (e.g., when an oxide layer has grown sufficiently thick that the oxidation rate becomes parabolic). However, the basic conclusion that N_V is proportional to r holds if the oxidation rate does not change appreciably over time on the order of d/α .

For a given oxidation rate or a set of oxidation rates, the area ratio parameter A/a will determine the steady-state vacancy concentration. If N_V is below a critical value N_V^c , no voids will form, but the WSi_2/Si interface will migrate toward the substrate due to the \vec{J}_{WSi} flux. If N_V exceeds N_V^c , vacancies will condense to form voids. The results depicted in Fig. 3 and 4 show the role the area ratio parameter A/a plays in determining whether or not N_V exceeds N_V^c .

In order to confirm the dependency of void formation on the oxidation rate, dl/dt , the structure in Fig. 1 was capped with 50 nm of CVD oxide prior to thermal oxidation. In this manner, the initial oxidation rate was substantially reduced from that of the uncapped structure. Accordingly, no voids formed in the B regions, even when the area ratio was as large as 15.

The vacancy concentration times α is shown in Fig. 6 as a function of oxidation time and area ratio, A/a . The curves are based upon oxidation rate data produced by Roberts (13) and upon Eq. [10]. As can be observed from the graph, the structure with the A/a ratio represented by curve 1 has the highest vacancy concentration at the start of the wet oxidation cycle, and it is this structure that results in voids in the substrate. The oxidation conditions represented by curves 1 and 2 do not result in voids in the substrate. Thus, the critical vacancy concentration to nucleate voids must lie between the peak concentrations of curves 1 and 3 for this structure.

Fig. 6. Vacancy concentration in the substrate as a function of the patterned oxide structure in Fig. 5 and of the oxidation cycle.

Silicide oxidation.—Another phenomenon that may occur upon oxidation of the polycide structure is that the silicide layer itself may be oxidized. Several authors have looked at the oxidation of tungsten silicide films deposited on SiO_2 (2, 14-16), on single-crystal silicon (14), and on polysilicon (2, 16). Mohammadi *et al.* (14) have demonstrated that dry oxidation of WSi_2 films on SiO_2 at 1000°-1200°C results in the formation of SiO_2 and WO_3 , the latter of which is a volatile oxide at these temperatures. Sinha (15) has shown that when WSi or WSi_2 are deposited on SiO_2 and oxidized at temperatures at or above 900°C, the silicon in the silicide film oxidizes first and then the remaining free tungsten oxidizes.

This results in the silicide film breaking up and lifting off the substrate in localized areas, and the oxidation is then regarded as being "destructive." Zirinsky *et al.* (2) have demonstrated that, when deposited on polysilicon, the WSi_2 layer maintains its integrity when subjected to steam oxidation.

In the course of the present experiments, blanket WSi_2 films were deposited on polysilicon films and on oxidized silicon wafers. These films were then oxidized at 1000°C in wet oxygen (steam) for 12 or 22 min; the results are shown in Fig. 7. The lighter regions on the wafers are where the silicide layer has been destructively oxidized. After an oxidation time of 12 min, more than half of the WSi_2 layers on the SiO_2 film has oxidized. After 22 min, nearly all of the silicide layer on the SiO_2 film had oxidized, but only a small portion of the silicide on the polysilicon film had oxidized. The results of this experiment suggest that the presence of an underlying oxide film results in the oxidation of the silicide layer, and the rough oxide region propagates with oxidation time.

An SEM micrograph of a region where the silicide film in the polycide structure had begun to oxidize is

Fig. 7. Blanket WSi_2 films on polysilicon or on SiO_2 . The wafers have been oxidized in wet oxygen at 1000°C for the specified times. The light regions are where the WSi_2 layer has been "destructively" oxidized.

Fig. 8. The polycide structure in which the silicide layer has been oxidized. Voids are observed in the polysilicon layer and at the silicide/oxide interface.

shown in Fig. 8. In the micrograph, voids are present in the polysilicon film, indicative of pinholes in the polysilicon native oxide. The oxidized silicide layer is $0.95 \mu\text{m}$ thick, which is about three times thicker than the as-annealed silicide film. Finally, a layer of presumably SiO_2 is on top of the oxidized silicide layer, and small voids are observed at the SiO_2 /silicide interface. The expansion of the silicide film and the formation of voids at the SiO_2 /silicide interface probably result from the formation of the volatile WO_3 compound within the silicide film.

Although silicon diffuses from the polysilicon layer during the oxidation process, apparently the rate of silicon oxidation is greater than the diffusional supply of silicon from the polysilicon layer. Consequently, the silicide film itself also starts to oxidize. This is believed to occur when there are extended native oxide regions on the polysilicon layer, so that the A/a ratio is very large.

Summary

Several unique features, with regard to the oxidation of the polycide structure, have been discussed in this paper and are summarized as follows:

1. Upon oxidation of the polycide structure, voids may form in the polysilicon layer. These voids nucleate at the polysilicon/silicide interface and grow into the polysilicon film itself.

2. The voids are due in part to a polysilicon native oxide which acts as a barrier to the diffusion of silicon from the polysilicon to the top silicide surface. The diffusion of silicon from the polysilicon films takes place at localized regions at the silicide/polysilicon interface where there are believed to be pinholes in the native oxide.

3. As a result of the localized diffusion of silicon from the polysilicon layer, there is a counterflux of vacancies from the free surface to the polysilicon layer. These vacancies condense to form voids in the polysilicon layer.

4. Two process and/or material parameters influence the formation of voids in the polysilicon layer. The first of these is the relative area of pinholes in

the polysilicon native oxide. If the ratio of the area being oxidized, A , to the area of the pinhole in native oxide, a , is nearly equal to 1, then voids are not likely to form. If, however, $A/a \gg 1$ then voids will tend to form. Consequently, voids are more prevalent near the edges of patterned polycide structures than in the interior of such structures. The second factor which promotes void formation is a high oxidation rate.

5. Despite the formation of voids in the polysilicon layer, the oxide above the silicide film is of uniform thickness and does not reflect the presence or absence of voids in the underlying polysilicon film. This uniform oxide thickness results from the rapid lateral diffusion of silicon in the silicide film relative to the oxidation rate of silicon at the oxide/silicide interface.

6. Under certain oxidation conditions, the silicide layer itself may oxidize, resulting in an expansion or thickening of the silicide layer up to three times its original thickness. The oxidation of the silicide layer is favored by the same oxidation conditions that promote voids in the polysilicon layer, namely, rapid oxidation rates and an oxide layer which inhibits the diffusion of silicon from an underlying silicon source.

Acknowledgments

The authors would like to thank B. L. Crowder for pointing out the role of polysilicon native oxides. We also wish to thank H. J. Geipel, E. E. Gardner, and P. C. Velasquez for many helpful discussions during the course of this work.

Minimum Wafer Thickness by Rotated Ingot ID Wafering

C. P. Chen and M. H. Leipold

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91190

ABSTRACT

The efficient utilization of materials is critical to certain device applications such as silicon for photovoltaics or diodes and gallium-gadolinium-garnet for memories. A variety of slicing techniques has been investigated to minimize wafer thickness and wafer kerf. This paper presents the results of analyses of ID wafering of rotated ingots based on predicted fracture behavior of the wafer as a result of forces during wafering and the properties of the device material. The analytical model indicated that the minimum wafer thickness is controlled by the depth of surface damage and the applied cantilever force. Both of these factors should be minimized. For silicon, a minimum thickness was found to be approximately 200×10^{-6} m for conventional sizes of rotated ingot wafering. Fractures through the thickness of the wafer rather than through the center supporting column were found to limit the minimum wafer thickness. The model suggested that the use of a vacuum chuck on the wafer surface to enhance cleavage fracture of the center supporting core and, with silicon, by using $\langle 111 \rangle$ ingots could have potential for reducing minimum wafer thickness.

Some devices are much more dependent on material cost than others. Such devices include photovoltaics, high power diodes, and magnetic bubble memories. Improved wafering technology to reduce both wafer thickness and kerf loss has been employed in an attempt to increase material utilization. One approach which has been proposed and investigated is to rotate the ingot during ID wafering. This permits the use of thinner blades because of the reduced depth of cut. Additionally, the smaller lever arm of the unsupported wafer should reduce stresses and tendency to fracture. The apparent advantages of this technique have not been realized in practice and this study was made in an attempt to analyze the reasons for the unsatisfactory performance and to determine if fundamental limitations existed or if further modifications to the technique might be useful. Experimental efforts to use rotated ingot ID wafering generally resulted in fracture of the wafers as wafer thickness was reduced. The failure usually took the form of circular cracking often to the point where the entire center of the wafer was broken out. This occurred in spite of efforts to precisely align the axis of the rotated ingot perpendicular to the ID blade.

In a previous paper, Ref. (1), fracture mechanics analysis was utilized to derive an equation describing the stress conditions of a wafer during conventional ID wafering. This equation predicted the minimum wafer thickness as a function of diameter for ID sawing. The required wafer thickness increased with increasing wafer diameter and, for silicon, was appreciably smaller than existing SEMI standard.

In this paper, fracture mechanics concepts were extended to analyze the loading conditions of a wafer during rotation ingot ID wafering. It is anticipated that this analytical model can provide a guideline estimating the allowable wafer thickness *vs.* diameter for rotation ingot ID wafering in terms of fracture mechanics parameters. The analysis was conducted for silicon but would be applicable to other materials using appropriate input data.

Fracture Mechanics Model

A wafer with center support subjected to a cantilever force can be considered to represent the stressed condition of a wafer during rotation ingot ID wafering as shown in Fig. 1. The diameter of the rigid center support, d , can be considered to be the diameter of the center core (uncut area) during rotation ingot wafering. The applied cantilever force, P , on the wafer may be due to saw blade vibration and surface tension; it increases with cutting rate (1). The force on a wafer during slicing could be either a distributed loading or

a concentrated force. In either case, an equivalent concentrated force P (as shown in Fig. 1) could be used to describe the force conditions affecting a wafer during rotation ingot ID slicing.

Fracture of materials is the result of the extension of a pre-existing flaw under stress. Fracture mechanics defines that (for a given stress level) the flaw size required for the onset of rapid propagation and fracture is called the critical crack size (a_c). This critical size in turn depends upon the values of the critical stress intensity factor (K_{IC}) for the material. Therefore, the fracture strength of material is controlled by a_c and K_{IC} of the material. For a small semicircular flaw, the relationship equation of fracture stress (σ) as a function of a_c and K_{IC} was derived (1) and can be approximately expressed as

$$\sigma = \frac{K_{IC}}{\sqrt{\pi a_c}} \quad [1]$$

Thus, to determine the failure in any direction, it is necessary to determine σ from K_{IC} and a_c . K_{IC} is a material constant, although directional, and a_c is a function of wafering technology, related to the surface damage.

Application of a force P at the edge of the wafer results in a stress both in the wafer and in the center support (see Fig. 1). These stresses can result in failure by propagation of microcracks in directions A or B, respectively. The propagation through the wafer thickness (A direction) destroys the wafer; propagation through the central core (B direction) results in a usable wafer with a central nib.

Considering first the stress in the wafer (failure in direction A), the maximum stress in the wafer was

Fig. 1. A circular thin wafer, center supported, is subjected to a cantilever force P .

Key words: silicon, photovoltaic, fracture mechanics analysis.

found to occur at the edge of the center support and can be expressed analytically (2) in an equation

$$\sigma_A = \frac{P}{t^2} \beta \tag{2}$$

where σ_A = stress in the wafer at the edge of the center support, P = applied cantilever force, t = wafer thickness, $\beta = \frac{3}{\pi} \sum_0^\infty e_n$, and $\sum_0^\infty e_n$ is Fourier series in which e_n is a function of ν = Poisson's ratio, d = diameter of center support, D = wafer diameter, $n = 0, 1, 2, \dots \infty$.

Substituting Eq. [1] into Eq. [2], the wafer thickness, t , can be written as

$$t^2 = \frac{\sqrt{\pi a_{cA}}}{K_{IC}} P_A \beta \tag{3}$$

where a_{cA} = critical flaw size for propagation in direction A and P_A = allowable force to cause crack propagation in direction A. A computer calculation of β as a function of d/D for n up to 30 and $\nu = 0.22$ for silicon (3) is shown in Fig. 2. Thus Eq. [3] expresses the relationship between the required wafer thickness and diameter.

Next, considering the tendency of the stress in the center support to cause crack propagation in direction B, the fiber stress, σ_B can be expressed from structure analysis (4) as follows

$$\sigma_B = \frac{16P_B D}{\pi d^3} \tag{4}$$

Substituting Eq. [1] into Eq. [4], the allowable applied force (P_B) of the center core in terms of wafer diameter and fracture mechanics parameters, can be written in the form

$$P_B = \frac{\sqrt{\pi}}{16} \frac{K_{IC} d^3}{\sqrt{a_{cB}} D} \tag{5}$$

In this equation, P_B and a_{cB} are allowable force and critical crack size, respectively, for the center core. However, in this case, the total length of the crack in B direction should be the depth of the cut plus the surface damage flaw in the center core.

Application of Analytical Model to Silicon

Application of the model to ID wafering of rotated ingots is straight-forward. The analysis here will be limited to silicon but can be applied to other materials. The fracture mechanics studies (5) on single crystal silicon found that the critical stress intensity factor K_{IC} in several crystalline planes is as follows

$$\begin{aligned} K_{IC} &= 0.82 \text{ MNm}^{-3/2} \text{ in } \{111\} \\ K_{IC} &= 0.90 \text{ MNm}^{-3/2} \text{ in } \{110\} \\ K_{IC} &= 0.95 \text{ MNm}^{-3/2} \text{ in } \{100\} \end{aligned} \tag{6}$$

Thus the easy fracture direction is {111}. However, because the differences in K_{IC} are small, the difference

Fig. 2. Factor β as function of d/D for silicon

will be ignored and all calculations will use {111} fracture data. Figure 3 shows the difference between {100} and {111} fracture in the B direction. The typical wafer surface damage from ID sawing was measured (6) and found to be approximately 50 μm or

$$a_c = 50 \times 10^{-6} \text{m} \tag{7}$$

Substituting these values of K_{IC} and a_c into Eq. [3], the allowable applied force, P_A , for wafer failure at several wafer thicknesses for slicing $100 \times 10^{-3} \text{m}$ ingots is shown in Fig. 3. Equation [3] shows that P_A decreases with increasing a_{cA} .

As shown in Fig. 3, the minimum required wafer thickness without cracking at the very small values of d (e.g., $3 \times 10^{-3} \text{m}$) is very sensitive to the force P (in general $P = P_A = P_B$). Therefore, decreasing the cutting rate near the small d region is very important for rotation ingot wafering in order to minimize deflection of the wafer and P .

Predictions for the wafering operation from Fig. 3 can be summarized as follows:

1. At each wafering thickness, the allowable force on the wafer decreases with decreasing center core diameter. In other words, the probability of cracking a wafer during rotation ingot wafering increases with increasing depth of cutting.

2. The allowable applied force P for a wafer decreases very rapidly as the center core diameter is reduced to a very small value (e.g., $3 \times 10^{-3} \text{m}$). Therefore, cracks in the wafer in direction A are usually found near the center of the wafer from rotation ingot wafering.

3. During typical conventional ID slicing at a cutting rate of $51 \times 10^{-3} \text{m/min}$, "P" has been estimated (1) to be 0.5N. Using $P = 0.5 \text{N}$, a $200 \times 10^{-6} \text{m}$ -thick wafer is very likely to crack at $d = 50 \times 10^{-3} \text{m}$, and a $300 \times 10^{-6} \text{m}$ -thick at $d \approx 14 \times 10^{-3} \text{m}$.

A successful rotation ingot wafering occurs when a wafer is broken off from the ingot at the center core without generating cracks in the wafer. According to this model, the force for crack propagation in the "B" direction must be reached before that in the "A" direction. As mentioned before, the total crack size in Eq. [5] is expressed as

$$a_{cB} = \frac{1}{2} (D - d) + a_c \tag{8}$$

Since $a_c \ll \frac{1}{2} (D - d)$, the crack size in B direction can be written as follows

Fig. 3. Fracture force (P) vs. core diameter for rotated ingot wafering of 100 mm wafers.

$$a_{cB} = \frac{1}{2} (D - d) \quad [9]$$

Substitution of Eq. [9] into [5], the allowable fracture force (P_B) of the center core is written in a form

$$P_B = \frac{\sqrt{2\pi}}{16} \frac{d^3}{D\sqrt{D-d}} K_{IC} \quad [10]$$

Using $K_{IC} = 0.82 \text{ MNm}^{-3/2}$, the fracture force P_B in Eq. [10] for the center support core in B direction as a function of core diameter is plotted in Fig. 3. If any applied force P_B is again equivalent to 0.5N, the fracture of the wafer center supporting core for a $100 \times 10^{-3}\text{m}$ diameter wafer can occur. In Fig. 3, at $d = 2.3 \times 10^{-3}\text{m}$, Eq. [5] states that P_B vs. the d is independent of the wafer thickness. Thus $600 \times 10^{-6}\text{m}$ thick wafers can be sliced at regular cutting speed (P equivalent = 0.5N) and the center core will fracture at $2.3 \times 10^{-3}\text{m}$ (see point X on Fig. 3). A $500 \times 10^{-6}\text{m}$ thick wafer can be sliced by reducing cutting force (0.5N) from near $d = 3.5 \times 10^{-3}\text{m}$ at a rate following its P vs. d curve to $d = 1.9 \times 10^{-3}\text{m}$ where fracture of the center core occurs at $P = 0.29\text{N}$ (see point Y on Fig. 3). Wafer thickness smaller than $300 \times 10^{-6}\text{m}$ is possible as the force P be further reduced to smaller than 0.05N. This analytically calculated d value and wafer thickness have the same magnitude as that observed in typical silicon wafers (7).

Special procedures in wafering have demonstrated the ability to reduce surface damage to $8 \times 10^{-6}\text{m}$ (8). Substituting $a_{cA} = 8 \times 10^{-6}\text{m}$ into Eq. [3], the curves of P vs. d for $t = 100 \times 10^{-6}\text{m}$, $200 \times 10^{-6}\text{m}$, and $300 \times 10^{-6}\text{m}$ are plotted in Fig. 3. The intersections of these curves and P_B curves suggest that a minimum wafer thickness can be further reduced to less than $200 \times 10^{-6}\text{m}$. Therefore, this analytical model suggests that it is very important to minimize the wafer surface damage and the applied force, especially at small d region, to achieve the minimum usable wafer thickness.

The present rotation ingot wafering of silicon is mostly carried out with $\langle 100 \rangle$ ingots. Because the fracture strength of the material is directly proportional to K_{IC} , as shown in Eq. [1], the allowable fracture force for the center core in $\langle 100 \rangle$ can be greater than that in $\langle 111 \rangle$ axis, because K_{IC} on $\{100\}$ is greater than K_{IC} on $\{111\}$ as shown in Eq. [6]. Thus, if $\langle 111 \rangle$ ingots were used, easier fracture in the central core would occur. However, the difference is small for silicon, as shown in Fig. 3. A possible useful feature of $\langle 111 \rangle$ silicon ingot is that the fracture surface of silicon in $\{111\}$ was found (5) to be a clean cleaved fracture, while fracture surface in other crystalline planes reveals rough crack branching.

It may also be possible to control fracture by increasing the applied stress in B direction. This might be accomplished by means of a uniform force on the wafer parallel to its axis (e.g., by a vacuum chuck). The application of a vacuum chuck to rotation ingot wafering is shown schematically in Fig. 4. The total vacuum force on a wafer can be calculated by

$$F = q \frac{\pi D^2}{4} \quad [11]$$

where q = vacuum pressure, max q is 1 atm = 0.1 MNm^{-2} .

The relationship of D and d can be expressed in a form

$$\frac{D}{d} = \frac{\sqrt{\sigma_n}}{q} \quad [12]$$

where σ_n = nominal stress in the center core.

Because of the existence of stress concentration in a deep groove, Eq. [12] can be rewritten as

Fig. 4. Schematic showing the application of vacuum chuck to rotation ingot wafering.

$$\frac{D}{d} = \frac{\sqrt{\sigma_c}}{k_t q} \quad [13]$$

where k_t = stress concentration factor in the bottom of the groove and σ_c = stress on the flaw.

The stress concentration factor, k_t , for a grooved bar in tension is normally determined from the ratio of groove root radius (r) and d and D . For rotation ingot ID slicing, the typical value of r/d is very small (e.g., 0.02), and D/d is very large (e.g., 20). Available data (9) do not cover the appropriate range of values for r , d , and D , and thus k_t is imprecise. However, this factor in a machined notch of brittle materials has a very large value because microcracks are usually found in the bottom of the notch. The radius of the microcrack (r) may be on the order of 10^{-9}m and the value of r/d can be an extremely small value. K_t is taken conservatively here as 15, but could easily be as high as several hundred.

Assume that

$$\begin{aligned} D &= 100 \times 10^{-3}\text{m} \\ k_t &= 15 \\ K_{IC} &= 0.82 \text{ MNm}^{-3/2} \\ a_{cB} &= 50 \times 10^{-6}\text{m} \end{aligned}$$

Substituting these values into Eq. [1] and [13], the calculations indicated that the fracture of the center core occurs at $D/d = 6.6$ or $d = 15 \times 10^{-3}\text{m}$, as indicated by the line in Fig. 3. In this case, considerable saving in cutting time and blade wearing can be expected. In addition, this auxiliary force on the wafer can increase the clearance for the blade. It should be noted that it is important to use an ingot in which minimum K_{IC} is aligned parallel to the wafer surface ($\{111\}$ for Si) to maintain clean cleaved fracture in B direction as mentioned previously.

These results suggest that rotational ID wafering does have potential for very thin wafers. The analysis should be interpreted only that such an approach is possible. Technical difficulties, such as proper lubrication, minimization of vibration, and control of blade entry into the ingot, are not minor.

Conclusions

1. An analytical model of a thin circular wafer, supported by a center core and subjected to an equivalent cantilever force at the wafer edge was used to describe the loading condition of a wafer during rotation ingot ID wafering.

2. A fracture mechanics concept was found to be useful to derive the relationship equation for the allowable wafer thickness vs. diameter as

$$t^2 = \frac{\sqrt{\pi a_{cA}}}{K_{IC}} P_A \beta \quad [14]$$

where β is a factor relating to the ratio of D and d and Poisson's ratio ν .

3. It is important to reduce applied force "P" by minimizing saw vibration and cutting rate in order to

maintain minimal wafer thickness, especially at small center core diameter.

4. The allowable thickness is dependent upon the depth of surface damage (flaw size a_c) of the wafer. The minimum wafer thickness can be further reduced to approximately 200×10^{-6} m for the conventional wafer diameters of 100×10^{-3} m when the depth of wafer surface damage can be reduced to less than 8×10^{-6} m.

5. Proper alignment of easy fracture direction ($\{111\}$ for silicon) with the wafer surface and use of a vacuum chuck to assist fracture in the center core direction is shown to have great potential to obtain minimum thickness wafers. Considerable saving in cutting time can be expected.

The Semiconductor-Electrolyte Interface

Photocurrent and Related Parameters in Cadmium Telluride

J. L. Sculfort,* R. Triboulet,¹ and P. Lemasson*

Laboratoire d'Electrochimie Interfaciale du CNRS 92195 Meudon Principal Cedex, France

ABSTRACT

The CdTe-aqueous electrolyte interface is studied both in the dark and under illumination for n- and p-type single crystals. From the anodic and cathodic currents are deduced information about the stability of the semiconductor electrode which agrees fairly well with decomposition potentials calculated from thermodynamic data. For n- and p-CdTe, hydrogen evolution prevails to cathodic decomposition. For n-CdTe, linear Schottky plots are obtained only after a photoetching in 1M NaOH solution. The flatband potential then measured is consistent with that obtained for p-CdTe. Both are pH independent. The minority carrier diffusion length and the Urbach's slope are deduced from photoelectrochemical measurements. They change with the dopant and the free carrier concentration and agree with each other. Information is then obtained about the quality of the samples.

The II-IV compound cadmium telluride presents different properties (energy gap ca. 1.5 eV, direct transition, n- or p-type conductivity, large atomic numbers of the components, etc.) which make it attractive for applications as different as gamma and x-ray detectors or photovoltaic devices (1). However, the practical use of this material up to now is limited mainly by the imperfections of the crystalline structure both in the bulk and in surface. For example, the diffusion length of the minority carrier, a parameter which reflects the perfection of the crystal, remains generally small (ca. 1 μ m) thus limiting, e.g., the efficiency of CdTe solar cells.

In electrochemistry, cadmium telluride received attention mainly in view of solar applications. However, n-CdTe presents a poor stability under illumination in aqueous solvents; further, the problems of the electrode surface preparation are numerous and not yet solved (2). The p-type cadmium telluride also received attention, but the flatband potential value severely hinders its use as a photocathode in a liquid photovoltaic cell though the electrochemical behavior appears to be simpler than for n-type (3).

In the present work, we present the electrochemical behavior of n- and p-type CdTe in supporting electrolyte (pH range 0-14) both in the dark and under il-

lumination. Thus an attempt is presented to correlate the nature of the dopant and the free carrier density with two selected physical parameters (minority carrier diffusion length and Urbach's slope of the absorption tail).

Experimental

Single crystal cadmium telluride wafers are cut from ingots grown either by a Bridgman technique (n-type) or the traveling heater method (THM) (p-type). Various doping and free carrier concentrations are used:

n-type: 1.5×10^{15} cm⁻³ not intentionally doped
 8×10^{17} cm⁻³ In doped

p-type: 4×10^{15} cm⁻³ not intentionally doped
 3×10^{16} cm⁻³ and 7×10^{16} cm⁻³ P doped.

The electrode surface in contact with the electrolyte is ca. 10 mm² and the back face is provided with an ohmic contact:

n-type: In-Hg amalgam under H₂ atmosphere for 2 mn at 300°C

p-type: a chemical deposit of gold is diffused by heating to 300°C in H₂ atmosphere for 3 mn

In each case, a gold wire is soldered to the ohmic contact and the electrodes are glued in epoxy resin except the front face which is polished to a mirror finish (dia-

Key words: II-VI semiconductor, electrode, optics, doping.

mond paste 0.25 μm). Prior to electrochemical operation, the electrodes are chemically etched: 15s in 1% bromine-methanol solution at ca. 5°C (n-type) and 3 mn in 10M NaOH solution at 40°C (p-type). These etchants preserve the surface stoichiometry of the samples and avoid the growth of oxide layers that are too thick (4).

Electrolytes are prepared from Millipore purified water and high purity grade chemicals (Merck suprapur). Stirring of the solution is achieved by gas bubbling (O_2 or Ar) when necessary. The reference electrode is a mercury-mercurous sulfate electrode denoted by MSE (0V vs. MSE = +0.65V vs. NHE). NHE: normal hydrogen electrode.

A 250W tungsten halogen lamp is used as a light source, and light fluxes are measured by means of a silicon photodiode (PIN 10D-SB, UDT). Measurements consist mainly of steady-state current voltage curves in the dark and under illumination and of impedance measurements. Further details about the experimental techniques have already been published (5).

Results and Discussion

Steady-state current-voltage curves for n- and p-type CdTe in the dark and under illumination at pH 0 and 14 are presented in Fig. 1 and 2. The main results coming from these measurements are collected in Table I and II. We notice first that the observed reduction and oxidation currents, correlated to reactions, are in good agreement for n- and p-type electrodes both at pH 0 and 14. Further experiments at intermediate pH values have been achieved whose results match well those reported here; therefore in the following we deal only with pH 0 and 14. Thermodynamic energy values used in the computation of the standard potentials E_0 are taken from the literature (6).

Oxidation reactions.—According to previous work (3a), possible decomposition reactions are

pH = 14

Such reactions are possible with n-type materials in the dark only at large band bendings. They can take place at illuminated n-type electrodes or p-type electrodes in the dark as soon as holes are available in surface.

Experimentally, anodic reactions are observed at potentials E_{ox} such as

Fig. 1. Typical current and photocurrent (modulated) vs. potential characteristics for CdTe/1M NaOH junctions. The photocurrent is measured at 850 nm. n-CdTe: $1.5 \times 10^{15} \text{ cm}^{-3}$, dashed line; p-CdTe: $3 \times 10^{16} \text{ cm}^{-3}$, full line.

Fig. 2. Typical current and photocurrent (modulated) vs. potential characteristics for CdTe/1M HClO_4 junctions. The photocurrent is measured at 850 nm. n-CdTe: $1.5 \times 10^{15} \text{ cm}^{-3}$, dashed line; p-CdTe: $3 \times 10^{16} \text{ cm}^{-3}$, full line.

$$\text{pH} = 0 \quad \begin{cases} \text{n-type (illuminated)} & E_{\text{ox}} \cong -0.8\text{V vs. MSE} \\ \text{p-type (dark)} & E_{\text{ox}} \cong -0.8, -0.7\text{V vs. MSE} \end{cases}$$

$$\text{pH} = 14 \quad \begin{cases} \text{n-type (illuminated)} & E_{\text{ox}} \cong -0.8\text{V vs. MSE} \\ \text{p-type (dark)} & E_{\text{ox}} \cong -0.95\text{V vs. MSE} \end{cases}$$

At both pH's, the experimental potential values are in good agreement with the thermodynamic reactions reported in Eq. [1]-[2]. From the above considerations, it is possible to deduce that the oxidation process of CdTe takes place without energy barrier as soon as the free carriers involved (holes) are available in sufficient amount close to the semiconductor surface.

In the dark, at n-CdTe electrodes, anodic decomposition takes place at potentials greater than +0.8 to +1.0V and only for free carrier densities sufficiently large ($> 10^{17} \text{ cm}^{-3}$). We deduce then that the associated processes do not involve holes from the valence band but electrons from species in solution which are injected in the conduction band by tunneling. Such processes necessitate large band bendings and have been observed with other n-type semiconductors such as ZnSe (7).

Reduction reactions.—These processes seem more complicated than in the former case due to the possibility of hydrogen evolution.

Experimental evidence of cathodic currents takes place in the following potential ranges (Table II)

$$\text{pH} = 0 \quad \begin{cases} \text{n-type (dark)} & E_{\text{red}} \leq -0.8, -1.0\text{V vs. MSE} \\ \text{p-type (illuminated)} & E_{\text{red}} \leq -0.7\text{V vs. MSE} \end{cases}$$

$$\text{pH} = 14 \quad \begin{cases} \text{n-type (dark)} & E_{\text{red}} \leq -1.0\text{V vs. MSE} \\ \text{p-type (illuminated)} & E_{\text{red}} \leq -1.0\text{V vs. MSE} \end{cases}$$

These experimental values must be correlated with the thermodynamic data (3a)

Table I. Anodic and cathodic currents at the CdTe/1M HClO₄ interface

Potential (V)	-3.0	-1.8	-1.65	-1.2	-0.8	-0.73	-0.7	-0.65	-0.3	+1.0

particular indications a)		V_{fb}^n	E_d^n			E_d^p		H^+/H_2	V_{fb}^p	

a) V_{fb}^n is the flat band potential for n-CdTe ; V_{fb}^p for p-CdTe

E_d^n : standard potential of the cathodic decomposition $CdTe + 2H^+ + 2e^- \rightarrow Cd + H_2Te$

E_d^p : standard potential of the anodic decomposition $CdTe + 2p^+ \rightarrow Cd^{++} + Te$

Table II. Anodic and cathodic currents at the CdTe/1M NaOH interface

Potential (V)	-3.5	-2.11	-1.8	-1.46	-1.2	-1.0	-0.97	-0.8	-0.3	+0.8
n-CdTe	← reduction					← no current			→ oxidation →	
n-CdTe	← reduction					no current			→ oxidation →	
p-CdTe	← reduction	← no current						→ oxidation		
p-CdTe	← reduction						→ oxidation			
particular indications a)		E_d^n	V_{fb}^n	H_2O/H_2			E_d^p		V_{fb}^p	

a) V_{fb}^n and V_{fb}^p have the same meaning as in table I.

E_d^n : standard potential of the cathodic decomposition $CdTe + 2e^- \rightarrow Cd + Te^{--}$

E_d^p : standard potential of the anodic decomposition $CdTe + 2OH^- + 2p^+ \rightarrow HCdO_2^- + H^+ + Te$

It appears that hydrogen evolution reaction may compete with decomposition. At p-type electrodes and for small photon fluxes ($< 10^{14} \text{ cm}^{-2}$), hydrogen can be experimentally produced without further modification of the electrochemical behavior. At n-type materials, hydrogen evolves in the dark at potential below $-1.0V$ vs. MSE and the electrode remains unperturbed. The latter case will be discussed later together with the determination of the flatband potential value.

However, at p-type electrodes and pH's 0 and 14 a cathodic decomposition of the semiconductor together with hydrogen evolution can be evidenced for large band bendings (potential below $-3V$ vs. MSE) and large photon flux thus suggesting that decomposition is a slow process as compared to hydrogen evolution.

Influence of dissolved oxygen.—This influence is noticeable with p-type materials for which a dark cathodic current exists correlated to the presence of

oxygen in solution. This dark current is diffusion limited thus suggesting that oxygen reduction takes place by hole injection into the semiconductor valence band. Due to the lack of influence of the addition of H_2O_2 in solution, the mechanisms of oxygen reduction are not yet clear.

Flatband potential.—In the previous sections, the slight influence of pH on the experimental potential values must be outlined. Such an observation suggests that the flatband conditions do not depend on the pH. In this direction, determination of the flatband potential V_{FB} has been achieved both by capacitance (C) and modulated photocurrent (i_{ph}) measurements. In the latter case, a linear plot i_{ph}^2 vs. V enables the determination of V_{FB} (8).

N-type.—A good Schottky behavior (linear plot C^{-2} vs. V) is obtained only after a photoetching of the electrode (3 mn at $V = +1.0V$ vs. MSE in 1M NaOH solution). The importance of photoetching for II-VI semiconductor electrodes has recently received particular attention (9). This treatment is necessary to obtain reproducible results in the whole pH range. Results are presented in Fig. 3. We found

$$V_{n_{FB}} \simeq -1.8V \text{ vs. MSE}$$

a result in fair agreement with literature (2). This value is almost pH independent.

P-type.—The Schottky behavior is obtained with only the chemical etching (see above). The result is

$$V_{p_{FB}} \simeq -0.3V \text{ vs. MSE}$$

The plot of i_{ph}^2 vs. V is shown in Fig. 3 and is pH independent.

We observe that

$$|V_{n_{FB}} - V_{p_{FB}}| \sim E_g = 1.5 \text{ eV}$$

The invariance of V_{FB} with pH may probably be accounted for by a specific interaction between the aqueous electrolyte and the telluride anion of CdTe. Such a behavior has already been observed for other II-VI compounds, especially for CdS (10), and explained by a similar argument.

We now compare the potential V_{H_2} at which hydrogen evolution takes place at n-CdTe (see above) and $V_{n_{FB}}$. We have

$$V_{H_2} \simeq -1.0V \text{ vs. MSE}$$

and the difference

$$|V_{H_2} - V_{n_{FB}}| \simeq 0.8V$$

is very large. A similar phenomenon is observed with many other n-type semiconductors and particularly n-GaP for which a specific interaction with H^+ ions has been invoked (11). In view of the results obtained with p-CdTe electrodes, a similar assumption seems possible here.

Material characterization.—The above results suggest that the conditions can be fulfilled in order to achieve a photoelectrochemical determination of a physical parameter such as the minority carrier diffusion length L . These conditions have been detailed elsewhere (12), and we do not emphasize them in this paper. We only mention that the L determination lies on the use of the Gärtner model (13) for the description of the i_{ph} vs. V characteristic.

Fulfillment of conditions

$$\begin{cases} \alpha L \ll 1 & \alpha = \text{optical absorption coefficient} \\ \alpha W \ll 1 & W = \text{space charge region width} \end{cases} \quad [5]$$

enables us to express the photocurrent i_{ph} as

$$i_{ph} = K\alpha(W + L) \quad K = \text{constant} \quad [6]$$

By plotting i_{ph} (in arbitrary units) vs. W (computed by the Schottky relation), the determination of L becomes simple. The L values for CdTe are reported in Table III and can be compared to other results (13). We notice that for similar doping and free carrier densities, our results are in fair agreement with those obtained by other methods. The L values we obtain are rather small ($< 1 \mu m$) and verify a posteriori condition [5] and justify the method. Generally, small L values have been obtained for CdTe which are attributed to defects in the material. Another possibility to correlate the defect density (connected with the dopant) with a physical parameter is given by the Urbach's rule which indicates that the optical absorption tail obeys the analytical equation

$$\alpha = \alpha_0 \exp[S(E_g - E)] \quad [7]$$

where α_0 is a constant, E_g the energy gap, E the photon energy, and $S (= \sigma/kT)$ is Urbach's slope. The complete Urbach's rule which includes the variation with temperature of S has already been extensively studied for CdTe (14). Different interpretations are possible for relation [7] (15), we only keep in mind that

Fig. 3. Reciprocal squared capacitance and squared photocurrent vs. potential plots for CdTe/1M NaOH junctions. ●: n-type; $V_{n_{FB}} = -1.8V$ vs. MSE. Capacitance measured at 100 kHz. ○: p-type; $V_{p_{FB}} = -0.3V$ vs. MSE. Wavelength 850 nm.

Table III. Minority carrier diffusion length (L) and Urbach's slopes (S) deduced from photoelectrochemical measurements. The free carrier concentration (N) is measured by Hall effect (Van der Paw)

Conduction	p	p	p	n	n
Dopant	Undoped	P	P	Undoped	In
N (cm^{-3})	4×10^{15}	3×10^{16}	7×10^{16}	1.5×10^{15}	8×10^{17}
S (eV^{-1})	93	35	27	94	52
L (μm)	0.85	0.15	0.09	0.25	0.15

Urbach's slope is directly connected with the defects of a semiconductor and their ionization, possibly introduced by a dopant, and that a small value of S corresponds to a large amount of defects (Fig. 4).

In the absorption tail, the α values are low and conditions [5] hold. Thus, the related photocurrent i_{ph} can be expressed by relation [6] which combined with Eq. [7] leads to

$$i_{\text{ph}} = K\alpha_0 (W + L) \exp [S(E_g - E)] \quad [8]$$

This equation indicates that the photocurrent tail and the absorption tail may lead to similar information about the defects in a semiconductor (S value).

Equation [8] is verified with our CdTe samples and the results which are independent of the band bending in the semiconductor are reported in Table III. We notice that a doping with phosphorus leads to S values much smaller than in the other cases. This observation may probably be correlated with the particular property of P to produce defects in CdTe (16).

Summary

The CdTe-aqueous electrolyte interface presents behavior which is analyzed carefully. The information deduced from electrochemical measurements indicates that this interface presents a reproducible Schottky behavior which enables us to determine the minority carrier diffusion length and the Urbach's slope of a set of different CdTe samples. These parameter determinations may be accurately compared to others and enable us to produce information about the defects in the CdTe single crystals.

End Point Detection for Reactive Ion Etching of Aluminum

Kwang O. Park and Fredrick C. Rock

GTE Laboratories Incorporated, Advanced Components Technology, Waltham, Massachusetts 02254

The fabrication of VLSI circuits requires many steps of delicate dry etching processes to delineate fine-line patterns. In dry etching processes, a viable technique that enables the detection of the completion of an etching process is required to prevent over or under-etching. In a typical end-point detection scheme, a particular chemical species produced during the etching process is observed by monitoring a relevant spectral line as the etching process consumes the substrate material. The time to terminate the process can then be inferred from the changes in chemical composition of the plasma. In the past, when Al was etched especially in the pure CCl_4 , SiCl_4 , or BCl_3 gas, the 261 nm band has been used for end-point detection. This is because it is a major molecular AlCl emission band in the UV range overshadowing the 522-nm emission in the visible range. In this note we report results on the use of the 522 nm band emitted from molecular AlCl for end-point detection of Al etch in the free chlorine containing gas plasma and the relative merits of this procedure.

Etching was performed in a planar-type etcher with parallel-plate electrodes, as shown in Fig. 1. Chamber pressure during etching was maintained at 0.6 torr. A 13.56 MHz RF power supply was employed in this experiment. A monochromator (Instrument SA Model H-2) was used to take emission spectrum. A signal from a band of interest was obtained by tuning the monochromator to the peak of the band, and the intensity *vs.* time profile was recorded on a strip chart recorder. A Hamamatsu Model R928 photomultiplier was used as the detector.

Al and its alloys have been reactively ion etched effectively in plasmas consisting of SiCl_4 , Cl_2 , and BCl_3 gases (1, 2). The transient emission spectrum measured from a plasma consisting of 130 cm^2 SiCl_4 , 100 cm^2 Cl_2 , and 50 cm^2 BCl_3 is shown in Fig. 2. It has been found experimentally that this particular gas composi-

tion results in an excellent etch rate (about 400 nm/min at 0.5W/cm² applied power density) with an anisotropic profile and quickly removes native aluminum oxide. The spectrum shows Cl_2 bands at 257 and 307 nm, SiCl bands at 282 and 287 nm, and BCl bands at 272 and 278 nm. All of these molecules are reactant species in the plasma. The spectrum also shows additional bands at 261 and 522 nm due to molecular AlCl (3), which is the major reaction product of Al etching (2). The 261-nm band is assigned to the transition $\text{A}^1\Pi \rightarrow \text{X}^1\Sigma$ in the singlet state, and the 522-nm band may be attributable to the transition $\text{B}^3\Sigma \rightarrow \text{A}^3\Pi$ in the triplet state (4). Atomic Al(1) lines at 394 and 396 nm are also seen. Several of these bands have been previously used for end-point detection. Specifically, the 261-nm band due to AlCl has been widely used for this purpose because it is well resolved and is of high intensity during Al etch with CCl_4 , SiCl_4 , BCl_3 , etc. (5-7). When Al is etched, especially with mixtures of SiCl_4 , Cl_2 , and BCl_3 , the 261-nm band has a high intensity when there is aluminum remaining. This high intensity starts to fall as the etching is completed. However, there is an overlapping intense and broad Cl_2 band at 257 nm which is reduced during the etching and begins to return as the etching approaches completion (8). The result is that the signal at 261 nm first decreases as the etching is completed and then begins to increase again as the Cl_2 band returns, as shown in Fig. 3. Consequently, end-point detection with this signal can be uncertain, especially when Cl_2 gas is added to the other gases to enhance Al etch rates. The intensity of the 261-nm signal is expected to in-

crease sharply once etching is initiated. It then reaches a steady-state maximum. However, it has been observed that in Al etching there is always an induction period of some degree which is associated with the removal of native aluminum oxide (2). The duration of an induction period depends strongly on the quality of Al films, the composition of etchant gases used, and other factors, including the environmental conditions of the etching chamber. The initial gradual increase in the intensity of the 261-nm signal, as shown in Fig. 3, is attributable to the slow etching caused by native aluminum oxide. The extent of the duration of the peak intensity is related to the Al film thickness and

Fig. 5. An SEM picture of 1 μm -thick Al + 1%Si film which was etched using the end-point detection technique shown in Fig. 4.

the etch rate. However, while Al(1) lines at 394 and 396 nm are free from interference, they tend to have low intensities and sometimes are difficult to find. The 522 nm band not only has a high intensity, but also is well isolated and easy to locate because it is free from interference with the neighboring bands.

Figure 4 shows the actual use of the 522-nm signal for end-point detection during reactive ion etching of three sample 3-in wafers 1 μm thick Al + 1%Si films with an above-mentioned gas mixture. Some delay in 522 nm emission after initiation of the RF discharge is apparent in Fig. 4. This is because of the time required for the proper matching of the system impedance. As the etching is completed, the signal intensity starts to fall; it drops eventually to the sustaining level of the discharge. The end point of the etching is clearly evident because there are no conflicting emissions overlapping the 522 nm band signal near the end of the etching process. To clear the residues remaining on the substrate, the substrate was deliberately over-etched by extending the etching period by about 20% past indicated etch completion. Figure 5 shows an SEM picture of 1.0 μm thick Al + 1%Si film, which was etched employing the 522 nm end-point detection technique.

Improved Conductivity in Polysilicon Films by Pre-annealing

C. P. Wu and G. L. Schnable

RCA Laboratories, Princeton, New Jersey 08540

B. W. Lee¹ and R. Stricker²

RCA Solid State Division, Somerville, New Jersey 08876

Doped polycrystalline silicon is used as MOS transistor gates and interconnects in many kinds of micro-electronic devices and integrated circuits. The polysilicon film is usually deposited by low-pressure chemical vapor deposition (LPCVD) techniques, and subsequently doped by either a POCl_3 diffusion process at approximately 1000°C for 30 min, or by ion implantation followed by annealing at between 850 and 950°C . Doping of polysilicon films by ion implantation is becoming more popular because often it means fewer processing steps and/or lower processing temperatures, which is important for VLSI fabrication.

With ion implantation for doping polysilicon films, it is difficult to obtain sheet resistivities below $40\text{-}50 \Omega/\square$, because a large fraction of the implanted atoms diffuse to the polysilicon grain boundaries upon postimplant annealing, become trapped and, therefore, do not contribute to electrical conductivity (1). The electrical conductivity of doped polysilicon thin films can be influenced by many factors (1-8), including crystallite size and orientation; potential barriers (8), dopant (4, 5) and oxygen segregation (6) at grain boundaries; and stress and other effects. Increased polysilicon conductivity has been achieved by pulsed (9, 10) or cw laser annealing (11-13), which affords a means to increase the active carrier concentrations and to increase the size of the crystallites and so achieve higher conductivity in polysilicon films.

Recently, we have found that significantly lower resistivity of ion-implanted polysilicon films can be obtained by preannealing at a temperature between 1000° and 1200°C for 30 min in an inert ambient prior to doping the polysilicon by ion implantation, or by POCl_3 diffusion (14). The polysilicon film samples were prepared by LPCVD at 620°C . The films were $0.5 \mu\text{m}$ thick, deposited on $0.5 \mu\text{m}$ of SiO_2 thermally grown on (100)-orientation single-crystal silicon wafers. This ensured that there would be no epitaxial regrowth during the preannealing process. It is also the configuration in which doped polysilicon films are most frequently used in integrated circuits.

Except for the controls, the samples were preannealed at temperatures ranging from 1000° to 1200°C for 30 min in dry nitrogen prior to doping by ion implantation. They were then ion-implanted either with $^{31}\text{P}^+$ ion at 50 keV with a fluence of 10^{16}cm^{-2} , or with $^{11}\text{B}^+$ ions at 50 keV with a fluence of $6 \times 10^{15} \text{cm}^{-2}$. All samples were capped with $\sim 0.5 \mu\text{m}$ of SiO_2 by CVD at 450°C to prevent cross contamination before furnace annealing at 950°C for 30 min to activate the implanted atoms. The capping oxides were then stripped and the sheet resistivities were evaluated using four-point probes.

Table I summarizes the results of sheet resistivity measurements by four-point probes on ion-implanted polysilicon films that were preannealed at $1000^\circ\text{-}1200^\circ\text{C}$. The control samples were not preannealed, and their sheet resistivities are in the range usually obtained. Samples preannealed at 1000°C showed a slight improvement in sheet resistivities; this varied from 6% to 9%. Substantial improvements in sheet re-

sistivities were obtained for 1100°C preanneal, 30% for the ^{31}P -implanted polysilicon sample and 48% for the ^{11}B -implanted sample. These improvements increased to well over 50% if higher preanneal temperatures could be tolerated. Obviously, higher preanneal temperatures and/or longer preanneal times resulted in the growth of larger average crystallite size and, therefore, fewer grain boundaries to trap the implanted ions.

The above-described experiments were repeated with LPCVD amorphous silicon deposited at 560°C . Polysilicon formed from amorphous silicon is currently being used instead of LPCVD polysilicon in many device and circuit applications because of its improved surface smoothness (15-19). Table II summarizes the results of preannealing of LPCVD amorphous silicon films prior to doping by POCl_3 diffusion at 950°C for 30 min, or by ion-implantation (and subsequent post-implant anneal at 950°C for 30 min). For samples doped by the POCl_3 diffusion technique, the improvements are 11% for preannealing at 1000°C and 23% at 1100°C . Results for the ion-implanted samples show improvements varying from 4% for samples preannealed at 1000°C to 32% at 1100°C . Thus, preannealing of silicon films deposited in either polycrystalline or amorphous form results in substantial improvement in film resistivity, even for conventional doping with a POCl_3 source, which can be considered to provide an infinite source of dopant impurities. Scanning electron microscopy was used to examine the various samples in the above experiments, and no detectable change in surface roughness could be observed at 20K magnification. Similar results were obtained by Harbeke *et al.* (15).

Table I. Sheet resistivities of polysilicon films deposited in polysilicon form (LPCVD at 620°C), preannealed at different temperatures, followed by doping by ion implantation and subsequent annealing

Preanneal temp. (30 min preanneal)	Sheet resistivity, Ω/\square	
	^{31}P implant, 50 keV, 10^{16}cm^{-2} dose	^{11}B implant, 50 keV, $6 \times 10^{15} \text{cm}^{-2}$ dose
Control (no preanneal)	48.6 ± 2.2	87.5 ± 0.7

Key words: ion implantation, diffusion, anneal, CVD.

In conclusion, we have shown that a preannealing step of 1100°C for 30 min in dry nitrogen, applied to either polysilicon films or LPCVD amorphous silicon films, can substantially improve sheet conductivity and be incorporated into many IC processes, in which such preannealing can precede source and drain implants to minimize dopant diffusion.

Use of a Liquid Electrolyte Junction for the Measurement of Diffusion Length in Silicon Ribbon

Ronald H. Micheels

Mobil Solar Energy Corporation, Waltham, Massachusetts 02254

R. David Rauh*

EIC Laboratories Incorporated, Newton, Massachusetts 02158

In the last 10 years there has been a rapid expansion in the technology of silicon sheet growth (1). A key parameter for the evaluation of this material for photovoltaic applications is the minority carrier diffusion length. For single crystal and epitaxial silicon the surface photovoltage (SPV) technique (2) is a standard ASTM test method for the determination of minority carrier diffusion length (3). However, the conductive oxide glass pressure contact which is used to detect the surface photovoltage in the ASTM method is unsuitable for sheet silicon because of the uneven nature of the surfaces. The liquid-semiconductor junction, which acts very much like a Schottky barrier (4), lends itself very well to the problem of contacting irregular surfaces. The feasibility of using a liquid junction for diffusion length measurement was first demonstrated by Fabre *et al.* (5), who reported spectral response measurements of Si photoelectrodes. More recently Moore (6) has applied the liquid junction to measurement of diffusion lengths in n-type amorphous silicon using the SPV method. We would like to report the successful application of a liquid electrolyte-semiconductor junction to the measurement of SPV diffusion lengths in p-type, polycrystalline silicon ribbon. The use of the liquid junction greatly reduces the time and labor involved in the measurement compared to that required with a more conventional Al-Schottky barrier process which was previously employed in this laboratory (7). By using the liquid junction it has been found possible

to measure samples directly from crystal growth, thus eliminating etching or any other sample processing.

The p-type Si ribbon used in this study was grown by the edge-defined film-fed growth (EFG) technique (8) with a typical resistivity of 3-5 Ω -cm and thickness in the range of 0.25-0.40 mm. A Teflon cell, shown in Fig. 1, was used to hold 1×2 in. ribbon samples. A 0.1M solution of tetrabutylammonium perchlorate ($(C_4H_9)_4NClO_4$) in methanol was used as the electrolyte. Initial measurements were made with 0.002M methylviologen hydrate added to the solution to form a redox couple with a potential near the conduction band. However, it was found that the addition of methylviologen was unnecessary due to the Fermi level pinning effect produced by surface states at the silicon-solution interface (9). A Pt wire was used as a solution reference electrode. A layer of In foil was pressed against the ribbon to make the back contact. Subsequent to this study it was found that a sheet of silver impregnated rubber (Chomerics Materials Incorporated, Woburn, Massachusetts) was a more practical contact material. A 2V reverse bias voltage was applied across the liquid junction to prevent any significant band bending from occurring at the back contact, which is weakly rectifying in nature. The SPV apparatus basically consists of a chopped monochromator light source with a feedback control circuit which adjusts the light intensity to maintain a constant photovoltage at the sample junction. The monochromator wavelength is stepped through 12 points between 870 and 1000 nm. The $1/e$ penetration depth of the light

Fig. 1. Cross section of liquid junction cell

$(1/\alpha)$ ranges from 22 to 120 microns between these wavelengths. The data are collected and fitted with a computer. The apparatus and data analysis is described in more detail in Ref. (7). The absorption coefficients used in the analysis were determined from absorption and reflection spectra of polished ribbon samples and are given in Table I.

In order to determine whether the minority carrier diffusion lengths (L_n) measured with the liquid junction cell were correct, two comparison experiments were conducted in which samples were measured both with an aluminum-Schottky barrier and with the liquid junction. In the first experiment a set of 7 Si ribbon and 5 float-zone Si samples were processed into Al-Schottky diodes with sintered Al back contacts, using the procedure given in Ref. (7). The float-zone samples were annealed at 1200°C for various times up to 1h in an Ar/O₂ ambient which degraded the diffusion lengths from 145 down to 14 microns. The L_n values were measured, and the samples were then etched in a 50% solution of HF in H₂O to remove the Al-Schottky barrier from the front surface. The samples were then remeasured with the liquid junction cell. The L_n results which are plotted in Fig. 2a indicate that both junctions yield the same L_n values with experimental error. A least squares fit of the data gives a slope of 1.00 ± 0.05 and an intercept of 2 ± 3 microns, with standard deviations given for the uncertainties. One problem encountered with some of the samples measured with the liquid junction was a slow exponentially decaying component in the photovoltage, having a magnitude of 5-15% of the initial photovoltage. The decay typically had a time constant in the range of 3-5 min and significantly decreased in magnitude after the cell was illuminated with strong white light (50 mW/cm²) for 1 min. This slow decay in the photovoltage was not observed with Al-Schottky junctions, indicating that it is a surface phenomenon occurring in the vicinity of the silicon-electrolyte interface. In the second experiment a set of 33 ribbon samples was measured with the liquid junction cell, unetched, as received from crystal growth. The photovoltages observed in these samples were in general lower by a factor of 3-5 than the etched samples previously mea-

Fig. 2. Comparison of diffusion lengths measured with the liquid junction vs. an Al-Schottky junction. (a) Etched samples with sintered Al back contacts, measured with liquid junction subsequent to measurement with Al-Schottky barrier: Δ ribbon samples, \odot O₂ at annealed float zone Si samples. (b) Ribbon samples measured, unetched, with liquid junction first and then with Al-Schottky barrier after etching.

sured, but the drift problem was no longer present. The samples were subsequently etched for 90s in a standard 4:1 (HNO₃/HF) solution and for 15s in a 9:1 etch, to remove the SiC/SiO₂ surface films formed in crystal growth. Next, the samples were treated with a 3:1 30% H₂O₂/H₂SO₄ solution for 1 min to produce a thin oxide layer on the surface and a 125Å Al film was evaporated on the front surface to form a transparent Schottky barrier. The diffusion lengths were then remeasured and the results for both junctions are plotted against each other in Fig. 2b. The least squares fit of this data gives a slope of 0.998 ± 0.038 and an intercept of 0.2 ± 1.1 microns, confirming that both types of junctions yield the same results. It should be noted that the differences in transmission and reflectance between the Si-Al junction and the liquid junction were found to be insignificant over the wavelength range used.

In order to verify that the nonohmic pressure contact to the back of the samples was not introducing any error into the L_n measurements, a set of 8 unetched ribbon samples was measured with the liquid junction cell and then remeasured after being provided with an

Table I. Absorption coefficients of Si ribbon

λ (nm)	870	900	910	920	930	940	950	960	970	980	990	1000

ohmic back contact. The ohmic contact was formed by etching the back surface with 4:1 and 9:1 etchants and then rubbing on a layer of GaIn eutectic alloy. The addition of the ohmic back contact did not have any effect on the L_n values measured.

In conclusion, the liquid-electrolyte junction described here provides a practical means of measuring the SPV diffusion length of p-type EFG Si ribbon and should be applicable to other types of sheet grown Si.

The Current-Voltage Characteristics of MOS Structures as Measured with Triangular and Sinusoidal Voltage Sweep Methods

K. Nitsch, I. Turlik, and M. Slaby

Institute of Electron Technology, Technical University of Wrocław, Poland

The triangular voltage sweep method has been generally used for evaluating the mobile charge concentration (1,2,3). The fundamental analytical expression and the method for estimating the mobile charges concentration with current-voltage characteristics to the triangular voltage have been presented in papers by Marciniak and Tangena (3,4). It has been shown that the fundamental relations of the TVS method enables one to determine the mobile charge density in MOS structures when a sinusoidal signal of a low frequency is used. It is also possible to use the same measurement system for investigating the dielectric relaxation effects with a small dc signal. This is an additional advantage of the method proposed here (5).

The equivalent conditions of both methods have been defined by the comparison of TVS and SVS characteristics.

THE RESPONSE OF THE MOS STRUCTURE TO SINUSOIDAL AND TRIANGULAR SIGNALS IN A QUASI-EQUILIBRIUM STATE

The essential condition for identification of the mobile charge in dielectric films of the MOS structure is a quasi-equilibrium state during the experiment; that is, under sweep conditions so slow that the ionic charge distribution can equilibrate continuously with the externally applied voltage (1). Usually in the TVS method, this quasi-equilibrium condition can be realized experimentally at the elevated temperatures in the range above 150°C at sweep rates less than 100 mV/s.

Based on the analysis of current-voltage characteristics of MOS structures in a quasi-equilibrium state presented by Kuhn, the current response of the MOS structure to an ac signal may be written as

$$i = - \frac{dQ(V,t)}{dt} = \frac{d}{dt} \int_0^V C(V) dV + \frac{d}{dt} \int_{x_0}^{x_1} \rho(x,t) dx \quad [1]$$

where: $Q(V,t)$ is the total charge induced at the semiconductor electrode; $C(V)$ is the differential MOS capacitance; $\rho(x)$ is the mobile charge concentration in the dielectric layer; and x_0 is the thickness of the dielectric layer (the direction of the x-coordinate is chosen so that $x=0$ for the metal-dielectric surface, and $x=x_0$ for the dielectric-semiconductor surface).

For the triangular signal, $V = \pm \alpha t$, and using $d/dt = \pm \alpha d/dV$ from Eq. [1] we obtain

$$i(V) = \pm \alpha C(V) \pm \alpha \frac{d}{dV} \int_{x_0}^{x_1} \rho(x,V) dx \quad [2]$$

Further, if we choose a sinusoidal signal as the applied voltage, $V = V_m \cdot \sin \omega t$, and using $d/dt = \pm V_m \omega \cos \omega t$, we can get the following form

$$i(V) = \pm V_m \omega \cos \omega t C(V) \pm V_m \omega \cos \omega t \frac{d}{dV} \int_{x_0}^{x_1} \rho(x,V) dx \quad [3]$$

Thus, it is possible to calculate the density of mobile charges in quasi-equilibrium conditions for triangular and sinusoidal signals from Eq. [2] and [3], respectively

$$\rho_0 = \frac{1}{\alpha} \int_{-V_0}^{V_0} [i(V) - \alpha C(V)] dV \quad [4]$$

$$\rho_0 = \frac{1}{V_m \omega \cos \omega t} \int_{-V_0}^{V_0} [i(V) - V_m \omega \cos \omega t C(V)] dV \quad [5]$$

Comparing Eq. [4] and [5], we notice that the density of the mobile ion charge defined by a triangular signal is equivalent to the density determined by a sinusoidal one when

$$\alpha = V_m \omega \cos \omega t \quad [6]$$

For $\omega t=0$ we obtain

$$\omega = \frac{\alpha}{V_m} \quad [7]$$

This allows one to measure the frequency of a sinusoidal signal corresponding to the applied potential sweep rate in the TVS method. For example, using $V_m=5V$ and the typical values of the potential sweep rate ($\alpha=5\div 50$ mV/s) for the quasi-equilibrium state, we obtain the frequency range of a sinusoidal signal

$$\omega = 10^{-3} \div 10^{-2} \text{ Hz} \quad [8]$$

The density of the mobile charge defined by Eq. [4] and [5] is directly proportional to the area between the polarization current curve and the envelope of the rectangle or the ellipse corresponding to the capacitance of the dielectric layer (in practice, at elevated temperature, $C(V) \approx C_{OX}$ in all the range of applied voltages) (Fig. 1).

Fig. 1. Illustration for determining the density of the mobile charge by TVS and SVS methods.

The formula for calculating the density of the mobile ion charge using the TVS method has the following form (3)

$$Q = g \frac{kT}{q} \frac{I_p \text{ max}}{\alpha} \quad [9]$$

For a sinusoidal signal, this formula may be written as

$$Q = g \frac{kT}{q} \frac{I_p \text{ max}}{V_m \omega} \quad [10]$$

The quality evaluation of the dielectric layer can also be made by measuring the material parameters by means of a small ac signal of a very low frequency (5) in the same measurement system.

A typical I-V characteristic of an ac small signal is shown in Fig. 2.

Fig. 2. I-V characteristic of MOS structure for a small ac signal at an elevated temperature.

The material parameters (the components of the complex capacitance $C^*=C' + jC''$ and $\tan \delta$) can be determined from the following relationships

$$C' = \frac{I_0}{V_{\text{max}}} \quad [11]$$

$$C'' = \frac{\sqrt{I_{\text{max}}^2 - I_0^2}}{V_{\text{max}}}$$

$$\tan \delta = \sqrt{\frac{I_{\text{max}}^2}{I_0^2} - 1}$$

Taking into account the geometrical capacitance, we can estimate the components of the complex permittivity.

RESULTS AND DISCUSSION

The I-V characteristics of the MOS structures have been measured for comparison of

the results of TVS and SVS methods. The MOS structures were formed by the thermal oxidation of the n-type silicon wafers of a resistivity $\rho = 3 \div 6 \Omega \text{ cm}$ with the aluminum gate. The thickness of the oxide layer was 100 nm, and the contacts were made by evaporated aluminum dots about 1mm diam and $0.3 \mu\text{m}$ thick. Some measurement results have been shown in Fig. 3 and 4.

Fig. 3. Experimental SVS characteristics for $T = 480 \text{ K}$. (1) $\omega = 0.4 \text{ Hz}$; (2) $\omega = 0.2 \text{ Hz}$; (3) $\omega = 0.04 \text{ Hz}$; and (4) $\omega = 0.02 \text{ Hz}$.

Fig. 4. Experimental TVS characteristics for $T = 480 \text{ K}$. (1) $\alpha = 1 \text{ V/s}$; (2) $\alpha = 0.5 \text{ V/s}$; (3) $\alpha = 0.1 \text{ V/s}$; and (4) $\alpha = 50 \text{ ms/s}$.

The current-voltage characteristic was measured using Keithley 610C electrometer, Hewlett Packards H203A function generator and a slow triangular wave function generator.

The measured frequency was chosen according to Eq. [7]. The concentration of the mobile charge has been evaluated based on the I-V characteristics of the MOS structures for the sinusoidal and triangular voltage sweep methods. The agreement of results for both methods has been obtained, however, the differences in measured values were caused by the integration error of the experimental curve ($\pm 1\%$). Table I shows the typical values of Q measured using TVS methods.

Table I.

TVS		SVS	
$\alpha \left[\frac{\text{mV}}{\text{s}} \right]$	$Q [10^{-10} \text{C}]$	$\omega [\text{Hz}]$	$Q [10^{-10} \text{C}]$
50	8.62	$2 \cdot 10^{-2}$	8.68
100	5.53	$4 \cdot 10^{-2}$	5.53
500	4.94	$2 \cdot 10^{-1}$	4.91

The results obtained using the TVS and SVS methods confirm that these methods are equivalent, because the results are nearly the same. Thus, the TVS and SVS methods can be used interchangeably depending on the measurement setup. The differences in values of the mobile charge concentration for both methods are contained within the range of the method's error. The advantage of applying this method is the possibility of determining the dielectric parameters. These parameters can be obtained in the known way from I-V characteristics during one measurement cycle. Results of the SVS method may be compared in a simple way with results obtained by the TVS method according to the relationship in Eq. [6] given in this paper.

Determination of the Minimum Surface Enrichment of Molybdenum Required to Inhibit Active Dissolution of an Fe-Cr-Ni-Mo Alloy

R. C. Newman* and E. M. Franz

Brookhaven National Laboratory, Materials Technology Division, Upton, New York 11973

It is becoming clear that molybdenum inhibits localized corrosion of stainless steels through its effect on the anodic dissolution kinetics, rather than by any mechanism which could be discovered by analyzing the fully developed passive film. Wanklyn (1) has emphasized the importance of MoO_2 as a compound which is readily formed and is stable at relatively active potentials in mildly acidic solutions. It is also kinetically stable in strongly acidic solutions because of the necessity for reductive dissolution as Mo^{3+} . In the passive state at much higher potentials there is a tendency for depletion of Mo in the passive film. Hashimoto et al (2) and Goetz and Landolt (3) have both detected high concentrations of Mo on surfaces subjected to prolonged active dissolution. The chemical state of Mo in these experiments is controversial - perhaps $\text{Mo(VI)}(2)$. Brox and Olefjord (4), using an Fe-Cr-Mo alloy, showed in addition that elemental Mo was enriched in the surface following active dissolution, and suggested that an "intermetallic surface phase" was present. With respect to localized corrosion, it is likely that Mo is enriched on the surface during the small amount of dissolution which precedes repassivation of an incipient localized corrosion site; the excess Mo may then dissolve during prolonged passivation, or may be present so locally that it cannot be detected by surface analysis. In the present work we have measured the charge density required to deactivate freshly generated surfaces of an Fe-Cr-Ni-Mo alloy in the range of potentials where rapid active dissolution occurs in the absence of Mo. This charge density is used to calculate the maximum possible surface coverage of Mo as a function of exposure time of the new surface.

A novel dual electrode assembly was used to compare the bare surface behavior of Fe-Cr-Ni and Fe-Cr-Ni-Mo alloys (compositions in Table 1). Annealed 1 mm plates of both alloys were mounted on edge in a block of epoxy resin, with a spacing between them of about 1 mm, and ground to a 600 grit finish. A separate electrical connection was made to each specimen (Figure 1). The specimen block was fixed to the

bottom of a plastic cell containing a platinum counter electrode and a saturated calomel reference electrode (SCE). Two Stonehart model BC1200 potentiostats were used in the inverted mode to control the potentials of the two specimens at the same value, with the platinum counter electrode grounded. The two current outputs were fed through 60 Hz filters to two channels of a Nicolet digital oscilloscope (model 2090). A diamond pencil was used to make a single scratch across the width of both electrodes. Although the width and depth of the scratches were only reproducible to within about 25%, they were always constant to within 10% across both electrodes for a given scratch. This gave a high degree of confidence in the comparison of the bare surface behavior of the two alloys. The scratch width was $75 \pm 20 \mu\text{m}$, with a depth of about $20 \mu\text{m}$; the apparent scratch area was therefore taken as $0.1 \pm 0.03 \text{ mm}^2$. The scratch currents were low enough (and the solution conductivities high enough) that no noticeable interactions occurred between the ohmic potential fields of the two electrodes. The maximum IR drop to a scratch was less than 10 mV (5).

Most of the measurements were made using 1.5M H_2SO_4 at 22°C; a few were made with 1M HCl. For the sulfuric acid, both electrodes were passivated at +300 mV (SCE) before pulsing to the potential of interest; reactivation was slow enough to permit scratching in the active range with a low base current. For HCl, where passivation of one alloy was not possible, the electrodes were coated with a thin layer of lacquer and the scratches made through this layer.

Molybdenum sharply reduced the anodic current densities in the active range, as shown for sulfuric acid in Figure 2. The steady-state active to passive transition for alloy A was at $-275 \pm 5 \text{ mV}$ for this solution. When the alloys were scratched in the passive range for 1.5M H_2SO_4 , their current decays were virtually indistinguishable as shown in Figure 3. This is evidence that Mo does not influence the early growth of the passive film, and therefore that its effects should be sought in the active

*Electrochemical Society Active Member

range of potentials. Figure 4 shows the transients obtained at -300 mV, where passivation did not occur; very similar results were obtained in both H₂SO₄ and HCl at -350 mV. Both alloys showed an initial current peak, but within 200 ms the current on the Mo alloy (B) had fallen sharply below its companion. After 2 s the ratio of the currents was about 10, and alloy A had almost reached its steady state. By comparing this steady state with that of the surface as a whole, it was shown that the estimate of the scratch area was accurate and that the roughness of the scratch was comparable with that of a 600 grit finish. Using the apparent scratch area, the charge density passed on alloy B after 2 s was about 3.5 mC/cm². For a mean oxidation number of just over 2 and a roughness factor of about 2 for the scratched surface, this represents at most 5 atom layers of alloy oxidized (the roughness factor is not likely to be less than 2). For a bulk Mo concentration of 2.7 wt.% (1.6 at.%), the maximum possible surface concentration of Mo at this stage is therefore no more than 8 at.%. The initial peak seen for both alloys is probably due to preferential dissolution of iron, leaving a surface enrichment of nickel and chromium - it is notable that the charge density under this peak (~4 atom layers) would leave about one monolayer of (Cr + Ni) if iron was perfectly selectively dissolved.

Mechanism of Molybdenum Effect

The present results could be consistent with several possible effects of molybdenum, of which we will give two examples. First, Mo may be retained in the elemental form during preferential dissolution of iron; 8 at.% is then a reasonable surface concentration at which agglomeration of Mo atoms might begin to occur, for instance at surface steps (the mean Mo-Mo distance being between 3 and 4 substrate lattice spacings). Frankenthal (6) showed that the first stages of passivation of Fe-Cr alloys required charge densities equivalent to less than one monolayer of oxidized metal, and concluded that most of the initial current decrease involved deactivation of heterogeneities; if these were already saturated with elemental Mo, then the active current density could also be dramatically reduced by quite small coverages of Mo. Second, 8 at.% Mo may be sufficient to cover most of the surface if it reacts to form a hydrated oxide monolayer such as MoO₂·2H₂O (7). The main drawback of this mechanism is that bulk MoO₂ is not stable at pH = 0 and E_H ≈ -100 mV; however, thermodynamic data for the "two-dimensional" phase are not available. On balance we favor the accumulation of elemental Mo (to ~8 at.%) as the primary deactivating process; under appropriate conditions, this may be

followed by formation of a 2- or 3-dimensional network containing Mo(IV). Experiments with Fe-Cr-Mo alloys, where active dissolution occurs at lower potentials, are in progress and should resolve the role of MoO₂.

Conclusions

1. 1.6 at.% Mo does not affect the first few seconds of repassivation of an Fe-Cr-Ni alloy in 1.5M sulfuric acid.
2. 1.6 at.% Mo sharply decreases the active current density on a new surface after the passage of a quantity of charge equivalent to about 5 atom layers of alloy.
3. These results show that molybdenum acts at a sub-monolayer level in its primary inhibiting effect on active dissolution of stainless steels in sulfuric or hydrochloric acid, but has no effect on the repassivation rate in sulfuric acid.

Kenneth Sutter assisted with the experimental measurements. This work was sponsored by the US Department of Energy, Division of Basic Energy Sciences (contract DE-AC02-76CH00016).

Photoelectrochemical Response of GaPc-Cl Thin Film Electrodes Using Two Photon Sources and Two Illumination Directions

W. Buttner, P. Rieke, and N. R. Armstrong*

Department of Chemistry, University of Arizona, Tucson, Arizona 85721

The measurement of photocurrent response as a function of illumination wavelength, photocurrent spectroscopy, has been used in the characterization of many semiconductors and photoconductors (1-6). In our own studies of thin films of tri- and tetravalent metal phthalocyanines (Pc) and silicon phthalocyanines, photocurrent action spectra have been used to verify the identify of the majority photoproduced charge carriers, and estimate their average diffusion length (ℓ) before recombination (5, 6). The photocurrent spectra were found to depend upon the direction of illumination. For frontside illumination, illumination from the electrolyte side, the photocurrent spectra mimicked the absorbance spectra, a broad featureless peak between 550 and 850 nm. With backside illumination (made possible by illumination through the semitransparent conductive substrate) two maxima were observed at 575 and 795 nm with severe attenuation of the photocurrent in the highly absorbing region between these two peaks. This directional effect is explained by considering the relationships between the point of carrier creation, the direction in which it must migrate and the thickness of the GaPc-Cl film. The experimentally determined condition of oxidative current implies that either hole must move towards the dye/electrolyte interface or electrons must move in the opposite direction. Since in frontside illumination the photocurrent response parallels the absorption spectra we must conclude that the photocurrent does not depend on the penetration depth of the light, ($1/\beta$) where β is the absorption coefficient ($10^4 \leq \beta \leq 10^5 \text{ cm}^{-1}$ between 550 and 850 nm). Thus holes must be the mobile, photoproduced charge carrier. With backside illumination highly absorbed photons having a small penetration depth create holes very near the substrate/Pc interface. The photocurrent maxima occur

at the condition where $1/\beta = d - \ell$, where d is the thickness of the Pc film and ℓ is the average diffusion length before recombination (5). Using thin GaPc-Cl films (<200 nm), we estimate that $1/\beta \approx 5 \times 10^{-5} \text{ cm}$ at 575 nm and 795 nm. Estimates of the film thickness, $d \approx 700 \text{ nm}$, ascertained from visible spectra of the dissolved Pc film in pyridine, allows an estimation of $\ell = 200 \text{ nm}$ for Figure 1a.

Previous experiments have shown that polychromatic illumination of the Pc film produces photocurrents that seem to be in excess of those predicted by experiments using monochromatic sources (5-9). Photocurrents observed voltammetrically using polychromatic sources also show little dependence upon illumination direction in contrast to illumination with monochromatic sources. Figures 1, b-d, indicate the reason for these observations. The action spectra shown were all obtained using a monochromatized Xenon arc source, modulated at 100 Hz, and lock-in-amplifier (Ortec-Brookdeal) detection of the photocurrent response from the i/V converter of the potentiostat (ECO 551). Figures 1 b-d represent spectra obtained by backside illumination with that "probe" source and frontside illumination using an unmodulated "pump" laser source. In the case shown, a 632.8 nm He-Ne was used, but qualitatively similar results have been obtained using CW lasers at 514.7 nm, 457.1 nm (Argon ion laser) and 325 nm (He-Cd laser). As the power of the CW source was increased, the modulated photocurrent at each wavelength increased and the photocurrent maxima converged slightly, corresponding to a shift in the wavelength maxima of up to 25 nm. The ratio of β at 600 nm to that at 575 nm is ca. 1.5 to 1, $1/\beta$ decreases by a corresponding amount which indicates that ℓ has increased from 200 nm to ca. 350 nm. Since ℓ is a potential dependent parameter, a similar effect could also be produced by

*Electrochemical Society Active Member.

increasing the applied bias potential to the photoelectrode. If taken to its theoretical limit (which is generally not practical), the backside action spectra should converge on the frontside action spectrum or the absorbance spectrum.

The idea of using one modulated and one unmodulated illumination source has been previously reported for various photocurrent spectroscopies (1, 10). In most cases it was necessary for the modulated probe source and the CW pump source to illuminate the electrode at the electrolyte interface, since the electrodes were not thin films nor were they on optically transparent backings. As shown in Figure 2 for our experiments, the absorption profiles of the opposed pump source and probe source will overlap different regions dependent upon the absorptivity, β , of each. The pump source may produce charge carriers that occupy trap or recombination sites near the front surface -- the greatest distance away from the origin of the photoproduced holes. The presence of high concentrations of unmodulated charge carriers from the pump source increases the overall conductivity of the Pc film, allowing for a more efficient harvesting of the modulated carrier from the Au/Pc interface. The backside-induced photocurrent increases in accordance with the increase in λ to λ' .

The photocurrent enhancement at 632.8 nm using a modulated, low power, He-Ne source and two different pump sources is quantitated in Fig. 3. The maximum photocurrent enhancement obtained is greater than a factor of 2 for the 514.5 nm pump and slightly less than a factor of two for the 457.9 nm pump -- normalization to the absorptivities as these two wavelengths shows these enhancements to be nearly equal. The maximum enhancement is obtained with only small additions of pump power, corresponding to a probe-to-pump flux ratio of up to 300:1. Beyond this point the effect of each pump source decreases and the photocurrent enhancement saturates. In this same region of pump

flux to the frontside of the Pc film, the total photocurrent (a.c. + d.c.) increased non-linearly with increasing light flux ($i \propto I^{0.65}$). Such a non-linear relationship coincides with the expectations of the model of Rose which postulates a distribution of shallow and deep hole traps in the band gap region of the photoconductor (11). Experiments in progress also show that the effect of the pump light source may also be to reduce the barrier height for charge transfer at the Au/Pc interface which should likewise yield a non-linear photocurrent vs. light intensity dependence.

Polychromatic illumination of the Pc film and other photoconductor thin films results in a sizeable fraction of the charge carriers produced being used to create a more conductive channel for a small hole population, which actually produces the photocurrent response. Further optimization of these photoconductive materials requires that the barriers to hole transport be significantly reduced, i.e., that λ be made comparable or larger than the Pc film thickness. Two-photon photocurrent spectroscopies are promising in their ability to quantitate the effect on photoelectrochemical performance of defect states. These experiments also suggest ways by which the photoconductivity of thin films for photoelectrochemical or reprographic applications might be controlled using multiple sources which illuminate the photoconductor from two different directions.

This research was supported by grants from the National Science Foundation, CHE 17571, and from IBM Corporation. We also gratefully acknowledge the use of a He-Cd laser for these and subsequent studies from the San Francisco Laser Center. We also thank Prof. J. E. Pemberton of this Department for the loan of the argon ion laser. P. Rieke acknowledges support in the form of the C. S. Marvel Graduate Fellowship.

REVIEWS AND NEWS

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1983, the following graduate students received \$1500, representing the three Summer Fellowship Awards of The Electrochemical Society.

Ms. Rosalie G. Tompson, University of Missouri-Columbia, was designated as the winner of the Edward Weston Fellowship.

Mr. Bob L. Wheeler, The University of Texas at Austin, was awarded the Colin Garfield Fink Fellowship.

Mr. David F. Tessier, University of Ottawa, Canada, was selected as the recipient of the Joseph W. Richards Fellowship.

The Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need, to a fellow or teaching assistant pursuing work between the degrees of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." They are intended to cover a period during which the recipient has no financial support for the continuance of his or her work.

The Edward Weston Summer Fellowship Report

Ms. Tompson's report is given below.

The goal of this work was to use inelastic electron tunneling spectroscopy (IETS) to study the reaction of SOCl_2 with aluminum oxide and, in particular, to determine intermediate products in the reaction. IETS (1) is a sensitive technique for detecting monolayer coverages of a molecular species adsorbed on an oxide layer. Tunnel junctions are fabricated as a sandwich of metal (usually Al), metal oxide, dopant (molecule of interest), and metal (usually Pb). To obtain spectra, the junctions are cooled to 4.2 K, and a variable d-c bias voltage and an a-c modulation signal are applied. Peaks in the resulting second harmonic vs. bias voltage correspond to the vibrational frequencies of the dopant molecule and phonons of the sandwiching metal electrodes. The useful range is 30 meV (240 cm^{-1}) to 500 meV (4000 cm^{-1}). Previously, IETS has been successfully used in our laboratory to determine the reaction intermediates of the CCl_2 /aluminum oxide system (2).

This project was based on literature studies of the reactions of SOCl_2 with metals and metal oxides (most notably with Li in a Li/ SOCl_2 battery system). These studies had indicated that metal chlorides, free sulfur, and SO_2 could be expected to result from such a reaction. Other products could include SO_2Cl_2 , S_2Cl_2 , SCl_2 , S_2O , and HCl (from reaction with water on the aluminum oxide surface). Reaction intermediates might also be seen (e.g., various metal chloride and sulfur chloride radicals, SO and SO radicals and SOCl^-). Further, sulfur bonded to bare Al atoms of the oxide surface might possibly be observed although such bonds are often difficult to detect with tunneling. The first step in the process was to fabricate aluminum oxide tunnel junctions doped with SOCl_2 . The usual doping and fabrication procedures, and modifications thereof, did not provide high quality junctions or spectra. Junctions doped with 4-12 μl of pure SOCl_2 were unusable since the SOCl_2 reacted strongly with the thin oxide layer and the underlying Al. Junctions doped with 4-12 μl of SOCl_2 dissolved in benzene at concentrations ranging from 0.1 to 10% SOCl_2 by volume were also of poor quality (low resistance with noisy spectra). The spectra from these junctions, however, did yield surprising results. No metal chloride stretches were seen, nor were there any other stretches observed which involved chlorine. There were indications of Al-S bonds, of SO_2 and other sulfur-oxygen type bonds, and possibly of benzene on the surface. One possible interpretation of these results is that the SOCl_2 chlorinated the benzene before the solution was applied to the metal oxide surface. As a consequence, the complex was adsorbed on the oxide surface. Previously, benzene when used as a solvent has not been seen in tunneling spectra. Since these spectra were noisy, the results obtained are not yet conclusive. Current plans include attempting to fabricate tunnel junctions with very small amounts of pure SOCl_2 .

The Colin Garfield Fink Summer Fellowship Report

Mr. Wheeler's report is given below.

A method for the simultaneous determination of the absorption coefficient, α , and the minority charge carrier diffusion length, L , of semiconductor electrodes was evaluated. The method is based on electronically differentiating the photocurrent as a function of applied potential and, hence, is called the differential photocurrent (DPC). This method, first proposed by Sukegawa *et al.* (1) for solid-state devices, involves the simultaneous modulation of the incident radiation (at f_1) and the applied potential (at f_2) with detection of the intermodulation photocurrent (at $|f_2 - f_1|$). α and L were determined for a p-GaP single-crystal in contact with an aqueous Eu^{3+} solution. The values for α were $400 \text{ nm} - 8.1 \times 10^4 \text{ cm}^{-1}$ and $450 \text{ nm} - 6.9 \times 10^4 \text{ cm}^{-1}$. The value of L determined for the sample was $0.10 \pm 0.01 \mu\text{m}$. The values agree quite well with literature values. The DPC technique has the advantage that the measurements are conducted with the semiconductor in the same configuration normally used in photoelectrochemical cells. One drawback, however, is that any deleterious effects the electrolyte has on the semiconductor, such as surface recombination or the formation of surface states, could affect the measurement. An additional complication is a filter effect caused by the species produced at the photoelectrode. This effect would be absent in solid-state measurements on step junctions and care must be used in matching the wavelengths of interest to regions where the redox couple to be used does not absorb. In addition, the method is very model dependent (*i.e.*, the photocurrent is fit to the Gärtner model, and any inaccuracies in the model will be manifested in the results). Apart from the determination of α and L , this method holds promise as a means for detecting surface states which play a role in the production of the photocurrent. When the photocurrent increases steadily towards saturation as a function of the reverse bias, as predicted by the well known Gärtner model, the differential photocurrent decreases monotonically and reaches zero as the photocurrent reaches saturation. Any inflection in the steady increase in the photocurrent will be magnified in the plot of the differential photocurrent with respect to reverse bias. This inflection in the photocurrent can be attributed to surface states acting as recombination sites. This has been illustrated by a plot of the differential photocurrent vs. voltage for n-MoSe₂, which has been shown by the a-c impedance technique to have surface states. At the same potential at which the states were found by a-c impedance, a large dip occurs in the differential photocurrent. However, except for determining the energy distribution of the surface states with respect to the bandedges, no quantitative information appears readily available.

In addition, polycrystalline films of MoSe₂ were studied. The films were grown by vapor transport from MoSe₂ powder and I₂ as a transport agent. The chemicals were placed in a quartz tube and evacuated at liquid nitrogen temperature and sealed. The tube was then placed in a split tube furnace kept at 900°C for approximately one week. At that time, a suitable portion of the tube was held under running water to condense the I₂ vapor. Polycrystalline films of MoSe₂ had grown above the original charge. The films were quite sturdy and could be removed from

the quartz in most cases. Electrodes were made with both the rough surface, which was towards the charge during growth, and the smooth surface, which was against the quartz tube, exposed to the electrolyte. Preliminary results show that both types of electrodes were able to photo-oxidize bromide.

The Joseph W. Richards Summer Fellowship Report

Mr. Tessier's report is given below.

The electrochemical hydrogen evolution reaction (HER) has proved a useful model system in the study and kinetic treatment of simple, as well as of more complex electrode reactions (1,2). Much work has been done on the elucidation of the rate-determining step(s) in the HER at metals of widely differing adsorptive and catalytic properties and from diverse electrolyte solutions (3-5). Of equal interest has been the question of the mechanism and molecular mechanics of the initial step, in acid media, of the discharge of the hydrated proton and the transfer and chemisorption of the resulting H atom on the electrode surface.

Comparative studies at various metal electrodes on the discharge of, and H₂ evolution from the unhydrated H₃O⁺ ion as found in salt-like strong acid "monohydrates" and from H⁺_{aq} in solutions of the same acid in excess water have recently been reported by Conway and Tessier (6). The steady-state polarization behavior at Hg electrodes differed markedly from that at the more catalytic Ni and Pt surfaces. In particular, at Pt and Ni, the observed rates of the HER from 1M CF₃SO₃H are ca. 10-25× greater than from the monohydrate, CF₃SO₃-H₃O⁺; this order was found to be reversed at Hg cathodes. The temperature dependence of the HER was discussed in terms of current ideas about electron and proton transfer in electrochemical reactions, the state of hydration of H⁺, and the role of discharge from paired CF₃SO₃⁻ and H₃O⁺ ions.

Linear potential sweep cyclic voltammetry experiments allow the elementary H-adsorption/desorption step in the HER at Pt to be studied independently from the overall H₂ evolution process. The electrochemical reaction responsible for the formation of adsorbed H at Pt in acid solution can be written as

where Θ is the fractional coverage of the surface by H, k_f and k_r are the indicated rate constants, C_0 is the concentration of H⁺ in the outer Helmholtz plane, and the surface concentration of metal sites is represented by the quantity $(1 - \Theta)$.

In the absence of mass-transport limitations and of diffuse double layer effects, the net current density for reaction [1] at any potential, E , is given by (7)

$$-Qd\theta/dt = i = -Q\{k_f(1 - \Theta)C_0 \exp(-\beta FE/RT) - k_r\Theta \exp[(1 - \beta)FE/RT]\} \quad [2]$$

In a linear potential sweep experiment, $E = E_{in} + St$, and under reversible conditions (low sweep rate, S), the coverage Θ adjusts to an equilibrium value for every value of potential, corresponding to the electrochemical adsorption isotherm for H on M. However, at relatively higher sweep rates, the current is determined increasingly by one or other of the two terms in Eq. [2], and the peak potential $E_{p,irr}$ progressively differs from that obtaining under reversible conditions, $E_{p,rev}$ (7).

Under completely irreversible conditions, at a sufficiently high sweep rate, the quantity $E_p = E_{p,irr} - E_{p,rev}$ is given by (7)

$$E_p = b \log(S_{0,p,c}) = b \log(-S) \quad [3]$$

where $b = RT/\beta F$ and $S_{0,p,c} = (RT/\beta F) k_f^{(1-\beta)} k_r^\beta C_0^{(1-\beta)}$. Thus a Tafel-like extrapolation of E_p vs. $\log(S)$ to $E_p = 0$ yields $\log(S_{0,p})$, the reversibility parameter, which is related to the standard rate constant k_0 by

$$S_{0,p} = (RT/\beta F) k_0 C_0^{(1-\beta)} \quad [4]$$

The characteristic rate parameter, k_0 , derived from the estimated $S_{0,p}$ for the elementary H-adsorption/desorption process

at Pt is then susceptible to a temperature study so that an analysis of the activation parameters analogous to that reported previously for the overall HER from H⁺ in different states of hydration (6), can be made.

This part of the work, concerned with the temperature dependence of the kinetics of the H-adsorption process at Pt, was carried out during the tenure in 1983 of the Joseph W. Richards Summer Fellowship of the Electrochemical Society.

Experimental

The potentiodynamic sweep method was employed as described elsewhere (7). A Nicolet 2090 digital oscilloscope served to record the i - E profiles. An internal reference electrode or a specially-made low-impedance reference electrode compartment was used in the measurements at high sweep rates. Cell design and minimization of the Pt working electrode surface area reduced the magnitude of IR losses which were offset by means of an adjustable positive feedback IR-drop compensator (12). High purity CF₃SO₃H solutions were prepared from the purified monohydrate as described previously (6). The anhydride, (CF₃SO₂)₂O, prepared by the dehydration of the acid over "P₂O₅" (13), was reacted with D₂O to yield CF₃SO₃-D₃O⁺ which was further purified.

The anodic H-desorption process was studied since, at higher S , the conjugate H-adsorption/desorption peaks overlap and are obscured by the onset of H₂ evolution currents. A slow (1 Vs⁻¹) cathodic sweep and a cathodic potential holding period of 0.2s was used in order to achieve surface equilibration prior to the analytical anodic scans.

Results

Typical cyclic voltammograms obtained at Pt electrodes in the "monohydrate" salt CF₃SO₃-H₃O⁺ and 1M aqueous CF₃SO₃H are shown in Fig. 1.

In the 1M solution, the H-adsorption region of the i - E profile is similar to that previously observed in HClO₄ solutions (7), indicating a relatively small degree of specific adsorption of the anion. The competitive adsorption of CF₃SO₃⁻, e.g., with SO₄²⁻, PO₄³⁻, and ClO₄⁻, has been studied previously by cyclic voltammetry in dilute aqueous solution (8), and it was concluded that CF₃SO₃⁻ is adsorbed to approximately the same extent as ClO₄⁻. Electrical double layer capacitance studies at Hg have indicated that the anion is not strongly adsorbed at this metal either (9).

In the acid monohydrate, the H adsorption region is appreciably shifted to less positive potentials as is evident in the cyclic voltammogram (Fig. 1); also the onset of surface oxidation of Pt is shifted to more anodic potentials. Both these observations probably result from greater anion adsorption in the monohydrate "melt". Such effects on the Pt profile are known to occur in the presence of strongly adsorbed anions, e.g., in sulfuric acid solutions containing even trace quantities of halide ions (10, 11).

The characteristic sweep rates, $S_{0,p}$, above which the anodic desorption of H from Pt is kinetically irreversible, is shown in the plot of E_p vs. $\log(S)$ plot in Fig. 2. $S_{0,p}$ for the 1M solution is com-

Fig. 1. Cyclic voltammetry i - E profiles for CF₃SO₃-H₃O⁺ and 1M CF₃SO₃H at 313 K at a Pt electrode. Sweep rate 92 mV s⁻¹.

Fig. 2. Tafel-type plots for H-desorption from Pt in $\text{CF}_3\text{SO}_3\text{H}$ solutions at 313 K.

Fig. 3. Tafel-type plots for H- and D-desorption from Pt in 1M $\text{CF}_3\text{SO}_3\text{H(D)}$ at 313 K.

parable to the values reported for HClO_4 solutions (7). In the monohydrate, a smaller value of $S_{o,p}$ is observed; slower kinetics were also observed under steady-state polarization for the HER at Pt from the monohydrate as compared with the 1M acid solution (6), in contrast to the steady-state behavior at Hg. Note that in dilute acid media, the presence of strongly adsorbed anions on the Pt electrode surface has been shown to increase the rate of H-desorption (7).

Apparent activation energies, ΔH_{app}^\ddagger , were determined from plots of $S_{o,p}/T$ ($\propto k_0$) vs. T^{-1} derived from experiments over the temperature ranges 273–333 K (1M aq $\text{CF}_3\text{SO}_3\text{H}$) and 313–345 K ($\text{CF}_3\text{SO}_3^- \text{H}_3\text{O}^+$). The resulting ΔH_{app}^\ddagger values and the derived frequency factor ratio, corrected for double layer effects (6), appear in Table I. The frequency factor ratio, $A(1\text{M})/A(\text{H}_3\text{O}^+) = 73$ is significantly greater than the value of $ca. 10^{-1}$ for the steady-state HER at Pt (6). This difference is primarily due to the comparable ΔH_{app}^\ddagger values for the H-desorption reaction in these two solutions; the changes in the rates themselves between the two solutions are similar for the overall HER, and for the elementary H-desorption process. Based on the observed frequency factor ratios, the conjugate H-adsorption/desorption reactions do not

Table I. ΔH_{app}^\ddagger value and derived frequency factor ratio corrected for double layer effects

Solution	$\Delta H_{app}^\ddagger/\text{kJ mol}^{-1}$	$S_{o,p}/\text{V s}^{-1}$
$\text{CF}_3\text{SO}_3^- \text{H}_3\text{O}^+$	24.4	7.3
1M $\text{CF}_3\text{SO}_3\text{H}$	19.7	82.0

Frequency factor ratio $A(1\text{M})/A(\text{H}_3\text{O}^+) = 73$ at 313 K.

seem to be important in determining the rate of the HER at Pt from these solutions. However, there may be some similarity in behavior of the HER at Hg (where electron transfer is believed to be rate determining), and of the H-desorption reaction at Pt.

The H/D kinetic isotope effect was also investigated for the H-desorption process and the E_p vs. $\log(S)$ plot for the 1M $\text{CF}_3\text{SO}_3\text{H(D)}$ is shown in Fig. 3. A decrease in $S_{o,p}$ of $ca. 2x$ was found on substitution of D for H. Further work is currently in progress on the study of the H/D isotope effect on this reaction at Pt in the 1M aqueous and the monohydrate solutions as a function of temperature.

The results described briefly above, combined with other work related to the HER, will be presented in detail in a forthcoming publication. Additional experimental studies on the growth of surface oxide films at Pt in the novel $\text{CF}_3\text{SO}_3^- \text{H}_3\text{O}^+$ "melt" will also be reported shortly.

Acknowledgment

Support of this work by the Joseph W. Richards Summer Fellowship is gratefully acknowledged. The recipient is grateful for the continuing generous help and guidance of Professor B. E. Conway.

Chemical Reactions in Lithium Sulfur Dioxide Cells Discharged at High Rates and Temperatures

W. L. Bowden, L. Chow, D. L. Demuth, and R. W. Holmes

Duracell Laboratory, Duracell Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The discharge capacity of Li/SO₂ cells was examined at high current and temperatures. D cells rated at 8 Ah delivered over 7 Ah at 5A current and 55°C, while cells discharged at 72°C gave 7 Ah at 3A. The cells were analyzed for residual lithium and sulfur dioxide. Spent cathodes were analyzed by infrared spectroscopy. A parasitic reaction was found in which Li₂S₂O₆ and S were formed, presumably by reaction of Li₂S₂O₄ with SO₂. This reaction became noticeable only under extreme combination of high rate and temperature.

Lithium/SO₂ cells are useful power sources for devices requiring high drain performance at low temperatures. Such cells generally are of a jelly roll design with layers of lithium foil, separator, and porous carbon cathode. The electrodes are surrounded by a highly conductive nonaqueous electrolyte consisting of an organic solvent (usually acetonitrile), a salt (usually lithium bromide), and sulfur dioxide, which serves as a soluble cathode material (1). In the course of cell discharge the lithium anode is oxidized, and the SO₂ soluble cathode is reduced. The discharge product, identified as lithium dithionite (2), precipitates in the porous cathode and eventually may passivate it. Such cells have open-circuit voltages near 3V and discharge at around 2.8V, delivering 140-150 Wh/lb over the cells' life (3, 4). Typical SO₂ D cells have short-circuit currents of over 100A and can deliver 30A pulses at specific powers of over 300 W/lb. In the course of discharging cells at elevated temperatures, it was observed that some cells delivered less than the usual capacity. We discharge a number of LO25SX and LO26SX D-type SO₂ cells at different rates and temperatures to determine the extent and magnitude of this decline in capacity. We used infrared spectroscopy and specific chemical analysis to identify products of the cells. We report the results here.

Experimental

The LO26SX, a hermetically sealed spirally wound D cell, was selected as a test vehicle for this study. The LO26SX is distinguished by its balanced cell chemistry in which the ratio of Li metal and SO₂ soluble cathode is near unity. This particular cell is rated at 8 Ah at 267 mA at 25°C. Capacities were calculated to a 2V cutoff and cells used for chemical analyses were not discharged below 2V. Cells were discharged at 21°, 55°, and 72°C on selected loads, as well as at constant currents, with data collection either by a Linseis LD-12 recorder or an HP 1000 computerized data-acquisition system.

Cells which were used for chemical analysis were placed in a specially made stainless steel bomb and punctured. The volatile acetonitrile and SO₂ were

withdrawn under vacuum and collected by cooling a flask with liquid nitrogen. The sulfur dioxide removed from the cell was then determined iodometrically. The remaining cell with its electrodes was then transferred to an argon-filled glove box and disassembled. Residual lithium was estimated by weighing the remaining anode. The carbon cathode was then analyzed by a variety of methods. Sulfur in the discharged cathode was determined gravimetrically by extracting the cathode with CH₂Cl₂ in a Soxhlet extractor. The CH₂Cl₂ was then removed with a rotary evaporator and the remaining sulfur weighed. Dithionite was determined by leaching the cathode with deaerated pH 10 buffer. The leachate was analyzed for dithionite by adding an aliquot to an excess of the Cu(II) ammine complex and spectrophotometrically measuring the destruction of Cu(II) (5). Dithionate was determined by first oxidizing the leachate with alkaline KMnO₄. The MnO₂ product was removed by filtering. All sulfur oxyanions except dithionate are converted to sulfate in this step. The solution of dithionate was then digested with metavanadate in H₂SO₄. The dithionate was then determined by back titration with KMnO₄ (6).

The extremely interesting compound lithium dithionite (Li₂S₂O₄) was prepared by reduction of sulfur dioxide with the lithium benzophenone ketyl. THF was refluxed with CaH₂ under argon for several days and then distilled into a carefully dried flask. The flask was taken into an argon-filled glove box where a slight excess of vacuum-dried benzophenone was dissolved in the THF. To this solution small pieces of lithium foil were added with stirring. The solution rapidly turned the intense blue of the benzophenone radical ion. Sulfur dioxide was then bubbled into this solution through a fritted-glass tube. The blue color of the solution rapidly disappeared, replaced by a milky white suspension in the THF. The white solid was collected by filtering, washed with CS₂ to remove any sulfur, and washed with CH₃CN to remove residual benzophenone. Purity was determined to be approximately 70% by Rohm's method (5). Lithium dithionate was prepared by oxidation of SO₂ with MnO₂ to form a mixture of manganous dithionate and sulfate. The sulfate and Mn(III) were removed by precipitation with hot saturated Ba(OH)₂. The result-

ing barium dithionate hydrate crystallized after water was removed with a rotary evaporator. The BaS_2O_6 was dissolved in water and converted to $Li_2S_2O_6$ by precipitating the Ba^{2+} with Li_2SO_4 solution. The extremely soluble $Li_2S_2O_6$ was isolated as a crystalline hydrate after reducing the solution in volume. Anhydrous material was obtained by vacuum drying at approximately $60^\circ C$. Lithium thiosulfate was prepared by metathesis of potassium thiosulfate with $LiClO_4$ in water. The slightly soluble $KClO_4$ was filtered off and the $Li_2S_2O_6$ crystallized on cooling after the solution was concentrated. The remaining sulfur oxyanions were obtained from Ventron or Pfaltz & Bauer. Infrared spectra were recorded with a Perkin-Elmer Model 683 spectrometer. The solid samples were finely ground with KBr in an agate mortar and pressed into a disk to give consistent samples. Considerable care was required to get a satisfactory spectrum of a discharged cathode because of the carbon present. Best results were obtained by using a very dilute KBr pellet combined with expansion of the transmittance scale.

Results

Cell testing.—Standard LO26SX cells were discharged at 21° , 55° , and $72^\circ C$ on loads varying from 0.4 to 55Ω . Capacities, shown in Tables I-III, were calculated to a 2V cutoff. Cell capacity is shown as a function of load and discharge temperature in Fig. 1. The increased currents drawn from the cells have little effect on capacity at $21^\circ C$, where the LO26SX delivers near its rated 8 Ah at currents of over 6A. As the temperature is increased, cell capacity remains essentially unchanged at lower currents with cells delivering the 8 Ah rated capacity on 5Ω load (approximately 0.55A). The combination of high current and high temperature resulted in a decreased cell capacity. This decrease can amount to 3.5 Ah under the extreme conditions on $72^\circ C$ temperature and 0.4Ω load.

From the plot in Fig. 1, it is clear that the LO26SX drops below the rated 8 Ah capacity only under high current discharge and high temperatures. The results at 21° , 55° , and $72^\circ C$ clearly show that the progressive nature of this phenomenon with temperature. The heat generated by the cell on discharge also plays an important role. The voltage and wall temperature of an LO26SX cell discharged at 2A are shown in Fig. 2. The wall temperature rose to some $89^\circ C$ during the discharge, and it can be safely presumed that more severe temperatures could be measured internally. The decline in capacity only at high currents and high tem-

peratures is due to an internal temperature well over $72^\circ C$. At these high temperatures, side reactions may occur which are unimportant at lower temperatures.

Analysis of cells.—We evaluated the processes taking place in the cell by infrared spectroscopy and

Fig. 1. Capacity to 2V of LO26SX cells as a function of average discharge current.

specific chemical analysis. Infrared spectroscopy is a particularly suitable technique for studying the cathode, since it can detect relatively unstable materials *in situ* before possible reaction during extraction or isolation procedures. After some preliminary experiments with mulls, we selected dilute samples of finely ground cathode in KBr as a sampling technique. Infrared spectra of cathode from cells discharged at room temperature and 72°C at 1Ω are shown in Fig. 3 and 4. Both cathode spectra are characterized by absorbances at approximately 1090, 1020, and 905 cm⁻¹, while the cathode discharged at elevated temperature has three additional bands at 1240, 1170, and 970 cm⁻¹. A series of spectra of cathodes from cells discharged under increasingly severe conditions revealed that the bands at 1240, 1170, and 970 become relatively more intense as the severity of temperature and rate increases.

The increase in intensity of the new bands led us to suspect that at high rates and temperatures the expected Li₂S₂O₄ (lithium dithionite) product might either decompose or fail to form. To test this hypothesis we had a number of cells analyzed for sulfur dioxide and lithium dithionite after discharge. Results are shown in Table IV. As shown by the data in Table IV, cells discharged at high rates and currents had substantially less dithionite than calculated from the diminished capacity, and only approximately 50% as much as cells discharged at room temperature. The analyses of discharged cell cathodes clearly showed that new chemistry was appearing under the extremely severe discharge conditions. To see whether this new chemistry was due to dithionite decomposition, we compared the infrared spectra of Na₂S₂O₄ before and after heating at 5°C/min in a sealed Ni-monic crucible in a Mettler TA2000 DTA. The DTA exotherm occurred at 192°C. The only identified decomposition product was Na₂S₂O₃ from its IR. We noted that the IR of Na₂S₂O₄ was not similar to that of a discharged cathode containing Li₂S₂O₄ and specu-

Fig. 5. Infrared spectrum of $\text{Na}_2\text{S}_2\text{O}_4$

by SO_2 in carefully dried THF. Quantitatively our product was only about 70% pure. The infrared spectrum of this material (Fig. 6) was almost identical to that of a discharged cathode. Thermal analysis demonstrated that $\text{Li}_2\text{S}_2\text{O}_4$ showed no reaction below 170°C , only slightly lower than $\text{Na}_2\text{S}_2\text{O}_4$. This was somewhat unexpected given the difficulty of preparing $\text{Li}_2\text{S}_2\text{O}_4$. Figure 7 shows the DSC results for $\text{Li}_2\text{S}_2\text{O}_4$ heated at $40^\circ\text{C}/\text{min}$ in a Perkin-Elmer DSC-4.

Examination of cathode spectra from cells tested at high temperature pointed to the presence of a dithionate in the cathode. A commercial sample of $\text{Na}_2\text{S}_2\text{O}_6$ is shown in Fig. 8. The absorbance at 1240 cm^{-1} is very similar to that in the cathode spectrum, while the band at 1000 cm^{-1} could be masked by the 1020 cm^{-1} dithionite band. A specific analysis for dithionate determined that 0.055 mols of $\text{Li}_2\text{S}_2\text{O}_6$ were present in a cell discharged at 72°C on 1Ω load. We prepared an authentic sample of $\text{Li}_2\text{S}_2\text{O}_6$ and found its IR pattern to be similar to that of $\text{Na}_2\text{S}_2\text{O}_6$. A dis-

charged cell was analyzed for sulfur by leaching the cathode with methylene chloride. The solid product (0.96g) was identified as elemental sulfur by its characteristic powder diffraction pattern. While this identified two products of the high temperature reaction, namely, S and $\text{Li}_2\text{S}_2\text{O}_6$, there were still two absorbances in the infrared which had not been assigned, 1170 and 970 cm^{-1} . To identify the source of these absorptions a number of salts of sulfur oxyanions were examined by IR. The unassigned absorbances are not due to Li_2SO_4 , Li_2SO_3 , or $\text{Li}_2\text{S}_2\text{O}_3$, as shown by Fig. 9, for example. The anions $\text{S}_2\text{O}_7^{2-}$ and $\text{S}_4\text{O}_6^{2-}$ were also eliminated. The IR spectra of $\text{K}_2\text{S}_2\text{O}_5$ and $\text{Na}_2\text{S}_2\text{O}_5$ were generally similar, and we suggest that $\text{Li}_2\text{S}_2\text{O}_5$ is also present in the cathode, as shown in Fig. 10.

To determine whether this capacity degradation at high current and temperature was related strictly to cell discharge or could be created in storage of partly discharged cells, LO26SX cells were 50% discharged at 25°C and then stored at 72°C for a week. At the end of the week the infrared spectra of the cathodes showed only the three absorbances due to lithium dithionite. This observation suggests that the reactions responsible for the capacity decline occur mainly during the formation of lithium dithionite rather than as a subsequent reaction in the cell.

Discussion

The reduction of SO₂ in aprotic solvents is known to occur via an initial one-electron transfer to form a radical anion, (8, 9). In extremely dilute solutions in a coordinating medium like DMF, the electron transfer process is reversible

The SO₂⁻ radical anion itself is an unstable species and may react by a variety of methods. In acetonitrile solvent with a Li⁺ supporting electrolyte, the most easily available mode of reaction is dimerization to dithionite followed by rapid precipitation of the lithium salt (2, 13). This dithionite formation from the short-lived radical ion occurs almost quantitatively in SO₂ cells discharged at 25°C, as shown by the average dithionite yield of 95.9% based on the stoichiometry in reactions [1] and [2]

In DMF or under more unusual conditions the SO₂⁻ radical ion may coordinate with SO₂ to form a complex ion (8, 10)

We suggest that this complex ion might react further with the radical ion to form a dianion, apparently similar to trithionate, which would decompose to give the

detected products of lithium dithionate and sulfur

The characteristic 1200 cm⁻¹ band of trithionate was never observed in a cathode IR spectrum, however.

The SO₂⁻ ion has also been found to disproportionate in solution to give sulfite and sulfur monoxide. The sulfur monoxide is extremely unstable and will disproportionate to rapidly form sulfur and SO₂ (11)

The sulfite ion itself is known to form pyrosulfite in aqueous solutions (12). Thus we have a plausible mechanism for explaining the presence of pyrosulfite as well

It is at least as notable that the infrared spectra gave negative evidence for the presence of two expected byproducts, Li₂SO₄ and Li₂S₂O₃. The lithium sulfate had been found on analysis of cells stored for extremely long times at high temperatures, while thio-sulfate has been proposed as a cell product in certain circumstances. The different pattern of products clearly points to the electron transfer involving SO₂⁻ being involved in these reactions, as opposed to slow side reactions involving the LiBr and SO₂ electrolyte components.

The amount of dithionate found, 0.055 mols, corresponds roughly to the capacity decrease in such a cell. It is quite tempting to ascribe the capacity loss to a reaction such as

In this reaction three equivalents of SO₂ produce two of current with formation of S and Li₂S₂O₆. Coupled with disproportionation of the SO₂ radical ion to eventually form S and Li₂S₂O₅, this offers a facile explanation for the capacity loss phenomenon, although the available data are far from definitive.

Conclusion

Lithium/sulfur dioxide cells discharged under conditions of high current and high temperature deliver less capacity than cells discharged at the same currents at room temperature or at elevated temperature and low rates. Analysis of these cells with diminished capacity revealed substantially less Li₂S₂O₄ discharge product than in normally discharged cells. The quantity of dithionite present was only 75% of that expected from the cell capacities. The loss in capacity is also accompanied by side reactions forming elemental S, Li₂S₂O₅, and Li₂S₂O₆. It is likely that these side reactions occur during discharge, since partly discharged cells stored at 72°C do not show spectroscopic evidence of deterioration. The side reactions appear to lead to premature cathode passivation, since cells had both Li and SO₂ present at the end of discharge. Our results show that the redox chemistry of SO₂ in organic solvents is a complex problem. Cell capacity and cell chemistry are both sensitive to factors which are not yet completely understood.

Electrochemical and Ellipsometric Investigations of Passive Films Formed on Iron in Borate Solutions

I. The Kinetics of Film Growth on Iron at Constant Anodic Potentials

Z. Szklarska-Smialowska¹ and W. Kozlowski

Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT

The kinetics of passive film formation on iron in borate buffer solution has been studied at different anodic potentials. The process of film growth has been found to occur in four distinct stages. About 80-90% of the total film thickness formed in 1h grows during the initial two stages which last for only 1-3s (depending upon potential). The electric field strength across the film is not constant but decreases with progressing film growth. The thickness of the film determined ellipsometrically is less than that calculated from the electric charge consumed. The process of anodic film formation is accompanied by the dissolution of iron which occurs over the whole range of potentials.

The rates at which passive films grow on the surface of iron have been studied either by electrochemical techniques, in which the anodic current density is measured as a function of time (1, 2), or ellipsometrically by measuring the optical parameters for the evolving film (3-6). This latter technique directly yields the film thickness as a function of time which can be used to test various models for the growing anodic film. In the majority of cases, ellipsometric measurements began approximately 1 min after a constant anodic potential was applied, i.e., at a time subsequent to the development of a major part of the film. As far as we are aware, only in two studies (3, 6) have attempts been made to determine the rate of film growth during the initial minute following the application of the potential.

A particularly large body of information on the initial process of film growth on iron has been provided by Kruger and Calvert (3). They found that film growth occurs in three stages. In the first stage, a linear relationship exists between the film thickness and the square root of time. The authors (3) suggest that during this stage the film growth is controlled by the diffusion of OH⁻ ions to the electrode surface. During the second stage, a number of complex processes occur which cannot be characterized by any simple rate law. The third stage, i.e., that of the steady-state growth, can be described equally well by either a logarithmic or inverse logarithmic law. From the inverse logarithmic relationship, the so-called jump distance has been estimated to be 10Å, and the activation energy equal to 1.8 eV. This value of the jump distance is much larger than the value expected for Fe₂O₃, which is about 3Å. It is worth mentioning that other authors (4, 5) have also found jump distances much larger than 3Å.

Many theoretical models have been proposed to explain the kinetics and mechanisms of film growth on metals. The inverse logarithmic model proposed by

Mott and Cabrera (7) assumes field-assisted cation diffusion and uniform field strength across the film. The logarithmic model of Fehlner and Mott (8) proposes that anion diffusion is responsible for film growth and that the field strength in the film is independent of thickness. Another logarithmic model developed by Sato and Cohen (9) postulates that field-assisted place exchange of metal-oxygen pairs is responsible for film thickening. This model is applicable to very thin films only. Chao *et al.* (10) recently proposed a model based on the movement of point defects in a chemical potential and electrostatic field. These authors propose that oxygen anions are responsible for growth of the primary passive film.

Most models presented to date consider passive films to be semiconductors or "incipient" semiconductors by virtue of dielectric breakdown (10). A different approach has been adopted by Cahan and Chen (11). In their "chemiconductor" model, the passive film on iron is pictured as an insulating ferric oxyhydride. Small nonstoichiometry, primarily due to Fe²⁺ near the metal-film interface and to Fe⁴⁺ near the film-solution interface, affect the local conductivity in the film.

The objective of the present work was to use electrochemical and ellipsometric techniques to characterize the kinetics of film growth on iron in borate buffer solution of pH 8.45. Experimental data has been collected from the first few moments (~0.2s) to up to 1h after the application of a constant anodic potential. Particular emphasis has been placed on correlating the results obtained using the electrochemical and ellipsometric techniques, so that a consistent picture can be developed of the evolution of the passive film as a function of time.

Experimental Procedure

An Armco iron specimen with an exposed area of 0.5 cm² was mounted in a Teflon holder. The specimen surface was first mechanically ground with emery papers finishing with 800 grit, then polished with 1

¹ Present address: Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210.

μm diamond paste, and finally electropolished in a mixture of glacial acetic acid and perchloric acid (20:1) at a current density of $2 \text{ A} \cdot \text{cm}^{-2}$ for 2-5s. This treatment did not cause etching or roughness. Before initiating experimental measurements, the specimen was washed with distilled water and methanol.

Two borate buffer solutions of pH 8.45 were used: $0.02\text{M H}_3\text{BO}_3 + 0.005\text{M Na}_2\text{B}_4\text{O}_7$ (solution 1); and $0.15\text{M H}_3\text{BO}_3 + 0.0357\text{M Na}_2\text{B}_4\text{O}_7$ (solution 2). These solutions were prepared using Analytical Reagent grade chemicals and triple distilled water. The solutions were deaerated by bubbling argon (99.99%) for at least 24h before the experiment. All measurements were made at 22°C .

The ellipsometer used was a Rudolf Research Model 2000 equipped with a revolving analyzer. The light source was a tungsten iodine lamp from which monochromatic light of 546.1 nm wavelength was obtained using an interference filter.

The McCrackin (12) computer program was used to evaluate the optical constants of iron and of the film formed on it. In the case of double layer films, the refractive indexes were calculated on the assumption that these films were composed of two homogeneous layers, one on the top of another, with different optical constants.

Before measurements of the optical constants of iron, the specimens were cathodically reduced with a current density of $0.02 \text{ A} \cdot \text{m}^{-2}$ during 20 min. During the last period of the cathodic reduction, the solution in the electrolytic cell was exchanged.

Optical parameters were measured for films formed at constant potentials at 100 mV intervals over the range of -0.5 to 0.8V .

The Δ and Ψ parameters were measured with an accuracy of $\pm 0.03^\circ$ and $\pm 0.01^\circ$, respectively, which corresponded to an accuracy of film thickness determination of ± 0.01 to $\pm 0.02 \text{ nm}$.

All potentials are referred to the saturated calomel electrode. The kinetics of film growth were studied for periods extending from about 0.2s to 60 min after application of the potential, during which time changes in the optical parameters and current densities were recorded.

Results

In order to characterize electrochemically the studied system, anodic polarization curves were obtained in both solutions at a scan rate of 1V per min (Fig. 1). The maximum current corresponding to the active/passive transition occurred at -0.6V . The passive potential region extended up to 0.85V . The current density in the whole potential region was higher in the more concentrated solution (solution 2).

Fig. 1. Anodic polarization curves for Armco iron in: solution 1 $0.02\text{M H}_3\text{BO}_3 + 0.005\text{M Na}_2\text{B}_4\text{O}_7 \cdot 10 \text{ H}_2\text{O}$ pH 8.45; and solution 2 $0.15\text{M H}_3\text{BO}_3 + 0.375\text{M Na}_2\text{B}_4\text{O}_7 \cdot 10 \text{ H}_2\text{O}$ pH 8.45.

The optical parameters of films obtained after passivation of the iron for 60 min in both solutions are shown in Fig. 2. The values of n (refractive index) and k (absorption coefficient) changed significantly in the range of potentials from -0.5 to about -0.1V in solution 1 and from -0.5 to -0.3V in solution 2. Within these potential regions, the values of n and k increased in solution 1 from 2.1 to 2.45 and from 0.09 to 0.22, respectively and in solution 2 from 1.7 to 2.2 and from 0.06 to 0.15, respectively. In stagnant solutions, a second layer developed on those films which exhibited lower optical parameters ($n = 1.6-1.8$ and $k = 0.015-0.05$). In stirred solutions, this second layer was not formed.

In the second potential region, i.e., from -0.1 to 0.8V in solution 1 and from -0.3 to 0.8V in solution 2, the films could be described by only one value of n and k in both stirred and unstirred solutions. As shown in Fig. 2, these values also changed with the passivation potential, but this effect was less pronounced in the second potential region. In solution 1, n increased from 2.45 to 2.6 and k from 0.22 to 0.36, while in solution 2, n increased from 2.2 to 2.5 and k from 0.15 to 0.25.

As is clearly shown in Fig. 3, the changes in optical parameters occurred only during the initial 30s of polarization; after this both n and k reached time independent values in both solutions.

Fig. 2. Dependence between optical parameters n and k and potential measured in solutions 1 and 2.

Fig. 3. Optical parameters n and k vs. time measured in solutions 1 (dashed line) and 2 (solid line) at 0.0V (Δ , \triangle), 0.4V (\square , \blacksquare), and 0.8V (\circ , \bullet).

Due to film thickening, the current density decreases with increasing passivation time at constant potential. An example is given in Fig. 4. In solution 1, at potentials ranging from 0 to 0.8V, the dependence of $\log i$ on $\log t$ is nonlinear in the initial period from 0.2 to 1.2s, thereafter, two linear regions can be distinguished: from 1.2 to 5-10s; and from 5-10 to 1200-1800s. After this period, i drops below $0.01 \text{ A} \cdot \text{m}^{-2}$. At the same passivation potentials, the initial current density is higher in the more concentrated solution 2 than in solution 1 and in the initial second, the i vs. t curve is more pronounced in solution 1, and within the third passivation region, the slopes of all i vs. t curves are similar.

An example of the relationship between film thickness (d) as determined ellipsometrically in solution 1 and $\log t$ is plotted for different passivation potentials in Fig. 5. In this figure, I denotes the initial process of oxidation lasting from about 0.2 to 0.5s. It is noted that d is a nonlinear function of $\log t$ and is potential dependent. Within the next region (II), the relationship between d and $\log t$ is linear. Higher rates of film growth and larger film thicknesses are observed with increasing potential. This oxidation stage ends at ~ 2 s at 0.6V and at ~ 6 s at -0.2 V. The third stage (III) of

Fig. 4. Changes of current density during passivation of iron in solutions 1 (▲●) and 2 (△□○) at 0.0, 0.4, and 0.8V.

Fig. 5. Dependence between film thickness determined ellipsometrically and passivation time in solution 1 at different potentials. Consecutive steps of film formation at 0.8V are marked in the graph.

approximately 8-30s duration is characterized by intermediate oxidation rates between stages II and IV. This stage can be regarded as transition from stage II to IV. In the fourth stage (IV), the relationship between d and $\log t$ is linear and the oxidation rate is relatively low. Relationships between d and $\log t$ measured in solution 2 do not differ substantially from those obtained in solution 1.

From these data it is apparent that, at a given anodic potential, 80-90% of the film thickness attained in 1h of passivation is formed within the initial 10-30s.

Figures 6 and 7 show the effect of potential on film thickness at the end of each passivation stage in solutions 1 and 2, respectively. In Fig. 8, the film thickness measured in solution 1 is plotted as a function of the charge density (Q) calculated from the $\log i$ vs. $\log t$ curve. It should be noted that in Fig. 8 only the final three stages of film growth can be distinguished, as the initial stage of about 2s duration cannot be calculated by the technique employed. The same types of curves were obtained in solution 2.

Discussion

These ellipsometric measurements indicate that the optical parameters of passive films formed in 1h are potential dependent. Two potential regions can be distinguished. In the first region, which occurs at more negative potentials, the composition and properties of the film, as characterized by its optical parameters,

Fig. 6. Thickness of film formed in solution 1 measured at the end of each consecutive step of film growth as a function of potential.

Fig. 7. Thickness of film formed in solution 2 measured at the end of each consecutive step of film formation as a function of potential.

Fig. 8. Dependence between film thickness measured ellipsometrically in solution 1 vs. potential and charge density.

change more significantly with passivation potential. Also, the refractive indexes of the film are relatively low, suggesting the formation of hydroxides or oxyhydroxides. In the second region, at more anodic potentials, the effect of potential is less pronounced, and the optical parameters suggest that the film is composed of oxides and hydroxides. Initially, the values of n and k vary as a function of time, but in about 10-30s they assume constant levels.

Some characteristic differences occur in the optical parameters of films formed in solution 1 as compared with those formed in solution 2. At the same passivation potential, lower n and k values were measured in solution 2. This suggests that films formed in solution 2 are relatively less dense and contain a greater ratio of oxyhydrates to oxides. Furthermore, a greater amount of boron may be occluded from solution 2 as boron is incorporated in films formed in borate solutions (13-15).

Simultaneous ellipsometric and current decay measurements at constant potential show that film growth occurs in several stages. Four stages can be distinguished in plots of film thickness vs. log time, but only three stages appear in plots of d vs. charge density (Q), because the method employed for the determination of Q does not reveal the initial stage I.

Based on the film thickness as a function of potential data shown in Fig. 6 and 7, the field strength values (ϵ) corresponding to different passivation periods have been calculated using the formula

$$\epsilon = \frac{\Delta V}{\Delta d} \quad [1]$$

where V is the applied anodic potential, and d is film thickness. The results given in Table I indicate that the average field strength is the highest in stage I and decreases significantly during the following passivation periods as d and t increase.

Table I. Mean field strength of passive films, ϵ (in $V \cdot cm^{-1}$)

Passivation period	Solution 1 ϵ	Correlation coefficient	Solution 2 ϵ	Correlation coefficient
Stage I	1.8×10^7	0.74	1.6×10^7	0.96
Stage I + II	5.4×10^6	0.92	4.3×10^6	0.99
Stage I + II + III	4.9×10^6	0.97	4.0×10^6	0.98
Stage I + II + III + IV	3.9×10^6	0.98	3.5×10^6	0.98

Using all of the electrochemical and ellipsometric data, the anodic charge per unit volume of film during each passivation period has been calculated as shown in Fig. 9 for solution 1. The charges consumed in stages I and II and I-III are greater in solution 1 than in solution 2, but the total charge consumed after polarization for 1h is greater in solution 2. In Fig. 9, the ratios of $\Delta Q/\Delta d$ for different oxides, hydroxides, and oxyhydroxides of iron are also included. For these calculations, the following densities (expressed in $g \cdot cm^{-3}$) have been taken into consideration: Fe_2O_3 5.249; Fe_3O_4 5.18; γ - $FeOOH$ 4.09; $Fe(OH)_3$ 3.6 and 2.44; and $Fe(OH)_2$ 3.4. As noted before, two potential regions in the relationship between oxidation potential and n and k are noted in Fig. 9. For states I and II and I-III, the increase in $\Delta Q/\Delta d$ is more pronounced at lower potentials. This is especially true in solution 1. However, for the total I-IV period, increases in $\Delta Q/\Delta d$ are more pronounced at higher potentials. By comparing the theoretical values of $\Delta Q/\Delta d$ with experimental data, it can be assumed that within the first potential region between -0.5 and $0V$ the film being formed contains iron in the oxidation state of $+2$ and $+3$. The charge per unit volume corresponds approximately to that of $Fe(OH)_3$ and $Fe(OH)_2$. The increase in $\Delta Q/\Delta d$ with increasing potential can be attributed to a larger Fe^{3+}/Fe^{2+} ratio and to a reduced content of water in the film. The fact that the charge associated with stages I and II is less than the theoretical value for γ - $FeOOH$ formation seems to suggest that hydroxides are also formed.

The effects of potential on $\Delta Q/\Delta d$ for stages III and IV in solution 1 are shown in Fig. 10. During stage III in both solutions, these ratios increase with increasing potential from about $-0.2V$, but are only slightly affected by changes in E . It is evident that for both stage II and IV, the values of $\Delta Q/\Delta d$ greatly exceed those theoretically predicted for any oxide or hydroxide of iron. The omission of surface roughness coefficient which is estimated at 1.2-1.6 (16-18) cannot be the main reason for this discrepancy, because to match the experimental results with theoretical values one should assume a roughness coefficient for film IV to be 7-8 which would be unrealistic. Another reason may be associated with the occurrence of the iron dissolution in addition to film formation. To determine whether dissolution may occur during the anodic oxidation of iron in borate solution, colorimetric analyses were made on specimens after 45h of anodic polarization at various potentials in solution 1. Unfortunately,

Fig. 9. Effect of potential on Q/d for stages I and II, I-III, and I-IV of passivation in solution 1.

the analytic technique employed was not precise enough to determine the amount of iron dissolved in short time periods. The results plotted in Fig. 11 indicate that in addition to Fe^{3+} , small amounts of Fe^{2+} are also present. In this figure, the calculated amounts of Fe^{3+} which can be dissolved during ellipsometric measurement for 1h are indicated by dashed lines for both solution 1 and 2. Based on the charge density values used in film formation at various potentials and on the calculation of the charge densities required to form films of thicknesses determined ellipsometrically, the excess of the charge was estimated. For this estimate, a roughness coefficient of 1.0 was used. In solution 1, the film was assumed to be Fe_2O_3 having a density of $5.0 \text{ g} \cdot \text{cm}^{-3}$. In solution 2, an average value for the assumed mixture of Fe_2O_3 with FeOOH corresponding to the formula $\text{Fe}_2\text{O}_{2.25}\text{OH}$ provided a density of $4.7 \text{ g} \cdot \text{cm}^{-3}$. The estimated excess charge was used to calculate the amount of Fe^{3+} dissolved. These calculations indicated that larger amounts of iron were dissolved during passivation in solution 2 than in solution 1.

If it is assumed that the dissolution rate does not change with time, the amount of Fe^{3+} determined analytically after 1h of passivation was less than that estimated. This difference could be attributed to a time-dependent dissolution rate where the rate decreases

with increasing passivation time, and/or to the occurrence of iron in the film at a valency higher than 3+.

As stated earlier, the development of passive films at constant anodic potentials has been found to occur in four stages. This agrees in essence with the findings of Kruger and Calvert (3), but we have found an additional stage so that our stages I and II appear as stage I in their study.

Stage I.—It is impossible, in practice, to determine the effect of oxidation time on film thickness in stage I as it lasts for only 0.2s, and a very thin film forms in this stage. Presumably, its thickness does not exceed a unit cell of Fe_2O_3 , i.e., about 0.83 nm. It appears reasonable that initially an adsorption film forms which is then transformed into a tridimensional phase film.

Stage II.—After a critical film thickness is attained at the end of stage I, the growth rate increases and d becomes a linear function of $\log t$. At the beginning of stage II, d is a function of \sqrt{t} , and 70-80% of the film developed in this stage grows at a square root relationship between thickness and time (Fig. 12). It was found that the growth rate was higher in solution 2, but the duration of proportionality between d and \sqrt{t} was shorter in solution 2 than in solution 1.

Fig. 10. Q/d as a function of potential for oxidation stages III and IV in solution 1.

Fig. 11. Concentration of Fe^{3+} and Fe^{2+} determined colorimetrically (solid line) and concentration of Fe^{3+} in solutions 1 and 2 estimated from the surplus of charge (dashed line).

Fig. 12. Dependence of film thickness on time for films grown in solution 1.

A linear relationship occurs between t and the anodic charge density, Q . This appears to indicate that the total charge is used in the formation of only one compound. Calculations have shown that, during film growth in both solutions, the field strength decreases significantly in this stage, from about $10^7 \text{ V} \cdot \text{cm}^{-1}$ to $4\text{--}5 \times 10^6 \cdot \text{cm}^{-1}$.

It should be noted that during the initial period of stage II, two linear relationships are effective as follows

$$1/d = A + B \log t \quad [2]$$

and

$$1/d = A' + B' \ln t/d^2 \quad [3]$$

Constants B and B' are linear functions of the passivation potential, but the "jump distance" calculated on these bases is approximately 10^{-3} nm instead of the predicted value of about 0.3 nm . This suggests that in stage II the inverse logarithmic model of film growth is not valid.

Stage III.—The film growth rate in this stage is intermediate between those in stage II and IV. A slight increase in optical parameters is noted suggesting either (i) changes in the composition of the whole film or (ii) formation of a new layer on top of the previous film. The first assumption should be rejected as it has been shown by cathodic reduction experiments that the film formed in stage II does not change its properties (21).

The relationship between film thickness and charge density is not linear which appears to indicate that complicated processes occur in this stage. During part of this stage, a linear dependence is observed between both d and $1/d$ vs. t . However, calculations based on the inverse logarithmic relationship indicate jump distance values of approximately 0.01 nm instead of the predicted 0.3 nm .

Stage IV.—In agreement with Kruger and Calvert (3) and Lukac *et al.* (5), stage IV is the steady-state growth stage which can be described by either a logarithmic or inverse logarithmic rate law. The use of Eq. [2] for calculation of the jump distance gives values of 0.94 and 0.86 nm for solutions 1 and 2, respectively, while the respective values obtained using Eq. [3] are 0.92 and 0.83 nm .

Assuming that the film growth kinetics are controlled by a diffusion process with no ion migration, the following equation can be used to calculate the apparent diffusion coefficients that are effective during the various oxidation stages observed up to $t = 60 \text{ min}$

$$d = \sqrt{6Dt} \quad [4]$$

where D is the effective (apparent) diffusion coefficient

(diffusivity), and d is the film thickness (diffusion distance) attained in oxidation time t . The data plotted in Fig. 13-15 for films obtained at passivation potentials of $0, 0.2, 0.4,$ and 0.8 V indicate that in the majority of instances D is a linear function of d . Only for the time period covering stages I-III in solution 2 do

Fig. 13. Apparent diffusion coefficient as a function of film thickness at the end of the period of time covering stages I and II in solutions 1 (\circ) and 2 (\bullet).

Fig. 14. Apparent diffusion coefficient as a function of film thickness at the end of the period of time covering stages I-III in solutions 1 (\circ) and 2 (\bullet).

Fig. 15. Apparent diffusion coefficient as a function of film thickness after 60 min of passivation in both solutions 1 and 2.

two experimental points deviate greatly from the linear relationship. For films of the same thickness formed in the time periods covering stages I and II and I-III, calculations lead to much higher D values for films formed in solution 2 as compared with solution 1. Calculations also show that the apparent diffusivities in stages I and II are four orders of magnitude larger, and in stages I-III are three orders of magnitude larger than D values computed for the whole passivation time of 60 min (Fig. 15). The conclusion can be drawn, therefore, that the outermost film layer formed in stage IV is primarily responsible for the sharp decline of the film growth rate and for the increased passivity of iron.

The D values calculated for stages I and II are of the order 10^{-14} $\text{cm}^2 \cdot \text{s}^{-1}$, hence too small to correspond to diffusion processes occurring in an aqueous electrolyte, and they should be attributed to the diffusion of some species in the solid film. Even though the apparent diffusion coefficient was calculated on the basis of a simplified assumption, the results indicate that the properties are not homogeneous to the whole film. It appears reasonable to conclude that either different species control diffusion in stage IV than in preceding stages or significant changes occur in the composition of the outermost film layer during stage IV.

It is generally accepted that passive films on iron contain water. For example, Rahmer (19) found that the amount of water diminishes with passivation time. According to Konno and Nagayama (13), external film layers contain less water than internal ones. Okamoto (20) claims that the concentration of water in the passive film on stainless steels decreases when both the anodic potential and passivation time are increased. Sato (21-23) assumes that the inner part of the film is anhydrous while the outer part is hydrated.

The ellipsometric data indicate that with increasing potential the film increases in density. This effect is more pronounced in stage I than in stage III, and probably is due to increased concentration of iron cations and decreased concentration of water in the latter stage.

No change in the optical parameters between stages I-III and stage IV are revealed ellipsometrically, but this may be due to the relative thinness of the outermost layer, and hence its insignificant contribution to the optical properties of the whole film obtained in 60 min. Distinction between the inner and outer layer would be possible if the optical parameters of both layers were significantly different, which does not seem to occur.

Calculated D values for films obtained in both solutions 1 and 2 during the total passivation period (stages I-IV, $t = 60$ min) are identical and suggest that the external layers in these two solutions are the same.

As is known (24, 25), ions derived from the electrolyte (for example, Cl^-) may be incorporated in the external and, as we believe, most protective film layer; this seems not to occur in the internal layer. It can be assumed, therefore, that the external layer is composed of hydroxides together with anions incorporated from the electrolyte. The presence of water (hydroxyl ions) might be responsible for the more protective properties of the outer film layer. For example, the high resistance of Fe-Cr alloys is attributed to the presence of chromium hydroxide in the passive film (26). However, some more sophisticated experiments should be made to verify the above interpretation.

On the basis of the data obtained, it can be stated that the kinetics of film growth on iron is a very complicated process which cannot be described satisfactorily by any of the existing models as there is insufficient information in the mechanisms of processes occurring in different stages of film growth. For example, little useful basic data exists on: (i) the effect

of pH and electrolyte composition on film growth, especially in the initial stage; (ii) the distribution of Fe^{3+} , Fe^{2+} , H^+ (OH^-), and O^{2-} in the film at different anodic potentials; and (iii) the quantity of iron dissolved during anodic passivation under various experimental conditions.

Conclusions

1. In both solutions examined, the electric charge consumed in film formation in the initial period of anodic oxidation (stages I and II, $t > 1$ s) is less than the theoretical charge calculated for Fe_2O_3 formation, even if the roughness coefficient is not considered. This implies that, during this initial oxidation period, compounds with lower densities form, such as hydroxides or oxyhydroxides.

2. With increasing oxidation time, the charge consumed per unit of film volume increases to values exceeding that required for Fe_2O_3 formation.

3. Oxidation occurs in four distinctive stages characterized by different rates of film growth and different values of the electric field.

4. The electric field strength decreases as oxidation proceeds from stage I to stage IV.

5. The film formed in stage I is very thin, probably monolayer or less.

6. The film formed in stage II is thickest and grows at the highest rate relative to the other oxidation stages.

7. The growth rate in stage II increases with increasing anodic potential, but the effect of potential is insignificant in both stages III and IV.

8. The optical constants of the film change significantly in stage II and slightly in stage III, but remain constant in stage IV.

9. In stage II, the film thickness is a linear function of \sqrt{t} , while films formed in stages III and IV grow according to a logarithmic rate law.

10. None of the existing models can be applied to the experimentally observed kinetics of film growth on iron in borate solutions.

11. Growth of anodic films on iron in borate solutions is accompanied by the transmission of iron ions to the electrolyte.

Halide Nuclei Theory of Pit Initiation in Passive Metals

T. Okada

Industrial Products Research Institute, Ministry of International Trade and Industry, Yatabe, Tsukuba, Ibaraki 305, Japan

ABSTRACT

A kinetic approach is used to test the theory of pit initiation in passive metals in contact with a solution containing aggressive ions. A new process, hemispherical halide nuclei formation at the surface of the passive film and inward growth under restricted conditions, is introduced. The possibility of nuclei growth is discussed, taking into account the irreversible thermodynamic stability of the system. The direction of the irreversible change of a system consisting of the metal substrate, the passive film, the halide nuclei, and the solution is determined using the general evolution criterion of irreversible thermodynamics proposed by Glansdorff and Prigogine. A critical radius of the halide nucleus r^* is deduced. This radius must be surpassed for growth and pitting to take place. The present theory explains the nature of the pit initiation processes, especially some characteristic values of the pitting phenomenon, such as the critical pitting potential and the induction period of pit nucleation.

Pitting is a specific feature of localized corrosion in which areas of a passive metal surface break down locally as a result of preferential attack by aggressive ions in a corrosive environment. Pitting has attracted much attention recently because of its practical implications. According to the "Alles oder Nichts-gesetz" of passivity (1), active and passive areas should not coexist on a uniform metal surface. However, during the pitting process, the condition of the metal-solution interface at the bottom of the pit becomes different from the rest of the metal surface (2, 3). Once the surface of a passive metal is destroyed locally, this itself brings about a more corrosive environment, due to the local halide ion concentration, a change in the pH of the local solution, and the subsequent local polarization at the pit bottom. Thus, pitting turns out to be a stable condition (4).

Generally, two stages of the pitting process are considered by most authors (3, 5): the stage of pit initiation which terminates with the appearance of the first pit after a certain time of incubation, and the stage of pit propagation and its preservation due to the subsequent local corrosive environment. The former stage is assumed to include the degeneration of the passive film, but this mechanism is not yet clear. The process of pit generation is regarded as a stochastic process (6), which turns to the next stage where local dissolution proceeds at the pits thus formed.

Sometimes shallow hemispherical pits are observed during pitting corrosion of aluminum or stainless steel (3). These cases resemble the situation during electropolishing of the metal. Here the continuation of the dissolution reaction caused by a degeneration of the metal surface is more significant than the change in composition of the solution at the pit bottom (7). It seems plausible that the degeneration of the metal surface occurs prior to the appearance of the pits.

Key words: pitting corrosion, irreversible thermodynamics, halide nucleation, initiation.

Vetter (8) and Vermilyea (9) stressed in their theory of pitting corrosion that when the potential of a passive metal was shifted anodically in halide solutions, the state changed from the passive film being stable to the metal halide being stable thermodynamically. This theory appears to be valid, especially when electropolished-like pitting is considered. However, these authors only examined the interchange between two phases, the metal oxide and the metal halide, from the point of view of thermodynamic stability, and did not microscopically consider how the metal halide was generated on the surface of a passive metal.

On the other hand, according to the "transitional halide complex" theory of pitting corrosion (10), pitting starts at the point where sufficient halide ions jointly adsorb on the passive film so that they form a transitional complex with a lattice cation at the passive film-solution interface. This idea seems attractive, because it deals with the formation of a metal halide from a microscopic point of view.

In this study, an attempt was made to describe the process of pit initiation beginning with the premise that pitting occurs through formation of metal halides on the passive film, thereby taking into account the microscopic stability of the halides. A theoretical basis is presented, with the assumption that the process of pit initiation consists of passive film degeneration by halide nuclei formation on the film and growth inwards.

The model.—Figure 1 illustrates the process of pit formation on a passive metal. Suppose that a halide "nucleus", hemispherical in shape and with a radius r , is formed on the passive film surface of thickness L . If this nucleus is stable and grows continuously, it will penetrate the passive film which protects the metal surface. Then the uncovered metal dissolves rapidly through the nonprotective metal halides, thus forming a pit. But if this nucleus is not stable and does not grow, it disappears and the metal remains in a passive state.

Fig. 1. Illustration of a process leading to pit initiation. M: metal, MO: passive film, MX: metal halide, Sol.: solution.

Whether the nucleus grows or not should be determined referring to the irreversible thermodynamic stability conditions, because the system under consideration is in a nonequilibrium state. As will be shown later, the nucleus starts to grow in a stable manner when its radius passes the critical value r^* , but it eventually disappears when the radius is smaller than r^* . This situation resembles the case of the precipitation of a solute from a saturated solution, in which a critical radius also exists for the formation of a solute nucleus (11).

Theory

The general evolution criterion.—One of the most general relationships so far obtained in irreversible thermodynamics which indicates the direction of the irreversible change of a system is the so-called general evolution criterion proposed by Glansdorff and Prigogine (12)

$$\delta_X P \equiv \int_k \sum J_k d_i X_k dV \leq 0 \quad [1]$$

That is, in a system of time-independent boundary conditions, an irreversible change proceeds so that the time derivative of the forces multiplied by the conjugated fluxes becomes negative until the system reaches a steady state. Suppose that the temperature is kept constant so that the heat flux can be ignored. Then the processes occurring in the system shown in Fig. 1 are: the transport of ion species in the passive film; the interface reaction where the metal oxide changes into the metal halide; and the transport of species through the metal halide and the dissolution reaction at the interface between the passive film or the metal halide and the solution, so that

$$\delta_X P = \delta_X P_{MO} + \delta_X P_{MO/MX} + \delta_X P_{MX} + \delta_X P_{MX/S} + \delta_X P_{MO/S} \quad [2.1]$$

with

$$\delta_X P_{MO} = \int_{MO} \sum_k J_k d_i X_k dV_{MO} \quad [2.2]$$

$$\delta_X P_{MO/MX} = \int_{MO/MX} \sum_k J_k d_i X_k dS_{MO/MX} \quad [2.3]$$

$$\delta_X P_{MX} = \int_{MX} \sum_k J_k d_i X_k dV_{MX} \quad [2.4]$$

$$\delta_X P_{MX/S} = \int_{MX/S} \sum_k J_k d_i X_k dS_{MX/S} \quad [2.5]$$

$$\delta_X P_{MO/S} = \int_{MO/S} \sum_k J_k d_i X_k dS_{MO/S} \quad [2.6]$$

in which V_{MO} is the volume of the passive film, $S_{MO/MX}$ is the interface between the oxide and the halide nuclei, V_{MX} is the volume of the halide nuclei, and $S_{MX/S}$ and $S_{MO/S}$ are the halide nuclei-solution and the oxide-solution interfaces, respectively

Processes occurring within the system are depicted schematically in Fig. 2. The constituent metal and the oxygen ions take part in the transport processes in the passive film. The x-axis is perpendicular to the metal surface and is directed towards the solution. For simplicity, only one-dimensional transport along the x-axis will be taken into account. Designating the metal and the oxygen ions as M and O, respectively, the flux of each species per unit cross section in the oxide film is

Fig. 2. Schematic representation of processes occurring within the system consisting of the metal, the passive film, the halide nucleus, and the solution.

expressed by the following transport equation (13, 14)

$$J_i = \frac{z_i}{|z_i|} \nu_i n_i a \exp \left(- \frac{U_i - \alpha_i |z_i| F a \Delta \Phi_0 / \delta}{RT} \right), \quad i = M, O \quad [3]$$

where ν_i is vibrational frequency, n_i is concentration of i-species in the oxide layer, a is "jump-distance", α_i is "transfer coefficient", z_i is charge of the ionic species, $\Delta \Phi_0$ is potential difference within the oxide layer, and δ is thickness of the oxide layer.

The force corresponding to each flux is

$$X_i = - \frac{1}{T} \frac{\partial \tilde{\mu}_i}{\partial x}, \quad i = M, O \quad [4]$$

where $\tilde{\mu}_i$ is the electrochemical potential of i-species in the oxide layer. Suppose that a major part of the gradient of electrochemical potential arises from the electric field in the oxide layer, and that the potential changes linearly through the oxide layer, so that

$$X_i = \frac{1}{T} z_i F \frac{\Delta \Phi_0}{L - r'}, \quad i = M, O \quad [5]$$

Here r' is the "thickness" of the metal halide in the simplified model in which hemispherical halide nuclei are scattered over the surface of the passive film surface, and accordingly, would have the order of magnitude

$$r' = \gamma r \quad [6]$$

where the ratio of the area occupied by the halide nuclei on the surface of the passive metal is designated as γ .

Consider now the imaginary time derivative δr of the radius r of the halide nucleus. The resultant change of the force δX_i would be expressed as follows

$$\delta X_i = \frac{z_i F}{T} \left\{ \frac{\delta \Delta \Phi_0}{L - r'} + \frac{\gamma \Delta \Phi_0}{(L - r')^2} \delta r \right\}, \quad i = M, O \quad [7]$$

Using the above relationship, Eq. [2.1] can be written as

$$\begin{aligned} \delta_X P_{MO} &= \frac{1}{T} \{ z F J_M - 2 F J_O \} \left\{ \frac{\delta \Delta \Phi_0}{L - r'} \right. \\ &\quad \left. + \frac{\gamma \Delta \Phi_0}{(L - r')^2} \delta r \right\} \left(L - \frac{2}{3} \pi r^3 N \right) S \\ &= \frac{1}{T} I^\circ \left(\delta \Delta \Phi_0 + \frac{\gamma \Delta \Phi_0}{L - r'} \delta r \right) \quad [8] \end{aligned}$$

where I° is the total current passing from the metal to the solution, S is the surface area of the metal in contact with the solution, and N is the number of halide nuclei generated per unit area of the metal surface.

The following reactions are considered to occur at the interface between the halide nuclei and the passive oxide

The partial reaction current density of the respective reactions, i_M and i_O , can be expressed as follows if the backward reaction rate is ignored

$$i_M = k_M \exp \left[\frac{\mu_M(1)}{RT} \right] \exp \left[\frac{z\mu_X(2)}{RT} \right] \exp \left(\frac{\alpha_M z F \Delta \Phi_{MO/MX}}{RT} \right) \quad [10.1]$$

$$i_O = k_O \exp \left[\frac{\mu_O(1)}{RT} \right] \exp \left[\frac{2\mu_H(2)}{RT} \right] \exp \left(\frac{2\alpha_O F \Delta \Phi_{MO/MX}}{RT} \right) \quad [10.2]$$

where k_M , k_O are the rate constants, $\mu_M(1)$, $\mu_O(1)$ are chemical potentials of M^{z+} and O^{2-} , respectively, in the passive film at the interface with the halide nuclei, $\mu_X(2)$, $\mu_H(2)$ are chemical potentials of X^- and H^+ , respectively, in the halide nuclei at the interface with the oxide, α_M , α_O are transfer coefficients, and $\Delta \Phi_{MO/MX}$ is the Galvani potential difference at the interface between the oxide and the halide nuclei. The chemical affinity of each reaction is

$$A_M = \mu_M(1) + z\mu_X(2) + zF\Delta\Phi_{MO/MX} \quad [11.1]$$

$$A_O = \mu_O(1) + 2\mu_H(2) - 2F\Delta\Phi_{MO/MX} \quad [11.2]$$

So that Eq. [2.3] becomes

$$\delta_X P_{MO/MX} = \frac{2\pi r^2 NS}{T} \left\{ \frac{i_M}{zF} [\delta\mu_M(1) + z\delta\mu_X(2) + zF\delta\Delta\Phi_{MO/MX}] - \frac{i_O}{2F} [\delta\mu_O(1) + 2\delta\mu_H(2) - 2F\delta\Delta\Phi_{MO/MX}] \right\} \quad [12]$$

Transport of M^{z+} , X^- , H^+ , and H_2O occurs in the halide nuclei. Suppose that the ionic conductance is relatively high in the halide so that a linear relation holds between the fluxes and the forces. In this case, Eq. [2.4] could be written as (Appendix A)

$$\delta_X P_{MX} = \frac{2\pi r^2 NS}{3T} \left\{ J'_M \left[\delta\mu_M(2) - \delta\mu_M(3) + zF\delta\Delta\Phi_X - \frac{J'_M}{\bar{n}'_M v'_M} \delta\tau \right] + J'_X \left[\delta\mu_X(2) - \delta\mu_X(3) - F\delta\Delta\Phi_X - \frac{J'_X}{\bar{n}'_X v'_X} \delta\tau \right] + J'_H \left[\delta\mu_H(2) - \delta\mu_H(3) + F\delta\Delta\Phi_X - \frac{J'_H}{\bar{n}'_H v'_H} \delta\tau \right] + J'_W \left[\delta\mu_W(2) - \delta\mu_W(3) - \frac{J'_W}{\bar{n}'_W v'_W} \delta\tau \right] \right\} \quad [13]$$

where J'_M , J'_X , J'_H , J'_W are fluxes of M^{z+} , X^- , H^+ , and H_2O , respectively, in the halide nuclei; $\mu_i(2)$, $\mu_i(3)$ ($i = M, X, H, W$) are chemical potentials of each species in the halide at the interface with the oxide and with the solution, respectively; \bar{n}'_i ($i = M, X, H, W$) is the average concentration of each species within the halide; and v'_i ($i = M, X, H, W$) is the mobility per unit force of each species within the halide.

The following reactions might proceed at the interface between the halide and the solution

Ignoring the backward rate, the partial reaction current density of each reaction is

$$i'_M = k'_M \exp \left(\frac{\mu_M(3)}{RT} \right) \exp \left(\frac{\alpha'_M z F \Delta \Phi_{MX/S}}{RT} \right) \quad [15.1]$$

$$i'_X = k'_X \exp \left(\frac{\mu_X(4)}{RT} \right) \exp \left(\frac{\alpha'_X F \Delta \Phi_{MX/S}}{RT} \right) \quad [15.2]$$

where k'_M , k'_X are the rate constants, $\mu_X(4)$ is the chemical potential of X^- in the solution, α'_M , α'_X are transfer coefficients, and $\Delta \Phi_{MX/S}$ is the Galvani potential difference at the interface between the halide nuclei and the solution. The chemical affinity of each reaction is

$$A'_M = \mu_M(3) - \mu_M(4) + zF\Delta\Phi_{MX/S} \quad [16.1]$$

$$A'_X = \mu_X(4) - \mu_X(3) + F\Delta\Phi_{MX/S} \quad [16.2]$$

Equation [2.5] becomes

$$\delta_X P_{MX/S} = \frac{\pi r^2 NS}{T} \left\{ \frac{i'_M}{zF} [\delta\mu_M(3) - \delta\mu_M(4) + zF\delta\Delta\Phi_{MX/S}] + \frac{i'_X}{F} [\delta\mu_X(4) - \delta\mu_X(3) + F\delta\Delta\Phi_{MX/S}] \right\} \quad [17]$$

Following the same procedure as stated above for the reactions occurring at the interface between the oxide and the solution where the halide nuclei is not generated, it might be true for Eq. [2.6] that

$$\delta_X P_{MO/S} = \frac{(1-\gamma)S}{T} \frac{i''_M}{zF} [\delta\mu_M(3') - \delta\mu_M(4') + zF\delta\Delta\Phi_{MO/S}] \quad [18]$$

where i''_M is the dissolution current density of M^{z+} through the oxide-solution interface; $\mu_M(3')$, $\mu_M(4')$ are the chemical potentials of M^{z+} within the oxide and the solution, respectively, at the oxide-solution interface; and $\Delta \Phi_{MO/S}$ is the Galvani potential difference at the oxide-solution interface. It is assumed that the passive film does not grow or dissolve at the interface with the solution and, consequently, that the steady dissolution of M^{z+} takes place while the reaction participated in by O^{2-} is nearly in equilibrium.

Equations of continuity.—A relationship should exist between the fluxes for each portion of the system; the metal, the passive oxide, the halide nuclei, and the solution. Here fluxes are described in a steady state and no materials or charges are accumulated or consumed locally because the change of the system proceeds very slowly.

The total current I° from the metal to the solution is written as if there is no electron conduction in the oxide layer

$$I^\circ = (zFJ_M - 2FJ_O)S = I_M + I_O \quad [19]$$

where I_M and I_O are the contributions by M^{z+} and O^{2-} , respectively, to the total current I° . I° can be divided into two parts; I , which flows through the halide nuclei into the solution, and I' , which flows directly through the oxide-solution interface

$$I^\circ = I + I' \quad [20]$$

The change in the current I° resulting from the change in τ is mainly due to I , because the current density of dissolution through the halide nuclei is much larger

than that through the oxide-solution interface, so that

$$\delta I^\circ \stackrel{\circ}{=} \delta I \quad [21]$$

It is obtained from Eq. [3] and [19] that

$$\delta I^\circ = \frac{\alpha_M z F a I_M + 2\alpha_O F a I_O}{RT} \left\{ \frac{\delta \Delta \Phi_O}{L - r'} + \frac{\gamma \Delta \Phi_O}{(L - r')^2} \delta r \right\} \quad [22]$$

it was assumed here that $\delta n_i/n_i \stackrel{\circ}{=} 0$ ($i = M, O$) in the oxide film. Equation [3] then becomes

$$\delta_X P_{MO} = \frac{1}{T} \frac{RT(L - r') I^\circ}{\alpha_M z F a I_M + 2\alpha_O F a I_O} \delta I^\circ \quad [23]$$

It can be written at the oxide-halide nuclei interface that

$$I = 2\pi r^2 NS (i_M + i_O) \quad [24]$$

Taking the derivative of Eq. [24] and using Eq. [10.1] and [10.2]

$$\begin{aligned} i_M [\delta \mu_M(1) + z \delta \mu_X(2)] + i_O [\delta \mu_O(1) + 2 \delta \mu_H(2)] \\ = \frac{RT}{2\pi r^2 NS} \left(\delta I - \frac{2}{r} I \delta r \right) \\ - (i_M \alpha_M z F + 2i_O \alpha_O F) \delta \Delta \Phi_{MO/MX} \quad [25] \end{aligned}$$

Assuming that M^{z+} and O^{2-} are nearly in equilibrium in the oxide film so that

$$2\delta \mu_M(1) + z \delta \mu_O(1) = 0 \quad [26]$$

and further assuming that an approximation of the equilibrium condition holds between the chemical potentials of H^+ and X^- in the halide

$$\delta \mu_H(2) + \delta \mu_X(2) = 0 \quad [27]$$

Substituting Eq. [25]-[27] into Eq. [12], and assuming for simplicity that

$$\alpha_O \stackrel{\circ}{=} -\alpha_M \quad [28]$$

it is shown that

$$\begin{aligned} \delta_X P_{MO/MX} = R \frac{i_M + i_O}{zF i_M - 2Fi_O} \left(\delta I - \frac{2}{r} I \delta r \right) \\ + \frac{2\pi r^2 NS}{T} (1 - \alpha_M) (i_M + i_O) \delta \Delta \Phi_{MO/MX} \quad [29] \end{aligned}$$

It can be written for the transport of species within the halide nuclei that

$$I = \pi r^2 NS (zF J'_M - F J'_X + F J'_H) \quad [30]$$

Taking the derivative of Eq. [30] and rearranging

$$\begin{aligned} zF \bar{n}'_M v'_M [\delta \mu_M(2) - \delta \mu_M(3)] \\ - F \bar{n}'_X v'_X [\delta \mu_X(2) - \delta \mu_X(3)] \\ + F \bar{n}'_H v'_H [\delta \mu_H(2) - \delta \mu_H(3)] = \frac{1}{\pi r NS} \delta I - \frac{I}{\pi r^2 NS} \delta r \\ - (z^2 F^2 \bar{n}'_M v'_M + F^2 \bar{n}'_X v'_X + F^2 \bar{n}'_H v'_H) \delta \Delta \Phi_X \quad [31] \end{aligned}$$

It is assumed that an approximation of equilibrium condition holds between the chemical potentials of M^{z+} and X^- and between the chemical potentials of H^+ and X^- in the halide

$$\delta \mu_M(s) + z \delta \mu_X(s) = 0, \quad s = 2, 3 \quad [32.1]$$

$$\delta \mu_H(3) + \delta \mu_X(3) = 0 \quad [32.2]$$

Substituting Eq. [27], [31], [32.1], and [32.2] into Eq. [13] and ignoring the flux of H_2O , it can be shown that

$$\begin{aligned} \delta_X P_{MX} = \frac{2\pi r^3 NS}{3T} \left\{ \frac{I \delta I}{\Lambda_X (\pi r^2 NS)^2} - \left[\frac{1}{\Lambda_X} \left(\frac{I}{\pi r^2 NS} \right)^2 \right. \right. \\ \left. \left. + \frac{J^2_M}{\bar{n}'_M v'_M} + \frac{J^2_X}{\bar{n}'_X v'_X} + \frac{J^2_H}{\bar{n}'_H v'_H} \right] \frac{\delta r}{r} \right\} \quad [33] \end{aligned}$$

where

$$\begin{aligned} \Lambda_X &\equiv z^2 F^2 \bar{n}'_M v'_M + F^2 \bar{n}'_X v'_X + F^2 \bar{n}'_H v'_H \\ &= \frac{z n'_M \lambda'_M}{T'_M} \quad [34] \end{aligned}$$

and λ'_M and T'_M are the ionic equivalent conductance and the transport number of M^{z+} , respectively, in the halide.

The following equation holds at the interface between the halide nuclei and the solution

$$I = \pi r^2 NS (i'_M + i'_X) \quad [35]$$

Taking the derivative of Eq. [35] and using Eq. [15.1] and [15.2]

$$\begin{aligned} i'_M \delta \mu_M(3) + i'_X \delta \mu_X(4) = \frac{RT}{\pi r^2 NS} \left(\delta I - \frac{2I}{r} \delta r \right) \\ - (\alpha'_M z F i'_M + \alpha'_X F i'_X) \delta \Delta \Phi_{MX/S} \quad [36] \end{aligned}$$

Disregarding the chemical potential change of ions in the solution

$$\delta \mu_i(4) = 0, \quad i = M, X \quad [37]$$

and assuming for simplicity that

$$\alpha'_M = \alpha'_X \quad [38]$$

Eq. [17] can be rearranged as follows

$$\begin{aligned} \delta_X P_{MX/S} = \frac{R}{zF} \left(1 + \frac{i'_X}{i'_M} \right) \left(\delta I - \frac{2I}{r} \delta r \right) \\ - \frac{\pi r^2 NS}{T} \left[\frac{\alpha'_M}{zF} \left(1 + \frac{i'_X}{i'_M} \right) (zF i'_M + F i'_X) \right. \\ \left. - (i'_M + i'_X) \right] \delta \Delta \Phi_{MX/S} \quad [39] \end{aligned}$$

The chemical potential of M^{z+} at the interface between the passive film and the solution does not shift greatly, so that

$$\delta \mu_M(3') = \delta \mu_M(4') = 0 \quad [40]$$

Then Eq. [18] becomes

$$\delta_X P_{MO/S} = \frac{1}{T} I \delta \Delta \Phi_{MO/S} \quad [41]$$

From Eq. [2], [21], [23], [29], [33], and [41] it is shown that

$$\begin{aligned} T \delta_M P = \left\{ \frac{RT(L - r') I^\circ}{\alpha_M z F a I_M + 2\alpha_O F a I_O} + \frac{2}{3\Lambda_X} \frac{I}{\pi r NS} \right. \\ \left. + \left[\frac{i_M + i_O}{zF i_M - 2Fi_O} + \frac{1}{zF} \left(1 + \frac{i'_X}{i'_M} \right) \right] RT \right\} \delta I \\ - \left\{ \frac{2}{3} \pi r^2 NS \left[\frac{1}{\Lambda_X} \left(\frac{I}{\pi r^2 NS} \right)^2 + \frac{J^2_M}{\bar{n}'_M v'_M} \right. \right. \\ \left. \left. + \frac{J^2_X}{\bar{n}'_X v'_X} + \frac{J^2_H}{\bar{n}'_H v'_H} \right] + \left[\frac{i_M + i_O}{zF i_M - 2Fi_O} \right. \right. \\ \left. \left. + \frac{1}{zF} \left(1 + \frac{i'_X}{i'_M} \right) \right] RT \frac{2I}{r} \right\} \delta r + (1 - \alpha_M) I \delta \Delta \Phi_{MO/MX} \\ + \left(1 - \frac{\alpha'_M}{zF} \frac{zF i'_M + F i'_X}{i'_M} \right) I \delta \Delta \Phi_{MX/S} + I \delta \Delta \Phi_{MO/S} \quad [42] \end{aligned}$$

Empirical relations.—The current I passing through the halide nuclei increases with an increase in r , because the current coming out of the metal substrate concentrates mostly on the halide nuclei in spite of the large resistance of the oxide film. The following relationship is now assumed

$$I = A \pi r^2 NS \quad [43]$$

here A and χ are constants. χ takes a value between 1 and 2. A is almost the dissolution current per cross section of the halide nuclei (Appendix B), and can be expressed empirically using the externally applied potential of the metal E and the concentration of X^- in the solution C_X

$$A \stackrel{\circ}{=} i = k_X C_X^n \exp\left(-\frac{\xi FE}{RT}\right) \quad [44]$$

where k_X , n , and ξ are constants.

The current passing through the interface between the oxide and the halide nuclei can be expressed empirically as

$$I = 2\pi r^2 NSK \exp\left(\frac{\beta F \Delta \Phi_{MO/MX}}{RT}\right) \quad [45]$$

where K and β are constants. From Eq. [43] and [45]

$$\delta \Delta \Phi_{MO/MX} = -\frac{2-x}{r} \frac{RT}{\beta F} \delta r \quad [46]$$

Similarly, the current passing through the interface between the halide nuclei and the solution can be expressed empirically as

$$I = \pi r^2 NSK' \exp\left(\frac{\beta' F \Delta \Phi_{MX/S}}{RT}\right) \quad [47]$$

where K' and β' are constants. From Eq. [43] and [47]

$$\delta \Delta \Phi_{MX/S} = -\frac{2-x}{r} \frac{RT}{\beta' F} \delta r \quad [48]$$

The potential difference at the oxide-solution interface is assumed to be nearly constant

$$\delta \Delta \Phi_{MO/S} \stackrel{\circ}{=} 0 \quad [49]$$

Actually, the composition of the solution in contact with the halide nuclei differs from that of the solution in contact with the passive film so that a potential difference should arise within the solution due to the ion transport, but this effect can be disregarded. Equation [42] can be rewritten using Eq. [43], [44], [46], [48], and [49], as

$$\delta_X P = F(L, r, i) \delta r \quad [50.1]$$

with

$$F(L, r, i) \equiv \frac{I}{r} \frac{R}{F} \left[\lambda_L X \left(\frac{L}{a} - \frac{\gamma}{a} r \right) - (2-x) \lambda_I - \frac{\lambda_X}{\Lambda_X} \frac{F}{RT} i r^{\chi-1} \right] \quad [50.2]$$

Here λ_L , λ_I , and λ_X are positive constants defined by

$$\lambda_L \equiv \frac{I_M + I_0}{\alpha_M z I_M + 2\alpha_0 I_0} \quad [50.3]$$

$$\lambda_I \equiv \frac{i_M + i_0}{z i_M - 2i_0} + \frac{1}{z} \left(1 + \frac{i'_X}{i'_M} \right) + (1-\alpha) \frac{1}{\beta} + \left(1 + \frac{\alpha'_M}{z} \frac{z i'_M - i'_X}{i'_M} \right) \frac{1}{\beta'} \quad [50.4]$$

$$\lambda_X \frac{I^2}{\Lambda_X r^2 NS} \equiv \frac{2}{3} \pi r^2 NS \left[-(\chi-1) \frac{1}{\Lambda_X} \left(\frac{I}{\pi r^2 NS} \right)^2 + \frac{J^2_M}{\bar{n}'_M v'_M} + \frac{J^2_X}{\bar{n}'_X v'_X} + \frac{J^2_H}{\bar{n}'_H v'_H} \right] \quad [50.5]$$

and have an order of magnitude of 1 (Appendix C).

Pit initiation.—According to Eq. [1], the whole system changes irreversibly so that the right-hand side of Eq. [50.1] becomes negative. Therefore, if $F(L, r, i)$ is negative, then $\delta r > 0$, and the halide nuclei would start to grow. In Fig. 3, the change of $F(L, r, i)$ with r was illustrated schematically. If there were a halide

Fig. 3. Variation of $F(L, r, i)$ (case $\chi \stackrel{\circ}{=} 2$ in Eq. [50.2]) as a function of the radius r of the halide nuclei. $E_1 > E_p > E_2$, E_p : pit initiation potential at which $r^* = r_{max}$.

nucleus whose radius were larger than the critical radius r^* , it would grow continuously until it broke through the passive film and caused pitting.

For simplicity let χ be 2, since the current coming out of the metal substrate easily concentrates in the halide nuclei because the passive film is not thick enough. The critical radius r^* in this case is

$$r^* = \frac{2\lambda_L \frac{L}{a}}{2\lambda_L \frac{\gamma}{a} + \pi \frac{\lambda_X}{\Lambda_X} \frac{F}{RT} i} \quad [51]$$

It can be seen from Eq. [44] and [51] that r^* increases proportionally to the passive film thickness L , and decreases with the increase in the potential of the metal E and the X^- concentration C_X in the solution.

In order for pitting to occur, r^* must be smaller than the maximum statistically attainable value r_{max} .¹ Equation [51] gives at $r^* = r_{max}$

$$\pi \frac{\lambda_X}{\Lambda_X} \frac{F}{RT} k_X C_X^n \exp\left(\frac{\xi FE_p}{RT}\right) = 2\lambda_L \frac{1}{a} \left(\frac{L}{r_{max}} - \gamma \right) \quad [52]$$

Consequently, a pit will form when the potential E exceeds E_p , as shown in Eq. [52]. This potential can be referred to as the pit initiation potential, or the potential of pit nucleation.

Discussion

An irregular current oscillation was observed before pit formation when the metal was polarized anodically in solutions containing halide ions (17). This observation agrees qualitatively with the present theory in which it was assumed that the pit is not generated immediately at the flaw of the passive film, but after the "halide nuclei" grow inwards or diminish at the surface of the passive film.

Substituting Eq. [B.1] and [B.5] into Eq. [51] and using the relationship

$$\Lambda_X R_X \stackrel{\circ}{=} 1 \quad [53]$$

the potential difference within the halide nuclei at the pit initiation potential can be estimated

$$\lambda_X \Delta \Phi_X \frac{F}{RT} \stackrel{\circ}{=} 2\lambda_L \frac{1}{a} (L - \gamma r_{max}) \quad [54]$$

¹ r_{max} can be replaced by L when the passive film is not very thick. Usually, r_{max} would have a value in nanometers.

The thickness of the passive film might be measured in nanometers or some tens of nanometers, whereas a would be several tenths of a nanometer so that L/a would have the magnitude of several tens of nanometers. It can be concluded from the above equation that $\Delta\phi_x$ is larger than some tenths of volts at the pit initiation potential. This implies that the pit initiation potential becomes more positive than the thermodynamically estimated potential for the halide formation on the surface of the metal by an order of magnitude of 1V.

If the passive film thickness is not very thick, then $x \approx 2$ in Eq. [43]. Equation [52] holds in this case, which states that pits will appear as the concentration C_x increases and the potential of the metal exceeds E_p . Equation [52] further predicts the relationship

$$E_p = \text{const.} - \frac{nRT}{eF} \ln C_x \quad [55]$$

which agrees with many experimental results (15, 18, 19).

On the other hand, if the passive film is thick, x in Eq. [43] is less than 2, so that there should be cases where pit initiation and passive film breakdown cannot occur when the film thickness increases with the increase in the potential or when it increases at a constant potential with time.

The induction period τ is considered to be one of the most characteristic variables of the pit initiation process. This is the time required for the first appearance of the pit after the establishment of conditions for pitting (19, 20). Suppose that the critical radius r^* , which is the minimum necessary size for growing halide nuclei, is given by Eq. [51]. The volume of the nucleus is $2\pi r^{*3}/3$. A sufficient number of X^- should be supplied by transportation at the passive film-solution interface so that this size of nucleus can appear by fluctuation or by any other process.² The time required to meet this condition can be regarded as τ , then the relationship

$$\sqrt{\tau} \propto r^* \quad [56]$$

should exist between τ and r^* . Equation [56] coupled with Eq. [44] and [51] leads to

$$\ln \tau = \text{const.} - 2n \ln C_x - \frac{2eFE}{RT} \quad [57]$$

Hoar and Jacob (10) experimentally obtained the relationship

$$\ln \tau = \text{const.} - m \ln C_x \quad [58]$$

and Heusler and Fisher (20) stressed the relationship

$$\ln \tau = \text{const.}/(\ln C_x/C_{xc})(\ln C_H/C_{hc})(E - E_p) \quad [59]$$

where C_{xc} and C_{hc} are the critical concentrations of X^- and H^+ , respectively, above which pitting can occur. The above two relationships coincide qualitatively with Eq. [57].

Aggressive ions are known to cause passive film thinning (19), which accelerates the pit formation. It should also be mentioned that once a flaw in the passive metal is attacked by aggressive ions, this creates preferential penetration of these ions at that point. These effects make the pitting phenomenon more complicated and are therefore not considered explicitly in this study.

Manuscript submitted Dec. 7, 1982.

² It should be noticed that halide formation has become thermodynamically stable under these conditions, and that halide nucleation is possible if one only considers the local situation around a halide nucleus to be generated. However, the irreversible system as a whole does not permit the stable existence of halide nuclei whose radius is less than r^* .

APPENDIX A

Let the x-axis pass through the center of a hemispherical halide nucleus into the solution. The flux of each species within the halide is considered to be so fast because of the high ionic conductance that it can be expressed similarly to the case of the transport of ions in solution, i.e.

$$J'_i = -n'_i v'_i \frac{\partial \tilde{\mu}_i}{\partial x}, \quad i = M, X, H, W \quad [A.1]$$

where n'_i , v'_i , and $\tilde{\mu}_i$ are the concentration, the mobility per unit force, and the chemical potential, respectively, of the i-species in the halide. In general, the flux can be expressed as a function of y' , the radial distance from the x-axis. Assuming that the electrochemical potential changes linearly along with the x-axis

$$J'_i(r') = \bar{n}'_i v'_i \frac{\tilde{\mu}_i(2, y') - \tilde{\mu}_i(3)}{\sqrt{r^2 - y'^2}} \quad [A.2]$$

where \bar{n}'_i is the average concentration of i-species within the halide, $\tilde{\mu}_i(2, y')$ is the chemical potential of i-species upon the interface between the oxide and the halide at the distance y' from the x-axis.

Let the equelectrochemical potential plane be parallel to the interface between the solution, so that

$$\tilde{\mu}_i(2, r') = [\tilde{\mu}_i(2, 0) - \tilde{\mu}_i(3)] \frac{\sqrt{r^2 - y'^2}}{r} + \tilde{\mu}_i(3) \quad [A.3]$$

Equations [A.2] and [A.3] give

$$J'_i(r') = J'_i = \bar{n}'_i v'_i \frac{\tilde{\mu}_i(2, 0) - \tilde{\mu}_i(3)}{r} \quad [A.4]$$

Then Eq. [2.4] leads to

$$\delta_x P_{MX} = \frac{2}{3} \pi r^3 NS \frac{1}{T} \bar{\Sigma} \bar{n}'_i v'_i \frac{\tilde{\mu}_i(2, 0) - \tilde{\mu}_i(3)}{r} \left[\frac{\delta \mu_i(2, 0) - \delta \mu_i(3)}{r} + z_i F \frac{\delta \Delta \phi_x}{r} - \frac{J'_i}{\bar{n}'_i v'_i} \frac{\delta r}{r} \right] \quad [A.5]$$

Designating $\tilde{\mu}_i(2, 0) = \tilde{\mu}_i(2)$, Eq. [A.5] becomes Eq. [13]. It should be noted that the rate and the affinity of the interfacial reactions between the oxide and the halide nuclei could be a function of y' generally, but such effects were disregarded here and they were all represented by those at $y' = 0$, i.e., at the deepest point of the halide nuclei (see Eq. [12]).

APPENDIX B

Suppose that the halide nucleus is an ionic conductor. If the specific resistance of the halide is designated by R_x , then

$$I = \frac{1}{R_x} \frac{\pi r^2 NS}{r} \Delta \phi_x \quad [B.1]$$

and

$$\delta I = \frac{I}{r} \delta r + \frac{\pi r NS}{R_x} \delta \Delta \phi_x \quad [B.2]$$

In the case where the halide nuclei have a very high ionic conductivity, so that the potential difference through the halide nuclei is substantially determined by the potential of the metal and is almost constant through the progress of the irreversible change, i.e.

$$\delta \Delta \phi_x \stackrel{\circ}{=} 0 \quad [B.3]$$

Eq. [B.2] becomes

$$\delta I = \frac{I}{r} \delta r \quad [B.4]$$

This case corresponds to $x = 1$ in Eq. [43].

On the other hand, in the case where the dissolution reaction rate through the halide nuclei can be assumed for hemispherical pitting corrosion (15, 16)

$$I = 2\pi r^2 NSi \quad [\text{B.5}]$$

here i is a dissolution current per unit of interface area of the halide nucleus which contacts with the oxide. In this case, $x = 2$ in Eq. [43]. Comparison of Eq. [B.1] or [B.5] with Eq. [43] would yield

$$A \doteq i \quad [\text{B.6}]$$

APPENDIX C

The case of $x = 2$ would be enough to verify the point. With the use of Eq. [30] and [34]

$$\begin{aligned} & \frac{2}{3} \pi r^2 NS \left[-\frac{1}{\Lambda_X} \left(\frac{I}{\pi r^2 NS} \right)^2 \right. \\ & \quad \left. + \frac{J_M^2}{\bar{n}'_M v'_M} + \frac{J_X^2}{\bar{n}'_X v'_X} + \frac{J_H^2}{\bar{n}'_H v'_H} \right] \\ & = \frac{2}{3} \pi r^2 NS [\bar{n}'_X v'_X (F n'_H v'_H J'_M \\ & - z F n'_M v'_M J'_H)^2 + \bar{n}'_H v'_H (F n'_X v'_X J'_M \\ & + z F \bar{n}'_M v'_M J'_X)^2 + \bar{n}'_M v'_M (F n'_H v'_H J'_X \\ & + F \bar{n}'_X v'_X J'_H)^2] / \bar{n}'_M v'_M \bar{n}'_X v'_X \bar{n}'_H v'_H \\ & \quad (z^2 F^2 \bar{n}'_M v'_M + F^2 \bar{n}'_X v'_X + F^2 \bar{n}'_H v'_H) \\ & = O \left(\frac{I^2}{\Lambda_X r^2 NS} \right) > 0 \quad [\text{C.1}] \end{aligned}$$

The left-hand side of Eq. [C.1] is put to $\lambda_X I^2 / \Lambda_X r^2 NS$.

Polarization Behavior of the Nickel Electrode in Molten Sulfides

C. T. Liu* and O. F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Polarization behavior of the Ni-200 electrode in 75% Na₂S-25% FeS at 1000°C under H₂-0.32% H₂S at 1 atm is linear over an overpotential range of $-600 \leq \eta \leq 600$ mV and is consistent with resistance polarization in the electrolyte. Similar polarization behavior of the 304 stainless steel electrode and of the Ni-200 electrode in 85% Na₂S-15% NiS suggests that the charge transfer mechanism is a sulfide/polysulfide exchange reaction. Nonelectrode dissolution of nickel in the 75% Na₂S-25% FeS melt occurs at 1.6×10^{-6} g cm⁻² s⁻¹, apparently due to oxidation by H₂S. Anomalously high dissolution rates are attributed to trace polysulfide.

The virtual omnipresence of sulfur in fossil fuels raises concern regarding sulfur-caused corrosion in high temperature fuel utilization and conversion processes. In particular, coal conversion processes operate under conditions of low oxygen potential (1), in which many metal sulfides are stable (2), and at temperatures sufficient for these sulfides to be molten, rendering reactor structures subject to catastrophic failure by hot corrosion (3). Similar concerns may be voiced concerning the sodium-sulfur battery, which operates at considerably lower temperatures (ca. 400°C) in the presence of sodium polysulfide (3). Considerable insight with regard to reaction rates and mechanisms in such hot corrosion processes may be gained through electrode polarization studies; our recent experience with the nickel electrode in molten sodium carbonate (4) prompted the following study of the polarization behavior of nickel electrodes and of the nonelectrode dissolution of nickel in molten sulfide mixtures.

Experimental System

Our polarization cell has been described previously (5). It is limited to temperatures not greatly in excess of 1000°C, and employs a reference electrode which is, in effect, reversible to sodium ion (6). The latter fact led us to consider sodium sulfide (Na₂S) as the corrosive electrolyte; however, the melting point of this compound has been reported as 1180°C, prohibitively high for our apparatus (7-10). (Other values as low as 950°C have been reported (11-13). These values, however, may be due to partial oxidation of the sulfide samples investigated; Courtois (8) reported a melting point of 1180°C for Na₂S, but a liquidus temperature of 950°C for the 87% Na₂S-13% Na₂SO₄ solution.) Consequently, we selected ferrous sulfide (FeS) as a melting point lowering solute, primarily because of the availability of considerable data on the Na₂S-FeS system (12, 14, 15), although in retrospect another alkali sulfide might have been preferable. We used the eutectic composition of 25 weight percent (w/o) FeS, melting at 650°C, reported

* Electrochemical Society Active Member.

Key words: electrode, nickel, sulfide, dissolution, polarization.

by Kopylov and Novoselov (14) to exist between Na_2S and $5\text{Na}_2\text{S} \cdot 2\text{FeS}$. A crude DTA measurement of this mixture gave a melting point of 686°C in reasonable agreement with the published value. Although FeS nominally displays excellent electronic conduction (it may contain as much as 20% excess sulfur and is, therefore, a p-type semiconductor through formation of Fe^{+3}), Velikanov *et al.* (15) reported that conductivities of molten Na_2S -FeS mixtures vary only slightly with composition up to 45 mol percent (m/o) (48 w/o) FeS, implying that in this range melt conductivity is primarily ionic. The equilibrium between solid iron and the 75% Na_2S -25% FeS melt at 1000°C was estimated (16) to occur at $P_{\text{H}_2\text{S}}/P_{\text{H}_2} = 2.4 \times 10^{-3}$, while the equilibrium between solid nickel and the nickel-saturated sulfide melt at 1000°C was given by Nagamori and Ingraham (17) as $P_{\text{H}_2\text{S}}/P_{\text{H}_2} = 4.0 \times 10^{-3}$, delineating a narrow range of gas compositions in which both the electrolyte and the nickel electrodes are stable. The cell environment was fixed at the midpoint of this range ($P_{\text{H}_2\text{S}}/P_{\text{H}_2} = 3.2 \times 10^{-3}$) using a certified standard mixture from the Matheson Company.

Experimental Procedure

Dissolution and polarization experiments were conducted in a vertical tube furnace with proportioning temperature control. The electrolyte cell was housed in a closed end mullite tube, 3.5 in. od, which terminated in a vacuum-tight water-cooled flange which permitted electrical, mechanical, and gas flow feed-throughs. Nickel specimens were prepared from Ni-200 rod 0.25 in. diam, mechanically polished with 600 grit SiC paper, and washed and dried prior to use. Specimens were approximately 0.4 in. long (ca. 2.3 cm^2 exposed surface) and were cemented to alumina tubes with alumina cement (Ultra-Bond 552, Aremco Products, Incorporated). The alumina tubes in turn passed through the vacuum flange closing the top of the furnace tube and permitted positional control through sliding O-ring seals as well as housing electrode wires during polarization. Approximately 100g of electrolyte was employed in each run. This was contained in a recrystallized alumina crucible for dissolution experiments, or graphite crucible for polarization experiments. The latter also served as counterelectrode. Ferrous sulfide was purchased as 99+ % FeS from Great Western Inorganics Company; Na_2S was prepared by dehydrating reagent-grade $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ from J. T. Baker Chemical Company in two stages: first, the hydrated sulfide was stored in a desiccator, which was evacuated daily, for several weeks; this removed approximately 70% of the water. Afterward, the desiccated sulfide was slowly heated to 200°C under a 1 torr vacuum and stored in a desiccator for future use. Thermogravimetric analysis demonstrated that this procedure removed 95% of the water, and that heating to higher temperatures was counterproductive in that sulfate was formed.

The components of the electrolyte were thoroughly mixed, then held at 200°C in the cell overnight under the $\text{H}_2\text{S}/\text{H}_2$ mixture. Subsequently the cell was slowly heated to 1000°C and held for a minimum of 1h to complete moisture removal and permit reduction of any sulfate present. The initial flow rate of the cell gas was $25 \text{ cm}^3/\text{min}$; prior to melting of the electrolyte it was set at $100 \text{ cm}^3/\text{min}$ for the remainder of the experiment. Equilibrium calculations indicated that the electrolyte was stable against oxidation at air-leak rates approximating the gas flow rate, while Kopylov's data indicate that Na_2S is stable against hydration at $P_{\text{H}_2\text{O}} = 1 \text{ atm}$ at temperatures above 190°C (18).

Potentiostatic polarization measurements were performed using the nickel specimen as working electrode, the graphite crucible as counterelectrode, and the previously described reference electrode (6). Potential

was fixed by standard instrumentation, employing a fixed step rate of $2 \text{ mV}/20\text{s}$. The potential sweep was from maximum cathodic potential (-800 mV) to maximum anodic potential (400 mV), and then back to maximum cathodic potential. Polarization data were directly recorded as potential *vs.* log current.

Several nonelectrode dissolution experiments were performed simultaneously by the simple expedient of suspending several mounted specimens over the melt at once. At the onset of the test, one specimen would be lowered into the melt, followed by the others at fixed intervals of 10 or 20h. No significant weight change occurred prior to immersion; *i.e.*, the nickel specimens were in theory and in fact inert to the cell atmosphere. Weight change was established by weighing clean specimens before and after immersion.

Results

Polarization was linear over the potential range studied; a typical curve, redrawn from the as-recorded semi-log plot, is shown in Fig. 1. The abscissa is not normalized to unit area because of the obvious change in specimen surface area that occurred during each test. The initial (cathodic-to-anodic) polarization curve has a slope of 0.78Ω ; this value was typical. In some, but not all, runs the anodic curve showed a slight hysteresis; Fig. 1 shows a slope of 1.02Ω for the anodic portion of the anodic-to-cathodic polarization. Using an aqueous electrolyte of known conductance, we estimated the cell constant to be 1.4 cm^{-1} ; with this value and the conductance measured by Velikanov, *et al.* (15) for 62% Na_2S -38% FeS at 1000°C , $1.8 \Omega^{-1} \text{ cm}^{-1}$, the electrolyte resistance was estimated as 0.78Ω . This excellent agreement (again, the data of Velikanov, *et al.* show very little variation with composition in this range) strongly implies that the observed polarization is attributable to ohmic resistance of the electrolyte. In agreement with this a comparable experiment using a different working electrode, 304 stainless steel, gave a cell resistance of 0.80Ω , demonstrating little, if any, effect of electrode material on cell resistance. The cell resistance at 900°C , using the nickel electrode, was found to be 0.75Ω , implying an activation energy for electrolytic charge transport of -1.16 kcal/mol . This may be meaningful; cell resistance was found to be reproducible and small, negative activation energies have been reported for other salts (11).

Nonelectrode weight loss measurements from three runs (thirteen specimens) are plotted in Fig. 2. All measurements save those for the longest immersion

Fig. 1. Linear polarization plot for Ni-200 in 75% Na_2S -25% FeS at 1000°C . Initial specimen area: 2.3 cm^2 . Potential measured vs. $\text{CO}, \text{CO}_2(\text{Pt})|\text{Na}_2\text{CO}_3$ electrode (0.38 atm CO , 0.62 atm CO_2).

Fig. 2. Nonelectrode weight loss measurements for Ni-200 in 75% Na₂S-25% FeS at 1000°C. Initial specimen area: 2.3 cm².

time in each run fit a linear dissolution rate of 3.7×10^{-6} g s⁻¹, or 1.6×10^{-6} g cm⁻² s⁻¹. This is clearly attributable to oxidation of nickel by H₂S

which must occur until the melt approaches saturation with nickel sulfide; that is, the value for $P_{\text{H}_2\text{S}}/P_{\text{H}_2}$ employed for these experiments is just below the value at which nickel and nickel-saturated nickel sulfide are in equilibrium ($a_{\text{Ni}} \sim a_{\text{NiS}} \sim 1$), while the electrolyte for these studies initially contains no nickel ($a_{\text{NiS}} = 0$) and never attains more than a few percent nickel ($a_{\text{NiS}} \ll 1$). In each run the specimen immersed first (i.e., that with the longest immersion time) shows a disproportionately high dissolution; this is discussed in the next section.

Discussion

The Butler-Volmer equation, which describes the net rate of a single electrode reaction controlled by electron transfer, is written

$$i = i_0 [e^{(1-\beta)\eta_a F/RT} - e^{-\beta\eta_a F/RT}] \quad [2]$$

where i is the observed current, i_0 is the exchange current, η_a is the activation overpotential, β is a symmetry factor ($0 < \beta < 1$), and R , T , and F have their usual meanings. The exponential terms may be expanded, and when η_a is sufficiently small, Eq. [2] reduces to

$$i = i_0 \eta_a F/RT \quad [3]$$

i.e., linear activation polarization. The region of validity of Eq. [3] is greatest when $\beta = 0.5$, in which case it may be shown that the linear relation is about 10% in error when $|\eta_a| = 1.5 RT/F$, or 0.165V at 1000°C. The region of validity is smaller for other values of β , approaching 0.022V as β approaches either 0.0 or 1.0. Linearity of current with potential was observed, however, over a significantly greater overpotential range, from -600 to +600 mV. Invoking a simple model, that the observed overpotential may be regarded as the sum of a charge transfer overpotential and an ohmic potential drop in the electrolyte, it is clear that only a small portion of the observed overpotential is attributable to charge transfer and that the remainder is ohmic. This is, of course, in agreement with the excellent correlation between measured cell resistance and published conductance values (15). As a corollary to this observation, the exchange current density must be relatively large to permit a cell current of 850 mA (current density ~ 370 mA cm⁻²) to be carried within the linear

range of Eq. [2]. That is, the overpotential is clearly the sum of two linear contributions; that due to conduction in the electrolyte is inherently linear, while that due to charge transfer is linear only if i_0 is greater than the ratio of the maximum current at which linearity is observed to the maximum value of $\eta_a F/RT$ at which linearity can be observed. Thus, we may infer that $i_0 \geq 370/1.5 = 250$ mA cm⁻².

We may postulate as likely candidates for the mechanism of charge transfer at the electrode surface the reactions

and

Of these, the similarity of the polarization behavior of Ni-200 and 304 stainless steel electrodes suggests that reaction [4] is not dominant. Similarly, a single polarization experiment performed with a nickel electrode in an electrolyte of 85% Na₂S-15% NiS yielded a curve identical to those obtained with the 75% Na₂S-25% FeS electrolyte, demonstrating that reaction [5] is not dominant.¹ Reaction [7] does not seem the probable charge transfer mechanism because it must necessarily experience concentration polarization; oxidation of CO and of H₂ at the nickel electrode in molten sodium carbonate at substantially higher pressures entails limiting diffusion currents of the order of a few mA/cm² (4, 19), values inconsistent with the high currents passed by this electrode.

Thus, by elimination we infer that the predominant charge transfer mechanism is a sulfide/polysulfide exchange. In this context, the departure from linearity seen during anodic polarization and the increased cell resistance during the anodic portion of the anodic-to-cathodic sweep could be interpreted as a concentration polarization involving sulfide by the following argument: as noted above, the measured overpotential may be regarded as the sum of an activation or charge transfer overpotential and an ohmic potential difference

$$\eta = \eta_a + \eta_r \quad [8]$$

From Eq. [3]

$$\eta_a = \frac{iRT}{i_0 F} \quad [9]$$

and, writing the ohmic resistance of the cell as r and the electrode area as A

$$\eta_r = iA r \quad [10]$$

or

$$\eta = \left(\frac{RT}{i_0 A F} + r \right) iA \equiv iA r_{\text{eff}} \quad [11]$$

where, again, iA is the measured cell current. The effective resistance of the cell (r_{eff}) increased from 0.78 to 1.02Ω as a result of anodic polarization. Inasmuch as the value of r_{eff} during subsequent cathodic polarization is not affected, it is clear that the parameter that controls the change in slope is not electrode area (A), but the exchange current density (i_0) for the anodic reaction. This parameter is proportional to the product of reactant activities (21), e.g., from reaction [6] $i_0 \propto a_{\text{S}_x} a_{\text{S}^{2-}}$, or, if $x = 1$ and transfer of a single electron is rate controlling, $i_0 \propto a_{\text{S}^{2-}}$. From the foregoing estimate that $i_0 \geq 250$ mA cm⁻² and given that $A = 2.3$ cm², it is clear that $RT/i_0 A F \leq 0.2\Omega$, which is close in magnitude to the observed change in r_{eff} . The mecha-

¹ Although in analogy to iron, nickel has higher oxidation states, the large positive free energy change for the reaction $\text{Fe}_2\text{O}_3 + 2\text{NiO} \rightleftharpoons 2\text{FeO} + \text{Ni}_2\text{O}_3$ ($\Delta G^\circ = 75.9$ kcal/mol at 25°C (13, 20)), suggests that these will be formed only at more oxidizing potentials than that required for formation of Fe³⁺.

nism for the change in slope is, thus, as follows: during initial anodic polarization the activity of sulfide, $a_{S^{2-}}$, at the electrode surface is large and the exchange current density is appreciably in excess of its minimum value, 250 mA cm^{-2} . During this portion of the polarization sweep, charge transfer polarization is insignificant in comparison to the ohmic potential difference. However, as a result of anodic polarization, the anolyte is enriched in polysulfide (S_{1+x}^{2-}) and the activity of sulfide is correspondingly decreased. The resulting decrease in the magnitude of the exchange current density causes a significant charge transfer contribution to the total overpotential; the effective increase in the cell resistance due to this effect can be 0.2Ω (approximately equal to the observed change) without entailing a substantive departure from linearity. The customary approach to asymptotic behavior associated with concentration polarization is, in fact, seen at the upper end of the cathodic-to-anodic sweep in Fig. 1; this region of the curve was somewhat smoother and of more traditional appearance in other experiments. This concentration polarization persists, i.e., η_a remains inversely proportional to the reduced value of i_0 , as long as the electrode is anodic. When the electrode becomes cathodic, reaction [6] reverses, S_{1+x}^{2-} is consumed, and the activity of sulfide is restored to its initial value.

Following both polarization and dissolution experiments in the 75% Na_2S -25% FeS melt, substantial quantities of a cubic Ni-Fe precipitate (Ni:Fe \sim 4:1) were recovered. We attribute this to a loss of sulfur from the melt due to reduction by hydrogen, coupled with a narrowing of the stoichiometric range of NiS and FeS as the melt was cooled to room temperature, rather than to cathodic reduction of the metals.

The disproportionately high weight loss of the first specimen immersed in each dissolution experiment is consistent with the existence of a low level of polysulfide ion in the as-melted electrolyte. Thomas and Rule have reported that sodium disulfide is extremely stable (22), and Tegman's postulated distributions of the concentrations of $S^=$, $S_2^=$, . . . $S_8^=$ as functions of equilibrium P_{S_2} (23) suggest at least trace levels of $S_2^=$ in our system, for which $P_{S_2} = 5.3 \times 10^{-8}$ atm. In our preparation of anhydrous Na_2S we observed a faint yellow color, which is associated with the presence of the disulfide Na_2S_2 (10, 24). The disulfide ion would function as an oxidizing agent, and the presence of 1% Na_2S_2 in the 100g melt would account for the dissolution of 0.6g of nickel via the reaction

which is of the order of the anomalous initial weight loss.

Figure 3 shows a polished section through the near-surface region of a specimen subsequent to a dissolution experiment. The high intra- and intergranular void density in this region is quite suggestive of hydrogen injection under the influence of a large fugacity gradient due to reaction [1], although a somewhat comparable structure with evidence of sulfide inclusions has been noted in gas-phase attack of iron by H_2S (25). However, EDX analysis showed no indication of sulfur in the sample shown in Fig. 3.

Conclusions

Polarization of Ni-200 and 304 stainless steel electrodes in 75% Na_2S -25% FeS and 85% Na_2S -15% NiS melts at 1000°C is linear over an overpotential range of -600 (cathodic) to 600 mV (anodic), with a cell resistance consistent with published values for conductivity of the electrolyte. Charge transfer overpotential can account for only a small portion of the measured overpotential and is apparently unrelated to corrosion of the electrode: It is attributed to a sulfide/polysulfide exchange reaction with an exchange current density in

Fig. 3. SEM micrograph of section through a Ni-200 specimen exposed to 75% Na_2S -25% FeS for 10h at 1000°C . The specimen surface is seen at the upper left-hand corner. Marker is $100 \mu\text{m}$.

excess of 250 mA cm^{-2} . Nonelectrode dissolution of nickel in the 75% Na_2S -25% FeS melt at 1000°C occurs at $1.6 \times 10^{-6} \text{ g cm}^{-2} \text{ s}^{-1}$, corresponding to a dissolution current at the rest potential of $5.3 \times 10^{-3} \text{ A cm}^{-2}$. An anomalously high initial dissolution rate is attributed to trace polysulfide in the melt.

Solution of Some Integral Equations Occurring in the Theory of Electrochemical Nucleation and Growth

S. Fletcher*

CSIRO, Institute of Energy and Earth Resources, Division of Mineral Chemistry, Port Melbourne, Victoria 3207, Australia

ABSTRACT

A formula is derived for the average value of any crystal growth parameter observed during electrochemical nucleation and growth. The formula contains a Volterra integral equation of the first kind and therefore cannot always be solved explicitly. However, it can be solved under certain conditions, and these are discussed. The most important solutions are collected into tables.

A large part of electrochemical nucleation theory deals with the prediction of the time evolution of the mean value properties of ensembles of crystals (1-3). The purpose of the present work is to describe some new solutions to this problem for the special case where all crystals have the same geometry, grow by the same mechanism, and are independent of each other and of electrode boundaries. Solutions are established using integral equation methods. As usual in the theory of integral equations, the Dirichlet notation $y = f(x)$ is used to mean both " y is a function of x " and " $f(x)$ is the value of the function y at a particular x ." Throughout the text, parentheses, (), are reserved for this notation, square brackets, [], for multiplication, and braces, { }, for functionals. The superscript primed, as in the function $f'(x)$, denotes the first derivative of the function with respect to the argument x .

Derivation of Ensemble Average Quantities in Terms of Integral Equations

We begin with an example. Suppose we are interested in the total volume of an ensemble of hemispherical crystals which are nucleating and growing on a battery plate over the interval $(0, t)$. One way to write this is as the sum of the volumes of all of the crystals considered independently (4)

$$V_N(t) = \sum_{j=1}^{N(t)} \frac{2\pi}{3} R_1(\tau_j, t)^3 \quad [1]$$

Where $R_1(\tau, t)$ is the radius of one crystal that appeared at time τ and is observed at time t , and $N(t)$ is the experimentally observed number of crystals at time t . Another way of writing $V_N(t)$, valid for large $N(t)$, is to approximate it by its expectation value $E\{V_N(t)\}$. This latter approach, which is useful when the τ_j are closely spaced, is used in the present work. In particular, $N(\tau)$ is chosen to be so large that it can be described by a continuous real-valued function of τ over at most a finite number of intervals in the range $0 \leq \tau \leq t$. Thus $N(\tau)$ is assumed to be arbitrarily close to its expectation value $E\{N(\tau)\}$, and since the conditional probability density of the times τ at which crystals appear has the form (4)

$$p(\tau|0 \leq \tau \leq t) = \begin{cases} \frac{N'(\tau)}{N(t)}, & 0 \leq \tau \leq t \\ 0, & \text{otherwise} \end{cases} \quad [2]$$

then it follows that the expectation value of the volume of one crystal is

$$E\{V_1(t)\} = \int_0^t \frac{2\pi}{3} R_1(\tau, t)^3 p(\tau|0 \leq \tau \leq t) d\tau \quad [3]$$

given only that all crystals grow via the same mechanism. Hence the expectation value of the total volume $V_N(t)$ of the ensemble of crystals is

$$E\{V_N(t)\} = \int_0^t \frac{2\pi}{3} R_1(\tau, t)^3 N'(\tau) d\tau \quad [4]$$

which is therefore a good approximation to Eq. [1] when $N(\tau)$ is large.

The above approach is easily generalized to the expectation values of other crystal growth parameters. Defining some extensive property $\lambda_N(t)$ of an ensemble of $N(t)$ crystals, then its expectation value is clearly

$$E\{\lambda_N(t)\} = \int_0^t \lambda_1(\tau, t) N'(\tau) d\tau \quad [5]$$

where $\lambda_1(\tau, t)$ is the value of λ for one crystal appearing at time τ and observed at time t , and the whole equation has the form of a Volterra integral equation of the first kind (5, 7).

A specialization of Eq. [5] of some experimental interest occurs when $\lambda_1(\tau, t)$ has a power law dependence on crystal radius, for crystal growth in any number of dimensions. In this case, the expectation value of $\lambda_N(t)$ can be expressed in the form

$$G(t; \kappa) = \int_0^t R_1(\tau, t)^\kappa N'(\tau) d\tau \quad [6]$$

where $G(t; \kappa)$ is some function of time for a specified κ . Experimental parameters that can be represented in this way include crystal volumes, surface areas, peripheral lengths, and electrical charges. The first derivative of Eq. [6] is interesting too. This is because other experimental parameters, such as linear crystal growth rates and electrical currents, have representations in

* Electrochemical Society Active Member.

Key words: electrodeposition, crystallization, kinetics, nucleation.

the form $G'(t; \kappa)$. Such derivatives are obtained by applying the generalized Leibnitz formula (8) to Eq. [6]. Hence, if $R_1(t, t) = 0$ then

$$G'(t; \kappa) = \int_0^t \kappa R_1(\tau, t)^{\kappa-1} \frac{\partial}{\partial t} R_1(\tau, t) N'(\tau) d\tau \quad [7]$$

Explicit Formulas for Ensemble Average Quantities for Cases Where Crystal Radii Have Power-Law Dependences on Elapsed Time

To compare theoretical and experimental values of ensemble average quantities it is desirable to solve Eq. [6] and [7] for specified $N(t)$ and $R(t)$. Of particular interest in electrochemical nucleation theory is the case when the kernel $R_1(\tau, t)^\kappa$ is a function of $[t - \tau]$ only (1, 2), for in that case the radius of a crystal appearing at time τ and observed at time t depends only on the elapsed time $[t - \tau]$, not on some complex parameter connected with time varying growth rates in the interval (τ, t) . Then Eq. [6] takes the form of a convolution integral of the first kind

$$H(t; \kappa) = \int_0^t R_1(t - \tau)^\kappa N'(\tau) d\tau \quad [8]$$

and from this a number of solutions can be obtained by means of Laplace transforms and the convolution theorem. A particularly interesting subset of solutions is that for which $R_1(t - \tau)^\kappa$ has a power-law dependence on elapsed time $[t - \tau]$, as is expected for crystal growth under interfacial control at constant potential (1, 2). Then Eq. [6] can be written in the form

$$M(t; y) = \int_0^t [t - \tau]^y N'(\tau) d\tau \quad [9]$$

which is soluble under a very wide range of conditions (9), being related to the Riemann-Liouville fractional integral of order $(y + 1)$.

Another advantage of seeking conditions for which the kernel $R_1(\tau, t)^\kappa$ has a power-law dependence on elapsed time is that the derivative of Eq. [9] is easily found. Thus

$$M'(t; y) = \int_0^t y [t - \tau]^{y-1} N'(\tau) d\tau \quad [10]$$

which is also related to the Riemann-Liouville fractional integral. In fact, it follows by induction from Eq. [9] and [10] that for a power-law dependence of $R(\tau, t)^\kappa$ on $[t - \tau]$ not only can crystal growth parameters be discussed in terms of Eq. [9] but so can their n -fold derivatives. This useful property means that, on the power-law model, the solutions of both Eq. [6] and [7] can be obtained directly by solution of Eq. [9].

Some explicit solutions of Eq. [9] are collected in Table I for various assumed functional forms of $N'(t)$, and some other forms of Eq. [9] are listed in Table II for certain values of y . Using the results in these tables it is possible to reconstruct all the known formulas for ensemble average quantities arising in nucleation/growth at constant potential (1, 2). Many new results can be derived also. To illustrate this assertion, two new formulas are now derived for electrical currents caused by two-dimensional nucleation and crystal growth.

Two Solutions of the Integral $M(t; y)$ of Experimental Interest

Power-law appearance rate and power-law growth rate of crystals in two-dimensional nucleation and growth.—A "classical" problem in electrocrystallization theory is the derivation of the electrical current caused by the two-dimensional nucleation and growth of independent circular crystals, in response to a potential step (1-3). The general result is found from Eq. [6] and [7]. It is

$y > -1$	$M(t; y) = \Gamma(y+1) \int_0^t \int_0^t \dots \int_0^t N'(t) \dots dt dt dt$ ($y+1$)-fold
$-1 < y < 0$	$N(t) = \frac{1}{\Gamma(y)\Gamma(1-y)} \int_0^t [t-\tau]^{y-1} M(\tau; y) d\tau$ (Abel's inversion formula)

$$I(t) = \frac{Q_{\text{mon}}}{A} \int_0^t 2\pi R_1(\tau, t) R'_1(\tau, t) N'(\tau) d\tau \quad [11]$$

Now let us assume that at constant potential the number of crystals has a power-law dependence on time

$$N(t) = at^x \quad [12]$$

Let us also assume that the radius of a circular crystal has a power-law dependence on elapsed time after nucleation

$$R_1(\tau, t) = b[t - \tau]^y \quad [13]$$

Then from Eq. [9] and Table I, we deduce

$$I(t) = \frac{Q_{\text{mon}}}{A} \pi a b^2 \frac{\Gamma(2y+1)\Gamma(x)}{\Gamma(2y+x+1)} [2y+x] t^{2y+x-1} \quad [14]$$

and if x and y are non-negative integers

$$I(t) = \frac{Q_{\text{mon}}}{A} \pi a b^2 \frac{(2y)! x!}{(2y+x-1)!} t^{2y+x-1} \quad [15]$$

A useful check on this result is that the cases of $(x, y) = (0, 1)$ and $(1, 1)$ are the familiar ones of instantaneous and progressive nucleation, respectively (1-3).

An active site model.—This model is identical to that considered above except that the number of crystals is controlled by the activation rate of special sites at which nucleation is preferred (4). Assuming a first-order depletion rate of sites, $N(t)$ is given by the following Fredholm integral equation of the first kind

$$N(t) = \int_0^{\infty} N_0 \left[1 - \exp\left(-\frac{\alpha t}{N_0}\right) \right] \Phi(\alpha) d\alpha, \quad \alpha > 0 \quad [16]$$

where N_0 is the total number of active sites and $\Phi(\alpha)$ is the probability density of sites having activation rate α . (It is assumed that α is not time varying.) This equation simplifies if all active sites have the same probability of nucleation; in that case

$$N(t) = N_0 \left[1 - \exp\left(-\frac{\alpha t}{N_0}\right) \right] \quad [17]$$

Inserting this equation instead of Eq. [12] into Eq. [11] leads to the analogue of Eq. [15]

$$I(t) = \frac{Q_{\text{mon}}}{A} \pi a b^2 t^{2y} {}_1F_1\left(1; [2y + 1]; -\frac{\alpha t}{N_0}\right) \quad [18]$$

where the function ${}_1F_1(a; c; z)$ is Kummer's confluent hypergeometric series (8), and y is given by Eq. [13]. A check on this result is the substitution $y = 1$, which yields

$$I(t) = \frac{Q_{\text{mon}}^2}{A} \pi a b^2 \left[\frac{N_0}{\alpha} \right]^2 \left[\frac{\alpha t}{N_0} + \exp\left(-\frac{\alpha t}{N_0}\right) - 1 \right] \quad [19]$$

a formula already known in the literature (2).

Conclusions

A general equation has been derived for ensemble average values of crystal growth parameters arising in electrochemical nucleation and growth (Eq. [5]). The equation has the form of a Volterra integral equation of the first kind. For cases of crystal growth in which the Volterra kernels had power-law dependences on elapsed time after nucleation, it was shown that the Volterra integral could be replaced by a simpler integral of the Riemann-Liouville type (Eq. [9]). Solutions of this last integral were tabulated for forms of $N'(t)$, and values of y , of interest to electrochemists (Tables I and II). To illustrate the use of these tables, two new formulas were derived for electrical currents caused by two-dimensional nucleation and growth. The formulas were checked by showing that well-known results were recovered when appropriate assumptions were made.

LIST OF SYMBOLS

V_N	total volume of N crystals considered independently
$R_1(\tau, t)$	radius of one crystal appearing at time τ and observed at time t
$p(\tau)$	probability density of times τ at which crystals appear
$p(\tau 0 \leq \tau \leq t)$	conditional probability density of times τ at which crystals appear, given that they appear only in the range $0 \leq \tau \leq t$
$N(t)$	number of crystals at time t
$N'(t)$	appearance rate of crystals at time t [i.e., the first derivative, with respect to time, of $N(t)$]
$E(x)$	expectation value of x
$I(t)$	electrical current at time t ...
$I_1(\tau, t)$	electrical current at time t due to a single crystal appearing at time τ
Q_{mon}	electrical charge required to form a monolayer
A	electrode area
$\lambda_N(t)$	any time varying property of an ensemble of crystals
$G(t; \kappa)$	a Volterra integral equation of the first kind for specified κ
$H(t; \kappa)$	a convolution integral equation of the first kind for specified κ
$M(t; y)$	an integral equation of importance in nucleation theory, related to the Riemann-Liouville fractional integral of order $(y + 1)$
a, b, x, y	numerical constants
(a, b, c, z)	(in Dirichlet notation). Variables of hypergeometric series
α	constant activation rate of sites
${}_1F_1(a; c; z)$	Kummer's confluent hypergeometric series (8)
${}_2F_1(a, b; c; z)$	Gauss's hypergeometric series (8)
$\Gamma(a)$	gamma function (8)
$\gamma(a, z)$	incomplete gamma function (8)
$B(a, z)$	beta function (8)

Initiation of Electroless Nickel Plating on Copper, Palladium-Activated Copper, Gold, and Platinum

J. Flis* and D. J. Duquette

Materials Engineering Department, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The catalytic activity of copper, palladium-activated copper, gold, and platinum for electro-oxidation of hypophosphite and electroless nickel plating was investigated in an ammoniacal solution of pH 8.8 at 50°C by potential measurements and linear sweep voltammetry from -0.3 to -0.92V vs. SCE. Early stages of nickel plating on copper-palladium substrates were studied by scanning electron microscopy in conjunction with EDAX. It was found that palladium-activated copper and gold were catalytically active in the entire range of potentials examined; copper was active below -0.6; platinum was not active at all. Small amounts of electrolytically deposited nickel considerably increased the electro-oxidation rate of hypophosphite on copper, gold, and palladium. TEM examinations showed that activation of copper in a PdCl₂/HCl solution resulted in the deposition of palladium in the form of separate patches. Electroless nickel deposition on copper substrates with separate palladium spots took place on copper and palladium independently of each other. The deposition on palladium was faster than that on copper. It was concluded that the activation of copper substrates around palladium spots occurred solely through a spontaneous potential shift, induced by electro-oxidation of hypophosphite on the palladium spots. It was suggested that small amounts of one metal synergistically enhanced the catalytic activity of the other metals.

Electroless nickel plating (1-3) is an autocatalytic process whose initiation is the result of the catalytic activity of a given substrate. After initiation of the plating, the process proceeds spontaneously on the deposited-nickel layer. It is believed that the rate of film growth is largely determined by the activity of the newly formed nickel layer. This is certainly true for thick layers; however, the growth of thin layers may still be affected by the substrate.

The authors of this work have previously reported (4) that the growth of nickel deposits on palladium occurred more rapidly than the growth on molybdenum, even when the deposits were of the order of 17 nm thick. This enhanced growth may be caused by small amounts of palladium being exposed in the deposit, and it may indicate a synergistic effect of small amounts of palladium on the catalytic activity of subsequent nickel deposits. A synergistic effect of one metal on catalytic activity of another metal seemed to appear in systems of palladium with nickel and palladium with molybdenum (4). This effect may account for the observation by Lelental (5) that electroless deposits of nickel on copper had higher catalytic activity than on nickel alone. It can be expected that small amounts of nickel, deposited at the start of plating, may also alter the catalytic activity of a substrate. This can be important, especially for substrates with generally poor catalytic activity and for substrates whose inherent activity is masked by surface reaction products.

The objective of this work was to investigate the initiation and early growth of electroless nickel plating on copper, palladium-activated copper, gold, and platinum. These metals were chosen because of differences in catalytic activity and in other chemical properties, characteristic of the elements of the VIII and IB groups of the periodic table. Palladium and gold are

Key words: electroless, nickel plating, copper, palladium, gold.

good catalysts for electroless nickel plating (1); copper can be made active by an anodic treatment (3) or by addition of chloride ions into the bath (6, 7); platinum is not active under open-circuit conditions (1). The inertness of platinum is in contrast to the behavior of other transition metals, which are good catalysts both for electroless nickel plating and for hydrogenation-dehydrogenation reactions (1, 2).

This work examines the effects of early nickel deposits on the catalytic activity of the substrates and the effects of palladium and copper substrates on more advanced stages of electroless nickel plating in an ammoniacal hypophosphite solution.

Experiments

Investigations were performed on 0.1 mm-thick foils of high purity copper, on vacuum deposited gold, and on platinum wire.

The copper foil was electropolished in a solution of 20% HNO₃ in methanol at a voltage of 6V at about 0°C, rinsed with distilled water and methanol, and then masked with lacquer to obtain an uninsulated-surface area of 1 cm². Thin foils for TEM were prepared by double-jet electropolishing in a solution of 33% HNO₃ in methanol at a temperature below -20°C. Activation of copper was achieved by immersion into a solution of 1 g/l PdCl₂ + 1 ml/l concentrated HCl or 0.2 g/l PdCl₂ + 0.2 ml/l HCl for 5s (for electron microscopy). Specimens for SEM and EDAX examinations were activated by placing separate droplets of the solution of 1 g/l PdCl₂ + 1 ml/l HCl on the surface and leaving them until dry.

Gold substrates were obtained by vacuum evaporation of gold on electropolished copper foils.

Platinum wires were cleaned in 35% HNO₃ and then cathodically polarized in 0.1M H₂SO₄ at a current density of 100 A · m⁻² for 600s.

Specimens were examined in the solutions listed in Table I. The solutions were prepared from analytical-grade reagents and distilled water. Sulfuric acid (98%)

Table I. Composition of solutions

Solution designation	NaH ₂ PO ₃ ·H ₂ O, g/l	NiSO ₄ · 6H ₂ O, g/l	KNa tartrate KNaC ₄ H ₄ O ₆ · 4H ₂ O, g/l	28% NH ₄ OH, ml/l	98% H ₂ SO ₄ , g/l
Plating solution	13.25 (0.125 mol/l)	13.1 (0.05 mol/l)	28.2	70	~ 15
Supporting solution	—	—	28.2	70	~ 15

Supporting solution with sodium hypophosphite	13.25	—	28.2	70	~ 15

was added in amounts appropriate for adjusting the pH of the solutions to 8.8 (at 25°C). All measurements were carried out on stationary specimens at $50.0 \pm 0.5^\circ\text{C}$ (pH at 50°C was 8.3) in a 250 ml round-bottom flask provided with a reflux condenser, Luggin capillary, and a platinum wire as an auxiliary electrode. The solutions were deaerated by purging with purified nitrogen gas.

Electrochemical examinations involved (i) monitoring of open-circuit electrode potentials after immersion of the specimens into the solutions, and (ii) linear sweep voltammetric (LSV) measurements. Potentials were measured against saturated calomel electrode (SCE) at 25°C via Luggin capillary, and throughout this paper are referred to as SCE. Voltammetric measurements were performed using a single cathodic sweep at a rate of $1\text{ mV} \cdot \text{s}^{-1}$, beginning at -0.3V .

The growth rate of the deposits at controlled potentials was determined from weight gains.

Results

Open-circuit potential.—Changes of electrode potentials of the substrates after immersion into the plating solution or a similar solution without Ni^{2+} ions are shown in Fig. 1. All potentials shifted in the cathodic direction on immersion, but only in the cases of palladium-activated copper and gold did they reach a potential of about -0.87V (characteristic of electroless plating of nickel). The potentials of copper and of platinum attained stationary values of about -0.45 and -0.65V , respectively, at which no plating took place. In the solution without Ni^{2+} ions, the potential of gold dropped to a value about 0.5V more negative than that in the plating solution.

As determined previously (4), the electroless nickel deposits contained from 2.2 to 2.9 weight percent (w/o) P.

Voltammetric measurements.—The measurements were made in the supporting solution with and without components essential for plating (cf. Table I) by scanning the potential in the cathodic direction from -0.3 to -0.92V or below. This potential range and direction of scanning were chosen in order to model

Fig. 1. Open-circuit potential of copper, palladium-activated copper (activation in the solution of $1\text{ g/l PdCl}_2 + 1\text{ ml/l HCl}$ for 5s), gold, and platinum after immersion into a plating solution (solid lines) or into a supporting solution with NaH_2PO_2 but without Ni^{2+} ions (dashed line).

the spontaneous shift of potential under open-circuit conditions (Fig. 1). Voltammograms for the substrates examined are shown in Fig. 2-5.

From Fig. 2 it can be seen that electro-oxidation of hypophosphite on freshly electropolished copper started at potentials slightly below -0.6V . This was manifested by the appearance of anodic current loops in the solutions containing NaH_2PO_2 . In solutions without NaH_2PO_2 , the current was cathodic in this potential region. The electro-oxidation current was diminished when the solution was aerated or when air-formed film was present on the copper surface. In order to grow the oxide film, electropolished specimens were kept in air for two weeks. Figure 3 shows that the anodic current loop on copper with an air-formed oxide appeared at more negative potentials than on freshly electropolished copper. On freshly electroplated copper a significant difference was observed

Fig. 2. Voltammograms on freshly electropolished copper and palladium-activated copper (activation in $0.2\text{ g/l PdCl}_2 + 0.2\text{ ml/l HCl}$ for 5s) in the supporting solution with and without other components (cf. Table I), starting at -0.3V . Below the discontinuities in the curves the current is cathodic, except where the anodic current is denoted by i_+ .

Fig. 3. Voltammograms on electropolished copper, stored in laboratory air for two weeks.

between anodic current loops in the NaH_2PO_2 containing solution with and without Ni^{2+} ions, when potentials were below about -0.7V (Fig. 2). The anodic current in the solution without Ni^{2+} ions decreased, whereas in the solution with Ni^{2+} ions it increased markedly at potentials below -0.7V . From the curve in the solution with added Ni^{2+} ions alone it can be concluded that the reduction of Ni^{2+} ions began at about -0.7V .

The marked increase in the electro-oxidation current in the plating solution below -0.7V can thus be associated with electrolytic deposition of nickel on the copper substrate. It may also be noted that electro-oxidation on copper with an air-formed oxide (Fig. 3) started at approximately the same potential as the deposition of nickel, and may be related to the nickel deposition.

An increase in the electro-oxidation current below the potential of electrolytic deposition of nickel was also apparent for the palladium-activated copper (Fig. 2), and for gold (Fig. 4). Electro-oxidation of hypophosphite on these substrates took place in the entire potential range from -0.3V through the mixed potentials. At potentials below -0.7V , the anodic current decreased in the solution without Ni^{2+} ions, and in the solution with Ni^{2+} ions it increased with a maximum at approximately -0.8V .

Voltammograms on platinum (Fig. 5) in the supporting solution and in the solution with NaH_2PO_2 were similar, indicating that hypophosphite did not undergo electro-oxidation on this substrate in the potential range examined. However, an anodic current was observed as a deflection in the cathodic current curve below -0.8V in the solution with NaH_2PO_2 and Ni^{2+} ions (plating solution). The deflection started at a potential at which there also appeared a deflection of a cathodic curve in the supporting solutions with Ni^{2+} ions. The latter deflection showed a decrease in the hydrogen-evolution current caused by deposition of nickel on platinum. This potential is designated as $E_{\text{Ni}^{2+}/\text{Ni}^0}$. Evidently, electro-oxidation of hypophosphite occurred on a layer of nickel, electrolytically deposited on platinum during the potential scan.

The Tafel slopes for the cathodic curves of hydrogen evolution in the supporting solution were about 250, 120, and 60 mV/decade on copper, gold, and platinum, respectively.

Fig. 4. Voltammograms on gold in the supporting solution as a function of solution additives, starting at -0.3V .

Fig. 5. Voltammograms on platinum in the supporting solution as a function of solution additives, starting at -0.3V .

Discontinuities in the voltammograms correspond to rest potentials. They indicate that in Fig. 1, the rest potential of copper (-0.45V) was at its corrosion potential, and that of platinum (-0.65V) corresponded to the potential of the hydrogen electrode. The plateau potential of -0.87V observed in the plating solution was a mixed potential for electroless nickel plating. In the absence of Ni^{2+} ions, the mixed potential was -0.92V .

The voltammograms shown in Fig. 2 and 4 suggest that electrolytic deposition of nickel on copper and gold started at around -0.7V . In order to determine the deposition of nickel at specific potentials, plating was performed on copper under potentiostatic conditions. Average deposition rates were evaluated from weight gains after potentiostatic polarization in the plating solution for periods ranging from 15 min to 2h. Results are given in Fig. 6. The deposition was already discernible at -0.725V , and increased with decreasing potential, attaining a Tafel-type dependence with a slope of 90 mV/decade below -0.78V . These results provide evidence that deposition of nickel on copper started at least at -0.725V , or about 0.15V more positive than the plateau potential of electroless nickel plating (Fig. 1).

TEM, SEM, and EDAX examination.—An electron micrograph of a copper foil after activation in a PdCl_2/HCl solution is shown in Fig. 7. The elongated black patches and smaller gray dots are deposits of palladium. The micrograph shows that the copper substrate surface contains islands of palladium rather than uniform coverage. Nevertheless, it was highly active for electro-oxidation of hypophosphite and for nickel plating (Fig. 2).

In order to examine the palladium islands in more detail, separate droplets of the activating solution of 1 g/l PdCl_2 + 1 ml/l HCl were placed on a copper surface and allowed to dry. Figure 8 shows an SEM micrograph of the copper surface, with two circular spots formed by droplets of the activating solution. A part of one of the spots is shown at higher magnification in Fig. 9. The irregular black features are sites of localized dissolution of copper (pits), around which enhanced deposition of palladium occurred (light diffuse features). The small white islands ($\sim 0.2\ \mu\text{m}$ diam) are palladium.

These features indicate that there were areas on the activated copper surface, such as the pits or regions

Fig. 6. Potential dependence of the rate of nickel deposition on copper in the plating solution. The slope of the linear portion is 90 mV/decade.

Fig. 7. Electron micrograph of a copper foil after immersion into a solution of 0.2 g/l PdCl₂ + 0.2 ml/l HCl for 5s. The black patches are deposits of palladium.

between the islands, which remained free of palladium. Nickel plating on these areas would be expected to occur differently from plating on the deposited palladium.

Specimens containing palladium deposits were partly masked with lacquer and exposed to the plating solution. The time of plating was measured from the moment when the open-circuit potential attained a value of -0.80V, and varied from 1 to 12s.

Figure 10 shows the interface between palladium containing and palladium-free surfaces, after plating for 3s. The small black dots on the palladium-deposited surface are corrosion pits in copper; and the dark patches on the palladium-free surface are discontinuities in the nickel deposit. The discontinuities are characteristic of early stages of nickel plating. They

Fig. 9. SEM micrograph of the copper substrate as in Fig. 8, showing the palladium containing spot (below arrow) at higher magnification. The irregular black sites are corrosion pits, while the diffuse lighter regions around them are deposits of palladium.

Fig. 10. SEM micrograph of nickel deposits on copper substrate with palladium (below arrow) and without palladium (above arrow), after electroless plating for 3s. Note the nonuniformity of the deposit on the copper substrate without palladium.

also occurred on the palladium-deposited surfaces when the plating time was shorter (1s). As the nickel deposits became thicker, the discontinuities disappeared.

The difference in the appearance of nickel deposits on the areas with and without palladium indicates that the rate of deposit on the copper surface was slower than that on the palladium surface, or, alternatively, that the initiation of nickel deposition is delayed on copper relative to palladium. This implies independent nucleation of the deposits on each of the surfaces. An enhanced deposition of nickel on the copper surface occurred only in the regions adjacent to palladium, suggesting a short-range effect of the palladium.

The independent nucleation on the two substrates was observed to be independent of plating time. SEM micrographs of partially masked specimens plated for 6 and 12s are shown in Fig. 11 and 12, respectively.

The independence of the nickel deposition on copper and palladium was also shown by the EDAX examinations. The EDAX spectra from copper substrates with and without palladium, after plating for various times, are shown in Fig. 13. It can be seen that the nickel peak on the spectrum from copper with palladium appeared earlier and was larger than the nickel peak from copper alone. This indicates that the rate of

Fig. 11. SEM micrograph of a copper substrate with palladium containing spots, after plating of an unmasked area (left from arrow) for 6s.

Fig. 12. SEM micrograph of a copper substrate with a palladium containing spot, after plating of an unmasked area (below arrow) for 12s.

Fig. 13. EDAX spectra from a copper substrate with and without palladium, after electroless plating for 1, 3, 6 and 12s. Arrows indicate x-ray energy peaks of palladium ($\text{Pd } L_{\alpha 1} = 2.383 \text{ keV}$) and nickel ($\text{Ni } K_{\alpha 1} = 7.477 \text{ keV}$).

nickel deposition on palladium was greater than on copper alone. After plating for 12s, the nickel peak on copper with palladium was about 1.6 times higher than the peak on copper alone. From the data shown in Fig. 6, it follows that the deposition rate at an open-circuit potential of -0.86V was about $15 \text{ mg} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$. Assuming the density of deposits to be approximately 7.85 kg/l (8), the deposit on copper after a 12s plating would be expected to be about 23 nm thick (65 lattice parameters of nickel), and the deposit on copper with palladium to be about 37 nm thick (105 lattice parameters). It should be noted that the effect of the palladium on the deposition process was still observed after this thickness of nickel deposit accumulated.

Discussion

This work agrees with earlier results (1-3), which showed that gold and palladium-activated copper exert high catalytic activity for electroless nickel plating, while copper alone and platinum are not active under open-circuit conditions. Voltammetric measurements have shown that electro-oxidation of hypophosphite occurs on gold and palladium-activated copper at their open-circuit potentials, and that on copper it occurs only at more negative potentials. On platinum it does not occur unless nickel is electrolytically deposited on this substrate.

It is apparent that the catalytic activity of the substrates cannot be directly related to their electronic structure, in particular, to the filling of d electron shells. In electrocatalysis, it is essential that reacting species first adsorb on the catalytic surface before any charge transfer takes place. It has been suggested that in the electro-oxidation of hypophosphite the reacting species are hypophosphite anions (1-3). Adsorption of these ions on an electrode surface takes place by displacement of other species such as oxides, adsorbed water molecules, or organic compounds.

Presumably, platinum lacks catalytic activity for electroless plating as a result of chemisorption of non-reacting species, which prevents adsorption of hypophosphite anions. The presence of a strongly adsorbed species on platinum is suggested by the high value of

the Tafel slope in the solutions used (~ 60 mV/decade, see Fig. 5). This value is twice as large as the Tafel slope observed on platinum in acid media [32 mV/decade at 50°C (9)]. A large value of the Tafel slope for hydrogen evolution also was observed on copper electrodes. In the supporting solution the slope was measured as 250 mV/decade (Fig. 2); in acid media it is 128 mV/decade at 50°C (9). Nevertheless, the lack of catalytic activity at noble potentials can be associated with the presence of surface oxides rather than adsorbed organic species. The significance of oxide films in diminishing the catalytic activity of copper is apparent from Fig. 2 and 3.

The catalytic activity of the substrates is effective only during the initiation period. This activity is altered as soon as nickel deposits begin to form. The voltammetric measurements have shown that on copper, palladium-activated copper, and gold, the catalytic activity increased markedly at a potential of approximately -0.7V , when nickel started to deposit. Apparently, at this potential nickel was deposited electrolytically without the participation of hypophosphite and accordingly was free of phosphorus. In practice, the phosphorus-free nickel will be expected to electrolytically deposit during the spontaneous potential shift, before the subsequent electroless deposition of phosphorus containing layers. The nickel thus deposited induces subsequent electro-oxidation of hypophosphite on platinum substrates (Fig. 5), and also considerably increases the electro-oxidation current on all other substrates (Fig. 2 and 4). The increase of the electro-oxidation current on copper and gold results primarily from the higher activity of nickel itself. However, it is also possible that small amounts of nickel act synergistically with the substrates. A synergistic action has been suggested previously in the systems of molybdenum with palladium and of palladium with nickel (4). Synergism seems to be also plausible for substrates of copper or gold with nickel. This suggestion for the copper-nickel system can be supported by the observation of Lelental (5), who showed that the catalytic activity of nickel with copper was higher than that of pure copper.

The occurrence of a synergistic effect appears to be ever more probable for the palladium-nickel system. The high catalytic activity of palladium is further increased at the start of nickel deposition at about -0.7V , as seen for the palladium-activated copper in Fig. 2. Also, electroless nickel deposition on the palladium spots occurred more rapidly than that on the copper substrate (Fig. 10 and 13), and continued to be more rapid for a significant period, even when the palladium could be expected to be almost entirely covered with the nickel deposit.

Under open-circuit conditions copper did not initiate electroless plating, because its corrosion potential ($\sim -0.45\text{V}$) was more noble than the potential region of catalytic activity (below -0.6V). In order to activate copper, the electrode potential must be shifted below at least -0.6V . It is suggested that the activation of copper by isolated patches or spots of palladium is accomplished solely by the potential shift resulting from electro-oxidation of hypophosphite on the palladium patches or spots.

At potentials active to $\sim -0.6\text{V}$, the copper substrate becomes active, and below about -0.7V it is additionally activated by electrolytically deposited nickel. Electro-oxidation of hypophosphite and electroless plating on the copper substrate thus proceed independently of the palladium patches or spots.

The activation of the copper by palladium spots is limited to the initiation period. This is demonstrated by the independent growth of the nickel deposits on copper and the palladium spots (Fig. 10 and 13), and by the lack of any radial spreading of nickel deposits growing on the palladium spots.

Initial deposits of palladium and nickel on copper differed in appearance from those on molybdenum (4). On copper the palladium deposits were irregular and diffuse (Fig. 7), while on molybdenum they were circular and sharply defined. Nickel deposits on molybdenum had elongated discontinuities, while on copper they were free of such discontinuities. It was also observed that adhesion of electroless nickel to copper was stronger than to molybdenum. The difference in the appearance and adhesion of the deposits on copper and molybdenum is largely associated with the absence or presence of surface oxides. The potential-pH diagrams of these metals in water (10) indicate that, at the pH and potentials prevailing during electroless plating, the copper substrates should be free of oxides, but that the molybdenum substrates may be covered with MoO_2 .

Conclusions

Potential scans from -0.3 to -0.92V vs. SCE indicated that electro-oxidation of hypophosphite in an ammoniacal solution occurred on gold and on palladium-activated copper over the entire potential range, while on copper it occurred only below -0.6V . In the presence of air-formed oxides, the electro-oxidation on copper started at more negative potentials. Platinum was not catalytically active in the potential range examined; however, electro-oxidation of hypophosphite on this substrate occurred after nickel had been electrolytically deposited during the potential scan.

Small amounts of electrolytically deposited nickel strongly enhanced the electro-oxidation current of hypophosphite on copper, gold, and palladium. This can be associated with the high catalytic activity of freshly deposited nickel and/or with a synergistic effect of small amounts of nickel on the catalytic properties of the other metals.

Activation of copper by immersion into a PdCl_2/HCl solution resulted in the formation of separate palladium patches on the copper substrate. In the plating solution, the nickel deposition on copper with individual palladium spots took place on the palladium spots and on copper independently of each other, the deposition on the palladium spots being considerably faster than that on copper.

It is concluded that the activation of the copper surface surrounding separate palladium spots occurs solely through a spontaneous potential shift due to the electro-oxidation of hypophosphite on the palladium spots. No radial spreading of nickel deposits growing on the palladium spots was observed.

Electrodeposition of Copper on Platinum (111) Surfaces Pretreated with Iodine.

Studies by LEED, Auger Spectroscopy, and Electrochemistry

John L. Stickney, Stephen D. Rosasco, and Arthur T. Hubbard

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Studies by low energy electron diffraction (LEED) and Auger spectroscopy of copper electrodeposited on well-characterized platinum (111) surfaces from aqueous sodium perchlorate solutions are reported. Prior to electrodeposition, the platinum (111) surface was pretreated with I_2 vapor in ultrahigh vacuum to form a Pt(111) ($\sqrt{7} \times \sqrt{7}$) R19.1°-I superlattice, which protected the platinum surface and the surface of the electrodeposit from attack by the electrolyte and contamination by residual gases. The results were as follows: electrodeposition took place in two narrow, overlapping underpotential deposition linear scan voltammetric peaks followed by one conventional bulk copper deposition peak. Underpotential deposition produced an ordered layer. The first underpotential deposition peak formed a (3×3) superlattice in which the unit cell contained four iodine atoms and a comparable number of Cu atoms per nine surface Pt atoms ($\theta_{Cu} = \theta_I = 4/9$). At completion of the underpotential deposition process a (10×10) coincidence lattice was present in which $\theta_{Cu} = 8/9$ and $\theta_I = 4/9$. The iodine Auger signal was not appreciably affected by Cu deposition, indicating that the iodine atoms were present in the topmost layer of the surface at all Cu coverages.

Electrodeposition and electrocrystallization are the subject of numerous interesting studies (3). Surface structure of an electrodeposit at the atomic level is an aspect about which there is little information, however, since most work has dealt with conventional (i.e., structurally undefined) surfaces. In two previous articles we reported studies of electrodeposited silver on iodine-pretreated Pt(111) by LEED (1, 2) and quantitative Auger spectroscopy (2). Studies by LEED of the structures of a wide variety of surfaces in ultrahigh vacuum have revealed that structures resembling single-crystal planes are formed on the surface of a single crystal only under very special circumstances (4). Chemisorbed layer structure is likewise a sensitive function of many variables (4). Each stage of underpotential deposition is sensitive to surface structural characteristics, as evidenced directly by data in the previous articles (2, 3) and indirectly by results reviewed in (5) and (6). In particular, studies of deposition of copper on conventional Pt surfaces have been reported (6, 7). Vapor deposition of metals on well-characterized surfaces has been the subject of studies (8). Halogen chemisorption on well-defined surfaces is also beginning to receive attention (9-12). In the present article we report an exploration of the structure and composition of copper electrodeposited on well-characterized iodine-pretreated Pt(111) surfaces using LEED, Auger spectroscopy, and cyclic voltammetry. The purpose of pretreating the Pt(111) surface with iodine vapor (9) was to protect the Pt(111) substrate and the electrodeposited copper from side reactions with the electrolyte and residual gases (11).

Experimental

The instruments and procedures employed for these studies were described in previous articles (1, 9, 10, 13-15). The Pt(111) single-crystal electrode was oriented and polished so that all six faces were crystallographically equivalent. Before each use, the crystal was cleaned by Ar^+ ion bombardment and annealed by resistance heating, after which LEED and Auger spectroscopic characterization confirmed that an

ordered, atomically clean Pt(111) surface was present. After treatment with an I_2 vapor beam equivalent to 10^{-6} torr (9) for several minutes, the crystal was again characterized. The resulting Pt(111) ($\sqrt{7} \times \sqrt{7}$) R19.1°-I superlattice (9) was then valved off from the LEED chamber, brought to ambient pressure with argon, and the electrochemical cell was introduced. The cell was then rinsed and filled with electrolyte, the crystal immersed into the solution, and voltammetric current-potential scans run. Electrode potentials were measured with respect to a Cu/Cu^{2+} ($10^{-3}M$ in $1M$ $NaClO_4$) half-cell; however, for the sake of continuity, potentials are reported with respect to the $Ag/AgCl$ ($1M$ $NaCl$) reference, based upon direct comparative measurements involving the two half-cells. All apparatus contacting the solutions were constructed of Pyrex glass and Teflon, and thoroughly cleaned to remove surfactants. Solutions were prepared with water pyrolyzed with oxygen (16), distilled, and then saturated with pure nitrogen. Following completion of the electrolysis, the electrolyte was drained away, the crystal was rinsed with water, and the electrochemical cell was valved off from the crystal. After sorption and cryogenic pumping (5 min), the crystal was characterized once again by LEED and Auger spectroscopy. At the end of the procedure, copper was removed by electrolysis followed by brief ion bombardment. Each result was verified at least five times. These electrodeposition processes proved to be highly reproducible.

Results

Pt (111) and iodine.—The clean Pt (111) surface yielded the ideal (1×1) LEED pattern reported by other workers (17) (Fig. 1a) corresponding to the hexagonal (111) surface structure shown in Fig. 2a. Saturation of the surface produced the LEED pattern shown in Fig. 1b, corresponding to the Pt (111) ($\sqrt{7} \times \sqrt{7}$) R19.1°-I structure shown in Fig. 2b. This " $\sqrt{7}$ " surface, previously shown to be resistant to attack by a variety of solvents, surfactants, and electrolytes (1, 2, 11) was the starting point for the electrodeposition studies described in this article.

Auger spectra of the Pt (111) surface (Fig. 3a) contained only transitions assignable (18) to Pt, in agreement with previous work (19). Auger spectra of the Pt (111) ($\sqrt{7} \times \sqrt{7}$) R19.1°-I surface (Fig. 3b) contains a doublet due to iodine (507 and 518 eV) and Pt intensities decreased to 65% of the levels for clean Pt (111). Previously reported (1, 2, 9, 10) quantitative Auger (14) results were duplicated in this work; at maximum clarity of the $\sqrt{7}$ LEED pattern, the surface unit cell contained three iodine atoms per seven surface Pt atoms ($\theta_1 = 3/7 = 0.43$). Numerous replicate LEED patterns and Auger spectra were obtained for this superlattice. No evidence of beam damage or other artifacts was found. Auger data are summarized in Table I.

Immersion of the surface in aqueous solutions.—

Previous work has shown that the $\sqrt{7}$ superlattice is stable toward the argon atmosphere, aqueous perchlorate electrolytes, and evacuation (1, 2). No changes in Auger spectrum or LEED pattern were found after evacuation of the crystal following exposure to the argon atmosphere, or immersion into 1M aqueous perchlorate containing dilute Cu^{2+} (followed by rinsing with water). That is, aqueous $\text{HClO}_4/\text{NaClO}_4/\text{Cu}(\text{ClO}_4)_2$ mixtures did not react chemically with the $\sqrt{7}$ surface, and were removed by water, which evaporated without detectable residues. These tests illustrate the passivating influence (11) of iodine atoms chemisorbed on Pt (20). Without such pretreatment, platinum reacted with perchloric acid during emersion (removal) or evacuation with partial loss of surface order and formation of a deposit of chlorine and oxygen (13). Pretreatment of the surface with iodine was therefore helpful in maintaining the surface in a well-defined state for the purposes of the present experiments.

Electrodeposition of copper.—When immersed at open circuit into aqueous Cu^{+2} (10^{-3}M) in 1M HClO_4 ($\text{pH} = 3$), the $\sqrt{7}$ surface yielded the current-potential trace (21) shown in Fig. 4; the figure shows the first scan starting from the rest potential. This negative going initial scan consisted of two narrow (10 mV full width at half of maximum) underpotential deposition peaks very close together (0.252 and 0.244V vs. Ag/AgCl), and a wave for deposition of bulk copper with a half-wave potential of about -0.03V . A wave rather than a peak resulted from the use of a very slow scan rate (0.28 mV/s) combined with slight vibration of the crystal. The heights and areas of the first two peaks were independent of Cu^{2+} concentration above about 10^{-4}M and were directly proportional to scan rate, as expected for underpotential deposition (5, 6). The third peak was proportional to Cu^{2+} concentration and displayed the morphology of a process controlled by

the diffusion of Cu^{2+} . When the direction of potential scan was reversed, the corresponding dissolution peaks were observed. Noticeable differences in morphology between negative and positive going scans indicate that these processes involve small but not negligible activation energy. As can be seen from Fig. 4, the deposition trace contains barely perceptible shoulders on the two prominent underpotential peaks. When a second cycle was recorded, minor changes in morphology occurred, particularly the disappearance of the small shoulders. Otherwise the traces were constant. Appearance or disappearance of those small shoulders correlated with the presence or absence of a slight excess of iodine above that required to form the $\sqrt{7}$ superlattice. When Cu^{2+} was omitted from the solution, the voltammetric current was negligible (less than 1% of the corresponding peak height). This lack of background current further illustrates the passivating effect of iodine pretreatment (20, 22), and incidentally testifies to the purity of the reagents and the structural regularity of the substrate.

Electronic integration of the electrolysis current as a function of time yielded the coulometric data in Table I, in which Q represents the charge ($\mu\text{C}/\text{cm}^2$) to deposit copper, starting from the initial potential (typically 0.365V) and scanning to the specified potential at which the electrode was emersed from the solution. The electrolytic charge to return to 0.365V (via the positive going dissolution scan) corresponded very closely to that for the deposition scans in the potential range from 0.365 to -0.10V . Packing density of copper was calculated by means of the Faraday law

$$Q - Q_b = nFA\Gamma_{\text{Cu}} \quad [1]$$

where A is the geometric area of the single-crystal electrode (0.7723 cm^2), Γ_{Cu} is the packing density expressed in mols/ cm^2 , and n is the number of electrons to reduce the Cu^{2+} ion. The magnitude of n was assumed to be two in this system, since Auger spectra did not indicate the presence of counterions (Fig. 3c) necessarily present if the adsorbed copper atoms were partially charged. Also, this n value is consistent with structures indicated by the LEED patterns, as described below. A similar situation was reported in a previous work (2). Dividing Γ_{Cu} by the packing density of Pt atoms in the Pt (111) plane converts the results into more familiar units

$$\theta_{\text{Cu}} = \Gamma_{\text{Cu}} / (2.490 \times 10^{-9}) \quad [2]$$

Based upon coulometric data, the two underpotential deposition peaks taken together (from the starting point of the scan, 0.365V, to completion of the peaks at 0.200) resulted in deposition of $\theta_{\text{Cu}} = 0.84$, which is noticeably less than a full monolayer. It is not possible

to separate the areas of the two peaks without making assumptions regarding their morphologies.

Auger spectra of electrodeposited copper.—Auger spectra observed following electrodeposition of Cu onto the $\sqrt{7}$ surface are typified by Fig. 3c, obtained on completion of the first underpotential deposition peak. Only peaks due to I, Pt, and Cu are present in the spectra. A striking feature of the spectra is that the iodine Auger signal, seen as a doublet at 507 and 518 eV, was influenced only slightly by deposition of Cu; while the Pt signals steadily vanished as the Pt was covered over with Cu. Clearly, iodine always constituted the outermost surface layer. Each new Cu layer was apparently located beneath the iodine layer. Multiple cycles of Cu deposition and dissolution spanning periods of 1h or more did not lead to removal of iodine, even though the solution contained no dissolved iodine. Removal of iodine occurred only when the surface was strongly anodized. Potentials greater than 1.0V were required (20). This dissolution process gave rise to a prominent positive peak at 1.0V (2)

Of the Auger signals attributed to Cu (18), only the

peak at 920 eV was resolvable from signals due to Pt (Fig. 3c). The signal-to-noise characteristics of the Cu peaks were judged insufficient for quantitation in the present experiments.

LEED patterns of electrodeposited copper.—LEED patterns, obtained for deposition of amounts of Cu on the $\sqrt{7}$ surface corresponding to emersion at various points along the voltammetric curve, are shown schematically in Fig. 4. Photographs of the LEED patterns appear in Fig. 1. Sharply defined LEED patterns were present at all stages of Cu deposition or dissolution. Accordingly, the structure of the surface was readily monitored. Stability of the electrode potential of the system is illustrated by the observation that for deposition of copper, emersion, rinsing with distilled water at open circuit, examination by LEED and Auger, and immersion back into Cu^{2+} solution at open circuit, the rest potential was found to be close to the initial emersion potential. Subsequent voltammetry showed no changes from the behavior represented by Fig. 4, indicating the absence of any reconstruction during rinsing, LEED examinations, etc.

Simple immersion and emersion at 0.365V without appreciable electrodeposition conserved the $\sqrt{7}$ LEED

Fig. 2. Surface structures. A: Pt(111) (1×1) clean surface structure; Pt surface atoms are located at points of intersection of the grid. B: Pt(111) ($\sqrt{7} \times \sqrt{7}$) $R19.1^\circ$ -1 superlattice; circles represent van der Waals radii of I atoms. C: Pt(111) (3×3) ($\theta_{Cu} = \theta_I = 4/9$); CuI(111) layer forming a (3×3) coincidence lattice with Pt(111); solid circles represent I atoms; open circles, Cu atoms. D: Pt(111) (10×10) ($\theta_{Cu} = 8/9$, $\theta_I = 4/9$).

pattern unchanged from that prior to immersion. At the top of the first underpotential peak, the LEED pattern was (3×3) (Fig. 1c, 0.252V, $\theta_{Cu} = 0.25$). LEED observations made at several points along the first peak revealed that the $\sqrt{7}$ pattern faded and the (3×3) beams brightened as deposition proceeded. Beginning near the midpoint between the underpotential peaks, the (3×3) pattern began transforming into the (10×10) pattern, as shown at two different beam energies in Fig. 1e and 1f, in which spots forming rhombic groups of four spots located near the integral-index, and ($\pm 1/3$, $\pm 2/3$) and equivalent positions displayed the greatest intensity. Beam intensity varied sharply with energy as usual. As a result not all of the beams were visible at any given energy. At completion of the UPD peaks, the Cu coverage was $\theta_{Cu} = 0.84$.

When the direction of potential scan was reversed, dissolution of the Cu deposits occurred (peaks 1', 2', and 3' of Fig. 4). LEED patterns obtained at various stages during dissolution appear in Fig. 1g through 1i. As can be seen, these patterns were equivalent to those observed at the same Cu coverages during deposition. Complete dissolution of Cu occurred, producing the $\sqrt{7}$ pattern (Fig. 1i) equivalent to that observed prior to deposition (Fig. 1b). Oxidative dissolution of adsorbed iodine atoms and oxidation of the Pt surface commenced at about 0.95V, as usual (20), and produced a disordered oxygenous layer.

Fig. 3. Auger spectra. A: Clean surface, Pt(111). B: Pt(111) ($\sqrt{7} \times \sqrt{7}$) $R19.1^\circ$ -1 (spectrum was the same after immersion in 1M HClO₄). C: Between UPD peaks 1 and 2.

Fig. 4. Cyclic current-potential curve for deposition of Cu at the Pt(111) ($\sqrt{7} \times \sqrt{7}$) $R19.1^\circ$ -1 surface. Experimental conditions: 10^{-3} M Cu²⁺ in 1M NaClO₄. Scan rate, 0.28 mV/s.

Effect of surface disorder on electrodeposition.—Pt (111) surfaces which had been subjected to ion-bombardment or electrochemical oxidation and reduction were subjected to electrodeposition under conditions identical to those described above for the $\sqrt{7}$ superlattice.

Ion-bombardment of the Pt (111) surface for a few minutes (500 eV Ar⁺ ions, 5.6 μ A/cm²) caused the LEED pattern to become diffuse, as usual. Subsequent treatment with I₂ vapor produced a disordered adsorbed layer having an iodine Auger signal about 20% weaker than for the $\sqrt{7}$ superlattice.

One cycle of electrolytic oxidation and reduction of the $\sqrt{7}$ surface (a scan at 10 mV/s from 0.2 to 1.2 to 0.0 and back to 0.2V vs. AgCl, in 1M HClO₄ electrolyte saturated with iodine) produced a diffuse LEED pattern and an iodine Auger signal which was a few percent weaker than for the $\sqrt{7}$ superlattice.

A comparison of the behavior of surfaces thus prepared toward voltammetric electrodeposition of Cu is provided in Fig. 5, where the first sweep is shown in each case. As can be seen, one effect of the disorder introduced either by ion-bombardment or by electrolytic redox was to degrade the sharply defined voltammetric peaks into a broad hump having no distinguishable fine structure. LEED patterns for Cu electrodeposited on the disordered surfaces were diffuse. A 10 mV shift of the underpotential deposition process toward less positive potentials was found for the disordered surfaces. The amount of Cu electrodeposited at underpotential increased somewhat because of the disorder; the increase was most noticeable (27%) for the electrolyzed surface.

Discussion

LEED patterns obtained for amounts of deposited Cu present at numerous points along the cyclic current-potential curves were sharply defined, demonstrating that underpotential deposition of Cu on Pt (111) ($\sqrt{7} \times \sqrt{7}$) R19.1°-I is an ordered process at all stages. This rule is illustrated by the LEED photograph in Fig. 1d, which was obtained midway through

Fig. 5. Electrodeposition of Cu at the $\sqrt{7}$ superlattice and surfaces disordered by ion-bombardment or electrolytic cycling. A: — Pt(111) ($\sqrt{7} \times \sqrt{7}$)R19.1°-I surface. B: - - - ion bombarded, then saturated with I₂ vapor. C: ···· electrolytically cycled, then saturated with aqueous I₂. Experimental conditions as in Fig. 4.

the underpotential deposition process; spots of the (3 × 3) and (10 × 10) patterns are present. That is, each new structure formed on a portion of the surface, leaving the remainder of the surface unchanged until the entire surface was converted to the new structure. Similar results were found for Ag on the $\sqrt{7}$ surface (1, 2).

It can be seen from the data in Table I, that the first stage of Cu underpotential deposition (peak 1 of Fig. 4) forms a surface unit cell having (3 × 3) symmetry and containing four iodine atoms and a comparable number of Cu atoms per nine surface Pt atoms. Qualitative LEED does not define the locations of atoms in the interior of the unit cell, however. A model structure consistent with the results appears in Fig. 2c. In constructing this model, the Cu and I atoms were assigned to their relative positions parallel to the (111) plane in the cubic (zinc blende, also called sphalerite) structure of CuI (23). In the (111) direction of CuI, the Cu and I atoms form a hexagonal network with a Cu-I interatomic distance of 2.63Å. Superimposed on Pt (111), this hexagonal network would form the (3 × 3) lattice illustrated in Fig. 2c. The distance between Cu atoms is somewhat smaller in CuI (3.72Å) than in the (3 × 3) superlattice (4.16Å). A relaxation of that sort is attributable to differences in bonding of the bilayer in CuI relative to adsorption on Pt (111). Iodine was assigned to the upper plane and Cu to the lower plane in agreement with the constancy of Auger intensity for iodine. Placement of the CuI bilayer in relation to the Pt (111) net is arbitrary at this time. The qualitative significance of this model is that the spectacular stability and orderedness of the (3 × 3) structure appears to stem from its close relationship to the (111) plane of crystalline CuI.

Stable (3 × 3) structures have been reported for chemisorption systems involving HBr (24), Cl₂, and Br₂ (12a) on Pt (111), and Br₂ (12d) on Ag (111). A considerably less stable (3 × 3) structure was formed by treatment of the Pt (111) surface with I₂ vapor (12a) or an aqueous solution of I₂ (11). This lesser stability of the (3 × 3) structure in the absence of Cu is attributable to the lack of a simple bilayer structure such as CuI (111).

A related structure was postulated to explain the (3 × 3) LEED pattern for electrodeposited Ag on Pt (111)-I (2), in view of the observation that the Cu coverage ($\theta_{Cu} \leq 4/9$) is less than that for the corresponding Ag structure ($\theta_{Ag} = 5/9$). This surface structural difference finds a parallel in the structural differences which exist between solid AgI and CuI. For instance, AgI adopts hexagonal (wurzite) and cubic (zinc blende) structures, while CuI exhibits only the zinc blende structure (23).

Upon completion of the underpotential peaks ($\theta_{Cu} = 0.84$) and continuing into deposition of bulk Cu, the LEED pattern contained fractional-index beams at some of the positions characteristic of Pt (111) (10 × 10) symmetry (Fig. 1d-g). The brightest of these fractional-index beams were present as rhombic groups located near the ($\pm 1/3$, $\pm 2/3$) and equivalent positions, as well as near the integral-index beams. This same LEED pattern was observed for Cu (111) after saturation with Cl₂ vapor (12d); that is, electrodeposition of Cu on a halogen pretreated Pt (111) surface produced the same LEED pattern as halogen adsorption on a Cu (111) single-crystal surface. The rhombuses of 1/10-index spots are parallel to the larger rhombuses defined by the (1 × 1) unit mesh. Accordingly, the fractional-index mesh is not rotated and therefore the R30° aspect of the ($6\sqrt{3} \times 6\sqrt{3}$) R30° structure proposed in Ref. (12d) cannot be correct, although $6\sqrt{3} = 10.39$ is close to the observed unit mesh size of (10 × 10). Accordingly, this is a (10 × 10) pattern with systematic absences. A model structure consistent with these observations is shown in Fig.

2d. This structure is derived from the previous one (Fig. 2c) by adding one Cu atom at each unoccupied center of the large equilateral triangles formed by the previously deposited Cu atoms, and compressing the resulting superlattice slightly along the furrows of the Pt (111) surface. The resulting structure preserves the original CuI (111) bilayer structure, while forming an octahedral environment around the Cu atoms in the bilayer, adding a second layer of Cu atoms. Pairs of Cu atoms are separated by distances of approximately $\sqrt{3}$ and $\sqrt{3}/2$ in the $R30^\circ$ direction, but achieve exactly (10×10) registry with the Pt (111) substrate. Slight compression of the lattice is understandable in terms of increased rigidity of the superlattice when another layer of Cu atoms is added to the original CuI bilayer. In keeping with the experiment, the structure of this (10×10) superlattice would not permit deposition of further Cu without bond breaking, disruption of the structure, or other difficult steps. Similar LEED patterns have been reported for Kr on the basal plane of graphite by Chinn and Fain (25), and for I on Ag (111) and Au (111) by Farrell *et al.* (12), and for Cl on Ni (111) by Erley and Wagner (26). For each of these latter systems, a $(\sqrt{3} \times \sqrt{3}) R30^\circ$ LEED pattern appeared (12) at a halogen packing density of $\theta = 1/3$, followed by the complete (10×10) or related pattern at higher packing densities. In agreement with these observations, the (10×10) structure in Fig. 2d is closely related to the intermediate (3×3) structure (Fig. 2c) and also to the preceding intermediate state consisting of halogen atoms chemisorbed on the (111) plane (Fig. 2b). Formation of this structure would require only small adjustments in atomic coordinates and does not appear to involve any difficult stages.

Dissolution of Cu preserved the LEED patterns observed with the corresponding coverage along the deposition scans. Removal of Cu was apparently quantitative, since the familiar $(\sqrt{7} \times \sqrt{7}) R19.1^\circ$ LEED pattern (Fig. 1b) reappeared (Fig. 1i) following the final dissolution peak (1' of Fig. 4). Clearly, the deposition and dissolution processes approached structural reversibility under the conditions of these experiments.

Comparison of LEED data for vapor-deposited metals (8) with patterns observed for electrodeposited Ag (1, 2) and Cu reveals some interesting differences. Vapor deposits tend to give complex LEED patterns resembling coincidence lattices, and in many cases are disordered until annealed, whereas the electrodeposits reported here were formed in an ordered state at room temperature. A clear analogy exists between I, which preserves surface order and cleanliness in the deposition of Ag and Cu on Pt, and As which promotes epitaxy in vapor deposition of Ge on GaAs (27). The $(\sqrt{7} \times \sqrt{7}) R19.1^\circ$ LEED pattern observed for I_2 (9, 12a) and HI (10) on Pt (111) has been reported also for Na on Ag (111) and Bi on Cu (111) (8b).

Extension of Darby's Model of a Hydrophylic Gas Fed Porous Electrode

R. E. White,* M. A. Nicholson,* L. G. Kleine, J. Van Zee,** and R. Darby

Department of Chemical Engineering, Texas A&M University, College Station, Texas 77843

ABSTRACT

A model presented previously by one of the authors (1,2) is reviewed and extended. Aspects of this model which were not previously available in the open literature are considered, and the model is extended to include previously neglected terms in the governing differential equations, fractional reaction orders in the current density-overpotential expression, and mass-transfer coefficients to account for mass-transfer resistance of the reactants to the faces of the porous electrode. The model is used to predict quantities of interest for oxygen reduction in an acidic aqueous solution in a porous carbon electrode.

Many models of gas fed hydrophylic porous electrodes have been proposed as reviewed recently by Chizmadzhev and Chirkov (3) and by Tilak *et al.* (4). Unfortunately, neither of these reviews mentions Darby's model (1, 2) which is based essentially on measurable quantities of the wettable porous electrode of interest and the transport and kinetic properties of the reactants involved. The purpose of this work is to extend Darby's homogeneous model (1) and to present predictions based on this model which include fractional reaction orders and external mass-transfer coefficients for the reactants.

Homogeneous Model

Darby's (1) homogeneous model is a conceptualization of the chemical, electrochemical, and physical processes that occur within a hydrophylic gas fed porous electrode. Figure 1 schematically presents the representation used here for a region of a gas fed porous electrode which is assumed to be small compared to the dimensions of the electrode. Note that the figure shows the gas pore to be open at both ends, which may be the case in some small volume elements within the electrode; however, the figure does not mean that large gas channels exist from the gas side to the electrolyte side of the electrode. A closer look at Fig. 1 reveals that the gaseous reactant in the pore is assumed to be in local chemical equilibrium with the liquid phase as indicated by $C_{G1}(z)$, which represents the liquid phase composition of the gaseous reactant at the gas-liquid interface (where a liquid pore intersects a gas pore). Further inspection of Fig. 1 indicates that the concentration of the dissolved gaseous reactant varies with depth (y) into the liquid filled pore as indicated by $C_G(y, z)$. Also, note that the coordinate y is normal to the gas-liquid interface and, consequently, is not in the same direction with respect to z for all pores (see Fig. 1 and the List of Symbols).

Once the gaseous reactant has dissolved into the electrolyte at the mouth of a liquid-filled pore, the dissolved gas diffuses into the pore and reacts along the walls of the pore. It is assumed here that no concentration gradient exists across the liquid-filled pore. The flux of the dissolved gaseous reactant (N_G) is given by

$$N_G = -D'_{GJ} \frac{dC_G}{dy} + \frac{C_G}{C} (N_G + N_J) \quad [1]$$

where J represents the liquid phase solvent whose concentration is approximately C and

$$D'_{GJ} = D_{GJ} \frac{\phi_1}{\tau} \quad [2]$$

(ϕ_1 and τ will be discussed later). Since C is typically

* Electrochemical Society Active Member.

** Electrochemical Society Student Member.

Key words: fuel cell, diffusion, mass transport.

$\gg C_G$, Eq. [1] can be simplified to

$$N_G = -D'_{GJ} \frac{dC_G(y, z)}{dy} \quad [3]$$

The electrochemical reaction that occurs along the pore walls is

and the material balance for the dissolved gaseous reactant is

$$\frac{dN_G}{dy} = -\frac{gi'_{os}}{nF} \left[\left(\frac{C_G(y, z)}{C_{G0}} \right)^{g'} \left(\frac{C_L(z)}{C_{L0}} \right)^{l'} \exp \left(\alpha \frac{nF}{RT} \eta \right) \right] \quad [5]$$

where cathodic current density and overpotential have been chosen to be positive in order to be consistent with Darby (1, 2). The boundary conditions that apply are as follows

$$\text{at } y = 0 \quad C_G = C_{G1}(z) \quad [6]$$

and

$$\text{as } y \rightarrow \infty \quad C_G(y, z) = 0, \text{ and } \frac{dC_G}{dy} = 0 \quad [7]$$

which when applied to Eq. [5] yields

for $g' = 1$

$$C_G = C_{G1} \exp(-K_1^{1/2} y) \quad [8]$$

and

for $g' \neq 1$

$$C_G(y, z) = C_{G1}(z) \left\{ \frac{g' - 1}{2^{1/2} (g' + 1)^{1/2}} \xi_1 + 1 \right\}^{2/(1-g')} \quad [9]$$

where

$$\xi_1 = y K_1^{1/2} [C_{G1}(z)]^{(g'-1)/2} \quad [10]$$

and

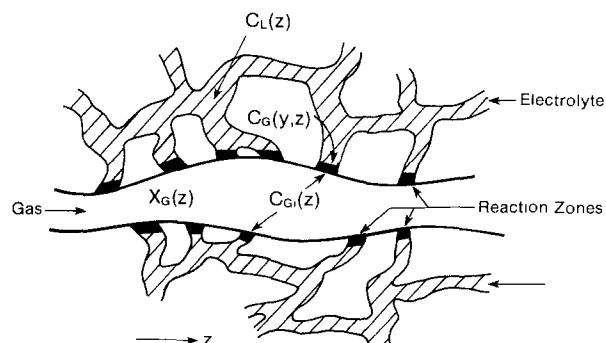

Fig. 1. Schematic of the homogeneous model for a single gas pore (1).

$$K_1 = \frac{i_0 s g}{D'_{GJ} n F C_{G_0} g'} \left[\left\{ \frac{C_L(z)}{C_{L_0}} \right\}^{1'} \exp \left\{ \frac{\alpha n F}{RT} \eta \right\} \right] \quad [11]$$

It is important to note that Eq. [8] and [9] apply only when the dissolved gaseous species is consumed.

Equation [9] can be used to derive an expression for the rate of consumption of the gaseous reactant per unit of electrode volume (R_G)

$$R_G = -a_g D'_{GJ} \frac{dC_G}{dy} \Big|_{y=0} \quad [12]$$

which by using Eq. [9] becomes

$$R_G = a_g D'_{GJ} \left\{ \frac{2K_1}{g' + 1} \right\}^{1/2} [C_{Gi}(z)]^{(g'+1)/2} \quad [13]$$

where a_g is the surface area of the gas-filled pores per unit of electrode volume and will be discussed below.

The dissolved gas that is consumed by the electrochemical reaction must be supplied by diffusion of the gaseous reactant from the electrode/gas interface. This gives rise to the material balance equation for the gaseous reactant within the gas-filled pores

$$\frac{dN_G}{dz} + R_G = 0 \quad [14]$$

The flux of the gaseous reactant (N_G) is

$$N_G = -D'_{GI} \frac{P_0}{RT} \frac{dX_G}{dz} + X_G(N_G + N_I) \quad [15]$$

where

$$X_G = P_G/P_0 \quad [16]$$

and

$$D'_{GI} = D_{GI} \frac{\phi_g}{\tau} \quad [17]$$

(ϕ_g will be discussed presently). Since $N_I = 0$ (I represents N_2 typically), Eq. [15] can be simplified to

$$N_G = -\frac{P_0 D'_{GI}}{RT(1 - X_G)} \frac{dX_G}{dz} \quad [18]$$

Substitution of Eq. [13] and [18] into Eq. [14] and letting

$$\xi = z/d \quad [19]$$

yields

$$\frac{d}{d\xi} \left\{ \frac{D'_{GI} P_0}{(1 - X) RT} \frac{dX_G}{d\xi} \right\} = d^2 a_g D'_{GJ} \left\{ \frac{2K_1}{g' + 1} \right\}^{1/2} [C_{Gi}(z)]^{(g'+1)/2} \quad [20]$$

Equation [20] can be simplified by using Eq. [11] for K_1 , Henry's law for $C_{Gi}(z)$ and C_{G_0}

$$C_{Gi}(z) = X_{Gi}(z) \frac{CP_0}{H} \quad [21]$$

where at $z = 0$ (for no mass-transfer resistance to the electrode from the bulk gas)

$$C_{G_0} = C_{Gi}(z=0) = X_{G_0} \frac{CP_0}{H} \quad [22]$$

and the definition of the mol fraction of the liquid reactant (X_L)

$$X_L = C_L(z)/C \quad [23]$$

and its value at the electrode/electrolyte interface at $z = d$ (for no mass-transfer resistance to the electrode from the bulk electrolyte)

$$X_{L_0} = C_{L_0}/C = C_L(z=d)/C \quad [24]$$

When mass-transfer resistance occurs, \bar{X}_{G_0} still repre-

sents the mol fraction of the gaseous reactant in the bulk gas, but $X_G(\xi = 0)$ is no longer equal to X_{G_0} and similarly for $X_L(\xi = 1.0)$ and X_{L_0} . Since $X_G = X_{G_0}$, substitution of Eq. [21]-[24] into Eq. [20] yields

$$\frac{d}{d\xi} \left\{ \frac{1}{1 - X_G} \frac{dX_G}{d\xi} \right\} = K_G X_G^{(g'+1)/2} X_L^{1/2} \quad [25]$$

where

$$K_G = \frac{a_g d^2 RT}{D'_{GI} (g' + 1)^{1/2}} \left\{ \frac{2i_0 s g D'_{GJ} C}{n F P_0 H X_{G_0} X_{L_0}} \right\}^{1/2} \left\{ \exp \left\{ \alpha \frac{nF}{RT} \eta \right\} \right\}^{1/2} \quad [26]$$

A similar equation can be derived for the mol fraction of the liquid reactant. The starting point is a flux expression for the liquid phase reactant

$$N_L = -CD'_{LJ} \frac{dX_L}{dz} + X_L(N_L + N_J) \quad [27]$$

where

$$D'_{LJ} = D_{LJ} \phi_l / \tau \quad [28]$$

N_J and N_L are often related in a simple manner through the stoichiometry of the electrochemical reaction. For the case considered here, the electrochemical reaction is

in an aqueous solution.¹ Thus, J is H_2O and H^+ is the liquid reactant L . Then, according to Eq. [29], the flux of J is related simply to the flux of L

$$N_J = -\frac{1}{2} N_L \quad [30]$$

which when substituted into Eq. [27] yields

$$N_L = \frac{-CD'_{LJ}}{1 - \frac{X_L}{2}} \frac{dX_L}{dz} \quad [31]$$

Equation [4] (or [29]) shows that the rate of consumption of the liquid reactant is related simply to the rate of consumption of the dissolved gaseous reactant

$$R_L = \frac{l}{g} R_G \quad [32]$$

The liquid phase reactant must be supplied from the bulk electrolyte as described by the material balance equation for L

$$\frac{dN_L}{dz} + R_L = 0 \quad [33]$$

Substitution and simplification as before yields

$$\frac{d}{d\xi} \left(\frac{1}{1 - \frac{X_L}{2}} \frac{dX_L}{d\xi} \right) = K_L X_G^{(g'+1)/2} X_L^{1/2} \quad [34]$$

where

$$K_L = \frac{a_g l d^2}{D'_{LJ} (g' + 1)^{1/2}} \left\{ \frac{2i_0 s D'_{GJ} P_0}{g n F C H X_{G_0} X_{L_0}} \right\}^{1/2} \exp \left\{ \frac{\alpha n F}{2RT} \eta \right\} \quad [35]$$

Equations [25] and [34] are the governing equations for the mol fractions of the gaseous reactant within the gas-filled pores (X_G) and of the liquid reactant within the liquid-filled pores (X_L). The boundary con-

¹ It should be noted that in systems operating above the boiling point of the electrolyte the water produced in Eq. [29] would evaporate and leave the cell via the gas phase.

ditions for these equations are as follows

at $\zeta = 0$

$$\frac{dX_L}{d\zeta} = 0 \tag{36}$$

$$k_{mg} [X_G(\zeta = 0) - X_{G0}] = -\frac{D'_{GI}}{d} \frac{dX_G}{d\zeta} \tag{37}$$

and

at $\zeta = 1$

$$\frac{dX_G}{d\zeta} = 0 \tag{38}$$

$$k_{ml} [X_L(\zeta = 1) - X_{L0}] = \frac{D'_{LJ}}{d} \frac{dX_L}{d\zeta} \tag{39}$$

where k_{mg} and k_{ml} are external mass-transfer coefficients. (Note that when both k_{mg} and k_{ml} become infinitely large, Darby's original boundary conditions are obtained.) Values for k_{mg} and k_{ml} can be predicted for simple systems such as flow between flat plates [see Ref. (5), *e.g.*,] and can be determined experimentally for more complicated systems.

Before proceeding with a solution of the governing equations for $X_G(\zeta)$ and $X_L(\zeta)$, let us consider the distribution of the porosity of the electrode between the gas and liquid pores. The differential pressure ($P = P_0 - 1$ atm) determines the fraction of the porosity (ϕ) filled with gas (ϕ_g) and the fraction filled with liquid (ϕ_l) by assuming that the radius of the largest flooded pore is

$$r_e = \frac{2\gamma \cos \theta}{P} \tag{40}$$

Equation [40] states that the gas pressure in the gas-filled pores is balanced by the surface tension of the liquid in the flooded pores. If we assume that the pores wet easily, all pores larger than r_e will be gas-filled and all pores smaller than r_e will be flooded. A cumulative pore size distribution function [$f(r_e)$] can be defined as the fraction of the total pore volume which has pore radii greater than r_e

$$f(r_e) = \int_{r_e}^{\infty} \alpha(r) dr \tag{41}$$

where $\alpha(r)$ is the pore size distribution function and is assumed here to be normal

$$\alpha(r) = \frac{1}{\sigma\sqrt{\pi}2} \exp \left[-\frac{1}{2} \left(\frac{r - \bar{r}}{\sigma} \right)^2 \right] \tag{42}$$

where \bar{r} and σ represent the mean pore radius and the standard deviation of the distribution, respectively. Substitution of Eq. [42] into Eq. [41] yields

$$f(r_e) = \int_{r_e}^{\infty} \left\{ \frac{1}{\sigma\sqrt{\pi}2} \exp \left[-\frac{1}{2} \left(\frac{r - \bar{r}}{\sigma} \right)^2 \right] \right\} dr \tag{43}$$

which can be rewritten in a more convenient form by first breaking the integral into two parts

$$f(r_e) = \int_0^{\infty} \left\{ \frac{1}{\sigma\sqrt{\pi}2} \exp \left[-\frac{1}{2} \left(\frac{r - \bar{r}}{\sigma} \right)^2 \right] \right\} dr - \int_0^{r_e} \left\{ \frac{1}{\sigma\sqrt{\pi}2} \exp \left[-\frac{1}{2} \left(\frac{r - \bar{r}}{\sigma} \right)^2 \right] \right\} dr \tag{44}$$

and by defining a dimensionless pore radius r'

$$r' = \frac{1}{\sqrt{2}} \frac{r - \bar{r}}{\sigma} \tag{45}$$

Then, in terms of r' Eq. [44] becomes

$$f(r'_e) = \int_0^{\infty} \frac{1}{\sigma\sqrt{\pi}2} \exp(-r'^2) \sigma\sqrt{2} dr' - \frac{1}{\sigma\sqrt{\pi}2} \int_0^{r'_e} \exp(-r'^2) \sigma\sqrt{2} dr' \tag{46}$$

or

$$f(r'_e) = \frac{1}{2} - \frac{1}{\sqrt{\pi}} \int_0^{r'_e} \exp(-r'^2) dr' \tag{47}$$

which simplifies to

$$f(r'_e) = [1 - \text{erf}(r'_e)]/2 \tag{48}$$

Thus, the fraction of the porosity filled with gas (ϕ_g) is simply

$$\phi_g = \phi f(r'_e) \tag{49}$$

and the fraction filled with liquid (ϕ_l) is

$$\phi_l = \phi - \phi_g \tag{50}$$

Both ϕ_g/τ and ϕ_l/τ are used to modify the free stream diffusion coefficients (see Eq. [2] and [17]). The value used here for τ was chosen arbitrarily. (It may be possible to determine a value for τ by measuring both ϕ and D'_{GJ} .)

The porosity (ϕ), gas phase porosity (ϕ_g), and the BET-type specific surface area (a) can be used to determine an expression for the surface area of the gas-filled pores per unit of electrode volume (a_g).

The desired expression for a_g can be obtained by assuming that the pores are tortuous cylinders with a mean pore radius of \bar{r} and by considering the ratio of a to ϕ

$$\frac{a}{\phi} = \frac{\frac{\text{pore wall surface area}}{\text{electrode volume}}}{\frac{\text{pore volume}}{\text{electrode volume}}} = \frac{2\pi\bar{r}\tau d}{\pi\bar{r}^2\tau d} = \frac{2}{\bar{r}} \tag{51}$$

or

$$\frac{a}{\phi} \bar{r} = 2 \tag{52}$$

(or some other constant). If Eq. [52] is true for the electrode as a whole, then it is reasonable to assume that it is also true for the gas-filled pores

$$\frac{a_g}{\phi_g} \bar{r}_g = 2 = \frac{a}{\phi} \bar{r} \tag{53}$$

where \bar{r}_g is the mean pore radius of the gas-filled pores which can be normalized in a manner similar to r_e

$$\bar{r}'_g = \frac{1}{\sqrt{2}} \frac{\bar{r}_g - \bar{r}}{\sigma} \tag{54}$$

Expressions for \bar{r}'_g and then a_g can be obtained in terms of the pore size distribution parameters (\bar{r}, σ) as follows. Since \bar{r}'_g is defined to be the normalized pore radius such that one-half of the gas pore volume is contained in pores with radii larger than \bar{r}'_g , the cumulative pore size distribution function $f(\bar{r}'_g)$ is simply one-half of the cumulative pore size distribution for the gas-filled pores [$f(r'_e)$]

$$f(\bar{r}'_g) = f(r'_e)/2 \tag{55}$$

An expression for \bar{r}'_g can be obtained from Eq. [55] by using an equation for $f(\bar{r}'_g)$ which is analogous to Eq. [48] for $f(r'_e)$

$$[1 - \text{erf}(\bar{r}'_g)]/2 = f(r'_e)/2 \tag{56}$$

which can be rearranged to

$$\text{erf}(\bar{r}'_g) = 1 - f(r'_e) \tag{57}$$

or

$$\bar{r}'_g = \text{erf}^{-1} [1 - f(r'_e)] \tag{58}$$

Then according to Eq. [49] and [50], Eq. [58] can be written as

$$\bar{r}'_g = \text{erf}^{-1}(\phi_1/\phi) \quad [59]$$

which when combined with Eq. [54] yields an expression for \bar{r}'_g

$$\bar{r}'_g = \bar{r} + \sqrt{2} \sigma \text{erf}^{-1}(\phi_1/\phi) \quad [60]$$

Substitution of Eq. [60] into Eq. [53] yields

$$a_g = \frac{a\bar{r}'\phi_g/\phi}{\bar{r} + \sqrt{2} \sigma \text{erf}^{-1}(\phi_1/\phi)} \quad [61]$$

which, by using Eq. [48]-[50], becomes the desired expression for a_g

$$a_g = \frac{a\bar{r}'(1 - \text{erf } r'_e)}{2\{\bar{r}' + \sqrt{2} \sigma \text{erf}^{-1}[(1 + \text{erf } r'_e)/2]\}} \quad [62]$$

Figure 2 shows the dependence of a_g on the difference between the gas pressure and the electrolyte pressure (P). As shown in Fig. 2, a_g is very sensitive to P from about 7 to 12 psi.

Results and Discussion

The apparent current density (total current/projected area of the electrode) of the porous electrode can be determined from the flux of the gaseous reactant into the porous electrode

$$\frac{gi}{nF} = N_G|_{\zeta=0} \quad [63]$$

which by using Eq. [18] becomes

$$i = \frac{K_A}{1 - X_G} \frac{dX_G}{d\zeta} \Big|_{\zeta=0} \quad [64]$$

where

$$K_A = \frac{nFP_0 D'_{GI}}{gdRT} \quad [65]$$

The gradient of the mol fraction of the gaseous species ($dX_G/d\zeta$) needed in Eq. [64] can be determined from $X_G(\zeta)$ which can be obtained by solving Eq. [25] and [34] subject to the boundary conditions given by Eq. [36]-[39]. Darby (1) found $X_G(\zeta)$ [and $X_L(\zeta)$] by assuming that X_G and $X_L \ll 1$ so that the governing equations for X_G and X_L become

$$\frac{d^2 X_G}{d\zeta^2} = K_G X_G^{(g'+1)/2} X_L^{l'/2} \quad [66]$$

$$\frac{d^2 X_L}{d\zeta^2} = K_L X_G^{(g'+1)/2} X_L^{l'/2} \quad [67]$$

Fig. 2. Dependence of the surface area of the gas pores per unit of electrode volume (a_g) on the differential pressure across the electrode (P).

According to Sepa *et al.* (6), $g' = 1$ and $l' = 1$ or 1.5 for reaction [29] depending on the overpotential. Darby (2) solved approximately Eq. [66] and [67] for $g' = 1$ and $l' = 1$ by assuming that

$$X_G = X_{G0} \left[1 - b \left(\zeta - \frac{\zeta^2}{2} \right) \right] \quad [68]$$

and

$$X_L = X_{L0} [a' + (1 - a') \zeta^2] \quad [69]$$

which satisfy the boundary conditions (Eq. [36]-[39]) for infinitely large external mass-transfer coefficients and by substituting Eq. [68] and [69] into Eq. [66] and [67] and evaluating the result at $\zeta = 0$ to determine a' and b

$$a' = 1 + \frac{K_L^2 X_{G0}^2}{8X_{L0}} - \left[\left(1 + \frac{K_L^2 X_{G0}^2}{8X_{L0}} \right)^2 - 1 \right]^{1/2} \quad [70]$$

$$b = K_G (X_{L0} a')^{1/2} \quad [71]$$

Finally, application of Eq. [64] gives the desired expression for the current density

$$i = X_{G0} K_A b \quad [72]$$

Again, Eq. [72] is based on the assumption that X_G and X_L are both much less than 1 which is not a good assumption if X_{G0} and X_{L0} are on the order of 0.1 as is the case here. To relax this assumption, Eq. [25] and [34] were solved by using Newman's numerical technique (5, 7) for the fixed and variable parameters considered here as shown in Table I (see Table II for a typical set of calculated parameter values).

Figure 3 shows a comparison between the predicted mol fraction distributions for the simplified and complete governing equations cases, and Fig. 4 presents a comparison of the predicted current densities for both cases. Also shown in Fig. 4 is the predicted limiting current density according to Austin (8, Eq. 6.38a)

$$i_L = \left(\frac{nFD'_{GI}}{d} \right) \frac{X_{G0} P_0 f}{RT} \quad [73]$$

where

$$f = \frac{\ln[(1 - X_{G0})^{-1}]}{X_{G0}} \quad [74]$$

$$\begin{aligned} \phi_1 &= 0.4867 \\ \phi_g &= 0.0133 \\ a_g &= 2.29 \times 10^2 \text{ cm}^2/\text{cm}^3 \\ K_G &= 2.19 \\ K_L &= 3.12 \\ K_A &= 2.23 \times 10^{-2} \text{ A/cm}^2 \end{aligned}$$

Fig. 3. Mol fraction distributions for the complete governing equations model (Eq. [25] and [34]) with infinitely large k_{mg} and k_{ml} , and Darby's approximate solutions (Eq. [68] and [69]) to the simplified governing equations (Eq. [66] and [67]).

Fig. 4. Comparison of predicted current densities by the complete model with infinitely large k_{mg} and k_{ml} , Darby's approximate solutions, and Eq. [73] for the limiting current density with $i_0 = 10^{-5}$ A/cm².

Substitution of the appropriate values from Tables I and II into Eq. [73] and [74] gives $i_L = 5.27 \times 10^{-3}$ A/cm². Notice in Fig. 4 that for large values of η , the predictions of the complete model are significantly different from those of Darby's approximate solution. This is due to the importance of the neglected terms in the governing differential equations for the two cases (compare Eq. [25] and [66] and Eq. [34] and [67]). It is interesting that the prediction of the limiting cur-

rent density by Austin's equation falls between these two cases. This is due to using an effective diffusion coefficient for oxygen (D'_{GI}) in Austin's equation which is the same as the effective diffusion coefficient (D'_{GI}) used in both of the other cases. If D'_{GI} is determined by multiplying D_{GI} by ϕ/τ , instead of ϕ_g/τ , then the limiting current density predicted by Austin's equation is 37.6 (i.e., ϕ/ϕ_g) times larger than that shown in Fig. 4.

The limiting current density for the complete model (as shown in Fig. 4) is plotted in Fig. 5 together with other limiting current density values at different differential pressures P . Also shown in Fig. 5 are the limiting current density predictions of Darby's approxi-

Fig. 5. Limiting current density dependence upon P for the complete model with infinitely large k_{mg} and k_{ml} , Darby's approximate solution, and Eq. [73] with $i_0 = 10^{-5}$ A/cm².

Fig. 6. Predicted current density dependence on η and P for the complete model with infinitely large k_{mg} and k_{ml} where $i_0 = 10^{-5}$ A/cm².

mate solution and Eq. [73] again with D'_{GI} determined with ϕ_g instead of ϕ (note that ϕ_g depends upon P). Figure 5 clearly shows that a maximum limiting current density is predicted at approximately $P = 12$ psi for the system considered here.

Figure 6 shows how the current density below the limiting current density depends on the differential pressure (P) for various values of η . Experimental current density values (3) have a similar dependence on P and η as shown in Fig. 7. Figures 6 and 7 are presented here for qualitative comparison only, since not enough information is available for a quantitative comparison between Darby's model and the experimental data presented in Fig. 7.

Figures 8 and 9 demonstrate how the kinetic parameters l' and i_0 effect the predicted current densities. These figures show that predicted current densities depend upon these parameters to the extent that it should be possible to determine values for l' and i_0 by

Fig. 7. Experimental current density (3) dependence on η and P .

Fig. 8. Comparison of predicted current densities for various liquid reactant reaction orders for the complete model with infinitely large k_{mg} and k_{ml} when $i_0 = 10^{-5}$ A/cm².

Fig. 9. Effect of the exchange current density on the predicted current densities for the complete model with infinitely large k_{mg} and k_{ml} .

comparison of data to predicted values using least squares, nonlinear fitting, for example.

Finally, the effect of the external mass-transfer coefficients is demonstrated in Fig. 10 and 11. Figure 10 shows how the mass-transfer resistance to the electrode can alter the mol fraction distributions within the electrode, and Fig. 11 presents the effect of finite values of k_{mg} and k_{ml} on the predicted current density. Figure 11 clearly demonstrates that for large values of η the predicted current density can be reduced significantly if external mass-transfer resistance of the reactants to the electrodes is important.

Fig. 10. Effect of external mass-transfer coefficients (k_{ml} and k_{mg}) on the predicted mol fractions for the complete model when $i_0 = 10^{-5}$ A/cm².

Fig. 11. Effect of external mass-transfer coefficients (k_{m1} and k_{mg}) on the predicted current densities for the complete model when $i_0 = 10^{-5}$ A/cm².

Conclusion

Darby's model of a gas fed hydrophilic porous electrode is useful because it includes important features of hydrophilic porous electrodes which are often neglected. For example, it includes a pore size distribution for a porous electrode which can be determined experimentally and used in the model.

The extensions presented here (considering the complete governing equations, fractional reaction orders, and mass-transfer coefficients) should aid in data analysis and electrode design.

LIST OF SYMBOLS

a	specific surface area, cm ² /cm ³
a_g	gas pore surface area per unit electrode volume, cm ² /cm ³
C	total liquid phase concentration, mol/cm ³
C_L	concentration of liquid reactant, mol/cm ³
C_{Gi}	concentration of the dissolved gas G at the gas-liquid interface, mol/cm ³
C_{Go}	concentration of gaseous reactant at the gas-electrolyte interface at $z = 0$ (see Eq. [22]), mol/cm ³
d	electrode thickness, cm
D_{GI}	diffusivity of the gas phase reactant in gas phase inert component, cm ² /s
D'_{GI}	effective diffusivity of gas phase reactant in gas phase inert component in a porous medium, cm ² /s
D_{GJ}	diffusivity of the gas phase reactant in liquid phase solvent, cm ² /s
D'_{GJ}	effective diffusivity of the gas phase reactant in liquid phase solvent in a porous medium, cm ² /s
D_{LJ}	diffusivity of liquid phase reactant in liquid solvent, cm ² /s

D'_{LJ}	effective diffusivity of the liquid phase reactant in porous medium, cm ² /s
F	Faraday's constant, 96487C/mol
$f(r'_e)$	fraction of total pore volume in gas-filled pores (i.e., cumulative pore size distribution for r'_e)
g	stoichiometric coefficient for gas phase reactant in overall electrode reaction
g'	reaction order with respect to gas phase reactant
H	Henry's law constant, dyn/cm ²
i	current density, A/cm ²
i_0	exchange current per unit of projected area of the electrode, A/cm ²
i'_0	exchange current per unit of active catalytic surface area, A/cm ²
K_A	parameter used to calculate i , A/cm ²
K_G	dimensionless parameter for gas phase component
K_L	dimensionless parameter for liquid phase component
k_{mg}	gas phase mass-transfer coefficient, cm/s
k_{ml}	liquid phase mass-transfer coefficient, cm/s
l	stoichiometric coefficient for liquid phase reactant
l'	reaction order with respect to liquid phase reactant
N_i	molar flux of species i ($i = G, J, I, L$), mol/cm ² -s
n	number of electrons involved in overall electrode reaction
n'	number of electrons in electrode reaction
P	differential pressure = $P_0 - 1.01325 \times 10^6$ dyn/cm ²
P_G	partial pressure of the gaseous reactant G , dyn/cm ²
P_0	absolute gas pressure, dyn/cm ²
R	gas constant, 8.3143J/mol-K
r_e	radius of a pore in which gas-liquid interface will be located, cm
$\frac{r'_e}{\bar{r}}$	normalized radius of the largest flooded pore
\bar{r}	mean pore radius, cm
\bar{r}_g	mean pore radius of gas-filled pores, cm
\bar{r}'_g	normalized mean pore radius of gas-filled pores
s	specific accessible catalytic surface area, cm ² /cm ³
T	absolute temperature, K
X_G	mol fraction of gas phase reactant
X_{Go}	mol fraction of gaseous reactant at the bulk phase-electrode interface ($\xi = 0$)
X_L	mol fraction of liquid-phase reactant
X_{Lo}	mol fraction of liquid reactant-bulk phase ($\xi = 1$)
y	depth into a liquid filled pore, normal to the gas-liquid interface, not in the same direction with respect to z for all pores, cm
z	distance from the bulk gas-electrode interface into the porous electrode, cm

Greek Symbols

α	transfer coefficient
$\alpha(r)$	pore size distribution, cm ⁻¹
η	polarization (driving force), V
γ	surface tension of electrolyte, dyn/cm
ϕ	porosity
ϕ_g	porosity of gas-filled pores
ϕ_l	porosity of liquid-filled pores
σ	standard deviation of pore size distribution function, cm
τ	tortuosity
θ	contact angle, degrees
ξ	dimensionless coordinate, z/d

Electrochemical Photocapacitance Spectroscopy Method for Characterization of Deep Levels and Interface States in Semiconductor Materials

Ron Haak and Dennis Tench

Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

The recently developed electrochemical photocapacitance spectroscopy (EPS) method for characterization of deep levels in semiconductors is described. Topics discussed include the advantages of the method, experimental considerations, and the determination of state densities and kinetic parameters (associated with state population/depopulation). Both steady-state and transient capacitance changes are treated mathematically. Data for n-GaAs, p-GaAs, n-CdSe, a-Si and p-Zn₃P₂ are presented to illustrate the wide applicability of the method and its sensitivity to both bulk and interface states, including those observed by other characterization methods.

Electrochemical photocapacitance spectroscopy (EPS) has recently been shown to be a sensitive means for characterization of deep levels in semiconductor materials (1). In the present paper, the EPS technique is described and illustrative results are presented for a variety of single-crystal and polycrystalline materials. Since the intent of the authors is to encourage and facilitate use of EPS by both physicists and electrochemists, considerable detail is given in areas expected to be unfamiliar to either group of scientists. It should also be emphasized that the focus here is on covering the practical aspects of applying the method rather than on providing a comprehensive quantitative treatment.

EPS Method

In EPS, the capacitance of a reverse-biased semiconductor electrode is measured as a function of the wavelength of incident sub-bandgap light. The electrostatic situation and possible phototransitions for an n-type semiconductor are depicted in Fig. 1. In the dark, all of the negative charge in the electrolyte Helmholtz layer must be compensated by fixed ionized donors so that the space-charge layer extends deep into the semiconductor. At sufficiently anodic bias voltages (except at very high charge-carrier concentrations), the space-charge capacitance is generally small ($<0.1 \mu\text{F}/\text{cm}^2$) compared to the Helmholtz layer capacitance ($\sim 20 \mu\text{F}/\text{cm}^2$). In this case, the impedance of the interfacial region is dominated by the space charge, so that additional charge, introduced by optical population/depopulation of traps or interface states, significantly affects the thickness of the space-charge layer and is readily detected as a change in capacitance. Transitions from bandgap states (electron traps) into the conduction band introduce additional fixed positive charge to the semiconductor space-charge region (or at the interface), reducing the thickness of the space-charge layer and increasing the capacitance. Similarly, transitions from the valence band to bandgap states (hole traps) result in a decrease in capacitance. Charge may also be introduced into the semiconductor space-charge region by localized transitions from the ground state

to an excited state of an impurity (or defect center), followed by thermal injection of charge into one of the semiconductor bands (see Fig. 1). For p-type semiconductors, the capacitance change associated with a given type of transition is opposite in sign to that for an n-type material.

Typical plots of capacitance vs. wavelength (for sweeps from low to high photon energies) yield a series of plateaus and/or peaks, each corresponding to the population/depopulation of a given bandgap state. Plateaus are obtained for transitions that directly involve one of the semiconductor bands and can consequently be effected by light covering a wide range of energies above a certain threshold. Peaks are obtained for localized transitions which are effected only by light of a relatively specific energy. The onset energy of the capacitance change yields the energy of the state, relative to the appropriate bandedge. For localized transitions, the peak energy may be more de-

Fig. 1. Schematic representation of a reverse-biased n-type semiconductor, and typical phototransitions involved in electrochemical photocapacitance spectroscopy.

Key words: semiconductor traps, electrochemical detection, gallium arsenide, cadmium selenide, amorphous silicon, zinc phosphide.

scriptive. When trap saturation is attained, *i.e.*, all states of a given energy are populated/depoppedulated by the available light, the magnitude of the capacitance change yields the density of states. Otherwise, the latter can often be determined from the time dependence of the photocapacitance after initiating illumination. In many cases, bulk and interface states can readily be distinguished from the effect of the electrode bias voltage, which determines the thickness of the space-charge layer and thus the number of bulk states responding but has little effect on the potential drop at the interface, *i.e.*, across the Helmholtz region.

The advantages of the EPS method can be summarized as follows. First, charged or discharged states produced by phototransitions generally accumulate in the space-charge layer or at the interface, causing an integral effect on the capacitance so that the sensitivity of EPS is greatly enhanced in comparison to techniques based on simple photocurrent measurements. Also, in contrast to EPS, techniques based on a net flow of current cannot readily distinguish the effects of charge transfer mediators in the solution from those associated with interface states. Compared to the analogous solid-state photocapacitance technique, EPS is also more sensitive, since leakage currents can be considerably reduced in electrochemical systems by adjusting the availability of electronic states in the electrolyte, and the monolayer-sharp junction with transparent electrolytes permits more light to be focused on the area of interest, *i.e.*, the space-charge region. In addition, compared to techniques like deep level transient spectroscopy (DLTS), EPS is relatively straightforward and can be performed rapidly, since the blocking contact is formed simply by immersing the semiconductor in an electrolyte, and measurements are performed at ambient temperature and pressure. Although slower wavelength scans requiring several hours may be required to study slow states or to minimize data scatter, EPS spectra with good resolution can often be obtained over a 2 eV range in 15 min. With the proper choice of electrolyte, EPS is also nondestructive. On the other hand, since EPS is an *in situ* electrochemical technique, the electrolyte can be chosen to permit characterization of electronic states associated with the semiconductor-electrolyte interface or passive films, *e.g.*, oxides. EPS could also be used for electrochemical profiling, in which layers of the semiconductor are electrochemically dissolved between measurements. It should also be mentioned that EPS is sensitive to both donor and acceptor states in the same material, whereas minority carrier traps are extremely difficult to characterize by DLTS. EPS may also be applicable to the characterization of oxide films on metal electrodes.

Density of bulk states.—In calculating densities of states, it is convenient to assume that exhaustive depletion of charge carriers within the semiconductor space-charge region prevails; this is justified for the small photocapacitance changes normally observed. In this case, the contribution of ionized bulk states of density n to the capacitance C is given by the well-known Mott-Schottky (2, 3) expression

$$\frac{1}{C^2} = -\frac{8\pi E}{\epsilon_{sc} e n} \quad [1]$$

for which kT/e and the potential drop in the electrolyte have been neglected (other symbols are defined below). The net number of ionized states, which determines the magnitude of the measured capacitance, is equivalent to the net semiconductor charge resulting from the equilibrium between thermal and optical emission/capture processes for both positively and negatively charged centers. Since we are concerned with the change in capacitance associated with optical population/depopulation of specific deep levels, it is appropriate to write the net density of ionized states (n_t) as

$$n_t = n_i + n_o \quad [2]$$

where n_t is the density of optically populated/depoppedulated traps of a specific energy, and n_o is the net density of ionized states present under illumination with light of energy just below the onset of the transition of interest. Note that the sign of the change in charge produced by the specific phototransition under study must be considered, *i.e.* n_t increases when the existing space charge is enhanced and decreases when it is diminished.

Rewriting Eq. [1] in terms of n_t and n_o and substituting in Eq. [2], we obtain

$$n_t = \pm \frac{8\pi E}{\epsilon_{sc} e} (C_o^2 - C^2) \quad [3]$$

where C is the capacitance measured with light of sufficient energy for population/depopulation of the trap, C_o the capacitance measured with light of energy just below the onset for the trap under study, E the electrode bias potential *vs.* U_{FB} (flatband potential), ϵ_{sc} the semiconductor dielectric constant, and e the electronic charge. Thus, the density of bulk traps (per cm^3) populated/depoppedulated by illumination can be readily calculated from the associated photocapacitance change according to

$$n_t = \pm \frac{1.4 \times 10^{20} E}{\epsilon_{sc}} (C_o^2 - C^2) \quad [4]$$

where capacitance is in $\mu\text{F}/\text{cm}^2$, and E is in volts *vs.* U_{FB} . When the trap is initially populated/depoppedulated totally and is fully depoppedulated/populated (saturated) by the light, $n_t = N_t$ (the total trap density). This is the case for a sufficiently deep trap (for which thermal emission is negligible) when the associated capacitance plateau or peak is insensitive to the light intensity. An implicit assumption, of course, is that the population of only one trap level changes in the spectral region of interest.

Density of interface states.—For the treatment given here, it is assumed that interface states do not themselves respond to the measurement voltage perturbation and, therefore, affect the capacitance (only when charged) via a change in the potential distribution between the semiconductor space charge region and the electrolyte Helmholtz layer.¹ In this case, we rewrite the Mott-Schottky expression still assuming that the semiconductor space-charge capacitance dominates the electrode impedance, but now allowing for the electrode potential being distributed between the semiconductor and the electrolyte, *i.e.*

$$\frac{1}{C^2} = -\frac{8\pi \Delta\phi_{sc}}{\epsilon_{sc} e n_o} \quad [5]$$

and since

$$\Delta\phi_{sc} = E - \Delta\phi_H \quad [6]$$

and

$$\Delta\phi_H = \frac{e n_i}{C_H} \quad [7]$$

where $\Delta\phi_{sc}$ is the potential drop across the semiconductor space-charge region, n_o the bulk charge-carrier concentration, $\Delta\phi_H$ the potential drop across the electrolyte Helmholtz layer, n_i the density of ionized interface states (per cm^2), and C_H the capacitance of Helmholtz layer. Thus we have

$$\frac{1}{C^2} = -\frac{8\pi (E - \Delta\phi_H)}{\epsilon_{sc} e n_o} = -\frac{8\pi E}{\epsilon_{sc} e n_o} + \frac{8\pi e n_i}{\epsilon_{sc} n_o C_H} \quad [8]$$

Since $\Delta\phi_{sc} \cong E$ when $n_i = 0$

$$\frac{1}{C^2} = \frac{1}{C_o^2} - \frac{8\pi n_i}{\epsilon_{sc} n_o C_H} \quad [9]$$

¹Note that in the absence of interface states the potential drop across the Helmholtz layer is practically constant with electrode potential over the range of interest to the present work.

so that

$$n_i = \pm \frac{\epsilon_{sc} n_o C_H}{8\pi} \left(\frac{1}{C_o^2} - \frac{1}{C^2} \right) \quad [10]$$

where C is the capacitance with interface states ionized, and C_o the capacitance in the absence of interface state ionization.

Taking $C_H = 20 \mu\text{F}/\text{cm}^2$, which is its typical value (4), we have

$$n_i = 8.7 \times 10^{-7} \epsilon_{sc} n_o \left(\frac{1}{C_o^2} - \frac{1}{C^2} \right) \quad [11]$$

where capacitance is in $\mu\text{F}/\text{cm}^2$.

Deep level kinetic characteristics.—The kinetics of processes involved in filling and emptying deep trap levels can also be studied by EPS. In this case, the photocapacitance transients are measured after initiation and after interruption of illumination. The general expression² for the change in the concentration of ionized states with time is

$$\frac{dn_s}{dt} = k_i(N_s - n_s) - k_n n_s \quad [12]$$

where n_s is the density of ionized states, N_s the total density of trap states, k_i the ionization constant, k_n the neutralization constant, and t time. Note that k_i and k_n include terms for both thermal and optical processes.

Integration of Eq. [12] yields

$$\ln [(k_i + k_n)n_s - k_i N_s] = - (k_i + k_n)t + K \quad [13]$$

where K is the integration constant.

The components of k_i and k_n depend on the nature of the state. For a state that becomes more positive when ionized

$$k_i = e_n^t + e_n^o + c_p \quad [14]$$

$$k_n = e_p^t + e_p^o + c_n \quad [15]$$

whereas for a state that becomes more negative when ionized

$$k_i = e_p^t + e_p^o + c_n \quad [16]$$

$$k_n = e_n^t + e_n^o + c_p \quad [17]$$

where e_n^t and e_p^t are thermal emission rate constants, e_n^o and e_p^o optical emission rate constants, and c_n and c_p capture rates for electrons and holes, respectively. The various processes involved can be visualized with the aid of Fig. 2. Note that an increase in positive charge produces an increase in C for an n-type semiconductor but a decrease for a p-type material; a decrease in positive charge produces the opposite effects.

The capture rates include a factor for the appropriate minority carrier concentration, *i.e.*

²The treatment given here is similar to that presented by Miller *et al.* (5) except that the equations are derived in terms of ionized states.

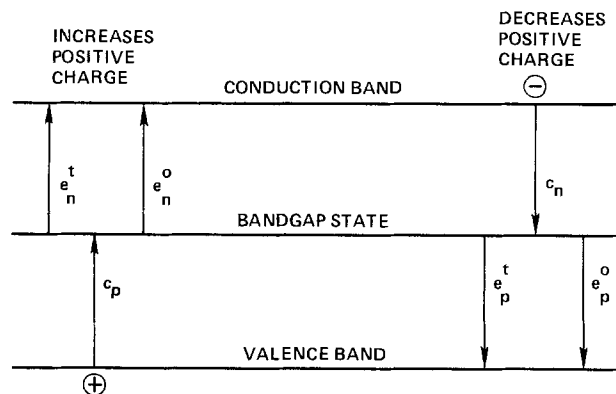

Fig. 2. Schematic diagram depicting the various ionization and neutralization processes for a semiconductor bandgap state.

$$c_n = \sigma_n \nu_n n \quad [18]$$

$$c_p = \sigma_p \nu_p p \quad [19]$$

where σ_n and σ_p are capture cross sections, ν_n and ν_p average thermal velocities, and n and p charge carrier concentrations. Equations [18] and [19] are for electrons and holes respectively.

Deep levels in wide-bandgap materials.—Of special interest from a practical standpoint is the characterization of deep traps in relatively wide-bandgap extrinsic semiconductors, for which thermal emission processes and the concentration of minority carriers can often be ignored. For a specific example, consider an n-type material containing a deep electron trap that is neutral when filled and positively charged when empty. In this case, e_n^t and c_p are taken as zero, *i.e.*

$$k_i = e_n^o \quad [20]$$

and

$$k_n = e_p^t + e_p^o + c_n \quad [21]$$

First consider repopulation of the states in the dark after at least a portion of them have been ionized by illumination. Since e_n^o and e_p^o are also zero in this case, $k_i = 0$ and $k_n = e_p^t + c_n$, so that Eq. [13] reduces to

$$-\ln n_s = (e_p^t + c_n)t + K \quad [22]$$

Substitution of n_t and n_i from Eq. [3] and [10] for n_s yields

$$-\ln \left[\frac{8\pi E}{\epsilon_{sc} e} (C_o^2 - C^2) \right] = (e_p^t + c_n)t + K \quad [23]$$

for bulk states, and

$$-\ln \left[\frac{\epsilon_{sc} n_o C_H}{8\pi} \left(\frac{1}{C_o^2} - \frac{1}{C^2} \right) \right] = (e_p^t + c_n)t + K \quad [24]$$

for interface states. Solving for K at $t = 0$, we have

$$\ln \left(\frac{C_o^2 - C_t^2}{C_o^2 - C_{t=0}^2} \right) = - (e_p^t + c_n)t \quad [25]$$

for bulk states, and

$$\ln \left[\left(\frac{1}{C_o^2} - \frac{1}{C^2} \right) / \left(\frac{1}{C_t^2} - \frac{1}{C_{t=0}^2} \right) \right] = - (e_p^t + c_n)t \quad [26]$$

for interface states (where C_t and $C_{t=0}$ represent C at time t and $t = 0$, respectively).

Thus, plots of $\ln [(C_o^2 - C_t^2)/(C_o^2 - C_{t=0}^2)]$ for bulk states or $\ln [(1/C_o^2 - 1/C_t^2)/(1/C_o^2 - 1/C_{t=0}^2)]$ for interface states *vs.* time should yield a straight line of slope $(e_p^t + c_n)$. For states sufficiently above the valence band in energy, e_p^t can also be taken as zero and c_n is obtained directly. When this is not the case, c_n , which is proportional to n , can be evaluated from the effect of injecting a known concentration of majority carriers (electrons). This can be accomplished by momentarily reducing the bias voltage (6). Alternatively, in electrochemical systems, it is possible to adjust the dark current, which determines the overall value of n through the space charge region by adding appropriate solution redox couples that inject majority carriers into the semiconductor. The more negative the redox potential of the couple, the greater the tendency to inject electrons. It should be mentioned that analogous procedures could be used to evaluate minority carrier capture rates from EPS measurements. In this case, minority carriers would be injected by momentarily forward biasing the semiconductor (6) or employing solution redox couples that are sufficiently positive for n-type semiconductors or sufficiently negative for p-type materials.

Now consider the change in photocapacitance with time after initiating illumination. Since $n_s = 0$ at $t = 0$,

Eq. [13] becomes

$$-\frac{1}{(k_1 - k_n)} \ln \left[1 - \frac{(k_1 + k_n)}{k_1 N_s} n_s \right] = t \quad [27]$$

Having determined k_n from photocapacitance decay studies we can readily calculate k_1 when N_s is known, *i.e.*, when trap saturation can be attained. Otherwise, k_1 and N_s can be determined by iteration to attain the best fit for Eq. [27]. If the photon flux (I) is known, the optical cross section (σ_n°) can be extracted from e_n° (which equals k_1 in this case) since $e_n^\circ = \sigma_n^\circ I$.

Experimental Considerations

Electrolyte selection.—For studies of a specific electrochemical system, EPS measurements are, of course, made *in situ* in the electrolyte of interest. In other cases, however, an electrolyte must be selected.

Interface states associated with oxygen adsorption or surface oxides can readily be studied by EPS in aqueous solutions, in which oxide interfacial structures are apparently stable. Note that for n-CdSe (see Results section), interface states associated with oxygen adsorption are found to be practically unchanged in aqueous systems compared to the vacuum. In EPS, the environment, *i.e.*, electrode potential and solute/solvent, can also be easily varied. Such studies can provide valuable information about oxidation/passivation phenomena.

In cases for which there is flexibility in the choice of electrolyte for EPS measurements, two prime considerations are the electrolyte optical transmission and electrical conductivity. Ideally, the electrolyte should be transparent to light ranging in energy from the bandgap down to midgap, which permits the entire bandgap region to be probed (via transitions involving both bands). Solvents that are sufficiently polar can generally be rendered electrically conductive via dissolution of appropriate salts. Tetraalkylammonium salts are typically used with the nonaqueous solvents.

Optical transmission spectra for some key solvents are shown in Fig. 3 and 4; the cell path length was 1.0

Fig. 3. Optical absorption spectra for water and acetonitrile (1.0 mm path length).

Fig. 4. Optical absorption spectra for chloroform and deuterated chloroform (1.0 mm path length).

mm, which is approximately equivalent to the thickness of electrolyte through which light passes in the EPS cell used in the present work. The useful range for water (Fig. 3), which is limited by the onset of absorption associated with O-H stretching, is seen to extend down to about 0.9 eV (1350 nm). Note that the transmission cutoff for alcohols would be similar to that of water. Acetonitrile (Fig. 3) exhibits no significant absorption features down to about 0.75 eV (1650 nm) where the onset of sharp absorption peaks associated with the C-H bond is observed. At energies between 0.75 and 0.55 eV, several sharp spectral features are evident, but considerable light transmission also occurs. Thus, acetonitrile can be used with little concern down to 0.75 eV, and between 0.75 and 0.55 eV with caution. In all cases, EPS spectra should be closely examined to determine which features might result from solvent absorption. The effects of the latter can be checked by varying the solvent or the thickness of the electrolyte layer in the light path. Chloroform, which contains only one C-H bond, exhibits significantly weaker absorption (the only pronounced spectral features are two sharp peaks at 0.52 and 0.73 eV) so that its useful range extends to at least 0.5 eV (Fig. 4). The effects of solvent absorption features associated with hydrogen can be even further reduced by use of deuterated solvents. Figure 4 also shows the transmission spectrum for deuterated chloroform (a readily available solvent); the good transmission characteristics extend to beyond 0.5 eV (the only pronounced spectral feature is a sharp peak at 0.55 eV), permitting bandgaps in the 1 eV range to be probed.

Another consideration in selecting a solvent is the stability of the semiconductor in the electrolyte. Although chemical instability may be a problem in some cases, the primary concern is the effect of photogenerated minority carriers, which migrate to the interface and can result in dissolution of the semiconductor and/or film formation. It should be emphasized at the outset that, in our experience, such effects are gen-

erally small and do not appreciably affect short-term EPS measurements. In the case of bulk states, even long-term measurements may not be affected by a slow rate of photodissolution, but film formation, when it occurs, is likely to cause the baseline capacitance to drift with time, making quantitative inferences more difficult. For studies of interface states, both photodissolution and film formation are likely to affect the structure of the interfacial region and interfere with EPS measurements. It should be mentioned that although the less polar nonaqueous solvents generally provide greater inherent stability against semiconductor photodissolution, there is also a greater tendency toward film formation in such media.

Photodissolution and film formation processes can generally be greatly suppressed or practically eliminated by incorporation of suitable redox species in the electrolyte. In this case, photogenerated minority carriers are removed as they arrive at the interface (before semiconductor degradation can occur) by reaction with the redox species, which is simultaneously converted to another soluble species. The stabilizing effect of redox species is to some extent reflected in the redox couple potential, but other factors are also important in this respect, and the effect of the couple on the interface characteristics and dark current must be considered. For example, specific adsorption of redox species can affect the interfacial structure and the semiconductor/electrolyte potential distribution, and may result in an increase in dark current. Ideally, both halves of the couple should be transparent to light in the energy range of interest (or be present in small concentration) and should not adsorb strongly on the semiconductor. Fortunately, a large number of redox couples have been studied for use in stabilizing electrochemical solar cells; even the least stabilizing of those reported in the literature would probably be effective for the extremely small currents flowing during EPS measurements.

It should also be mentioned that some electrolyte redox species may exchange electrons with interface states, affecting their population and hence the magnitude of any corresponding EPS spectral feature. Such effects may be undesirable in some cases, but can also be exploited to investigate the extent to which a particular interface state mediates electron transfer between the semiconductor and the electrolyte. Charge transfer mediation undoubtedly plays an important role in the functioning of many electrochemical systems, particularly those involving electrocatalysis, but its fundamental aspects have remained obscure.

Measurement frequency.—The voltage perturbation frequency employed in EPS measurements can to some extent be used as an adjustable parameter to maximize the signal to noise ratio and, in that manner, the sensitivity to capacitance changes. In this case, the frequency is chosen to yield a relatively large value for the capacitive reactance, as indicated by a large phase shift (70° – 90°) between the voltage perturbation and the current response. When there is appreciable frequency dispersion, this procedure will lead to some uncertainty in the calculated densities of states, but the associated error is generally very small for smooth single-crystal electrodes and is typically much less than an order of magnitude even for polycrystalline materials. In any case, measurements made at a given frequency should provide a relative measure of the density of a particular state.

Errors associated with frequency dispersion can be minimized if the source of the dispersion is known. Generally speaking, high frequency measurements, for which the effects of surface inhomogeneities and lattice defects are minimal, are considered more reliable. This is often not the case for polycrystalline films having appreciable porosity, since, because of the tortuous current paths involved, a large portion of the perturba-

tion voltage at high frequencies may fall across the electrolyte rather than the semiconductor. Therefore, for porous films low frequency measurements may be more reliable.

Measurements at various perturbation frequencies can also provide additional information. For example, the exchange of electrons between interface states and electrolyte species in response to the voltage perturbation, which may occur under some bias potential conditions, is likely to be a relatively slow process which contributes to the measured capacitance only at low frequencies. In this case, the associated EPS spectral feature will vanish as the perturbation frequency is increased,

Electrode bias voltage.—The electrode bias potential is typically varied over the range where the semiconductor is reverse biased and the dark current is minimal. As already mentioned, the magnitude of EPS spectral features associated with bulk states generally varies linearly with the space-charge depletion width, whereas those associated with interface states are relatively potential insensitive. Thus, bulk and interface states can typically be distinguished from the effect of the electrode bias potential. Identification made in this way can readily be verified by changing the solvent or adding surfactants to the electrolyte. The surfactants typically have a large effect on the energies/population of interface states but have little effect on the EPS characteristics of bulk states.

Changes in the population of interface states with electrode bias voltage can also be detected by EPS. In this case, the magnitude of the photocapacitance change corresponding to the interface state should vary rather abruptly over a limited potential range as the state population changes; this contrasts with the Mott-Schottky behavior associated with a bulk state. It should also be mentioned that the potential dependence of the population of an interface state is likely to be affected by the presence of redox species in the electrolyte, which can exchange charge with the state.

Experimental Details

Figure 5 shows a block diagram of the apparatus used in the present work. Complete computer control was provided by a Hewlett Packard 9826 desktop computer. The real and imaginary components of the electrode impedance were determined by a Solartron Model 1172 frequency response analyzer which automatically averages over many perturbation cycles. The perturbation voltage was typically 10 mV (rms), although larger voltages are sometimes used for highly resistive materials. The impedance of the counterelectrode (Pt) and lead inductance effects were eliminated from the measurement by use of a Stonehart Model BC 1200 potentiostat (which employs a dual working electrode lead) in the three-electrode mode. A Tektronix Model AM501 differential amplifier was employed between the potentiostat and the frequency response analyzer. Monochromatic illumination (1 – 2 mW/cm²) having a bandwidth of ~ 8 nm (depending on the slit dimensions and diffraction grating) was provided by a 1000W tungsten-halogen lamp³ via an Instruments SA Model HT-20 turret monochromator. Appropriate ordering/neutral density filters were inserted automatically.

With the apparatus described here, capacitance changes of 0.01% can be measured. This corresponds to a detectability limit for both bulk and interface states (the latter expressed per cm²) of 0.02% of the overall charge carrier concentration.

The electrochemical cell was glass with a quartz optical window and a Teflon top through which cell connections were made. The electrolyte volume was ~ 200 ml. An inert atmosphere was maintained via

³ The spectral output for this lamp is relatively monotonic; for most other light sources, particularly Xe lamps, it is important to take into account intensity variations with wavelength.

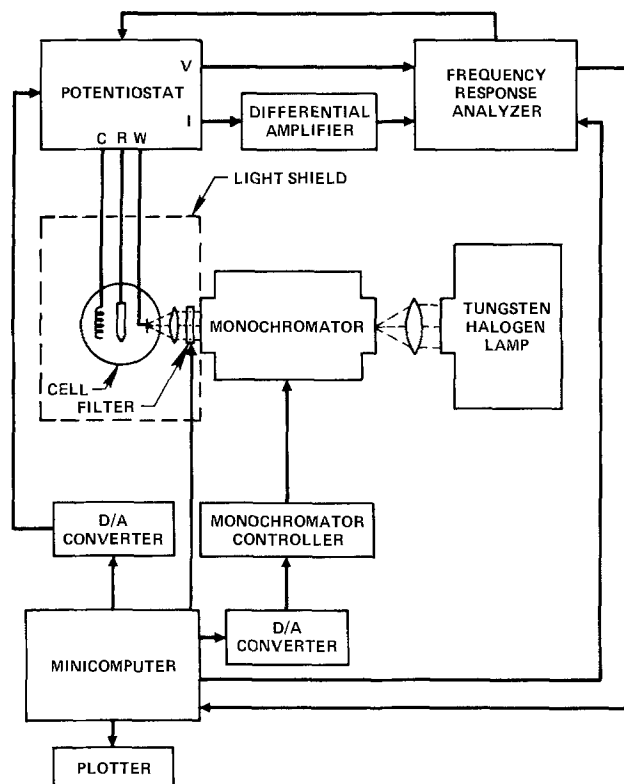

Fig. 5. Block diagram of the EPS apparatus

argon bubbling through the solution. The platinum counterelectrode was isolated from the main cell compartment via a glass frit. The reference electrode was a double junction saturated calomel electrode (SCE) or Ag/AgCl in aqueous solutions, and an Ag/Ag⁺ (acetonitrile/0.1M AgNO₃/0.1M tetraethylammonium perchlorate) in nonaqueous electrolytes. All bias voltages are given relative to the flatband potential (U_{FB}), which was determined by ac impedance measurements as a function of potential (values typically agreed with those observed for photocurrent onset).

Semiconductor electrodes, with appropriate ohmic contacts, were mounted in polyester resin (Torr Seal, Varian, Incorporated) so that only the desired surface was exposed to the electrolyte. The area of the exposed semiconductor surface was usually 0.2 cm², permitting total illumination of the surface. For larger electrodes, the dark capacitance associated with the unilluminated portion of the exposed surface was subtracted from all measured capacitance values. Single crystal electrodes were generally polished using aqueous slurries of successively finer alumina powders to a particle size of 0.3 μ m before etching; thin film materials received no mechanical pretreatment. The following etching procedures were used. GaAs electrodes were immersed in 50/50 volume percent (v/o) H₂SO₄/H₂O₂ (30%) for ~10s. CdSe electrodes were etched in ~50 v/o HNO₃ for ~10s, then dipped in aqueous polysulfide solution (1.0M S + 2.5M Na₂S + 1.0M KOH) to remove excess Se from the surface. Amorphous Si specimens were used as obtained. Zn₃P₂ electrodes were etched in 1 v/o bromine/methanol for 5-10s.

Results and Discussion

Deep traps in n-GaAs.—The sensitivity of EPS to some of the more common deep traps in n-GaAs is illustrated by the spectrum for horizontal Bridgman material (<100>) shown in Fig. 6; corresponding phototransitions are depicted in the insert. The important features apparently correspond to the "B" state (7, 8) (decrease in capacitance at 0.73 eV), the "EL2" level (9, 10) (increase in C at 0.83 eV), chromium (11) (peak at 0.92 eV superimposed on EL2 wave), and an

Fig. 6. EPS spectrum (measured at 5 kHz) and associated energy levels/phototransitions for n-GaAs (0.5V vs. U_{FB}) in 0.1M tetraethylammonium perchlorate/acetonitrile solution.

unidentified donor state at 1.09 eV. All of these transitions exhibit the electrode-potential dependence expected for bulk states. Some surface pretreatments introduce an additional donor state at about 0.70 eV which apparently resides at the interface, since the associated capacitance change is potential independent. Based on the capacitance changes, the densities of all bulk states detected are $\sim 10^{14}/\text{cm}^3$, which are reasonable values when compared to literature data for similar material. Also secondary ion mass spectroscopy (SIMS) analysis indicated that the chromium concentration in our material was $2 \times 10^{14}/\text{cm}^3$.

Comparison with DLTS.—A direct comparison between EPS and DLTS was made for a liquid-encapsulated Czochralski (LEC) p-GaAs specimen (<100>); a typical EPS spectrum and the assumed phototransitions are shown in Fig. 7. With DLTS, only the hole trap (acceptor level) corresponding to the sharp capacitance increase at 0.69 eV in the EPS spectrum was detected. Both methods yielded about the same density, for this state, $10^{15}/\text{cm}^3$. Three additional states were detected by EPS, corresponding to a capacitance decrease at ~0.74 eV (electron trap), a peak at 0.9 eV (probably a localized impurity transition), and an increase in capacitance at 1.06 eV (hole trap). Although the sum of the energies of the 0.69 and 0.74 eV levels corresponds closely to the bandgap (1.42 eV), complementary transitions involving the same center are not involved. This was shown clearly from the time dependence of the capacitance upon shifting the wavelength from one value to another or interrupting illumination. For example, if 1500 nm light is blocked, the capacitance rapidly increases to a slowly decaying value because the lifetime of the occupied 0.74 eV level is relatively short (<1s), whereas that of the occupied 0.69 eV hole trap is very long (at least several minutes).

Interface states at n-CdSe.—The sensitivity of EPS to interface states is best illustrated by data obtained for n-CdSe, for which interface states associated with

Fig. 7. EPS spectrum (measured at 10 kHz) and associated energy levels phototransitions for LEC p-GaAs (0.4V vs. U_{FB}) in 0.1M tetrabutylammonium perchlorate/0.1M benzoquinone/acetonitrile.

oxygen adsorption play a dominant role (12, 13). Figure 8 shows an EPS spectrum and associated phototransitions for a chemically etched single crystal of

Fig. 8. EPS spectrum (measured at 5 kHz) for chemically etched single-crystal n-CdSe (0.7V vs. U_{FB}) in 0.5M KOH solution (curve 1) and surface photovoltage spectra for oxygen-adsorbed (curve 2) and vacuum-cleaved (curve 3) single-crystal n-CdSe. Surface photovoltage data taken from Ref. (12); Δ CPD = change in contact potential difference. Reproduced with permission of North Holland Publishing Company, Amsterdam, from *Surf. Sci.*, 69, 62 (1977).

n-CdSe (cleaved perpendicular to c-axis) in a basic aqueous electrolyte (curve 1), as well as surface photovoltage spectra (curve 2 and 3) reported by Brillson (12) for oxygen-adsorbed (70% coverage) and vacuum-cleaved (LEED-ordered) single-crystal n-CdSe surfaces. Three capacitance increases/plateaus, associated with transitions from donor states at 1.04, 1.28, and 1.34 eV to the conduction band, are evident. Note that there is also a barely discernible capacitance decrease at \sim 1.6 eV, which corresponds to a transition from the valence band to an ionized donor state located just below the conduction band; this state occurs in much higher concentrations in some polycrystalline materials.

The similarity between the surface photovoltage spectrum for the oxygen-adsorbed surface and the EPS spectrum is striking, indicating that the surface oxide structure is similar in the two environments and that the same bandgap states are involved. The 1.04 eV transition, and possibly the transition at 1.28 eV (not resolved by the vacuum technique), must involve interface states associated with oxygen adsorption, since no change in surface photovoltage was observed for the vacuum-cleaved CdSe (curve 3) in this energy range. The 1.34 eV transition is apparently intrinsic to CdSe, since it is evident in the photovoltage spectra for both vacuum-cleaved and oxygen-adsorbed CdSe crystals. EPS data for n-CdSe single crystals with various surface pretreatments also indicate that both the 1.04 and 1.34 eV transitions are associated with interface states. For example, although the same transitions are observed in all cases, concentrations of the 1.04 and 1.34 eV states are reduced by photoetching and greatly increased by mechanical polishing. EPS data for n-CdSe in aqueous solutions also correlate extremely well with other solid-state literature data for oxygen-adsorbed surfaces [e.g., (13)]. As an indication of the sensitivity of the EPS method, the concentration of the 1.04 eV interface state calculated according to Eq. [2] from the data in Fig. 8 is $3 \times 10^{12}/\text{cm}^2$, and that of the 1.28 eV state is $5 \times 10^{11}/\text{cm}^2$.

Amorphous silicon.—EPS has also been applied successfully to characterization of amorphous silicon. Figure 9 shows an EPS spectrum on three different scales

Fig. 9. EPS spectrum for a-Si (measured at 10 kHz) in 0.1M tetrabutylammonium perchlorate/acetonitrile.

(offset) for an a-Si specimen (deposited on stainless steel) in an acetonitrile electrolyte. Two relatively weak transitions (onsets at 1.13 and 1.34 eV) and four stronger transitions (onsets at 1.41, 1.50, 1.58, and 1.77 eV) are resolved as a series of plateaus, all corresponding to excitations from states within the mobility gap to the conduction band. Apparently, both band-tail states and gap states (14) in a-Si can be detected by EPS.

Kinetic studies.—Finally, EPS evaluation of deep-level kinetic parameters will be illustrated for one specific case. Figure 10 shows a typical EPS spectrum obtained for thin film p-Zn₃P₂ (prepared by chemical vapor deposition on tungsten-coated silicon steel). Note that at wavelengths longer than 1100 nm the capacitance scale is 100-fold more sensitive and the EPS curve is offset. There are two well-defined peaks (0.74 and 1.02 eV) presumably corresponding to localized impurity transitions, and two capacitance increases (onsets at 1.08 and 1.27 eV) corresponding to transitions from the valence band to bandgap states. The 1.08 eV level is apparently an interface state since it varies considerably with surface pretreatment, sometimes obscuring the 1.02 eV peak. The other states apparently reside in the bulk.

Consider the 0.74 eV bulk state in p-Zn₃P₂. The time dependence of the photocapacitance after initiation and interruption of 1680 nm illumination is shown in Fig. 11. Figure 12 shows a plot of $\ln [(C_o^2 - C_t^2)/(C_o^2 - C_{t=0}^2)]$ vs. time in the dark, which, according to Eq. [25], should yield a straight line of slope k_n . The good linearity at longer times is evident. Note that the initial rapid decrease in C , which results in a non-zero intercept, is probably caused by edge effects. Figure 13 shows the photocapacitance rise data from Fig. 11 and the theoretical curve (solid line) obtained by computer fitting the data to Eq. [27] using the k_n value from Fig. 12; the good fit is evident. Calculated values for N_s and k_o are also given in Fig. 13. The value for N_s ($1.4 \times 10^{16}/\text{cm}^3$) is slightly higher than that calculated from the overall capacitance change ($8.5 \times 10^{15}/\text{cm}^3$), since trap saturation had not been attained. In cases for which the capacitance change is independent

Fig. 10. EPS spectrum (measured at 5 kHz) for thin film p-Zn₃P₂ (0.3V vs. U_{FB}) in 0.1M tetrabutylammonium perchlorate/acetonitrile.

of illumination intensity, the two calculated values for N_s are found to be equivalent.

Summary and Conclusions

EPS has been demonstrated to be an extremely sensitive means for characterization of deep electronic levels in a wide variety of semiconductor materials. Application of the method, which is nondestructive and provides *in situ* electrochemical information, is relatively straightforward and rapid; the blocking contact

Performance and Discharge Characteristics of Ca/LiCl, LiNO₃/LiNO₃, AgNO₃/Ni Thermal Battery Cells

G. E. McManis,* M. H. Miles,* and A. N. Fletcher*

Chemistry Division, Research Department, Naval Weapons Center, China Lake, California 93555

ABSTRACT

Thermal battery cells utilizing molten LiNO₃ as an oxidizing electrolyte with calcium anodes have been characterized for high rate discharge conditions. The presence of small amounts of AgNO₃ greatly improves the cathode reaction. Half-cell studies of anode characteristics show little variation of anode potential with temperature. Gassing at the anode-electrolyte interface increases with temperature and current density. Overall anode consumption rates increase with increasing temperature, while anode coulombic efficiencies drop at high rates of discharge (300 mA/cm²). Cathode half-cell data reveal that high rate reduction of AgNO₃ dissolved in LiNO₃ yields masses of dendritic growth at low temperatures (260°-275°C) while at higher temperatures (> 400°C) correspondingly fewer dendritic structures are observed. Cell experiments show anticipated current-voltage-temperature relationships, effectively mirroring half-cell experiments. Cell voltages sustain over 2V at 75 mA/cm² for periods which vary according to temperature of discharge.

Extensive research has been directed toward the development of a new generation high power-density thermal battery system for high rate discharge applications to replace the Ca/LiCl-KCl/CaCrO₄ system, which has been in use since World War II. The Ca/CaCrO₄ system exhibits a highly complex cathodic reaction. Furthermore, CaCrO₄ is a known carcinogen, and chromium is a strategic material with minimal

* Electrochemical Society Active Member.

U.S. reserves (1). An ideal thermal battery system would be capable of rapid activation, achieving high energy and power densities over a wide operating range of temperatures, and sustaining high current densities without utilizing strategic or toxic materials.

Much progress has been made in the development of new anode materials (LiAl, LiSi, LiB) and in the development of transition-metal sulfide cathodes (FeS, FeS₂), but the electrolyte most commonly used re-

mains the LiCl-KCl eutectic melting at 352°C (2). A lower electrolyte melting point would minimize both the quantity of pyrotechnic heating material and the quantity of insulation required for cell activation and discharge.

Lithium nitrate is a strong oxidizing agent with the dried reagent grade melting near 255°C. As an oxidizing salt, the need for a separate cathodic layer (such as CaCrO_4) is eliminated (3). The calcium anode in contact with molten LiNO_3 without added halide passivates, and rapidly forms a nonstoichiometric calcium oxide film. This film prevents reaching the true equilibrium potential and the passage of large current densities (4). The addition of halides produces corrosive attack of the film with subsequent pitting and thinning of the film allowing for high rate discharge at useful potentials (4-6). Chloride ion concentrations over 20 mol percent (m/o) have been found optimum for high rate discharges (7).

Although nitrate species are reducible, the electrode product of insoluble Li_2O precipitates on the cathode and prevents high rate discharge due to film resistivity (8, 9). The presence of AgNO_3 in the LiNO_3 electrolyte allows the reduction of silver ions to be utilized as the cathodic reaction, as well as the reduction of nitrate ions (10). The silver-ion reduction in molten LiNO_3 has been shown to sustain 100 mA/cm^{-2} without severe polarization.

A thermal battery system utilizing these concepts has evolved with a cell configuration of Ca/LiCl , $\text{LiNO}_3/\text{LiNO}_3$, AgNO_3/Ni . LiNO_3 is incorporated into a fiberglass binder/separator with LiCl layered near the anode and a layer of AgNO_3 in LiNO_3 with Cab-o-Sil binder near the cathode current collector. Such a design assures Cl^- concentration and isolation at the anode-electrolyte interface and maximizes the AgNO_3 concentration near the nickel current collector. The fiberglass LiNO_3 separator effectively prevents the formation of dense insoluble resistive AgCl layers. The catholyte layer of AgNO_3 in LiNO_3 with Cab-o-Sil binder allows for an optimal concentration of AgNO_3 near the cathode. The Cab-o-Sil serves to improve the low temperature characteristics by controlling catholyte flow and dendritic growth of silver reduced onto the Ni current collector.

Experimental

Nickel current collectors were cut from 0.010 in. thickness of Ni (99.9%, ROC/RIC), leads were 18 gauge Ni wire and spot-weld attached. Anodes were constructed by spot welding disks punched from Ca ribbon of 0.020 in thickness (99%, ROC/RIC) to Ca/Fe bimetal disks. Both the Ca foil and the bimetal disks were degreased in dichloroethane and cleaned in a dilute solution of HNO_3 in dimethylformamide until no dark oxide film was visible prior to spot welding.

LiCl (Mallinkrodt, Analytical Reagent), KCl (Matheson, ACS reagent), LiNO_3 (Baker, "Baker-Analyzed" Reagent), and LiNO_2 (Great Western Inorganics, 99% pure, monohydrate) were dried overnight at 125°C under vacuum prior to use. Some decomposition of the $\text{LiNO}_2 \cdot \text{H}_2\text{O}$ was noted, and weight loss was consistent with the loss of a water of hydration. AgNO_3 (Baker and Adams, ACS Reagent) was ground to a fine powder by mortar and pestle before use.

Anode performance experiments to determine current-voltage-temperature-calcium consumption relationships were conducted in porcelain crucibles (Coors) with 0.25 in diam anodes, Pt foil counterelectrodes, and Ag/Ag^+ reference electrodes. Temperature control was to $\pm 10^\circ\text{C}$ on a thermostated porcelain-surface hot plate.

Cathode performance characteristics for deposition potential and deposit morphology experiments were conducted in similar crucibles with 20 m/o AgNO_3 in

LiNO_3 solutions. Temperature control was $\pm 10^\circ\text{C}$. The solution was quiescent except for convective currents.

Cell testing procedures have been discussed previously (7). Anode vs. reference-electrode potentials were determined with a digital electrometer (Keithley Model 615). Galvanostatic conditions were maintained using a constant current source (Keithley Model 225). Temperature was monitored by a digital thermometer with analog output (Fluke Model 2165A). Cell voltages, applied current, and temperature were monitored by multimeters (Hewlett-Packard Model 3938A) and logged by a thermal printer (Hewlett-Packard Model 5051A). Other data channels were monitored on y vs. t recorders.

Results and Discussions

Anode performance characteristics.—Previous work showed that chloride ion concentration near the anode has a great influence on open-circuit and high current-density anode potentials (4, 7). Beyond 20 m/o, added Cl^- does not influence performance significantly. The thin layer of high Cl^- concentration near the anode allows for optimum discharge characteristics, but gives poor activation times because of the time required for solvation of the LiCl prior to depassivation of the anode. The effect of temperature on anode potential is minimal, as shown in Fig. 1. The duration of discharge for identical anodes, however, is seen to drop significantly at higher temperatures because of the rapid chemical oxidation of Ca by the LiNO_3 electrolyte. The variation in the amount of calcium was held to less than $\pm 0.25 \times 10^{-4}$ mols Ca (less than 10 m/o).

In Fig. 2, similarly treated anodes were discharged to 0.0V (vs. Ag/Ag^+ reference). As is shown, peak anode coulombic efficiency and consumption minimum occur in the region of about 310°C. Comparison to Fig. 1 reveals no significant difference in discharge curves other than time above 2V and a slightly higher anode potential at 310°C. It is thus apparent that anode film thickness, as governed by the corrosive activity of Cl^-

Fig. 1. Effect of temperature on calcium anode discharge curves at $300 \text{ mA}/\text{cm}^{-2}$ in LiNO_3 .

Fig. 2. Effect of temperature on anode consumption and anode efficiency for constant current discharges at 300 mA/cm^2 in LiNO_3 .

anions, limits discharge time and gradual film buildup at intermediate temperatures, allows for polarization, and hence less than 100% utilization of the calcium metal. At temperatures of 365°C and higher, the chemical oxidation rate is extremely rapid. The electrochemical oxidation is thus competing with rapid film formation by the direct reaction of Ca and LiNO_3 , and cell discharge times are shortened and coulombic efficiency is lowered.

Figure 3 shows that the performance of the calcium anode is better at 305°C than at either 275° or 375°C . Anode polarization is significant at current densities above 100 mA/cm^2 at both 275° and 375°C . The 305°C discharges up to 200 mA/cm^2 show a nearly linear anode potential vs. $\log i$ relationship.

Previous studies (7, 11) of large cells containing LiClO_4 have revealed that calcium anode deflagrations occur at high temperatures because of O_2 generation at the anode-electrolyte interface. During the present studies on molten nitrates, it was noted that gas evolution at the anode electrolyte interface was a function both of temperature and of current density. This gassing is due to the chemical reaction of calcium with

Fig. 3. Effect of temperature on anode potentials at various current densities in LiNO_3 .

molten nitrates to produce N_2O and N_2 but not O_2 (12)

The comparative voltammetric stability of the calcium anode at low temperatures despite vigorous gas evolution suggests that the reaction does not produce oxygen. At higher temperatures (over 425°C) Ca/LiCl, $\text{LiNO}_3/\text{LiNO}_3$, AgNO_3/Ni cells show occasional anode deflagrations, which may be due to O_2 generation by the thermal decomposition of LiNO_3 , as in Eq. [2].

Cyclic voltammetric studies have noted an increase in nitrite oxidation-wave peak currents consistent with LiNO_3 thermal decomposition in the region of 400° - 500°C (9, 13). Other workers have reported that the decomposition becomes appreciable only above 720 K (447°C) (13).

The alternative decomposition reaction (Eq. [3]) has been reported to be negligible up to 600 K (327°C) (13). Thermogravimetric analysis (TGA) of LiNO_3 confirms those reports, but reveals that above 550°C , decomposition to the oxide becomes quantitative

The use of fiberglass binders in molten LiNO_3 appears to be feasible only for short-term (less than 20 min) battery applications. LiNO_3 attacks SiO_2 over a period of time at temperatures up to 350°C with a more rapid attack at higher temperatures. Pure molten LiNO_2 immediately attacks SiO_2 , forming jellylike SiO_3^{2-} compounds. Much of the observed attack of LiNO_3 on SiO_2 may be attributed to the combined aggressive activity of Li^+ and NO_2^- . The NO_2^- species must be characterized as a definite binder aggressor.

Anode efficiency and consumption are complex functions of anode size and available calcium. It should be remembered that CaO is formed both by the chemical and the electrochemical reactions.

Cathode performance characteristics.—Half-cell studies of the silver ion cathode center on the morphologic characteristics of deposited silver metal and the deposition potential as a function of temperature. Galvanostatic depositions on nickel substrates at high rates show large masses of dendritic material when the electrolyte is at 260° - 285°C . Above 400°C , little dendritic growth is seen because of the extreme oxidizing nature of the molten LiNO_3 electrolyte.

Cell performance characteristics.—A total of 48 Ca/LiCl, $\text{LiNO}_3/\text{LiNO}_3$, AgNO_3/Ni thermal battery cells were discharged at constant temperature and constant current. In Table I, data are shown for constant temperature, constant current discharges at 261° , 310° , and 400°C . Data (where relevant) are indicated as mean \pm standard deviation of the individual values. Below 250°C , LiNO_3 is solid, and the cell is not electrochemically active. At temperatures over 425°C , anode deflagrations prompted by O_2 generation from the thermal decomposition of nitrate occur.

Figure 4 represents a typical complete cell discharge for a $1/2$ in diam cell approximately 4 mm thick utiliz-

Table I. Cell discharge characteristics

Parameter	261°C	310°C	400°C

ing the catholyte layer at 12 weight percent (w/o) Cab-o-Sil in (20 m/o AgNO_3 + 80 m/o LiNO_3) with applied facial pressure ($\sim 10^5 \text{ Pa}$). Oxide ions generated at the cathode form both CaO and Li_2O . The resistive effects of oxide precipitation and anode passivation produce lower cell voltages than those seen in half-cell discharges from the outset of discharge. Cell resistance is found to increase to a maximum at the end of discharge. Overall anode potential shows somewhat poorer performance than in half-cell tests. This is probably because of silver ion migration to form resistive AgCl , and blocking of active anode sites by insoluble resistive CaO .

Conclusion

Thermal battery cells based on the system Ca/LiCl , $\text{LiNO}_3/\text{LiNO}_3$, AgNO_3/Ni show promise for thermal

battery high rate discharge applications without utilizing strategic or toxic materials. While cell performance characteristics have yet to be fully optimized, 1.26 cm^2 cells producing over 2V at 75 mA/cm^2 have been demonstrated with 60s discharge times. Anode functional range is between $275^\circ\text{--}425^\circ\text{C}$ with applied facial pressure and a minimal amount of calcium. Anode potential is relatively insensitive to temperature, but discharge capacity is optimized at about 310°C for $75\text{--}100 \text{ mA/cm}^2$ discharge rates.

The Lithium-Boron Alloy Anode in Molten Nitrate Electrolytes

G. E. McManis,* M. H. Miles,* and A. N. Fletcher*

Chemistry Division, Research Department, Naval Weapons Center, China Lake, California 93555

ABSTRACT

Potentiostatic studies of Li(B) anodes in molten LiNO_3 at 300°C indicate that at 80% peak open-circuit voltage, a broad flat discharge at 780 mA cm^{-2} is obtained. Galvanostatic discharge studies show stable anode potentials more negative than -3V (vs. Ag^+/Ag) in LiNO_3 at 300 mA cm^{-2} over a temperature range of $270^\circ\text{--}350^\circ\text{C}$. At temperatures above 350°C , deflagrations of the anode were often observed, particularly after deep discharge. Electrolyte composition is a key factor in determining the current density-potential and potential-temperature characteristics of the Li(B) anode in molten nitrates. Experiments in equimolar $\text{LiNO}_3\text{--KNO}_3$ exhibit open-circuit anode potentials up to 0.2V less electronegative to that seen in equimolar $\text{LiNO}_3\text{--NaNO}_3$ electrolyte. In a like fashion at 300 mA cm^{-2} and 300°C , the use of $\text{LiNO}_3\text{--KNO}_3$ equimolar electrolyte results in Li(B) anode potentials up to 0.45V more positive than those seen in $\text{LiNO}_3\text{--NaNO}_3$ equimolar electrolyte and up to 0.85V more positive than that seen in LiNO_3 electrolyte. Single cell tests integrating the Li(B) anode with existing silver ion cathode technology exhibit stable cell potentials in excess of 3V at 300 mA cm^{-2} at 300°C . The two phase composition of the Li(B) alloy allows for exceptional anode stability at the high anode potential of elemental lithium.

The lithium-boron alloy has been developed as an alternative anode material for thermal battery applications demanding high cell voltages, high discharge

* Electrochemical Society Active Member.

Key words: cell, current density, fused salts, oxidation.

rates, and good energy and power density characteristics. Previous studies by other workers have been done in LiCl-KCl eutectic electrolyte and have characterized the Li(B) alloy as a two phase composite material having a refractory Li_7B_6 matrix supporting intersti-

tial elemental lithium which acts as the anode material to produce potentials near those of free elemental lithium (1-12).

The Li_7B_6 matrix retains structural integrity up to 600°C or higher (1, 4, 5) in LiCl-KCl electrolyte. The structural integrity of the anode is particularly important above 188°C where interstitial elemental lithium is molten and labile. Elemental lithium within the matrix "wicks" to the anode-electrolyte interface similar to the behavior of nickel-feltmetal-lithium anodes, thus presenting a continually renewed lithium surface for electrochemical reaction (1, 4, 5). This capability allows for extremely high discharge rates with reported discharges to 8000 mA cm^{-2} in LiCl-KCl eutectic electrolyte without severe anode polarization (5).

Molten nitrate electrolytes are attractive media for thermal battery applications because of their oxidizing nature, low toxicity, and low melting points. In electrochemical cells utilizing active metal anodes in molten nitrates, corrosion processes are inhibited through the formation of nonstoichiometric passivating oxide films (13, 14). The thickness, structural integrity, and ionic conductivity regulate cation migration across the film and hence the current density which may be passed without extensive anode polarization due to cation accumulation within the film (13, 14).

The presence of aggressive species at the film-electrolyte interface that compete for adsorption with passivating nitrate anions introduces corrosive attack at the film. Adsorbed nitrate anions tend to "heal" the film while the addition of an aggressive anionic species (e.g., Cl^- , Br^- , or I^-) produces breaks and localized pitting corrosion on the anode (14). Film breakdown allows for free passage and migration of cationic species and thus an unimpeded anode reaction at close to the equilibrium potential (13).

Previous studies in molten nitrate electrolytes have considered primarily the calcium anode in systems with either added halide or oxyhalide anion species (13-17). A relatively tight calcium oxide film is rapidly formed on the calcium anode in molten LiNO_3 . This film acts to polarize the anode by retaining cationic species within the film unless depassivating halide species attack. Potentiostatic experiments reveal a surge of current indicative of film breakdown immediately on addition of Cl^- , Br^- , or I^- species (13). Thermal battery cells based on calcium anodes in molten lithium nitrate electrolytes utilize a thin layer of LiCl near the anode which attacks the passive film on solvation by molten LiNO_3 at activation (15).

The molten nitrate electrolyte thermal battery cells, as previously reported, utilize the reduction of silver ions as the major cathode reaction (15, 17, 18). This is accomplished by utilizing a catholyte layer composed of 20 mol percent (m/o) AgNO_3 in LiNO_3 that is rendered immobile by the addition of 12 weight percent (w/o) Cab-O-Sil as a binder. The electrolyte per se is LiNO_3 with a fiberglass (SiO_2) binder.

The objective of this work was to integrate extant molten nitrate thermal battery cell technology with the Li(B) alloy anode material to achieve a thermal battery cell capable of the high cell voltages and high rate discharges characteristic of lithium anodes while retaining the low melting point and oxidizing advantages of the molten nitrate electrolyte. Li(B) availability and experimental considerations limited work presented here to electrolyte temperatures over 250°C . A future communication will discuss Li(B) anode behavior below 250°C in molten nitrates.

Experimental

All salts were reagent grade and were dried overnight under vacuum at 125°C - 130°C prior to use. The electrolyte wafers were constructed by dipping fiberglass filter paper disks (Gelman Type A, 0.3 mm thickness and 6.35 mm diam) into molten electrolyte. The

electrolyte wafers were immediately assembled into cells to minimize moisture pickup.

Anodes were constructed by punching disks (6.35 mm diam) from 75 atom percent (a/o) (65 w/o Li) Li(B) foil (0.5 mm thickness) in an argon-filled dry box and prompt spotwelding of Li(B) disks to a stainless steel backing followed by spotwelding a nickel lead wire. Completed anodes were used immediately. An L-shaped reference electrode (0.1m Ag^+/Ag) was used to monitor anode potential.

Cyclic voltammetric and potentiostatic experiments were conducted either in platinum crucibles where the crucible acted as counterelectrode or in porcelain crucibles where a platinum screen acted as the counterelectrode. Cyclic voltammetric experiments utilized a Pt working electrode, while a Li(B) working electrode was used in potentiostatic experiments. Cyclic voltammograms were generated using a Princeton Applied Research Model 173 potentiostat with a PAR Model 175 universal programmer.

Galvanostatic experiments utilized a Keithley Model 225 constant current source and a Hewlett-Packard data acquisition system which has been previously described (15). Temperature measurements utilized Chromel-Alumel thermocouples with a digital thermometer (Fluke, Model 2165A). Cell testing technique has been previously described (15, 16).

Results and Discussion

At current densities of 300 mA cm^{-2} , cell voltages of approximately 3V are obtained as shown in Fig. 1. The cell construction featured the lithium (boron) alloy anode in contact with a LiNO_3 binder wafer which, in turn, contacted a layer of $\text{AgNO}_3\text{-LiNO}_3$ in binder with a platinum cathode current collector. During discharge, slight gassing was noted at the anode-electrolyte interface.

Half-cell studies of Li(B) anode discharges revealed an extremely high current density capability when potentiostated at 80% of the peak open-circuit voltage. Figure 2 demonstrates the potentiostatic discharge of a Li(B) anode at -2.56V vs. the Ag^+/Ag reference. The broad flat characteristic curve corresponds to a current density of 780 mA cm^{-2} which represents the maximum sustained current density for the Li(B) anode in molten LiNO_3 assuming an 80% peak voltage cutoff.

Fig. 1. Cell discharge at a constant current density of 300 mA cm^{-2} (anode area) at 310°C . Peak cell potential = 3.02V .

Fig. 2. Potentiostatic discharge of the Li(B) anode at 290°C in LiNO_3 . Open-circuit potential was -3.2V vs. Ag^+/Ag . The anode was potentiostated at 80% peak OCV (-2.56V).

The electrolyte composition is also a major factor in determining anode performance characteristics below 350°C. Figure 3 illustrates the effect of varying electrolyte composition on anode current-potential relationships at 300°C. It is evident that in equimolar $\text{LiNO}_3\text{-KNO}_3$ severe anode passivation occurs at 300 mA cm^{-2} while in LiNO_3 and in equimolar $\text{LiNO}_3\text{-NaNO}_3$ electrolytes much less polarization due to passivation is noted.

The passive film on Li(B) alloy anodes differs qualitatively from that seen on Ca anodes. The addition of LiCl to $\text{LiNO}_3\text{-KNO}_3$ electrolytes with Li(B) anodes at 300 mA cm^{-2} serves only to cause the anode potential to become less electronegative. This is in contrast to Ca anodes that polarize severely in pure molten LiNO_3 at 300 mA cm^{-2} , but show a decrease in passivation as halide concentration increases.

The Li(B) anode may be modeled as a molten lithium liquid phase supported on a rigid matrix of Li_7B_6 . Elemental lithium is held within the matrix by its own surface tension and, as the reaction proceeds, expended lithium at the anode-electrolyte interface is replaced by fresh elemental lithium "wicking" from the depths of the anode. The actual lithium-electrolyte interface is governed by a Li_2O film (19, 20) but, owing to the mechanical instability of a film floating on a molten anode, passivating or blocking effects are minimal (13, 14).

Li(B) anodes often deflagrate in molten nitrate electrolytes at temperatures above 350°C. The prediction to deflagrate at high electrolyte temperatures is accentuated during deep discharge. At 380°C, the tendency for anode deflagration decreases in the order $\text{KNO}_3 \gg \text{NaNO}_3 \gg \text{LiNO}_3$. The probability of anode deflagration drops with temperature. Below 350°C in molten LiNO_3 electrolyte, the Li(B) anode is relatively stable and deflagration-free.

Fig. 3. Effect of current density on anode potential in various molten nitrate electrolytes at 300°C.

During the discharge of Li(B) anodes, significant anode oxidation products precipitated and were identified as elemental boron resulting from oxidation of the supportive Li_7B_6 matrix to lithium ions and elemental boron. The degree of attack in the Li_7B_6 matrix is dependent on temperature, current density, and electrolyte composition with greater amounts of elemental boron precipitate noted in KNO_3 and NaNO_3 containing electrolytes than in LiNO_3 electrolytes.

Addition of KO_2 to a $\text{LiNO}_3 \cdot \text{KNO}_3$ melt with a Li(B) anode was observed to increase the corrosion rate of the Li_7B_6 matrix. In addition, Li(B) anodes immersed in molten NaNO_3 or KNO_3 showed immediate formation of an elemental boron precipitate followed by deflagration of the anode. These results suggest that O_2^{2-} and O_2^- species that exist in NaNO_3 and KNO_3 melts are aggressive agents against the Li_7B_6 matrix. In LiNO_3 containing melts, O_2^{2-} and O_2^- species exist at much lower concentrations than the more stable O^{2-} ion. However, owing to the observed corrosive power of O_2^{2-} and O_2^- , even small amounts in the nitrate melt are sufficient to severely degrade the Li_7B_6 matrix. The presence of O_2^{2-} and O_2^- species has also led to corrosive attack on such inert metals as Pt and Ni in molten nitrates (21).

In high temperature melts (over 350°C), two factors predispose the anode to deflagration. First, electrolyte attack on the supportive matrix increases to form larger and larger surface pools of elemental lithium and, secondly, the surface tension of the lithium within the matrix decreases according to the relation (22-24)

$$\gamma = \gamma_0 (1 - T/T_c)^n \quad [1]$$

where γ is the surface tension and T_c is the critical temperature of the molten metals; n relates a scaling constant which may be assumed to be unity (22-24). As the surface tension of the elemental lithium decreases, the "wicking" rate increases and the net area of exposed lithium increases. The freshly exposed lithium reacts rapidly with the melt but, owing to the mechanical instability of a film on a liquid surface, unpassivated Li is continuously exposed. The reaction of the melt with freshly exposed lithium becomes dominant at higher temperatures and, as its rate increases, so does the likelihood of thermal runaway and anode deflagration. Also, as the anode area increases, so does the quantity of resistive Li_2O precipitate formed and thus, cell potential and anode potentials reflect a growing resistive Li_2O layer.

As would be expected from the above model, a significant temperature-potential relationship is noted at applied current. Anode potentials at open circuit and at 100 mA cm^{-2} as a function of temperature are shown in Fig. 4. Figure 5 illustrates the effect of varying current density on anode potentials at three fixed temperatures.

A thermodynamic examination of Li(B) cells is complicated by the role that the Li_7B_6 matrix and its reaction products may play in the discharge reaction.

Fig. 4. Effect of temperature on anode potential in molten LiNO_3 electrolyte. B is open-circuit potential, A is potential at 100 mA cm^{-2} .

Fig. 5. Effect of current density on anode potential at three temperatures in LiNO_3 electrolyte.

Previous calculations have indicated the high theoretical anode and cell potentials possible with elemental lithium/molten nitrate electrolytes (19, 20).

Cyclic voltammetric studies at 100 mVs^{-1} of the LiNO_3 electrolyte before and after Li(B) anode discharge reveal an extensive nitrite oxidation peak appearing after discharge and no anomalous peaks which might be associated with lithium-boron oxides or electroactive anode reaction products. It should be noted that elemental boron is insoluble and readily precipitates.

Assuming the Li_7B_6 matrix is inert and that the reaction is chiefly lithium oxidation, the thermodynamic calculations for the cell reaction

yields $\Delta G^0 = -79.4 \text{ kcal at } 300^\circ\text{C}$, hence $E^0 = 3.44\text{V}$.

Summary

An examination of the Li(B) alloy anode in molten nitrate electrolytes reveals high rate discharge characteristics in the temperature region $270^\circ\text{--}350^\circ\text{C}$.

Galvanostatic studies show no appreciable anode polarization in molten LiNO_3 at 300 mA cm^{-2} . High current density polarization is more evident in $\text{LiNO}_3\text{--NaNO}_3$ and $\text{LiNO}_3\text{--KNO}_3$ electrolytes.

Above 350°C , anode degradation in molten nitrate electrolytes is severe and deflagration may occur. This is attributed to both an increase in the Li_7B_6 degradation reaction rate and to the increased mobility and fluidity of elemental lithium within the Li_7B_6 matrix.

Potentiostatic studies of the Li(B) alloy anode at 300°C in LiNO_3 at 80% peak open-circuit voltage reveal a flat discharge rate at approximately 780 mA cm^{-2} . This high current density is approximately an order of magnitude above that obtainable in conventional Ca/LiCl , KCl/CaCrO_4 thermal battery cells.

Single cell tests at 300 mA cm^{-2} utilizing a Ag^+ cathode in conjunction with the Li(B) anode in molten LiNO_3 demonstrate concept feasibility at high rate discharges with cell voltages of approximately 3V.

The Electrocatalysis of Oxygen Evolution on Perovskites

John O'M. Bockris* and Takaaki Otagawa*†

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

Measurements of the oxygen evolution reaction have been made on eighteen substituted perovskites containing first-row transition metal ions. Rates are reported at equilibrium and at an overpotential of 0.3V. Electrode kinetic parameters are given, including roughness factors. The rate does not depend on semiconductor-type properties. It increases as the pH of zero charge, at which the occupancy of OH⁻ and H⁺ at the interface becomes equal, moves in an alkaline direction, with decrease of magnetic moment, with decrease of stability of the perovskite lattice, with decrease of the enthalpy of formation of the transition metal hydroxides, and with increase in the number of d-electrons in the transition metal ion. The accuracy of the roughness factor measurements are affected by weakness in knowledge of true double layer capacities. The value assumed here, 60 μF cm⁻², may be accurate to only ±100%. Models are given which suggest that the pores are active throughout. The correlations between the rate and electronic properties are consistent with rate-determining steps which involve desorption of OH radicals, e.g., M^z-OH + OH + ^{z,d,s}M^z . . . H₂O₂ + e⁻. An MO discussion suggests that the electrocatalysis increases with increased occupancy of the antibonding orbitals of M^z-OH. Earlier interpretations include the concept that an increase of the rate occurs because of increasing overlap between the e_g orbitals of the transition metal ion and the sp_σ orbital of O. However, this theory is based on only three different materials, in which rate-determining step changes. An interpretation based upon nonstoichiometry is shown to be consistent with observed trends, but insufficient to explain their magnitude. The electrical and chemical contributions to the rate are analyzed. The value of α is related via bond strength considerations to the M^z-OH bond strengths. The relative electrocatalysis discussed is limited to an overpotential which corresponds to a practical range of rates on the faster catalysts. A volcano relation for oxygen evolution on perovskites seems likely. Future electrocatalysts are predicted.

General concepts of electrocatalysis based on the fundamental aspects of the rate equation for electron transfer, particularly for hydrogen evolution and oxygen reactions on phase oxide-covered (or free) metals, have been thoroughly discussed by Appleby (1).

The first attempt to rationalize the electrocatalysis of oxygen evolution was made by Ruetschi and Delahay (2) in 1955. They plotted the overpotential at constant current density against M-OH bond strength [but cf., Conway and Bockris (3)].

More recently, several theoretical approaches to rationalize the electrocatalysis of oxygen evolution on oxides have been made by Tseung and Jasem (4), Trasatti (5) and Matsumoto *et al.* (6-10).

Tseung and Jasem (4) suggested that there is a correlation between the redox potential of an oxide couple of the electrocatalyst and the reversible potential of the oxygen evolution reaction. No mechanistic rationalization was suggested. Correspondingly, Trasatti (5) found that a somewhat volcano-shaped curve could be obtained by plotting overpotentials as a function of the enthalpy change for the lower-to-higher oxide transition in the catalyst.

Between 1977-1981, Matsumoto *et al.* (6-11), developed the theory of σ* band formation. The essential condition for high catalytic activities of oxygen evolution on perovskites is that a broad σ* band is formed and that the transition metal cation exists in a higher oxidation state. These authors' concepts do not involve chemical bonding.

In this work, a systematic investigation was made to correlate the electrocatalytic properties of perovskites (ABO₃) for oxygen evolution with their electronic structures, with stress upon the characterization of the bonding of surface oxygenated intermediates, as a correlating factor.

Experimental

Preparation of perovskites.—The transition metal oxides with substituted perovskitic structure [(A_{1-x}A_{x'}BO₃), where A is a lanthanide (mainly La), A' is an alkaline earth (mainly Sr), and B is a first-row transition metal] were chosen in order to study the electrocatalytic activities for oxygen evolution systematically.

† Present address: Argonne National Laboratory, EES Division, Argonne, Illinois 60439.

Key words: electrocatalysis, oxygen evolution, perovskite.

The addition of the A' ion was necessary to give sufficient conductivity for most of the compounds.

The perovskites were synthesized by high temperature solid-state reactions (11-20). Binary oxides or carbonates with high purity (~99.999%, Aldrich or Alfa) were used as starting materials. The appropriate amount of each reagent required to give the desired metal ion stoichiometry was weighed and mixed mechanically for 2h. The uniformly mixed powder was then placed in a Pt-covered Alundum combustion boat (Fisher) and fired in an appropriate atmosphere (12-20) at 1100°-1400°C for a total of 30-70h, with frequent regrinding and refring of the products. The pure lanthanum nickelate crystals were synthesized by a coprecipitation technique (21). X-ray diffraction patterns were taken for each powder to confirm the compound concerned. The electrodes (in pellet form) were then made by pressing powders at 300 kg cm⁻² and sintering at 1000°C. No binder was added.

Solid-state surface studies.—The resistivities and Hall effects for the surface of pellets were obtained by the method of van der Pauw (22). Impedance measurements were carried out by a lock-in analyzer approach (23). Measurements of the magnetic susceptibilities were carried out by the Faraday method (24). The physicochemical characterizations of La_{0.9}Sr_{0.1}CoO₃ electrodes by XPS are reported elsewhere (25).

Electrochemical kinetic studies.—Electrode kinetic parameters were determined mainly in 1M NaOH by potentiostatic current/time relations at varying potentials. A PAR Model 173 potentiostat/galvanostat, fitted with a PAR Model 376 current/voltage converter, was used to control the electrode potential. The detailed procedures for the steady-state potentiostatic experiments to obtain various kinetic parameters are described elsewhere (26).

Surface areas.—The surface areas of powders and electrodes were determined by BET and by double layer charging curves, respectively.

Cyclic voltammograms, taken in the flat double layer (dl) charging region and limited to a 50 mV potential range, were used to obtain a dl capacitance (27, 28). This value was then used to determine the roughness factor by assuming a theoretical value of the dl capacitance for a smooth surface. The potential was swept by connecting the output of a PAR Model 175 universal

programmer to the external potential signal input of the potentiostat. An X-Y recorder (Hewlett Packard Model 7010B) was used to plot the current/potential curves. Errors in, and the significance of, these surface area measurements are discussed below.

Measurements of acid-base properties.—The potentiometric acid-base titration method (29-33) was used to investigate the concentration of OH⁻ groups on the surface of perovskites in powdered form in aqueous solution. The experiments were made using a pH meter (Orion Research Model 811) with a combination pH electrode (Silver-Silver Chloride Internals, Miniature, Sargent-Welch, cat. no. S-30078-10). A glass titration cell, containing a water jacket, was used. A powder of ~0.3g was introduced into an aqueous solution¹ (25 ml) of 0.004M KOH and 0.01M KCl (J. T. Baker Chemical Company) and kept suspended overnight. Stirring was accomplished by means of a Teflon-covered magnet and a magnetic stirrer (Thermolyne Corporation Model S-7805). A constant temperature circulator (HAAKE Model FK) was used to keep the solution temperature at 25°C. The titration cell was sealed carefully and was under a CO₂-free N₂ stream, to avoid any CO₂ contamination from air, throughout the experiments. The titrant was 0.1M HCl (J. T. Baker Chemical Company). A microburette with a Teflon plug stopcock (Sargent-Welch, cat. no. S-10945-50C) was used.

Then, the titration was carried out by adding 0.05-0.1 ml quantities of the titrant successively. pH values were continuously recorded on an X-t recorder (Fisher Recordall Series 5000) to ensure the establishment of a steady state.

The titration curve thus obtained was compared with that previously obtained in the blank solution to determine the excess OH⁻ charge on the surface and, thus, to obtain the pH at which the amount of OH⁻ and H⁺ at the surface becomes equal (zero point of charge [zpc]).

Results and Experimental Rate Correlations

Solid-state parameters.—Solid-state parameters are summarized in Table I.

¹ This gives rise to a pH value of ~11.4. It is important to keep the powder in an alkaline solution initially, since perovskite-type oxides tend to dissolve in a strong acid solution.

The electrodes were all p-type semiconductors; the charge carrier densities were 10¹⁷-10¹⁸ cm⁻³, and the resistivities were 10⁻³-10⁻¹ Ω cm. The Hall mobility averaged around 30 cm² V⁻¹ s⁻¹. The Mott-Schottky plots indicated a p-type semiconductor behavior at the surface with a flatband potential of 0.20-0.50 (V vs. NHE).

The magnetic susceptibility (Fig. 1) varies with temperature and also varies greatly among the perovskites examined. LaNiO₃ showed a paramagnetism (even below 100 K), while La_{0.9}Sr_{0.1}CoO₃ showed a ferromagnetism with T_c = 221 K (i.e., La_{0.9}Sr_{0.1}CoO₃ becomes paramagnetic at room temperature). Strong ferromagnetism and antiferromagnetism were observed at room temperature, on La_{1-x}Sr_xMnO₃, and La_{1-x}Sr_xFeO₃, respectively (T_c for LaMnO₃ was 346 K).

Surface areas.—The BET measurements showed surface area values of ~15 m² g⁻¹ for powders and varied little among the compounds (Table I). The values of 15 m² g⁻¹ are in agreement with those obtained in an examination of perovskites by Crespin and Hall (35a). However, they differ from values observed by Matsumoto *et al.* (11), who obtained a value in the region of 2 m² g⁻¹. Doubtless these differences arise from differences in particle size of starting materials.

Typical cyclic voltammograms at various sweep rates for La_{0.9}Sr_{0.1}MnO₃ and La_{0.9}Ce_{0.1}CoO₃ are presented in Fig. 2. The anodic and cathodic currents were equal in magnitude, and the charging current was linear with the sweep rate. The dl capacitance was calculated from the slope of the charging current vs. sweep rate. The roughness factors were then determined by assuming a dl capacitance of 60 μF cm⁻², according to the views of Levine and Smith for oxide surfaces (34).

The dl capacitance values and roughness factors on various perovskite electrodes are summarized in Table I. The electrochemically active surface areas (roughness factors) were 100-1000 in terms of the ratio of the active to the apparent external surface area. The electrode prepared by a coprecipitation technique (LaNiO₃) extended this factor to about 5000.

Surface charges.—Figure 3 shows a typical titration curve on LaCoO₃. The coverage (θ [surface charge density, q_±]) vs. pH relations of cobaltates is shown in Fig. 4. 1.4 × 10¹⁵ sites cm⁻² was assumed to be a full

coverage (35a). The values of q_{\pm} were estimated from the difference between the titration curves, with and without powders, using the following relation (29, 31)

$$q_{\pm} = \frac{F \cdot \Delta V \cdot C}{S \cdot \omega} \quad [1]$$

where F is the Faraday constant, ΔV the difference in the volume of the titrant (0.1M HCl) in the presence and/or absence of the powder at a given pH, C is the concentration of the titrant (0.1M), and S is the BET surface area and ω is the amount of powder used.

The surface charge depends linearly on pH. The figures reveal several different linear sections of the coverage vs. pH relation for each material. At pH in the alkaline region, the coverage approaches $100 \mu\text{C}$ of OH^- per actual BET-based cm^2 of the electrode material in powdered form. A similar tendency was observed on the other perovskites.

These values may be compared with those in the literature. Thus, Levine and Smith (34) show a theoretical plot for the charge as a function of pH which is similar, though slightly more curved, to that of the experimental values obtained here. Aktinson *et al.* (33a) obtained coverage-pH data for, e.g., FeOOH in KCl, which resemble in shape those obtained in the present work. In particular, the work of Kita *et al.* (29), who worked in the presence of KCl, had straight line sections in charge-pH plots similar to those observed here.

It is possible to derive capacitances from the measurements obtained here (cf. Fig. 4) by assuming that the behavior of the surface is Nernstian (32) whereupon

$$C = \frac{\delta q}{\delta V} = \frac{\delta q}{\delta \text{pH}} \cdot \frac{\delta \text{pH}}{\delta V} \quad [2]$$

with

$$\frac{\delta V}{\delta \text{pH}} = 0.059$$

On the basis of Eq. [2], capacitance values of approximately $200 \mu\text{F cm}^{-2}$ in the vicinity of zpc are obtained for most of the perovskites studied.

In comparison with this are the values quoted by Levine and Smith (34) where the maximum values are said to be $160 \mu\text{F cm}^{-2}$ for SiO_2 and ZnO , and the work of Bowden *et al.* (33b) who give values of about $200 \mu\text{F cm}^{-2}$ for most oxides other than SiO_2 . Thus, our present values are clearly consistent with those in the literature. It could be that they may need, however, correcting downwards because we have used, in the evaluation of the area, the BET values for packed powders, whereas the values in dispersions would be expected to be somewhat higher (35b).

The values of the pH at which the surface-adsorbed OH^- and H^+ are equal (zpc) were 7-9 (pH) (Table I). This value increased with an increase in the degree of Sr substitution.

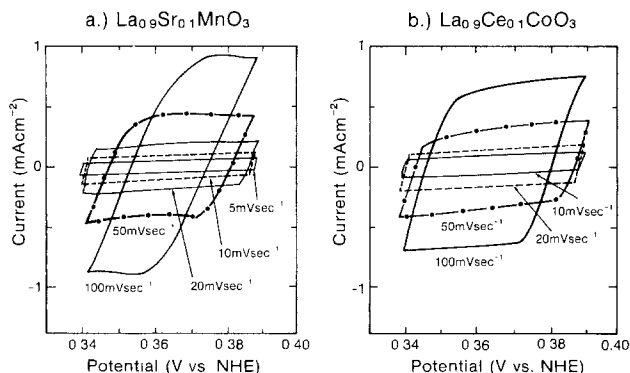

Fig. 2. Cyclic voltammograms, limited to the potential range of 0.34-0.39 (V vs. NHE), in O_2 -saturated 1M NaOH at 25°C , for $\text{La}_{0.9}\text{Sr}_{0.1}\text{MnO}_3$ (a) and $\text{La}_{0.9}\text{Ce}_{0.1}\text{CoO}_3$ (b).

Kinetic parameters for oxygen evolution on perovskites.—The potential vs. $\log i$ plots for $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ are presented in Fig. 5. The Tafel slopes for oxygen evolution at lower overpotentials were 43, ~65, ~120,

Fig. 4. Coverage (surface charge density) of cobaltates as a function of pH. 1.4×10^{15} sites cm^{-2} was used for full coverage.

~125, 200, and 175-235 mV/decade^{-1} for LaNiO_3 , $\text{A}_{1-x}\text{A}'_x\text{CoO}_3$ ($\text{A} = \text{La, Nd, Gd}$; $\text{A}' = \text{Sr, Ce, Th}$), $\text{La}_{1-x}\text{Sr}_x\text{FeO}_3$, $\text{La}_{1-x}\text{A}'_x\text{MnO}_3$ ($\text{A}' = \text{Sr, K, Ca}$), $\text{La}_{1-x}\text{Sr}_x\text{CrO}_3$, and $\text{La}_{1-x}\text{Sr}_x\text{VO}_3$, respectively. The reaction order, with respect to OH^- , was close to unity.

Table II summarizes the kinetic parameters for oxygen evolution (26). Current densities are expressed in terms of real surface area, taking into account the roughness factors. It is interesting to note that the reaction order in Table II shows a decrease which parallels the decrease of α or the increase of Tafel parameter a . The reaction order may be a sensitive parameter with oxides and may be related to the details of the mechanism. An example of such mechanisms to account for this parallelism is fully discussed elsewhere (26).

Correlations with physicochemical properties.—Flat-band potential (V_{FB}), carrier density (n), and Hall mobility (μ_{H}) are typical bulk properties of semiconducting perovskite-type oxides. However, no obvious correlations between catalytic activities and the parameters were found.

A fair correlation was found between the electrocatalytic activities and the pH at which the surface-adsorbed H^+ and OH^- are equal (zpc). The catalytic activity increases as the zpc becomes more alkaline. However, some scatter was observed in this correlation and it is possible that this arose from the fact that the solutions in which the zero point of charge was measured contained Cl^- , which could have been adsorbed to a different extent upon the various perovskites (although KCl concentration was 10^{-2}M , the adsorption would not be expected to have been great).

The reaction rates for oxygen evolution on perovskites are plotted against magnetic moments (μ_{eff}) in Fig. 6. The values of μ_{eff} for $\text{La}_{1-x}\text{Sr}_x\text{FeO}_3$ were estimated from those for LaFeO_3 and SrFeO_3 . The plot for LaMnO_3 was omitted, since it gave an anomalously

Fig. 5. Potential vs. $\log i$ plots on cobaltates in 1M NaOH at 25°C (iR corrected).

high value of μ_{eff} ($\mu_{eff} = 14.94$). However, this value is indicative of a strong ferromagnetism and was associated with a poor catalytic activity. If one ignores the plot for La_{0.8}Sr_{0.2}CrO₃, which showed little oxygen evolution due to instability under the anodic condition, it may be seen in Fig. 6 that the electrocatalytic activity decreases as the magnetic moment increases. or as the magnetism changes from paramagnetism to ferro/antiferromagnetism.

Correlations with thermodynamic properties.—Nakamura *et al.* (36) studied the chemical stability of perovskites LaBO₃ (B = V, Cr, Mn, Fe, Co, Ni) by thermogravimetry at 1000°C in a controlled P_{O2} atmosphere. The stability limits of the perovskite phases expressed in terms of $-\log P_{O_2}^*$ (P_{O2}^{*} = critical oxygen partial pressure in bar) were greater than 21.1 for LaCrO₃ and LaVO₃, 16.95 for LaFeO₃, 15.05 for LaMnO₃, 7.0 for LaCoO₃, and ~ 0.6 for LaNiO₃; hence, lattice oxygens become easily released in this sequence. The electrocatalytic activities of oxygen evolution are plotted against this critical oxygen partial pressure in Fig. 7.

Fig. 6. Current density (based on real surface area) for oxygen evolution on perovskites at an overpotential of 0.3V vs. effective magnetic moment, μ_{eff} .

There is a tendency that the lesser the stability at 1000°C, the better the electrocatalysis.

The reaction rates of oxygen evolution on perovskites are plotted against ΔH_f° of the hydroxides and M-OH bond strength in Fig. 8 and 9, respectively. The M-OH strength was calculated, based on the method of Ruetschi and Delahay (2), with corrections made by including the electronegativity term, as suggested by Conway and Bockris (3). Table III summarizes these thermodynamic properties. A linear correlation, limited to the descending branch of a volcano curve, is seen (Fig. 9); the electrocatalysis decreases as the M-OH bond strength increases.

The thermodynamic data to which reference can be made here are unfortunately not those of the perovskite itself, nor to that of the substituted perovskites containing, *e.g.*, strontium. Appropriate thermodynamic data have not yet been published for these materials. What we have used here, encouraged by the correlations obtained, are data for the corresponding oxides, *e.g.*, Cr(OH)₃, etc. We have limited these oxides to those of the trivalent metal. This arises out of the evidence from the work of Nakamura *et al.* (20), and also some ESCA measurements (25) referred to below, that the surface of La_{0.9}Sr_{0.1}CoO₃ consists of the trivalent cobalt and oxygen vacancies over the range of potentials which we used in the present work.

^d D_{cov}(M-OH) = 10.35 - ΔH_f[°]/3, where 10.35 (kcal mol⁻¹) and ΔH_f[°] are the enthalpies of formation of OH(g) (37) and M^{III}(OH)₃, respectively (2).

^e D_{ion}(M-OH) = 23.06 (χ_M - χ_{OH})², where χ_{OH} was estimated as ~3.3 (40).

^f D(M-OH) = D_{cov}(M-OH) + D_{ion}(M-OH).

^g ΔH_f[°] for V₂O₅ was used.

Correlations with d-electron configuration.—In Fig. 10, the catalytic activities for oxygen evolution on perovskites are plotted against the number of d-electrons of each transition metal ion in perovskites. The number of d-electrons was assigned based on the trivalent transition metal ions in perovskites. The reaction rate increases with an increase of the number of d-electrons.

Discussion

Degree of validity of the roughness factor measurements.—There are two assumptions in the roughness factor measurements: (i) the only reason for the difference of the capacitance observed is due to roughness; double layer capacitance for the perovskite per real unit area is that of a nonpolarizable interface which has a capacitance per real square centimeter of 60 μF cm⁻²,² (ii) The capacitances used in the determinations were those of the solid/solution interface and not, e.g., those of the Schottky barrier within the semiconductor.

² Utilizing a similar method, it would be possible to select 16 μF cm⁻² as the reference value, because this is the capacitance of the Hg/solution interface on the negative branch. However, the present work was carried out (cf. Fig. 11) in a region near or positive to the flatband potential, and, hence, the more appropriate capacitance for reference is that of the Hg/solution interface on the positive branch. This is less constant in numerical value. 60 μF cm⁻² has been taken as a typical value (34).

In respect to the comparison with Hg, the validity is lessened by the discovery of Frumkin *et al.* (41), that the dl region on various metals which do not adsorb H significantly varies from ca. 16 to ca. 25 μF cm⁻² on the negative branch. Indeed, it has been suggested that the Thomas-Fermi screening length in a metal contributes to the net dl capacitance and could make the true values of this quantity a parameter characteristic of the metal (42, 43) [however, the limits of this variation do not seem to exceed the range 16-25 μF cm⁻² (41)].

These contributions lessen the numerical certainty of the method used. Because of these intrinsic difficulties, the roughness factors probably do not have absolute significance better than ±100%.

It is interesting to note that the electrochemical and BET areas are not parallel. A parallelity would be expected if the samples used for both methods had been the same (44). Unfortunately, it was not possible to subject the pellets which were used as the electrodes to a BET examination because the BET apparatus which was available was not sufficiently sensitive to register pressure changes with pellets. Therefore, lightly packed powders were used and this difference in form is probably the origin of the fact that there is no constant ratio between the electrochemical and BET measurements.

Fig. 8. Current density (based on real surface area) for oxygen evolution on perovskites at an overpotential of 0.3V vs. enthalpy of formation of corresponding hydroxides: M^{III}(OH)₃. The transition metal ions (M) in perovskites are indicated with different symbols.

Fig. 9. Current density (based on real surface area) for oxygen evolution on perovskites at an overpotential of 0.3V vs. M-OH bond strength. The transition metal ions (M) in perovskites are indicated with different symbols.

Fig. 10. Current density for oxygen evolution on perovskites at an overpotential of 0.3V vs. number of d-electrons of transition metal ions in perovskites. The transition metal ion in perovskites are indicated with different symbols.

With respect to the dl nature of the capacitance observed, this would depend on the shape of the capacitance/potential curve. An example is shown in Fig. 11. There are clearly three regions. In the cathodic side, a Mott-Schottky plot is visible. In the anodic region positive to ca. 0.8V (NHE), a pseudo-capacitance region is visible and correlates with the region of measurements of O_2 evolution. The values of capacitance in the region near 0.4V and positive to it, including the characteristic hump, seem likely to represent predominantly dl capacitances. The potential range of 0.34-0.39V was used in the determination of the dl capacitance by the cyclic voltammetry technique on the substance shown ($Nd_{0.9}Sr_{0.1}CoO_3$).

Pseudo-capacitance effects which could arise from the oxidation of the B^{III} - B^{IV} certainly should not be expected in the range in which the capacities have been taken because of the evidence from the ESCA data

Fig. 11. Capacitance vs. potential plot and Mott-Schottky plot on $Nd_{0.9}Sr_{0.1}CoO_3$ in O_2 -saturated 1M NaOH at 25-100 Hz. Values are expressed in terms of geometric surface area.

that, in the case of the cobalt perovskites, the cobaltic ions remain the dominating occupiers of the surface, together with some oxygen vacancies which would increase with the value of substitution, x (25). It must be recalled that there is only a very small potential range in which the capacitance values were taken. This range was particularly chosen so that it was outside indications of pseudo capacitance or the influence of the possible space charge in the perovskite, as shown in, e.g., Fig. 11.

A rationalization of the change in properties from those characteristic of a semiconductor (see also values of carrier densities in Table I) and those of a metal can be made on the basis of the specific adsorption of OH^- ions. In Fig. 4, it is shown that at $pH \sim 12$ in the region of potential at which the measurements were made (open-circuit potential), OH^- ions are strongly adsorbed.³ It is shown elsewhere (26) that an occupancy of $\sim 10\%$ of the surface states would make changes of potential in the Helmholtz layer ~ 100 times greater than changes within the semiconductor. It is noteworthy that on $Nd_{0.9}Sr_{0.1}CoO_3$, the OH^- adsorption becomes detectable at about 0.2V (NHE), near the region at which the capacitance/potential curve changes its nature (i.e., metallization begins).

Porosity and activity on perovskites.—The large roughness factor raises the question of a model by which so much of the interior surface of these microporous electrodes could be active. One may justify the order of magnitude of the surface area by the following example. Suppose the porous electrode consists of uniform cylindrical pores of 1 μm diam; its porosity is 50%, and the depth of a pore is 0.5 mm. The real area of such a body per apparent square centimeter of surface is 1000 cm^2 . Various assumed shapes and depths of pores gave results in this order (46).

The real exchange current density (i_0) for oxygen evolution on perovskites was typically varied over the range 10^{-12} - 10^{-9} A cm^{-2} (Table I). This observation indicates that the oxygen evolution reaction is highly irreversible; therefore, the diffusion impedance becomes small in influence, and the reactivity would be expected to spread uniformly to a considerable fraction of the interior surface of the microporous electrodes (47). The highest real current density was 10^{-5} A cm^{-2} ; bubbles tended to form at about 10^{-3} A cm^{-2} . Most of the internal area is, therefore, free of bubbles.⁴

One may, therefore, regard the microporous perovskite electrodes as planar electrodes in dealing with their kinetics. This view may be supported by the following observations made on RuO_2 electrodes. In the case of Ti-supported RuO_2 electrodes, in which RuO_2 layers are highly porous with large surface area values, it has been shown that the rate of chlorine evolution was independent of both the roughness factor and the oxide loading of these anodes (48), while the oxygen evolution rates were dependent upon the true (rather than the apparent) area of these electrode surfaces (49). This observation indicates that the chlorine evolution reaction, which is highly reversible, occurs mainly at the external surface of these microporous electrodes, while a much greater degree of the electrode area is active in oxygen evolution.

Interpretation of rate correlations.—The following observations can be made based on the rate correlations given in the Results section.

³ The values of adsorption of OH^- on perovskites (e.g., on manganese) correspond to those near full coverage. But this would not be possible if there were a charge retention of unity [anion repulsion (45)]. Hence, the highly covered surfaces indicate OH^- ions, i.e., partial charge transfer and the consequent formation of quantum states in the surface associated with such bonding.

⁴ The freedom from bubbles and low diffusional impedance leaves only a potential ohmic impedance to reduce the activity of the pores. In an ideal cylindrical pore 0.05 cm deep, and with a maximum real current density of 10^{-5} A cm^{-2} , the ohmic p.d. in the pore is 10⁻⁶V.

First, anodic oxygen evolution on perovskites occurs on metallized structures. Thus, no correlation exists between reaction rates and V_{FB} . Bond, rather than band, concepts should be stressed (50).

Second, the value of the pH at which the concentration of OH^- and H^+ particles is equal (zpc) is a measure of OH^- bond strength of the surface to OH^- . It was found that a weak correlation exists between $(i)_{0.3V}$ and the pH of zero charge. Those perovskites which have a more alkaline pH of zero charge would tend to have a weaker bond strength of OH^- .

Third, ferro-antiferromagnetism in perovskites lies in the superexchange interaction between the transition metal ion and the lattice oxygen (13, 51-53). Hence, a strong interaction would be expected between the transition metal ion and the oxygenated species on the perovskites which exhibit a ferro/antiferromagnetism. This would explain the correlation in Fig. 6, in the sense that electrocatalysis of oxygen evolution decreases as the bond strength of $\text{M}^z\text{-OH}$ increases (cf. Fig. 9).⁵

Fourth, the tendency, shown in Fig. 7, to increase catalysis with decreased stability of the oxide may indicate that a high catalytic activity for oxygen evolution on perovskites is associated with ease of loss of lattice oxygens and/or ease of formation of oxygen vacancies, i.e., weaker bonding of oxygenated species to the lattice.

Fifth, the d-correlation shown in Fig. 10 suggests that the reaction site for oxygen evolution on a perovskite-type oxide is a first-row transition metal ion (B ion).

Sixth, in gas phase catalysis, a double peak pattern predicted by crystal-field effects on bond strength is observed (55, 56). The observed d-correlation in Fig. 10 does not follow a double peak pattern, indicating that the crystal-field effect upon electrocatalysis is not significant in perovskites. This observation may suggest that a rearrangement of d-electron configuration occurs at the surface of a perovskite as a result of more splittings of d-orbitals due to the unsaturated coordination (57). This new d-electron configuration could have a decisive role in electrocatalysis in terms of bond formation between an intermediate and the surface.

Seventh, it has been shown that electrocatalysis of oxygen evolution on perovskites depends primarily on the local interaction between a reaction site (transition metal B ion) and an intermediate. The observations in Fig. 8 and 9 suggest that the reaction rate of oxygen evolution on perovskites is determined by the difficulty of removal of OH intermediates, rather than adsorption of OH intermediates. Breaking of the $\text{M}^z\text{-OH}$ bond is involved in the rate-determining step.

Therefore, it seems reasonable to assume that a common rate-determining step occurs in a path of oxygen evolution reaction on a series of perovskite-type oxides. The correlation between rate at a constant potential and the calculated value of bond strength (Fig. 9) is an analog of a similar correlation observed for hydrogen evolution (3), in which rate-determining electrochemical desorption occurs on the various transition metals.

Electrocatalysis in terms of a rate-determining OH desorption mechanism.—The facts adduced above show that the likely mechanism underlying electrocatalysis of oxygen evolution on perovskites involves a rate-determining M-OH desorption (M is B ion in ABO_3). However, it has been found (58, 59) that there are a number of individual kinetic characteristics of the electrolytic oxygen-evolution reaction that demand some variation in the details of the mechanism, and an investigation (26) has shown that consistency can

be brought to these facts by the assumption that differing M-OH bond strengths among the perovskites give rise to different isotherms.

The mechanism⁶ found most consistent with the kinetics data is

Step d:

Two dimensional potential-energy diagrams, based on a Morse function approach (60, 61), for the proposed mechanism for oxygen evolution, are qualitatively shown in Fig. 12.

In Step a, the water molecule, originally adsorbed to a reaction site (M^z) can be replaced by an OH^- ion by means of proton transfers. Hence, a successful electron transfer (transmission coefficient $\kappa \sim 1$) may occur.

In Fig. 12, the dashed curve represents a situation with a lower adsorption energy for OH species as expected in nickelates, i.e., a smaller activation energy for Step b. Ferrites would be expected to have a higher adsorption energy and, hence, a larger activation energy. This view is consistent with the correlations shown in Fig. 6, 7, 8, and 9.

Electrocatalysis in terms of MO theory.—A schematic of a model for the active surface of the perovskite is shown in Fig. 13. The $\{001\}$ plane containing the transition metals is likely to be an active reaction surface. A simple model of such an oxide surface is the MO_5 (M is a transition metal ion; O is an oxygen ion) cluster; 3d (e_g, t_{2g}) levels will split further because of the lower symmetry near the surface.

According to the calculations for SrTiO_3 by Wolfram *et al.* (57, 62, 63), the e_g levels of the MO_6 cluster (bulk) split into the $d_{x^2-y^2}$ and d_{z^2} levels, with the d_{z^2} state lying below the $d_{x^2-y^2}$ state at the surface. The t_{2g} levels split into the double degenerated d_{xz} and d_{yz} states and the singlet d_{xy} state. These energy levels are schematically shown in the upper part of Fig. 14.

Assuming that these d-levels calculated for SrTiO_3 also hold for other perovskites, one may assign the d-electron configuration of the transition metal ion at

⁶ In the case of lanthanum nickelate, the participation of lattice oxygens is considered (26), which gives the reaction order with respect to OH^- as unity.

Fig. 12. Potential energy diagrams for a rate-determining OH desorption mechanism.

⁵ Well-known suggestions by Tseung (54), which relate the paramagnetism of O_2 to its positioning on the electrode surface, apply to the O_2 reduction process, but O_2 cannot be involved in the rate determining in the evolution reactions reported here.

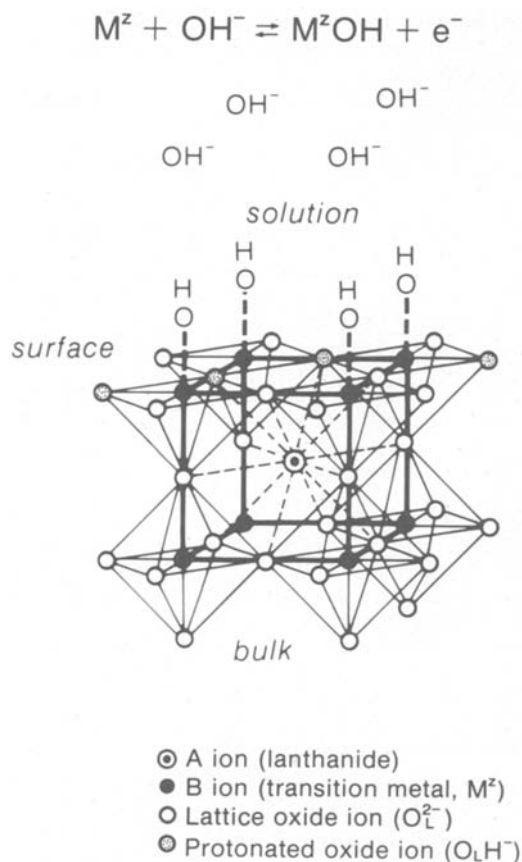

Fig. 13. Schematic model for the active surface of the perovskite, in which transition metal B ion is electrochemically active.

the surface of perovskite-type oxides, as shown in Fig. 14. The energy differences can be seen only qualitatively. In cobaltates, a high spin configuration (64) is shown. A low spin configuration is also possible. It can be seen in Fig. 14 that the d_{z^2} orbital will be occupied by an electron only in cobaltates or nickelates.

A likely electronic structure of OH is: $1s^2 2s^2 (2p_x + 1s)^2 2p_x^2 2p_y^1$ (57). The bonding state is an oxygen $2p_z$ orbital σ -bonded to a hydrogen $1s$ state. The oxygen $2p_x$ and $2p_y$ orbitals remain as nonbonding.

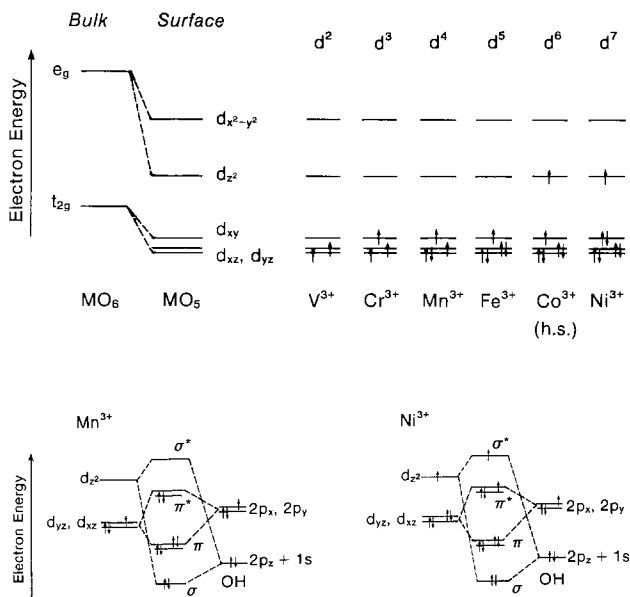

Fig. 14. d -electron configuration of transition metal ions at the surface of perovskites (above); MO diagrams for the M^z -OH bonding at the surface of perovskites; manganites and nickelates (below).

The possible orbital interactions between a transition metal ion at the surface of perovskites and an OH species are as follows. The d_{z^2} of a transition metal ion⁷ will overlap with the $2p_z + 1s$ orbital of an OH, forming σ -type orbitals, while the d_{xz} (d_{yz}) orbital will interact with the $2p_x$ ($2p_y$) of an OH, giving π -type orbitals. Neither the $d_{x^2-y^2}$ nor the d_{xy} orbital will mix with the OH orbitals, because of symmetry conservation.

Based upon the d -electron configuration and the possible orbital overlaps, MO diagrams for the M^z -OH bonding at the surface of perovskites are shown for manganites and nickelates in the lower part of Fig. 14. The following observations can be made from the qualitative MO diagrams.

First, the OH species is a saturated ligand, having almost filled p -orbitals. Therefore, the contribution of π -bondings, i.e., back bonding (65), to the M^z -OH bonding would be negligible, especially in the case of Co^{3+} or Ni^{3+} .

Second, since the bonding orbitals of M^z -OH are readily occupied by electrons from OH species, electrons from the d -orbitals of the surface transition metal in perovskites will occupy the antibonding orbitals of M^z -OH. Thus, it is expected that the bond strength of M^z -OH would decrease as the number of d -electrons increases.

Third, it has been postulated that the bond order is approximately proportional to the bond energy (66). The estimated bond orders for M^z -OH bonding at the surface of perovskites decrease in the following sequence. $V^{3+}:2.5$, $Cr^{3+}:2.5 > Mn^{3+}:2 > Fe^{3+}:1.5 > Co^{3+}:1-1.5^8 > Ni^{3+}:1$. The trend in bond order is in agreement with that bond strength determined thermodynamically (Fig. 9).

Fourth, electrons in the d_{z^2} orbital, e.g., in Ni^{3+} or high spin Co^{3+} , may play an important role in achieving high reaction rates, since these electrons tend to occupy the σ^* antibonding of M^z -OH, resulting in a weaker bond.

Fifth, the observed poor catalytic ability on vanadates and/or chromites may be interpreted by the fact that a higher oxidation state easily forms on these materials (38), forming a too stable surface complex of OH species. Thus, these perovskites cannot serve as electrocatalysts, since further reactions, which lead to the formation of oxygen, have difficulty in proceeding.

Earlier interpretations.—Matsumoto *et al.* have contributed many publications (6-11, 67) in which an interpretation of the relative reaction rates measured according to the geometric surface are given. The essence of their view concerns the overlap integrals between the sp_σ orbital of O (or O containing species) and the e_g orbital of the transition metal ion, which are seen as being related to the σ^* character of the bands in the perovskite.

According to them, the important part of the evolution of oxygen depends upon the discharge of H_2O or OH^- to adsorbed OH through the σ^* band, which is assumed to extend to the surface. The rate-determining steps assumed by Matsumoto *et al.* are based on experiments with only three transition metals, namely, Mn, Fe, and Co. These elements and their perovskites are taken, in their view, to give rise to a rate-determining step of the discharge of OH^- for the Mn containing compounds (6). For the iron and cobalt compounds, they conclude that $MOH + OH^- \rightarrow MO^- + H_2O$ is the rate-determining step (7, 8, 10).

The introduction of band theory by Matsumoto *et al.* is appreciated, although it has some counter difficulties in neglecting bond concepts which seem fruitful in catalytic discussions. The principal difficulty is the

⁷ The x -axis is taken in the direction perpendicular to the reaction surface in Fig. 13.

⁸ B.O. = 1 for low spin. B.O. = 1.5 for high spin.

lack of possibility of making plots with their work that extend over more than three materials. It is easy to change the rate-determining step and obtain agreement with Tafel slopes in ad hoc manner if there is no requirement for consistency within a group of materials. In the present work, (e.g., as shown in Fig. 10) there is a consistent correlation between the current at an overpotential of 0.3V and six different materials. It is difficult to avoid the conclusion that the rate-determining step in this group must be the same and to see this as a more likely model than that of Matsunoto *et al.* with changing rate-determining steps. A more certain judgment with respect to their work, compared with our own, must await a provision of data involving more transition metals.

Trasatti (5) [cf. Tseung and Jasem (4)] considers that a volcano relation should exist for the electrocatalysis of oxides in the sense that the rate should at first increase with the enthalpy change of the lower-to-higher oxide transition and then decrease (after the enthalpy has reached about 80 kJ mol⁻¹). Some degree of structural rationalization can be seen in the sense that adsorption of a component (e.g., OH) on the oxide concerned would be expected to parallel the heat of formation on the compound in the next valency state. Conversely, Trasatti does not relate his observations to any particular mechanism for oxygen evolution and, correspondingly, to any rate-determining step, although the direction of the dependence of the rate upon bonding considerations would vary with this.

Plotting our data as a function of the enthalpy change of the lower to the higher oxide transition (ΔH_t°) gives the correlation shown in Fig. 15, which is consistent with those made in Fig. 7, 8, and 9. There is, thus, consistency between the detailed mechanistic view suggested here and the more general indications of Trasatti (5) [cf. those of Tseung and Jasem (4)]. Thus, the parameter of ΔH_t° would be expected to be parallel to the M-OH bond strength.

Potential of comparison for electrocatalysis.—Normally, the i_0 values are used in electrocatalytic comparisons (1). However, such values may not offer useful data from the viewpoint of a comparison of rates at practical current densities. Table II shows that LaNiO₃ has an i_0 value among the lowest of the materials examined, but, as a consequence of the low Tafel slope, the value of the real current density passed at an overpotential of 0.3V is the highest observed (21).

Fig. 15. Current density (based on real surface area) for oxygen evolution on perovskites at an overpotential of 0.3V vs. enthalpy change of lower-to-higher oxide transition. The transition metal ions in perovskites are indicated with different symbols.

It is clear that the practically important region for comparison is that of the low overpotential section of the Tafel region, and here the overpotential of 0.3V has been arbitrarily chosen as the comparison potential.

However, such use of current density at a certain overpotential means that if the Tafel slopes differ, as they do here (see Table II), there will be a different electrical contribution to the rate, i.e., interpretations of electrocatalysis cannot be made on the basis of bonding considerations alone without relating the change of such contributions to other factors (e.g., radical coverage which may alter Tafel slopes and, therefore, the electrical contribution for a given overpotential). Table IV shows the contribution to the rate of the $e^{\alpha n F/RT}$ term in the Tafel equation.

Of relevance here is the plot of the overall transfer coefficient (α) as a function of the number of d-electrons in the transition metal ions of perovskites (Fig. 16). Thus, α increases smoothly with the number of electrons which occupy the d-levels. This can be seen to influence directly the strength of OH bonds to the transition metal ion, when the latter becomes weaker as the d-occupancy increases. In turn, the steady-state OH coverage affects the isotherm effective in the kinetics and changes α , i.e., changes the electrical contribution to the free energy of activation.

Therefore, the general rule found here, that increasing weakening of the M-OH bond for the group of perovskites concerned increases the rate, is unimpaired by considerations which separate chemical and electrical contributions to practical values of the catalysis. But the discussion shows that the relative rate of oxygen evolution on these catalysts is strictly dependent upon a choice of potential range. The present range considered refers to current densities of over 100 mA cm⁻² (based on geometric area) on the better catalysts.

The effect of substitution and nonstoichiometry.—In order to obtain sufficient conductivity in the perovskites (ABO₃), it is necessary to substitute some of the A ions by ions of lower valency, e.g., Sr²⁺. When a certain amount of divalent strontium substitutes for the trivalent lanthanum in a perovskite, there may be two results to compensate for the change of charge. Some of the B³⁺ ions can be changed into B⁴⁺. Alternatively, oxygen vacancies can be introduced.

We choose to accept the latter model because of the work of Nakamura *et al.* (20). These workers examined the perovskite La_{0.9}Sr_{0.1}CoO₃ in respect to the rate of oxygen desorption from the surface. They concluded that the effect of the increase of the Sr²⁺ content x is to introduce oxygen vacancies rather than Co⁴⁺ ions. Additional evidence was obtained in our own work in examining the same substance by ESCA (25). The results show that in the potential range for

oxygen evolution reaction there existed in the surface of the perovskite only Co^{III} and oxygen vacancies. On this basis it is assumed that a similar model exists for the rest of the perovskites reported on in this paper.

In Fig. 17 it is shown that some increase in the current at constant overpotential occurs with x . This is indeed consistent with our model, according to which the rate of oxygen evolution would increase with an increasing lessening of the B-OH bond strength, and also with the description of Nakamura *et al.* (20), who found that the desorption of O increases in rate as the Sr²⁺ content increases, i.e., as the number of oxygen vacancies is increased. Thus, the increase of oxygen vacancies can be seen as a decrease in the average bonding energy of O to the lattice.

A contrast in this view can be seen with that which would arise had it been assumed that the effect of increasing the substitution x upon the lattice is to cause a corresponding number of Co⁴⁺ ions to exist in the

Fig. 17. Current density (based on real surface area) for oxygen evolution on perovskites at an overpotential of 0.3V vs. degree of Sr-substitution, x .

surface. Then, as x increases, the B-OH bond strength would increase and one would expect, on the present model, for the rate to fall. The fact that Fig. 17 shows, however, an increase in the rate is consistent with the weakening of M-O bonding in the lattice, which corresponds to the introduction of oxygen vacancies.

Our view is consistent with the prediction of Trasatti (5) that an important factor in oxide electrocatalytic activity is related to the degree of nonstoichiometry. However, it correspondingly shows that this is not the main factor involved in the variation of the electrocatalytic activity, which changes over three orders of magnitude with alteration of the transition metal ion at constant stoichiometry.

A volcano relationship?—The data in the present paper suggest that rate increases as M^z-OH decreases. A rate-determining step consistent with this is (*inter alia*)

The analogy which this step forms to that in hydrogen evolution on transition metals (1, 3)

suggests that, as the bonding to the oxide surface further weakens, the rate of Eq. [4] increases sufficiently so that another reaction in the same kinetic sequence becomes rate determining. By analogy with the situation in hydrogen evolution, this would be

An elementary consideration of potential energy surfaces shows that the dependence of rate upon M^z-OH would reverse in trend; the rate would decrease with increasing occupancy of the antibonding orbital of M^z-OH. Thus, a plot of rate at a given overpotential against some measure of M^z-OH strength would pass through a maximum. Such a plot is shown in Fig. 18. A similar suggestion, without mechanistic commitment, has been made by Trasatti for oxide catalysts (5).

A low value of ΔH_f^o of Rh₂O₃, -68.3 kcal mol⁻¹ (37) (cf. Table III), suggests that the perovskites with a second-row transition metal ion, e.g., La_{1-x}Sr_xBO₃ (B = Mo, Ru, Rh) (68, 69), may exhibit a very weak bonding of M^z-OH, and, hence, could be members of the left-hand branch of a volcano plot. The molybdenum containing compound may show a faster rate than the other compounds mentioned because of the relatively high ΔH_f^o of MoO₂ [-130 kcal mol⁻¹ (37)].

Fig. 18. Hypothetical volcano plot for oxygen evolution on perovskites. Transition metal B ions in perovskites are indicated with different symbols.

It must be stressed that the points shown in Fig. 18 refer to speculative predictions of oxygen evolution on perovskites containing the metals indicated. They have, for example, nothing to do with expectations of the relative oxygen-evolution rate on, e.g., RuO_2 (or NiO) where there is evidence that the rate predicted here for perovskites would be reversed for oxides (59).

Prediction of electrocatalysis.—Figure 19 gives the plots of Tafel line intercepts (Tafel parameter a)⁹ of oxygen evolution vs. the number of d-electrons of transition ions in the various perovskite-type oxides. This correlation in terms of number of d-electrons can be further rationalized by plotting Tafel line intercepts against the number of electrons occupying the antibonding orbitals of $\text{M}^z\text{-OH}$ (cf. Fig. 14), as shown in Fig. 20. In Fig. 20, the electrocatalytic activity based on Tafel line intercepts increases as the number of electrons occupying the antibonding orbitals increases.

Thus, lanthanum nickelate (LaNiO_3) gives the highest electrocatalytic activity among the perovskites studied (21). The high catalytic activity observed on the NiCo_2O_4 spinel (4) is in agreement with this prediction, since it contains catalytically active species, Ni^{II} and Co^{III} .

On the basis of Fig. 20, one might predict that LaCuO_3 (71) would be a better catalyst than LaNiO_3 , since its d^8 electrons would contain a greater number of antibonding positions. However, instability of the Cu^{III} compounds would be expected in aqueous solution (72); it is possible that stabilization could be achieved by replacing some Cu^{3+} by Cu^{2+} in a compound such as $\text{La}_{1-x}\text{Ce}_x\text{CuO}_3$.

Stability of electrocatalysts.—Some of the catalysts examined were polarized for times up to 40h. A typical example obtained on $\text{La}_{0.9}\text{Sr}_{0.1}\text{CoO}_3$ is shown in Fig. 21. Under the anodic polarization at 25 mA cm^{-2} , the electrode potential rose gradually during the first 26h. It became constant after 20h. XPS study showed that the cobalt species present was only Co^{III} at the surface after this anodic polarization (25).

⁹This method of comparing electrocatalysis has been used particularly by Srinivasan *et al.* (70).

Fig. 19. Tafel line intercept (Tafel parameter a , based on real surface area) of oxygen evolution on perovskites vs. number of d-electrons of transition metal ions in perovskites. The transition metal ions in perovskites are indicated with different symbols.

Fig. 20. Tafel line intercept (Tafel parameter a , based on real surface area) of oxygen evolution on perovskites vs. number of electrons occupying the antibonding orbitals of $\text{M}^z\text{-OH}$. The averaged values for high spin and low spin cases were used for cobaltates. The transition metal ions in perovskites are indicated with different symbols.

Fig. 21. Time variation of potential on $\text{La}_{0.9}\text{Sr}_{0.1}\text{CoO}_3$ electrodes in O_2 -saturated 1M NaOH at 25°C under a galvanostatic condition.

Also, LaNiO_3 exhibited a stable performance for over 70h at 100 mA cm^{-2} , which corresponds to an overpotential of 300 mV.

Summary

An increase in the catalytic activity for electrolytic evolution of oxygen on perovskites occurs in parallel with a high occupancy of antibonding orbitals of $\text{M}^z\text{-OH}$.

Acknowledgments

The authors are grateful to Professor S. Trasatti, Dr. A. Damjanovic, Dr. A. J. Appleby, and Dr. O. J. Murphy for helpful critical discussion of this work. The support of this work by the Robert A. Welch Foundation (Grant no. A-740) is gratefully acknowledged.

The authors are also grateful to Dr. M. B. Hall for a helpful discussion on MO theory and to Mrs. Lynn McCartney-Murphy for her editing and typing of this manuscript.

Manuscript submitted Dec. 20, 1982; revised manuscript received July 12, 1983.

Texas A&M University assisted in meeting the publication costs of this article.

Adsorption of 3-phenyl-1-propanol on Gold Electrode from Perchloric Acid Solutions

K. Katoh and M. Koseki

Department of Applied Chemistry, Faculty of Engineering, Niigata University, 2-8050, Ikarashi, Niigata, 950-21, Japan

ABSTRACT

Adsorption parameters of 3-phenyl-1-propanol and some other ω -phenyl alkanols were calculated after the isotherm of $\theta/(1-\theta)^n = K_{\text{ads}} \cdot X_{\text{org}}$. The adsorption peaks appeared at 0.70 and 0.35V (*vs.* SCE) for the adsorbate. The peak near 0.70V seems to be due to π -electron interaction of the benzene ring and another peak at 0.35V to the alcohol group as side chain. The peak height of coverage-potential curve at 0.35V became larger depending upon the number of carbon atoms in the aliphatic alcohol group on the benzene ring. The differential capacity was measured by a rapid rectangular single-pulse technique, and the voltage-time curve was memorized electrically set by a "Wave Memory." Then, the reproducibility of the capacity measurement became approximately within $\pm 6\%$. The values of n and the standard free energy of adsorption (ΔG°) of the adsorbate at 0.70V were calculated as 2.8 and -7.4 kcal/mol, respectively.

In the adsorption of benzene compounds on electrode surface, the π -electron interaction between the adsorbed molecule and the electrode surface plays a dominant role (1). As reported in a previous paper (2), the adsorption peak of benzoic acid appears at 0.60V (*vs.* SCE), and the peak seems to be due to adsorption of benzene ring by its π -electron interaction on the gold electrode. In this report, adsorption of 3-phenyl-1-propanol (PPA) on gold electrode was studied. The adsorption peak was found at 0.70V. However, we found out that the new peak appeared at 0.35V. Peak height of the coverage-potential curve became larger depending upon the number of carbon atoms in the aliphatic alcohol group on the benzene ring from the coverage data of benzyl alcohol, 2-phenyl ethanol, and 3-phenyl-1-propanol. Kinetic parameters were calculated after the concept of competitive adsorption by Bockris and Swinkels (3, 4), Dahms and Green (5), and Conway and Dhar (6). They assumed that one molecule of an organic substance took the place of n molecules of water on the electrode surface. Lawrence and Parsons (7) calculated the n value from the geometrical ratio of the area occupied by the organic molecule to the one by water molecule. Dahms and Green (5) calculated the value for adsorption of aromatic hydrocarbons on gold electrode with radiotracer technique.

Experimental

Gold electrode.—The gold electrode which was used as the working electrode which was made from polycrystalline pure gold (99.99%, Tokuriki Manufacturing Company Limited) and was sheathed in a Teflon rod (2). The electrode surface was polished before each series of electrochemical works with very fine emery papers and then polished with dilute suspension of 600 mesh dichromium trioxide polishing powder. The electrode surface was reduced by setting the potential near -0.20 V for 20 min or more. The surface condition of the reducing process was observed by drawing a cyclic voltammetric curve of the gold electrode. The apparent surface area of the electrode was 0.049 cm², and the roughness factor as calculated with the method of Brummer and Makrides (8) was 1.4.

Counter and polarizing electrodes.—A gold cylindrical mesh and plate were used as counter and polarizing electrodes, respectively. All potentials were measured against SCE. The electrochemical cell contained main and standard cell units of SCE with a Haber-Luggin capillary. The standard cell was separated from the main cell by a glass frit and a closed stopcock.

Key words: adsorption, gold electrode, 3-phenyl-1-propanol, differential capacity.

Measurements.—Perchloric acid solution (0.1M) was prepared as the supporting electrolyte. PPA as the adsorbate was dissolved in the solution. All the experiments were carried out at 30°C in thermostated solutions which were deoxygenated with pure nitrogen gas bubbling. The working gold electrode was polarized by a potentiostat (HA 101, Hokuto Denko Company Limited). The potentials and currents were checked by a digital multimeter (DMM-126A, TOA Electronics, Limited) during the run.

Differential capacity measurement was performed with rapid rectangular single pulse techniques (9). This method consists of measuring the slope of a voltage-time curve of the working electrode at the onset, or at a time close to it, of a rectangular current pulse. The voltage-time curves were memorized by a set of "Wave Memory" (E-5001, NF Circuit Design Block Company, Limited) with 2 ms/word input and displayed them on a X-Y recorder (at 10 ms/word) output or on an oscilloscope. The differential capacities were computed from the curves by our original computer program. This was based on Barradas and Valeriotte's (10). The reproducibility of the capacity data became less than 6% in the range of 0.0-0.9V.

Results and Discussion

Coverage-potential curves.—Differential capacities were measured in the range -0.2 - 0.9 V with 0.05 V step for 1.0×10^{-2} to 1.0×10^{-4} M of PPA aqueous solutions. The capacity-potential curves in 0.1M perchloric acid with different additions of PPA are shown in Fig. 1. Schmid and Hackerman (11) described the magnitude of the capacities. The shapes of the capacity-potential curves were dependent on the exposed face of gold electrode and the concentration of perchloric acid as the supporting electrolyte. In the capacity-potential curve of 0.1M perchloric acid in Fig. 1, the magnitude of the capacities was a little lower than the data of Schmid and Hackerman, and the shape was close to the results of a (110) face single-crystal gold electrode for 0.1M of the acid (11). The differential capacity data of the saturated PPA solution (0.04M) were calculated by the straight line relationship between logarithmic concentration of an adsorbed substance and its capacity (12). The calculated differential capacities were used as the ones of full coverage.

Coverages were calculated with the simplified form (14) from Frumkin's model (13)

$$C = C_0(1 - \theta) + C_1 \cdot \theta \quad [1]$$

where C_0 is the capacity of the supporting electrolyte, C_1 the one of full coverage, and C the capacity for coverage θ .

Coverage-potential curves are shown in Fig. 2 from 1.0×10^{-4} to 0.01M of PPA; the curve of 2-phenyl

ethanol (EPA) of 5.0×10^{-4} M (dotted line) is presented for comparison. The adsorption maximum of their solutions of PPA showed at 0.35 and 0.70V. In the case of EPA solutions, the peak heights at 0.35V were relatively smaller than the ones at 0.70V. In

PPA solutions, the heights at 0.35V became larger than the ones at 0.70V in any concentration.

Calculations of adsorption parameters.—For selection of adsorption isotherm, an excellent review was presented by Conway *et al.* (15). The problems of molecular size factor and evaluation of interaction terms in adsorption isotherms were reported by Conway and Dhar (16). Adsorption of a solute from a solution must be a competitive process between the adsorbate molecule and the solvent one. The competitive adsorption of two species from a liquid phase has been treated by numerous authors by means of Langmuir isotherm (17-19). Temkin's isotherm was applied to the adsorption of neutral molecules by Delahay and Mohilner (20). The competitive adsorption of species with different sizes was discussed by Dahms and Green (5), Bockris and Swinkels (3, 4), and Conway and Dhar (6).

After Dahms and Green (5), an equilibrium is assumed to be established between solvent, adsorbed solvent, organic species in aqueous solution, and adsorbed organic species

where n is the number of adsorbed water molecules which occupy the same surface area as one molecule of the adsorbate.

Under ideal conditions, the electrochemical potential of the adsorbed organic entity in Eq. [2] may be written

$$\bar{\mu}_{\text{org, ads}} = \bar{\mu}_{\text{org, ads}}^{\circ} + RT \ln \theta \quad [3]$$

and the electrochemical potential of the adsorbed water is given by

$$\bar{\mu}_{\text{w, ads}} = \bar{\mu}_{\text{w, ads}}^{\circ} + RT \ln (1 - \theta) \quad [4]$$

The electrochemical potentials of the adsorbate in aqueous solution are written by

$$\bar{\mu}_{\text{org, sol}} = \bar{\mu}_{\text{org, sol}}^{\circ} + RT \ln X_{\text{org, sol}} \quad [5]$$

$$\bar{\mu}_{\text{w, sol}} = \bar{\mu}_{\text{w, sol}}^{\circ} + RT \ln X_{\text{w, sol}} \quad [6]$$

where $X_{\text{org, sol}}$ and $X_{\text{w, sol}}$ are the mol fractions of organic and water, respectively.

The difference in standard free energy is expressed by using the electrochemical potentials

$$\Delta \bar{G}^{\circ} = \bar{\mu}_{\text{org, ads}}^{\circ} - \bar{\mu}_{\text{org, sol}}^{\circ} - n(\bar{\mu}_{\text{w, ads}}^{\circ} - \bar{\mu}_{\text{w, sol}}^{\circ}) \quad [7]$$

Dahms and Green obtained finally the following isotherm from dilute aqueous solutions of the organic adsorbate

$$\frac{\theta}{(1 - \theta)^n} = X_{\text{org, sol}} \cdot \exp\left(-\frac{\Delta \bar{G}^{\circ}}{RT}\right) = K_{\text{ads}} \cdot X_{\text{org, sol}} \quad [8]$$

where $X_{\text{org, sol}}$ represents the mol fraction of the organic species in the solution, and K_{ads} is the adsorption equilibrium constant expressed with mol fraction.

Equation [8] can be expressed by using mol concentration (c)

$$\frac{\theta}{(1 - \theta)^n} = B \cdot c \quad [9]$$

where B is the adsorption equilibrium constant expressed with mol concentration. B is related to K_{ads} as $K_{\text{ads}} = 55.5 \times B$ (6). The relationship between coverage and $\log c$ for PPA is shown in Fig. 3. The observed values (plots) agreed with the solid line which was calculated from Eq. [9] as $n = 2.8$, except at higher coverages. In the case of higher coverages, the interaction parameter (a) should be considered. Various isotherms with the parameter a were proposed by Frumkin (17), Hill (21), and others.

Fig. 3. Coverage-log c curve of 3-phenyl-1-propanol. Open circle: experimental values. Solid line: calculated line with Eq. [9] as $n = 2.8$.

The Eq. [9] can be modified by introducing the a as follows

$$B \cdot c = \frac{\theta}{(1 - \theta)^n} \exp(-2a\theta) \quad [10]$$

This equation was proposed by Parsons (22). From Eq. [10], values of a were calculated as 0.13 and 0.37 for 0.01 and 0.005M of PPA, respectively. The positive value of a means an attractive interaction between the adsorbed molecules. The other parameters are shown in Table I for benzyl alcohol (BZA), EPA, and PPA.

The values of $\Delta\bar{G}^\circ$ (at 30°C) at 0.70V for benzene (23), BZA, and PPA were -4.9 , -7.5 , and -7.4 kcal/mol, respectively. Thus, the two ω -phenyl alcohols seem to adsorb strongly and benzene weakly among these compounds on a gold electrode.

According to the experimental results, the adsorption peaks appeared at 0.65, 0.70, and 0.70V for BZA, EPA, and PPA, respectively. These peaks seem to be due to the interaction between π -electrons of the benzene rings and the electrode surface. A peak at 0.35V seems to be due to the alcoholic groups as side chains. This conclusion was supported by the evidence that the n -propyl alcohol was adsorbed on a gold electrode at 0.35V. Thus, PPA showed a two-position adsorption at 0.35 and 0.70V on a gold electrode. Taking into account the geometric ratios of the ω -phenyl alkanols to water molecules, the values of n in Table I are reasonable.

Conclusion

In the differential capacity measurements by a rapid rectangular single pulse technique, the "Wave

* The data were obtained with Pt (counter, polarizing) and Au (working) electrodes.

Memory" was successfully employed for the voltage-time curve measurements. The calculation process of the capacities became easier and faster then, and the reproducibility of the capacity data was less than 6%.

3-phenyl-1-propanol showed a two-position adsorption at 0.35 and 0.70V vs. SCE on a gold electrode. The adsorption peak at 0.70V seems to arise from the interaction between the π -electron of the benzene ring and the electrode surface. Another peak at 0.35V seems to be due to an adsorption of alcoholic group on the benzene ring.

The peak heights of coverage-potential curves at 0.35V increased with the number of carbon atoms in the alcoholic groups.

The values of n at 0.70V for benzyl alcohol, 2-phenyl ethanol, and 3-phenyl-1-propanol were 3.7, 2.9, and 2.8, respectively. These values were reasonable, taking into account the geometric ratios of the ω -phenyl alkanols to water molecules.

The standard free energy of adsorption $\Delta\bar{G}^\circ$ for benzyl alcohol and 3-phenyl-1-propanol at 0.70V were -7.5 and -7.4 kcal/mol, respectively.

Adatom Coverage Dependences and Specificity Effects on the Rate of Formic Acid Electro-oxidation at Polycrystalline Platinum

Mani Shabrang,* Haruo Mizota, and Stanley Bruckenstein*

Department of Chemistry, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

The catalysis and inhibition of formic acid electro-oxidation that may accompany metal-submonolayer formation on polycrystalline platinum was studied quantitatively using the rotating ring-disk electrode (RRDE) technique. Under controlled flux conditions one can attain limiting current behavior for the oxidation of formic acid and thereby determine the upper limit for the optimum adatom coverage for lead and bismuth. These values are found to be 30-35% of the real area of the platinum electrode. The electro-oxidation experiments in this paper are correlated with the literature dealing with polycrystalline and single-crystal studies of hydrogen adsorption and formic acid oxidation at platinum to explain differences of the behavior of various underpotential deposited (UPD) species. The poisoning of the electro-oxidation process of formic acid requires the presence of adsorbed hydrogen or unhindered access to the first adsorbed intermediate COOH that is produced. During the initial stages of UPD, submonolayers of silver or copper do not deposit significantly on Pt(100), the plane that is responsible for most of the electro-oxidation of formic acid. Therefore, UPD silver or copper cannot inhibit poisoning of the formic acid oxidation process by decreasing hydrogen adsorption, or restricting access to COOH via a third body mechanism. Bismuth, lead, and other UPD species with radii larger than platinum do deposit significantly on Pt(100) at low UPD coverages, and can therefore slow the poisoning of the formic acid process on this plane.

Research on the oxidation of formic acid on noble metals and its electrocatalysis has been going on for more than a century (1-3). Interest in this process has gained considerable momentum in the past two decades due to the process's significance in the fuel cell technology and because of the simplicity of the formic acid molecule provides a model for the electro-oxidation of other organic fuels. A formic acid oxidation mechanism that describes the principal experimental results involves, as the initial stage, an oxidative electroadsorption step (4, 5) resulting in the weakly adsorbed carboxyl adradial, COOH, and H⁺. The carboxyl adradial is bonded to one electrode site and may then either be electro-oxidized directly to CO₂ and H⁺ or react with other adsorbed species on the platinum surface and transform into organic poisons. These poisons inhibit further oxidation of formic acid by blocking those reaction sites required in the initial stage of the oxidation. The similarity between adsorption products produced from formic acid and methanol oxidation under potentiodynamic (4) and potentiostatic (6, 7) control, and that the initial interaction of CH₃OH with an activated electrode results in the loss of the three hydrogens on the carbon atom (8), led Capon and Parsons to deduce that the chemical composition of the major poisoning species in formic acid oxidation is COH, which is strongly adsorbed at three adjacent electrode sites. A minor poisoning species, with the structure C(OH)₂ occupying two adjacent sites, has also been suggested as being involved in the inhibition process (4). A detailed review of the work in acidic media prior to 1973 (9) and the interpretation of the cyclic voltammograms on noble metals (10) are available.

Significant catalysis of the oxidation of formic acid is caused by the presence of submonolayer amounts of some foreign metal atoms, *e.g.*, Hg (11), Tl, Cd, Bi, and Pb (12). These submonolayers form by the underpotential deposition (UPD) on platinum and other noble metals. Also, other strongly adsorbed species, such as SH⁻, CH₃CN, etc., catalyze the electro-oxidation of formic acid (11). UPD of Cu and Ag on platinum inhibit this reaction (12). Two theories are currently used to explain the catalytic effect of UPD monolayers: (i) UPD prevents hydrogen adsorption on platinum and thereby interferes with COH formation (12, 13); and (ii) the UPD species functions as a so-called

"third body" which diminishes the probability of an encounter between two adsorbed species that results in the formation of poisons (11, 14). A similar process is believed to decrease the hydrogen evolution rate along with UPD of copper (15). The poisoning of the hydrogen evolution process by species such as R-CN, S, and SH⁻ is also explained through this effect. Thus, the word "catalysis" is used in the context of formic acid electro-oxidation in the sense of preventing a decrease in the initially rapid rate, rather than increasing the initial rate at an activated electrode.

In this work, the rotating ring-disk electrode (RRDE) technique was applied to study the effect of varying UPD submonolayer coverages of lead and bismuth on the catalysis of formic acid electro-oxidation at platinum electrodes in acidic media. Concentrations of formic acid in the range of 10⁻⁶ to 10⁻²M were used. Under these conditions, mass-transfer limited currents could be achieved that not only allowed the study of the catalytic effects in a simple manner, but also made possible the control of the rate of electrode poisoning during the establishment of the UPD adatom equilibrium-coverage isotherm. The electrocatalysis by UPD lead and bismuth and the inhibition effects of UPD copper and silver are explained in terms of platinum site preference on Pt(100) and Pt(111) of the UPD species and the formic acid oxidation reactions.

Experimental

Chemicals and equipment.—Solutions were prepared with water purified in a Milli-Q™ Reagent-Grade Water System (Millipore Corporation, Bedford, Massachusetts). Reagent grade chemicals were used in the preparation of the supporting electrolyte and stock solutions. Concentrations reported for formic acid assumed 90% purity of the reagent-grade formic acid. Nitrogen was used to remove oxygen from the solutions.

Experiments were performed at 25° ± 0.5°C. Electrode potentials were measured using a saturated calomel electrode (SCE).

All electrode potentials reported in the text are given *vs.* SCE. Note that the term "underpotential" is used in the text, and that it differs from the term "potential." The "underpotential" is the quantity most closely related to the equilibrium isotherm for the adatom being studied. For example, it is advantageous to describe processes involving the UPD of lead in terms of its underpotential, where the "underpotential" is the difference between the potential applied to the

* Electrochemical Society Active Member.

Key words: surface coverage, formic acid oxidation, electrocatalysis, underpotential deposition, platinum active sites, third body effect.

disk electrode and the potential of a bulk lead electrode in that particular solution.

Unless otherwise stated 0.12M HClO₄ solution was used as the supporting electrolyte.

The two platinum-ring, platinum-disk electrodes used in the experiments were constructed in this laboratory. Their dimensions were: (i) disk radius of 0.38 cm; ring-inner radius of 0.40 cm; and ring-outer radius of 0.49 cm. (ii) disk radius of 0.38 cm; ring-inner radius of 0.40 cm; and ring-outer radius of 0.52 cm. Teflon was used as the insulating material. The ring-disk electrode parameters N (16) and $\beta^{2/3}$ (17) were $N = 0.38$ and $\beta^{2/3} = 1.08$ for the first electrode, and $N = 0.42$ and $\beta^{2/3} = 1.4$ for the second electrode. These electrodes were polished before each experiment to a final mirror finish using 0.05 μ β -alumina on Buehler microcloth (Buehler Limited, Evanston, Illinois). The counterelectrode was a platinum wire. The electrode rotator was manufactured by Pine Instruments Company (Grove City, Pennsylvania).

The design of the four-electrode potentiostat has been described elsewhere (18). An Eclipse S/200 mini-computer (Data General Corporation, Southboro, Massachusetts) was the basis of a digital data-acquisition system developed in this laboratory (19, 20). All experimental sequences were computer controlled and the data were stored on magnetic-disk cartridges.

Preparation of lead-ring, platinum-disk electrode.—Hydrogen evolution on platinum strongly interferes with lead deposition from Pb²⁺ solutions in acidic media ($E^\circ = -367$ mV) and a meaningful convective-diffusion controlled current for the reaction $\text{Pb}^{2+} + 2e \rightarrow \text{Pb}$ at the ring electrode cannot be attained under these conditions. A simple pretreatment of the ring electrode (19), which forms a few monolayers of the UPD metal, does not yield reproducible ring responses for collection and shielding experiments. Hence, prior to each UPD experiment between 50 and 100 monolayers of lead were deposited on the ring electrode from a 0.015M Pb(II)/1M NaClO₄ solution (slightly acidified to pH = 5 by HClO₄) at -0.55 V (very low current density) while the disk electrode was potentiostated at $+0.5$ V. The ring currents for the reduction of Pb²⁺ that were then observed in dilute solutions of Pb²⁺ (10^{-6} – 10^{-4} M) were stable to within 5%, provided the ring electrode had been potentiostated at negative potentials (< -0.55 V). Thick lead deposits were avoided in order to minimize variations in the collection efficiency.

The ring pretreatment for the bismuth UPD studies followed the procedure of Reidhammer *et al.* (19).

Calculation of lead and bismuth coverage.—The surface coverage of adatom (θ) is defined in terms of the number of platinum surface sites occupied by the adatom. The number of occupied platinum surface sites is calculated from the charge required to form one monolayer of adsorbed hydrogen, as determined in the manner described below, minus the charge required to oxidize adsorbed hydrogen from an electrode on which adatoms have adsorbed. The determination of the bismuth adatom surface coverage was based on the procedure described by Cadle and Bruckenstein (25), who in turn used the approach originally suggested by Bowles (26). The charge required to form one monolayer of bismuth atoms from Bi³⁺ is, on this basis, 460 $\mu\text{C cm}^{-2}$ for an electrode with a roughness factor of 1.43 (25). For lead (atomic radius = 1.75Å), a close packed layer was assumed. This corresponds to a value of 260 $\mu\text{C cm}^{-2}$ for the charge required to form a monolayer from Pb²⁺ (27, 28). All coverages reported have been corrected for the surface roughness of the platinum disk electrode.

Determination of platinum-disk area by hydrogen adsorption charge measurement.—The surface roughness of the platinum-disk electrode was determined according to the modified procedure suggested by

Biegler *et al.* (21) and adopted by Capon and Parsons (4); the charge in the area bounded by the horizontal portion of the current-potential (i - E) curve after oxide reduction, and the potential at the current minimum just before the rising portion of the hydrogen evolution curve corresponded to a fractional hydrogen coverage of 0.77. In 0.12M HClO₄, the potential range for current integration is between $+0.16$ and -0.23 V. This procedure has also been verified using independent ring-disk electrode techniques (22).

First, the electrode was potential cycled between oxygen and hydrogen evolution for a few minutes in the supporting electrolyte (at 0.2 V s⁻¹) and reproducible i - E curves were obtained. Next, the disk was potentiostated at 0.0V for 15s and then at 1.2V for 60s. The potential of a stationary disk was then scanned cathodically at several scan rates. The charge required for hydrogen adsorption was measured and averaged and the surface roughness calculated using the generally accepted value of 210 $\mu\text{C cm}^{-2}$ for the monolayer charge density of adsorbed hydrogen (23). The precision and reproducibility of this method is the same as other recently proposed methods for platinum surface area measurement that are also based on hydrogen-adsorption charge (24). The platinum electrode surface roughness typically ranged from 1.8 to 2.6.

Determination of the Nernst potential for Pb²⁺ solutions in 0.12M HClO₄.—The equilibrium (Nernst) potential (E_N) was determined by measuring the open-circuit potential of the lead-ring electrode of the RRDE at a rotation speed of 2500 rpm before and after each experiment. The experiments, repeated daily, yielded a value of -0.492 ± 0.003 V for 10^{-4} M Pb solution.

The open-circuit potential of the lead-ring electrode in the pretreatment solutions was -0.418 ± 0.002 V. The Nernst potentials for bismuth were measured according to Ref. (19) and (25).

Disk potential programming for the determination of UPD coverage of lead and bismuth.—The disk-program sequence for lead coverage determination is shown schematically in Fig. 1. The purpose of the steps are as follows: (A) Removes any lead and oxidizable impurities from the electrodes. (B) Reduces the platinum oxide formed in step A. Electrode rotation is stopped during this step in order to minimize mass transfer of Pb²⁺ to the disk. (C) Removes unwanted UPD lead formed during step B by an anodic pulse of short duration. (D) Deposits UPD lead at the disk potential of interest and sets the desired rotation speed simultaneously. (E) Strips lead by potential-scanning in a positive direction (linear scan rate = 200 mV s⁻¹).

The ring-shielding response during step D and the ring-collection response during step E were recorded and processed to determine UPD coverages.

The ring- and disk-potential sequences used by Reidhammer *et al.* (19) were followed (with addition of step C above) for the determination of underpotential bismuth coverage.

Results and Discussion

Irreversible deposition of bismuth on platinum.—Irreversible deposition of UPD bismuth on platinum has already been demonstrated by the RRDE technique (25). During the stripping of UPD bismuth only 90% leaves the platinum surface and the remaining 10% is irreversibly adsorbed. This 10% must be taken into account when calculating the UPD bismuth coverage, for once Bi³⁺ has been introduced into the solution, the platinum surface will never be entirely free of bismuth after the first UPD deposit forms. Only mechanical polishing can remove this irreversibly adsorbed bismuth.

In the case of lead, however, no measurable irreversible UPD occurs on platinum. No significant differences were detected (between 0.0 and 1.2V among the disk current-disk potential (i_D - E_D) curves obtained by

Fig. 1. Potential program sequence for UPD lead on a bare platinum electrode. Details and significance for each step is given in the text.

repetitive scanning (from -0.5 to $1.2V$) a freshly made and polished platinum electrode in $0.12M$ $HClO_4$, and the same thoroughly rinsed electrode that was subjected to any one of the following treatments in which the electrode was: (i) subjected to 30 min of continuous deposition and stripping of lead monolayers, (ii) exposed for 12h to $0.1M$ lead nitrate solution, or (iii) tested for irreversible deposition on an oxidized electrode (25).

After a bulk lead deposit is stripped off the platinum-ringing electrode, it must be potential-cycled a few minutes in $HClO_4$ solution before it recovers the original platinum i - E characteristics in the oxide-formation region.

Behavior of lead in the UPD region.—The difference between the work functions of lead and platinum is about 1.4 eV. This produces a UPD region for lead of $\sim 0.6V$ that begins, in a $10^{-5}M$ solution of Pb^{2+} , just negative of platinum oxide formation and extends well into the hydrogen evolution region. The UPD behavior of lead at platinum in acidic solutions can only be studied practically in the region positive of the hydrogen evolution. This UPD region coincides with the formic acid oxidation region.

A typical platinum disk (i_D - E_D) curve (29), along with the corresponding lead-ring current, disk potential (i_R - E_D) curve at a ring potential of $E_R = -0.6V$ is shown in Fig. 2. Shielding of the ring begins at a disk potential of $+0.05V$.

Unlike the UPD behavior of lead at gold (30), where more than one UPD current peak is observed (31), the ring-collection current accompanied the electro-oxidation (stripping) of the UPD lead from the platinum-disk surface shows only one prominent peak. Hydrogen evolution obscures the stripping process of bulk lead in acidic ($pH < 4$) solutions. The unshielded lead-ring electrode current is slightly higher than the lead convective-diffusion current for a $10^{-5}M$ Pb solution ($11.5 \mu A$) probably because hydrogen evolution occurs at the ring electrode edges, or on bare Pt sites.

An example of the effect of the plating time on disk-stripping and ring-collection currents is shown in Fig.

Fig. 2. Disk current-disk potential curve and corresponding ring current-disk potential curve for the second electrode in $1 \times 10^{-5}M$ Pb^{2+} - $0.12M$ $HClO_4$ solution $E_R = -0.6V$ (vs. SCE), $\omega = 2500$ rpm, and scan rate = 50 mV s^{-1} .

3 for $10^{-5}M$ Pb^{2+} in $0.12M$ $HClO_4$ at an underpotential, $E_{UPD} = +0.5V$ (step D in Fig. 1). E_{UPD} is the difference between the potential applied to the disk electrode and the potential of a bulk lead electrode in the solution being studied. The growth of the lead UPD deposit is virtually complete after 20, 45, and 200s in 10^{-4} , 10^{-5} , and $10^{-6}M$ solutions of Pb^{2+} , respectively. The effect of disk plating potential on disk-stripping and ring-collection currents (step E in Fig. 1) is shown in Fig. 4 for $E_{UPD} > +0.5V$. The time response of the disk electrode current and the ring electrode shielding current during the adsorption of lead on the platinum disk are shown in Fig. 5 for different values of E_{UPD} . The ring current becomes unshielded as the disk current drops to zero. The interpretation of the transient behavior for the ideal system of silver UPD on gold was taken from Swathirajan and Bruckenstein (32).

The procedures for the determination of coverage by using the underpotential ring-collection (Fig. 4) and ring-shielding (Fig. 5) responses are described in detail elsewhere (19, 33, 34). The lead UPD coverage values obtained by these two independent methods agree within 5%, while individual experiments are reproducible within 2% from day to day. The total lead coverage as a function of the E_{UPD} is shown in Fig. 6. This isotherm agrees with the isotherm reported by Schmidt and Wuthrich (35), who employed the thin layer-twin electrode technique.

Limiting currents for the formic acid oxidation at an RDE.—According to Capon and Parsons (4), in the region where H_{ad} is thermodynamically unstable, the disproportionation reaction [2], which involves the formic acid molecule ($pK_{diss} = 3.75$), occurs parallel to the main oxidation pathway, reaction [1]

Fig. 3. Effect of plating time on disk-stripping and ring-collection currents for $E_{UPD} = +0.5V$ in $10^{-5}M Pb^{2+}$ - $0.12M HClO_4$ solution. Deposition times are: 5s (A), 7s (B), 10s (C), 15s (D), 30s (E), and 45s (F) $E_R = -0.6V$ (vs. SCE), $\omega = 2500$ rpm, and scan rate = 200 $mV s^{-1}$.

Fig. 4. Effect of plating potential on disk-stripping and ring-collection currents in $10^{-5}M Pb^{2+}$ - $0.12M HClO_4$ solution. E_{UPD} values are $+1.0V$ (A), $+0.95V$ (B), $+0.9V$ (C), $+0.8V$ (D), $+0.7V$ (E), $+0.6V$ (F), and $+0.5V$ (G). $E_R = -0.6V$ (vs. SCE), $\omega = 2500$ rpm, and scan rate = 200 $mV s^{-1}$.

Reaction [2] is the principal poisoning reaction.

Decreasing the supply of dissolved $HCOOH$ should preferentially reduce the rate of poison formation. The latter rate is slow (4) as compared to the rate of the main current producing reaction sequence, Reaction [1], which becomes mass-transport limited. However, in the hydrogen adsorption region, the main poisoning reaction

is very fast (4), and the surface becomes inactivated before mass transport of formic acid becomes rate determining.

As expected, outside the H_{ad} region formic acid oxidation indeed exhibits limiting current behavior at low concentrations (10^{-5} - $10^{-2}M$) in the presence of lead or bismuth at platinum RDE. Figures 7 and 8 show typical i - E curves for the first disk electrode in $2 \times 10^{-3}M$ formic acid solutions. At low rotation speeds a wider limiting current potential range can be achieved under potentiodynamic conditions before the surface is deactivated by the poisoning species or the surface oxides.

The plot of the limiting current (obtained during the positive going potential scan) vs. $\omega^{1/2}$ is linear between 400-3600 rpm for 10^{-3} to 5×10^{-3} concentrations of $HCOOH$ in the presence of $10^{-4}M$ bismuth or lead. The diffusion coefficient for formic acid, calculated from the improved form of the Levich equation, assuming a two-electron overall reaction, is $0.97 \times 10^{-5} cm^2 s^{-1}$ in the presence of lead and $0.98 \times 10^{-5} cm^2 s^{-1}$ in the presence of bismuth. The value obtained from a Kou-

tecky-Levich analysis of the kinetics in $1.52 \times 10^{-3}M$ formic acid in $2 \times 10^{-2}M HCOONa$ and $1M KCl$ is $1.5 \times 10^{-5} cm^2 s^{-1}$ (36).

It is interesting to note that in the presence of bismuth (Fig. 8), a wider limiting current potential range is obtained during the positive going potential scan, since part of the adatom layer always remained on the surface.

The limiting current at the rotating platinum-disk electrode is not maintained, if the potential is held constant in the UPD region. Enough $HCOOH$ eventually diffuses to bare platinum surface sites and then participates in the disproportionation reaction [2]. The disk current decays steadily, and the surface continues to poison until no sites are available for the initial oxidative electroadsorption step (reaction [1]). The decay rates vary with underpotential, a result that demonstrates the effect of the UPD coverage on the rate of the poison formation. During the initial stages of the poisoning process, this variation in poisoning rate can be correlated with the instantaneous adatom coverage determined in the presence of formic acid. In Fig. 9 the time dependence of the limiting current decay is shown as a function of potential in the presence of lead adatoms. Because of the changing adsorption characteristics of electrodes held at constant potential (10, 37), we did not attempt to study the initial poisoning rates quantitatively. However, these rates increase with an increase of the mass-transfer rates to the electrode.

Determination of UPD coverage in the presence of formic acid.—In $0.1M$ unstirred solutions of $HCOOH$ several minutes are required for the platinum surface to become saturated by the organic residues formed at $0.0V$ (4). This saturation time is longer than 20s when

Fig. 5. Time dependence of disk- and ring-electrode currents at various underpotentials in $10^{-5}M Pb^{2+}$ - $0.12M HClO_4$ solution. E_{UPD} values are $+0.9V$ (A), $+0.8V$ (B), $+0.7V$ (C), $+0.6V$ (D), $+0.5V$ (E). $E_R = -0.6V$ (vs. SCE) and $\omega = 2500$ rpm.

Fig. 6. Lead coverage on platinum (θ) as a function of electrode plating potential (vs. SCE). Concentrations of Pb^{2+} in $0.12M HClO_4$ is $10^{-4}M$ (\uparrow), $10^{-5}M$ ($*$), $2 \times 10^{-6}M$ (\square), $10^{-6}M$ (\circ).

the disk electrode rotates at 600 rpm (38). Therefore, we conclude that at concentrations of formic acid below $10^{-3}M$ and for cation concentrations above $10^{-5}M$, the formation of adsorbed intermediates is slow and that the available platinum surface is not appreciably reduced, while Pb^{2+} and Bi^{3+} ions reach equilibrium coverage. The conditions for this assumption are best at anodic potentials ($>0.0V$) where the organic residues are less stable (4) and equilibrium UPD coverage is reached rapidly because of lower equilibrium coverage values. For example, in $10^{-4}M Pb^{2+}$ solutions,

Fig. 7. Disk electrode $i-E$ curves for $2 \times 10^{-3}M$ formic acid in $0.12M HClO_4$ in the presence of $10^{-4}M Pb^{2+}$ showing the dependence of the limiting currents on the rotation speed. $\omega = 400$ rpm (A), 900 rpm (B), 1600 rpm (C), 2500 rpm (D), and 3600 rpm (E). Scan rate = $50 mV s^{-1}$.

Fig. 8. Disk electrode $i-E$ curves for $2 \times 10^{-3}M$ formic acid in $0.12M HClO_4$ in the presence of $10^{-4}M Bi^{3+}$ showing the dependence of the limiting current on the rotation speed. $\omega = 900$ rpm (A), 1600 rpm (B), 2500 rpm (C), and 3600 rpm (D). Scan rate = $50 mV s^{-1}$. First electrode.

equilibrium surface coverage at $0.3V$ ($\sim 25\%$) is established in less than 5s at 2500 rpm.

Fig. 9. Decay of the limiting current as a function of potential for second electrode in 2×10^{-3} solution of HCOOH in 0.12M HClO_4 and in the presence of 10^{-4}M Pb^{2+} . $\omega = 900$ rpm. The electrode potential was held at 0.20V (vs. SCE) (A), 0.25V (B), 0.28V (C), 0.32V (D), 0.36V (E), 0.38V (F), and 0.42V (G).

The effect of the formic acid concentration on the ring-collection current peak is shown in Fig. 10 for 10^{-4}M Pb^{2+} . At high concentrations of formic acid, the UPD lead coverage does not have time to reach its equilibrium value before products from the poisoning reaction cover a significant fraction of the electrode surface. This effect is more pronounced at lower concentrations of the cation. We assume that the equilibrium adatom isotherm and the equilibrium isotherm for the organic residues are relatively independent of one another.

Fig. 10. Effect of the formic acid concentration on the ring electrode collection currents for 10^{-4}M Pb^{2+} in 0.12M HClO_4 . Ring potential = -0.6V (vs. SCE). No HCOOH (A), $5 \times 10^{-5}\text{M}$ (B), 10^{-3}M (C), $2 \times 10^{-3}\text{M}$ (D), and $5 \times 10^{-3}\text{M}$ (E). $\omega = 2500$ rpm. Scan rate = 200 mV s^{-1} . First electrode.

The formic acid oxidation current, 10 min after establishing an equilibrium lead coverage, was obtained at a number of underpotentials at 400 and 900 rpm. These data were used to obtain plots of formic acid oxidation current vs. lead UPD coverage, and are shown in Fig. 11. The slowest rate of poisoning occurs at a lead coverage range of $(30 \pm 3)\%$.

The optimum lead adatom coverage value reported by others (39) was about 50%. We suggest that these higher coverage estimates (39, 40) result from the way in which the microscopic area of the platinum electrode was determined. The potential just before the rise of the current due to a hydrogen evolution on the platinum electrode corresponds to a hydrogen coverage of 0.77 (4, 21), not unity. The unity assumption that was made leads to an underestimate of $\sim 20\%$ of the microscopic platinum surface area, and the reported values of 50% would then become $50 \times 0.77 = 39\%$.

Previous workers have determined adatom coverages by integrating stripping peaks. Since there is a change in point of zero charge with UPD coverage, there could be a systematic error associated with a charging current that accompanies the change in coverage (41, 42). However, under certain conditions the potential scan can lead to a compensating charging current. This entire matter is discussed elsewhere (31).

The optimal bismuth coverage occurs at $(35 \pm 3)\%$ also, as is seen in Fig. 12. In this case again the HCOOH oxidation current becomes insignificant at $\theta = 50\%$.

The optimal adatom coverages for maximum electrocatalysis reported above constitute the upper coverage limit for such measurements. Experiments performed at higher HCOOH concentrations in unstirred solutions (12, 39) must result in a significant partial coverage of the platinum surface by the organic poisons before UPD equilibrium is reached. Therefore, UPD coverages estimated under such conditions will yield coverage values lower than the true ones.

Inhibition effects by UPD.—The underpotential deposition of copper or silver on platinum inhibits the oxidation of formic acid (12). This effect is more pronounced with silver. Both silver and copper are not electrocatalysts for the formic acid oxidation reaction; therefore, it is not surprising that when they cover the

Fig. 11. Formic acid oxidation current as function of lead monolayer coverage on platinum. The points were sampled after a 10-min wait at 400 rpm (O) and 900 rpm (X). Lead concentration: 10^{-4}M . Second electrode.

Fig. 12. Formic acid oxidation current as a function of bismuth monolayer coverage on platinum. The points were sampled after a 90s wait at 2500 rpm. Bismuth concentration: $5 \times 10^{-5}M$. First electrode.

platinum surface by more than a monolayer the oxidation process stops. Reaching monolayer coverage is possible, under equilibrium conditions, in the potential region where formic acid oxidation takes place (excluding the formic acid third anodic peak). However, even a very small UPD silver coverage on platinum has an inhibiting effect.

In Fig. 13 the effect of $5 \times 10^{-6}M$ Ag^+ on the $i-t$ curve of $10^{-3}M$ $HCOOH$ in $0.12M$ $HClO_4$ is shown. The potential was jumped to $+0.29V$ after the electrode pretreatment (steps A, B, and C in Fig. 1). More than 20s was required for equilibrium silver coverage to be reached in $2 \times 10^{-5}M$ silver solutions (43). In $5 \times 10^{-6}M$ solutions of Ag^+ , the UPD rate was much slower, $\sim 50s$ (32). If a third-body (11, 14) catalytic mechanism were operative over the entire polycrystalline platinum surface, the Ag adatoms would prevent poison formation (11, 14) during the initial stages of UPD. However, this result was not found.

Fig. 13. Effect of silver UPD on the oxidation current of $10^{-3}M$ $HCOOH$ in $0.12M$ $HClO_4$. The potential was jumped to $+0.29V$ (vs. SCE) after the electrode pretreatment. Solid curve: no Ag^+ . Dotted curve: $5 \times 10^{-6}M$ Ag^+ . $\omega = 2500$ rpm. Second electrode.

Potentiodynamic experiments also show this accelerated poisoning effect. Figure 14 shows the $i-E$ curve in the same solution used in Fig. 13. Equilibrium silver coverage is not reached at a high potential scan rate of 200 $mV s^{-1}$ in very dilute solutions; however, the formic acid oxidation current is substantially decreased. Likewise, no catalysis occurs during the initial stages of the copper underpotential deposition.

Clearly, the hydrogen inhibition, or the third-body mechanism, does not apply to formic acid oxidation in the case of submonolayer amounts of silver and copper. However, these kinetic data can be explained using the results of recent studies at single-crystal platinum, as can the electrocatalysis by UPD lead, bismuth, and other UPD species of atomic radii greater than platinum.

The oxidation of formic acid is strongly dependent on the platinum plane at which it occurs (44). In particular, the UPD studies of formic acid oxidation lie in the potential region where the oxidation in the absence of UPD occurs principally at Pt(100), since the rate at Pt(100) is about ten times the rate at Pt(111) (44). The rate on Pt(110) is also significant: about 40% of Pt(100). Thus, if any adatom is preferentially deposited on Pt(111) during its initial stages of UPD, the hydrogen inhibition or third-body effect will operate solely on this plane, which contributes only to a small extent to the total formic acid oxidation current. Simultaneously, the Pt(100) and Pt(110) planes, which have little or no adsorbed adatoms, will poison quickly, and the total external current will drop rapidly. If the adatom deposits to a significant extent on Pt(100) and Pt(110) during its initial stages of UPD, it will inhibit hydrogen adsorption and will also be available as a third body, and thus inhibit the poisoning process on the faces which are most responsible for the oxidation current. As will be shown below, silver and copper initially deposit on Pt(111) at $\theta < 0.5$, while lead, bismuth, and other adatoms with radii larger than that of platinum do not preferentially deposit on Pt(111) at low UPD coverages.

Fig. 14. Effect of silver UPD on the $i-E$ curve of $10^{-3}M$ $HCOOH$ in $0.12M$ $HClO_4$. Solid curve: no Ag . Dotted curve: $5 \times 10^{-6}M$ Ag^+ . $\omega = 2500$ rpm. Scan rate = 200 $mV s^{-1}$. Second electrode.

Low surface coverages (<0.5) of silver, copper, and adatoms preferentially inhibit the adsorption of weakly bound hydrogen sites on polycrystalline platinum (29, 45). These weakly bound hydrogen sites have been associated with Pt(111) (46-48). We conclude that the initial stages of UPD of silver and copper at polycrystalline platinum occur at Pt(111) on sites having similar surface energies. In contradistinction, lead and bismuth show no significant preferential inhibition of the various hydrogen adsorption sites at low UPD coverages (29), and therefore a significant amount of adatom deposition can occur on Pt(100) and Pt(110). Thus, the initial stages of adatom coverages of silver, copper, lead, and bismuth meet the requirements set forth in our hypothesis for explaining the differences in electrocatalytic behavior of different adatoms.

In general, adatoms with radii greater than that of platinum tend to be more randomly distributed on the various platinum faces of polycrystalline substrate, and so should show electrocatalysis of the formic acid oxidation process at polycrystalline platinum. For example, mercury, with a radius greater than platinum, catalyzes formic acid electro-oxidation (11) and shows no preferential inhibition of hydrogen adsorption (29).

Figure 15 illustrates the various points made above. It contains the I_D-E_D curves for the UPD-catalyzed electro-oxidation of $10^{-3}M$ formic acid solution in $0.12M$ $HClO_4$ at different lead ion concentrations. It is clear from the positive-to-negative potential scans that substantial poisoning by reaction [2] to form COH occurs until at least $10^{-5}M$ lead ion is present in solution and that increasing the concentration of lead ion to as high as $10^{-3}M$ improves this particular problem only slightly.

It is also clear that a very low concentration ($10^{-6}M$) of lead ion catalyzes the oxidation of formic acid only modestly compared to a solution without any lead ion during the positive-to-negative potential scan. This is the potential region in which the poisoning process to COH occurs via reaction [2]. During the negative-to-positive potential scan, the extent of poisoning is markedly reduced by the presence of $10^{-6}M$ lead ion. In the potential region more negative than 0 V, the poisoning process to form COH proceeds via electroadsorbed hydrogen according to reaction [3]. This poisoning inhibition indicates that low surface coverages of lead readily block those surface sites upon which hydrogen electroadsorbs. This conclusion is consistent with our previous comments and does not imply that UPD lead is adsorbed on only one kind of surface site. Also, we note that the poisoning path through electroadsorbed hydrogen is significantly suppressed by low coverages of UPD lead, a result consistent with the possibility of

UPD lead to block two adsorbed hydrogen atoms per lead atom.

The UPD catalytic effect during the positive-to-negative potential scan is strongly concentration and potential dependent for potentials in the range $+0.23$ to $-0.10V$. This dependence arises from three sources, one that increases the rate of oxidation and two that decrease it.

Up to the optimum surface coverage at a given scan rate, poisoning is suppressed by higher UPD coverages. This optimum coverage is reached at different potentials for different solution concentrations of lead ion because the nonequilibrium surface coverage is proportional to both solution concentration and time (and hence potential). After the optimum coverage is exceeded, physical blocking of platinum sites interferes with the primary electro-oxidation path of formic acid. Also, the rate of the uncatalyzed electro-oxidation of formic acid decreases for classical electrochemical reasons, i.e., the rate constant of reaction [1] decreases as the potential decreases. The interplay of these three factors will result in an optimum solution concentration of lead ion for the catalytic process at a particular rotation speed for a given rate of potential scan in the positive-to-negative direction.

The negative-to-positive potential scan $I-E$ curves merge, for practical purposes, for lead-ion concentrations above $10^{-5}M$ when the potential is more positive than $0.25V$. This situation arises because the surface coverage of UPD lead approaches equilibrium in these solutions at the experimental scan rate. Coverage is determined by potential. The observed differences between the $I-E$ curves under discussion arise from the slight concentration dependence of isotherm depicted in Fig. 6.

The interpretation of potentiodynamic data is complicated, as was realized by previous workers who used cyclic voltammetry at a stationary electrode to study the oxidation of formic acid (12). The use of the rotating disk and ring-disk electrodes simplifies this interpretation by providing reliable estimates of UPD surface coverage during the potential scan.

Conclusions

The residues formed on the surface of a platinum electrode during the electro-oxidation of formic acid can decrease the amount of the platinum surface area available for the underpotential deposition process of a foreign adatom necessary to catalyze the oxidation reaction. The amount of this decrease will be determined by the concentrations of the dissolved species. The surface of the platinum electrode not covered with organic residues must be determined in order to calculate the actual adatom coverage during the formic

Fig. 15. Effect of lead ion concentration on cyclic voltammograms at a rotating disk electrode. $1 \times 10^{-3}M$ $HCOOH$ in $0.12M$ $HClO_4$. $\omega = 2500$ rpm. Potential scan rate is 50 mV s^{-1} , and scan limits are 1.15 to $-0.25V$ (vs. SCE). $i-E$ curves are these obtained on repetitive scanning. No Pb^{2+} (A), $10^{-6}M$ Pb^{2+} (B), $10^{-5}M$ Pb^{2+} (C), $10^{-4}M$ Pb^{2+} (D), and $10^{-3}M$ Pb^{2+} (E).

acid oxidation process. This problem can be minimized by using low concentrations of formic acid and enhanced mass transfer of the UPD species. Under these conditions, a limiting formic acid oxidation current can be obtained over a wide potential region at the rotating disk electrode. The decay of this limiting disk current can then be monitored as a function of the adatom surface coverage, which is determined by using the ring electrode of the RRDE.

The dependence of the oxidation current of formic acid and the selectivity for adatom UPD on the orientation of the crystal planes of platinum explains why adatoms with radii greater than the platinum atom are capable of catalyzing formic acid oxidation, while very low coverages of atoms with smaller radii appear to have substantial inhibiting effects.

The Transport and Kinetics of Photogenerated Carriers in Colloidal Semiconductor Electrode Particles

W. John Albery* and Philip N. Bartlett*

Department of Chemistry, Imperial College, London SW7 2AY, England

ABSTRACT

The transport and kinetics of photogenerated majority and minority carriers in a spherical semiconductor particle of colloidal size are considered. The Poisson-Boltzmann equation is solved for the sphere, and the potential distribution in the particle is obtained. The recombination of the carriers according to Hall-Shockley-Read kinetics gives rise to a number of different cases, for which equations describing the flux of photogenerated species in the external solution are obtained. Kinetic case diagrams show how the different cases are related to each other and how they depend upon such variables as the irradiance, the Fermi level in the electrolyte, the surface rate constants, and the radius of the particle. Three different strategies which could lead to devices for efficient solar energy conversion are found and discussed.

The use of semiconductor particles as microheterogeneous electrodes for solar energy conversion (1, 2) or photocatalysis (3, 4) has aroused considerable interest. In discussing these systems most authors have assumed that the semiconductor particles behave in a similar fashion to macroscopic electrodes made of the same material. For instance, Grätzel and Frank (5) have published a simple description of the response of a particle to a pulse of light. In this paper we present a more complete theoretical description of the photogeneration of holes and electrons in the particle, their transport and recombination kinetics, and the kinetics of their reactions at the surface of the particle. We give expressions for the efficiency of the particle system and how it depends upon the above-mentioned parameters. We show that the particles behave very differently from their macroscopic analogues. We find a number of different kinetic cases, and from these cases we deduce that there are three different ways of achieving efficient solar energy conversion. The conditions for these three different strategies are derived and discussed. Throughout we present the theory for p-type particles.

Model

We consider a spherical particle of radius r_s doped so that the Debye length of the material is L_D ; the absorption coefficient for the light (α) gives rise to an absorption length, L_e , where $L_e = \alpha^{-1}$. We assume that the particle is so small that $r_s \ll L_e \sim 10^{-4}$ cm, leading to uniform irradiance (I) inside the particle and uniform photogeneration of holes and electrons (g), where

$$g = I/L_e \quad [1]$$

In this paper we consider only the steady state. Under steady-state conditions, the net flux of electrons (j) leaving the conduction band of any particle must balance the net flow of holes from the valence band. The collection efficiency (N) of the particle is then the ratio of photogenerated electrons or holes leaving the particle compared to the number of photons absorbed by the particle. Using Eq. [1]

$$N = \frac{4\pi r_s^2 j}{(4/3)\pi r_s^3 g} = \frac{j}{1/3 r_s g} = \frac{3jL_e}{I r_s} = \frac{j}{J} \quad [2]$$

The parameter J ($= 1/3 I r_s L_e^{-1}$) describes the inward flux of photons that are absorbed by each particle. In writing Eq. [2], we assume that the loss of electrons and holes from the particle takes place in a reasonably uniform fashion all over the surface of the particle. A more complicated situation will be found if, for instance, the particle is coated with Pt in a

single localized patch. Under these conditions the transport and kinetics of the carriers will depend upon the detailed geometry of the coating, and one cannot expect to devise a general theory for such a situation. Providing that the materials like Pt are dispersed over the whole surface, we can describe the kinetics of the removal of electrons or holes by the following equations

$$j = k_n' n_s = k_p' p_s - k_{-p}' \quad [3]$$

where n_s is the surface concentration of electrons in the conduction band, and p_s is the surface concentration of holes in the valence band. In Eq. [3] we assume (for a p-type particle) that there is no thermal injection of electrons from the solution into the conduction band, but with k_{-p}' we allow for the thermal injection of holes (majority carriers) into the valence band. In the dark $j = 0$, and we can define p_s^D , the surface concentration of holes in the dark, as

$$p_s^D = k_{-p}'/k_p' \quad [4]$$

This concentration is fixed by the redox systems in the electrolyte. Using Eq. [4] we can eliminate k_{-p}' from Eq. [3] to obtain

$$j = k_p' (p_s - p_s^D) \quad [5]$$

The rate constants k_n' and k_p' are electrochemical rate constants with units of cm/s^{-1} . If either reaction is confined, say to Pt covering an area A on the surface, then

$$k_n' = k_n'' (A/4\pi r_s^2)$$

where k_n'' is the rate constant for the Pt catalyst.

Distribution of Potential

Since the particle has spherical geometry, we cannot assume, as others have done (5), that the width of the depletion layer is given by the equation for a planar macroscopic electrode; we must solve the Poisson-Boltzmann equation for the sphere. For the depletion layer, the Poisson-Boltzmann equation may be written in dimensionless variables as follows

$$\rho^{-2} \frac{\partial}{\partial \rho} \left(\rho^2 \frac{\partial \theta}{\partial \rho} \right) = 1 \quad [6]$$

where

$$\rho = r/L_D \quad [7]$$

$$\theta = \phi F/RT$$

r is the distance from the center of the particle, and ϕ is potential measured with respect to the center of the particle so that $\phi = 0$ at $r = 0$.

Integration of Eq. [6] yields

$$\theta = \frac{1}{6} (\rho - \rho_w)^2 (1 + 2\rho_w/\rho) \quad [8]$$

* Electrochemical Society Active Member.
Key words: solar energy conversion, photogenerated carriers, colloidal semiconductors.

where we have used the boundary conditions that θ and $(\partial\theta/\partial\rho) = 0$ at $\rho = \rho_W$, the inside edge of the depletion layer. For large particles where the width of the depletion layer is small compared to the radius of the particle, $\rho \approx \rho_W$ throughout the depletion layer, and Eq. [8] simplifies to

$$\theta = \frac{1}{2} (\rho - \rho_W)^2$$

This is the same result as for a planar electrode. For a thin depletion layer close to the surface of the sphere, the spherical geometry does not affect the potential distribution.

For small colloidal particles $r_s \sim 10^{-6}$ cm, the radius of the particle may be smaller than the width of the depletion layer, so that $\rho_W = 0$, with $\theta = 0$ and $(\partial\theta/\partial\rho) = 0$ at $r = 0$. Equation [8] then simplifies to

$$\theta = \rho^2/6 \quad [9]$$

Under these conditions, the whole of the particle is depleted of majority carriers and there is no field-free region.

We now discuss the conditions under which Eq. [9] will hold. In Fig. 1 we compare the potential distribution in a macroscopic planar electrode with that in a small spherical particle. For both cases we assume that the Fermi level is fixed by a redox couple in the electrolyte which has shifted its position by an amount corresponding to θ_F from its position at flatband. In the planar case (assuming no Fermi-level pinning), this means that θ_F describes the potential drop across the depletion layer of width W . For the particle, r_s is too small for this full potential difference to be developed. From Eq. [9] the maximum value of θ is

$$\theta_s = \frac{1}{6} (r_s/L_D)^2 \quad [10]$$

Fig. 1. Comparison of the potential distribution and Fermi levels for a macroscopic planar electrode and for a spherical particle.

Hence the particle will be completely depleted and Eq. [9] will hold when

$$\frac{1}{6} \left(\frac{r_s}{L_D} \right)^2 = \theta_s < \theta_F = \frac{1}{2} \left(\frac{W}{L_D} \right)^2$$

or when

$$r_s < 3^{1/2} W = (6 \theta_F)^{1/2} L_D \quad [11]$$

For colloidal particles where r_s is, for instance, 10^{-6} or smaller, it is likely that the condition in Eq. [11] will be satisfied, that is, that the particle will be completely depleted of its majority carriers and that the potential distribution will be given by Eq. [9]. This is a major difference between the small spherical particle and the macroscopic electrode. Furthermore, since θ_s may be much smaller than θ_F , there may be much less potential difference within the particle than within the macroscopic depletion layer. An even more extreme situation is when $r_s > 6^{1/2} L_D$ giving $\theta_s < 1$. Under those conditions the particle can be treated as being field free. Finally, θ_F may be related to p_{FB}^D

$$\theta_F = \ln p_{FB}^D - \ln p_s^D \quad [12]$$

where p_{FB}^D is the concentration of majority carriers in the dark at flatband and is equal to the charge-carrier density of the macroscopic material. The parameter θ_F plays the same role for semiconductor particles as the electrode potential does for the macroscopic case.

Transport in the Particle

The differential equation describing the photogeneration of the minority carriers, their transport by diffusion and by migration, and their recombination may be written, using Eq. [9], as

$$\frac{D_n}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial n}{\partial r} - \frac{nr^3}{3L_D^2} \right) + \begin{matrix} \text{Diffusion} & \text{Migration} & \text{Generation} \\ \text{(or drift)} & & \end{matrix} - \begin{matrix} \text{Recombination} \\ v = 0 \end{matrix} = g \quad [13]$$

where n is the concentration of electrons and v is the rate of recombination. Integration of Eq. [13] shows that providing

$$g \ll D n_s / L_D^2 \quad [14]$$

then the distribution of n is given by a Boltzmann distribution in the potential described by Eq. [9].

Substitution from Eq. [1], [2], and [3] allows us to rewrite the condition in Eq. [14] as

$$1 \ll \frac{N}{3} \frac{D_n}{L_D} \frac{r_s}{k_n' L_D} \quad [15]$$

In Eq. [15] it is likely that both D_n/L_D are larger than k_n' and r_s is larger than L_D ($\theta_s > 1$). Hence, unless N is very small, the condition in Eq. [15] is likely to hold, and the electrons will obey a Boltzmann distribution. The low value of N will be obtained when recombination kinetics are very rapid, and under these conditions the last two terms in Eq. [13] could give a uniform distribution in the particle. Such cases are so inefficient as to be uninteresting and will not be further considered. A similar argument can be used for the holes. The conclusion that both electrons and holes obey the Boltzmann distribution agrees with our earlier work (6) on recombination in the depletion layer of macroscopic electrodes. Figure 2 shows the resulting concentration profiles for the electrons and holes.

It should be noted that the characteristic time for the transport of the electrons in the depleted particle is given by L_D^2/D_n and not r_s^2/D_n as stated by Grätzel and Frank (5). Migration is more efficient than diffu-

Fig. 2. Typical concentration profiles for electrons and holes inside a p-type spherical particle where $\rho = r/L_D$ and ρ_s is the surface of the particle.

sion, and the field assists the transport. It is, therefore, even more certain that carriers photogenerated in a small particle will reach the surface before being destroyed by recombination. Grätzel and Frank assume that once a carrier has reached the surface it is bound to be lost from the particle. We do not agree with this assumption. Next we explore the fate of the carriers. Will they be lost from the particle through the k_n' and k_p' reactions or will they recombine in the particle?

Recombination Kinetics

In our previous work (6) we expressed the equation for the Hall-Shockley-Read (7, 8) model in kinetic terms

$$\frac{1}{v} = \frac{1}{k_I n} + \frac{1}{k_{II} n p} + \frac{1}{k_{II} p} \quad [16]$$

I II III

In this equation n and p are given by the Boltzmann distributions

$$n = n_s \exp(\theta - \theta_s) \quad [17]$$

and

$$p = p_s \exp(\theta_s - \theta) \quad [18]$$

Because the particle is small, it is unlikely that all three terms in Eq. [16] will be significant. We therefore consider in turn four cases, I, II, III, and I/III. In the last case terms I and III become equal at some value of r inside the particle.

As shown in Fig. 3, the main losses from recombination for case I occur near the surface and for case III at the center. For case II the Boltzmann factors cancel out, and the loss is uniform throughout the particle. For case I/III, case I is found (low value of n) near the center and case III near the surface; the maximum loss is at the boundary between the two cases.

The general expression for N is

$$N = 1 - \frac{\int_0^{r_s} r^2 v dr}{\frac{1}{3} g r_s^3} \quad [19]$$

The problem is to work out the value of the integral and the numerator of Eq. [19] using Eq. [2], [3], [5], [7], [9], [16], [17], and [18]. The detailed working is given in the Appendix, and the results are collected in Table I. We also include expressions for a field-free particle which will arise when $\theta_s < 1$ and the field is negligible.

We now discuss these expressions. The terms in the denominators compare the rate constants for recombination k_I , k_{II} , and k_2 with the rate constants for reaction at the surface k_n' and k_p' . For case I ($\theta_s > 1$), we may write

$$\frac{3k_I L_D^2}{k_n' r_s} = \frac{k_I}{k_n'} \left(\frac{\partial \theta}{\partial r} \right)_s^{-1} \quad [20]$$

This may be compared with the similar expression for the macroscopic case (9) where

$$\frac{k_I}{k_n'} \frac{L_D}{(2\theta_0)^{1/2}} = \frac{k_I}{k_n'} \left(\frac{\partial \theta}{\partial x} \right)_0^{-1} \quad [21]$$

Fig. 3. Kinetic case diagram for case A (see Eq. [27]) and for $\theta_s > 1$. The conditions and the zones of dominance for the different kinetic cases are displayed as a function of the flux j and the position of the Fermi level described by θ_F . For the mixed I/II zone, the boundary is at the surface of the particle on the solid lines passing through O and at the center of the particle on the broken lines passing through Q.

Table I. Results for N

Case ^a	$\theta_s = r_s^2/6L_D^2$ ^b	N
I	$\theta_s > 1$	$\frac{1}{1 + 3 k_1 L_D^2/k_n' r_s}$
	$\theta_s < 1$	$\frac{1}{1 + k_1 r_s/3k_n'}$
II ^c		$\frac{1}{1 + \frac{k_{11} r_s}{3 k_n'} \left[p_s D + \frac{N I r_s}{3 k_p' L_e} \right]}$
III ^d	$\theta_s > 1$	$\frac{1}{1 + \frac{k_2 L_D^3 C \exp(\theta_s)}{r_s^2} \left[\frac{3 p_s D L_e}{N I r_s} + \frac{1}{k_p'} \right]}$
	$\theta_s < 1$	$\frac{1}{1 + \frac{k_2 r_s}{3} \left[\frac{3 p_s D L_e}{N I r_s} + \frac{1}{k_p'} \right]}$
I, III ^{e,f}	$\theta_s > 1$	$\frac{1}{1 + \frac{3\pi}{2} \frac{L_D^2 r_s}{r_s^2} \left[\frac{k_1 k_2}{k_n'} \left\{ \frac{3 p_s D L_e}{N I r_s} + \frac{1}{k_p'} \right\} \right]^{1/2}}$

^a Cases I, II, and III refer to the dominant term in Eq. [16] for Hall-Shockley-Read kinetics.

^b $\theta_s > 1$ corresponds to particles with field. $\theta_s < 1$ means that the particles are field free.

^c The same result is obtained regardless of the size of θ_s .

^d $C = (3/2) (6\pi)^{1/2} = 6.51$.

^e There is no result for $\theta_s < 1$ because under these conditions there can be no shift in mechanism from I to III.

$$r_s^2 = r_s^2 + 3L_D^2 \ln \left[\frac{k_2 k_n'}{k'} \left\{ \frac{3 p_s D L_e}{N I r_s} + \frac{1}{k_p'} \right\} \right]$$

The inverse gradients in Eq. [20] and [21] describe the distances near the surface over which θ decreases by 1 or the concentration of electrons falls to e^{-1} of its value at the surface. The recombination in this distance can compete with the loss through the surface. Further into the particle (or macroscopic electrode), the field keeps the concentration of minority carriers so low that recombination is negligible. This is not true for the field-free case, where recombination takes place throughout the particle. The denominators of the other three cases in Table I contain 3 terms. This is because the concentration of holes may be dominated by either the concentration in the dark (p_s^D), with negligible perturbation by the light or by the photo-generated concentration. Inspection shows that the ratio of the last two terms in each case is the same. From Eq. [2] and [5]

$$p_s^D + \frac{N I r_s}{3 k_p' L_e} = p_s \quad [22]$$

For case II the exponential terms for the loss by recombination cancel out so that there is a uniform velocity of reaction throughout the volume of the particle. Both the recombination and the loss of minority carriers are proportional to n and so

$$\frac{k_{11} r_s p_s}{3 k_n'} = \frac{(4/3) \pi r_s^3 k_{II} p_s n_s}{4\pi r_s^2 k_n' n_s}$$

In this case the result does not depend upon the field. For case III, where the recombination is proportional to the concentration of holes, with the field, the largest concentration (p_0) is at the center and maintains its value for a sphere of radius of about $3L_D$. From Eq. [2] $3L_e/N I r_s = j^{-1}$ and so

$$\frac{k_2 L_D^3 C \exp(\theta_s) p_s}{r_s^2} \cdot \frac{3L_e}{N I r_s} = \frac{k_2 L_D^3 C p_0}{r_s^2 j}$$

This ratio compares the loss of holes by k_2 in the cen-

tral sphere with the loss through the surface. For the field-free case, the ratio is $1/3 k_2 r_s p_s/j$, and recombination takes place throughout the sphere.

Case I/III is more complicated. The parameter r_s describes the radius where term I and term III in Eq. [16] are equal. The rate of recombination is largest at this value, and r_s can vary between r_s , which corresponds to the boundary with case I, and L_D , which corresponds to the boundary with case III. Inspection shows that as a rough approximation the term in the denominator of case I/III is the geometric mean of those in terms I and III. This case does not exist for $\theta_s < 1$, because it is the field which changes the kinetics.

Kinetic Case Diagrams

We now discuss how the different cases in Table I are related to each other as a function of first the flux (j), of carriers leaving a particle, and second, the concentration of majority carriers in the dark, which is related by Eq. [12] to θ_F . The quantities j and θ_F are the analogues of the photocurrent and electrode potential for a macroscopic electrode. For a particle, θ_F will be fixed by the redox couples present in the electrolyte solution. We start by considering the cases where $\theta_s > 1$ and a field is present in the particle.

From Eq. [16] the boundaries between the different cases are as follows

$$I/II \quad p = k_1/k_{II} \quad [23]$$

$$II/III \quad n = k_2/k_{II} \quad [24]$$

The boundary between I and I/III will be when $\theta_s = \theta_s$ or from Eq. [A-16]

$$k_1 n_s = k_2 p_s \quad [25]$$

The boundary between I/III and III will be when $\theta_s = 0$ or from Eq. [A-16]

$$(k_1 p_s/k_2 n_s) = \exp(2\theta_s) \quad [26]$$

We find that depending on the ratio $(k_p' k_1/k_2 k_n')$ three different types of behavior can be found

$$(k_p' k_1/k_n' k_2) < 1 \quad [27]$$

$$1 < (k_p' k_1/k_n' k_2) < \exp(2\theta_s) = \exp \left[\frac{1}{3} (\tau_s/L_D)^2 \right] \quad [28]$$

$$\exp(2\theta_s) < (k_p' k_1/k_n' k_2) \quad [29]$$

We now consider each case in turn. Figure 3 shows the kinetic case diagram for Eq. [27]. The main zones on the diagram are the cases described by Eq. [27] and [28] with a small intermediate zone. The case described by (Eq. [29]) (the $k_2 p$ term) does not appear because the kinetic condition in Eq. [17] for Eq. [27] assumes that inside the particle the product $k_2 p$ will always exceed $k_1 n$. The reason for this is that k_p' is sufficiently small for it to be difficult for the holes to be lost at the surface. The dotted line OQZ divides the Eq. [28] case into a zone where the concentration of holes is determined by the unperturbed dark concentration (p_s^D) and a zone where the photogenerated concentration is significantly larger than p_s^D ; under these conditions the reaction at the interface is irreversible. The boundaries are then determined by Eq. [23]; the solid lines show where the terms are equal at the surface, and the broken lines where they are equal at the center of the particle. It is satisfactory that, apart from numerical terms, the expression for N for case II in Table I agrees with that for case I on the boundaries; the second term in the denominator for case II is dominant on the vertical boundaries, and, using Eq. [2] ($j = 1/3 N I r_s/L_e$), the third term on the horizontal boundaries.

Next we consider the intermediate case described by Eq. [28], where the kinetic ratio is roughly in balance. The kinetic case diagram is shown in Fig. 4. Comparing the horizontal lines, comparison with Fig. 3 shows that the boundaries OA and PQR are the same. The line QZ still separates the zones where the concentration of holes is determined by the thermal concentration or by the photogeneration. The boundaries OD, OB, and XY are given by Eq. [25], [24], and [30], respectively. The parameter θ_*^L is the limiting value of θ_* , and describes the location of the reaction zone for the I/III case inside the particle at the point where on increasing the irradiance the case II region ceases to exist

$$\exp(\theta_*^L - \theta_s) = (k_2 k_n' / k_1 k_p')^{1/2} \quad [30]$$

Above the line XQZ increasing irradiance increases j , n , and p , but does not alter the relative balance of

$k_1 n$ and $k_2 p$. Hence θ_* does not change; it remains equal to θ_*^L . Depending on the kinetics, θ_*^L can vary between 0 and θ_s . When θ_*^L is equal to θ_s nearly all the particle has case I kinetics. Under these conditions, Fig. 4 reduces back to Fig. 3 with the points O and X coincident and the line OB a distance θ_s above QR. Again it is satisfactory that the different expressions for N in Table I are in reasonable agreement on the boundaries.

Finally we turn to case C, expressed by Eq. [29], where the ratio is now large. The kinetic case diagram is shown in Fig. 5. Because of the large kinetic ratio at high irradiance there are not many holes (k_p' is large), and so term III will dominate the whole of the particle. Comparing Fig. 4 and 5 the boundaries OA, OB, OD, and PQ are identical. The boundaries QT and QU are derived from Eq. [26]. If in Fig. 4 one takes θ_*^L towards zero, the whole of the particle becomes

Fig. 4. Kinetic case diagram for case B (see Eq. [28]) and for $\theta_s > 1$. The boundaries AO and PQR are the same as in Fig. 3. The boundary OB now lies lower than the boundary OC in Fig. 3 corresponding to the difference between Eq. [27] and [28].

Fig. 5. Kinetic case diagram for case C (see Eq. [29]) and for $\theta_s > 1$. The boundaries OA, OD, OB, and PQ are the same as those in case B in Fig. 4. The boundary QR in Fig. 4 lies above the boundary QT in this figure, corresponding to the difference between Eq. [28] and [29].

case III. The points Q and X become coincident, and Fig. 4 and 5 match. The field-free cases in Table I are discussed below.

Discussion of Kinetic Cases

The kinetic case diagrams show how the different solutions for N in Table I are linked together and how they depend on the photogenerated flux (j) and on θ_F , where θ_F is determined by the redox properties of the solution. Several general conclusions can be drawn. First, the concentrations of the carriers and their fate inside the particle are very dependent on the rate constants for the reactions at the surface k_n' and k_p' . These rate constants will often depend on the concentrations of redox species in the solution and can therefore be varied. Second, since throughout its volume the particle is depleted of majority carriers, the concentration of majority carriers may be very small, and the terms majority and minority may be misleading. For instance, in the case where the concentration of photogenerated holes is significantly larger than the concentration in the dark, from Eq. [3]

$$n_s/p_s \simeq k_p'/k_n'$$

The relative size of the concentrations of holes and electrons depends on the ratio of the surface-rate constants and not at all on how the particle was originally doped. Third, for small particles the amount of band bending as given by θ_s will be much smaller than that found in macroscopic semiconductors. This suggests that the effects of the field are less important and that reasonable estimates of transport and kinetics may be obtained by assuming that the particle is field free. Fourth, the value of p_s^D determines the important parameter θ_F (see Eq. [2]), which plays the same role as the electrode potential for macroscopic electrodes. In any experiment this parameter should be controlled and not left to chance. Finally, which kinetic case is found may depend on the irradiance. Increasing the light intensity increases j , and this is equivalent to moving upwards on the kinetic case diagrams.

Turning now to some more particular points, in Fig. 6 and 7 we have simplified the kinetic case diagrams by ignoring all borderline cases. If θ_s is not too large (corresponding to small particles), then the zones of existence of the borderline cases will be small. The

simplified diagrams give approximate expressions for N from Table I, together with contours which show how N varies in the different zones, provided one assumes for the moment that $N \ll 1$. Decreasing the dark concentration of holes increases N in zones III, 1 and II, 1. It is interesting that in zone II, 2, the flux j will depend on the square root of the irradiance $I^{1/2}$. Zone II, 1 is curious because, if N is small, then one finds that

$$r_s^2 I/L\epsilon \simeq k_2 L_D^3 C p_s^D \exp(\theta_s) \quad [31]$$

This equation matches the photogeneration over the whole spherical particle with the case-III recombination, which is determined by the concentration of holes in the dark recombining at the center of the particle. Equation [31] has to hold all over zone III, 1. Relatively small changes in I or in p_s^D will violate the condition and lead to sharp changes in N and Nl . For instance, an increase in the irradiance (ΔI) where $\Delta I/I \sim N$, will shift the system from case I to case III, 2 giving a steep increase in N and the flux, $j = NI$. For low values of N , case III, 1 is metastable. The tie lines in the inset show how the system will change abruptly from the lower cases to case III, 2. The simplified diagrams in Fig. 6 and 7 also describe the field-free results in Table I.

Finally, it is interesting to note that for most cases a decrease in r_s leads to improvements in N . This is true of case III when one remembers that in the exponential term $\theta_s = r_s^2/6L_D^2$. For this case the advantage of the small particle is that there is no central haven where the holes can congregate before recombining. For case II, where the recombination rate is uniform, the smaller the value of r_s , the greater the area to volume ratio. Hence the surface processes are favored compared to recombination. The one exception is case I with the field. Here N is greater the larger the value of r_s is. This arises because in this case the field is helpful in that it concentrates the minority carriers at the surface. The optimum value of r for efficient solar energy conversion will be discussed below.

To understand these systems and to optimize their design for efficient conversion, it will be necessary to find out to which kinetic case a particular system belongs. The variation of N with variables such as the

Fig. 6. Simplified kinetic case diagram for case A (Eq. [27]). The schematic contours show that N increases as one moves toward the southeast corner of the diagram.

Fig. 7. Simplified kinetic case diagram for case C (Eq. [29]). The expressions given are for $\theta_s > 1$. For a field-free particle the corresponding expressions in Table I should be used for zones I and III. The inset shows how for small values of N , any system will pass rapidly through the III, I zone as the irradiance or θ_F is increased.

irradiance (I), the surface rate constants and their relevant concentrations (k_n' and k_p'), and the concentration of holes in the dark (p_s^D) should enable this to be done.

Solar Energy Conversion Efficiency

While N measures the efficiency of converting the flux of photons to a flux of chemical products, the power conversion efficiency also depends on the difference in free energy of the two products being produced. (For photogalvanic cells the equivalent quantities are current and voltage.) We are interested in this paper in the efficiency of the semiconductor particles, and we will ignore problems that occur after the production of the species in the electrolyte solution, such as concentration polarization or losses by homogeneous back reactions. In this paper we are not concerned with how the products are used. To find the power conversion efficiency, we therefore consider the following artificial system containing two redox couples, one of which reacts with the electrons in the conduction band, and the other of which reacts with the holes in the valence band

We also assume that the back reaction of R is negligible. To tap the energy we then further postulate that we have two wonderful selective electrodes, one of which, X , is reversible to the O/R couple and the other, Y , to the O'/R' couple. It is interesting that we also have to assume that the reaction between R and O' is negligibly slow. If this reaction does take place then there will be efficient recombination in the electrolyte and no current; this situation is the analog of using an unselective metallic electrode in a photogalvanic cell where recombination takes place in the electrode. Now the power produced per unit area of parti-

cle by such an arrangement will be given by the product of the flux (j) and the difference in the electrode potential of the two couples. This difference can conveniently be plotted as a Fermi level in the usual energy diagram, as shown in Fig. 8. In order to prevent the back injection of electrons into the conduction band, we have sacrificed a few kT in the position of the O/R couple. As shown, the O'/R' couple and the electrode Y play the same part in this system as the ohmic contact at the back of a macroscopic semiconductor electrode. It is this couple which determines p_s^D and θ_F . It can be seen that the further E_F' lies above the edge of the valence band, the lower p_s^D is but the more energy is lost. In the case of the macroscopic semiconductor this energy is lost in the semiconductor as the photogenerated carriers are separated by the field. In the case of the particle the free energy is lost in the irreversibility of the $R' \rightarrow O'$ reaction. It must be remembered that the position of the Fermi level for the O'/R' couple includes the $(RT/F) \ln ([O']/[R'])$ term, which arises from the entropy of mixing in the electrolyte solution. This discussion suggests that to obtain the largest possible voltage ΔE , one should locate E_F' so that $\theta_F = \theta_s$. This minimizes the voltage loss but maintains the field throughout the particle. However, as shown in Fig. 6 and 7, in certain cases N is increased if one lowers p_s^D or increases θ_F . The optimum power will be obtained by sacrificing voltage to obtain the maximum current.

We define the power conversion efficiency (γ) for monochromatic light of an energy that matches the bandgap as

$$\gamma = N(1 - \theta_F/\theta_{BG}) \tag{32}$$

where θ_{BG} describes the energy of the bandgap. The optimum value for a device for solar energy conversion (10) is

$$\theta_{BG} = 60 \tag{33}$$

which corresponds to a bandgap of 1.5 eV.

Fig. 8. Diagram showing the conversion of solar energy into electrical energy for a particle and for a macroscopic semiconductor (broken lines). The energy loss is given by θ_F in both cases; in the macroscopic semiconductor this occurs in the bulk of the semiconductor material, while in the case of the particle it occurs at the particle electrolyte interface.

Three Different Strategies for Efficient Conversion

With these considerations, three possible strategies emerge. Optimized devices can be found for cases I, II, 1, and III, 1 in Fig. 6 and 7. We need not consider cases II, 2, and III, 2, because for these cases increasing θ_F will not increase the collection efficiency, but will decrease $(\theta_{BC} - \theta_F)$ and hence γ .

We now discuss each strategy in turn. First we consider the situation where k_n' is large and the photo-generated minority carriers are removed rapidly from the particle. The low value of n then means that the kinetics are case I. Recombination inside the particle is not affected by the concentration of majority carriers. We assume that this concentration is relatively unperturbed from its value in the dark and is given by p_s^D . As discussed above, we can then set p_s^D so that

$$\theta_F = \theta_s = \frac{1}{6} (\tau_s/L_D)^2 = \frac{1}{6} \rho^2 \quad [34]$$

We would like θ_F to be as small as possible. This is achieved with a small value of ρ . The expression for N can be written

$$N = \frac{1}{1 + 3 \frac{k_1 L_D}{k_n' \rho}} \quad [35]$$

The kinetic ratio is smaller the larger the value of ρ . Hence there is an optimum value of ρ , and one does not want a field-free particle.

Substitution from Eq. [33], [34], and [35] in [32] followed by differentiation allows one to find for different values of $(k_1 L_D/k_n')$ these optimum values for ρ together with the corresponding values of N , γ , and θ_F . The results are plotted in Fig. 9. The insets show how, for any particular value of $(k_1 L_D/k_n')$, γ varies with ρ , or, in other words, how critical it is to match the radius of the particle to the Debye length. In the main part of the diagram the broken lines show the values of ρ where γ is 80% of its maximum value. From the results in Fig. 9, we can conclude that, even with the optimum choices of τ_s/L_D and of θ_F , the device will be hopelessly inefficient unless

$$k_n' > k_1 L_D \quad [36]$$

Systems that meet this condition do not require very precise matching of τ_s to L_D ; it is sufficient for the radius to be smaller than 8 times the Debye length.

It is also necessary to remove the holes from the particle, and this requires for $N \approx 1$ that

$$k_p' > J/p_s^D \quad [37]$$

where J is defined in Eq. [2]. If this condition is violated the concentration of holes will build up at the center of the particle. With the condition that $\theta_F = \theta_s$, the center of the particle is close to being field free, and so a significant increase in the concentration of holes will lead to the particle's becoming metallic. In Eq. [37] we can therefore write

$$p_s^D \approx p_{FB}^D \exp(-\theta_F) \quad [38]$$

giving

$$k_p' > J \exp(\theta_F)/p_{FB}^D \quad [39]$$

Turning next to case II, 1, the expression for N from Table I is

$$N = \frac{1}{1 + \frac{1}{3} k_{II} L_D p_{FB}^D \rho_s \exp\left(-\frac{1}{6} \rho_s^2\right) / k_n'} \quad [40]$$

The k_{II} term can be reduced to insignificance ($N \approx 1$) by increasing ρ_s in the exponential term. However, increasing ρ_s increases θ_F , and so once again there is an optimum value of ρ_s . Results for the optimum values of ρ_s , N , γ , θ_F , and k_p' are shown in Fig. 10. Again the insets show how γ varies with ρ_s . The condition for k_p' is the same as that for the strategy given in Eq. [39]. This condition is the same as the boundary between cases II, 1 and II, 2, and makes certain that the system has not crossed this boundary. Turning to k_n' , we find that for $N = 1$

$$k_1 L_D > k_n' > k_{II} J/k_2 \quad [41]$$

The first part of this condition means that N in case I is < 1 and that it is necessary to cross from I into II, 1 to increase N , even though this will reduce γ by reducing $(\theta_{BC} - \theta_F)$. The second part of this condition ensures that the system lies below the horizontal lines in Fig. 6 and 7 and so will cross from case I into case II, 1.

Returning to Fig. 10, it can be seen that in case II, 1, values of θ_F can usually be found which maintain N and γ close to unity. However, a large value of θ_F may violate the condition for k_p' in Eq. [39]. The results in Fig. 10 show that

$$\theta_F \approx \ln(k_{II} L_D p_{FB}^D/k_n') \quad [42]$$

since this is the value required to reduce the k_{II} term in Eq. [40] to insignificance. Substitution of this value in Eq. [39] gives

$$k_p' k_n' > k_{II} J L_D \quad [43]$$

For a successful II, 1 device we require k_n' to satisfy the conditions in Eq. [41] and k_p' to satisfy Eq. [43].

Fig. 9. The conditions for the optimum power production for case I. The diagram shows how the optimum values of N , γ , ρ_s , and θ_F depend upon the case I kinetic parameter ($3 k_1 L_D/k_n'$); k_p' must be greater than the values shown. The insets at each particular value of ($3 k_1 L_D/k_n'$) show how γ , the power conversion efficiency, varies with ρ_s ($= r_s/L_D$). The broken lines show the values of ρ_s , for which γ is 80% of its maximum value.

Furthermore, there has to be a fairly precise matching of the radius of the particle to the Debye length, as shown in Fig. 10.

Finally, for case III, 1 from the results in Table I, we find that with the field

$$N = 1 - \frac{3 C k_2 L_\epsilon \exp\left(\frac{1}{6} \rho_s^2\right) p_s^D}{\rho_s^3 I} \quad [44]$$

Differentiation shows that the kinetic term is minimized with

$$\rho_s = 3 \quad [45]$$

giving a similar result to that for the field-free particle. For this case, as discussed above, we want small particles with θ_s close to unity so as to prevent accumulation and loss of the holes in the center of the particle. The kinetic term is further reduced by reducing p_s^D , but this also increases θ_F . Substitution of Eq. [12], [44], and [45] in Eq. [32] for γ and differentiation shows that the optimum value is

$$p_s^D \simeq \frac{9I}{C \theta_{BG} e^{1.5} k_2 L_\epsilon} \quad [46]$$

giving

$$\gamma \simeq (1 - \theta_F/\theta_{BG}) \quad [47]$$

and

$$\theta_F = \ln [p_{FB}^D / (p_s^D)_m] \quad [48]$$

For these conditions to be possible and for the system to be in case III, 1 we require

$$k_p' > C \theta_{BG} e^{1.5} k_2 L_D/9 \quad [49]$$

$$k_n' < k_{II} J/K_2 \quad [50]$$

and

$$k_n' < C \theta_{BG} e^{1.5} L_D/9 \quad [51]$$

Equations [49], [50], and [51] refer to the III, 2, II, 1, and I boundaries of zone III, 1 in Fig. 7, respectively. A further condition for k_n' is that it must be large enough to prevent a buildup of electrons comparable to the doping density

$$k_n' > J/p_{FB}^D \quad [52]$$

Inspection of the conditions in Eq. [36]-[52] for the three different strategies shows that there are the three characteristic parameters of the system, as given in Table II. To simplify, we have assumed that $k_1 = k_2$. Typical values for each parameter are also given. We can now combine the conditions in Eq. [36]-[52] in a single diagram (Fig. 11), which shows how the strategy to be followed depends upon the vital kinetic parameters k_n' and k_p' .

It is not surprising that case I requires a large value of k_n' ($\sim 10^4 \text{ cm s}^{-1}$) to remove the minority carriers and has a much less severe condition for k_p' . Conversely, case III, 1 requires a large value of k_p' to remove the holes but a much less severe condition for k_n' . The intermediate case II, 1, where recombination is prevented by removing both holes and electrons, has a mixed condition involving both k_n' and k_p' . Figure 11 shows that for efficient conversion at least one of the rate constants k_n' or k_p' has to be rather large ($\sim 10^4 \text{ cm s}^{-1}$) in order to remove the carriers from the particle and thereby prevent recombination in the almost field-free particle. The value of θ_F required for optimization for an efficient device increase from case I ($\theta_F \sim 0$) through case II, 1 (Fig. 10) to case III (Eq.

Fig. 10. The conditions for the optimum power production for case II, 1. The diagram shows how the optimum values of N , γ , ρ_{sr} and θ_F depend upon the case II, 1 kinetic parameter ($k_{II} L_D p_{FB}^D / 3k_n'$); k_p' must be greater than the values shown. The insets at each particular value of ($k_{II} L_D p_{FB}^D / 3k_n'$) show how γ varies with $\rho_s (=r_s/L_D)$. The broken lines show the values of ρ_s for which γ is 80% of its maximum value.

[48]). In particular, for case III using the values in Table II we find that $\theta_F \approx 20$ or a third of the value of θ_{BC} . For this reason the natural strategy of removing the minority carriers rapidly (I) is to be preferred to strategy III, where the majority carriers are allowed to accumulate. In the latter case it would be better to change the doping type (n to p or p to n) of the semiconductor and hence convert a case III situation to a case I. Finally, our work shows the importance of matching the radius of the particle to the Debye length. For nearly all of the optimum cases the radius should be a few multiples of the Debye length.

APPENDIX

In this Appendix we derive the results in Table I. We start by deriving expressions for the surface concentration n_s and p_s by eliminating j between Eq. [2], [3], and [5]

$$n_s = \frac{1}{3} gr_s N / k_n' \quad [\text{A-1}]$$

and

$$p_s = p_s^D + \frac{1}{3} gr_s N / k_p' \quad [\text{A-2}]$$

Table II. The three parameters in Eq. [36]-[52]

Parameter	Typical value
$k_1 L_D \sim k_2 L_D$	$10^4 \text{ cm s}^{-1} \text{ a}$
$k_{II} J / k_2$	$10^{-1} \text{ cm s}^{-1} \text{ b}$
J / p_{FB}^D	$10^{-3} \text{ cm s}^{-1} \text{ c}$

^a $k_1 \approx 10^{10} \text{ s}^{-1}$ $L_D \sim 10^{-6} \text{ cm}$.
^b $J = 1/3 I (r_s / L_D) I \sim 10^{-7} \text{ mol cm}^{-2} \text{ s}^{-1}$ (10).
 $r_s \sim 3 \times 10^{-7} \text{ cm}$ $L_D \sim 10^{-4}$ giving $J = 10^{-10} \text{ mol cm}^{-2} \text{ s}^{-1}$; $k_{II} / k_2 \sim 10^9 \text{ mol}^{-1} \text{ cm}^3$ corresponding to a shift from term I to term III in Eq. [16] at $p \sim 10^{-9} \text{ mol cm}^{-3}$.
^c Value of J as in note b with $p_{FB}^D \sim 10^{-7} \text{ mol dm}^{-3}$.

Fig. 11. Diagram showing how the three different optimum strategies depend upon the values of the surface rate constants k_p' and k_n' . For simplicity we have assumed that $k_1 = k_2$. Efficient systems are found towards the northeast corner. The broken line separates case A systems from case C.

For each of the cases in Table I we have to evaluate the integral κ where

$$\kappa = \int_0^{r_s} r^2 v dr \quad [\text{A-3}]$$

and v is given by Eq. [16].

For case I

$$v = k_1 n = k_1 n_s \exp(\theta - \theta_s) \quad [\text{A-4}]$$

where from Eq. [9]

$$\exp(\theta) = \exp(\rho^2/6) = \exp(\lambda^2) \quad [\text{A-5}]$$

Substitution from Eq. [A5] and [A4] in Eq. [A3] gives

$$\kappa = k_1 n_s L_D^3 \exp(-|\theta_s|) 6^{3/2} \int_0^{\rho_s/6^{1/2}} \lambda^2 \exp(\lambda^2) d\lambda$$

where

$$\rho_s = r_s/L_D \quad [\text{A-6}]$$

Assuming that ρ_s is significantly greater than 1, say greater than 8, for there to be significant band bending ($\theta_s > 10$), then we can integrate by parts

$$\begin{aligned} 6^{1/2} \int_0^{\rho_s/6^{1/2}} \lambda^2 \exp(\lambda^2) d\lambda &= \frac{1}{2} \rho_s \exp(\theta_s) \\ &- \frac{1}{2} 6^{1/2} \int_0^{\rho_s/6^{1/2}} \exp(\lambda^2) d\lambda \\ &\simeq \frac{1}{2} \rho_s \exp(\theta_s) \end{aligned}$$

because the second integral is negligible compared to the original integral. Substitution in Eq. [4]-[6] gives

$$\kappa = 3 k_1 n_s r_s L_D^2 \quad [\text{A-7}]$$

Elimination of n_s and κ between Eq. [A-1], [A-7], and [19] gives the result for N in Table I. For n_s itself we obtain

$$n_s = \frac{\frac{1}{3} \rho_s^2 g}{3 k_1 + \rho_s k_{\pi}'/L_D} \quad [\text{A-8}]$$

For case II throughout the sphere

$$v = k_{II} n_s p_s$$

so that

$$\kappa = \frac{1}{3} k_{II} n_s p_s r_s^3 \quad [\text{A-9}]$$

Elimination of n_s , p_s , and κ between Eq. [A-1], [A-2], [A-9], and [19] gives the result for N in Table I.

For case II

$$v = k_2 p = k_2 p_s \exp(\theta_s - \theta) \quad [\text{A-10}]$$

Substitution from Eq. [A-5] and [A-10] in Eq. [A-3] gives

$$\begin{aligned} \kappa &= k_2 p_s L_D^3 \exp(\theta_s) 6^{3/2} \int_0^{\rho_s/6^{1/2}} \lambda^2 \exp(-\lambda^2) d\lambda \\ &\simeq C k_2 p_s L_D^3 \exp(\theta_s) \end{aligned} \quad [\text{A-11}]$$

where

$$C = (3/2) (6\pi)^{1/2} = 6.51$$

and we have assumed that $\rho_s/6^{1/2}$ is greater than 4.

Elimination of p_s and κ between Eq. [A-2], [A-11], and [19] gives the result for N in Table I. The result for p_s is

$$p_s = \frac{p_s^D + \frac{1}{3} g p_s L_D k_p'}{1 + C k_2 L_D \exp(\theta_s)/k_p' \rho_s^2} \quad [\text{A-12}]$$

For the I/III case we follow the approach of Sah *et al.* (11). From Eq. [16]

$$\frac{1}{v} = \frac{1}{k_1 n} + \frac{1}{k_2 p}$$

and there is some value of θ , θ_* ($0 < \theta_* < \theta_s$) where

$$k_1 n_* = k_2 p_* = k_0 \quad [\text{A-13}]$$

Then

$$v = \frac{1}{2} k_0 \operatorname{sech}(\theta - \theta_*) \quad [\text{A-14}]$$

and has its maximum value at $\theta = \theta_*$.

From Eq. [A-3] and [A-14]

$$\begin{aligned} \kappa &= 3(3/2)^{1/2} k_0 L_D^3 \int_0^{\theta_s} \theta^{1/2} \operatorname{sech}(\theta - \theta_*) d\theta \\ &\simeq 3(3/2)^{1/2} k_0 L_D^3 \theta_*^{1/2} \int_{-\infty}^{+\infty} \operatorname{sech}(\lambda) d\lambda \\ &= (3\pi/2) k_0 r_s L_D^2 \end{aligned} \quad [\text{A-15}]$$

where

$$r_s/L_D = (\theta_*/6)^{1/2} \quad [\text{A-16}]$$

Applying the Boltzmann distribution to Eq. [A13]

$$\exp(\theta_* - \theta_s) = (k_2 p_s/k_1 n_s)^{1/2} \quad [\text{A-17}]$$

and

$$k_0 = (k_1 k_2 p_s n_s)^{1/2} \quad [\text{A18}]$$

Elimination of p_s , n_s , k_0 , and κ between Eq. [A-1], [A-2], [A-15], [A-18], and [19] gives the results for N in Table I.

The expression for r_s in Table I is derived by substituting from Eq. [A-1], [A-2], and [A-17] into Eq. [A-15].

Mechanisms of Charge Transfer at the Semiconductor-Electrolyte Interface

I. Kinetics of Electroreduction at Dark of $\text{Fe}(\text{CN})_6^{3-}$ and IrCl_6^{2-} in Aqueous Solution on a Sintered Nb-doped n-SrTiO₃ Electrode: Influence of pH

ABSTRACT

The dark cathodic reduction of $\text{Fe}(\text{CN})_6^{3-}$ and IrCl_6^{2-} in aqueous solution on a sintered Nb-doped SrTiO₃ electrode, at acidic and basic pH, has been studied as a function of the potential and concentration of the oxidized species. With $\text{Fe}(\text{CN})_6^{3-}$, two different regions are observed. At low band bending (high current-density region), the current saturates with increasing concentration of oxidant species, and a pH-independent Tafel slope of ~ 130 mV is found. By contrast, at higher band bending (low current-density region), the current is proportional to the electrolyte concentration, and the Tafel slope increases dramatically at basic pH with respect to that at acidic pH. Ullman's model of isoenergetic electron transfer limited by transport resistance in the semiconductor depletion layer cannot account for this behavior. However, our results are compatible with the two-step kinetic model of charge transfer, involving bandgap surface states, proposed by Vandermolen *et al.* (16). At least two sets of surface states with different energies within the bandgap actively mediate charge transfer through the semiconductor electrolyte interface. Experiments with IrCl_6^{2-} show that these surface states could result from the interaction of the semiconductor surface with H^+ , OH^- , and H_2O solvent species.

Both n-TiO₂ and n-SrTiO₃ are wide-bandgap semiconductors whose behavior as photoanodes in photoelectrochemical cells for water splitting has been intensively studied. However, charge transfer at the interface is still far from being understood. Due to their strong ionic character these oxides have a high ionization potential, and consequently the overlap between the valence band and the filled levels of water molecules is negligible, which makes impossible a direct, isoenergetic transfer of electrons from the water molecules to the valence band during water photo-oxidation.

There is experimental evidence that bandgap surface states can capture holes photogenerated in the valence band (1-7). These surface states could mediate the isoenergetic transfer of electrons from the water molecules. We have recently shown (8, 9) that these surface states could involve surface hydroxyls generated by interaction of the semiconductor with the electrolyte. Both in n-TiO₂ and in n-SrTiO₃ the valence band is made up of filled O:2p orbitals, while the conduction band proceeds from the empty Ti:3d (*t_{2g}*) orbitals. At the surface, in the last atomic layer, the crystal field symmetry of the Ti⁴⁺ and O²⁻ ions is lower than in the bulk, which splits the Ti:3d and O:2p orbitals with formation of new energetic levels in the bandgap. This is supported by the cluster calculations of Kowalski *et al.* (10). Besides, both Ti⁴⁺ and O²⁻ surface ions have a great activity towards solvent OH⁻ and H⁺ ions, respectively, giving rise to different types of chemisorbed OH⁻ groups (surface states) (11), some of them with energies within the bandgap (10). These surface states have been recently used by the authors (12) in a simple model of water photo-oxidation.

Another unknown mechanism is that concerning the dark cathodic reduction of oxidized electrolyte species (13-18). The question arising is whether the transfer of electrons from the conduction band to the empty levels of the electrolyte is direct (isoenergetic) or if it is an inelastic process mediated by surface

states. The study of this process could lead to industrial applications, as the growing importance of electrocatalysis shows (19). We have shown recently (20) that dark reactions can act as back reactions during water photo-oxidation on SrTiO₃ and TiO₂ photoanodes in a photoelectrochemical cell, producing characteristic photocurrent transients responsible for an important decrease of the quantum efficiency.

Neither TiO₂ (15, 16) nor SrTiO₃ (16) follow the simple model for electron transfer from the conduction band to oxidized electrolyte species typical of other well-behaved semiconductor oxides like n-ZnO (21, 22): their Tafel slopes are higher than 60 mV, and the cathodic current tends towards a saturation value upon increasing the concentration of the oxidant. Bard *et al.* (15) were the first to invoke mediation of charge transfer by surface states in order to explain the anomalously high Tafel slopes. More recently, Vandermolen *et al.* (16) found Tafel plots with two different regions: at higher currents the Tafel slope was 60 mV and there was current saturation, while at lower currents the Tafel slope was higher than 60 mV and the current was proportional to the concentration of oxidant. They proposed a two-step kinetic model involving bandgap surface states to explain this phenomenon of current saturation, which had never before been observed in electrochemistry. Later, Ullman (23) attributed current saturation to transport resistance in the space-charge region due to the low carrier mobilities in the wide bandgap semiconductors used.

In the present work, we study the dark cathodic reduction of $\text{Fe}(\text{CN})_6^{3-}$ on a Nb-doped, sintered SrTiO₃ electrode, using as supporting electrolyte 1M Na₂SO₄ at pH 3 and 11. At smaller band bendings (*i.e.*, at higher currents) the cathodic current (*j*⁻) reaches a saturation value at increasing concentration of the oxidized species (*C_{ox}*). In this region, the Tafel slope is ~ 120 mV and pH independent. In the region of higher band bendings (*i.e.*, at lower currents), the current is proportional to the concentration of oxidant, and the Tafel slope is very sensitive to the electrolyte pH.

Key words: semiconductor, interface, electroreduction, kinetics.

These results cannot be explained by Ullman's model. However, they are compatible with the two-step mechanism proposed by Vandermolen *et al.* (16), involving mediation of charge transfer by surface states. We think that these surface states result from the interaction of the semiconductor surface with the different species (OH^- , H^+ , and H_2O) of the solvent (24), and whose energy within the bandgap depends on the pH.

These results are in agreement with our previous findings about the influence of pH on the dark electroreduction of O_2 on n-TiO₂ (18), giving further support to our previous model (8, 9), in which different OH groups covering the semiconductor surface in aqueous medium are active centers for charge transfer between the semiconductor and the electrolyte, not only in water photoelectrolysis, but also in the electroreduction at dark of dissolved oxidized species as well. Finally, we estimate some of the parameters characterizing these surface states and put forward some hypotheses about the influence of pH on their origin.

Experimental

Electrode.—The sintered SrTiO₃ electrode containing 5 weight percent (w/o) Nb₂O₅ was prepared by the Laboratoire de Chimie du Solide, Bordeaux, France, from the single oxides (25). The resistivity was 3 Ω cm, and the geometrical surface in contact with the electrolyte was ~ 0.25 cm². No chemical or mechanical pretreatment of the electrode was effected.

Materials.—All chemicals were reagent grade. The supporting electrolyte was 1M Na₂SO₄, whose pH was adjusted to 3 and 11 with H₂SO₄ and NaOH, respectively. The oxidized species were K₃Fe(CN)₆ and H₂IrCl₆, in concentrations from 10⁻³ to 10⁻¹M. Ultra-pure water was obtained from a Milli-RO+Milli-Q (Millipore, Bedford, Massachusetts) assembly; solutions were previously deoxygenated by N₂ bubbling with vigorous magnetic stirring.

Current measurement.—A simple one-compartment cell was used (18), with a smooth Pt sheet as auxiliary

electrode, and a saturated calomel electrode (SCE) as reference. The potentiostat was a Potentiostat POS 73 from Wenking. Currents were measured with a digital multimeter, Keithley 177 Microvolt DMM. Prior to experiments with each solution, the electrode was left in contact with it for 24h. Stationary currents were measured allowing 13-30 min at each polarization potential to ensure establishment of equilibrium. Fresh electrolyte was used in each measurement.

Capacitance measurement.—Tomkiewicz's method (26) was used in the range 60 Hz-10 kHz. The waveform generator was a Leader LAG-125, and the lock-in amplifier a PAR 5204.

Results

Characterization of the semiconductor; Mott-Schottky plots.—In Fig. 1 we give plots of $1/C^2$ vs. V (C = differential cell capacitance, V = polarization potential vs. SCE) in 1M Na₂SO₄, pH 11 at several frequencies. Each line is the result of a least squares fit to at least 30 points obtained at successively increasing and then decreasing potentials. The slope increased with increasing frequency, although all the lines had a common intersection point (flatband potential V_{FB}) with the abscissa axis. According to Tomkiewicz (26), if this behavior is due to electrode inhomogeneity, then the measurements at the highest frequency most accurately correspond to the space-charge layer. Therefore, in the following we only show measurements at 30 kHz, the maximum frequency we could use.

In Fig. 2 we give the Mott-Schottky plots in 1M Na₂SO₄ at pH 3 and 11. Addition of K₃Fe(CN)₆ or H₂IrCl₆ did not affect the results. Two straight lines with the same slope are obtained in the interval -0.6 to $+1V$ vs. SCE. The shift of V_{FB} with pH is of 63 mV/pH unit, the typical Nernstian behavior of oxides with H^+ and OH^- as potential determining ions (27).

From the slope of the Mott-Schottky equation

$$C_{\text{sc}}^{-2} = (2/q\epsilon\epsilon_0 N_D A^2) (V - V_{\text{FB}} - kT/q) \quad [1]$$

where C_{sc} is the differential capacitance of the semicon-

Fig. 1. Mott-Schottky plots of Nb-doped n-SrTiO₃ for several frequencies in 1M Na₂SO₄, pH 11

ductor depletion layer, we can obtain the donor concentration N_D , provided we know the semiconductor dielectric constant (ϵ) and the true surface area in contact with the electrolyte (A). (ϵ_0 is the vacuum permittivity). Assuming $\epsilon = 300$ (28) and a roughness coefficient ~ 4 , we obtain from the experimental slope $N_D \approx 10^{19} \text{ cm}^{-3}$. For comparison, N_D can be also calculated from the conductivity σ and the mobility μ through the equation $N_D = \sigma/q\mu$, assuming that most donors are ionized at room temperature, as is the case with Nb-doped TiO₂ (29). The value of the mobility necessary to obtain the same N_D as from Mott-Schottky plots is $\sim 0.1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, about two orders of magnitude lower than that of $6 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ measured for monocrystalline SrTiO₃ (30). This large decrease in mobility can be explained by carrier trapping at grain boundaries in the sintered material (31).

Mott-Schottky plots of highly doped semiconductors.

—For Eq. 1 to hold, it is necessary that

$$C_{sc} \ll C_H \quad [2]$$

(C_H = differential capacity of the Helmholtz layer), in which case it is

$$\phi_s \gg \Delta\phi_H \quad [3]$$

where ϕ_s and $\Delta\phi_H$ represent the potential drop in the depletion layer of the semiconductor and the change in the potential drop (ϕ_H) of the Helmholtz layer brought about by polarization, respectively. Linearity of C^{-2} vs. V plots is usually taken to mean that Eq. [2] and [3] apply to the system under study. However, de Gryse *et al.* (32) have shown that in highly doped semiconductors, as is the case here ($N_D \approx 1 \times 10^{19} \text{ cm}^{-3}$), C^{-2} vs. V plots are also linear, although Eq. [1]–[3] do not hold. According to them, under these circumstances, i.e., when the capacity of the depletion region is comparable to that of the Helmholtz layer and therefore a sizable fraction of applied potential drops in the Helmholtz layer, Eq. [1] must be substituted for with

$$C^{-2} = C_H^{-2} [1 + (2C_H^2/\epsilon\epsilon_0 A^2 q N_D) (V - V_{FB} - kT/q)] \quad [4]$$

It is remarkable that Eq. [1] and [4] predict the same slope in C^{-2} vs. V plots, although in Eq. [4] the intercept with the abscissa axis is shifted, relative to that of Eq. [1], towards more negative potentials by the amount

$$\Delta V = q\epsilon\epsilon_0 N_D / 2C_H^2 \quad [5]$$

For $C_H = 2 \times 10^{-5} \text{ F cm}^{-2}$, ΔV becomes already significant at $N_D \approx 10^{19} \text{ cm}^{-3}$.

De Gryse *et al.* (32) also obtained a formula relating $\Delta\phi_H$ to N_D

$$\Delta\phi_H = \left(\frac{2\epsilon\epsilon_0 q N_D}{C_H^2} \right)^{1/2} \left(\phi_s - \frac{kT}{q} \right)^{1/2} \quad [6]$$

This formula, together with the obvious

$$V - V_{FB} = \phi_s + \Delta\phi_H \quad [7]$$

allows us to calculate $\Delta\phi_H/\phi_s$ as a function of polarization potential. Taking $\epsilon = 300$ and $C = 2 \times 10^{-5} \text{ F cm}^{-2}$, we have obtained in this way $\Delta\phi_H$ as a function of $(V - V_{FB})$ (Fig. 3). For the first 0.8V it is $\Delta\phi_H/\phi_s \sim 1$, i.e., about half of the change in applied potential goes to the Helmholtz layer and only the other half to the depletion region

The value of V_{FB} obtained from the Mott-Schottky plot in Fig. 2 should now be corrected by $\Delta V = 0.1V$ according to Eq. [5]. Therefore, V_{FB} is $-1.15V$ at pH 11, and $-0.65V$ at pH 3, about 200 mV negative of E° (H^+/H_2), as usually found for SrTiO₃ (28).

We can now construct with the help of Fig. 3 the diagram of energy levels in Fig. 4, which shows the potential dependence of the semiconductor energy levels with respect to those of the electrolyte. This diagram will be used later on. We have taken E°_{redox} ($Fe[C�]_6^{3-}/Fe[C�]_6^{4-}$) = $+0.25V$ vs. SCE, with a reorganization energy $\lambda = 0.75V$ both at pH 3 and 11. This value of λ is that obtained from measurements on ZnO (22) in the pH range 4.8–12.0 although, according to theoretical calculations (33), λ should change from 0.63V in a strongly basic medium to 1.5V in a strongly acidic medium.

Dark cathodic reduction of $Fe(CN)_6^{3-}$.—Residual currents in the absence of oxidized species were 10^{-7} – $10^{-8}A$. At potentials negative of the H^+/H_2 redox couple, there was a large increase of cathodic current corresponding to H_2 evolution. The residual currents, when significant, were subtracted from the currents of the oxidized species.

In Fig. 5 we give a semilog plot of the reduction current density vs. potential for different concentrations of $K_3Fe(CN)_6$. As mentioned above, the true area of the electrode was taken to be 1 cm^2 . The families of curves on the left- and right-hand sides correspond to pH 11 and 3, respectively. All the current values are free from mass-transport effects, for which purpose strong agitation was needed at the highest currents.

Fig. 3. Dependence of ϕ_s and $\Delta\phi_H$ on the applied polarization ($V - V_{FB}$) according to Eq. [24]. The following parameters were assumed: $\epsilon = 300$, $C_H = 20 \mu F cm^{-2}$, $N_D = 10^{19} cm^{-3}$.

Two segments can be clearly appreciated in each curve. At higher currents there is, both at pH 3 and 11, a segment with a slope of ~ 130 mV at potentials more negative than -0.1 and -0.55 V, respectively. However, at lower currents the behavior at pH 11 is very different from that at pH 3. At pH 11 there is a nearly horizontal plateau, with a slope of ~ 2.2 V, between

-0.5 and $+0.1$ V, while at pH 3 only a short segment with a slope of ~ 320 mV appears between -0.1 and $+0.1$ V. At potentials more positive than $+0.1$ V, the slope decreases drastically at the two pH values.

Dependence of the cathodic current on the concentration of $Fe(CN)_6^{3-}$.—As already found by Vandermolten *et al.* (16), at a given potential current saturation

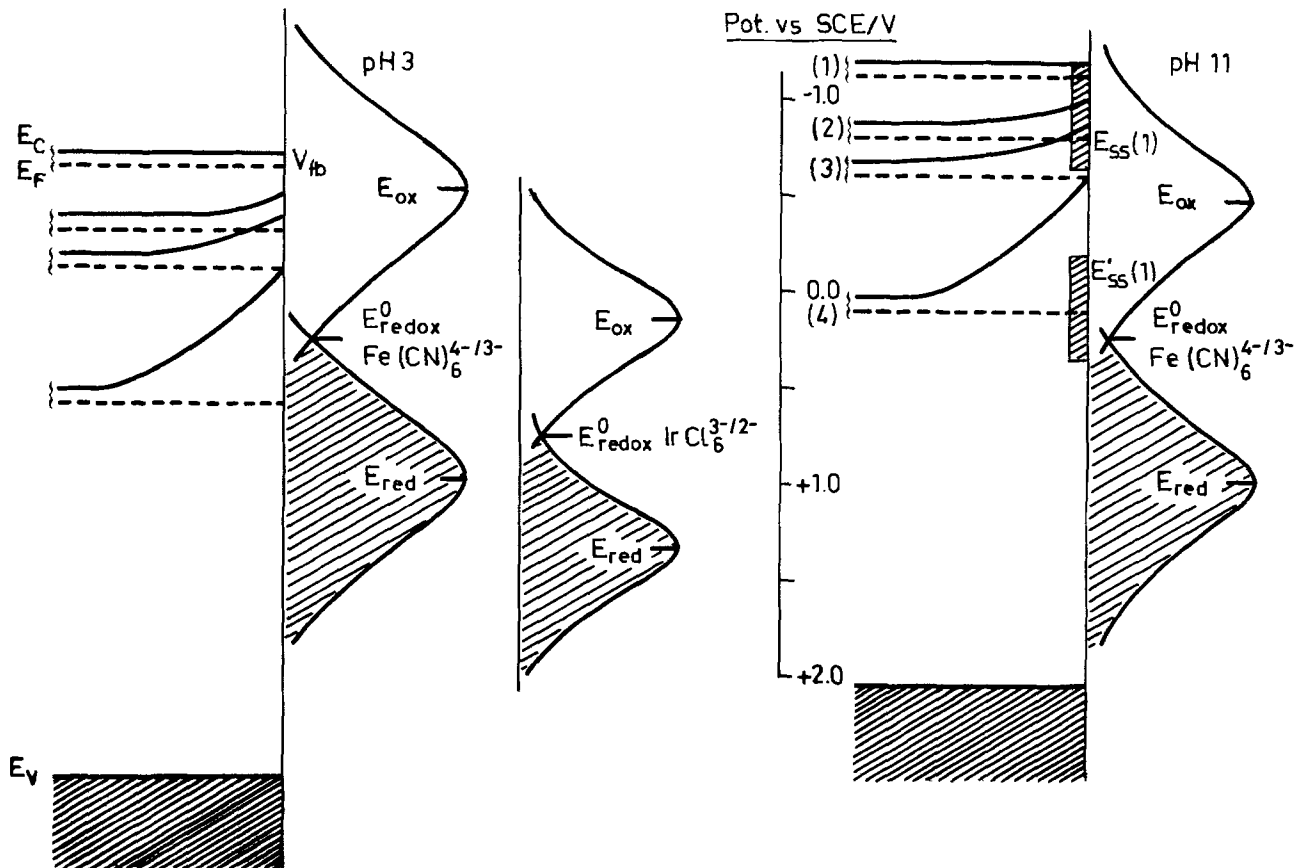

Fig. 4. Diagram of energy levels of n-Sr TiO_3 at pH 3 and 11, and of the empty and filled levels of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ and $IrCl_6^{2-}/IrCl_6^{3-}$ couples. The shift of E_c (bottom of the conduction band) at the semiconductor surface with increasing positive polarization has been taken from Fig. 3. In the diagram for pH 11 the two sets of surface states have been included; their position is that at the flatband condition. The energetic distribution of the surface states is not known.

Fig. 5. Tafel plots of the log of the current density vs. potential for different concentrations of $\text{Fe}(\text{CN})_6^{3-}$, at both pH 3 and 11

tion is found only in the segment of higher currents (in our case that with a slope of 130 mV), while the normal behavior (i.e., proportionality between current and concentration) was observed only in the segment of lower currents with a higher Tafel slope.

The empirical relationship between current j^- and concentration C_{ox} in the segment of higher currents was the same found for the first time by Vandermolen *et al.* (16)

$$j^- = \frac{j^-_{\text{sat}} \cdot C_{\text{ox}}}{K + C_{\text{ox}}} \quad [8]$$

In this equation of the Langmuir type, j^-_{sat} is the saturation current reached at high enough concentrations, and K is a constant. We show in Fig. 6 typical curves of j^- vs. C_{ox} at -0.6 and -0.8 V, where the typical saturation behavior can be appreciated. We can rearrange [8] into

$$\frac{1}{j^-} = \frac{K}{j^-_{\text{sat}}} \cdot \frac{1}{C_{\text{ox}}} + \frac{1}{j^-_{\text{sat}}} \quad [9]$$

A plot of $1/j^-$ vs. $1/C_{\text{ox}}$ gives a straight line of intercept $1/j^-_{\text{sat}}$ and slope K/j^-_{sat} . These plots are included in Fig. 6.

In Fig. 7 we have plotted $\log j^-_{\text{sat}}$ vs. V . Two parallel straight lines are obtained at pH 3 and 11, respectively. Their lateral displacement shows practically the same Nernstian behavior as found for V_{FB} (Fig. 2). In the segment of lower currents, the classical proportionality between current and concentration is obeyed at the two pH values, i.e.

$$j^- = K' \cdot C_{\text{ox}} \quad [10]$$

In Fig. 8 we show such behavior at different potentials

for pH = 11. Obviously, K' increases with increasing negative potential.

Dependence of $\log j^-$ on band bending.—With the data of Fig. 3 we can now plot $\log j^-$ vs. ϕ_s , at both pH 3 and 11. The plot for 10^{-2} M $\text{Fe}(\text{CN})_6^{3-}$ is given in Fig. 9. At lower band bendings ($\phi_s < 0.3$ V) and higher currents, the same plot with a Tafel slope of ~ 65 mV is obtained at pH 3 and 11, while at higher band bendings the currents at pH 11 are considerably higher than at pH 3.

Discussion

Models for charge transfer.—Two different mechanisms could be envisaged to account for the transfer of electrons from the conduction band to empty electrolyte levels: (i) isoenergetic transfer of electrons from the bottom of the conduction band at the surface to the empty levels of the oxidized species through the Helmholtz layer at the semiconductor-electrolyte interface. In the following, this will be designated the classical model of fluctuating energy levels. (ii) Inelastic charge transfer through bandgap surface states in a two-step mechanism: filling of surface states with conduction band electrons, and further isoenergetic transfer to empty electrolyte levels (15).

The model to be used must be coherent with the experimental results, which can be summarized by two main features: the current saturation with increasing oxidant concentration in the region of higher currents (i.e., lower band bendings), where the Tafel slope is ~ 130 mV and independent of pH, and the existence of a second region with lower currents (i.e., higher band bendings) where there is proportionality between current and oxidant concentration. In this region the Tafel slope strongly depends on the pH.

Fig. 6. Plots of the current density, j^- , vs. ferricyanide concentration, C_{ox} , at pH 11, for polarization potentials of $-0.8V$ (left) and $-0.6V$ (right) vs. SCE, which are within the saturation region, with a Tafel slope of 130 mV , in Fig. 5. The same data are also plotted as $1/j^-$ vs. $1/C_{ox}$ in order to show that they obey a Langmuir-type equation (Eq. [8]); the intersection with the vertical axis gives us j^-_{sat} .

Let us try the two models separately.

The classical model is isoenergetic charge transfer.— This model was first developed by Marcus (34) and then by Gerischer (35). Different mathematical approaches based on this fluctuating energy model have been made to find an explicit relationship between current and potential (36-39). Morrison (39) obtained the following simplified formula

$$j^- = qv\sigma_1 n_s d C_{ox} \left(\frac{kT}{\pi\lambda} \right)^{1/2} \exp \frac{-(E_{cs} - E_{ox})^2}{4\lambda kT} \quad [11]$$

In this approximation it is assumed that all ions within a distance d of the surface are active in capturing electrons and have the same capture cross section σ_1 , v is the thermal velocity of electrons in the conduction band, λ the reorganization energy, E_{cs} the bottom of the conduction band at the surface, and E_{ox} the more probable energy level of the oxidized species. n_s is the density of electrons at the surface, and depends on the band bending according to

$$n_s = n_b \cdot \exp -q\phi_s/kT \quad [12]$$

where n_b is the bulk density of conduction band electrons.

This classical model predicts that, provided E_{cs} does not change with polarization, the current is proportional both to n_s and C_{ox} , and therefore cannot give account of the observed current saturation. However, Ullman (23) has recently proposed that current limitation could be due to transport resistance in the space-charge region of low mobility materials, such as TiO_2 , $SrTiO_3$, and $\alpha-Fe_2O_3$, the only semiconductors in which this phenomenon has been observed.

The empirical Eq. [8] is also predicted by Ullman, according to whom it is

$$j^-_{sat} = (qD_n N_D/l) (e^{-\Phi}/Daw(\Phi))^{1/2} \quad [13]$$

and

$$K = D_n/k_c l Daw(\Phi)^{1/2} \quad [14]$$

where $D_n = \mu kT/q$ is the diffusion coefficient of the electrons, l is the Debye length of the space charge region

$$l = (2\epsilon\epsilon_0 kT/q^2 N_D)^{1/2} \quad [15]$$

$\Phi = q\phi_s/kT$ is the barrier height of the depletion layer in adimensional units, and $Daw(\Phi)^{1/2}$ is Daw's function, which, for $\Phi \geq 2.5$, is given with an error lower than 3% by the expression

$$Daw(\Phi)^{1/2} = (0.5 + 0.4/\Phi)(\Phi)^{1/2} \quad [16]$$

In our case, with $N_D = 1 \times 10^{19}\text{ cm}^{-3}$, $D_n = 2.5 \times 10^{-3}\text{ cm}^2\text{ s}^{-1}$ ($\mu = 0.1\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}$), and $\epsilon = 300$, for $\Phi = 11.7$ ($\phi_s = 0.3V$) the value of j^-_{sat} predicted by Eq. [13] is 0.2 A cm^{-2} , about 4 orders of magnitude higher than the experimental one (Fig. 7). Therefore, Ullman's model does not seem to fit our experimental

Fig. 7. Tafel plot of the saturation current density, (j^-_{sat}) vs. potential for ferricyanide, both at pH 3 and 11, taken from Fig. 6. Note the parallelism of the two straight lines with a slope of $\sim 130\text{ mV}$.

Fig. 8. Plot of current density vs. ferricyanide concentration at pH 11 in the proportionality region corresponding to the plateau in Fig. 5.

results. Furthermore, it cannot give account of the segments with high Tafel slope in the $\log j^-$ vs. V plots observed both by Vandermolen *et al.* (16) and in this paper.

The surface states trapping kinetic model.—As stated above, Bard *et al.* (15) were the first to invoke mediation of charge transfer by surface states in order

to explain anomalously high Tafel slopes. Later, Vandermolen *et al.* (16) (in the following designated as VGC) were the first to observe current saturation, which they interpreted with a two-step trapping kinetic model also involving surface states.

According to the VGC model, charge transfer is mediated by bandgap surface states overlapping empty

Fig. 9. Plots of current density vs. voltage for $10^{-2}\text{M Fe(CN)}_6^{3-}$ at pH 3 and 11, and for $10^{-2}\text{M IrCl}_6^{2-}$ at pH 3. Note different potential scales for pH 3 and 11; the shift of 0.45V is necessary to make the saturation region of Fe(CN)_6^{3-} at pH 3 coincide with that at pH 11. This shift corresponds to the difference between V_{FB} at pH 3 and 11, so that the three curves have the same horizontal axis of $(V - V_{\text{FB}})$, and therefore the same axis of ϕ_s . Values of $(V - V_{\text{FB}})$ and ϕ_s are given in the upper horizontal axis.

levels of the oxidized species, and therefore involves two steps: transfer of electrons from the conduction band at the surface to the surface states with a rate constant k_1 , and transfer of electrons from the surface states to the empty levels of the oxidized species with a rate constant k_2 . Assuming that the reverse rate constants are negligible, Eq. [7] of VGC (16) can be simplified to

$$j^- = -qN_{ss} \frac{k_1 n_s C_{ox}}{\frac{k_1}{k_2} n_s + C_{ox}} \quad [17]$$

From solid-state theory it is known that $k_1 = v\sigma$, where v is the mean thermal speed of conduction band electrons and σ is the electron-capture cross section of the surface states. k_2 depends on the degree of overlap of the levels of surface states with those of the oxidized species, according to the classical model.

Two limiting situations are readily apparent for the Langmuir-type Eq. [17]. At concentrations of the oxidized species high enough for the first step to be rate limiting, i.e., so high that

$$k_1 \cdot n_s \ll k_2 C_{ox} \quad [18]$$

and consequently all the surface states are practically empty, then the limiting value of the current (saturation current, j^-_{sat}) is given by

$$j^-_{sat} = -q \cdot N_{ss} \cdot k_1 \cdot n_s \quad [19]$$

where N_{ss} is the density of surface states. According to Eq. [19], the voltage dependence of the current is determined by $n_s(V)$ (Eq. [12]), which means that the value of the Tafel slope depends on whether all of the applied voltage changes drop in the semiconductor depletion layer (Tafel slope = 60 mV) or drop partially in the Helmholtz layer (Tafel slope > 60 mV).

The other limiting situation obtains when

$$k_1 n_s \gg k_2 C_{ox} \quad [20]$$

Then the transfer of electrons from the surface states to the electrolyte is rate limiting, and all the surface states are practically filled at the steady state. Under these conditions, the current is proportional to the concentration of oxidized species

$$j^- = qN_{ss}k_2C_{ox} \quad [21]$$

It is evident that in this range the current does not depend on n_s ; therefore, an infinite Tafel slope must be obtained when Eq. [20] holds.

The saturation range.—The VGC model predicts a Tafel slope of 60 mV in this range for the case of an ideal semiconductor where Eq. [2] holds. However, both at pH 3 and 11 we find a Tafel slope mean value of about 130 mV for $10^{-2}M$ ferricyanide, slightly variable with C_{ox} . This discrepancy has a ready explanation in the dependence of V_{FB} on the applied voltage (Eq. [5]). As we have shown in the experimental section, due to the high value of N_D , for $V - V_{FB} \leq 0.8V$, about half of the applied potential drops in the Helmholtz layer (see Fig. 3), which means that a Tafel slope of about 120 mV should be expected in our case. It could be thought that some degree of Fermi level pinning by surface states could produce an additional drop of the applied voltage in the Helmholtz layer. However, this possibility must be discarded, as the Mott-Schottky plots are linear (Fig. 2).

Dependence of the Tafel slope on the polarization. Necessity of postulating at least two sets of surface states.—The dramatic increase of the Tafel slope with increasing band bending (decreasing n_s) in the proportionality region ($j^- \propto C_{ox}$) (Fig. 5), where Eq. [20] holds, is incompatible according to Eq. [17] with a single monoenergetic population of surface states. For a monoenergetic distribution, E_{ss} , with a single k_1 , the

change from the saturation region ($k_1 n_s \ll k_2 C_{ox}$) to the proportionality region ($k_1 n_s \gg k_2 C_{ox}$) with increasing band bending requires, for constant C_{ox} , that k_2 decreases much more rapidly than n_s ; this is only possible if $\phi_s \ll \Delta\phi_H$, i.e., if there is Fermi level pinning, which is not the case here.

To explain this behavior, two sets of surface states mediating electron transfer can be invoked. For the sake of simplicity let us assume that these two sets are monoenergetic, and are characterized by the parameters (E_{ss} , N_{ss} , k_1 , k_2) and (E'_{ss} , N'_{ss} , k'_1 , k'_2), respectively (Fig. 4). Now Eq. [17] should be changed into

$$j^- = j^-_1 + j^-_2 = -qC_{ox}n_s \left[\frac{N_{ss}k_1}{\frac{k_1}{k_2}n_s + C_{ox}} + \frac{N'_{ss}k'_1}{\frac{k'_1}{k'_2}n_s + C_{ox}} \right] \quad [22]$$

where j^-_1 and j^-_2 represent the contribution of both sets of surface states to the total current.

Let us assume that in the potential region $-0.8V < V < +0.1V$ (Fig. 5) it is

$$k_2 C_{ox} \gg k_1 n_s \quad [23]$$

and

$$k'_2 C_{ox} \ll k'_1 n_s \quad [24]$$

Then, the total current can be written

$$j^- = -q(N_{ss}k_1n_s + N'_{ss}k'_2C_{ox}) \quad [25]$$

For large values of n_s , that is, in the more negative potential range of Fig. 5 ($-0.8V < V < -0.6V$), a Tafel slope of 120 mV is observed, which means that

$$\frac{\partial(\log j^-)}{\partial V} = \frac{\partial(\log j^-_1)}{\partial V} = \frac{\partial(\log n_s)}{\partial V} = 120 \text{ mV}$$

for this heavily doped semiconductor, as already discussed. Therefore, in this range the second term in the parenthesis of Eq. [25] can be neglected. As n_s decreases (increasing band bending) the first term in Eq. [25] becomes negligible, and $j^- = j^-_2 = -qN'_{ss}k'_2C_{ox}$. As far as $\partial k'_2/\partial V = 0$, it must be $\partial j^-_2/\partial V = 0$, and an infinite Tafel slope must appear. This situation holds approximately in Fig. 5 for $-0.6V < V < +0.1V$; a true plateau is not obtained in this potential region because of the fact that a fraction of the applied potential does drop in the Helmholtz layer (Fig. 3). At the more positive potentials (i.e., $V > 0.1V$) n_s is so low that Eq. [24] no longer holds; Eq. [25] must then be substituted for by

$$j^- = -qn_s(N_{ss}k_1 + N'_{ss}k'_1) \quad [26]$$

and a dramatic decrease of the Tafel slope is observed again.

Influence of pH on the proportionality (low current-density) region.—It is readily apparent in Fig. 5 that pH markedly affects the proportionality region. A similar, not so marked effect was observed by VGC. They attributed it to a change in the relative position of the energy levels at the semiconductor surface with respect to those in solution, causing a change in k'_2 . Effectively, from Fig. 4 it is evident that upon increasing the pH from 3 to 11, k_2 decreases and k'_2 increases, which explains why the currents in the proportionality range are higher at pH 11 than at pH 3. Actually, an energy distribution of surface states, instead of two separate monoenergetic populations, would explain the results at pH 3, where the increase of the Tafel slope is much lower than at pH 11. A second, separate set of surface states has to be postulated only when the Tafel slope increases dramatically in a

large voltage range, as is the case for pH 11 between -0.5 , and $+0.1V$.

A possible alternative explanation of the influence of pH on the proportionality region is that the states E'_{ss} are mainly present at basic pH, as a consequence of the interaction of the semiconductor surface with the solvent (H^+ , OH^- , and H_2O species). In order to elucidate this point, the dark electroreduction of $IrCl_6^{2-}$ at pH 3 has been compared to that of $Fe(CN)_6^{3-}$ at pH 11 (Fig. 9). The use of $IrCl_6^{2-}$ was dictated because its redox potential is $\sim 0.5V$ more positive than that of the ferro/ferricyanide. This value is approximately equal to the increase in V_{FB} brought about by a decrease of 8 pH units. Therefore, although λ of $IrCl_6^{2-}$ is 0.1-0.2 eV lower than that of $Fe(CN)_6^{3-}$ (33), the degree of overlap (and therefore the currents) should be essentially the same in the two cases, provided that first, the surface states are unaffected by pH changes, and second, neither anion adsorbs specifically, as is apparent from their lack of influence on the capacitance. The absence of a plateau in the Tafel plot of $IrCl_6^{2-}$ at pH 3 (Fig. 9) seems to give evidence that a new set of surface states appears at pH 11 that is not present at pH 3. The position of the higher limit of the new states, E'_{ss} , can be inferred from the positive limit of the plateau in Fig. 5, $+0.1V$ vs. SCE, assuming that the new surface states begin to be emptied at this potential. With the help of Fig. 3 it is readily obtained that the higher limit of E'_{ss} is $\sim 1.0V$ below the bottom of the conduction band, as is depicted in Fig. 4.

Tafel plot with $IrCl_6^{2-}$.—The Tafel plot obtained with $IrCl_6^{2-}$ at pH 3 is shown in Fig. 9. The currents are much higher than those observed with $Fe(CN)_6^{3-}$; they are even higher than the saturation currents depicted in Fig. 7, which runs contrary to the VGC model, according to which the magnitude of the saturation current is independent of the oxidized species. VGC (16) found that, effectively, the saturation current on TiO_2 and $SrTiO_3$ was the same for Fe^{3+} , $Fe(CN)_6^{3-}$, and $IrCl_6^{2-}$. Unfortunately, we could not conduct experiments at higher concentrations of $IrCl_6^{2-}$, as we were reaching diffusion limited currents. A possible explanation for this anomalous behavior is that in our electrode, perhaps because it was polycrystalline and heavily Nb-doped, the interaction of $IrCl_6^{2-}$ with $SrTiO_3$ at pH 3 created new surface states at a concentration low enough for them not to influence the capacitance, but high enough for the saturation current to be much higher than with $Fe(CN)_6^{3-}$.

The Tafel plot of $IrCl_6^{2-}$ is approximately a straight line with a slope of ~ 250 mV. The absence of a segment at higher currents with a slope of ~ 130 mV seems to indicate that with $IrCl_6^{2-}$ the rate-limiting step is the transfer of charge from the surface states to the oxidizing species (Eq. [20]), in agreement with the above hypothesis that j^-_{sat} is much higher than with $Fe(CN)_6^{3-}$. The slope of 250 mV is difficult to justify, as it is equal to $(\partial \log [N_{ss} \cdot k_2] / \partial V)^{-1}$ (see Eq. [21]) and both N_{ss} and k_2 change with electrode polarization in an unknown way.

Estimation of some characteristic parameters of the surface states.—The VGC model has been shown to explain qualitatively our experimental results. A quantitative analysis involves a precise knowledge of the actual distribution of surface states, which is far from being known. However, it can be useful to make

some calculations with the simplest approach of a monoenergetic population of surface states.

The saturation region yields several parameters. From the experimental data of ϕ_s (V) (Fig. 9) and j^-_{sat} (V) (Fig. 7), a combination of Eq. [12] and [19] yields the product $N_{ss}k_1 = j^-_{sat}/qn_s$. Besides, the slope of $1/j^-$ vs. $1/C_{ox}$ plots (Fig. 6) is equal to $k_1 \cdot n_s / k_2 \cdot j_{sat}$, from which k_1/k_2 and $N_{ss}k_2$ are easily obtained. The values of these parameters at pH 11 for two different potentials are given in Table I. It becomes evident that there is a distribution of surface states, as k_1/k_2 increases with increasing ϕ_s . For a monoenergetic population of surface states near the conduction band, k_1/k_2 should decrease, as k_1 must be constant and k_2 should increase with anodic polarization due to a better overlapping of the surface states with empty energy levels of the electrolyte (Fig. 4). It is therefore necessary to assume an energy distribution of surface states in which k_1 increases with decreasing energy.

Origin and nature of the surface states.—The results presented here seem to prove the presence on $SrTiO_3$ of surface states which are present at pH 11 and absent at pH 3, and that therefore would be originated by interaction of n- $SrTiO_3$ with the solvent (H_2O , H^+ , and OH^-). The surfaces of strongly ionic oxides such as TiO_2 or $SrTiO_3$ present two different intrinsic surface states, known as ionic or Tamm surface states which correspond to Ti_s^{4+} cations and O_s anions, respectively. Because of the lower symmetry of both Ti and O^{2-} sites at the semiconductor surface with respect to the bulk, the empty $Ti:3d(t_{2g})$ orbitals responsible for the conduction band should be shifted downwards into the bandgap at the same time that the full $O^{2-}2p$ orbitals responsible for the valence band are shifted upwards. However, it has been established by photoemission experiments that the electronic structure of these surface states is not different from that of the bulk (40), i.e., a decrease of the surface cation coordination seems not to be sufficient to generate bandgap surface states. Surface point defects associated to surface oxygen vacancies ($2Ti^{3+} - V_o$)_s give rise to bandgap surface states in both TiO_2 and $SrTiO_3$ (31). The interaction of these surface states with electrolyte OH^- ions has been thought to give rise to $Ti^{3+}-OH^-$ surface groups, behaving as electron traps, able to mediate electron transfer from the conduction band to electrolyte empty levels (12, 41). Both Ti_s and O_s^{2-} ionic surface states must interact strongly with the electrolyte (39). The Ti_s ionic states act as Lewis acids, taking a couple of electrons from the orbitals of OH^- with a fairly strong interaction that shifts the state nearer the conduction band.

The $O^{2-}:2p$ ionic states behave as Lewis bases, sharing their electron pair with the empty 1s orbitals of H^+ , also with a fairly strong interaction that shifts the state nearer the valence band

For water molecules contradictory results have been obtained about the dissociative character of their adsorption on TiO_2 and $SrTiO_3$. According to Somorjai *et al.* (42, 43), H_2O adsorbs on TiO_2 without dissociation on single-crystal stoichiometric surfaces, and dissociatively on very heavily Ti^{3+} -doped surfaces. The same authors found that H_2O seemingly adsorbs without

dissociation on SrTiO₃. More recently, Kurtz and Henrich (44) have shown that the presence of Ti³⁺ surface ions alone is not sufficient to catalyze the dissociative chemisorption of H₂O on either TiO₂ or Ti₂O₃: defect sites, associated with Ti³⁺-O-vacancy complexes, probably catalyze H₂O dissociation.

A polycrystalline sample of a given material should show a higher activity than a single crystal of the same material, due to the imperfections (defect sites) of the surface (45). Recent IR studies of anatase powder (46) have shown that TiO₂ in contact with water vapor is covered by a monolayer ($\sim 10^{15}$ mol cm⁻²) of water, half of which is physisorbed molecular water, and the rest is covered, 2/3 by Brönsted acid sites, (O⁻²:H⁺)_s, and 1/3 by Brönsted basic sites, (Ti-OH⁻)_s. The surface concentration of H⁺ and OH⁻ varies with pH, and for most semiconducting oxides this produces a Nernstian dependence of V_{FB} on pH, i.e., $\partial V_{FB}/\partial \text{pH} = 60$ mV (47). The point of zero charge (pzc) is the pH at which the surface concentration of H⁺ ions is equal to that of OH⁻ ions. At the pzc, which is near pH 7 both for TiO₂ and SrTiO₃ (48), the semiconductor surface could be schematized by the following model

which includes both acid and basic OH surface groups. The amphoteric character of the surface is manifested when the electrolyte pH is different from the pzc. At a pH < pzc, a fraction of OH groups (basic in character) coordinated to Ti surface ions capture protons from the solution

while the acidic O group will either remain unaltered or ionize

The net result will obviously be a decrease of the ratio $[\text{OH}^-]_s/[\text{H}^+]_s$. At pH > pzc water molecules coordinated to Ti_s groups will dissociate giving protons to the solution

while the acidic O group will be neutralized

and consequently the ratio $[\text{OH}^-]_s/[\text{H}^+]_s$ will increase. IR spectra of anatase powder that had been equilibrated with water of different pH values give support to this scheme (49).

Recently, Tomkiewicz (50) detected, by means of subbandgap electroreflectance spectroscopy, what he

believes to be intrinsic surface states at TiO₂ in an aqueous iodide solution, with a maximum 1.3 eV below the conduction band. According to him, in the absence of iodide these intrinsic states interact strongly with OH⁻ ions and/or H₂O molecules and shift towards the conduction band, which makes them undetectable by electroreflectance. It could be possible that these states correspond to surface Ti ions.

Origin of the anomalous electrochemical behavior of SrTiO₃, TiO₂, and α-Fe₂O₃.—Zinc oxide (ZnO) has about the same bandgap and electron affinity (and, therefore, ionization potential) as TiO₂ and SrTiO₃. However, its electrochemical behavior obeys the classical model of direct, isoenergetic charge transfer (22, 51, 52). This difference cannot be attributed to differences in overlap, as the position of the bands is about the same. Its origin, therefore, should be looked for in the difference of the respective intrinsic surface states.

The main difference between the electronic structure of ZnO and those of TiO₂ and SrTiO₃ is the character of the conduction band: it is 4s and 4p for ZnO (53), while for Ti oxides it is Ti: 3d (t_{2g}). Therefore, the interaction of the intrinsic surface states with the solvent should be different in the two cases. Truncation of the crystal lattice at the surface produces a splitting of the Ti⁴⁺:3d (t_{2g}) orbitals so that the Ti-OH⁻ surface groups should be below the conduction band. The ionic surface states associated with Zn²⁺:4s orbitals seem to lie less than 10 mV below E_c (54); therefore, it seems reasonable to assume that the Zn²⁺-OH levels are within the conduction band. This means that conduction band electrons in ZnO must be transferred isoenergetically from the bulk to overlapping electrolyte levels, while in the cases of TiO₂ and SrTiO₃ an electron arriving from the bulk to the surface goes to bandgap energy levels from which it can be transferred to overlapping electrolyte levels.

Current saturation in the dark cathodic reduction of oxidized electrolyte species has also been found with α-Fe₂O₃ (55), another transition metal oxide with 3d-type conduction band. Therefore, of the four wide bandgap semiconducting oxides whose electrochemical behavior has been studied, only ZnO, the only one without d-orbitals in its conduction band, shows the ideal behavior observed with low bandgap covalent semiconductors. This gives some support to the idea that the surface states present in transition-metal oxides and mediating charge transfer to the electrolyte involve 3d orbitals of the metallic cation interacting strongly with OH⁻ and H₂O donor species of the solvent.

Conclusions

The dark electroreduction of Fe(CN)₆³⁻ and IrCl₆²⁻ on a sintered SrTiO₃ electrode at pH 3 and 11, as a function of the concentration of oxidized species, cannot be explained by the classical mechanism of isoenergetic charge transfer, not even when Ullman's model (23) of current control by transport resistance in the space-charge region is used together with the classical mechanism. They can be explained by the two-step mechanism, with mediation of the charge transfer by surface states postulated by VGC (16).

We would like to stress that Ullman's model, although not applicable to our results, could fit other systems in which the charge transfer from the semiconductor to the electrolyte are limited by the charge transport within the space-charge region, and not by the charge transfer from the surface state to the electrolyte. In any case, the observation of saturation currents predicted by Ullman's model for low mobility materials, even in the absence of surface states participating in semiconductor-electrolyte charge transfer, as could be the case for ZnO, would necessitate the use of techniques where the measurements of high currents are not hindered by diffusion limitation.

We have found, as have VGC, that at lower band bendings (i.e., higher currents) the current saturates with increasing concentration of the oxidized species. This anomaly clearly indicates that at least two sets of surface states mediate charge transfer.

We have also found that in the proportionality range the Tafel slope drastically changes with pH, which shows that the set of surface states active in this range results from the interaction of intrinsic ionic surface states of Ti^{4+} :3d (t_{2g}) orbitals with donor species (OH^- and H_2O) of the solvent. This conclusion is reinforced by the fact that the Tafel plot at pH 3 with $IrCl_6^{2-}$, whose empty levels are at about the same energy relative to the semiconductor as those of $Fe(CN)_6^{3-}$ at pH 11, shows no plateau in the proportionality region. However, the electroreduction currents for $IrCl_6^{2-}$ ions reach values considerably higher than the saturation currents for $Fe(CN)_6^{3-}$. This fact is in contradiction with the results of VGC relative to single crystals, and with the prediction of the VGC model that saturation currents should be independent of the nature of the oxidized species. Although we have no proper explanation for this discrepancy, it could be assumed that in the same way that the surface states involved in the transfer of charge are sensitive to pH, they could be also influenced by the nature of the oxidized species, this effect being much more noticeable in sintered, polycrystalline electrodes.

ABSTRACT

Titanium, thermally oxidized titanium, and single-crystal TiO_2 have been coated with polyvinylferrocene by an argon-vinylferrocene radio frequency plasma discharge. Voltammetry is observed consistent with the oxidation of ferrocene sites in the polymeric coating at potentials 1.5V positive of the flatband potential for TiO_2 in CH_3CN . As the thickness of the oxide phase is increased, the ease with which ferrocene sites are oxidized decreases. Comparisons are made to TiO_2 substrates coated with polyvinylferrocene by evaporative deposition; these electrodes give a more classical blocking response. The plasma discharge physically alters the semiconductor surface, most likely by generating surface states. In addition, the voltammetric response for plasma-coated TiO_2 /polyvinylferrocene electrodes is improved if conducting materials (e.g., Pt or glassy carbon) are also present in the plasma reactor during plasma deposition. We show that very small minority carrier oxidation currents can be measured by trapping the oxidative charge as ferricenium in the polymer film via potentiostatic experiments at quite positive potentials.

Research on chemical modification of electrode surfaces anticipates the time when an electrode material, a chemical modifier, and a method of modification can be assembled as a package that will predictably perform in electrocatalysis, electrosynthesis, or some other area of electrochemical concern (1). Tailoring electrodes for specific applications relies, in large part, on the predictability of the electrochemical properties of the final product. Predictability may be jeopardized if the modification method unexpectedly alters fundamental characteristics of the electrode material itself. This paper describes such an example for n- TiO_2 .

Some modification methods do appear to affect the substrate, the prime example being radio frequency (RF) plasma treatments. Reactive surfaces, capable of bonding with *in situ* reagents, have been generated for carbon substrates by removal of surface oxides during plasma cleaning (2, 3). Recently, Armstrong reported that exposing a gold metallized-plastic electrode to an oxygen RF plasma created a form of reducible gold oxide that was not observed in the voltammetry of bulk gold or other types of gold films exposed to the plasma (4).

Work in our laboratories shows that RF plasma polymerization can affect changes in the inherent properties of an electrode substrate. The electrochemical response of TiO_2 electrodes plasma coated with polyvinylferrocene differs from that of untreated TiO_2 in a solution of ferrocene. Frank and Bard demonstrated that at potentials positive of -0.8V (SCE), only reductions are possible at single-crystal or polycrystalline TiO_2 in acetonitrile (5). The (dark) oxidation of ferrocene ($E^\circ = +0.4\text{V}$ [SSCE]) in solution at TiO_2 does not occur. By analogy, the oxidation of ferrocene sites immobilized at a TiO_2 surface should not occur. However, for plasma-coated TiO_2 , ferrocene sites are oxidized and in a potential region where n- TiO_2 ($E_{\text{BG}} = 3\text{ eV}$, $E_{\text{FB}} \sim -1.0\text{V}$ [SSCE] in CH_3CN) is normally considered blocked to electron transfer. We shall present evidence that this occurs because the plasma treatment alters the surface energetics of the semiconducting TiO_2 electrode.

Experimental

The vinylferrocene plasma-polymerization procedure has been described previously (3, 6). Plasma reactor geometry B (6, 7) was chosen; this geometry re-

sults in a high rate of polymer film formation and less degradation of ferrocene sites (8). Titanium, thermally oxidized titanium, single-crystal TiO_2 , platinum, and glassy carbon substrates were mounted as electrodes after plasma coating to avoid introduction of other materials into the plasma.

Because subtle changes in the polymer film's characteristics resulted after imbibing solvent from Varian Torr Seal (7), a very high MW epoxy was used to mount and mask the edges of electrodes. The two components (epoxy and versamide resin, 40-60 w/w) cross-link avoiding release of solvent, or any other small molecule, into the polymer. A sample of the hardened epoxy soaked in 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$ for 24h appeared physically unaltered, and the *i*-*E* background of the electrolyte at a Pt working electrode remained unaffected. Mounted electrodes were stored in air for several days before electrochemical use to increase the chemical stability of ferrocene sites in the plasma polymer film (7-9).

Ti disks (punched from 0.67 mm-thick 99.992% Ti foil, Alfa Ventron), 6 mm diam, were polished to a 1 μ finish with diamond paste (Buehler) and degreased with hexane. Titanium samples designated as Ti(0 min) were used without deliberate thermal oxidation, although the native oxide which forms upon exposure of Ti to moisture or air ($\sim 20\text{\AA}$) (10) was unavoidable. Specimens designated as moderately oxidized (Ti/ TiO_2 [*x* min]) were heated on a hot plate in air for *x* min. This mild form of thermal oxidation yielded shiny, golden Ti/ TiO_2 specimens from the polished, silvery Ti. Specimens designated as extensively oxidized (Ti/ TiO_2 [*x* min, 600°C]) were heated in air at 600°C in a muffle furnace for *x* min, colored samples resulted, where the color depended on length of heating. The dull, gray-colored oxide layer which results after heating Ti in a flame (11) was not seen. The depth of the oxide layer, as generated by either form of heating with time, was not measured. Based on color, a Ti sample heated even 1 min at 600°C had a thicker oxide layer than a sample heated for 30 min on a hot plate. Increasing the length of time the Ti was heated was used as a qualitative gauge of oxide depth. These samples were not reduced in hydrogen.

Single-crystal TiO_2 samples (1 \times 2 mm²) were a gift from Professor H. O. Finklea (Virginia Polytechnic Institute and State University). These samples had been reduced in hydrogen at 650°C for 10 min to increase the concentration of charge carriers. The face

Key words: semiconductor, modified electrode, voltammetry, trapping, plasma polymerization.

of the crystal was polished to 1μ , degreased in hexane, and etched for 10 min at 70°C in a solution of 5:1:4 HNO_3 : HF : H_2O . Pt and glassy carbon samples were polished to 1μ and degreased before plasma coating.

Films of conventional polyvinylferrocene [AIBN-initiated polymerization of vinylferrocene in benzene (12)] were deposited on Ti/TiO_2 and single-crystal TiO_2 by evaporating microliter aliquots of a solution of 0.1 mg PVFc/ml toluene (0.47 mM in Fc sites).

Electrochemical experiments were performed in conventional cells and referenced to a sodium-saturated calomel electrode (SSCE). A PAR 173 potentiostat/galvanostat with PAR 179 digital coulometer, PAR 175 universal programmer, and Houston 2000 XY recorder were used. X-ray photoelectron spectra were taken on a du Pont Model 650B electron spectrometer. Peak positions were referenced to C 1s as 285.0 eV. The Pt spectrum of Fig. 7 was obtained on a MacPherson Model 3600 electron spectrometer with positions referenced to Au 4f as 78.0 eV.

Vinylferrocene (Pfaltz and Bauer) was used as received. Bis-2,2'-bipyridine-bis-4-vinylpyridineruthenium(II) hexafluorophosphate was prepared and electropolymerized as previously described (13). Tetraethylammonium perchlorate (Southwestern) was dried at 50°C in a vacuum oven before use. Acetonitrile (MCB) was dried by storing over activated 4A molecular sieves (Linde) or used immediately after reflux and distillation from CaH_2 (Alfa Ventron).

Results and Discussions

XPS.—For uncoated, moderately oxidized Ti/TiO_2 samples, the binding energy difference of the O 1s and Ti $2p_{3/2}$ bands equals 71.5 eV. This value agrees with that reported by Armstrong for TiO_2 (14), demonstrating that our mild thermal oxidation procedure generates the titanium dioxide phase.

A three-minute argon-vinylferrocene plasma discharge produces a polymer film sufficiently thick to block most of the x-ray photoelectrons emitted from the TiO_2 . Compare Fig. 2d and 2b (uncoated *vs.* coated) to see the diminution of the Ti 2p signal after plasma coating moderately oxidized titanium.

The Fe $2p_{3/2}$ region for polyvinylferrocene films plasma deposited on TiO_2 under our RF plasma polymerization conditions shows the predominance of a narrow Fe(II) band at 709 eV. A broad, higher binding energy component due to plasma-damaged Fe(III) sites at 712 eV is always present (Fig. 1a). This general spectrum has been observed for polyvinylferrocene powder harvested from the plasma reactor walls, and for polyvinylferrocene films plasma deposited on Pt, glassy carbon, and RuO_2 (15). By XPS, the type of plasma polymer film that forms is independent of the substrate on which it deposits.

Electrochemistry

Thermally oxidized Ti plasma coated.—The aqueous and nonaqueous electrochemistry of polyvinylferrocene films plasma deposited on conducting substrates has been documented (3, 6, 8, 16, 17). The typical cyclic voltammetric response in CH_3CN is that of a symmetrically shaped wave, with small but nonzero peak separation, at a formal potential characteristic of the ferricenium-ferrocene couple.

Polyvinylferrocene-coated TiO_2 should not exhibit any faradaic response. Instead, Ti/TiO_2 /PPVFc exhibits voltammetry consistent with ferrocene oxidation and ferricenium reduction. The voltammetric response is related to the oxide layer thickness; voltammetric reversibility degrades as oxide thickness increases (see Fig. 2).

Both anodic and cathodic voltammetric peaks are observed for $\text{Ti}(0 \text{ min})$ /PPVFc samples. For the electrode shown in Fig. 2a, anodic peak current decreased 25% by the fifth cycle, faster than the decay of ferricenium sites in a comparably aged film on Pt (9). Cy-

Fig. 1. XPS spectra of the Fe $2p_{3/2}$ and Ti $2p_{3/2,1/2}$ regions for uncoated and plasma-polymerized-vinylferrocene-coated samples of moderately oxidized titanium. A: Fe $2p_{3/2}$ spectrum for Ti/TiO_2 /PPVFc, $S = 1640$ counts/s. B: Ti 2p spectrum for Ti/TiO_2 /PPVFc, $S = 205$ counts/s. C: Fe $2p_{3/2}$ spectrum for Ti/TiO_2 , $S = 680$ counts/s. D: Ti 2p spectrum for Ti/TiO_2 , $S = 5460$ counts/s.

cling $\text{Ti}(0 \text{ min})$ /PPVFc samples to voltages more positive than the ferrocene oxidation wave results in an initial increase in oxidation current that substantially diminishes on subsequent scans as the Ti passivates. The voltammetric response after such a voltage excursion resembles that for moderately oxidized plasma-coated samples, as discussed below. Electrochemical generation of an oxide layer is indicated.

The general response observed after plasma depositing PVFc on moderately oxidized titanium is seen in Fig. 2b and 2c. Well-defined anodic and cathodic peaks are present in the initial scan of the film, but are separated by more than 250 mV. Figure 2c is seen after several subsequent scans. The ferrocene oxidation wave is spread out, but, interestingly, the cathodic wave is still present and well defined, although shifted to more negative potentials. Ferricenium sites are being reduced, so ferrocene sites must continue to be oxidized, although a distinct oxidation wave is absent.

The average surface coverage calculated from the first anodic scan for six moderately heated samples (0, 1, 3, 5, 10, and 20 min), after batch plasma coating, was $8.0 \pm 1.0 \times 10^{-9}$ mol cm^{-2} , a coverage consistent with that observed when Pt, glassy carbon, or RuO_2 are plasma coated under the same experimental conditions (7). The variance in individual surface coverages from the mean is $\sim 12\%$. Thus, moderately reproducible polymeric coverage can be produced on multiple samples coated in a given plasma experiment.

Extensively oxidized titanium, plasma coated with PVFc, exhibits the behavior seen in Fig. 2d. An oxidation wave is never observed, even on the very first anodic scan or for Ti heated for just one minute at 600°C . However, a cathodic peak is still observed, but at a potential shifted to even more negative values, -0.3 to -0.5V (SSCE). This wave is not due to solu-

Fig. 2. Variability of the cyclic voltammetric response in 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$ for Ti, moderately oxidized Ti, and extensively oxidized Ti after exposure to a RF argon-vinylferrocene plasma. A: Ti (0 min)/PPVFc, $\nu = 0.2$ V/s. B and C: Ti/TiO₂ (20 min)/PPVFc, $\nu = 0.1$ V/s. B: initial cyclic, $S = 78$ $\mu\text{A}/\text{cm}^2$. C: fifth scan, $S = 32$ $\mu\text{A}/\text{cm}^2$. D and E: Ti/TiO₂ (1 min, 600°C)/PPVFc, $\nu = 0.2$ V/s. E: $E_{\text{SW},a}$ increased to +1.5V.

tion contaminants, as background scans at clean, uncoated Pt, or TiO₂ show no trace of it. Figure 2e demonstrates that the peak current for this cathodic process increases as the anodic potential limit ($E_{\text{SW},a}$) of the cycle is increased to more positive voltages.

We assign this cathodic peak at ~ -0.4 V to reduction of ferricenium. An anodic overvoltage exists; the ferricenium reduction peak is not observed unless the voltage sweep is extended well positive of the formal potential for the ferricenium/ferrocene couple. Roughly, as length of heating at 600°C is increased (and thus as oxide depth increases) the overvoltage for ferrocene oxidation is increased. The cathodic charge measured for the ferricenium reduction wave is, within certain voltage ranges, proportional to the anodic switching potential. Titanium samples heated for 5, 10, or 25 min at 600°C and then plasma coated with polyvinylferrocene have nearly equivalent slopes for the linear portion of their Q_c vs. $E_{\text{SW},a}$ curves, Fig. 3a-3c (281, 255, 287 μF , respectively). A sufficiently thick oxide layer can be prepared, e.g., 100 min at 600°C, to cause the ferricenium reduction peak to vanish, i.e., the originally predicted cyclic voltammetric response of Ti/TiO₂/PPVFc between +2.0 and -1.0V is now observed.

Observing ferrocene oxidation at Ti/TiO₂ is the primary phenomenon. The ferrocene/ferricenium electrochemical process at TiO₂ is not nernstian reversible, even when both anodic and cathodic waves are present in the voltammogram. Oxidation of ferrocene sites in the polymer becomes increasingly more difficult to achieve as the TiO₂ phase deepens. Despite the variability in the voltammetric response for TiO₂/PPVFc, the common factor, regardless of oxide depth, is that ferrocene sites, immobilized in a plasma-deposited polymer at TiO₂, can be oxidized at potentials 1.5V positive of E_{FB} for TiO₂ in CH₃CN.

Thermally oxidized Ti evaporatively coated.—Ferrocene centers can also be placed at the semiconductor surface by evaporation of solutions of polyvinylferrocene prepared by conventional polymerization methods. This less active form of modification was investigated to distinguish between the effects of plasma exposure on TiO₂ and possible Fermi-level pinning of the semiconducting phase (18) due to coating of the surface with a redox polymer.

In the XPS of PVFc films evaporatively deposited from toluene, only the narrow band at 709 eV for Fe(II) is seen; oxidized and/or damaged iron sites are not present in such films, as indicated by the absence of a band at 712 eV (15). Plasma polymerized films are cross-linked and incorporate oxygen upon exposure to air (19). Consequently, the environment surrounding ferrocene sites in a plasma-prepared sample of polyvinylferrocene should differ from that in conventionally prepared polyvinylferrocene. Nonetheless, the ferrocene moiety is known to remain reversibly oxidizable for both types of films deposited on conducting substrates (15-17).

The voltammetry of PVFc evaporatively deposited on Ti/TiO₂ substrates does not mirror that of plasma-deposited polyvinylferrocene films. The results still depend on the oxide thickness, however. Ti/TiO₂ (10 min, 600°C)/PVFc exhibits neither an oxidation wave nor ferricenium reduction peak (Fig. 4a), unlike the plasma-coated analog, where a rereduction peak is observed after sweeping to potentials more positive than 0.8V. An evaporatively coated, moderately oxidized substrate (Ti/TiO₂ [25 min]) also shows no ferrocene oxidation wave, unlike its plasma-coated analog (Fig. 2b), but does show a rereduction wave at negative potentials after sufficiently positive potential sweeps (compare Fig. 4b and 4c).

Evaporating PVFc on freshly polished Ti produces voltammetry as in Fig. 4d and 4e. On the first scan (Fig. 4d) a broad, ill-defined oxidation wave occurs followed upon scan reversal by a reduction peak at -100 mV; by the second scan (Fig. 4e), the Ti has passivated to the extent that no oxidation wave is present at all, but a small cathodic peak at -100 mV persists. For comparison, the voltammetric response of Pt evaporatively coated with PVFc is seen in Fig. 4f. Based on the voltammetry, these evaporatively coated electrodes respond as though a much thicker oxide layer were present than on the plasma-coated Ti/TiO₂ electrodes.

These comparisons show that exposure to the plasma discharge has had a great effect on the appearance and quality of ferrocene/ferricenium electrochemistry at TiO₂. The plasma-coated Ti/TiO₂ is better behaved electrochemically, i.e., it is easier to see the oxidation and re-reduction of ferrocene sites in the polymer overlayer. Based on the similar electrochemistry observed for evaporatively vs. plasma-coated polyvinylferrocene films on metallic and metallic-like substrates (15-17), the polymeric environment can be assumed not to cause these differences for coated Ti/TiO₂.

Single-crystal TiO₂/polyvinylferrocene.—A plasma discharge is a very active means of creating a polymer-coated electrode, unlike solvent evaporation. One reason that Ti/TiO₂/PPVFc reacts electrochemically as though a thinner oxide were present might be due to thinning of the oxide phase during exposure of Ti/TiO₂ to the plasma discharge. Thermal oxidation of Ti produces a more crack-free oxide than one electrochemically generated, but channels still exist (20). A thinner oxide provides more direct access to the underlying Ti through such channels.

To explore the possibility of plasma thinning, we used single-crystal TiO₂ as the substrate in both evaporative and plasma coating experiments. No conducting Ti was present, so plasma thinning should have been of no consequence. Accordingly, we expected little difference between the electrochemistry observed

Fig. 3. Cathodic charge measured for the reduction of ferricenium sites in films of plasma-polymerized vinylferrocene deposited on extensively oxidized titanium as a function of the anodic switching potential. $\nu = 0.2$ V/s, $0.1M$ Et_4NClO_4/CH_3CN . A: Ti/TiO₂ (10 min, 600°C)/PPVFc. B: Ti/TiO₂ (25 min, 600°C)/PPVFc. C: Ti/TiO₂ (5 min, 600°C)/PPVFc. D: Ti/TiO₂ (50 min, 600°C)/PPVFc. E: Ti/TiO₂ (100 min, 600°C)/PPVFc.

for plasma- and evaporatively applied coatings; specifically, no ferrocene oxidation should have been observed either directly (an anodic peak or anodic current) or indirectly (a cathodic peak resulting from the reduction of obliquely oxidized ferrocene sites). This result was obtained; cyclic voltammetric scans of both plasma- and evaporatively coated films of polyvinylferrocene on single-crystal TiO₂ in blank electrolyte between +2.0 and -1.0V are identical and indistinguishable from a background scan of uncoated TiO₂ in the same solution. A more forcing voltammetric experiment produced the results described below.

Single-crystal TiO₂ charge trapping.—A reduction peak is not observed when uncoated single-crystal

TiO₂ is potentiostated at very positive potentials in a ferrocene solution and then cycled to negative potentials. If a small oxidation current does flow, and any ferrocene molecules are oxidized, they diffuse away before being detected by their reduction at a potential closer to E_{FB} of the material. Ferrocene embedded in a polymeric film and coated at the electrode surface cannot diffuse away. Any ferrocene centers which do get oxidized are retained as ferricenium centers and can be detected in a negative potential scan. The charge under the cathodic peak is, thus, a measure of the leakage oxidation current. Recognizing this, we briefly explored the charge trapping property of ferrocene polymer layers as a method of detecting ex-

Fig. 4. Voltammetric response for TiO₂ substrates evaporatively coated with conventionally prepared polyvinylferrocene, $0.1M$ Et_4NClO_4/CH_3CN . D and E: Ti (0 min)/PVFc, $\nu = 0.1$ V/s, $S = 32 \mu A/cm^2$. D: first scan. E: second scan. F: Pt/PVFc, $\nu = 0.1$ V/s, $S = 140 \mu A/cm^2$. G and H: single-crystal TiO₂/PVFc, $\nu = 0.2$ V/s, $S = 4 \mu A/cm^2$. G: potentiostated at 1.56V for 5 min prior to scan to negative potentials. H: potentiostated at 1.73V for min.

tremely small levels of ferrocene oxidation at very positive, normally blocking potentials at single-crystal TiO_2 . These potentiostatic experiments also showed that greater leakage currents flow when the polymer film is applied by plasma deposition.

After potentiostating an evaporatively coated single-crystal TiO_2 electrode at +1.56V for 5 min, a trace of a cathodic wave is observed at -0.66V (see Fig. 4g). By increasing E_{pot} to +1.73V and t to 50 min, the results in Fig. 4h are obtained. The position of the peak remains at -0.66V and, as expected, the peak magnitude has increased. The increase in discharged ferricenium sites is 30% for the 10-fold increase in time. Thus, even for single-crystal, evaporatively coated TiO_2/PVFc , some ferrocene sites become oxidized at very positive potentials with time. We estimate from the accumulated charge that the current flowing to produce these peaks must be of the order of a few hundred picoamperes.

Single-crystal TiO_2 electrodes plasma coated with polyvinylferrocene ($\text{TiO}_2/\text{PPVFc}$) and potentiostated for 5 min at positive voltages produce larger cathodic peaks than evaporatively coated single-crystal TiO_2 electrodes. As with the cyclic experiments at $\text{Ti}/\text{TiO}_2/\text{PPVFc}$, a threshold potential exists. A reduction wave is not seen if the applied E_{pot} is negative of this threshold potential, even though positive of $E^{\circ'}$ for ferrocene oxidation (see Fig. 5). The threshold potential lies between +0.75 and +1.0V (SSCE). As the curves obtained for $E_{\text{pot}} > +1.0\text{V}$ illustrate, once positive of this threshold potential, more positive potentials produce larger reduction peaks; the charges under these cathodic peaks are 0.3, 1.6, and 5.5 μC , respectively.

Increasing the duration of potentiostatic control for $\text{TiO}_2/\text{PPVFc}$ also results in a larger cathodic peak. Two minutes at +1.5V produces the wave seen in Fig. 5a; the wave in Fig. 5b results after increasing the time

Fig. 5. Linear potential sweep voltammograms for single-crystal TiO_2 plasma coated with polyvinylferrocene after a potentiostatic experiment at positive voltages for 5 min, 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$, $\nu = 0.2\text{ V/s}$. A and B: $\text{TiO}_2/\text{PPVFc}$ held at 1.6V for the stated times. A: 2 min. B: 5 min.

to 5 min. If a constant oxidation leakage current is assumed ($i = q/t$), 4.2 and 4.9 nA anodic currents would produce the cathodic peaks in Fig. 5a and 5b, respectively. At least a 20-fold increase in the observed oxidation leakage current results from exposing single-crystal TiO_2 to the RF plasma. This result is consistent with the above results on Ti/TiO_2 , so that plasma thinning of the TiO_2 film on $\text{Ti}/\text{TiO}_2/\text{PPVFc}$ electrodes can be ruled out as the primary origin of the improved electrochemical behavior of these electrodes.

Unfortunately, ferrocene is a poor candidate as a charge storage medium because ferricenium is chemically unstable. The electrochemical activity of ferrocene-modified metallic electrodes decreases with time poised in the ferricenium state (9, 22). For plasma-polymerized films of polyvinylferrocene on Pt, a ferricenium half-life of approximately 20 min is obtained after curing the film in air for 2 weeks (9). $\text{TiO}_2/\text{PPVFc}$ also exhibits an apparent loss of ferricenium sites. The charge for the curve in Fig. 5 obtained at +1.5V (5.5 μC ; 5 min potentiostating) is 3.7 times greater than that later obtained for Fig. 5b (1.5 μC ; same t , E_{pot}). The electrode had undergone several potentiostatic experiments between the time these curves were recorded; some ferricenium decay undoubtedly occurred. Consequently, we briefly explored an alternative charge storing film.

$\text{TiO}_2/\text{poly}-[\text{Ru}(\text{bpy})_2(\text{vpy})_2]^{2+}$.—Polypyridylruthenium complexes are known for their chemical stability and durability. TiO_2 can be coated by the electropolymerization of vinyl monomers of pyridine or bipyridine coordinated to Ru(II) (13). Electropolymerization occurs after cycling into the ligand-centered reductions, reactions which occur at potentials where TiO_2 is not blocked. The oxidation of the Ru(II) centers ($E^{\circ'} \gg E_{\text{FR}}$) has not been reported for these polymer films on TiO_2 .

$[\text{Ru}(\text{bpy})_2(\text{vpy})_2]^{2+}$ was electropolymerized from CH_3CN onto Ti/TiO_2 (5 min, 600°C) and single-crystal TiO_2 . In monomer-free electrolyte, the ligand-centered reductions are observed at both types of coated specimens, confirming that the polypyridylruthenium polymer is present. Under cycling conditions, no oxidation to Ru(III) or its re-reduction wave is ever seen, for either electrode substrate.

If Ti/TiO_2 (5 min, 600°C/poly- $[\text{Ru}(\text{bpy})_2(\text{vpy})_2]^{2+}$ is potentiostated at potentials positive of the $E^{\circ'}$ for this couple (at metallic electrodes, 1.25V (SSCE)), a cathodic wave appears at 170 mV upon sweeping to negative potentials. Cathodic peak current increases as E_{pot} is increased. A plot of Q_c vs. E_{pot} is linear for $E_{\text{pot}} > 1.8\text{V}$ (SSCE), with a slope of $64 \pm 3\ \mu\text{F}$.

The reproducibility of the amount of cathodic charge accumulated for a Ti/TiO_2 (5 min, 600°C)/poly- $[\text{Ru}(\text{bpy})_2(\text{vpy})_2]^{2+}$ specimen during repetitive potentiostatic/cathodic cycling experiments was investigated briefly. Table I shows that for repetitive scans at a given E_{pot} , the charge measured under the cathodic wave is nearly invariant. This indicates that charge trapping by the polymer film does not rapidly decay with time as it did in the polyvinylferrocene-coated electrodes.

A cathodic wave was, however, never observed for single-crystal $\text{TiO}_2/\text{poly}-[\text{Ru}(\text{bpy})_2(\text{vpy})_2]^{2+}$, even after potentiostating the modified electrode at +2.45V for 30 min. The formal potential of the polypyridylruthenium polymer is 850 mV more positive than that for the ferrocene polymer. Recall that single-crystal TiO_2/PVFc also required extremes in time and E_{pot} (50 min at 1.73V) to achieve a significant and well-defined response. Thus, while increased chemical stability of the electroactive center is necessary for a good charge storage candidate, a low oxidation potential (nearer that of ferrocene) is also important.

Plasma effects.—Gentle modification methods (evaporative deposition of polyvinylferrocene or electro-

polymerization of $[Ru(bpy)_2(vpy)_2]^{2+}$ onto Ti/TiO₂ or single-crystal TiO₂) produce polymer-coated electrodes which behave as classically anticipated based on the blocking behavior of this semiconductor at potentials positive of E_{FB} . As shown, it is only because the electroactive species are immobilized at the electrode surface that the more extreme electrochemical experiment of potentiostating at very positive voltages allows us to detect the production of any oxidized species by its subsequent discharge.

After plasma coating, TiO₂ electrochemically responds as though it were a more conducting material. The plasma discharge probably affects the surface energetics of the semiconductor through surface damage, although both the plasma power (several watts) and temperature (the gas temperature is near ambient) are mild. The relative ease of ferrocene oxidation at moderately and extensively oxidized Ti/TiO₂/PPVFc suggests that the plasma discharge has introduced intermediate levels (surface states) into the bandgap region.

We do not know the chemical identity of these states. We have found, however, that somewhat analogous effects can be produced by the presence of other materials in the Ar plasma discharge, as shown by the following experimental results. Reversible, persistent electron transfer for ferrocene/ferricenium sites is observed when moderately oxidized Ti is exposed to an argon-vinylferrocene plasma discharge in the pres-

Fig. 6. Cyclic voltammograms for moderately oxidized Ti plasma coated in a RF argon-vinylferrocene discharge with Pt electrode substrates present in the plasma reactor, 0.1M Et₄NClO₄/CH₃CN, $\nu = 0.2$ V/s. A: first scan, $S = 64 \mu A/cm^2$. B: scan after potentiostating at 0.75V for 15 min, $S = 16 \mu A/cm^2$.

ence of small pieces of conducting substrates (Pt, glassy carbon, RuO₂). The characteristic voltammetric response is seen in Fig. 6a. Both anodic and cathodic branches are present, with $\Delta E_p > 90$ mV. This is a smaller ΔE_p than is observed for the initial scan of moderately oxidized Ti plasma coated with PVFc in the absence of conducting substrates ($\Delta E_p > 250$ mV). More importantly, the anodic wave persists beyond five scans. Figure 6b is obtained after potentiostating the electrode of Fig. 6a at 0.75V for 15 min; this is the time equivalent (for $\nu = 0.2$ V/s) to more than 100 cycles without loss of the anodic wave or substantial shifting of $E_{p,c}$ to more negative potentials. Reversible oxidation and re-reduction of ferrocene centers ($q_a = q_c$) at the characteristic E° (0.4V) clearly occurs.

The only new variable in the deposition procedure is the addition of metallic substances into the plasma

Fig. 7. XPS spectrum of the Pt 4f region for a moderately oxidized Ti sample plasma coated in a RF argon-vinylferrocene discharge with Pt foil present in the plasma reactor.

reactor. The electrochemistry now resembles that of a conducting electrode coated with a ferrocene polymer. A possible explanation is that the oxide layer is now doped by atoms of the metallic substance.

The properties of Ti and TiO₂ have been shown to be markedly affected by the addition of trace quantities of noble metals. The presence of ppb Pt ions in a corrosive solution is known to reduce corrosion of Ti to negligible levels and improve its use as an electrode (23). Alloying Ti with <0.1% Pt, other noble metals, or even graphite also provides this protection (24). Deliberate doping of polycrystalline TiO₂ with noble metals has been shown to produce an impurity band in the bandgap region which affects the photoelectrochemical properties of the material, often decreasing the effective bandgap and shifting the photoresponse towards the visible (25).

If in our experiment, the plasma dislodges trace amounts of Pt (or C or Ru) into the plasma gas, introduction of a dopant onto the TiO₂ surface during plasma discharge would appear likely; an enhanced electrochemical response of Ti/TiO₂/PPFVc could then result. To confirm this hypothesis, a 1 min argon-vinylferrocene plasma-coated Ti/TiO₂ sample, prepared in the presence of a strip of Pt foil, was analyzed by XPS. In addition to the usual Fe 2p_{3/2} spectrum, the Pt 4f region clearly shows the Pt 4f doublet (Fig. 7). This confirms that the plasma discharge can transfer material from one substrate in the plasma reactor to another, even under conditions of low power discharge.

Conclusions

The RF plasma argon-vinylferrocene discharge modifies TiO₂ in two respects: first, by coating the electrode with an electroactive species, and second, by altering the surface energetics of the semiconductor, resulting in a less severe blocking response by TiO₂ at potentials positive of E_{FB}. Regardless of the depth of the oxide phase, a TiO₂ electrode plasma coated with polyvinylferrocene exhibits better ferrocene/ferricenium voltammetry than its evaporatively coated analog.

The mechanism for the improvement is the physical interaction of the plasma with the semiconductor surface; this most likely generates surface states in the bandgap region. This manner of introducing surface states/defects may have some utility for the photoelectrochemical and corrosion behavior of TiO₂ and other semiconductors. The plasma discharge may also be used to dope only the outer surface of the semiconductor. This approach is less material intensive than adding a uniform, bulk amount of dopant during the synthesis of the semiconductor, and may offer an alternative to ion implantation.

Immobilized redox sites at n-TiO₂, and presumably other semiconductors, capture and store charge leaked across the space-charge region. This storage is analogous to the preconcentration step in anodic stripping voltammetry where reduced ions amalgamate with the Hg electrode. In this case, holes are concentrated as oxidized sites in the polymer film and stripped from the film during the scan to more negative potentials. This analogy reveals the possibility of using polymer-modified semiconductor electrodes to analytically determine trace amounts of electroactive reactants.

Acknowledgments

The authors wish to thank P. Burgmayer (UNC) for early plasma experiments with thermally oxidized Ti,

Dr. J. M. Calvert (Geo-Centers) for preparation and electropolymerization of [Ru(bpy)₂(vpy)₂]²⁺, and Dr. J. R. Griffith (NRL) for supplying the high MW epoxy. One of the authors (D.R.R.) is especially grateful to Dr. G. G. Rolison (Stockton State College) and Professor H. O. Finklea (VPI) for discussions on the metaphysics of semiconductors.

PAS Testimony to Duplex Structure of Passive Film on Iron

Kotato Ogura*

Department of Applied Chemistry, Yamaguchi University Ube 755, Japan

Akira Fujishima* and Kenichi Honda

Department of Synthetic Chemistry, The University of Tokyo, Hongo, Tokyo 113, Japan

Photoacoustic spectroscopy (PAS) has been employed for the investigation of the solid surface (1-3). This technique has been applied to the examination of electrode surfaces; *e.g.*, to measure the absorption spectra of the electrode surface (4, 5). In these studies, however, the experimental procedure is accompanied by a transfer of an electrode into the PAS cell through the atmosphere. Such procedure is defective in applying PAS to the investigation of thin anodic film like on iron, because air-formed oxide must naturally affect the acoustic signal characteristic of anodic film. Hence, in the application of PAS to the study of thin anodic film, it is requisite that the experiment is performed *in situ* without involving a transfer of a sample to the atmosphere. One of our groups has recently developed an *in situ* PAS technique (6), and this method has been applied to the study of the electrode/solution interface involving the oxide layer on Au (7, 8) and the cathodic decomposition of CdS and ZnO (8).

The present paper describes the use of this method to investigate the passivity of iron. Optical studies of passivity of iron have been carried out extensively (9-18), and the optical thickness of the passive film has been well established. However, there is no agreement on whether the passive film consists of a single layer (9-13) or two layers (14-18) with different composition. Recent optical results seem to support single layer model. Revie *et al.* (11) claim from their data by Auger electron spectroscopy that the passive film is a hydrated ferrous oxide with gel-like structure, and this oxide is degraded to $\gamma\text{Fe}_2\text{O}_3$ during the heating by the beam in the electron diffraction camera. O'Grady (12) refused the existence of Fe_3O_4 from his Mössbauer study. Chen and Cahan (13) have described the passive film as an insulating ferric oxyhydroxide. However, our PAS data obtained here are incompatible with these models and prefer the two-layer model.

The optical evidence presented so far for the two-layer model is not sufficient. The electron diffraction pattern of $\gamma\text{Fe}_2\text{O}_3$ is very close to that of Fe_3O_4 , and the discrimination of Fe_3O_4 from $\gamma\text{Fe}_2\text{O}_3$ by this method is very difficult (19). In a polarizer reading (P)-reduction time plot that was obtained from the ellipsometric experiment by Ho and Ord (16), the inflection corresponding to the transition from $\gamma\text{Fe}_2\text{O}_3$ to Fe_3O_4 is very vague and, hence, is unable to be conclusive evidence for the existence of two layers. Seo *et al.* (17) interpreted their Auger spectra to suggest a duplex structure consisting of $\gamma\text{Fe}_2\text{O}_3$ and Fe_3O_4 . However, as pointed out by Revie *et al.* (11), the sample was transferred through the atmosphere in their experimental technique, and their Auger spectra must involve the spectrum characteristic of air-formed oxide.

* Electrochemical Society Active Member.

Experimental

A one-compartment cell was used with a Pt wire counterelectrode and a saturated calomel reference electrode (SCE). The working electrode was a 0.2 mm thick flat iron (purity: 99.9%) plate of about 1 cm² area. A TDK piezoelectric disk (PZT 51c-C10-2) was attached to the rear of the Fe electrode with epoxy resin. Care was taken to ensure that the Fe electrode was electrically insulated from the piezoelectric disk, and the disk from the solution by the epoxy resin. The Fe electrode surface was polished mechanically with emery papers before use. A Spectra Physics SP164 Ar ion laser was used as the light source. The incident light (wavelength 514.5 nm and its light power 0.2W) was interrupted at 80 Hz by a NF-CH-353 mechanical chopper, and irradiated on the Fe electrode. The signal from the piezoelectric transducer was synchronously detected with a NF-LI-574 lock-in amplifier. External acoustic and electric noise was reduced using a shielding box made of iron and lead.

Electrochemical measurements were carried out with a usual potentiostat together with a potential programmer. The electrolyte was 1.0M potassium phosphate + 0.05M sodium tetraborate buffer solution which was deaerated with nitrogen gas prior to the beginning of an experiment. Before each anodization, the specimen was polarized at -1.0V for 5 min in order to remove the air-formed oxide on iron.

Results and Discussion

Figure 1 shows the current-potential and the photoacoustic signal-potential curves of iron at pH 8.0. The *i*-*E* curves show the typical behavior of an iron electrode in a weak alkaline buffer solution (20) when the potential is scanned between -1.2 and -0.4V (curve a), -1.2 and 0V (curve b), and -1.2 and $+0.8\text{V}$ (curve c). In the acoustic curve a' corresponding to curve a, the signal begins to increase at approximately -0.8V at which anodic current commences to flow. The increase in the photoacoustic signal is due to an increase in the absorption of light at the electrode surface, which reflects the change in the absorptivity of the surface. Hence, this result leads to the conclusion that the iron surface starts to be covered with an oxide at -0.8V . On the reverse scan, the acoustic signal begins to decrease at the same potential; *i.e.*, the oxide starts to disappear. According to the electrochemical experiments combined with a chemical analysis (14), such oxide should be Fe_3O_4 .

In curve c', the acoustic signal continues increasing between -0.8 and $+0.8\text{V}$ on the anodic scan. However, the gradient of the magnitude of the acoustic signal *vs.* potential changes at about -0.4V . This implies that a different type of iron oxide begins to grow on Fe_3O_4 at about -0.4V . This oxide must be $\gamma\text{Fe}_2\text{O}_3$ or γFeOOH .

Fig. 1. Photoacoustic signal-potential and current-potential curves of the iron electrode in the 0.1M potassium phosphate + 0.05M sodium borate solution of pH 8.0. Potential scanning rate: 100 s/V; λ : 514.5 nm.

which has been assumed as an outer layer in the two layer model. On the reverse scan, the i - E curve shows a cathodic peak around $-0.4V$. This peak has been investigated in detail by the potentiodynamic or the galvanostatic method, and it is attributed to the reduction of $\gamma\text{Fe}_2\text{O}_3$ (21, 22). The corresponding acoustic signal decreases via two steps: first, at about $-0.4V$ and second, at $-0.9V$. This result therefore supports the existence of two layers on iron, and the reduction of $\gamma\text{Fe}_2\text{O}_3$ and Fe_3O_4 occurring at about -0.4 and

$-0.9V$, respectively. As seen from this figure, and also pointed out previously (22), the current peak corresponding to the reduction of Fe_3O_4 is not observed because of the large cathodic current of hydrogen evolution. This was one of the reasons why the existence of Fe_3O_4 was doubtful. However, these photoacoustic data evidently indicate the simultaneous reduction of Fe_3O_4 with the hydrogen evolution.

Acknowledgment

The authors express their sincere gratitude to Dr. H. Masuda, Mr. S. Morishita, and Y. Nagae for their experimental help.

Analysis of an Aluminum Plating Bath Using ^{27}Al -NMR Spectroscopy

G. A. R. van Dijk and H. C. A. M. Smoorenburg

Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

The electrodeposition of aluminum is not possible from an aqueous electrolyte because of the strong electronegativity of the metal. Deposition can be achieved in an ether-based bath, from which water and oxygen are excluded (1-3). It is difficult to determine the exact bath composition of such solutions, which contain AlCl_3 and LiAlH_4 , without interfering with the complex chemistry of the system. In this note, we show that ^{27}Al -NMR spectrometry is a suitable method for analyzing such solutions, and we present

Key words: electrolyte, electrode, spectra, electrodeposition.

results for a plating system based on AlCl_3 , LiAlH_4 , and tetrahydrofuran (THF). To identify possible bath components, we separately synthesized a number of complexes and compared their spectra with those of practical plating solutions.

^{27}Al -NMR Spectroscopy Results

Possible bath constituents.—The most important species which may be present in a plating bath based on $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ are listed in Table I. These species were prepared from mixtures of AlCl_3 and

Table I. Possible constituents of an Al-electroplating bath: characteristic ^{27}Al resonance lines

Chemical shift (^{27}Al) (ppm)	Component in THF-solution	Coupling multiplicity	Line-width ^a (Hz)	Coupling constant—JAl-H (Hz)
116	$\text{AlH}_2\text{Cl}_2^-$	singlet ^b (triplet expected)	1500	—
114	AlHCl_2^-	doublet	203	329
108	$\text{AlH}_3 \cdot 2\text{THF}$	singlet ^b (quarter expected)	3000	—
103	AlCl_4^-	singlet	5-20	—
97	AlH_4^-	quintet	54	175
90	$\text{AlH}_2\text{Cl} \cdot 2\text{THF}$	singlet ^b (triplet expected)	2500	—
77	$\text{AlHCl}_2 \cdot 2\text{THF}$	singlet ^b (doublet expected)	1300	—
64	$\text{AlCl}_3 \cdot 2\text{THF}$	singlet	317	—

0	$\text{Al}(\text{H}_2\text{O})_6^{3+}$	singlet	7	—

^a Linewidth as determined in the H-decoupled ^{27}Al -spectra.

^b Quadrupole relaxation dominates.

LiAlH_4 as described in Ref. (4, 5). $\text{Al}(\text{H}_2\text{O})_6^{3+}$ was used as an external chemical shift reference.

For these species, we determined the relevant ^{27}Al -NMR resonance lines (Table I). The measurements were made using a Nicolet NT 200 spectrometer (at $B = 4.7$ T; 52,130 MHz ^{27}Al frequency) with a multi-nuclear broad-band probe. The spectral width was 450 ppm. A 90° pulse with a pulse length of 21 μs was used.

"Fresh" bath.—From the data given in Table I, it is possible to obtain information about the composition of the plating bath. The spectrum of a fresh bath is shown in Fig. 1. The dipolar interaction between the Al and the H-nuclei can be removed by decoupling, which simplifies the spectrum (Fig. 2). From this particular spectrum, we obtained the values given in Table II for the concentration of the various species in a bath containing 14 mol percent (m/o) LiAlH_4 and 86 m/o AlCl_3 in THF (respectively, 0.2 and 1.2 mol liter $^{-1}$).

Fig. 1. ^{27}Al -NMR-spectrum of a "fresh" hydride-type Al electroplating bath.

Fig. 2. ^{27}Al -NMR-spectrum of a "fresh" hydride-type Al electroplating bath (decoupled).

Table II. Concentration of species in a "fresh" Al bath

Components	^{27}Al chem. shift (ppm)	Concentration (m/o)
$\text{AlCl}_3 \cdot 2\text{THF}$	64	70 { 36 34 18 12
$\text{AlHCl}_2 \cdot 2\text{THF}$	77	
AlCl_4^-	103	
AlHCl_2^-	114	

"Aged" bath.—With the protracted use of a given plating bath, the quality of the plated Al deteriorates. The NMR-spectrum for such an "aged" bath is shown in Fig. 3. This bath initially contained 1.3 mol liter $^{-1}$ AlCl_3 and 0.3 mol liter $^{-1}$ LiAlH_4 . After nine months operation, it was no longer possible to deposit Al layers of satisfactory quality. The adhesion of the metal to the substrate was poor, and the plated metal, which showed a black surface, reacted with water. In Table III, the composition of this "aged" bath is given.

It is clear that the components which contain hydride ($\text{AlHCl}_2 \cdot 2\text{THF}$ and AlHCl_3^-) are no longer present in the plating solution. Possible causes are leakage of oxygen or water into the plating vessel.

"Replenished" bath.—If the deterioration of the bath described above is caused by the loss of the hydride compounds, it should be possible to restore the original bath quality by adding hydride containing components. One could directly add the missing species or compounds capable of forming the missing hydride containing components by reacting with the remaining chloride. In Fig. 4 we see the effect of the addition of LiAlH_4 to the "aged" bath. Replenishing is also possible with $\text{AlH}_3 \cdot 2\text{THF}$, which can be easily prepared as a crystalline solid (6). This has the great advantage of avoiding the addition of extra lithium ions to the system. The Li is codeposited with the Al at bath concentrations above 0.6 mol liter $^{-1}$ or at high plating rates. The quality of aluminum deposited from the replenished bath was comparable to that obtained from the fresh bath.

Cyclic Voltammograms

To illustrate the effect of bath aging on the electrochemistry, cyclic voltammograms were taken for the

Fig. 3. ^{27}Al -NMR-spectrum of an "aged" hydride-type Al electroplating bath.

Fig. 4. ^{27}Al -NMR-spectrum of a "replenished" hydride-type Al electroplating bath (decoupled).

Table III. Concentration of species in the "aged" Al bath

Components	²⁷ Al chem. shift (ppm)	Conc (m/o)
AlCl ₃ · 2THF	64	56
AlCl ₄ ⁻	103	44

Original components: 1.3 mol liter⁻¹ AlCl₃ + 0.3 mol liter⁻¹ LiAlH₄ in THF.

Table IV. Concentration of species in the replenished bath

Components	²⁷ Al chem. shift (ppm)	Concentration (m/o)			
AlCl ₃ · 2THF	64	74 { 38			
AlHCl ₂ · 2THF	76		{ 36		
AlCl ₄ ⁻	103			{ 22	
AlHCl ₃ ⁻	114				{ 4

Original components: 1.3 mol liter⁻¹ AlCl₃, 0.3 mol liter⁻¹ LiAlH₄; 0.25 mol liter⁻¹ LiAlH₄ added for replenishing.

The AlCl₃ · 2THF-AlHCl₂ · 2THF-peak has been separated with curve fitting.

three bath compositions described above (Tables II-IV).

Because of the nature of our system, the direct use of a reference is not possible. We used an Al-quasi-reference electrode (99.999% Al wire). This was placed behind the Pt working electrode and connected by a Luggin capillary through the working electrode with the active surface. This was done to decrease the IR drops considerably (7). The counterelectrode was 99.999% Al. Contact between the counter and reference electrode was avoided by placing the reference electrode in a Teflon holder. Prior to the experiment, the working electrode was plated with an Al layer for 30s at 5 mA/cm⁻². The results are shown in Fig. 5. Curve 1 refers to a "new" Al plating bath from which layers of good quality are deposited. The anodic and cathodic waves are clearly recognizable. The peak-peak distance is rather large because of the still considerable IR drop ($R_u \approx 1\Omega$). Curve 2 shows the result of an "aged" bath. No currents above 0.2 mA are observed, indicating that with the depleted solution extreme polarization is required for the electrolytic deposition of metal. In this situation, either coprecipitation of Li and Al or reduction of the solvent is to be expected (8). Curve 3 shows that the anodic and cathodic waves are restored completely after replenishing.

The voltammogram is a clear indication that the hydride containing species are the essential catalytic

Fig. 5. Cyclic voltammograms of the Al electroplating bath using an Al quasi-reference electrode. Curve 1, "fresh" bath; curve 2, "aged" bath; curve 3, "replenished" bath.

species in the "cyclic" electrode process for Al electroplating (9).

Conclusion

²⁷Al-NMR spectroscopy is very suitable for identifying the constituents of an Al electroplating solution. The essential role of the hydride is clear and it is possible to keep such a plating bath in optimum condition by replenishing species which are lost by "dragged-in" water or oxygen.

Electrochemical Deposition of Conducting Ruthenium Oxide Films from Solution

D. P. Anderson and L. F. Warren

Rockwell International Science Center, Thousand Oaks, California 91360

In the last decade, ruthenium oxide, RuO₂ ($x \leq 2$), has been used extensively as the active anode electrocatalyst constituent for Cl₂ and O₂ evolution reactions, in chlorate production, and in metal electrowinning from mixed chloride-sulfate solutions (1-3). More recently, this material has been incorporated in several light-induced water electrolysis schemes (4-8) and

Key words: aqua Ru(II) complex, anodic deposition, oxygen catalyst.

apparently possesses the ability to inhibit CdS photocorrosion by acting as a hole scavenger (6-8). The numerous applications for this catalyst material certainly warrant further studies of its electrochemical properties on a variety of substrates, e.g., semiconductors. The lack of a simple technique for controlled deposition of ruthenium oxide onto conducting substrates prompted us to investigate an electrochemical approach to this problem. We describe here a new

method for electrodepositing conducting hydrated ruthenium oxide films from stable aqueous solutions containing a ruthenium(II) complex.

As with hydrous manganese oxide (MnO_x) (9-10) it was assumed that anodic electrodeposition of RuO_x may take place from an aqueous solution of the corresponding M^{2+} ion. Preparation and isolation of air-sensitive aqua ion $\text{Ru}(\text{OH}_2)_6^{2+}$ salts are, however, tedious procedures involving use of expensive and reactive RuO_4 and ion-exchange chromatography (11). A more accessible aqua ruthenium(II) species is $\text{Ru}(\eta^6\text{-C}_6\text{H}_6)(\text{OH}_2)_3^{2+}$; this is obtained from the very stable organometallic complex $[\text{Ru}(\eta^6\text{-C}_6\text{H}_6)\text{Cl}_2]_2$, which forms in virtually quantitative yield from commercial $\text{RuCl}_3 \cdot 3\text{H}_2\text{O}$ and 1,3- or 1,4-cyclohexadiene (12). Treatment of an aqueous solution of this species with two equivalents of AgBF_4 generated the yellow-aquated $\text{Ru}(\eta^6\text{-C}_6\text{H}_6)(\text{OH}_2)_3^{2+}$ species (12, 13), which appeared to be stable indefinitely over a wide range of pH values. (Although air sensitivity was not apparent, typically, the solutions were stored under an inert atmosphere.) The coordinated benzene stabilizes the ruthenium(II) oxidation state compared with the aqua $\text{Ru}(\text{OH}_2)_6^{2+}$ ion (11).

The anodic electrodeposition of hydrous RuO_x on a rotating Pt disk electrode (400 rpm) took place at a constant potential (+0.9V vs. SCE, corresponding to a current density of ca. 1 mA/cm²) from room temperature aqueous solutions containing the $\text{Ru}(\eta^6\text{-C}_6\text{H}_6)(\text{OH}_2)_3^{2+}$ complex (0.04M), adjusted to pH 5. 0.1M sodium perchlorate was used as supporting electrolyte. No precautions were made to exclude oxygen

Films of thickness corresponding to 20-30 mC/cm² were typically grown, though much thicker films are attainable because the deposits are conducting. Using a cubic approximation of the RuO_2 unit cell of 4.6Å, these charges correspond to nominal thicknesses of 600-1000Å, assuming 100% deposition efficiency.

The resulting smooth brown films were conducting in aqueous electrolytes; this was apparent from the stable anodic-deposition current and from their behavior in the presence of a redox couple. Figure 1 shows the current-potential characteristics of a 600Å film on Pt in a pH 4 buffer (phthalate) electrolyte with and without added $\text{Fe}(\text{CN})_6^{4-}$ ion; the voltammetric behavior of the redox couple is essentially unaffected by the presence of the oxide film. Similar behavior was observed with ferrocene in an acetonitrile/0.1M tetraethylammonium perchlorate electrolyte; however, the voltammetric response of the film itself was greatly suppressed in acetonitrile relative to aqueous electrolytes (14). These results parallel our findings with electrodeposited hydrous MnO_x and other transition metal oxide films (10).

The reversible nature of the electrodeposited ruthenium oxide was further demonstrated by its behavior in 0.1M perchloric acid (pH 1.5, shown in Fig. 2), where at any potential in the sweep an almost reversible behavior was observed as the sweep direction was changed. This was manifested as a rapid current change from anodic to cathodic at a magnitude nearly the same as that on the immediately previous anodic sweeps. The current-potential profiles for our electrodeposited films are qualitatively similar to those of the reversible films generated by anodic/cathodic potential cycling of ruthenized Pt and (oxidized) Ru-on-glass electrodes (15). Differences may be attributed to the particular electrolytes employed; in addition, our

Fig. 1. Cyclic voltammograms at 50 mV/s for an electrodeposited ruthenium oxide film (600Å) on Pt in a room temperature pH 4 buffer (phthalate), with (solid curve) and without (dotted curve) added ferrocyanide (0.01M).

Fig. 2. Cyclic voltammograms of an electrodeposited ruthenium oxide film (1000Å) on Pt in 0.1M HClO_4 (pH 1.5, room temperature); the potential sweep direction was changed (designated by arrows) from anodic to cathodic at increasing 100 mV intervals; sweep rate 50 mV/s. Sweeps start at -0.1V in the direction of more positive potentials.

films appear to be more prone to dissolution; this is perhaps indicative of greater porosity (16). The reversible behavior of these films has been attributed to a mixed valency $\text{Ru}(\text{III-IV})$ oxide/hydroxide in which a rapid redox process (involving protonation) can occur with kinetic facility (15), i.e., formally, $\text{RuO}_2 + \text{H}^+ + e^- \rightleftharpoons \text{RuO}(\text{OH})$.

Slow dissolution of the fresh electrodeposited ruthenium oxide films occurred during potential cycling in aqueous electrolytes. In the pH 4 buffer solution, the films remained intact provided cycling was limited to the range of +0.6 to -0.2V.¹ At more positive

¹The theoretical domain of passivation of ruthenium, corresponding to the formation of $\text{RuO}_2 \cdot 2\text{H}_2\text{O}$ and $\text{Ru}(\text{OH})_3$, is limited to a 600 mV range at pH 4 (17).

potentials in the anodic sweep, an anodic current resulted which was apparently due to both dissolution, involving soluble higher oxidation states, and water oxidation; at high pH's (>10), dissolution predominated, and orange RuO_4^{2-} streamed off the electrode surface. In acidic electrolytes, oxygen evolution was observed at potentials >0.8V; polarization curves in 0.5M H_2SO_4 indicated that the overvoltage for oxygen evolution on the RuO_x films is less by 320 mV than that on Pt (18). Dissolution was also evident, however, and emphasized the importance of stabilizing ruthenium oxide by combination with TiO_2 or other oxides (1, 15, 16, 19).

In conclusion, it is possible to electrochemically deposit conducting films of hydrated ruthenium oxide from an aqueous solution of the benzeneruthenium(II)-aqua complex. The films slowly dissolve in aqueous electrolytes upon potential cycling, yet appear to be catalytic with regards to water oxidation.

An Electrochemical Synthesis of Dichlorobutenes from Butadiene as a New Process in the Chloroprene Production System

Yoshio Takasu,* Yoshiharu Matsuda,* Michiko Harada, and Misao Masaki

Faculty of Engineering, Yamaguchi University, Ube, Yamaguchi, Japan

Hiroyuki Watanabe

Toyo Soda Manufacturing Company, Research Laboratory, Shin-nanyo, Japan

Chloroprene ($\text{ClCH}=\text{CHCH}=\text{CH}_2$), an important industrial material, is usually produced by elimination of hydrochloric acid from 3,4-dichloro-1-butene (3,4-DCB) which is synthesized from butadiene and chlorine by chemical reaction at about 300°C. In the latter reaction, trans-1,4-dichlorobutene (trans-1,4-DCB) is also formed, but it is isomerized to 3,4-DCB with a catalyst. The elimination of hydrochloric acid from 3,4-DCB is performed with ethylenediamine (EDA) forming EDA solution of $\text{EDA} \cdot 2\text{HCl}$. The authors have reported in the previous papers (1, 2) that dichlorobutenes (DCB) could be formed by electrolysis of butadiene in an anolyte solution of acetonitrile (MeCN)- CoCl_2 which was separated from

the catholyte ($\text{H}_2\text{O}-\text{NH}_4\text{Cl}$) by an anion-exchange membrane.

This work has been done to develop an electrochemical synthesis process of DCB as a new process in the production of chloroprene from butadiene utilizing the $\text{EDA} \cdot 2\text{HCl}$ solution and $\text{MeCN}-\text{CoCl}_2$ solution as the catholyte and the anolyte, respectively. The advantages of this process are as follows: (i) the elimination process of hydrochloric acid from $\text{EDA} \cdot 2\text{HCl}$ solution is utilized in the electrolytic chlorination process of butadiene; (ii) it does not need the use of expensive and toxic chlorine; and (iii) the chlorination of butadiene is performed at room temperature. Although studies on the electrolytic chlorination of alkenes have been carried out by many investigators (3-5), those of butadiene have scarcely been reported (6).

* Electrochemical Society Active Member.

Key words: butadiene, electrolytic chlorination, ethylenediamine, dichlorobutene.

Experimental

Potentiostatic electrolyses were performed by use of a conventional Pyrex glass H-type cell with a separator of an anion-exchange membrane (Asahi Glass Company, "Selemion-ASV" made of polystyrene; 3 cm diam). A graphite plate of 2 cm diam and a graphite plate of 3 cm diam were used as the anode and the cathode, respectively. Highly purified butadiene was bubbled into the anolyte (MeCN containing 0.5 mol dm⁻³ CoCl₂, 40 ml) during electrolyses in order to keep the concentration of butadiene in the anolyte at a constant value, ca. 2 mol dm⁻³. Tetraalkylammonium chloride was thought to be usable in the solute of the anolyte, but the current efficiency for the formation of DCB in the electrolysis using MeCN-Me₄NCl anolyte was low (ca. 60%). The catholyte (40 ml) was an aqueous solution of NH₄Cl, NaCl, HCl, or an EDA solution containing EDA · 2HCl. Acetonitrile was dried with molecular sieves (5A) and CaH₂, and then distilled twice. Butadiene and its derivatives were determined by gas chromatography (TCD; Silicone Gum SE30-Chromosorb WAW; He). The electrolytic cell was set in a water bath thermostated at 25°C.

Results and Discussion

Table I presents the experimental conditions and the current efficiencies for the formation of DCB. Appreciable amounts of butadiene derivatives other than 3,4-DCB and trans-1,4-DCB (such as cis-1,4-dichloro-2-butene or 4-vinyl-1-cyclohexene) were not detected on the gas chromatograms. The current efficiency for dichlorobutene formation is defined as the percentage of the quantity of electricity that passed through the cell, and was calculated by assuming that the chlorination was a two-electron reaction. The quantity of electricity passed in these runs, 483C, is that required to convert ca. 4% of butadiene initially dissolved in the anolyte into DCB. In the electrolyses using an aqueous solution of such salts as NH₄Cl, NaCl, or HCl as the catholytes, the current efficiencies for the formation of DCB were 96-98%. On the other hand, when EDA solution of EDA · 2HCl (0.5M) was used as the catholyte, the current efficiency attained only 42%. As shown in Fig. 1, the current efficiency in the electrolysis using this catholyte strongly depended on the concentration of EDA · 2HCl, and gave a maximum value at 1.5 mol dm⁻³. The low current efficiency obtained when EDA-EDA · 2HCl is used as the catholyte is most likely due to transport of EDA to the anolyte (solvating Cl⁻) and subsequent oxidation. The oxidation will occur either directly at the anode or mediated since EDA-EDA · 2HCl is likely to be more reactive than butadiene. Figure 2 shows that the addition of a small amount of water to the anolyte improved the current efficiency to nearly 100%. The addition of water might allow water solvation of Cl⁻ and thus less EDA transport across the membrane. The existence of a small amount of water

Table I. Current efficiency for the formation of dichlorobutenes using various compositions of electrolytes

Catholytes	Current efficiency		
	3,4-DCB	trans-1,4-DCB	Total
H ₂ O-NH ₄ Cl (1M)	46	52	98
H ₂ O-NaCl (1M)	44	53	97
H ₂ O-HCl (1M)	37	59	96
EDA-EDA · 2HCl (0.5M)	15	27	42
EDA-EDA · 2HCl (1.5M)	28	57	85
EDA-EDA · 2HCl (0.5M)-H ₂ O (1.7M)	37	61	98

Anolyte: MeCN-CoCl₂ (0.5M)-C₄H₆ (2M); separator: anion-exchange membrane; anode material: carbon plate; cathode material: carbon plate; anode potential: 1.7V vs. Ag/AgCl; amount of anolyte: 40 ml; amount of catholyte: 40 ml; amount of electricity passed: 483C; temperature: 25°C.

Fig. 1. Effect of EDA · 2HCl concentration in the catholyte on the current efficiency for the formation of dichlorobutenes. Anolyte: MeCN-CoCl₂ (0.5M)-C₄H₆ (2M); catholyte: EDA-EDA · 2HCl; separator: anion-exchange membrane; anode and cathode: carbon plates; anode potential: 1.7V vs. Ag/AgCl; amount of anolyte: 40 ml; amount of catholyte: 40 ml; amount of electricity passed: 483C; temperature: 25°C.

Fig. 2. Effect of H₂O concentration in the catholyte on the current efficiency for the formation of dichlorobutenes. Anolyte: MeCN-CoCl₂ (0.5M)-C₄H₆ (2M); catholyte: EDA-EDA · 2HCl (0.5M)-H₂O; other conditions are shown in the caption in Fig. 1.

in the EDA-EDA · 2HCl solution may be permissible in the recovery of EDA by distillation. It was observed, however, that the membrane was gradually harmed by the catholyte in the duration of the electrolysis when EDA-EDA · 2HCl was used as the catholyte.

If an anion-exchange membrane which is not harmed by these electrolytes can be obtained, this electrolysis process could be considered for industrialization. Because the current efficiency for the formation of DCB is high, this process can be combined with the elimination process of hydrochloric acid from EDA-EDA · 2HCl solution formed in the production process of chloroprene from DCB by EDA.

The following reaction schemes can be proposed for the reaction.

Preparation of Vanadium-Tungsten-Oxide Wadsley-Roth Phases by Electrolytic Reduction of Molten Salts

L. F. Schneemeyer and V. Tierney

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

Many framework metal oxides are interesting as materials which can reversibly incorporate lithium atoms into their crystal lattices (1). The extent and rate of the lithium insertion reactions makes some of them candidates for use as positive electrode materials for ambient temperature secondary batteries. Two compounds, $V_2WO_{7.5}$ and $V_{2.4}W_{0.6}O_7$ ¹ (2), both members of a class of compounds known as Wadsley-Roth phases (3), have recently been shown to be particularly suitable for such applications (4).

Wadsley-Roth phases have structures in which blocks of corner-shared MO_6 ($M = V, W$) octahedra are connected through regions of edge sharing, or crystallographic shear. These materials have previously been produced as powders by solid-state synthesis in which appropriate quantities of the starting materials V_2O_5 , VO_2 , and WO_3 are ground together, then heated in evacuated silica tubes until single-phase samples are obtained. Electrolysis of molten salts is an alternative method which has been used in the preparation of oxides containing transition metals in reduced oxidation states. Large well-formed crystals of alkali tungsten bronzes, vanadium spinels, and molybdenum dioxide are among the materials which have been obtained by this technique (5).

An attraction of electrochemical synthesis of materials such as $V_2WO_{7.5}$ and $V_{2.4}W_{0.6}O_7$ Wadsley-Roth phases is the deposition of a film of active material directly onto a conducting substrate to form an electrode for an ambient temperature secondary battery. The current work was undertaken to investigate the feasibility of preparing tungsten-vanadium-oxide Wadsley-Roth phases electrochemically. While no previously unknown phases were found in this study, the electrochemical synthesis of $V_2WO_{7.5}$ and $V_{2.4}W_{0.6}O_7$ from $V_2O_5 + WO_3$ melts at $T = 750^\circ\text{--}800^\circ\text{C}$ was achieved. Furthermore, single crystals of $V_2WO_{7.5}$ of substantial size, suitable for physical property measurements, have been grown.

Experimental

The apparatus used for the electrochemical crystal growth is shown in Fig. 1. The melt was contained in a high-purity recrystallized alumina crucible (Coors). Cracking of the crucible resulting from expansion of the melt upon cooling limited use of a crucible to one run. The crucible was seated in a graphite support. This assembly was contained under N_2 within a quartz vessel itself inside a Lindberg crucible furnace. Melts

were prepared from analytical-grade reagents which were dried before use. A high density, high purity pyrolytic graphite rod, Pt wire and foil, and tungsten foil (Alfa, 99.9%) were variously employed as cathode materials. A Pt-foil electrode served as the anode. No significant attack on the Pt by the melt was observed. Following deposition, traces of V_2O_5 and WO_3 were removed by washing with warm 5% aqueous NH_4OH .

A Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat equipped with a Model 179 digital coulometer was used for crystal growth experiments. Samples were examined by x-ray diffraction on a Rigaku Powder Diffractometer using $CuK\alpha$ radiation and a scan speed of 2°min^{-1} . Scanning electron micrographs were taken with an Autoscan 100 Scanning Electron Microscope (Cambridge Instruments) operated at 25 kV.

Results and Discussion

Wadsley-Roth phase tungsten-vanadium oxides of composition $V_2WO_{7.5}$ and $V_{2.4}W_{0.6}O_7$ were prepared by the electrolysis of fused mixtures of WO_3 and V_2O_5 . Table I lists the experimental conditions for the growth of these materials. Reductions were carried out

Fig. 1. Schematic representation of molten salt electrolysis system.

¹ The phase reported in the literature and referred to in this paper as having the composition $V_{2.4}W_{0.6}O_7$ has recently been shown to exist over the composition range $V_{2.5}W_{0.5}O_7$ – $V_{2.6}W_{0.4}O_7$.

Table I. Experimental conditions for the growth of some tungsten-vanadium-oxides by fused-salt electrolysis

Melt composition	Melt temperature	Current density	Cathode	Product
V_2O_5	800°C	100 mA/cm ²	Graphite rod	VO_2
1WO ₃ :12.5V ₂ O ₅	750°C	200 mA/cm ²	Pt foil	$V_2WO_{7.5}$ + $V_{2.4}W_{0.6}O_7$
1WO ₃ :9V ₂ O ₅	770°C	200 mA/cm ²	Pt foil	$V_2WO_{7.5}$ + $V_{2.4}W_{0.6}O_7$
1WO ₃ :4.5V ₂ O ₅	785°-800°C	50-400 mA/cm ²	Pt foil Pt wire Graphite rod	$V_2WO_{7.5}$
1WO ₃ :4V ₂ O ₅ 0.67Na ₂ WO ₄ :0.22V ₂ O ₅ :0.11WO ₃	820°C 700°C	— 20 mA/cm ²	— Graphite rod	— $V_{1-x}W_xO_5$ $x \approx 0.2$

under galvanostatic control. Current densities in the range of at least 50-200 mA/cm² were found to give crystalline deposits. At current densities below 50 mA/cm², little or no product was recovered, presumably because sufficient current must be passed to overcome a competing back reaction. The temperature in most experiments was held just above the melting point of the vanadium pentoxide-tungsten trioxide mixture. The melting point of this mixture increases with increasing proportion of tungsten trioxide. Runs for a given melt carried out at higher temperatures showed no significant variation in the phases produced or, qualitatively, in the product recovered.

The ratio of tungsten to vanadium in the melt is found to control the phase of the product formed. In the absence of WO₃, the electrolysis of molten V₂O₅ yields elongated prismatic crystals of VO₂ (6,7). At the lowest concentration of WO₃ examined in this study (1W: 25V), a mixture of V₂WO_{7.5} and V_{2.4}W_{0.6}O₇ is formed during the electrolysis. From a 1W: 9V melt, V₂WO_{7.5} is formed exclusively. The melting temperatures of mixtures with still higher tungsten trioxide concentration is above the temperature at which V₂WO_{7.5} is known to transform to a V₂O₅ structure type (8). Scanning electron micrographs of V₂WO_{7.5} crystals grown from a 1WO₃:4.5V₂O₅ melt (1W:9V)

Fig. 2. Scanning electron micrographs at two magnifications of V₂WO_{7.5} crystals deposited on Pt wire at 50 mA/cm² under galvanostatic control. $T_{melt} = 785^\circ C$.

at 785°C at a current density of 50 mA/cm² onto a Pt wire cathode are shown in Fig. 2 at two magnifications. Eight sided rod-shaped crystals ~0.5 mm long are observed. Crystals of up to several millimeters in length have been grown. Precession photographs of one crystal verified the unit cell as that reported for V₂WO_{7.5} and suggested some disorder along the unique axis of the monoclinic unit cell. A scanning electron micrograph of one end of one such V₂WO_{7.5} crystal is shown in Fig. 3. Evident are the well-developed faces of this crystal. The growth of this crystal resulted in a large void in its center. Similar voids were not observed in other crystals.

The electrochemical formation of the Wadsley-Roth phases (V₂WO_{7.5} and V_{2.4}W_{0.6}O₇), rather than W-substituted VO₂ phases, is interesting. The electrolysis of a sodium tungstate melt containing WO₃ and V₂O₅, as listed in Table I, does yield needles of W_xV_{1-x}O₂ with $x \sim 0.2$ as determined from relative peak heights in an x-ray fluorescence experiment. Since electrolyses of V₂O₅-WO₃ melts were carried out at temperatures of 750°-800°C while the Na₂WO₄ + V₂O₅ + WO₃ melt was maintained at 700°C, a difference of only 50°-100°C, temperature is assumed to be of minor importance in the determination of the phase of the resulting material. Of greater importance to the nature of the resulting material may be the relative acidity of the melt. In the preparation of members of the mixed spinel system (Co_{1+x}V_{2-x}O₄) by fused salt electrolysis, it was shown that more reduced products were formed with increasing basicity of the flux (9). Similar behavior is observed in this system. Here, the more basic melt formed from Na₂WO₄ + WO₃ + V₂O₅ yields as its product tungsten-substituted VO₂, while the relatively more acidic WO₃-V₂O₅ melts yield V₂WO_{7.5} and V_{2.4}W_{0.6}O₇. A relationship between melt composition and oxygen activity at the cathode thought to control the composition of the product phase in electrochemical tungsten-bronze syntheses (10) may also be a factor in this system.

Although crystalline samples of the Wadsley-Roth phase metal oxides (V₂WO_{7.5} and V_{2.4}W_{0.6}O₇) have been obtained electrochemically, the present study does not address optimization of product yields. Also,

Fig. 3. Scanning electron micrograph of one end of a V₂WO_{7.5} crystal deposited onto a Pt wire at 50 mA/cm² under galvanostatic control. $T_{melt} = 785^\circ C$.

traces of the melt which cling to the samples following deposition are difficult to preferentially dissolve. The use of alternative melts such as alkali halide-based melts to achieve the deposition of $V_2WO_{7.5}$ and $V_{2.4}W_{0.6}O_7$ or optimization of deposition conditions based on the present melt are possible approaches to countering these limitations.

In summary, the electrochemical synthesis of $V_2WO_{7.5}$ and $V_{2.4}W_{0.6}O_7$ in the form of crystalline deposits on conducting substrates as economical as carbon has been demonstrated, and shows promise for the fabrication of battery electrodes. Growth of single crystals of $V_2WO_{7.5}$ of suitable size and quality for physical property measurements has been achieved.

Oxidation Characteristics and Electrical Properties of Low Pressure Dual TCE Oxides

Y. C. Cheng and B. Y. Liu*

Department of Electrical Engineering, University of Hong Kong, Hong Kong

ABSTRACT

A detailed investigation is conducted on the oxidation characteristics and electrical properties of very thin gate oxides (70-400Å), prepared by a novel two-step trichloroethylene (dual TCE) oxidation process. It is demonstrated that very thin oxide films can be accurately and reproducibly prepared under a variety of oxidation conditions. A reversal of relative oxidation rate of (111) and (100) silicon surfaces is observed at low oxygen partial pressure similar to that reported by earlier researchers. In addition to this observation, we find that the reversal is also strongly dependent on the TCE flow rate. Minima are observed in ΔV_{FB} and V_{FB} as a function of TCE flow rate. While the former results agree with earlier work, the minimum in the latter case is located differently, at a lower flow rate. The breakdown fields on oxides grown by various techniques are compared, and dual TCE oxides are shown to have good breakdown characteristics.

Recently, great interest has been expressed in very thin gate oxide (1). This has been motivated by the requirement of a very thin gate as the key element in the basic circuit device in VLSI circuits, and the application of thin oxide in electrically alterable read-only memory devices. For 1 μm channel length MOSFET's, oxides of the order of 200Å will be used as the dielectric layer under the gate electrode. In order to routinely produce reliable oxides of this thickness, various oxidation techniques have been proposed (2-7). These novel oxidation methods are necessary because the well-established standard dry oxidation at high temperature is not satisfactory, mainly because of (i) difficulty in controlling accurately the thickness of the thin oxide layer because of the fast oxidation rate, and (ii) poor oxide quality as manifested by low electric field breakdown and a large amount of interface charge.

To circumvent the former difficulty, the oxide is usually grown either at low temperature or under low partial pressure (2, 3). The second problem can basically be solved by a two-step process (5-7), which consists of an initial period of low temperature oxidation to provide a high dielectric breakdown strength, and a final phase of high-temperature oxidation to provide a good oxide-silicon interface (8). In order to encompass both of the above advantages and to provide additional beneficial passivation ability against mobile ions, a two-step HCl oxidation technique has been proposed (6). While it has been established that HCl oxidation (9) provides a number of benefits, it does have some practical problems in implementation, as HCl is a highly corrosive and dangerous gas. As a better alternative, a dual TCE process has recently been suggested to grow reliable thin gate oxide (7). It was reported that very thin oxide (70-400Å) with high integrity can be routinely produced with this technique.

However, in order to assess whether or not the dual TCE oxidation technique can be eventually adopted and implemented in any practical manufacturing

process requiring thin oxide layers, the oxidation characteristics and the properties of these oxides must be well understood. This article is a detailed investigation of the dual TCE process.

Experimental Methods and Results on Oxidation Characteristics

For the present studies, p-type <111> oriented silicon wafers with a resistivity of 1-4 $\Omega\text{-cm}$, and n-type <100> oriented wafers with 2-3 $\Omega\text{-cm}$ were used. These were cleaned by a standard cleaning procedure and were subsequently oxidized in a resistance-heated furnace at various temperatures in the presence (or absence) of a small amount of TCE. TCE vapor was added to the oxidizing ambient, which consisted of dry oxygen and dry nitrogen. The partial pressure of oxygen was controlled by adjusting the relative proportion of oxygen and nitrogen. The amount of TCE was controlled by varying the flow rate of another dry nitrogen inlet through a bubbler filled with purified liquid TCE kept at 0°C.

The dual TCE process consists of a low temperature dry oxidation, a low temperature TCE oxidation, and a high temperature TCE oxidation with low oxygen partial pressure. This can be followed by nitrogen annealing if necessary. More detailed information on this

Table I. Summary of two dual TCE oxidation processes and a two-step dry oxidation process

* On leave from South China Institute of Technology, Guangzhou, China.

Key words: thin silicon oxide, oxidation, trichloroethylene.

oxidation technique can be found elsewhere (7). The essential features of two dual TCE processes and a two-step dry oxidation (for comparison) are summarized in Table I.

The oxide film thickness was measured by a Rudolph ellipsometer at a wavelength of 5461Å, taking the silicon refractive index to be 4.040-0.031i (3). Dielectric breakdown measurement was performed with the aluminum dots biased negatively for p-Si, or positively for n-Si, i.e., with n-type or p-type Si in accumulation. The breakdown voltage was measured when the current reached a magnitude of 0.01 mA. Fixed oxide charges and mobile ions were deduced from the flat-band voltages based on the high frequency capacitance measurements.

As indicated in Table I, the dual TCE oxidation technique actually consists of two processes (7). Therefore, the relationship between the overall thickness and time must be accurately determined for a given dual TCE oxidation process. The experimental

plots of oxide thickness as a function of TCE treatment time at P_{O_2} (oxygen partial pressure) = 0.05, 0.1, and 1.0 atm are shown in Fig. 1a-c), respectively.

In Fig. 1a, where the oxygen partial pressure is very low ($P_{O_2} = 0.05$ atm), experimental results from both high and low oxidation temperature show that the oxidation rate is faster on a (100) surface than on a (111) surface. This is consistent with the observation of the occurrence of a reversal of relative oxidation rates of $\langle 111 \rangle$ and $\langle 100 \rangle$ oriented substrates at low oxygen partial pressures (2, 3). However, there is one major difference: earlier observations were made in an atmosphere containing oxygen or water vapor and inert gases, whereas the case in question contained chlorine species in addition to the above gases. However, the same phenomenon of reversal occurs in both situations.

The oxide thickness vs. time characteristics are similar to the generally observed linear-parabolic type of behavior (2). The higher the oxidation temperature, the faster and closer to the parabolic behavior is the

Fig. 1. (a, upper left) Measured oxide thickness vs. TCE oxidation time for p-type (●) and n-type (×) Si at $P_{O_2} = 0.05$ atm. Total oxidation time is 10 min dry oxidation + TCE oxidation time at 850°C, and 5 min dry oxidation + TCE oxidation time at 1050°C. (b, upper right) Same as a, but $P_{O_2} = 0.1$ atm. (c, left) Same as a, but $P_{O_2} = 1.0$ atm.

growth. At a lower temperature, the growth is slow, as expected, and the characteristics are almost a straight line. However, there is another important controlling factor, i.e., the TCE flow rate, which modifies the oxidation rate in a significant manner. In fact, a higher TCE flow rate behaves as if it transforms the oxidation characteristics to that of a higher temperature.

Figure 1b shows similar oxidation characteristics, but at somewhat higher oxygen partial pressure ($P_{O_2} = 0.1$ atm). An interesting observation is found at 1050°C . When the TCE flow rate varies, a reversal of relative oxidation rates of (111) and (100) surfaces occurs. This happens when there is hardly any change of oxygen partial pressure and the temperature is constant. The oxidation characteristics at lower TCE flow rate and at lower temperature are similar to those normally observed, i.e., the oxidation rate at the $\langle 111 \rangle$ oriented surface is faster.

Figure 1c presents results when the oxygen partial pressure is 1 atm. The oxidation characteristics are similar to the case of oxidation in pure oxygen, except that the rate is faster due to the presence of trichloroethylene.

The effect of oxygen partial pressure and TCE/ N_2 flow rate on the oxide thickness of two dual TCE oxidation processes is summarized in Fig. 2. In general, silicon substrates with $\langle 111 \rangle$ oriented surfaces are oxidized more readily than substrates with $\langle 100 \rangle$ orientations at the same oxidation temperature and oxidant pressure. However, at lower P_{O_2} ($P_{O_2} \sim 0.07$ atm at 1050°C and $P_{O_2} \sim 0.04$ atm 850°C), this dependence of oxidation rate on orientation is reversed. As mentioned earlier, this behavior is almost identical to that of oxidation in pure oxygen (2).

Another reversal in the oxidation rate was observed when the TCE/ N_2 flow rate was increased. Typical experimental results are summarized in Fig. 3 to illustrate the effect of TCE flow rates on the oxide growth at different oxygen partial pressures. A comparatively higher TCE flow rate will bring a reversal in the oxidation rate. The higher the oxygen partial pressure,

Fig. 2. The effect of O_2 partial pressure on the thickness of p-type (●) and n-type (×) SiO_2 films grown by TCE oxidation process at 850°C and 1050°C . $t_{\text{oxid}} = 10$ min dry oxidation + 10 min TCE oxidation at 850°C , and $t_{\text{oxid}} = 5$ min dry oxidation + 10 min TCE oxidation at 1050°C . $N_2 + O_2 + TCE/N_2 = 1500$ ml/min and $TCE/N_2 = 4.5$ ml/min.

Fig. 3. The effect of TCE/ N_2 flow rate on the thickness of TCE oxides for 1050°C oxidation at different partial oxygen pressure. $t_{\text{oxid}} = 5$ min dry oxidation + 40 min TCE oxidation and N_2 : O_2 :TCE/ $N_2 = 1425$:75:V for $P_{O_2} = 0.05$ (broken line); $t_{\text{oxid}} = 5$ min dry oxidation + 20 min TCE oxidation and N_2 : O_2 :TCE/ $N_2 = 1350$:150:V for $P_{O_2} = 0.1$ (solid line).

the higher the TCE flow rate needed to affect the reversal. In general, the higher the TCE flow rate, the faster will $\langle 100 \rangle$ oriented surfaces be oxidized compared to $\langle 111 \rangle$ oriented surfaces, at both 0.05 and 0.1 atm of oxygen partial pressure.

The experimental data show that the oxide thickness can be accurately and reproducibly controlled by the oxidation time, once a particular set of oxidation conditions is given. The oxidation kinetics are not fully understood at present, and further discussion is deferred to a later section.

Electrical Properties of Dual TCE Oxides

To assess the overall quality of the dual TCE oxides, we have measured the flatband voltages, analyzed the passivation ability, and examined the dielectric breakdown characteristics. Figure 4 summarizes the experimental results of flatband voltages as a function of the TCE flow rate. Similar to earlier results (10), a minimum in flatband voltage is observed. However, the location of the minimum in the present case is different from that of the earlier work; the present minimum occurs when the TCE flow rate is about 10 ml/min, whereas in the other case it occurs when the flow rate is around 50 ml/min. To appreciate the difference, we should note that in the present work the oxide thickness is of the order of 100–200 Å, while in the previous work (10) the oxide thickness varied from 900 to 1650 Å. It has been reported (11) that fixed oxide charge density depends on the thickness of the oxide layer; it increases in magnitude as the oxide thickness decreases. This effect may be related to our observation. Another important difference is that the oxygen partial pressure in the present case is low compared to that of earlier work. However, it remains to be confirmed whether or not the location of the minimum varies with the oxide thickness and/or oxygen partial pressure.

The usual temperature bias stress is applied to the samples to deduce the amount of mobile Na^+ ions from the flatband shift, ΔV_{FB} . Figure 4 shows a typical

Fig. 4. The effect of TCE/N₂ flow rate on V_{FB} and ΔV_{FB} at $P_{O_2} = 0.1$ atm, $T = 1050^\circ\text{C}$, $t_{\text{oxid}} = 5$ min dry oxidation + 20 min TCE oxidation and $N_2:O_2:TCE/N_2 = 1350:150:V$ for n-type $\langle 100 \rangle$ Si.

set of the experimental data. A minimum is observed in ΔV_{FB} and occurs around the same region as in the earlier work (10) when the TCE flow rate is approximately 50 ml/min. In terms of mobile ion density, the minimum value of ΔV_{FB} corresponds to $2-3 \times 10^9 \text{ cm}^{-2}$, showing the effectiveness of the passivation ability.

Figure 5 summarizes two sets of experimental results for two different dual TCE processes. These curves clearly show that the passivation effect is not achieved abruptly as a function of the oxidation time. This experimental result implies that the usual threshold behavior observed in HCl oxides is not found here. Instead, the passivation ability, i.e., in terms of diminishing the mobile ion density, is acquired gradually, as shown in Fig. 5. In order to achieve a minimum acceptable level of mobile ions, a minimum period of

Fig. 5. The effect of TCE treatment time and TCE flow rate on sodium passivation at 1050°C . $t_{\text{oxid}} = 5$ min dry oxidation + TCE + treatment time. $N_2:O_2:TCE/N_2 = 1350:150:50$ (●) and $1425:75:40$ (×).

TCE treatment time is required. This effect may set a limit on the minimum attainable oxide thickness. An optimum process design must be determined from the oxidation characteristics, the effect of TCE flow rate, and the passivation properties, if the dual TCE process is to be implemented as a production process.

Another important electrical property is the breakdown characteristics. In an earlier work (7), we presented an analysis of the dielectric breakdown strength as a function of various TCE oxidation processes. Figure 6 shows typical breakdown characteristics of two-step dry oxides and dual TCE oxides. The dry oxide MOS diode showed a fast transition from an initial high resistive state (Fig. 6a) to a conductive state (Fig. 6b) once the maximum field exceeded the breakdown field strength. However, this type of abrupt transition was not observed in dual TCE oxides (Fig. 6c and 6d) until the current increased to a level of a few hundred microamperes. This breakdown characteristic suggests that the breakdown is nondestructive before maximum equilibrium current is exceeded. This implies that its breakdown voltage is improved somewhat over that of a two-step dry oxide sample.

The breakdown current (i.e., the maximum equilibrium current just prior to breakdown) of various oxides is summarized in Table II. The two-step dry oxidation sample yields a breakdown current only of the order of $10 \mu\text{A}$. The breakdown current in oxide films grown by two different dual TCE oxidation processes is larger by one to two orders of magnitude, at about $150-215 \mu\text{A}$ and $500-800 \mu\text{A}$, respectively. These results suggest that oxide films, obtained by the dual TCE technique, have good oxide integrity and superb dielectric breakdown properties, attributes that are ideally suited as the key element in MOS circuits in very large scale application.

Fig. 6. Typical breakdown characteristics of the different oxides for $\langle 100 \rangle$ n-Si. Positive voltages were applied to $0.6 \times 0.6 \text{ mm}^2$ Al dot electrodes. a) and b) are for two-step dry oxide (260Å) just prior to breakdown (5V per horizontal division) and after breakdown ($10 \mu\text{A}$ per vertical division), respectively. c) is for dual TCE oxide A, where oxide thickness is 240Å with $100 \mu\text{A}$ per vertical division and 5V per horizontal. d) is for dual TCE oxide B, where oxide thickness is 310Å with $50 \mu\text{A}$ per vertical division and 5V per horizontal.

Table II. Comparison of the breakdown properties, fixed charge density, and passivation capability against mobile ions for various oxides

Oxidations cycles	Oxide thickness (Å)	Breakdown field (MV/cm)	Breakdown current (μA)	Fixed charge density, Q_{ss} (cm ⁻²)	Mobile Na ⁺ density (cm ⁻²)
Dual TCE A	240	10.42	150-215	5.38 ~ 6.49 × 10 ¹⁰	3.8 × 10 ¹⁰ ~ 1.9 × 10 ¹¹
Dual TCE B	310	10.32	500-800	5.71 ~ 6.20 × 10 ¹⁰	2 × 10 ⁹ ~ 4.5 × 10 ⁹
Two-step dry oxide	260	7.69	< 10	3.86 ~ 4.31 × 10 ¹⁰	1 × 10 ¹¹ ~ 1.03 × 10 ¹¹

To give an overall comparison of samples prepared from various oxidation processes, Table II summarizes the breakdown properties, charge density, and passivation capability against the mobile ions. From this table, it can be inferred that the dual TCE B oxidation cycle gives an overall superior oxide film in most respects. The improvement in qualities over that of the standard or two-step dry oxidation is remarkable. More investigation could be done to facilitate a practical implementation.

Discussion and Conclusion

In the search for a viable method to routinely grow very thin gate oxides with reliable qualities, we have examined in some detail a novel technique called dual TCE process. It is similar to a two-step dry oxidation method, except that the oxidation atmosphere contains also a small amount of trichloroethylene, and so provides the added benefits of a high dielectric breakdown strength and passivation against mobile sodium ions. It is also analogous to a two-step HCl technique, except that TCE is known to be easier and safer to handle than HCl.

There are a few characteristic properties concerning the dual TCE process. A reversal of relative oxidation rates of <111> and <100> oriented silicon substrates is observed at low oxygen partial pressures and at comparatively fast TCE flow rates. The observed reversal is similar to that reported for dry oxidation at low pressure (2, 3), except it is complicated by the presence of TCE. The oxidation kinetics of the pressure-dependent reversal, with respect to the orientation of the substrate, cannot be satisfactorily explained in terms of the Deal-Grove or Cabrera-Mott mechanisms, even for an atmosphere of only oxygen and inert gas. With the added complication of the active role played by trichloroethylene in oxidation, the kinetics is even more complex than the previous case. In addition to pressure-dependence on oxygen, the observed reversal in the relative oxidation rates is a strong function of TCE flow rate. The mechanism demands a more detailed investigation, and a model is being developed.

The influence of trichloroethylene on flatband voltages of MOS capacitors has been reported by Heald *et al.* (10). Similar observations are also made in the present investigation, with the exception of one major difference in the experimental results and at least two important differences in the experimental conditions. In the earlier work (10), minima were observed in flatband (V_{FB}) and shift in the flatband voltage (ΔV_{FB}) as a function of TCE flow rate, and both minima occur at about 50 ml/min. Our result for ΔV_{FB} agrees with that of Heald *et al.* (10), but our minimum in V_{FB} is at a much lower TCE flow rate. This difference may be due to the fact the oxygen partial pressure is very low in the present case, of the order of 0.1 atm compared to about 1 atm in the other case, and also to the fact our oxide is very thin, on the order of 200Å as compared to about 1600Å of earlier work. As a consequence it is impossible to simultaneously minimize V_{FB} and ΔV_{FB} as a function of the TCE flow rate. This restriction means that we can only locate a range of flow rate, e.g., between 30 and 40 ml/min where both the fixed oxide charge density and the mobile ion density are relatively low, but not at a minimum value.

While the dual TCE oxide possesses a good passivation ability, the acquiring of the capability against mobile ions is rather gradual, not exhibiting the threshold behavior as in the standard HCl oxide (12). This result implies that there is a lower limit on the oxide thickness, since a minimum TCE treatment time is required to obtain the passivation capability. The mechanism of the chlorine atoms' neutralizing the sodium ions has not been investigated in detail. It is not known whether the passivation mechanism is the same in both thin and thick oxide layers. In particular, the dependence on the TCE flow rate requires a very detailed and systematic investigation if the mechanism is to be well understood.

In this paper, we have presented general properties of a novel oxidation process to grow ultrathin but reliable oxide layer. We find that the overall qualities are acceptable for semiconductor application, when compared to the existing two-step dry oxidation and dual HCl process. With its added advantages over HCl oxidation, the dual TCE oxidation technique presents itself as a very promising candidate to become a viable manufacturing process to prepare the necessary thin oxide layers in semiconductor work. In summary, we find that the present oxidation process provides an accurate control of the oxide thickness, good oxide integrity in terms of high breakdown field, low density of interface charges, and passivation ability against mobile ions.

However, we still have occasionally observed hysteresis, especially if the optimum TCE flow rate is not used, in a manner similar to that reported in the earlier TCE work (10). This can be eliminated by applying bias stress cycling a couple of times. This aspect of properties will further be investigated, together with our ongoing work on studies in surface mobility of very thin oxide MOSFET's, analysis of the oxidation kinetics, and experimentation with novel IC structures employing thin oxide layers from dual TCE process.

Surface Charges in a ZnO-B₂O₃-SiO₂ Glass/Silicon System

Y. Misawa, H. Hachino, S. Hara, and M. Hanazono

Hitachi, Limited, Hitachi Research Laboratory, Hitachi, Ibaraki, Japan

ABSTRACT

ZnO-B₂O₃-SiO₂ glasses of different compositions were prepared and the surface charges in glass/silicon systems in which these glasses were used, were studied by measuring the capacitance-voltage curves of metal-glass-silicon capacitors. The effects of glass film thickness, glass composition, and conductivity (n- and p-types) of silicon substrates on surface charges in glass/silicon systems were investigated. The surface charge density of n-type silicon changed in the negative direction with increasing glass film thickness and became constant with a thickness of more than 20 μm . The more negative the glass charge, the lower was its surface-state density. The surface-charge density of glass coated n-type and p-type silicon substrates were found to be linearly related. The surface charge density of mixed glasses with different surface charge density was also investigated.

Glasses which have as principal components ZnO-B₂O₃-SiO₂ are widely used as surface passivants for such silicon power devices as thyristors, transistors, and diodes. Since these glasses are electrically stable at high temperatures and in high electric fields (1, 2), they can readily be applied as a thick film, and they are resistant to humidity and have low ionic mobility. However, in order to allow better designing of glass passivated silicon devices, it is necessary to understand the surface charge configuration in a glass/silicon system. The effects of additives to ZnO-B₂O₃-SiO₂ tertiary glasses on the surface charge density and C-V (capacitance-voltage) shift with B-T (bias-temperature) treatment have already been reported (3). We have described the surface charge configuration of ZnO-B₂O₃-SiO₂ glasses to which PbO, Sb₂O₃, and SnO were added (4) when fired under various conditions.

However, no one has yet reported on the surface charge configuration of the tertiary ZnO-B₂O₃-SiO₂ glass/silicon system. Therefore, we prepared samples of ZnO-B₂O₃-SiO₂ glasses of different compositions and investigated the surface charge configurations in the resultant glass/silicon systems. We also investigated the surface charge configurations in a mixed glass/silicon system.

Experimental

Glass preparation.—The zinc oxide, boron oxide, and silicon oxide components were each weighed considering the weight loss that occurs during the fusion process. The weight loss of each material was computed from the weight change during the fusion process. These materials were then mixed in a revolving mixer. The mixed powder was fused at 1300°C in air. The fused glass was then poured into cold water. The glass frits that were produced were ground in a ball mill to give mean particle sizes of about 4 μm . Table I shows the composition of the glasses produced.

Measurements.—The surface-charge density (N_{FB}) in a glass/silicon system was measured by forming metal-glass-silicon (MGS) capacitors. The MGS capacitors were prepared according to the following procedure. An electrophoretic method was used to deposit the glass powder on a silicon substrate (Table II). Before glass deposition, about 2 μm of the silicon wafer surface was etched off. The deposited glass powder was fired in oxygen at 700°C. Metal electrodes (diameter 2 mm) were formed on the glass film by evaporating aluminum. Deviation of glass film thickness under the electrode of each sample was less than

3 μm . Samples with large bubbles and pin holes in glass films were not used for the C-V measurements. The capacitance of the MGS capacitors was measured with an MIS capacitance meter (Model MI 312F, Sanwa Radio Measurement Works) at a frequency of 1 MHz. Voltage was applied to the sample using a dc voltage source connected to the capacitance meter. Voltage ramping was done manually. The voltage shift, with hysteresis, of the C-V curve was about several volts. This voltage corresponded to a surface charge density of 10^{10} cm^{-2} , which was very small, and hence neglected.

Results and Discussion

Relation between surface-charge density and glass film thickness.—MGS capacitors using glass no. A in films of various thicknesses were prepared by controlling the deposition time. The relationship between surface charge density and glass film thickness is shown in Fig. 1. The sign of the surface-charge density is defined as follows. The positive sign is the direction of accumulation on n-type silicon surfaces, while the negative sign is the direction of inversion on the same surfaces. When a glass film is thin, the surface charge is positive. However, the surface charge shifts rapidly in the negative direction with increasing film thickness and becomes negative with a glass film thickness of 9 μm . The surface charge density is constant with a glass film thickness of more than 20 μm .

This tendency is the same as that of Al₂O₃-Si system (5). Therefore, assuming that the surface-charge dis-

Fig. 1. Relationship between surface-charge density and glass film thickness.

tribution is the same for the same glass film thickness, the relation between surface-charge density (N_{FB}) and glass film thickness can be approximated for the Al_2O_3 -Si system (5) by

$$N_{FB}(X) = -(A - B^{-\alpha x}) \quad [1]$$

where $N_{FB}(X)$ is the surface-charge density of a MGS capacitor with a glass film thickness of x , and A , B , and α are constant values. When A , B , and α are calculated from the experimental values in Fig. 1, $A = 2 \times 10^{11}$, $B = 1.9 \times 10^{12}$, and $\alpha = 2.39 \times 10^3$. The experimental relationship between surface charge density and glass film thickness can be expressed as follows

$$N_{FB}(X) = -(2 \times 10^{11} - 1.9 \times 10^{12} e^{-2.39 \times 10^3 X}) \quad [2]$$

Equation [2] is shown as a solid line in Fig. 1. In Fig. 1 the calculated solid line agrees well with the experimental values. From this curve, it can be deduced that many positive charges exist at the glass-silicon interface and in the glass film near that interface. Negative charges exist deeper in the glass film. It is believed that the positive charges are mainly donor type surface states.

Effect of glass composition on surface charge density.—Four glasses with different compositions were prepared and the surface-charge density and surface-state density of the glass/n-type silicon systems in which these glasses were used, were measured. Table III shows the surface-charge densities obtained by the measurements. The values represent the means for six samples. Surface-charge density depends strongly on glass composition. The surface-charge density shifts in the negative direction with increasing B_2O_3 and decreasing ZnO and SiO_2 content. Figure 2 shows the relationship between surface-state density and energy level for glasses with different surface-charge densities. As can be seen from Fig. 2 and Table III, the more negative the surface-charge density of a glass, the lower is its surface-state density. The energy level of the maximum surface-state density does not depend on glass composition. If surface states are donor type, those which exist above the Fermi level (above 0.3

Fig. 2. Surface-state density of glasses with different surface-charge density fired on n-type silicon vs. energy level.

eV) act as positive charges and those which exist below the Fermi level (below 0.3 eV) act as neutral charges. Therefore, the more negative the surface-charge density of a glass, the lower its positive charges due to surface states. On the other hand, if surface states are acceptor type, those which exist above the Fermi level act as neutral charges and those which exist below, act as negative charges. Therefore, as surface-charge density of a glass becomes more negative, there are more negative charges due to surface states. As mentioned above, whether donor or acceptor types, the more negative the surface-charge density of a glass, the more negative charges there are due to surface states. That is, glass composition mainly affects the surface-state density of a glass/silicon system.

Effect of the conductivity type of silicon substrates on surface charge density.—We have already reported briefly on the effect of the conductivity type of silicon substrates on surface charge density (3). In this paper, the relation between the surface-charge density of glass fired on n-type or p-type silicon is described as shown in Fig. 3. The linear relationship indicates that there is no difference in the surface-charge density

Fig. 3. The relationship between surface-charge density of glasses fired on n-type silicon and p-type silicon.

Table III. Measured surface-charge density for glasses fired on n-type silicon substrates

Glass no.	Surface-charge density (unit/cm ²)
A	-2×10^{11}
B	0
C	-3×10^{11}
D	$+5 \times 10^{11}$

Fig. 4. The relation between surface-charge density of mixed A-B glasses and the mixing ratio.

for glass fired on n-type or on p-type silicon; it is the same regardless of the glass composition. The relationship between the two surface-charge densities can be expressed by the following empirical equation

$$N_{\text{FB}}(n) = \frac{2}{3}N_{\text{FB}}(p) - 2 \times 10^{11} \quad [3]$$

where $N_{\text{FB}}(n)$ is the surface-charge density of the glass fired on n-type silicon and $N_{\text{FB}}(p)$ is the surface-charge density of the glass fired on p-type silicon. Surface-charge density due to fixed charges and mobile charges does not depend on the energy level of silicon, that is, the Fermi level. Therefore, it is believed that the difference in the surface-charge density observed for glass fired on n-type and p-type silicon originates in the surface states that exist between the Fermi levels of n-type and p-type silicon.

Surface-charge density of mixed glass with different surface-charge density.—Glasses A and B with measured surface-charge density of $-1.8 \times 10^{11} \text{ cm}^{-2}$ and $+0.4 \times 10^{11} \text{ cm}^{-2}$, respectively, and with the same particle size distribution were mixed together in different ratios. Figure 4 shows the relationship between

surface-charge density and mixing ratio. The surface-charge density of the mixed A-B glass, which changed in proportion to the mixing ratio, is between the density of the individual glasses. The diameter of the glass powders ($4 \mu\text{m}$) is small compared with that of the electrode (2 mm) on an MGS capacitor. Therefore, it is assumed that the composite surface-charge density is the average of the surface-charge density of glass no. A and glass no. B.

Conclusions

Surface charges in a ZnO-B₂O₃-SiO₂ glass/silicon system were studied by changing the glass film thickness and glass composition. The surface-charge density of the glass/silicon system was observed to shift in a negative direction with increasing glass film thickness, becoming constant at a thickness of more than $20 \mu\text{m}$.

The surface-charge density shifted in a negative direction with increasing B₂O₃ and decreasing ZnO and SiO₂ content. Glasses with a more negative surface charge density had a lower surface-state density. A linear quantitative relation existed between the surface-charge density of glass fired on n-type silicon and that fired on p-type silicon. The surface-charge density of mixed glasses with different surface-charge density changed in proportion to the mixing ratios.

Purification of Optical Waveguide Glass Forming Reagents: Phosphorus Oxychloride

J. W. Mitchell and J. E. Kessler

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Low temperature sublimation is shown to significantly reduce the metal and —P—OH containing impurity levels of practical-grade phosphorus oxychloride. Regular distillation and sub-boiling distillation are also effective for removing —P—OH impurities and provide products with 114-119 ppm of residual —P—OH. The purification efficiencies of these physical methods are compared with that resulting from chemical treatment to convert —P—OH impurities into other species. A method based on chemical reaction followed by low temperature sublimation is described for removal of —POH from practical-grade material and reduction of trace materials to low ng/ml levels.

Volatile glass forming reagents of high purity with respect to trace transition elements, —H, and —OH molecular impurities are now widely used for pro-

Key words: trace metal impurities, IR spectra of POCl₃, sublimation, sub-boiling distillation.

duction of optical waveguide glass compositions via vapor-phase oxidation at elevated temperatures. Needs for analytical and purification methods for vapor-phase glass forming chemicals have motivated several previous investigations (1, 2, 3). The advantages and

efficiency of low temperature sublimation for the purification of reagents, which are liquid at ambient conditions, have already been reviewed (2). The potential broad applicability of the method for removing soluble and particulate metal containing species from a variety of fluids was demonstrated by the easily executed sublimation of a variety of reagents and solvents. In particular, several reagent liquids now used as semiconductor dopants or CVD reagents are easily sublimed at low temperature. This paper reports results of investigations of the application of this method to the purification of phosphorus oxychloride (POCl_3), a phosphorus dopant for optical waveguide fabrication.

Experimental

Apparatus and procedures.—The apparatus used for batch scale production of 0.5 liter quantities of purified POCl_3 is shown in Fig. 1. The apparatus, constructed of fused silica and Teflon, was operated inside of a PVC exhaust hood. To minimize container contamination, all parts of the apparatus were leached for several days in 1N HNO_3 , followed by rinsing in distilled water. After a final 12h leaching in 1N HCl at 80°C and soaking in distilled water for several hours, the apparatus was rinsed with distilled, demineralized water and dried in a laminar flow hood. Air admitted to the assembled and evacuated vessel was prefiltered through 0.4 μ Teflon filters.

Sublimation was accomplished by freezing the sample to be purified as a thin shell on the walls of the round-bottom flask by rotating the container and contents continuously in a cryogenic bath. After this flask was attached to the apparatus, the entire system was evacuated to a few mm of Hg pressure. The reagent was sublimed from the round-bottom flask, and the sublimate was collected in the chamber, which was placed in a Dewar filled with a dry-ice-methanol mixture. A source for latent heat of sublimation was provided by room air in contact with the sublimator flask during sublimation. Additional heat was some-

times provided by a heat lamp. Mass flow of vapors from the sublimator to the collector was induced by continuous evacuation of the apparatus.

Following sublimation, the purified sample was recovered from the collection vessel by dismantling the apparatus, crushing the solid with Teflon rods, and then transferring the solid to precleaned and well-dried containers. However, it proved most convenient to allow the sublimate to melt in the assembled apparatus and then to transport the liquid via suction through Teflon tubing connecting the collection vessel to an evacuated container from which transfer to the final storage vessel was made. Samples were then stored as the frozen solid in Teflon bottles.

A standard Pyrex apparatus was used for refluxing or distillation of POCl_3 . A modification of a previously described apparatus (4) was used for sub-boiling distillations under a positive pressure of nitrogen which was dried by passage through a Drierite column.

Reagents and analysis.—Reagent grade POCl_3 (Alfa Ventron) was prefiltered for some studies by vacuum suction through a 0.2 μ FG-fluoropore (Millipore) filter unit.

Aliquots of the original and purified samples were analyzed for trace metals by atomic absorption spectroscopy (AAS) following complete hydrolysis and direct injection of the resulting solution into carbon rod analyzers. Details of the analytical procedure have been reported elsewhere (5). Monitoring of the —P—OH impurity levels was done by infrared spectroscopy. The procedure described by Pasteur provided semiquantitative results on the overall —P—OH levels of starting reagents and purified products (6). All IR spectra were measured in either 3 or 4 mm pathlength cells.

Results and Discussion

Trace metal impurities.—Reagent grade POCl_3 is badly contaminated with trace metals. This is indicated by AAS determinations of a chemical showing 440, 1450, <5, 135, 5, 11, and 23 ng/g of Fe, Ni, Cu, Cr, Co, Mn, and Zn, respectively. Analysis of five lots of POCl_3 for Fe showed 689, 2220, 310, 210, and 253 ng/ml. The levels of Ni, Fe, and Mn are reduced drastically by simply filtering the reagent, as shown by the results in Table I. These data add to a growing body of evidence documenting that metallic impurities present in particulate matter are a primary factor limiting the ultimate state of purity attainable for powdered and liquid reagents. Water, soluble solid reagents Na_2CO_3 , NaCl , NaAc , and KI particulates, separated by filtration and analyzed by x-ray milliprobe fluorescence, showed significant amounts of elemental impurities (7). Unfiltered silicon tetrachloride has been found by analyses to be heavily contaminated with metal impurities (8). However, careful filtration transforms this chemical into an ultrapure reagent. All elements of interest except Fe are below the 1 ng/ml level.

Results in Table I also show significant further improvement in the purity of unfiltered reagent-grade

POCl_3 by processing through a single sublimation. The impurity level of the singly sublimed sample (23 ng/g Fe, <1 ng/g Ni) compares well with that of expensive commercially available purified materials, Product 1 (15 ng/g Fe and 19 ng/g Ni) and Product 2 (37 ng/g Fe, <1 ng/g Ni). Further reduction in the iron level of additional POCl_3 samples has occurred, with 15 ng/g being the lowest level achieved for reagent-grade POCl_3 after a single sublimation. This level of purity via low temperature sublimation is not the ultimate with respect to iron. Such is indicated by significantly better results for aqueous hydrazine where a reagent with an initial iron level of 41 ng/ml was reduced to the 2 ng/ml level (9). Using the sublimation method, 1 kg quantities of POCl_3 have been purified and supplied to various investigators.

—*POH impurities.*—Phosphorus oxychloride contains significant levels of —POH impurities, as indicated by the IR spectrum in Fig. 2a. Gas chromatographic-mass spectrometric analytical studies to identify specifically the various P—OH impurities are underway. These impurities may include $(\text{HO})_x\text{—PO}(\text{Cl})_{3-x}$, where $x \leq 3$, HPO_3 , H_3PO_2 , H_3PO_3 , and H_3PO_4 . Because of the higher volatility of POCl_3 in comparison to these various possible —POH containing impurities, badly contaminated POCl_3 (> 1% —OH impurities) is purified significantly during a single sublimation (Fig. 2b). The sublimed material contained ≈ 260 ppm of —POH impurities. Determining whether these residual impurities were originally present in the starting materials and were sublimed simultaneously with POCl_3 or whether they resulted from moisture contamination during the sublimation process is important for further improvement of the purification efficiency with respect to —OH.

Hydroxyl containing impurities in phosphorus oxychloride can also be removed during simple distilla-

tion. Crude reagent-grade material (> 1% —POH) is converted during one distillation into a product containing 110 ppm of P—OH (Fig. 3a). Further careful distillation or reagent-grade material via repetitive sub-boiling distillations yielded a product of similar purity 120 ppm of P—OH (Fig. 3b). In view of the quiescent nature and high separation efficiency of the sub-boiling distillation process, it is not likely that the residual P—OH impurity resulted from entrainment or covaporization of impurities originally present in the starting material. Contamination of the product by residual moisture within the nitrogen-purged distillation system is the more probable source of the residual P—OH. Although either sublimation or controlled distillation may be applied to produce a reasonably high purity product (15 ppb Fe and ≤ 250 ppm —P—OH) from crude, commercially available, reagent-grade POCl_3 , maintenance of the —P—OH purity level over long periods of storage will require the most stringent precautions against contamination by moisture.

In a previous report, chemical reactions between —P—OH and PCl_5 were proposed for the "drying" of phosphorus oxychloride (10). It was also projected that refluxing slightly hydrolyzed POCl_3 to create chlorophosphorus anhydrides would be useful for removal of —P—OH. The P—OH content of practical-grade POCl_3 (> 1% —P—OH) is unchanged by vigorous refluxing with 1% PCl_3 for 2h in a dry nitrogen-purged reflux condenser. Thus reflux reactions of —P—OH such as

appear to be negligible (Fig. 4a). However, under con-

ditions prescribed for the *in situ* generation of PCl_5 , significant chemical reaction of $-\text{POH}$ occurred, as indicated in Fig. 4b. A second 1% (v/v) fraction of PCl_3 was added to the 500 ml sample shown in Fig. 4a, and Cl_2 was added until the solution acquired a distinct yellow coloration. After a 5 min irradiation in a Rayonet Photochemical Reaction, the solution was

purged with dry nitrogen for 1h. Reduction in $\text{P}-\text{OH}$ is clearly evident, while broadening of the 2600 cm^{-1} band could reflect the formation of anhydrides of phosphorus acids. The broad-banded region 3600 to 2900 cm^{-1} indicate the presence of residual amounts of several different types of $-\text{P}-\text{OH}$. Thus, infrared estimates of the residual $-\text{P}-\text{OH}$ content could not be attempted.

Barns (10) found the procedure described above for treatment of the sample in Fig. 4b to remove most of the $-\text{P}-\text{OH}$ from commercially available Ultrex POCl_3 . This product had been preliminarily purified by the supplier to remove trace metals using a fractional freezing process. However, it was grossly contaminated with $-\text{P}-\text{OH}$. The satisfactory chemical conversion of $-\text{P}-\text{OH}$ in the prepurified material indicates that the practical-grade product contained structurally different $-\text{P}-\text{OH}$ containing impurities which are resistant to chemical conversion. Such compounds would have been removed from Ultrex reagents during purification by fractional freezing. The predominant $\text{P}-\text{OH}$ species in this material would then be the expected product resulting from the reaction of POCl_3 with atmospheric moisture according to

This product in turn seems to react readily with PCl_5

while more complex species, for example $(\text{OH})_x-\text{POCl}_{3-x}$ ($x = 2$ or 3), appear to be more chemically resistant.

Practical grade POCl_3 (Fig. 2a) has been decontaminated completely with respect to $-\text{P}-\text{OH}$ impurities by chemically converting sublimable $-\text{P}-\text{OH}$ moieties (reaction 3) into less volatile products via reaction 4. Following treatment of the initial sample (Fig. 2a) with 1% PCl_3 , addition of Cl_2 , UV irradiation (3000Å) for 15 min, and purging with nitrogen, the spectrum in Fig. 5a was obtained. Low temperature sublimation of

Fig. 5. IR spectra of chemically reacted and sublimed POCl_3 . a, top: 1% PCl_3 added, Cl_2 saturated, UV irradiated, and N_2 purged. b, bottom: sample A sublimed at low temperature.

this product provided the sample with the spectrum shown in Fig. 5b. This essentially complete removal of —P—OH combined with a simultaneous significant reduction of trace elements has converted inexpensive, practical-grade reagents into high purity fiber-optic-grade material. The batchwise sublimation step could in principle be replaced by a continuous distillation with negligible loss in purification efficiency. Substitution of the distillation step would be dependent upon a knowledge of the physical properties of reaction products and those of any remaining impurities. Identification of such impurities are important areas for ongoing analytical investigations.

Computer Simulation of Carbothermic Silica Reduction Processes

Thomas Johansson

ABSTRACT

Several types of alternative carbothermic reduction processes for the production of silicon metal were studied by using a model which is applicable to nonequilibrium systems with countercurrently flowing phases. The processes studied include a conventional silicon arc furnace, a silicon arc furnace working at elevated pressures, and a new process called the boot furnace (BF) process. The results indicate that the high pressure alternative cannot compete with the conventional furnace. The BF process should give markedly higher silicon yields as well as a purer product but complicated process equipment is demanded. Many of the alternatives studied might constitute improvements compared with the conventional process, but additional experimental results are required for conclusive evidence.

The conventional carbothermic reduction process of silica to metallic silicon in submerged arc furnaces is very complex. Several gaseous, liquid, and condensed species are involved in chemical reaction because of the high temperatures within the process area. At the same time the chemical environment makes a detailed practical investigation nearly impossible. Additionally, the infeasibility of controlling the internal heat and mass flows implies that the current process yields are far below the theoretically attainable. Practical and theoretical aspects of silicon production have been thoroughly discussed in several previous publications, (e.g., (1-4)).

Consistent mathematical models for the conventional silicon arc furnace process are normally built upon mass and energy balances and the computation of chemical equilibria considering only a limited number of reaction formulas. However, if the aim is to study conceptual, alternative processes, the need to specify a reaction scheme in advance can be a major obstacle. The lack of experimental data may also render the results from such a thermodynamic analysis doubtful. Fortunately, computer programs employing free-energy minimization or any other equivalent sophisticated algorithm for the calculation of chemical equilibria eliminate the need to specify such reaction schemes, and thereby allow the use of a generalized formalism.

Key words: inorganic, plasmas, thermodynamics, reduction.

SOLGASMIX (5) is a free-energy minimizer where the equilibrium mixture may contain a gas phase and condensed phases of invariant or variable composition. Parametrized activity coefficient expressions for species in nonideal phases must be specified by the user. A recently developed extended routine, SOLGASMIX-REACTOR (6), simulates nonequilibrium processes with countercurrently or cocurrently flowing phases. A reactor is conceptually divided into a number of segments, and the SOLGASMIX free-energy minimizer is utilized for computing rates and temperatures of the steady-state flows over the segment boundaries for each species, i.e., for a condition characterized by a total balance in material and enthalpy inputs and outputs. Heat transfer and chemical kinetics are considered indirectly by allowing a portion of the flowing material to bypass some stages of the reactor bed without any reaction. This approach has been successfully applied to several alternative carbothermic reduction processes for silicon or silicon-alloy production (2, 7).

In this paper a model better than those published earlier (2, 6) for the conventional silicon furnace (CSF) process will be described. The new feature is that the model furnace contains a hot part which should depict the arc zone of an operating silicon furnace. Results from SOLGASMIX-REACTOR simulations will also be presented for a new process, the boot furnace (BF) process, and for two modifications of the CSF process, one in which the formation of

metallic silicon in the upper part of the furnace is considered, and one working at elevated pressures.

The Silicon Arc Furnace Process

General overview.—The chemical processes taking place inside a silicon arc furnace, where silica is carbothermally reduced to silicon metal, can be outlined by two overall reactions. These reactions are based partly upon results from a previous simulation (2), and partly upon experimental observations of the formation of metallic silicon in the upper parts of the furnace (8).

In the upper parts of the furnace an exothermic reaction occurs as follows

The y value, which is dependent on the amount of available energy, increases with decreasing reaction temperature. The u value is a measure of the amount of silicon metal formed by disproportionation of SiO(g). This is due to the low surface temperature of the silica lumps, which, unlike the carbon supplied, do not take part in any exothermic chemical reactions. Moreover, the further reaction of the condensates Si(l) and SiO₂(s,l) may be hampered by kinetic barriers. A more detailed discussion is given below. The gaseous reaction products, predominantly CO and unreacted SiO, escape from the furnace, whereas the condensed phases descend and react in the lower regions where the main part of the energy is supplied. The overall reaction can be written

The x value, which is determined by the relation between charge consumption and energy supply, increases with increasing reaction temperature. The variable v represents the amount of unreacted carbon originating from the electrodes or from the charge.

The economy of a silicon furnace is strongly dependent on the extent of reaction [2]. An increased value of x , which corresponds to a higher equilibrium temperature and a higher energy consumption per mol silica charged, implies an improved yield of silicon metal and a lower SiO content and thermal potential of the gases leaving the lower regions of the furnace. This has the effect that the amount of SiO lost as top gas is depressed. Thermal potential is used here to denote the energy which can be emitted by the gas by cooling and by chemical reaction during its passage through the charge. The relative influence of x on the metal recovery is much more pronounced than the influence on the energy consumption. By assuming that the partial pressure of SiO is close to constant in the hotter zone of the furnace, an increased value of v results in reduced amounts of SiC reacted and Si produced. The factor u may also be of importance if the silicon metal formed in the upper part of the furnace is inaccessible for reaction until it reaches the lower regions.

The reactions [1] and [2] can be combined to give a total reaction formula for the silicon furnace

where n denotes the carbon-to-silica ratio in the charge. The silica yield (mol Si produced per mol silica charged) is denoted by z and is equal to

$$z = [3u(n - v) + (2x - v - 1)(2ny - nu - n + 3)] / (2vy - vu - v + 3) \quad [4]$$

The following conclusions can be made about the various variables in reaction [3]. z should be as large as possible. n should be as large as possible, but the SiC production, a dirigible factor, must be limited. Higher y values give improved silica yields and an almost unchanged energy consumption, but technical problems with the condensation products arise. Higher u values give improved silica yields, but increased amounts of the condensation products give rise to mechanical problems. x should be as large as possible, but is nearly impossible to control. v should be as low as possible, and has limited dirigibility.

Model description.—In the SOLGASMIX-REACTOR (6) approach, the system is divided into a small number of segments and the program calculates rates and temperatures of the steady-state flows over the segment boundaries. The solution technique employed is one of repetitive substitution, and the iteration process may proceed in either direction throughout the reactor, from top to bottom or from bottom to top. Flows opposite to the iteration direction calculated from a previous iteration (or initial estimate) are used as inputs to the next iteration, whereas flows in the other direction are calculated as the iteration proceeds.

By introducing user-specified distribution coefficients, an approximate means is provided for including chemical kinetic effects and heat transfer in the program. These coefficients were originally designed to reproduce the macro/micro channeling effect in arc furnaces, where gases from the bottom may escape rapidly through the furnace top without the recondensation of volatiles or temperature equalization which equilibrium would predict. In effect, these coefficients give the user a means of preventing some of the gases or condensed phases incoming to a specific segment from entering into reaction and/or heat exchange. Thus, some portion of the raw material input or the intermediate reaction products is allowed to bypass one or several segments. Since the values which these distribution coefficients assume are difficult to predict, they must be determined by empirical comparison between calculation and experiment. They are influenced by the number of segments chosen for the model and the temperature distribution in the segments, but are useful for inclusion of kinetic effects without the additional complexity of calculating individual reaction and/or heat transfer rates.

The thermodynamic data for the chemical system considered (Si, C, O, Al, Ca, Fe) is taken from the JANAF Thermochemical Tables (9), which gives values for temperatures up to 6000 K. In addition to the gas phase containing 28 species, there is a metallic phase assumed not to contain any molecular associations, i.e., the atomic species Si, Al, Ca, and Fe, and a slag phase containing the distinct compounds SiO₂, AlO_{1.5}, CaO, and FeO. The solid phases considered are C, SiO₂, SiC, Al₂O₃, CaO, and FeO. No data in the literature could be found giving activity coefficient expressions in the dilute solution range for the multicomponent liquid phases, which therefore are treated as ideal with activities equal to mol fractions. This simple model for the chemistry of the contaminating metals is thought to be justified at least for qualitative considerations, because of the low concentrations of the impurities and the uncertainties in the thermodynamic data for the constituents of the liquid phases.

The conventional silicon furnace process.—In order to get results as generalized as possible in the modeling, a conventional silicon furnace (CSF) is defined. This does not relate to a specific furnace but is a hypothetical one which behaves similarly to most modern furnaces. The parameters of the model, whose mean-

ing is described elsewhere (2), take values as follows. The reactor is divided into six segments. The raw material (1 mol SiO_2 , $2.5 \cdot 10^{-3}$ mol of the impurities Al_2O_3 , CaO , and FeO , and a calculated amount of carbon, see below) is supplied to the top segment (segment 1). The total energy supply (885 kJ/mol SiO_2 charged) is constrained to the temperature of segment 4, which is determined to be 2340 K in advance, and is distributed so that 80% goes to segment 5, 15% to segment 4, and 5% to segment 3. In addition, 5 kJ is withdrawn from the top segment because of the pyrolysis of the wood chips intermixed with the raw material. The carbon supply is adjusted so that a constant reaction temperature above the boiling point of the reactants (5500 K) is reached in the arc zone of the model (segment 5), which results in no net production/consumption of SiC. Of the total amount of carbon supplied (1.826 mol/mol SiO_2 charged), 0.15 and 0.10 mol reaches the segments 4 and 5, respectively, thereby simulating the low reactivity of the carbon electrodes in the upper parts of the furnace. The enthalpy of this chemically bypassed carbon is changed according to the reaction temperatures in the upper segments. The condensed phases entering one segment react completely in that specific segment, but the intermediate gaseous reaction products are distributed so that 80% reacts in the next upper segment, 15% bypasses one segment before reaction, and 5% bypasses two segments before reaction. Some of the condensed material will probably bypass the high temperature zone of an operating furnace. This is accounted for in the flow scheme by letting the chemical input to segment 6 consist of 1% of the slag produced in segment 3 and 50% of the metal produced in segment 4. The total pressure in segment 1 is 1.01 times the assigned pressure (101.325 kPa), in segment 2 the factor is 1.02, in segment 3 1.04, and in the remaining segments 1.07.

Figure 1 shows the calculated steady-state gaseous and condensed phase flows over the segment boundaries. To illustrate the chemical reactions taking place

Fig. 1. Calculated flows (mol/mol SiO_2 charged) in the conventional silicon furnace (top) and distribution of silicon and the contaminating metals between slag and other condensed phases (bottom). Parameter values are given in the text.

in the reactor, a linear change in flow is indicated within the segments. The calculated silica yield is 0.819, and the energy yield (mol Si produced per MJ energy supplied) is 0.925. The dependency of some key factors on the silica and energy yields has been investigated earlier (2). It was found that the correlation between the yields and the silica-to-energy feed ratio and the elementary carbon supply to the lower segments is significantly negative. An increased top cooling causes increased silica yields but influences the energy yield only to a minor extent. The impurity content of the raw material has only a marginal effect. However, in the production of silicon containing alloys, the Si activity in the metallic melt is reduced and substantially higher yields can be obtained.

The influence of the variable u in reaction [1] is investigated by cooling 50% of the SiO leaving the reactor to 500 K. The enthalpy produced is supplied to segment 1, and the condensates Si and SiO_2 are recycled either to segment 1 or to segment 4. The remaining parameters are the same as for the CSF process.

The predicted result of this recycling is that the silica yield increases to 0.823 (segment 1) and 0.864 (segment 4), respectively. The silica yield is practically not modified at all for the first case, since the higher SiO activity in segment 1 induces only an enhanced silicon circulation within the reactor. The condensates are excellent reactants and when they are recycled to segment 4, the improved silica yield is obvious. The SiO activity is now determined by the constant temperature of 2340 K in segment 4, and the extra SiO (Si + SiO_2) supplied must react to some extent with SiC to produce Si and CO.

The overall reaction temperature in the part of an operating furnace where Si metal is formed is probably rather constant, and therefore the SiO disproportionation should be beneficial to the process. However, the condensates probably occur in a finely divided and reactive state which has the effect that the major part reacts before it reaches the metal formation zone of the furnace. The assumption that the amount of outgoing SiO is equal to that condensed to Si and SiO_2 within the furnace may be an overestimation, and that therefore the overall effect of the SiO disproportionation is limited. Figure 2 illustrates the flows within a reactor where the condensation products are recycled to segment 4.

At present, a direct quantitative comparison of temperature and composition of the internal flows of intermediate species in an operating furnace with the simulated condition in the model is not possible. However, the directly measurable factors, including carbon and

Fig. 2. Calculated flows (mol/mol SiO_2 charged) in a modified conventional silicon furnace where 50% of the SiO leaving the furnace is cooled to 500 K, the enthalpy produced supplied to segment 1, and the condensation products (Si and SiO_2) recycled to segment 4.

silica yields, energy yield after compensation for heat losses, temperature and composition of product and of the gases escaping from different parts of the charge surface, changes in operation when charge composition, energy supply, and furnace geometry is changed, have been shown to be in excellent agreement.

The agreement between simulation results and the real process is not surprising, since the fundamental principles of the algorithm are identical with those used for calculating typical countercurrent distillation processes. This can be exemplified by the term "segment" used here, which has its direct counterpart in theoretical plates. The requirements for using these principles are that the deviation from both enthalpy balance and chemical equilibrium in one point must be more or less proportional to the heat- or mass-transfer rates or the reaction rate, and that at least some phases have opposite flow directions. As is the case in the calculation of distillation processes, equilibria are never assumed or stipulated to be reached in any point. The departure from equilibrium only indicates the direction in which the reaction should proceed and to some extent the reaction rate. A silicon furnace is much more complicated than a distillation process, but SOLGASMIX-REACTOR is developed to cope with these complications.

Alternative Processes

Three alternative processes and one modification of the CSF process for carbothermic reduction of silica have been simulated: the silicon blast furnace (SBF) process (2), the bottom loaded furnace (BLF) process (6, 10, 11), the boot furnace (BF) process (10, 11), and the high pressure silicon furnace (HPSF) process.

Silicon blast furnace process.—In the SBF process, which is discussed in detail elsewhere (2), a mixture of silica and carbon is fed at the top and oxygen gas is injected at the bottom. The feasibility of the process is doubtful because of the high consumption and ensuing high costs of carbon and the large amount of impurities introduced. Combined production of silicon and heat energy by this method is theoretically possible, but the technical problems involved can hardly be solved within the limited economical scope available.

Bottom loaded furnace process.—In the BLF process (6, 10, 11), which seems to have many advantages, silica and energy are fed with a controlled speed into the bottom of the furnace. Compared with the CSF process, there is a reduction in the carbon consumption by 10%, while the silica and energy consumption is reduced by 20%. The economical incentive available for finding new technical solutions is thus great, and despite the fact that problems remain to be solved, the BLF process has a good chance of becoming more profitable than the conventional processes of today. The BLF process will be treated in greater detail in future work.

Boot furnace process.—The principle of the BF process (10, 11) is shown in Fig. 3. A mixture of silica and carbon, with a molar ratio $\text{SiO}_2/\text{C} \cong 1$, is fed to a zone within which the energy supplied is sufficient to cause the formation of an equimolecular gas of SiO and CO. Any surplus of silica which may be introduced after the gas production stage can then extract most of the contaminating metal compounds present in the gas. The purified gas flows into a reactor charged with carbon. Nearly 50% of the SiO reacts with SiC in the lower parts, producing Si and CO; almost all of the remaining SiO reacts with carbon, reproducing the consumed amount of SiC. The extra energy needed for silicon formation from SiO and SiC can be supplied at the sites of gas or silicon production or in between them. If the goal is to make metallurgical qual-

Fig. 3. Overall principle of the BF process

ity or if the feed material is sufficiently pure, the encircled part of Fig. 3 may be omitted.

By using SOLGASMIX-REACTOR, three different alternatives of the BF process have been simulated. In the first, 1 mol of SiO_2 and C, together with impurities and a sufficient amount of energy, is supplied into an arc heater represented by segment 5 (see Fig. 3 with the encircled part omitted). In the second alternative, 1.1 mol SiO_2 , 1 mol C, impurities and a sufficient amount of energy for volatilizing all carbon is supplied into an arc heater (segment 5). The slag and metal melts formed, containing most of the impurities, are discharged, while the gas phase is fed to the reactor proper (segment 4) together with more energy to obtain a maximum silica yield. The third alternative is equal to the second with the exception that the gas phase (from segment 6) reacts with another 0.1 mol SiO_2 (in segment 5) before it reaches the reactor. The input of impurities and the pressure gradient are the same as for the CSF process. The reactor (segments 2 through 4) and the gas burner (segment 1) are identical in the three different alternatives. The other parameters of the reactor model are chosen as described below.

The incoming material to the reactor consists partly of the volatile SiO_2 -C mixture to segment 4 and partly of a sufficient amount of carbon to segment 2 to give optimum yield. The amount of oxygen gas needed to combust CO and SiO completely is injected into segment 1. As mentioned previously, energy is supplied to segment 4, which always contains SiC (alternatives 2 and 3). Segment 1 has a constant temperature of 500 K, and enthalpy is gained by the cooling. No condensation reactions occur, and therefore the intermediary reaction products leaving one segment are assumed to react completely in the adjacent segment.

The predictions from the simulations indicate that this type of reactor produces silicon with a high yield, and with the alternatives 2 and 3 a high purity product is obtained. The carbon consumption lies between 2.065 and 2.094 mol/mol Si produced, but the part of the consumption which exceeds two leads only to SiC and/or SiO production. The variation in silica yield,

which is 0.954, 0.860, and 0.764 for the three cases, respectively, is caused by 9% (case 2) and 17% (case 3) of the silica charged being used only as an impurity extractant or absorbing medium for the gas before it enters the silicon producing reactor. If this fraction of the silica supply is withdrawn from calculation, the yield is over 0.9 for all three alternatives. The energy consumed/mol Si produced is nearly identical and lies between 1000 and 1037 kJ. The impurity content of the silicon metal produced varies in an interesting way. From being 0.5 mol percent (m/o) for the first alternative, it is reduced to only 0.05 m/o for the two other. This latter equality is caused by atomic iron remaining in the gas phase after the first washing stage. This iron will not be oxidized and extracted with the slag because of the low partial pressure of O_2 at the second supply of silica. Most of the iron is instead withdrawn in the metal melt in the gas producing segment. It is important to point out here that accurate activity coefficient expressions describing the nonideal mixing in the slag and metal phases are lacking and all solutions are treated as being ideal. It is thus impossible to draw any far-reaching conclusions concerning the fates of the contaminating metals, but the general trends between different results should give a good illustration of what will happen in an operating process. The enthalpy produced by the combustion in the gas burner is of the same order (757 to 767 kJ/mol Si produced) as the electrical energy supplied to the process.

In Fig. 4 the flow diagram of alternative 1 is presented. The silica and carbon supplied to segment 5 react to a 1:1 mixture of SiO and CO. Because of the surplus energy also supplied to segment 5, SiO reacts in segment 4 with SiC forming Si and CO. Most of the remaining SiO reacts with carbon to CO and SiC in the upper segments. A part of the carbon incoming to segment 2 reaches segment 4 because of the high temperatures in the reactor, which allow a certain pressure of SiO to exist over carbon. In the top segment there is a complete combustion of the incoming gases to CO_2 and SiO_2 .

The possibilities of a technical realization of a BF process are promising because the consumption of raw materials and energy is lower compared to the present-day process; moreover, there is no condensation of silica in the upper part of the furnace. Many technical problems are thereby avoided, for instance, the need for a mechanical treatment of the charge, and the electrodes need not pass through the charge. Since there is no need for connections from the outside to

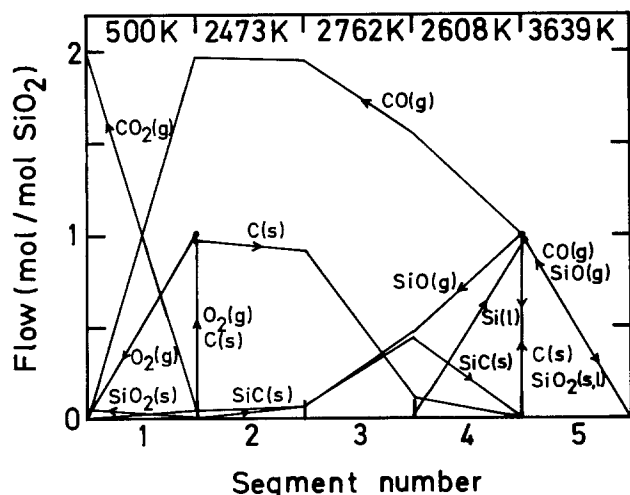

Fig. 4. Calculated flows (mol/mol SiO_2 charged) in a BF process where 954 kJ is supplied to segment 5 and where the charge consists of 1 mol of SiO_2 and C together with impurities to segment 5, 0.97 mol C to segment 2, and 1.01 mol O_2 to segment 1 (see Fig. 3 excluding the encircled part).

the inner parts of the furnace, except for gas supply and outlet, the closing of the furnace is simplified and the energy recovery process, exemplified by segment 1, will be much easier to realize. The process has some drawbacks. The efficiency of an arc heater is not as good as that of a carbon electrode. Also, the predicted temperatures in the reactor are very high, which may cause material problems. On the other hand, temperature may be lowered considerably before the yields drop to the same level as with current arc furnace technology.

The conclusions drawn from the modeling of the BF process indicate that this production method may be a viable alternative when the goal is to produce metallurgical silicon, high purity silicon, or silicon alloys.

High pressure silicon furnace process.—The principle of the HPSF process is merely a conventional silicon furnace working at elevated pressures. The parameter values for the CSF and HPSF processes are all identical, the assigned pressure excepted.

Figure 5 illustrates the consumption of carbon, silica, and energy per mol Si produced in the HPSF process relative to their respective values for the CSF process (Fig. 1) as a function of the assigned pressure. The raw material costs are drastically reduced at a pressure of 0.4 MPa. Between 0.4 and 0.8 MPa the conditions are practically constant. For pressures 0.8 MPa and above, the consumption of silica and energy increases according to the lower enthalpy content of the gases incorporated in the condensation reactions. Larger amounts of gas must then condense in order for the charge material to be heated. Moreover, the equilibrium is displaced to a greater extent towards SiO condensation by increasing pressure. These two factors cause a large flow of SiO_2 which must be compensated by a higher SiC production. Thereby the extra amount of carbon required in the charge would give rise to additional SiO condensation due to the cooling effect. The reactions in segment 4 are only moderately displaced with a slight increase in pressure. In this segment, the gas phase, consisting primarily of SiO and CO, is in equilibrium with the condensed phases SiC and Si, and because of the constant temperature of

Fig. 5. Carbon, silica, and energy inputs per mol Si produced for the HPSF process relative to their respective values for the CSF process.

2340 K, the quotient $p(\text{SiO})/p(\text{CO})$ is constant. At a total pressure in excess of 0.8 MPa, $p(\text{SiO})$ reaches the value at which SiO_2 can coexist with SiC and Si , causing the silica yield to drop. Since the energy needed for melting this SiO_2 is low below about 0.9 MPa and the energy consumption during gas production is still being reduced, the energy consumption increases later than the silica consumption.

At pressures above 0.9 MPa, the energy consumption for melting the growing amount of SiO_2 is so high that it markedly affects the overall energy consumption. Carbon consumption decreases with increasing pressure in the pressure interval studied because the carbon consumption caused by the SiO production decreases when the condensation becomes more efficient at higher pressures.

Figure 6 shows a flow diagram of an HPSF process with an assigned pressure of 0.6 MPa. It is evident that the condensation of SiO increases and the SiO losses decrease compared with the CSF process in Fig. 1.

The possibilities for a technical realization of an HPSF process are probably limited despite the process' many advantages. There are in principle four different connections to the inner part of the furnace which must be maintained. (i) The gas outflow must pass through a pressure reducing valve. (ii) The silicon melt must be discharged with pressure reduction but without a simultaneous escape of gas. (iii) Energy must be supplied, e.g., electrodes. (iv) The raw material must be entered via a lock system.

These four factors, as well as the greater need for mechanical treatment of the charge caused by the extended condensation, and the safety aspects of having high temperature and pressure inside a furnace, make it hard to believe that such a process will be economically justifiable with the normal size of present-day furnaces. This technique, however, may be utilized in small process units for production of special qualities.

Fig. 6. Calculated flows (mol/mol SiO_2 charged) in a modified conventional silicon furnace working at an assigned pressure of 0.6 MPa.

Future Aspects

The simulation of the six different types of furnace models discussed above indicates the kind of information which can be extracted from the calculations and the limitations of using the SOLGASMIX-REACTOR program. In the future, a detailed investigation of the possibilities of a technical realization of the BLF process will be presented. In a related project, several alternative production methods for ceramic materials, particularly Si_3N_4 , will be presented and evaluated.

Despite the fact that the usefulness of the SOLGAS-MIX-REACTOR model may be limited by the lack of critically assessed thermodynamic data in many systems, there is still at least one important area for program development; namely, treatment of geometric and dynamic information by a finite-element approach to account for static and dynamic effects of inductance, mass and heat transfer, material flow, diffusivity, and kinetics. Again, the drawback is the lack of data required for the calculations. As demonstrated in this work, it seems that the most advantageous way to get quantitative results is to use a method which treats empirical data. Different parameter combinations may then be varied until agreement with a known process is achieved. The parameter values thus found can then be used to simulate similar processes.

Thermal Oxidation of Transition Metal Silicides on Si: Summary

M. Bartur and M-A. Nicolet

California Institute of Technology, Pasadena, California 91125

ABSTRACT

Thin films of almost all transition metal silicides, on a Si substrate, oxidize and form SiO₂ on their surfaces upon annealing in an oxidizing ambient. In applications of these silicides as interconnects in integrated circuits, the oxidation characteristics of a silicide and the SiO₂ growth rate are important. A compilation of the available data concerning silicide oxidation kinetics is presented. Generalization based on the data as presented is difficult. In this summary, we explore the processes controlling the oxidation of metal silicides and point out commonalities and differences between different silicides. We review the four steps controlling silicide oxidation: oxidant transport through the oxide, reaction at the silicide/oxide interface, net transport of Si atoms with respect to metal atoms in the silicide, and reaction at the silicide/Si interface. The diffusing species through the silicide during oxidation correlates with the moving species in silicide formation. A discussion of a mechanism which explains why the oxidation rate of some silicides on a Si substrate is faster than that of bare Si is presented. It is concluded that silicides formed via metal diffusion oxidize faster than silicides formed via Si diffusion.

With the advances in Si technology, scaling of devices to micro size imposes severe requirements for the interconnection lines on the chip. The commonly used poly-Si becomes inadequate because its lowest practical resistivity is ~400 μΩ cm (1). The possibility to use silicides as interconnect material in integrated circuits has generated extensive explorations (2-5). The most important desired properties of an interconnect material are low resistivity and the possibility to form electrically insulating thermal oxide. The reported resistivities of all Si-rich transition metal silicides (6) are at least one order of magnitude lower than highly doped poly-Si. In this paper, we investigate the processes controlling the oxidation of metal silicides.

All metal disilicide films resting on an excess Si substrate investigated so far, except HfSi₂ and NbSi₂, form SiO₂ as a result of thermal annealing in an oxygen environment. Below the grown SiO₂ film, the silicide is preserved morphologically. The oxidation kinetics of different silicides are summarized in Table I. This table shows that different silicides have different oxidation kinetics, which differ from the kinetics of Si oxidation. The reported oxide thickness, which results from oxidation at the low temperature range, for different silicides varies by more than 50%. Also, different authors disagree about the oxidation behavior of a silicide under dry oxidation. For TaSi₂ (14) or WSi₂ (16), it has been reported that there is no oxide

Key words: oxidation, transition metal silicides, mass transport.

growth under dry conditions, but other researchers have shown that these silicides do oxidize in dry O₂. Such variations cannot be attributed solely to the different analytical techniques used by different authors (Tallystep, RBS, AES, and cross-section TEM, multi-beam interferometry). One explanation commonly advanced is that the oxidation behavior depends on the details of the silicide preparation technique. Also, the way the oxidation of the sample is started seems to be very important for some silicides (5, 13).

In this paper, the important processes controlling the oxidation kinetics are summarized, and the commonalities and differences between different silicides are pointed out.

Major Processes

The oxidation process can be separated into four distinct steps:

1. Diffusion of the oxygen containing molecules through the SiO₂ layer.
2. Reaction at the silicide/oxide interface.
3. Net transport of Si atoms relative to the metal atoms in the silicide.
4. Reaction at the Si/silicide interface which releases Si from the substrate.

We comment on these processes in sequence.

1. The transport through the growing oxide is the only diffusion-controlled process which yields a parabolic time dependence in the oxidation kinetics. We

adopt the linear-parabolic oxidation relation (7)

$$x^2 + Ax = B(t + \tau) \quad [1]$$

where x is the oxide thickness, t the oxidation time, B is the parabolic rate constant, B/A is the linear rate constant, and τ is a fitting parameter that takes into account the initial (transient) oxide growth. The value of B is controlled only by the diffusion process of the oxidant in the SiO_2 , while that of A depends on the reactions at the interfaces and the transport through the silicide layer. Figure 1 depicts a comparison of the parabolic rate constant B vs. temperature for oxide growth on Si and different silicides for wet and dry oxidation. For dry oxidation, the data generated by different authors (over a 30-year span) clearly fit one process with one activation energy. Even the data for wet oxidation can be taken as basically indicative of one process only. The data of Murarka *et al.* (14) for TaSi_2 (line 4a) do not agree with other reports (13, 20) nor do they with the general picture. We will ignore those data. Variation in the partial pressure of water vapor can explain some of the other differences there. The first-order conclusion is that the diffusion process through the oxide is the same during oxidation of all silicides. This fact implies that the equilibrium concentration of the oxidant in the oxide and the diffusion coefficient through the oxide are the same regardless of the substrate ($\langle \text{Si} \rangle$, poly-Si, or different silicides). In other words, the physical properties of the oxide are the same. In fact, a recent study (21) has shown that oxides grown on different silicides have similar properties (density, dielectric constant).

2. The reaction at the silicide/oxide interface is the most difficult step to explore. We will not discuss the reaction rate here. We will only elaborate on a first-order thermodynamics argument to predict the oxide formed. The oxidation of thin films does not necessarily follow such equilibrium laws, but the argument gives some general indication about the process. The generalized chemical equilibrium reaction at this interface, assuming limited oxygen supply (in other words, that all oxygen at this interface is reacted), and unlimited

supply of Si from the substrate can be written as

where $M_x\text{Si}$ describes generalized silicide with metal M and M to Si ratio of x , and $M_y\text{O}$ denotes generalized metal oxide with M to O ratio y . This equation expresses a balance between the formation of SiO_2 or the dissociation of the silicide and the formation of a metal oxide. Figure 2 [taken from Bartur (22)] depicts ΔH_R° —the standard heat of the above reaction. Positive ΔH_R° means that metal oxide will form, while negative ΔH_R° predicts SiO_2 formation (22).

From Fig. 2, we conclude that all transition metal silicides, except Zr and Hf, will grow SiO_2 . However, both exceptions, as well as Ti, Nb, and Ta, might be considered marginal cases, because the values used to calculate ΔH_R° are uncertain and apply only to room temperature. Kinetics may play a major role in these cases. Oxidation studies of ZrSi_2 have not been reported. HfSi_2 (23) and NbSi_2 (24) have been reported to disintegrate and to form a mixture of metal and Si oxides. TiSi_2 does form a SiO_2 layer upon oxidation (8, 9), but, according to a recent report (25), it does so only at temperatures above 900°C . Below this temperature, titanium oxide is formed. This observation might also explain the NbSi_2 oxidation results that were obtained at low temperatures. We can conclude that the thermodynamical argument correctly predicts the general oxidation behavior and identifies the marginal cases for which it cannot affirmatively predict the outcome. Thermodynamics, of course, attempts to predict only which oxides may form. The chemical reactions at that interface are not considered. These unexplored reaction rates are a factor in the linear rate constant B/A .

3. The Si transport (relative to the metal atoms in the silicide) during oxidation is a second factor that might affect A . The argument that the method of silicide preparation affects the oxidation kinetics might be attributed to different characteristics of mass transport through the silicide layer. Here, we concentrate on the question of which species moves. The diffusion

Fig. 1. Arrhenius plot of the parabolic rate constant (B) of oxide growth on different silicides and on Si for dry and wet oxidation.

Fig. 2. The difference between the standard heats of reaction ΔH°_R (per oxygen atoms) of the two reactions which preserve the stoichiometry of the silicide layer, forming SiO_2 on the silicide and reconstituting more silicide with the silicon substrate, and forming metal oxide and precipitating out elemental silicon. For metals that have more than one oxide, a range of ΔH°_R values that is determined by the reaction is shown.

mechanism and the diffusion coefficient will not be explored because of the lack of sufficient experimental data.

The possible cases of a diffusion of Si, metal, or both across the silicide are described in Fig. 3. For two independent moving species—moving singly or simultaneously in either direction—there are eight different possible combinations. Three possibilities can be ruled out since they do not preserve the silicide, as is observed experimentally. The fifth case is unlikely, but is retained for the sake of completeness. To resolve the possible cases experimentally, inert marker experiments must be conducted. The results of such experiments performed for silicide oxidation are matched to the proper schematic description and are also depicted in Fig. 3.

4. Reaction at the Si/silicide interface during oxidation is similar in nature to the reaction at that interface during silicide formation. Silicide formation is usually diffusion not reaction controlled (except CrSi_2) at low temperatures at which the reaction can be analyzed. The rates of Si consumption, however, are roughly the same in both the oxidation experiments performed at high temperatures and these silicide formation experiments at the low temperatures. Because at those rates the reaction at the Si/silicide interface is fast, it must be negligible also at high temperature during oxidation.

Discussion

Table I shows that different silicides yield different oxide thicknesses for identical oxidation conditions. However, the data in Fig. 2 demonstrate that the diffusion of the oxidant through the SiO_2 proceeds similarly for all silicides (values of B in Eq. [1] are basically the same). The observed differences in the oxide thickness must be, therefore, caused by dissimilarities in the linear (early) part of the oxidation process (different values of B/A in Eq. [1]). According to Fig. 3, CrSi_2 , CoSi_2 , NiSi_2 , PdSi , and PtSi oxidize by dissociation with metal as the main diffusing species. The dissociation is induced by the reaction of the oxidant with the silicide. The fact that excess Si is generated for some silicides suggests that this reaction proceeds quite readily. The net Si transport through the silicide is much faster than the transport of oxidant through the oxide. If these two processes (reaction and transport) have high rates, the linear rate constant in Eq. [1] (B/A) must be large. As a result, the process is dominated entirely by the parabolic rate constant B , and Eq. [1] simplifies to

$$x^2 = Bt \quad [2]$$

Under this condition, since B is determined by the oxidant diffusion through the oxide, we expect the oxidation rate to be the highest possible, and independent of the substrate on which SiO_2 grows. Indeed, in the silicides that dissociate during oxidation (CoSi_2 , NiSi_2 , PdSi , and PtSi), we find oxidation rates higher than those of Si and the refractory metal silicides, especially at low oxidation temperatures. In effect, these silicides act as catalysts, because they oxidize (and dissociate) more easily than Si, and this promotes high oxidation rates.

To explore a possible connection between the transport across the silicide during oxidation and during silicide formation, we compared the dominant diffusion species during the two processes (Table II). From Fig. 3 and Table II, we find that dissociation during oxidation happens in all the silicides (NiSi_2 , PdSi , PtSi) where the metal is the moving species during silicide formation. For CoSi_2 , one expects, accordingly, that Co is the moving species during silicide formation, but this prediction has yet to be verified experimentally. An exception is CrSi_2 , which also dissociates, while Si moves during silicide formation. But this silicide grows linearly with time [is reaction limited (6)], so that the moving species during silicide formation might be set by the boundary condition and not by diffusivities. The comparison suggests a rule: during oxidation of a silicide that forms by a diffusion-limited process, the dominant moving species is the same as in the silicide formation. In silicide formation or oxidation we deal with the same bulk, and hence the same relative magnitude of diffusivities. If during silicide formation, which usually occurs at lower temperature than oxidation (for comparable Si consumption rates), the

Table II. Dominant diffusion species during silicide formation and oxidation

Silicide	Dominant diffusion species	
	During silicide formation	During silicide oxidation

process is already diffusion controlled, one expects that the reaction at the Si/silicide interface will not control the process during oxidation either. Hence (assuming similar activation energies), we infer similar boundary conditions generated by the chemical reaction at the interfaces. Therefore, similar bulk and interface properties result in similar atomic fluxes in both cases.

Conclusions

The variation in the oxidation kinetics between Si and silicides, and between the silicides themselves, is due to a different linear rate constant (B/A). In particular, silicides in which the metal is the moving species oxidize more rapidly than bare Si and only a parabolic growth rate is observed experimentally. Silicides in which Si is the moving species are usually formed at high temperatures and the limited Si diffusion through the silicide might impede the oxidation and cause linear rate term change. Enhanced oxidation rates are desirable in IC processing, since dopant diffusion in the Si with the already formed junctions should be minimized. The fact that an enhanced oxidation rate is associated with silicides formed by metal diffusion and can be successfully oxidized at low temperatures gives additional benefits for IC processing. Those silicides are usually formed at relatively low tempera-

tures (less than 450°C) with better control than refractory metal silicides, where Si diffuses during formation. When the metal moves during silicide formation, the Si/silicide interface is expected to be smooth. Kirkendall voids are not expected. Also, from line width considerations and for self-aligned devices, it is preferable (5) that the metal moves during silicide formation.

We thus conclude that, in those respects, silicides formed by metal diffusion have potential for IC interconnects.

Ion Beam Etching of Silicon, Refractory Metals, and Refractory Metal Silicides Using a Chemistry Assisted Technique

J. D. Chinn, W. Phillips, I. Adesida, and E. D. Wolf

National Research and Resource Facility for Submicron Structures, School of Electrical Engineering, Cornell University, Ithaca, New York 14853

ABSTRACT

The etching characteristics of silicon and two refractory metals (Ti, Mo) and four refractory metal silicides (TiSi₂, TaSi₂, MoSi₂, PtSi) are described using a technique called chemically assisted ion beam etching (CAIBE). In this technique, reactive Cl₂ gas is introduced into a sample chamber in conjunction with, and relatively independent of, a broad beam of Ar⁺ ions. Incremental increases in the Cl₂ partial pressure caused linearly increasing etch rates for all materials investigated, except for SiO₂. In the case of silicon, correlation between broad beam CAIBE and ultrahigh vacuum (UHV) etching studies was made. The relative etch rate increase of the refractory metals and silicides investigated were found to be related to the vapor pressures of the reaction products. Additional studies have shown that various residual gas contaminants such as hydrogen, oxygen, and H₂O can influence etching mechanisms by reducing the reactive Cl₂ flux or by forming stable oxides. Linewidths with dimensions below 0.6 μm have been obtained in polycide (a stacked silicide/polysilicon) structures with an etch selectivity > 9:1 between the film layers and SiO₂ using CAIBE.

As minimum feature sizes diminish in VLSI silicon gate-MOS devices, the relatively low electrical conductivity of polysilicon interconnects can decrease device performance by increasing RC time delays. Improved characteristics have been obtained by the use of refractory metals-metal silicide/polysilicon composite gate structures, which can significantly increase the conductivity and allow high temperature processing after metallization. However, fine-line patterning of composite structures can pose problems where low volatile metal halides are present. In general, a pattern transfer technique which combines both physical and chemical mechanisms is desired for high selectivity and for anisotropic etched walls. These mechanisms are involved in most dry etching techniques, such as plasma etching (PE) and reactive ion etching (RIE). However, one major drawback of planar plasma processing is in the indirect method of determining the process parameters (RF power, pressure, flow rate, etc.). Furthermore, planar techniques do not allow direct control of the fluxes arriving at the sample surface. Greater control over the fluxes can be achieved through the use of

broad-beam ion sources in which the ion energy and current can be varied independently. However, even in a technique like reactive ion beam etching (RIBE), there is little control over the chemical-etch component which results from the neutrals effusing from the ion source. In the technique used in this work, chemically assisted ion beam etching (CAIBE), a chemically reactive gas is introduced into the sample chamber in conjunction with either inert or reactive ion bombardment. This technique allows for a large range of relatively independent control over the chemical component of the etching process by varying the partial pressure of the reactive gas and the physical component by controlling the ion beam's energy and current. Large increases in selectivity and etch rates over ion milling have been reported for GaAs (1, 2) using this technique. In addition, it has been demonstrated that CAIBE can be used to control etch-wall profiles from directional overcut to undercut sidewalls in Si (3, 4).

For polycide structures, general pattern transfer requirements include anisotropic profiles without undercutting of the polysilicon layer along with a selective etch stop. Most of the work that has been reported on

Key words: plasma, integrated circuits, interconnects.

the patterning of refractory metals and their silicides has been confined to fluorine gas systems using RIE (5-10). Isotropic etching often occurs and undercut profiles can result in high fluorine-content environments. Less undercut in the patterning of polysilicon (11-13) and polycide structures (14) has been reported when chlorinated plasmas are used. In this paper, we report experimental results using the CAIBE technique to etch Si, refractory metals Mo and Ti, and refractory metal silicides $TiSi_2$, $TaSi_2$, $MoSi_2$, and $PtSi$ with Cl_2 as the reactive background gas. This technique has also been used to pattern polycide structures with dimensions below $0.6 \mu m$.

Experimental

The CAIBE experimental apparatus used in this study was a modified, Varian/Extrion RE-580 RIBE system; it is shown schematically in Fig. 1. Several modifications made on the system include a hollow cathode electron emitter within the ion source and a gas tube through which controlled amounts of Cl_2 gas can be admitted into the sample chamber. In a hollow cathode, thermionic ionization of argon occurs. From this small inert-gas plasma, electrons are extracted for impact ionization of either inert or reactive gases within the source. This type of cathode results in stable ion currents with less than 5% fluctuations over hours of operation. The ion source produces a flood beam capable of etching wafers up to 10 cm in diam. The diameter of samples processed in these experiments however did not exceed 2 cm. A Faraday cup is located adjacent to the sample and is connected to a current integrator-ratemeter for measuring the total ionic charge dose and current density.

The reactive chemical component is controlled by varying the flow rate of Cl_2 gas into the sample chamber. At chamber pressures of 10^{-4} torr, the mean free path of a gas molecule is sufficiently long that the chemical flux can have directionality. Etching in the CAIBE mode with directed chemical fluxes (1, 15-18, 29) has shown total etch-yield increases as high as 30 times compared to pure physical sputtering. However, etch uniformity and profile control under these conditions are dependent on the impingement direction of the chemical and ionic fluxes (1). Thus, in order to better utilize the CAIBE technique, etch uniformity was improved using a nondirected chemical flux arriving at the sample surface by diffusion processes.

Samples were mounted on aluminum wafers by mechanical clips and by thermal paste on the back side. Samples of Ti, Mo, $MoSi_2$, and $TaSi_2$ were prepared by sputtering from a pure metal or composite target. $TiSi_2$ and $PtSi$ were prepared by E-beam evaporation of the pure metals, and silicide formation was performed by heating in a vacuum furnace. N^+ polysilicon was grown by LPCVD followed by a phosphorus implant of $5 \times 10^{15}/cm^2$ and drive in. Samples for etch yield and etch rate studies were patterned by photolithography with AZ1350 resist and measured by

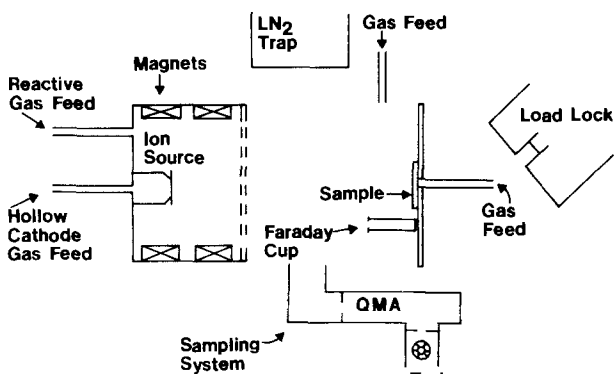

Fig. 1. Schematic of CAIBE system

an Alpha-Step surface profiler. High resolution patterns ($< 0.6 \mu m$) were prepared by E-beam lithography followed by Cr metal liftoff. By using the current integrator, Faraday cup, and load-lock system, samples were exposed to a predetermined charge dose for a fixed ion current density and time. Sample temperature was maintained below $80^\circ C$ under all etch conditions by clamping the sample holder to a freon-cooled stage and by passing argon between the stage and sample.

Results and Discussion

Over the past several years, UHV plasma chemistry studies have provided valuable information and insight into dry etching mechanisms. One such area is in the importance of ion-surface interactions. This has led to rapid development of RIE, and its use instead of the earlier PE technique. However, direct comparisons between ideal UHV environments and etching systems used for semiconductor manufacturing generally cannot be made, because of fundamental differences between the two. In the planar techniques of PE and RIE, the sample is immersed in a plasma and exposed to high fluxes of ions, electrons, and radiation. In the CAIBE technique, experimental conditions are more closely related to UHV environments. In this study, we compared experimental data obtained by Gerlach-Meyer *et al.* (15) in a UHV environment to data obtained in our modified commercially available machine. Good correlation between the two systems is obtained.

In Fig. 2, the etch rate of silicon is shown for various ion energies with incremental increases of Cl_2 gas admitted into the sample chamber. It can be observed that for flow rate increments of 3 sccm of Cl_2 , nearly linear increases in the Si etch rate were measured. Higher etch rates with the same relative etch rate increases were observed with further Cl_2 gas additions until constrained by the pumping speed of system. Etch rates up to five times larger than ion milling rates were obtained. In examining these enhanced etch rates, the Ar^+ -sputter yield was used as a comparative reference. The sputter yields obtained in these experiments show fairly good agreement with other published data (16-17), as shown in Table I. Our slightly higher sputter yields can be attributed to nonideal conditions of a higher residual gas back-

ground as compared to the UHV environment. Cl₂ gas was then admitted into the sample chamber, and a partial pressure was estimated using a quadruple mass spectrometer. By using a zero order approximation, we measured a partial pressure increase of $\sim 5.0 \times 10^{-5}$ torr of Cl₂ for each increase of 3 sccm admitted into the sample chamber. The chemical flux of Cl₂ impinging on the sample surface was estimated using statistical mechanics through the following expression

$$\text{Flux} = \frac{nc}{4}$$

where c is the mean velocity and n the particle density for a room temperature gas. This gives an estimated Cl₂ flux on the sample of $\sim 3.6 \times 10^{15}/\text{cm}^2\text{-s}$ at a flow rate of 9 sccm. Using the data of Fig. 2, these etch conditions (1000 eV with 9 sccm Cl₂ flow) gave a total yield of ~ 2.7 Si atoms per incident ion. This is in good agreement with results obtained in a UHV environment (15), as shown in Table II. The slightly lower total yields obtained in our experiments probably results from using a nondirected chemical flux and a rough estimation of the actual Cl₂ partial pressure. In addition, sputter deposited Si was used in the UHV study, and a higher porosity could result in higher etch yields in the presence of Cl₂ under Ar⁺ bombardment than obtained in our studies, in which crystalline Si was used. In the work by Gerlach-Meyer, Cl₂ gas was directed at the Si surface in the presence of low ion currents (~ 0.01 mA/cm²) with a chemical-flux-to-ion-arrival-rate ratio $\sim 160:1$. The total atom yield showed a nearly linear dependence on the Cl₂ flux below some saturation flux. Above a certain saturation flux (high Cl₂ impingement rates), the total Si atom yield was independent of the flux and was determined by the mass and energy of the incident ions.

High chemical-flux-to-ion-arrival-rate ratios comparable to those obtained in the UHV studies could not be obtained in our experimental apparatus, because of vacuum pumping constraints and operation of the ion source. Thus, a Cl₂ impingement rate in which surface saturation is observed in the UHV studies could not be obtained in these experiments. The etch yields at the Cl₂ partial pressures used were thus limited by the availability of Cl₂ for reaction with Si. The etch yields increased linearly with changes in the Cl₂ partial pressure, as indicated in Fig. 2. The ion currents pro-

Table II. Comparison of total silicon atom yields for various Cl₂ gas flux-to-ion-ratios

ref. 15		2.8	40

duced by the broad-beam source were also an order of magnitude greater than from the UHV ion gun. Under our experimental conditions, the chemical-flux-to-Ar⁺-arrival rate ratio was $\sim 2.3:1$ (vs. 160:1), and fairly good agreement in the total yield was still obtained between the ideal UHV and our broad beam results. This suggests that the etch yields are dependent on the energy of the incident ion and the reactive chemical flux, but not on the ion flux below some saturation level of the chemical flux. For a higher ion current, the total atom yield is still the same, but the Si atoms are removed at a faster rate determined by the ion flux. This is an advantage of the CAIBE technique over other planar techniques in finding the desired process parameters. From UHV or CAIBE yield data, the relative etch-rate ratios (the selectivity) for different film layers with the same background gas conditions are only determined by the ion flux. In PE or RIE techniques, various parameters have to be adjusted in order to determine the optimum selectivity.

In the operation of broad-beam ion sources, an order of magnitude pressure difference across the extraction grids usually exists. The transmission of the grid set used in these experiments was approximately 50%. Thus, a portion of the reactive gas background diffuses upstream into the source, where it is ionized and then accelerated back toward the substrate. As the flow of reactive gas into the sample chamber is increased, the higher chamber pressure results in increased currents both within the source and the extracted beam. Hence, Cl₂⁺ and Cl⁺ ions are present in the extracted beam. In order to qualitatively measure the amount of chlorine within the beam, the increase in the beam current for changes in the background gas pressure were measured. In Fig. 3, it can be observed that for large flow rates of Cl₂ gas into the sample chamber, the beam composition approaches nearly 65% Ar⁺ and 35% Cl₂⁺ and Cl⁺. In these experiments, operation of the ion source was adjusted to maintain a constant ion current density. The role of Cl₂⁺- and Cl⁺-ion bombardment in the presence of Cl₂ gas on the total etch yield has not been investigated in UHV environments. Studies are needed in this area to determine if the reactive ions significantly increase the etch yield or behave effectively like Ar⁺ ions in initiating etch reactions. Preliminary etch rate experiments of Si and Cl₂⁺ and Cl⁺ ions with Cl₂ gas impinging on the background gas have indicated that the chlorine ions behave similarly to Ar⁺ ions or that the ion-assisted reaction between the Cl₂ background gas and the Si surface dominates the etching mechanisms.

Fig. 3. Total ion beam current for various Cl₂ flow rates. The increase in ion beam current is attributed to the Cl₂ background gas entering the source. The amount of Cl₂⁺ and Cl⁺ is shown as a percentage of the total beam current. It is assumed that the Ar⁺ in the ion beam remains constant.

Table III. Comparison of etch rate increases

• Ar⁺ Beam ⊙ Normal Incidence 500 eV
DOSE = 0.04 C/cm² 0.26 mA/cm²
Increments of 3 sccm Cl₂ in Background

Under similar experimental etch conditions, Ti, TiSi₂, TaSi₂, Mo, MoSi₂, and PtSi samples also showed linear incremental etch-rate increases with Cl₂ additions. However, the enhanced etch rates were lower than those of Si. Figure 4 shows the etch rates obtained for TaSi₂ under the same conditions as the Si experiments. Table III lists the relative etch-rate increases caused by adding 3 sccm increments of Cl₂ gas for different materials. By examining the vapor pressures (19-22) of the various chloride reaction products, it can be observed that the relative etch-rate increases of Table III correspond to the relative chloride vapor pressures of Fig. 5. A high vapor pressure implies a high etch-rate increase. Etch rates of other types of materials should be dependent on the vapor pressure of the final reaction products. In Fig. 5, we have listed the downstream mass spectrometry reaction products for the materials etched.

In CAIBE, substrate temperatures have also been reported to add nonlinear effects to the etch rates (18) especially with materials which form low vapor pressure reaction products. Our sample temperatures are assumed to be the same for all materials since the ion dose and current were the same. The substrate temperature effect has been reported in the etching of GaAs with plasmas containing chlorine (23, 24) and bromine (25). This implies that raised sample temperatures in beam processing aid in increasing the etch rates. However, in a beam process, the actual surface temperature

where the ion beam deposits energy with the substrate is unknown. It may be quite high.

Refractory metals often exhibit the property of forming stable and low sputter yield oxides. Thus, background oxygen containing gas contaminants can influence etching mechanisms and etch rates. In most chlorine containing systems, H₂O is a common residual gas, and is known to significantly influence the etch rate of other materials which have a high affinity for oxygen, such as aluminum. In order to investigate the effects of the background gas contaminants, trace amounts of H₂, O₂, HCl, and Cl₂ (with traces of H₂) were added to the sample chamber with the results illustrated in Fig. 6. Additions of H₂ to the sample chamber had no measurable effect on the etch rates. However, when small traces of O₂ were added, etch rates were dramatically reduced on all refractory metals and silicides except for PtSi. In ion milling, Ti is a popular masking material because it has a high affinity for oxygen and low sputter yield. The etch-rate decrease observed with oxygen additions is attributed to the gettering property of the material and the low sputter yield of the oxide.

HCl was the most abundant residual gas in our system. This is a common occurrence even in well-pumped and well-trapped vacuum systems which have been exposed to chlorine containing compounds. When additional amounts of HCl were added to the sample chamber, the etch rates showed little change, as in the case with H₂ additions. When traces of H₂ were

Fig. 4. Etch rates of TaSi₂ using the same conditions as in Fig. 2

Fig. 5. Chloride vapor pressures for various refractory metal chlorides.

Fig. 6. Relative etch rate changes for gas additions of Cl_2 , H_2 , O_2 , HCl , and Cl_2 with H_2 .

added with Cl_2 additions, a decrease in the etch rates occurred. The reaction of H_2 and Cl_2 to form HCl has presumably occurred. HCl is thought to be a stable molecule that does not contribute to the etching mechanisms. Thus, introducing H_2 is believed to reduce the Cl_2 partial pressure, which reduces the etch rates. Additions of H_2 to fluorocarbon gas systems in PE and RIE reduces the fluorine concentration by forming stable HF (26-27), which does not contribute to the etching mechanisms of Si and SiO_2 . A similar effect is thought to have occurred in these CAIBE experiments.

Oxides are not readily etched in most chlorine gas systems. This property can be utilized to pattern selectively polycide structures. The etch rates of polysilicon and most refractory metals increased over ion milling rates under ion bombardment in the presence of Cl_2 , while the SiO_2 etch rate remained approximately the same. To demonstrate the applicability of the CAIBE technique to device fabrication, we have etched submicron features in a TaSi_2 /polycide stacked structure (Fig. 7). No undercut of the polysilicon was observed, and a selective etch was achieved. Damage to gate oxides is thought to be similar to other etch-

Fig. 7. Scanning electron micrograph of a TaSi_2 polycide structure. Etch conditions: Ar^+ at 570 eV for 180s followed by Ar^+ at 400 eV for 300s with a Cl_2 flow rate of 9 sccm.

ing techniques, such as RIE. In CAIBE, surface damage was shown to be related to the dose of the Cl_2 flux (28) in compound semiconductors. With a high chemical flux, ideality factors of Schottky diodes using current-voltage (I-V) measurements were found to be near unity and increased with lower chemical fluxes. CAIBE should be useful in device fabrication.

Summary

Comparative studies of broad-beam Ar^+ ion processing and UHV studies were made using Cl_2 as the chemical assist component, and good correlation with the etch yields of Si was obtained. The etch rates of various refractory metals and metal silicides have been compared in CAIBE, and the relative etch-rate increases observed are directly related to the vapor pressure of the reaction products. Background gas contaminants, such as oxygen and H_2O , can influence the etch rates by reducing the Cl_2 flux and by forming stable oxides.

ABSTRACT

By an EMF method, we measured the activity of silica (a_{SiO_2}) as a function of composition in the homogeneity range of forsterite (Mg_2SiO_4) including the compositions in equilibrium with the pure neighboring phases (MgO and MgSiO_3 , respectively) in the phase diagram. The experiments were performed at $1300 \leq T \leq 1780$ K using a solid electrolyte which contained MgF_2 dispersed in a Mg_2SiO_4 matrix. On the basis of the results, published data on the ionic conductivity and the resulting ideas on the dominant defects are critically discussed. Consequences for future transport experiments are investigated.

Magnesiumorthosilicate (Mg_2SiO_4) is a model substance for earth scientists and materials scientists. Despite an increasing number of papers on the physical and chemical properties of this compound and its olivine-type solid solutions, it has not yet been possible to unambiguously identify the lattice defects via which transport of matter occurs in pure Mg_2SiO_4 (forsterite) at high temperatures. Assuming dilute solution theory to be valid, defect equilibria in ternary oxides, including silicates with olivine structure, especially Mg_2SiO_4 , had already been formulated some decades ago. The progress made since those days with regard to the formal aspects of the problem may be gathered from the bibliographies of recent papers published in this field (1-3, 10). (For the sake of brevity we only quote the most recent article on pure forsterite of the respective research groups or a review paper.) The experimental data referred to most frequently are the electrical conductivity measurements of Pluschkell and Engell (4). Recent diffusivity measurements (5-9), which in principle also may be used as a test of the theoretical hypotheses, could not yet be interpreted unambiguously. This seems to be due to an insufficient characterization of the samples used during most of the experiments.

It must be stated that the original questions are not fully answered. This is mainly due to two facts, which are somewhat interrelated: first, the physical proper-

ties (ionic conductivity κ , diffusivities D_i) were measured either as a function of concentration [$\kappa(x_{\text{SiO}_2})$ (4)] or on samples with poorly defined composition [D_i (5-9)]; instead, they should have been measured as a function of the thermodynamic activities of two of the constituent elements in the homogeneity range of the ternary oxide in order to allow a sound thermodynamic treatment. Second, with high defect concentrations the dilute solution approach, usually practiced in defect thermodynamics (2), and the concept of constant mobilities (independent of the composition of the crystal at $P, T = \text{constant}$) (4) are no longer applicable as associations of defects may occur (1, 10).

In this paper, we present experimental results on the activity of a constituent oxide, SiO_2 , in Mg_2SiO_4 as a function of composition and of temperature at a fixed oxygen activity. With the results it is possible to define the silica-rich part of the homogeneity range of Mg_2SiO_4 between 1300 and 1780 K and to reinterpret published data on the ionic conductivity at least qualitatively with respect to the nature of the defects involved. Further, guidelines for planning and performing future diffusivity and deformation experiments can be derived.

Defect Equilibria

For the details on the formulation of defect equilibria within the frame of the dilute solution approach we refer to the literature mentioned above. Summarizing the preliminary results which, strictly speaking,

* Electrochemical Society Active Member.

¹ Present address: Fachbereich Metallurgie und Werkstoffwissenschaften, TU Clausthal, D-3392 Clausthal-Zellerfeld, Germany.

are sophisticated speculations based on crystal chemistry rules, the phase diagram, and only one set of experiments (4), the concept generally accepted until now may be described as follows: (i) pure forsterite, which is stoichiometric with regard to both the cation to anion ratio [$(n_{Mg} + n_{Si})/n_O = 3/4$] and the magnesium to silicon ratio ($n_{Mg}/n_{Si} = 2$), apparently has Frenkel-type defects in the magnesium sublattice as majority defects. (ii) At sufficiently high temperatures up to about 1800 K, Mg_2SiO_4 readily dissolves excess silica (several mol percent [m/o]), but appreciably less excess magnesia ($\lesssim 0.1$ m/o) (4). At still higher temperatures, according to recent results, the solubility of magnesia drastically increases and forsterite incorporates between 0.7 and 2.4 m/o of magnesia (11). In the case of magnesia-rich forsterite, the majority defects might be either $Mg_i^{2\cdot}$ and $V_{Si}^{4\cdot}$ or $V_O^{2\cdot}$ and $V_{Si}^{4\cdot}$ in the Kröger-Vink notation. The incorporation of silica is considered to create either $V_{Mg}^{2\cdot}$ and $V_O^{2\cdot}$ or $V_{Mg}^{2\cdot}$ and $Si_i^{4\cdot}$ as majority defects. Associations of defects are generally neglected (3).

This paper deals with experimental results for $a_{SiO_2} = f(x_{SiO_2})$ in the silica-rich portion of the homogeneity range of Mg_2SiO_4 . We therefore confine ourselves to the theoretical treatment of the corresponding defect equilibria. With the defect concentrations to be expected in this composition range according to the appreciable solubility of silica, dilute solution defect thermodynamics will no longer be applicable. Because of the high concentration of defects, a Debye-Hückel-type calculation of the electrostatic interaction only is not possible either. It will therefore be necessary to adopt a formal treatment including defect complexes.

We shall treat two models, which we shall call A and B. They will be formulated using the Kröger-Vink notation.

Model A.—1 $\hat{=} V_{Mg}^{2\cdot}$, 2 $\hat{=} V_O^{2\cdot}$, 3 $\hat{=} [V_{Mg}, V_O]^x$, 4 $\hat{=} Mg_i^{2\cdot}$, $a_i = x_i \cdot f_i$ being activities, x_i [or also (i)] being a molar fraction, f_i being an activity coefficient

$$SiO_2 \rightleftharpoons Mg_2SiO_4 + 2V_O^{2\cdot} + 2V_{Mg}^{2\cdot}$$

$$K_{2-1} = \frac{(V_O^{2\cdot})^2 (V_{Mg}^{2\cdot})^2}{a_{SiO_2}} \cdot f_{V_O}^2 \cdot f_{V_{Mg}}^2$$

$$= a_1^2 \cdot a_2^2 \cdot a^{-1}_{SiO_2} \quad [1]$$

$$Mg_{Mg}^x \rightleftharpoons V_{Mg}^{2\cdot} + Mg_i^{2\cdot}$$

$$K_{2-2} = (V_{Mg}^{2\cdot}) (Mg_i^{2\cdot}) \cdot f_{V_{Mg}} \cdot f_{Mg} = a_1 \cdot a_4 \quad [2]$$

$$V_O^{2\cdot} + V_{Mg}^{2\cdot} \rightleftharpoons [V_{Mg}, V_O]^x$$

$$K_{2-3} = \frac{[V_{Mg}, V_O]^x}{(V_O^{2\cdot}) (V_{Mg}^{2\cdot})} \cdot f_{[V_{Mg}, V_O]^x} \cdot \frac{1}{f_{V_O} \cdot f_{V_{Mg}}}$$

$$= a_3 \cdot a_2^{-1} \cdot a_1^{-1} \quad [3]$$

with the electroneutrality condition

$$(V_O^{2\cdot}) + (Mg_i^{2\cdot}) = (V_{Mg}^{2\cdot}) \quad [4]$$

and the mass balance with regard to oxygen

$$[V_{Mg}, V_O]^x + (V_O^{2\cdot}) = 2\delta, \quad \delta = x_{SiO_2} - 1/3 \approx 0 \quad [5]$$

where δ is the excess silica concentration ($\delta = 0$ corresponds to the stoichiometric composition of the forsterite).

The equilibrium constants K_{2-i} , $i = 1, 2, 3$ being unknown, the defect concentrations cannot be calculated. In order to get a formal similarity to the well-known relationships of the dilute solution approach, we combine Eq. [1], [2], [3], and [5], wherefrom we obtain upon differentiation

$$\frac{\partial \ln x_1}{\partial \ln a_{SiO_2}} = - \left[\left(\frac{\partial \ln \delta}{\partial \ln a_{SiO_2}} - \frac{1}{2} \right) (K_{2-3} f_1 f_2 f_3^{-1} x_1 + 1) + \frac{\partial \ln f_2}{\partial \ln a_{SiO_2}} + K_{2-3} \cdot f_3^{-1} \frac{\partial \ln f_3}{\partial \ln a_{SiO_2}} \right] \quad [6]$$

This equation reduces to $\partial \ln (V_{Mg}^{2\cdot}) / \partial \ln a_{SiO_2} = 1/4$ for $f_i = \text{constant}$, $K_{2-3} = 0$, and $(V_{Mg}^{2\cdot}) \sim \delta$.

The value of 1/4 for the characteristic slope corresponds to the absence of any defect association. The opposite extreme would be a complete association of the defects, which means $(V_{Mg}^{2\cdot}) \approx 0$, $\partial \ln (V_{Mg}^{2\cdot}) / \partial \ln a_{SiO_2} = 0$.

With $[V_{Mg}, V_O]^x \sim \delta$ and constant and finite values for the activity coefficients f_i , Eq. [6] yields in this limiting case $\partial \ln ([V_{Mg}, V_O]^x) / \partial \ln a_{SiO_2} = 1/2$ as in the dilute solution approach.

$$\text{Model B.}—1 \hat{=} V_{Mg}^{2\cdot}, 2 \hat{=} Si_i^{4\cdot}, 3 \hat{=} Si_{Mg}^{2\cdot}, 4 \hat{=} Mg_i^{2\cdot},$$

$$5 \hat{=} [V_{Mg}^{2\cdot}, Si_{Mg}^{2\cdot}]^x$$

$$2SiO_2 \rightleftharpoons Mg_2SiO_4 + 2V_{Mg}^{2\cdot} + Si_i^{4\cdot}, \quad K_{2-7} = \frac{a_1^2 \cdot a_2}{a_{SiO_2}^2} \quad [7]$$

$$Mg_{Mg}^x \rightleftharpoons V_{Mg}^{2\cdot} + Mg_i^{2\cdot}, \quad K_{2-2} = a_1 \cdot a_4 \quad [2]$$

$$V_{Mg}^{2\cdot} + Si_i^{4\cdot} \rightleftharpoons Si_{Mg}^{2\cdot}, \quad K_{2-8} = \frac{a_3}{a_1 \cdot a_2} \quad [8]$$

$$V_{Mg}^{2\cdot} + Si_{Mg}^{2\cdot} \rightleftharpoons [V_{Mg}^{2\cdot}, Si_{Mg}^{2\cdot}]^x, \quad K_{2-9} = \frac{a_5}{a_1 \cdot a_3} \quad [9]$$

with the electroneutrality condition

$$(Mg_i^{2\cdot}) + (Si_{Mg}^{2\cdot}) + 2(Si_i^{4\cdot}) = (V_{Mg}^{2\cdot}) \quad [10]$$

and the mass balance with regard to silicon

$$[V_{Mg}^{2\cdot}, Si_{Mg}^{2\cdot}]^x + (Si_{Mg}^{2\cdot}) + (Si_i^{4\cdot}) = \frac{\delta}{2} \quad [11]$$

From a procedure analogous to that which yielded Eq. [6], a rather complicated expression results. Simplifying by setting $f_i = \text{constant}$, we get

$$\frac{\partial \ln x_1}{\partial \ln a_{SiO_2}} = - \left(\frac{\partial \ln \delta}{\partial \ln a_{SiO_2}} - 2 \right) \cdot \left[\frac{K_{2-8} K_{2-9} f_5^{-1} x_1^2 + K_{2-8} f_3^{-1} f_1^{-1} x_1 + f_1^{-2} f_2^{-1}}{K_{2-8} f_3^{-1} f_1^{-1} x_1 + 2f_1^{-2} f_2^{-1}} \right] \quad [12]$$

Equation [12] reduces to $\partial \ln (V_{Mg}^{2\cdot}) / \partial \ln a_{SiO_2} = 2/3$ for $f_i = 1$, $K_{2-8} = K_{2-9} = 0$, and $x_1 = (V_{Mg}^{2\cdot}) \sim \delta$. This describes the absence of any defect association. If $(V_{Mg}^{2\cdot}) \approx 0$ and $\partial \ln (V_{Mg}^{2\cdot}) / \partial \ln a_{SiO_2} \approx 0$, which corresponds to the nearly complete association of the point defects (according to Eq. [9]), Eq. [12] reduces to $\partial \ln ([V_{Mg}^{2\cdot}, Si_{Mg}^{2\cdot}]^x) / \partial \ln a_{SiO_2} \approx 2$, which implies $([V_{Mg}^{2\cdot}, Si_{Mg}^{2\cdot}]^x) \sim \delta$, f_i being constant and finite. For partial association (according to Eq. [8]), Eq. [12] would yield $\partial \ln (V_{Mg}^{2\cdot}) / \partial \ln a_{SiO_2} = 1$ with the appropriate general assumptions as mentioned above being valid. Equations [6] and [12] relate the experimentally determined quantity $\partial \ln \delta / \partial \ln a_{SiO_2}$ to the variation of a defect concentration with composition $\partial \ln (V_{Mg}^{2\cdot}) / \partial \ln a_{SiO_2}$.

The (total) ionic conductivity $\kappa(a_{SiO_2})$ can be calculated from $\kappa(x_{SiO_2})$ (4) and $a_{SiO_2}(x_{SiO_2})$ (this work). In special cases (i.e., if the transference number of one defect species is close to 1) we get

$$\frac{\partial \ln \kappa}{\partial \ln a_{\text{SiO}_2}} \approx \frac{\partial \ln \kappa_1}{\partial \ln a_{\text{SiO}_2}} = \frac{\partial \ln x_1}{\partial \ln a_{\text{SiO}_2}} + \frac{\partial \ln u_1}{\partial \ln a_{\text{SiO}_2}},$$

$$t_1 \approx 1 \quad [13]$$

In the dilute solution approach, the mobilities u_i are assumed to be constant. As will be seen below, this is most probably not true for the silica-rich portion of the homogeneity range of forsterite.

Experimental

Preliminary remarks.—For the experimental determination of silica in forsterite, we used an electrochemical method which had been described elsewhere (12) and which is based on the application of a special fluoride electrolyte being present as a second phase in a so-called "inert skeleton."

We used the two concentration cells

The measured EMF (E) reflects the difference in the silica activities on both sides of the electrolyte

$$E = \left| \left(\frac{RT}{4F} \ln \frac{a_{\text{SiO}_2}(\text{II})}{a_{\text{SiO}_2}(\text{I})} \right) \right| \quad [16]$$

From our published data (12), standard free enthalpy values for the reactions

are taken for the calculation of the activity values a_{SiO_2} in forsterite.

From cell [14], one obtains

$$a_{\text{SiO}_2}(14\text{-II}) = \exp \left(\frac{4F |E_1| - 58,423 - 4.44 T}{RT} \right) \quad [19]$$

and from cell [15]

$$a_{\text{SiO}_2}(15\text{-II}) = \exp \left(\frac{-4F |E_2| - 18,247 + 8.96 T}{RT} \right) \quad [20]$$

Sample preparation.—Fine grain powders of reagent-grade MgO and SiO₂ were thermally pretreated, thoroughly mixed with a small amount of binder (oleine acid) and compressed (5×10^8 Pa) before being first sintered in air for 12h at 1200°C. Then, the temperature was increased to 1450°C for another 96h. Afterward, the samples were rapidly cooled to room temperature and controlled by optical microscopy and x-ray diffraction. Densities were determined. The complete set of samples is grouped in Table I together with the electrolyte.

EMF measurements and results.—The measurements were made in air. Up to about 1080°C, quartz glass was used for the construction of the apparatus; above 1080°C alumina was used.

Depending on the temperature, stable EMF values were reached after about 0.5-2h after a change of the measuring temperature. The EMF was measured with a digital vacuum tube voltmeter ($R = 10^{10}\Omega$). Table II shows the measured EMF values for cell [14] together with the a_{SiO_2} data calculated from Eq. [19], as a function of temperature and composition. Table III gives the corresponding information as obtained from cell [15]. With the aid of our data, we calculated the electrical conductivity as a function of temperature and silica activity from published literature values for the conductivity as a function of temperature and composition (4). The results are represented in Table IV.

Discussion

In order to facilitate the interpretation of the numerous data points in the silica-rich part of the homogeneity region, we refer to Fig. 1, 2, and 3. In Fig. 2, the temperature independent characteristic slope in the linear range is $n_\delta = \partial \ln \delta / \partial \ln a_{\text{SiO}_2} \approx 1.42$. Equation [12] shows us that $1 \leq n_\delta \leq 2$ might be tentatively explained by a complex formation involving the equi-

The states 0 and 1 in the last column correspond to the compositions with maximum and minimum values of the conductivity for a given temperature (see Fig. 3).

libria described by Eq. [8] and [9]. As absolute values of the defect concentrations are not known, the quantities in the term in brackets in Eq. [12] cannot be further discussed now. Accepting the idea that the

activity coefficients f_i do not vary too much with composition and that their numerical values are more or less close to 1, the numerical value of the term in brackets can be situated between about 0.5 ($K_{2-9}, K_{2-9} \ll 1$) and about 1 ($K_{2-9} \gg 1, K_{2-8} \gg 1$) according to the comments on Eq. [12] above.

With this in mind, we can estimate the dependence of defect mobility on the activity and/or concentration of silica. A general feature of the dependence of conductivity on activity (see Fig. 3) is a high value of the slope $n_\kappa = \Delta \ln \kappa / \Delta \ln a_{SiO_2} \approx 4.9$ in the central part and a region of saturation on both ends of the s-shaped

Fig. 1. The homogeneity range of forsterite. (The a_{SiO_2} values for $a_{MgO}(T) = 1$ and $a_{MgSiO_3}(T) = 1$ were calculated from (12), the connection to the experimental curves of this work being represented by broken lines.)

Fig. 2. Excess silica $\delta = x_{SiO_2} - 1/3$ in forsterite as a function of a_{SiO_2} . The extrapolation end points are calculated from (12).

Fig. 3. The ionic conductivity of forsterite as a function of silica activity. (The ionic conductivity data were taken from (4): for a given temperature, $\kappa = \text{constant}$ for $x_{\text{SiO}_2} \lesssim 0.3352$.) The slope of the full line yields $\Delta \ln (\kappa/\kappa_0)/\Delta \ln a_{\text{SiO}_2} = 4.9$ (see text and Table IV). For 1480 and 1300 K the $\lg \kappa$ - $\lg a_{\text{SiO}_2}$ curves show a similar behavior and yield the same slope in the linear part.

curves, which give rise to an apparent slope $\tilde{n}_\kappa \approx 1.1$ (see Table IV).

In the dilute solution approach (1, 2, 4) conductivity or diffusivity measurements are usually evaluated on the basis of constant mobilities u_i . In the case given here, such a procedure would (erroneously) yield the

clear cut answer: $\tilde{n}_\kappa \approx 1.1 \approx 1$; therefore $V_{\text{Mg}^{2+}}$ and $\text{Si}_{\text{Mg}^{2+}}$ should be the majority defects. In reality, the situation is much more complicated: inserting the experimental values in Eq. [12] and [13] and assuming

the simplest case of one mobile species $1 \hat{=} V_{\text{Mg}^{2+}}$, the dependence of the mobility u_1 on the activity of silica can be placed in the interval $4.3 \lesssim \partial \ln u_1 / \partial \ln a_{\text{SiO}_2} \lesssim 4.6$. This indicates a rather strong dependence on concentration. The possible objection that the discrepancy between $\partial \ln \kappa / \partial \ln a_{\text{SiO}_2} \approx 4.9$ and $\partial \ln \delta / \partial \ln a_{\text{SiO}_2} \approx 1.4$ may be entirely due to the term in brackets in Eq. [12] must be rejected because this would require a negative value for K_{2-8} .

Conclusion

From our experimental $a_{\text{SiO}_2}(x_{\text{SiO}_2})$ data and the $\kappa(x_{\text{SiO}_2})$ data of Pluschkell and Engell (4), it must be concluded that magnesium vacancies $V_{\text{Mg}^{2+}}$ and complexes of the type $[V_{\text{Mg}^{2+}}, \text{Si}_i^{4+}]^{2-}$ and $[2V_{\text{Mg}^{2+}}, \text{Si}_i^{4+}]^{\pm}$,

which have already been tentatively discussed by other authors (1, see also (10) for MgSiO_3), are the most probable majority defects in Mg_2SiO_4 , which contains excessive silica. Further, the reinterpretation of the published conductivity data on the basis of our experimental findings reveals a strong dependence of the mobility on the composition of the forsterite in the silica-rich part. As a further consequence, it cannot be excluded that the differences between the published values of silicon and oxygen diffusivities (5-9) may be partially due to the different states of the crystals used with regard to the value of the thermodynamic activity of silicon and magnesium. As the different crystal growth methods may lead to pronounced differences in composition of the single crystals an experimental control by an EMF measurement is strongly advisable prior to further measurements of transport properties or deformation kinetics.

Finally, EMF measurements of the type presented here should be carried out also in the silica-deficient part of the homogeneity range, and, if possible, at more than one value of the oxygen potential and as a function of total pressure at a given temperature. Further lattice dynamics calculations (13) may shed some light on the energetics of the defects postulated above from a more empirical point of view.

Acknowledgments

We are obliged to A. Kozłowska-Róg and to E. Ebeling for their skillful help with the experiments and to Chr. Ebeling, U. Amthor, and E. Voges for their patience in preparing the typescript. One of us (G.B.) is indebted to the French Government and to the Institut National Polytechnique de Lorraine for offering him a temporary position as an associate professor at ENSMIM, Nancy. Financial aid of the Deutsche Akademische Austauschdienst and of the Deutsche Forschungsgemeinschaft made this work possible. G.R. expresses his personal gratitude towards the Technische Universität Clausthal.

Defect Luminescence of Thin Films of Cu₂O on Copper

R. Gilbert Kaufman* and R. T. Hawkins

Standard Oil Company (Indiana), Amoco Research Center, Naperville, Illinois 60566

ABSTRACT

Films of Cu₂O, 30 μm thick, have been grown on copper metal foil at 1000°C in 1% O₂/Ar, heat-treated without O₂ present at a number of lower temperatures, and quenched in water. The room temperature emission at 980 nm and its excitation spectrum, attributed to relaxed excitons at copper vacancies, are similar to reported photoluminescence from thick crystals. Apparent quenching of luminescence by interaction among vacancies is observed for sufficiently high copper vacancy concentration. Heat-treatment does not produce copper vacancies, but redistribution of vacancies can increase their photoluminescence by nearly two orders of magnitude. Under the present copper oxidation conditions, the enhanced concentration of copper vacancies near the Cu₂O surface suggests that the rate of oxidation is limited by the diffusion of these vacancies.

The properties of Cu₂O have been studied for decades. This research has been largely confined to bulk crystalline samples. Another approach to the study of the properties of materials is to examine thin films. Such an approach raises the possibility that film properties may be found which are significantly different from bulk properties of the same material, as has, for example, been observed in the case of the luminescence of phosphors. Furthermore, the mechanisms which produce these differences in properties are in themselves of interest. For example, films are not necessarily uniform or in thermodynamic equilibrium, and the choice of conditions of formation of the film, especially the choice of substrate, can control the chemistry and structure of the resulting film. In particular, variations over the thickness of a film can produce gradients in material properties, such as defect structure.

Films of Cu₂O on copper metal constitute an interesting system for the study of such gradients of point defects. Good quality films are relatively easy to prepare, with at least one structure having substantial grain size (1). Such Cu₂O films are nonstoichiometric, with composition a function of oxygen partial pressure during film growth. Characteristic emission and excitation photoluminescence spectra of bulk Cu₂O have been attributed to relaxed excitons at copper and oxygen vacancies (2, 3). However, no analogous studies have heretofore been done for films of Cu₂O on copper, which would be expected to be copper rich in the region next to the metal and copper poor at the exterior surface of the film, nor has any effort been made to use photoluminescence to monitor vacancy concentrations. Since the usual Hall measurements and four point probe conductivity measurements to determine vacancy concentration are not possible with Cu₂O films on copper metal, photoluminescence appears to be a very sensitive, well developed technique to monitor vacancies.

We present here the results of a study of the correlation between the vacancy photoluminescence of films of Cu₂O on copper metal and the conditions of preparation of these films.

Experimental

Copper coupons 1.0 × 1.2 × 0.05 cm of Marz grade copper, nominally five nines purity, from Materials Research Corporation were oxidized at 1000°C in a flowing stream of 1% O₂ in 1 atm of argon to obtain Cu₂O films of 30 μm thickness, as measured by weight gain. The average grain size of the films was generally greater than 100 μm. These films were either left as grown or subjected to a heat-treatment, which consisted of holding the sample in flowing argon at a specific temperature in the 300°-700°C range for 15 min and then manually removing it from the argon

atmosphere and quenching it in water. The films maintained excellent optical quality throughout this preparation and thus required no polishing or etching.

Emission spectra were excited at 633 nm with an unfocused HeNe laser, and were measured using a Rofin 6000 monochromator (with a silicon photodetector) together with a series of prefilters for further wavelength discrimination. Excitation spectra were measured at 10 nm intervals over a 450-690 nm range, using as a source the emission of a 150W xenon arc lamp, filtered by a grating monochromator (Oriel Model 7240) in series with two 11 nm bandpass interference filters (Ditric) to eliminate second-order and scattered light from the grating. These excitation spectra were detected with a silicon photovoltaic and a series of cutoff filters, including a 1 mm thick CdTe crystal. Photoluminescence signals were all corrected to constant excitation intensity.

Results

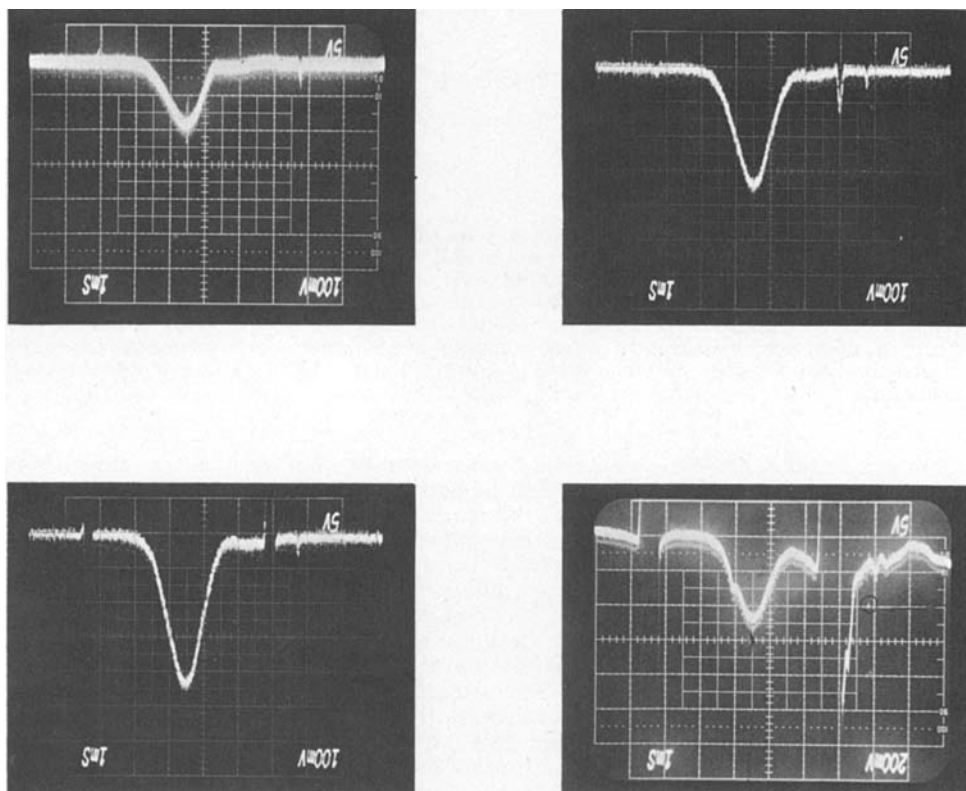

The photoluminescent emission of 30 μm thick Cu₂O films on copper metal at 25°C, excited by the 633 nm HeNe laser line, consists of a single band centered at 980 nm, as shown in Fig. 1. Several cutoff filters were used to remove the exciting light, which appeared in the first and second orders of the monochromator transmission with different intensities, so that any significant intensity of emissions at 700 and 800 nm could be observed. Neither are present at room temperature, although subsequent experiments have shown that they do appear under 633 nm excitation at 77 K. The CdTe filter was found to be the most efficient at removing exciting light while only reducing the 980 nm emission as shown in Fig. 1(d), and was therefore used in the subsequent measurements of excitation spectra.

The excitation spectra for 980 nm emission at 25°C are shown in Fig. 2 for four 30 μm Cu₂O films. Comparison of the spectra of (A) and (B) demonstrates that a 15s etch in 8N HNO₃, which removes 7-8 μm, increases the photoluminescence of as-grown films, while not causing any marked change in the spectral structure. Thus, a nonluminescing "dead" layer is apparently present on the surface. However, the excitation spectrum of (C), which was heat-treated at 500°C, is observed to differ qualitatively from that of (A), and also to be over an order of magnitude more intense. Moreover, etching clearly affects a heat-treated sample significantly more than an as-grown sample, as is shown by the difference between (C) and (D) in Fig. 2. More than half the luminescence is removed with the quarter of the film that was part of a dead layer before heat-treatment. Several features should be noted about these spectra. First, all spectra display excitation peaks at 570 and 620 nm. Second, the ratio of excitation efficiency in the λ > 480 nm region to that in the λ < 480 nm region is significantly greater for the heat-treated samples than for the other ones. Finally, the excitation

at 690 nm, although weak, is well above the background noise in all spectra and appears to be a part of a longer wavelength excitation which is not accessible with the apparatus at hand. This feature at 690 nm is thought (3) to be a direct excitation of a relaxed exciton at a copper vacancy.

Another experiment was performed to measure copper vacancy photoluminescence intensity as a function

Fig. 2. Excitation spectra for 980 nm emission: (A) as grown; (B) 15s etch in 8N HNO_3 ; (C) heat-treated at 500°C, but not etched; (D) heat-treated at 500°C and etched for 15s in 8N HNO_3 .

of depth in a Cu_2O film. For this purpose, an 80 μm thick film of Cu_2O was grown on copper and heat-treated at 500°C (15 min in argon followed by a water quench, as with the other samples discussed here). The emission intensity, excited at 690 nm and detected at room temperature with a CdTe filter, was repeatedly measured as the film was etched with 8N HNO_3 . The 80 μm thickness was chosen to increase the number of possible etch cycles over what would be the case for a typical 30 μm film. Figure 3 shows the photoluminescence intensity as a function of the thickness of Cu_2O remaining. The fluctuations and otherwise nonlinear behavior of the emission intensity as the first ~ 30 μm of Cu_2O was removed suggests that complex concentration gradients of the luminescing species exist in this surface region. In contrast, the linear behavior of emission intensity with the removal of the remaining 50 μm of Cu_2O suggests that the concentration of luminescing centers is constant in this region adjacent to the copper metal.

The emission intensity was found to have a strong dependence on the temperature used in the heat-

Fig. 4. Semilog plot of emission ($\lambda > 855$ nm) intensity vs. heat-treatment temperature for 570 and 690 nm excitation.

treatment procedure discussed earlier. Figure 4 shows the room temperature emission intensity excited at 570 and 690 nm as a function of heat-treatment temperature. For both excitation wavelengths, a maximum in the photoluminescence occurs in the range between 400° and 500°C. Furthermore, as can be seen in Fig. 4, and as is shown explicitly in Fig. 5, the ratio of the emission intensity excited at 570 nm to that excited at 690 nm increases monotonically with increasing heat-treatment temperature over the range experimentally studied. The causes of these heat-treatment effects will be discussed below.

Discussion

A portion of the stability diagram for the copper-oxygen system is shown in Fig. 6 (4). At 1000°C, Cu_2O

Fig. 5. Ratio of emission ($\lambda > 855$ nm) intensity for 570 nm excitation to that for 690 nm excitation vs. heat-treatment temperature.

is stable for a range of oxygen partial pressures over five orders of magnitude wide. For the experiments reported here, the Cu_2O film growth conditions (1000°C in a 10^{-2} atm oxygen partial pressure) were chosen to lie well within the stable region for Cu_2O in order to ensure that there would be no separate phase of CuO on the surface. Certainly, no Cu_2O film prepared in this work should be expected to have been in thermodynamic equilibrium with the oxidizing atmosphere throughout the film during growth. In fact, if the nonstoichiometry of Cu_2O is viewed as being due either to the solubility of CuO in Cu_2O , or equivalently to the concentration of copper vacancies in Cu_2O , then the layer of Cu_2O near the copper metal should have few copper vacancies, whereas the layer of Cu_2O near the exterior surface should have many copper vacancies, and might possibly have been near equilibrium with the oxidizing atmosphere during growth if the diffusion of copper vacancies away from the surface is slow compared to the oxidation of Cu_2O to CuO . The copper vacancy gradients across Cu_2O films grown in this manner and the modification of these gradients by subsequent heat-treatment strongly affect the photoluminescence properties of Cu_2O on copper, as will be discussed below.

For single-crystal Cu_2O , three broad photoluminescent bands have been reported in the literature (2, 3, 5, 6). Emissions at 720 and 820 nm (both at 77 K) are associated with relaxed excitons at oxygen vacancies, and the emission at 930 nm (also at 77 K) is due to relaxed excitons at copper vacancies. These assignments are supported by the observations that the two short wavelength emissions are completely suppressed by heat-treatment in atmospheres with O_2 partial pressures exceeding 1 torr, and that the long wavelength emission is suppressed by heat-treatment in vacuum. The copper vacancy emission feature has been observed (6) to broaden and shift to longer wavelengths with increasing temperature and remain resolvable at room temperature as a peak at about 960 nm. Therefore, identification of the 980 nm emission observed in this work as being due to relaxed excitons at copper vacancies is straightforward, especially considering the large concentration of copper vacancies expected with the Cu_2O growth procedure used here. Studies of Cu_2O excitation spectra at 77 and 1.6 K have shown that the relaxed exciton emission at copper vacancies is readily observable for all wavelengths from 830 to below 500 nm. The optical absorption of Cu_2O above 640 nm is very weak and an excitation band at ~ 780 nm has been attributed to direct excitation at copper vacancies (3). Below 640 nm, excitation is considered to be indirect with energy transfer from the absorbing host lattice to the luminescing vacancy center. The present observation of 980 nm emission excited from 450 to

Fig. 6. Stability diagram for the Cu/ Cu_2O /Cu system

690 nm at 25°C is therefore not unexpected and consistent with low temperature measurements.

The strong dependence of the intensity of photoexcited luminescence from relaxed excitons at copper vacancies upon the temperature of a brief heat-treatment of these Cu₂O films in the absence of oxygen is a new and fortunate observation. Copper vacancies are certainly not being produced by a 15 min heat-treatment in argon at 500°C, yet the intensity of the 980 nm emission excited at 690 nm is increased by over an order of magnitude with this procedure, as shown in Fig. 3. Thus, the implication is that the increase in copper vacancy photoluminescence is induced by a thermally assisted redistribution of these vacancies, as is consistently borne out by the experimental results reported here. As was mentioned above, the 1000°C oxidation of Cu₂O to CuO at the surface of a film may be viewed as the creation of copper vacancies there. These vacancies subsequently diffuse toward the copper substrate, so that if the rate of oxidation is faster than the rate of the subsequent diffusion, a layer of vacancies will collect on the surface. The data of Fig. 2 (C) and (D) support this diffusion-limited model of the oxidation process, since the removal of the surface region by etching a 500°C heat-treated sample removes a disproportionate part of the luminescence. Furthermore, the large peak in the luminescence from near the surface region in Fig. 3 also supports this model. In contrast, the rise in luminescence following etching of as-grown samples, as shown in Fig. 2 (A) and (B), as well as the dip in luminescence near the surface shown in Fig. 3, would seem on first inspection to refute a diffusion-limited model. However, these results can be explained with the additional assumption that the luminescence of relaxed excitons at copper vacancies is "concentration quenched" at sufficiently high concentrations, as is known to be the case with luminescence of F centers in alkali halides (7), presumably due to formation of a nonluminescent decay path by the interaction of two or more centers. The slight increase of 980 nm luminescence shown in Fig. 3 at the surface, as compared with the concentration quenched minimum just below the surface, may then be explained by a loss of oxygen, and thus copper vacancies, at the surface by the process

during the heat-treatment of this film, resulting in less concentration quenching at the surface.

Thus, heat-treatment supplies the necessary energy to give sufficient mobility to copper vacancies so that they can diffuse toward the copper metal substrate, thereby breaking up nonluminescent clusters of these vacancies near the surface. The effects of heat-treatment of temperatures up to ~500°C are dominated by the breakup of vacancy clusters, thereby reducing concentration quenching in the surface region and increasing photoluminescence. For heat-treatment temperatures above 500°C, enough vacancies diffuse to (and disappear at) the copper substrate during the 15 min procedure to reduce the luminescence, as is shown in Fig. 4. Figure 5 shows further evidence of the breakup of vacancy clusters by heat-treatment, in that the ratio

of the luminescence excited by the 570 nm light, which is strongly absorbed at the surface of the film, to that of the 690 nm light, which is absorbed weakly and therefore uniformly throughout the Cu₂O film, increases monotonically with increasing heat-treatment temperature. The completely absorbed 570 nm light is preferentially absorbed in the concentration-quenched dead layer on the surface, resulting in reduced photoluminescence efficiency. Heat-treatment removes the concentration quenching by vacancy diffusion, and the apparent efficiency of luminescence excited by 570 nm light increases.

Summary

In summary, this is the first report of room temperature copper vacancy luminescence in thin films of Cu₂O on copper metal. Films of good optical quality were prepared, without etching, which had photoluminescence emission and excitation spectra similar to those reported for much thicker crystals. Furthermore, this is the first demonstration that a brief heat-treatment of such films in the absence of oxygen will allow copper vacancies to diffuse, thereby reducing vacancy concentrations where luminescence is quenched by interactions among vacancies. Finally, this is the first reported use of photoluminescence to study vacancy gradients in films. The results suggest that for Cu₂O films grown on copper at 1000°C in a 1% O₂/Ar atmosphere, the rate-controlling step in copper oxidation is the diffusion of copper vacancies to the copper, since a steep gradient of CuO (or equivalently, copper vacancies) occurs near the Cu₂O surface. Moreover, when the CuO concentration is sufficiently high, the copper vacancies appear not to be luminescent.

ABSTRACT

A comparison of HCl and trichloroethylene (TCE) as chlorine bearing gaseous additives to the oxidizing ambient for growing thermal oxide on silicon at 1150°C was made. According to a thermodynamic analysis of the gas phase species at comparable partial pressures of chlorine in the reactor, the major difference in the gas phase composition is about an order of magnitude lower partial pressure of H₂O and HCl in the TCE system. The parabolic rate constants at 1150°C at approximately the same partial pressures of Cl₂ in both systems over a range of input HCl feed rates of 0-120 cm³/min HCl per liter of dry O₂ (and comparable rates of TCE/N₂ mixture) were similar, being only marginally lower for the TCE system, although the equilibrium HCl and H₂O contents of the TCE reactor were an order of magnitude lower. The addition of HCl and TCE were both found to result in significant increases on inversion times of carriers as determined by capacitance *vs.* time measurements of pulsed MOS capacitors.

With the recent concentration of semiconductor device fabrication in the MOS area, much research has originated to enhance the electrical properties of thermal oxide on silicon. Much of this research has been concerned with the addition of a chlorine bearing species to the oxidizing ambient. Initially work in this area was concerned with the addition of HCl to the oxidizing ambient (1-3). More recent studies indicate that trichloroethylene (TCE) may also be used to enhance the properties of thermal oxide layers (4-5).

Oxidation in the presence of these two halogen containing compounds is reported to increase both the oxide breakdown strength and the minority carrier lifetime in the silicon (6). In addition, the oxide charges associated with thermally oxidized silicon are reportedly reduced. Many of the studies done concerning HCl- and TCE-grown oxides have been done using several oxidation temperatures while maintaining a variety of fabrication constraints.

In this work, the effects of adding similar amounts of HCl and TCE during the oxidation process step while maintaining identical oxidation temperatures and device fabrication constraints in both systems were studied. A comparison of the HCl- and the TCE-oxidation systems was made on three bases. First, the equilibrium partial pressures of the chemical species present in the gas phase in each system were compared at similar additions of HCl and TCE. This comparison was made based on the partial pressure data obtained using the SOLGAS computer program (7). A second comparison of these two systems was made based on the oxide growth kinetics of each system. The final comparison of these two systems dealt with the measured minority carrier lifetime values of carriers in the bulk silicon of MOS test structures fabricated for this study.

Experimental Procedure

The oxidation temperature used in this study was held constant at 1150° ± 2°C in both systems. The gases in the HCl system were first preheated to the oxidation temperature, prior to entering the flat zone of the furnace. This procedure was undertaken in order to ensure that the gaseous reactions were completed prior to impinging on the silicon wafers. The flow rate of gaseous TCE was controlled by varying the flow rate of filtered dry nitrogen through a bubbler filled with liquid TCE. The bubbler temperature was
