High purity (99.999% pure) cobalt sheet was obtained from Johnson Matthey Chemicals, Limited. Metallic impurities detected were Si at 3 ppm and Al, Ca, Cu, Fe, Mg, and Ag (each) < 1 ppm. This sheet was cut into rectangular specimens roughly 15 × 10 × 1 mm. All samples were ground to 600 grit on SiC papers. Most of the samples were further polished to 0.05 μm on alumina wheels. This final polishing step had no major effect on the kinetics of the reaction or morphology of the product layer. However, 0.05 μm polishing did give better reproducibility between runs, particularly at the lower temperatures. After polishing, sample dimensions were measured, and the sample was cleaned in xylenes and acetone.

A diagram of the experimental apparatus is shown in Fig. 1. Weight gains were measured with a Sartorius Model 4104 balance, which had an accuracy of ±0.06 mg/cm² in this system. The output of the balance was connected to a microprocessor with a crystal controlled clock which was set to transmit weight gains to a printer at 1 min intervals. The sample was heated by a Hoskins alloy wound furnace, controlled to ±1°C by an ECS Model 6823 controller. This furnace was mounted on tracks for ease in loading and removing the sample. Sulfur dioxide-argon gas mixtures enter from the bottom of the quartz reaction tube. Note the presence of a porous alumina ceramic directly below the sample to bring the temperature of the reaction gas up to that of the sample. In order to prevent the hot sulfur dioxide from entering the balance mechanism, a counterstream of argon was passed through the top of the balance. All gases were dried over Drierite; argon was also deoxygenated over BASF copper catalyst (150°-200°C) or titanium sponge (700°C). Flow rates were controlled and monitored with Tylan Model FC-260 mass flow controllers.

Key words: cobalt, corrosion, sulfur dioxide.

Fig. 1. Schematic of experimental apparatus

One concern with this type of apparatus is the possibility of forming a thin oxide layer during specimen loading and thermal equilibration. In order to avoid this, the following procedure was employed. With the furnace at room temperature, the sample was loaded into the reaction tube. Next, the system was evacuated to better than 0.02 torr and backfilled with a 5% H₂/Ar mixture. This mixture was passed over the sample during furnace

heat-up. After about 1/2h, the furnace was slid over the sample and allowed to come to thermal equilibrium for about 2h. Then the flow of H₂/Ar was stopped and the system flushed with gettered argon for several minutes. After this, the flow of argon was stopped and the SO₂-argon mixture admitted to begin a run.

After a run, the furnace was lowered and the specimen rapidly cooled. The reaction gases were stopped and replaced with a stream of gettered argon. When the furnace had cooled to room temperature, the sample was removed from the reaction tube. Phases present were determined with x-ray diffraction and scale morphology examined with a scanning electron microscope. In order to examine scale cross sections, a ~1 mm thick layer of copper was electroplated on the sample from a copper sulfate solution. The plated sample was mounted and polished to 1 μm with diamond paste. Samples had to be very gently polished to avoid separation at the scale/metal interface.

Results

Figures 2 through 5 show kinetic results for 650°, 700°, 750°, and 800°C. Six to eight runs were performed at each temperature; the rate constants and final weight gains agreed to ±10%. Flow rates were chosen so that gas-phase diffusion was not rate limiting (11). For each temperature, experiments were done at linear flow rates of 40.7 and 61.1 cm/min at STP. These had little influence on the reaction rates.

The three lower temperature reactions exhibit parabolic regions of different duration. At 650°C, the sample reacts rapidly for the first 5 min and then reacts according to a slow parabolic rate for the next 2h. At 700° and 750°C, the sample follows a parabolic rate from the beginning of the reaction, with rate constants of 2.91 ± 0.31 and 7.18 ± 0.44 mg²/cm⁴-min, respectively. This is shown in Fig. 4. Note that after 30 min at 700°C and 60 min at 750°C, the parabolic rates tend to decrease. At 800°C, the sample reacts rapidly according to a linear rate law (K_L = 1.2 ± 0.1 mg/cm²-min) for about 30 min. After this, the sample reacts quite slowly.

All four temperatures produced the same product phases: CoO-Co₉S₈-CoS. Some investigators have reported only CoO and Co₉S₈ (6, 8, 9). It is possible that in their cases CoS decomposed on cooling, since it is unstable below 460°C. Samples run at each temperature were checked for sulfate with x-ray diffraction and a method based on the higher solubility of CoSO₄ in water than cobalt sulfides and oxides (12). The samples were placed in

Fig. 2. Reaction of cobalt with SO₂ at 650°C.

Fig. 4. Parabolic plot of Fig. 3

5 ml distilled water for several minutes and the water was checked for cobalt cations with an atomic absorption spectrometer. The concentration of cobalt cations for all samples was less than 1 ppm, which is the limit of resolution of the instrument. This indicates that if a sulfide layer is present, it is less than 100Å thick.

The morphology of the reaction product varied with temperature. The morphology of the reaction product formed at 650°C is shown in Fig. 6-10. The inner scale consisted of a fine distribution of sulfide in oxide matrix (Fig. 6 and 8). This inner scale grew during the first few minutes of reaction. The outer scale consisted of larger sulfide regions in the oxide matrix, which is also shown in Fig. 8. There is no clear evidence of an inner pure sulfide layer adjacent to the metal. However, the sulfide layer may be very thin or lost due to problems with scale/metal separation at this temperature.

At 700°, 750°, and 800°C, a morphology similar to that for nickel at 600°C is observed. There is a thin sulfide band adjacent to the metal, followed by a duplex sulfide-oxide layer. This morphology develops with the first few min-

utes of reaction. Figure 11 shows a cross section of a sample run at 750°C for 2h. The darker areas are the sulfide and the gray area is the oxide matrix. The sample consists of a ~1 μm thick sulfide layer adjacent to the metal followed by an oxide matrix with a fairly even distribution of sulfide. This sulfide band and sulfide distribution were evident in samples run at the three higher temperatures. Four point resistivity measurements gave very low values (~0.5 Ω-cm), indicating that the sulfides are interconnected. Sulfides have a higher electrical conductivity than oxides and therefore an interconnected sulfide structure should give these low resistivity values.

Discussion

Figure 12 shows the cobalt stability diagram as a function of oxygen and sulfur potentials at 650°C (13, 14). Also shown is a line indicating the sulfur and oxygen potentials due to SO_2 dissociation. It is likely that the oxygen content of the system is 1 ppm or higher, due to the manufacturer's reported oxygen impurities in the reaction gas. Figure 12 shows that under 0.1 atm SO_2 and 1

ppm O₂, cobalt sulfate is the stable phase. This is also true at 700°C. A similar situation exists for nickel at 600°C (1, 2). At 750° and 800°C, cobalt oxide is stable under 0.1 atm SO₂ and 1 ppm O₂. As indicated in Fig. 12, cobalt sulfide is thermodynamically stable at the oxygen potential that must exist near the scale/metal interface.

The accepted theory of formation of an inner sulfide layer (1, 2, 6) is based on the initial formation of a porous

Fig. 8. Cross section of a sample reacted for 2h at 650°C for 2h. Note the fine distribution of sulfide in the oxide matrix at the bottom. This was closest to the metal.

Fig. 9. Sulfur map of Fig. 8. Note the sulfide flames projecting into the gas phase.

metal oxide. SO₂ penetrates this oxide through the micropores and reacts to form sulfide at the oxide/metal interface where the oxygen potential is low. This process very likely occurs in the reaction of cobalt and SO₂, since the inner sulfide layer forms in the first few minutes of reaction. However, it is still not clear how sulfide forms at or near the scale/gas interface. Some investigators have proposed that sulfide forms via a sulfate intermediate, which exists at the scale/gas interface (15). However, sulfate is stable only at the lower temperatures (650° and 700°C) and a sulfate layer has not been detected. Figures 8

Fig. 10. Oxygen map of Fig. 8

Fig. 11. Cross section of a sample reacted for 2h at 750°C. The sulfide is the darker area.

to 10 show a cross section of a sample reacted at 650°C and the large sulfide flames that project into the gas phase. Thus, one must conclude that the scale does not equilibrate with the gas.

Before discussing the kinetics of the reaction of cobalt and SO_2 , it is necessary to examine previous work on cobalt sulfidation (16-18). When cobalt reacts with 1 atm sulfur vapor, an inner Co_9S_8 layer forms and an outer CoS layer forms. Inert markers are observed between the two

Fig. 12. Stability diagram of cobalt in a sulfur-oxygen atmosphere at 650°C.

layers, suggesting that sulfur moves inward to form Co_9S_8 and cobalt moves outward to form CoS (16). From 500° to 750°C, cobalt reacts with sulfur vapor according to a parabolic rate law (17). It has been suggested that the diffusion of cobalt outward is rate limiting (18). Based on this, the diffusivity of cobalt in CoS can be calculated.

In a previous paper (1), it was shown that the parabolic rate constant is related to the metal ion diffusivity by the following expression

$$k_p = -2 D_{\text{Co}} c_{\text{Co}} \frac{\alpha f}{\beta \gamma} \Delta \ln a_{\text{Co}} \quad [2]$$

Here k_p is the parabolic rate constant ($\text{g}\cdot\text{cm}^{-2}\cdot\text{s}^{-1}$), D_{Co} is the diffusion coefficient of cobalt in CoS ($\text{cm}^2\cdot\text{s}^{-1}$), c_{Co} is the concentration of cobalt in CoS ($\text{g}\cdot\text{cm}^{-3}$), f is the volume fraction of CoS ($f = 1$ for a single phase), and β and γ are conversion factors which relate the emerging flux of cobalt to weight gain. α is a factor based on the distribution of sulfide. For a single phase or an evenly distributed phase in an oxide matrix, $\alpha = 1$; for isolated islands of sulfide in an oxide matrix, $\alpha = 0$; and for an uneven distribution of sulfide in an oxide matrix, $1 > \alpha > 0$. Expression [2] can be applied to the data of Mrowec and Werber (17) in order to calculate $D_{\text{Co}}(\text{CoS})$. Using the density of CoS (19): $\beta = 1.84$, $\gamma = 0.52 \text{ cm}^3\cdot\text{g}^{-1}$, and $c_{\text{Co}} = 3.53 \text{ g}\cdot\text{cm}^{-3}$. The cobalt activity difference can be calculated from the activity at the $\text{Co}_9\text{S}_8/\text{CoS}$ interface, which is determined by

and the activity at the scale/gas interface, which is determined by

Table I lists the values of $D_{\text{Co}}(\text{CoS})$ at each of the temperatures used in this study. Also shown are $D_{\text{Co}}(\text{CoO})$ in 1 atm oxygen (20) which are several orders of magnitude lower than $D_{\text{Co}}(\text{CoS})$. The values of $D_{\text{Co}}(\text{CoO})$ are for diffusion in a single crystal; however, they are within 10% of those calculated from oxidation of polycrystalline specimens (21). Given this kinetic background, the experimental results for the reaction of cobalt in sulfidizing-oxidizing environments can be discussed.

Consider first the reaction of cobalt with SO_2 at 700° and 750°C. As mentioned, conductivity measurements indicate the sulfides are interconnected and fairly evenly distributed (Fig. 11 and 13) in the oxide matrix. Thus, Eq. [2] can be applied and the diffusivity of cobalt in CoS can be calculated from the measured parabolic rate constants. These diffusivities can then be compared to those calculated from the data of Mrowec and Werber (17). To apply Eq. [2] to the data presented here: $\alpha = 1$, $\beta = 2.76$, and $\gamma = 0.62 \text{ cm}^3\cdot\text{g}^{-1}$. The volume fraction of sulfide was estimated by placing a grid over Fig. 13 and determining what fraction of the area was occupied by sulfide. This gave a value of 0.40, which was in agreement with the value of 0.42 obtained from the stoichiometry of the reaction

The change in cobalt activity can be estimated by the difference between the cobalt activity at the $\text{Co}_9\text{S}_8/\text{CoS}$ interface and the cobalt activity at the gas/scale interface,

Table I. Diffusivities of cobalt in CoO and CoS

Temperature °C	$D_{\text{Co}}(\text{CoO})$ Ref. (20)	$D_{\text{Co}}(\text{CoS})$	
		Calculated from Ref. (17)	This work
650	1.45×10^{-11}	3.9×10^{-9}	-----
700	3.82×10^{-11}	9.8×10^{-9}	2.2×10^{-8}
750	9.15×10^{-11}	2.7×10^{-8}	4.2×10^{-8}
800	2.02×10^{-10}	4.6×10^{-8}	-----

which is set by Eq. [5]. The values of $D_{Co}(CoS)$ calculated from the reaction of cobalt and SO_2 are listed in Table I. The agreement with the values calculated from Mrowec and Werber's sulfidation data is reasonable, indicating that under these conditions the diffusion of cobalt outward through the interconnected sulfides is primarily rate limiting.

It is important to recognize that the reaction cannot be entirely diffusion controlled. This is because the scale does not equilibrate with the gas, *i.e.*, sulfide is observed at the scale surface and this means a substantial change in sulfur activity at the gas/scale interface. The reaction probably undergoes mixed control, with diffusion being the major contributor to the rate and a surface step being the minor contributor. This explanation also accounts for some of the differences in the diffusivities calculated from sulfidation and those calculated from sulfidation-oxidation.

As mentioned previously, both the 700° and 750°C parabolic plots (Fig. 4) show slower parabolic rates after 30 and 60 min, respectively. This is very likely due to a changing sulfide distribution in the oxide matrix as shown in Fig. 13 and 14. Figure 13 shows a portion of the scale which grew during the first hour at 750°C. Note the fairly even distribution of sulfide, indicating $\alpha = 1$. Figure 14 shows a portion of the scale which grew after 1h; the sulfide is now unevenly distributed, containing sulfide regions connected by constricted sulfide channels. Now $\alpha < 1$ which results in a slower parabolic rate.

This change in reaction rates due to a change in sulfide distribution is also evident at 650°C. Figure 2 show the reaction is quite rapid for the first 5 min and then slows down for the next 2h. During the first 3 min of reaction, a microstructure develops with many sulfides poking out of the oxide matrix into the gas phase (Fig. 6). These many available transport paths account for the rapid rate observed at the start of the reaction. After 5 min of reaction, the scale surface contains less sulfides and those

Fig. 13. Inner portion of duplex region of a sample reacted at 750°C for 2h. Note the even sulfide distribution (darker region).

Fig. 15. Underside of a scale formed in 2h at 800°C. This is an oxide matrix and the voids are areas where there was once sulfide.

that remain grow larger (Fig. 7). A cross section (Fig. 8) suggests that the larger regions of sulfide are connected by constricted areas of sulfide. These two factors, the smaller amount of sulfide and the constrictions in the interconnected network, may limit cobalt ion diffusion outward and result in a slower rate.

At 800°C, the reaction initially shows a rapid linear rate and then slows dramatically after about 40 min. The linear rates suggest that cobalt diffusion outward is so rapid that an interfacial reaction, presumably SO_2 dissociation, becomes rate limiting. The latter reaction stage is more difficult to interpret. When a sample which had reacted for 2h at 800°C was cooled, the scale separated at the sulfide layer-duplex layer interface. Figure 15 shows the portion of the duplex layer which was adjacent to the sulfide layer. Note there are voids where there were once sulfides, only the oxide matrix is visible. It is possible that void formation causes a decrease in scale/metal contact area, which slows the reaction.

Conclusions

In the reaction of cobalt with SO_2 at 650°-800°C, the rapid diffusion of cobalt outward through an interconnected sulfide phase is important. The different kinetic behavior observed in this temperature range is due both to the increasing diffusivity of cobalt and differing morphologies of the product phase. At 650°C, the rates are initially rapid due to many available sulfide channels. After about 5 min, the rates decrease due to a decreased number of sulfide channels. At 700° and 750°C, diffusion of cobalt through these sulfides is primarily rate limiting and the calculated $D_{Co}(CoS)$ calculated compare favorably with those calculated from a previous sulfidation study. At 800°C, diffusion through the sulfides is so fast that an interfacial step becomes rate limiting.

RF Recrystallization of Polycrystalline Silicon on Fused Silica for MOSFET Devices

Y. Kobayashi, A. Fukami, and T. Suzuki

Hitachi, Limited, Hitachi Research Laboratory, Hitachi, Ibaraki 319-12, Japan

ABSTRACT

A new zone melting recrystallization method that uses an RF-heated carbon susceptor in fabrication of silicon on insulator (SOI) structures has been developed. A fused silica substrate, on which a 0.5-1.0 μm thick polycrystalline silicon film had been deposited, was encapsulated with a 1.2 μm thick CVD- SiO_2 layer. This was moved across the carbon susceptor, which had a narrow high temperature zone. The continuous silicon films that were recrystallized had grains several tenths to a few millimeters wide, a few centimeters long, and a film orientation of (100). The electron mobility of MOSFET's fabricated on the films was about 700-1000 cm^2/Vs , which was higher than that of (100) orientated bulk single-crystal silicon. However, as some cracks occurred in the film, it was formed as islands and then the islands were recrystallized. This recrystallized silicon was a single crystal with an orientation of (111) and showed no cracks. The electron field effect mobility of the islands was about 300-600 cm^2/Vs , which was smaller than that of the recrystallized continuous film because of the (111) orientation. In order to obtain silicon without cracks and with an orientation of (100), a method that connected the polycrystalline silicon islands with narrow strips was proposed based on a thermal connection of silicon.

Silicon on insulator (SOI) structures offer many advantages for display devices such as active liquid crystal displays, for high speed integrated circuits and for three-dimensional circuits. The structures are produced by melt regrowth methods using laser beams (1, 2), electron beams (3-5), and incoherent energy sources such as strip carbon heaters (6-8) and arc lamps (9, 10). The laser and electron beam recrystallization methods have the potential to produce three-dimensional circuits, but have a small throughput. On the other hand, zone melting recrystallization using incoherent energy sources is not suitable for three-dimensional circuits because the entire wafer must be heated. However, a high quality silicon layer can be obtained, without seeding, as can high throughput (6-11). Therefore, this method is suitable for manufacturing very high speed circuits and display devices.

In the zone melting recrystallization method, temperature control in the melted silicon region and its proper distribution are necessary to prevent agglomeration of the melted silicon and to obtain a good surface uniformity.

The authors have developed a novel zone melting regrowth method using an RF-heated carbon susceptor, in which temperature and shape of the melted zone can be easily observed and controlled (11). This article describes the method and the results obtained while investigating the quality of the recrystallized silicon films produced.

RF-Heated Zone Melting Regrowth Method (RF-ZMR Method)

Figure 1 shows the recrystallization method. The upper figure (a) is a cross-sectional view of the apparatus, and the lower figure (b) is a schematic blowup of the wafer and carbon susceptor area. A 0.5-1.0 μm thick poly-

Fig. 1. (a, top) Schematic diagram and (b, bottom) illustration of the zone melting recrystallization method.

crystalline silicon film was deposited by decomposition of monosilane (SiH_4) on an optically polished, fused silica substrate. The silicon surface was then covered with a 1.2 μm thick layer of silicon dioxide by decomposition of tetraethoxysilane ($\text{Si}(\text{OC}_2\text{H}_5)_4$) at 760°C. This wafer was moved across the carbon susceptor surface (speed: 0.1-2 mm/s), which was RF-heated, and had the temperature distribution reproduced in Fig. 1b. In the high temperature region (1 or 2 mm wide), where the polycrystalline silicon was melted, a higher heat flow from the RF-heated carbon susceptor came into contact with samples. In the low temperature regions, the heat flow was partially shielded by fused silica or carbon thermal buffer plates. The temperature of the high temperature region, measured using an optical pyrometer, was about 1450°C; 100°C higher than that of other regions. Melting and regrowth took place in a nitrogen atmosphere which was evaporated from liquid nitrogen and was not passed through a purifier. The silicon layer was melted in the high temperature region and then, after moving on, was solidified to form a regrown layer.

Figure 2 is a photograph, taken during recrystallization, of the melted silicon. The vertical dark bands were shadows produced by the work coil, while the large circular region was the wafer (diam = 50 mm). The central light-colored strip was the high temperature region, while the slightly darker narrow ellipse inside it was the melted silicon region. The area of the melted silicon was probably darker than that of the surrounding unmelted silicon due to the lower emissivity of melted silicon as compared to unmelted silicon. The photograph demonstrated that the melted silicon could be easily observed and that recrystallization conditions could be easily controlled.

Characteristics of the Recrystallized Silicon

Figure 3 shows (a) an optical micrograph of an etched silicon surface after recrystallization and (b) its schematic. The etchant composition was $\text{HF}:\text{HNO}_3:\text{CH}_3\text{COOH} = 1:50:50$ (6). There were many elongated subgrains and cracks. The sizes of the subgrains were several tens of micrometers wide and several hundreds of micrometers long. All cracks were parallel or perpendicular. These crack patterns implied two things: (i) that the orientation of the recrystallized silicon was (100), because the direction of the cracks was $\langle 110 \rangle$ for single-crystal silicon; and (ii) that the subgrain boundaries were small angle grain boundaries, because the cracks were straight even when they crossed the subgrain boundaries. These points were studied in detail using transmission electron microscopy (TEM).

Figure 4 is a TEM of the recrystallized silicon. Three diffraction patterns which correspond to the indicated region are also shown. Dislocations and subgrain boundaries could be observed. The diffraction patterns showed that orientations of the three regions were (100). All the

Fig. 2. Photograph of the melted silicon region during recrystallization obtained by using an infrared transmitting glass filter.

patterns had the same rotation angle within one degree or less, verifying the conclusion that the subgrain boundaries were small angle grain boundaries.

Figure 5 is a magnified photograph of one diffraction pattern. The Kikuchi lines and bands could be clearly observed, indicating that the crystalline quality of the recrystallized silicon was high. Results of the TEM observations corresponded to those observed for the etched silicon surface.

Next, the subgrain boundary was studied using TEM. A subgrain boundary has been assumed to consist of an array of dislocations (8). Figure 6 is a 1000 keV TEM photograph of a subgrain boundary. Individual dislocations could be seen on the subgrain boundary; that is, the boundaries consisted of discrete dislocations. When the deviation of the orientation was estimated from the distance between these dislocations, a value of about 0.6 deg was obtained.

As shown in Fig. 7, an Al-gate n-channel MOSFET was fabricated on the recrystallized silicon, in order to investigate its electrical properties. The gate length and width were 20 and 723 μm , respectively. The thickness of the gate oxide film was 1000Å.

Figure 8 shows electrical characteristics of (a) a MOSFET fabricated on recrystallized silicon and (b) a MOSFET fabricated on bulk single-crystal silicon using the same process as the SOI/MOSFET fabrication. Electron mobility could be obtained from these characteris-

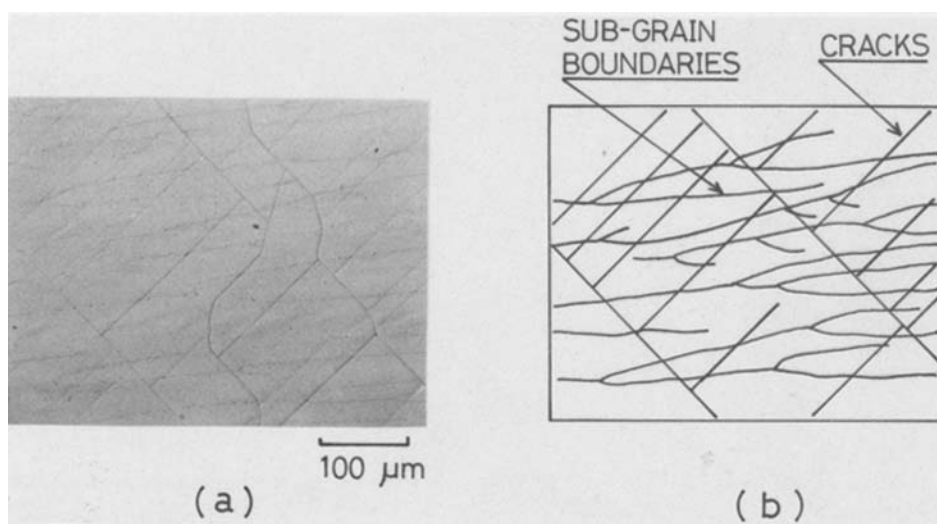

Fig. 3. (a, left) Optical micrograph of an etched silicon surface after recrystallization. (b, right) Schematic of the same optical micrograph.

Fig. 4. Transmission electron micrograph of a recrystallized silicon layer, and diffraction patterns from each subgrain area.

Fig. 5. Magnified photograph of a diffraction pattern

Fig. 6. 1000 kV transmission electron micrograph of a subgrain boundary.

tics. The maximum electron mobility in the saturated region of the recrystallized silicon was about $1020 \text{ cm}^2/\text{Vs}$, while the average value was about $860 \text{ cm}^2/\text{Vs}$. On the other hand, the electron mobility of bulk silicon was about $600 \text{ cm}^2/\text{Vs}$. That is, the mobility of the recrystallized silicon was about 1.4 times that of the bulk silicon. The reason for the higher electron mobility observed in the recrystallized silicon was tensile stress in the silicon due to a difference in the thermal expansion coefficients of fused silica substrate and silicon. The tensile stress in a (100) silicon plane reduced the effective mass of an electron, which increased electron mobility (7, 11-13).

These experimental results described above verified that this RF-ZMR method produced a high quality recrystallized silicon on a fused silica substrate.

Recrystallization of Polycrystalline Silicon Islands

In structures such as silicon on fused silica, cracking caused by the stress in the recrystallized silicon is a serious problem, as previously shown in Fig. 3. Figure 9a is a photograph of the surface of a MOSFET fabricated on recrystallized silicon having some cracks, while Fig. 9b

Fig. 7. Photograph of a MOSFET fabricated from recrystallized silicon.

Fig. 8. Electrical characteristics of MOSFET fabricated from (a, left) recrystallized silicon and (b, right) single-crystal bulk silicon.

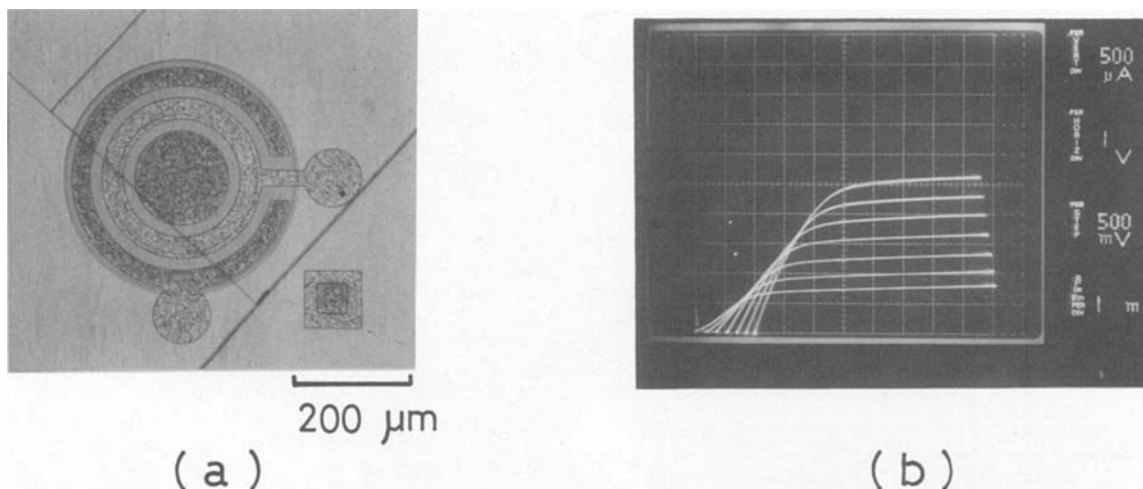

Fig. 9. (a, left) Photograph of a recrystallized silicon surface. (b, right) Electrical characteristics of a MOSFET having cracks.

shows its electrical characteristics. The characteristics of the devices were abnormal, indicating the necessity of eliminating cracks in the recrystallized silicon. Therefore, reduction of stress by forming silicon islands (14, 15) was tried.

The polycrystalline silicon film was etched with a dry etching technique to form islands with areas from 5×5

μm^2 to $4 \times 4 \text{ mm}^2$. Subsequent processes were the same as for the continuous silicon described above. The crack density of the recrystallized silicon was measured after the encapsulating SiO_2 layer was etched off.

As shown in Fig. 10, cracks disappeared when recrystallized islands of polycrystalline silicon were less than $250 \times 500 \mu\text{m}^2$ in size when silicon thickness was $0.5 \mu\text{m}$, and

when the islands were less than $50 \times 100 \mu\text{m}^2$ in size when the silicon thickness was $1 \mu\text{m}$.

Figure 11 shows a SEM photograph of the Sirtl-etched (16) silicon surface. The lines of dark dots were etch pits, corresponding to dislocations. These indicated that recrystallized silicon islands had some subgrain boundaries consisting of arrays of discrete dislocations, but no grain boundaries. Their absence indicated that the recrystallized silicon in an island was a single crystal. The orientation of the recrystallized silicon islands was observed with a TEM technique. Figure 12 shows a typical diffraction pattern for one island, and indicates its orientation was (111). Figure 13 shows an optical micrograph of the silicon island surface which was wider than the one in

Fig. 12. A typical diffraction pattern of the recrystallized silicon.

Fig. 13. Crack shapes in a silicon island which is wider than that for which no cracks occurred.

which no cracks occurred. As shown in this figure, there were many cracks and their arrangements were those of equilateral triangles. This meant that the orientation of the island was (111), because a crack line was $\langle 110 \rangle$. Orientations of all another islands were justified by the arrangements of the cracks, and were (111).

In order to study the electrical properties of the recrystallized silicon islands, ring type, Al-gate, and n-channel, MOSFET's were fabricated on them. The thickness of the gate oxide film was 1200\AA . Gate length and width were 20 and $680 \mu\text{m}$, respectively. Figure 14 shows the field effect mobilities of devices with a drain voltage of 0.1V. These mobilities depended on the threshold voltages of the devices. The reference MOSFET's were also fabricated in bulk silicon with an orientation of (111) using the same fabrication process. The field effect mobility of a device on the recrystallized silicon island was the same as that of a device on bulk silicon with an orientation of (111) for the same device threshold voltages. Leakage current was also measured at a drain voltage of 5V and found to be $1.5 \times 10^{-11} \text{ A}/\mu\text{m}$.

As described above, cracks were eliminated by recrystallization of the island polycrystalline silicon on fused silica substrate. The recrystallized silicon island was a single crystal having an orientation of (111), ensuring good electrical properties. However, tensile stress could not increase the electron mobility, such as in recrystallization of a continuous polycrystalline silicon film, because of the island orientation. Consequently, it was necessary to obtain (100) oriented silicon by recrystallizing in order to produce a high speed switching MOSFET. The difference in orientation of continuous and island silicon is discussed next.

Fig. 14. Field effect mobility of MOSFET's fabricated on recrystallized silicon.

THERMAL CONDUCTIVITY(W /mK)	
FUSED SILICA, CVD-SiO ₂	1.9
SILICON	84

A) IN CASE OF CONTINUOUS SILICON

B) IN CASE OF SILICON ISLANDS

Fig. 15. Schematics of the orientation difference between (a, top) recrystallization of a continuous silicon layer and (b, bottom) of silicon islands.

Figure 15 illustrates the orientation difference of continuous and island silicon. In the continuous silicon, heat flowed smoothly in a direction parallel to the surface of the silicon because the silicon was sandwiched between the SiO₂ film and the fused silica substrate, both of which had thermal conductivity coefficients two orders lower than that of silicon. On the other hand, in the island silicon, heat was held in the melted silicon region because the silicon was completely enclosed by the SiO₂ layer and the fused silica. So, the difference in orientation might be caused by a difference in heat flow during silicon recrystallization. In this recrystallization method, the melted region could be directly observed during the recrystallization, as shown in Fig. 2. A microscope was used to observe whether the islands were melted or solidified. Supercooling of the melted silicon island occurred at a temperature of more than 200°C below the melting point of silicon, supporting the above explanation.

Based on this explanation, a method for obtaining crackless and (100) oriented silicon on fused silica was proposed. As shown in Fig. 16, silicon was formed as an island in order to eliminate cracking. The islands were then connected to each other with fine polycrystalline

Fig. 16. Schematics of a connected silicon island pattern.

Fig. 17. Orientation of the recrystallized silicon islands which are connected with fine silicon regions.

silicon in order to achieve a smooth heat flow, and the polycrystalline silicon was recrystallized.

Figure 17 shows the orientation of silicon recrystallized by this method. The orientation was studied with the etch pit method (17) (figure schematic). The shape of the etch pits was square, indicating the orientation of the recrystallized silicon was (100) and the rotation angles of the squares were all the same within an island. Hence, the island silicon was a single crystal.

Conclusion

A new zone melting recrystallization method using an RF-heated carbon susceptor has been developed. This method allowed easy control of the temperature on the melted silicon region, an important factor in zone melting recrystallization. In continuous silicon film, the orientation of the film was (100) and the electron mobility was 700-1000 cm²/Vs. However, there were some cracks in the film. In the island silicon, recrystallized islands were single crystal with an orientation of (111) and without cracks. The electron field effect mobility was 300-600 cm²/Vs. These experimental results verified that (100) orientation was important for high speed devices which need high electron mobility in case of silicon on fused silica substrate. In order to obtain high quality crystalline silicon without cracks and with an orientation of (100), a recrystallization of connected polycrystalline silicon islands was also developed.

Acknowledgments

The authors would like to express their sincere thanks to Professor T. Imura and Dr. H. Saka for taking the 1000 kV transmission electron micrographs and their useful discussions regarding crystalline quality. They would also like to thank Dr. T. Takasuna and Dr. M. Okamura for their guidance and encouragement.

Thermodynamic Properties of Na₂O-V₂O₅ Melts, 1030-1210 K

S. K. Mittal* and J. F. Elliott

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The following electrochemical cell was employed for this study

The activity of Na₂O on Na₂O-V₂O₅ melts was measured in the temperature range of 1030-1210 K for melt compositions of $x_{\text{V}_2\text{O}_5} \geq 0.50$. The measured activities of Na₂O show large negative deviations from ideality. The activity of V₂O₅ was obtained by integrating the Gibbs-Duhem equation. The values of the partial molar and molar-free energies and enthalpies of mixing for the Na₂O-V₂O₅ system were calculated from the results. The free energies of formation of the compounds Na₂O · 6V₂O₅, Na₂O · 3V₂O₅, and Na₂O · V₂O₅ were estimated in the temperature range of 500°-600°C.

Vanadium and sodium are impurities in fuel oils and coals. In combustion, these elements are oxidized to vanadium oxide (V₂O₅) and sodium oxide (Na₂O), and in combination these oxides may form liquids whose melting temperatures may be as low as 600°C (Fig. 1). The liquid phase in the Na₂O-V₂O₅ system is extremely corrosive to the metal and ceramic parts of combustion systems, and corrosion of these parts degrades the performance of energy conversion systems and may cause economic loss. To improve our understanding of the corrosive action of liquids containing Na₂O and V₂O₅, a study of the thermodynamic properties of the Na₂O-V₂O₅ was undertaken. The results are reported here.

The Na₂O-V₂O₅ binary system has been studied by several investigators (1-3). Kolta *et al.* (1) have determined the Na₂CO₃-V₂O₅ phase diagram, as shown in Fig. 1, using DTA and x-ray diffraction methods. Kolta *et al.* (1) employed platinum crucibles to contain their samples. In the composition range of pure V₂O₅ to 75 mol percent (m/o) Na₂CO₃, they found that the Na₂CO₃-V₂O₅ system is essentially a Na₂O-V₂O₅ system because of complete evolution of CO₂ from the Na₂CO₃-V₂O₅ mixtures. Kolta *et al.* detected five compounds in this binary system at the following mol ratios of V₂O₅/Na₂O: 6/1, 3/1, 1/1, 1/2, and 1/3. During solidification of Na₂O-V₂O₅ melts at high V₂O₅ concentrations (m/o V₂O₅ ≈ 75%), oxygen is evolved from the sample by the following reaction

However, in the liquid phase the vanadium exists in the pentavalent state (V⁵⁺) only, and the weight of the Na₂O-V₂O₅ melt is equal to the sum of the weights of Na₂O and V₂O₅ only.

Lin (4) attempted to measure the activity of sodium oxide in the Na₂O-V₂O₅ binary system at 1179 K by an electrochemical cell employing sodium-β-alumina as the solid

electrolyte. However, he encountered serious difficulties because the Na₂O-V₂O₅ melt crept up the sodium-β-alumina electrolyte and penetrated a high temperature cement seal in his cell. In addition, the melts attacked the electrolyte and dissolved some alumina. This attack increased with higher activities of sodium oxide in the working melt.

Koehler (5) has measured the heats of formation of NaVO₃(c), Na₂V₂O₇(c), and Na₃VO₄(c) at 298.15 K by applying sodium hydroxide solution colorimetry. King and Weller (6) have determined the heat capacities and entropies at 298.15 K for the same compounds. These data were extrapolated to higher temperatures to evaluate enthalpies, entropies, and free energies of formation for the corresponding compounds by Mah (7) and Kubaschewski (8).

Experimental

A concentration emf cell was employed to measure the activity of sodium oxide in Na₂O-V₂O₅ melts. Because of the instability of sodium-β-alumina in Na₂O-V₂O₅ melts, fused silica was used as the solid electrolyte. Doremus (9) has shown that the transference number of Na⁺ ions in fused silica is essential unity. Mittal and Elliott (10) demonstrated that fused silica performs satisfactorily as a sodium-ion solid electrolyte for open-circuit emf measurements when the activity of sodium oxide in the melts is less than 10⁻¹³ and in the temperature range of 1050-1200 K. The work of Doremus (9) and Veltri (11) on the specific conductivity, σ, of fused silica has been extrapolated to the temperature range of interest (1050-1200 K). This extrapolation yields values of approximately 10⁻⁶ Ω⁻¹cm⁻¹ between 1050 and 1200 K, and these values of σ are considered large enough to establish a stable chemical-potential gradient of sodium across the fused-silica solid electrolyte.

Theoretical considerations.—The following electrochemical cell was employed to obtain the activities of so-

* Electrochemical Society Student Member.
Key words: glass, cell, free energy.

Fig. 1. The phase diagram V₂O₅-Na₂CO₃ (1)

dium oxide in Na₂O-V₂O₅ melts

where the subscripts V and W designate sodium oxide in the Na₂O-V₂O₅ melt and the Na₂O-WO₃ reference melt, respectively. The anodic and cathodic half-cell reactions are

and

respectively. Here O_{2(I)} and O_{2(II)} are the oxygen pressures at the cathode and the anode, respectively. The overall reaction can be written as

The Nernst equation for reaction [5] is

$$\log \mathcal{A}_{(\text{Na}_2\text{O})_V} = \log \mathcal{A}_{(\text{Na}_2\text{O})_W} + 1/2 \log [(p_{\text{O}_2})_{\text{I}} / (p_{\text{O}_2})_{\text{II}}] - 2F\epsilon / (2.303RT) \quad [6]$$

Thus the activity of sodium oxide in the cathode melt is obtained directly from the cell potential if the two pressures of oxygen and the activity of sodium oxide in the anode melt are known. In Eq. [6], ϵ is the reversible emf of the cell, R is the universal gas constant, F is the Faraday constant, and p_{O_2} is the partial pressure of oxygen. The partial pressure of oxygen over each melt was 1 atm during the measurements.

The activity of sodium oxide in Na₂O-WO₃ binary melts has been measured by Lin and Elliott (12). Their results expressed in terms of the partial molar free energy of mixing of Na₂O, G_N^M , in the Na₂O-WO₃ system at 1200 K are as follows

$$G_N^M = -95.10 - 347.2 x_w \quad (\text{kJ/mol}) \quad [7]$$

for $0.53 \leq x_w \leq 0.80$. The term x_w is the mol fraction of WO₃ in the Na₂O-WO₃ binary melt. The partial molar enthalpy of mixing of Na₂O (H_N^M) in the same system is given by

$$H_N^M = -709.80 + 262.57/x_w \quad (\text{kJ/mol}) \quad [8]$$

This equation applies in the composition range $0.53 \leq x_w \leq 0.80$ and the temperature range $1113 \text{ K} \leq T \leq 1230 \text{ K}$. The standard state for Na₂O is pure liquid Na₂O at 1 atm pressure.

The temperature range for the experiments was $1030 \text{ K} \leq T \leq 1210 \text{ K}$, so the experimental results of Lin and Elliott (12) for the Na₂O-WO₃ system were extrapolated to the lower temperature using the Gibbs-Helmholtz equation

$$\left| \frac{\partial(G_N^M/T)}{\partial(1/T)} = H_N^M \right|_{p, x_N} \quad [9]$$

and Eq. [7] and [8].

Materials preparation.—The Na₂O-V₂O₅ melts were prepared from mixtures of reagent-grade sodium carbonate (Mallinckrodt 7527) and reagent-grade vanadium pentoxide (Fisher V-7). The required amount of sodium carbonate was weighed into a platinum crucible and dried at 700 K (427°C) for 8h. The vanadium pentoxide was dried in a separate platinum crucible at 523 K (250°C) for 6h, and then the vanadium pentoxide was added to the crucible containing the sodium carbonate. The sample was mixed with a spatula, and the mixture was fused in a flowing stream of pure dry argon. All of the Na₂CO₃ reacted with the V₂O₅ above 1000 K to yield a Na₂O-V₂O₅ melt. The final weight of the melt was checked to ensure that all the CO₂ had been expelled. The agreement between the calculated theoretical weight of the Na₂O-V₂O₅ mixture and that measured after fusion was within 1% of the weight of Na₂O in the sample. The total weight of the Na₂O-V₂O₅ melt was approximately 2.5g.

The Na₂O-WO₃ reference melt was prepared by a procedure similar to that employed by DeYoung and Elliott (13). The compositions of the Na₂-WO₃ melt used were $x_w = 0.564$ and 0.5499 .

Measurements.—The general arrangement of the electrochemical cell used is shown in Fig. 2, and is similar to that employed earlier by DeYoung and Elliott (13). There are two principal differences in the current work. First, the solid electrolyte in these experiments was a tube of clear fused silica (General Electric 214, clear fused quartz, 6.2 mm od) which was closed at one end with a gas torch. Second, to ensure a good contact, the platinum lead wire to the cathode was twisted several times around another piece of platinum wire that was spot-welded to the crucible. Thus the platinum crucible became an electrode (cathode).

The temperature of the cell was measured by a Pt/Pt-10% Rh thermocouple calibrated against the melting point of gold (1337 K). A high impedance ($\sim 10^9 \Omega$) Beckman pH meter (Model no. 101900) was employed to measure the emf of the cell.

An atmosphere of pure oxygen was maintained over both the Na₂O-V₂O₅ melt and the Na₂O-WO₃ reference melt. The flow rate of oxygen gas was 75 ml/min over the Na₂O-V₂O₅ melt and 5 ml/min over the reference melt. Before passing into the cell, the streams of oxygen were dried.

The cell potential was periodically measured until it became steady; this required approximately 2h. Each cell

¹ Subsequently, the subscripts W, N, and V will denote WO₃, Na₂O, and V₂O₅, respectively.

Fig. 2. The electrochemical cell. 1: alumina tube. 2: fused-silica electrolyte. 3: Pt lead wire. 4: Pt crucible. 5: $\text{Na}_2\text{O}\text{-WO}_3$ reference melt. 6: working melt. 7: inlet gas tube. 8: Pt lead wire. 9: Pt wire hook.

was operated for about 10h. Reversibility of the cell was checked by cycling the cell temperature and, for a few cells, by polarizing the cell with an external current source. After polarization with 0.6 mA of current for approximately 10s, the potential of a cell returned to within 2 mV of the initial value within 20s and to within ± 0.05 mV in approximately 5 min.

After the experiment, the end of the fused-silica tube in contact with the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ melt was sectioned and inspected. There was no attack on the tube by the $\text{Na}_2\text{O}\text{-WO}_3$ reference melt. The wall of the fused silica in contact with the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ working melt, however, was dissolved to an extent that depended on the melt composition and temperature. No penetration by the melt through the wall of the fused silica electrolyte was observed. The dissolution of fused silica was greatest at higher temperatures and at higher sodium oxide contents in the melt ($x_N > 0.40$).

At high activities of sodium oxide (i.e., $\mathcal{A}_N > 10^{-6}$), the platinum crucible was attacked. Thus satisfactory measurements could be made only for compositions below $x_N \approx 0.5$.

Results

The activity of sodium oxide was calculated from the potential of the cell, the activity of sodium oxide in the cathode melt (Eq. [7] and [8]), and the pressures of oxygen at each electrode with the use of Eq. [6]. The results are shown in Fig. 3. The line through each set of data is a least squares line, the equation of which is

$$\log \mathcal{A}_N = A/T + B \quad [10]$$

where A and B are coefficients obtained in the correlation and T is the absolute temperature. The partial molar enthalpy and entropy of mixing, H_N^M and S_N^M , for sodium oxide for each composition of the anode melt are then obtained by the equations

$$H_N^M = 2.303 R \times A \quad [11]$$

and

$$S_N^M = 2.303 R \times B \quad [12]$$

The values of A and B and of the enthalpies and entropies of mixing of sodium oxide that were obtained from the data and Eq. [11] and [12] are listed in Table I.

The standard state for Na_2O in the analysis is the pure liquid at 1 atm pressure. The results obtained may be converted to the standard state of pure solid Na_2O by the

Fig. 3. Temperature dependence of $\log \mathcal{A}_{\text{Na}_2\text{O}(l)}$ in the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ binary system.

equation

$$\log \mathcal{A}_N(\text{solid ss}) = \log \mathcal{A}_N(\text{liquid ss}) + 3020.9/T - 2.20 \quad [13]$$

which was obtained from data in the JANAF tables (14).

Thermodynamic Calculations

Thermodynamic properties of V_2O_5 .—The activity coefficient and excess partial molar free energy of V_2O_5 were calculated from the data for the activity of sodium oxide by the Gibbs-Duhem equation in the form

$$\log \gamma_V(x_V) = \log \gamma_V(x_V = 1) - \int_{x_V=1}^{x_V} (x_N/x_V) d \log \gamma_N \quad [14]$$

and then

$$G_N^{\text{EX}} = 2.303 RT \log \gamma_V \quad [15]$$

The range of temperature of this study was 1030–1210 K, and the melting point of pure V_2O_5 is 943 K (14), so that the value of $\log \gamma_V$ ($x_V = 1$) in the calculations is zero, i.e., the pure liquid is the standard state. The integral in Eq. [14] was evaluated graphically. However, it was found that $\log \gamma_N$ was linear with respect to x_V in the range of $0.7 < x_V < 0.9$, and extrapolation of the line to $x_V = 1$ gave a value of -19.91 for the property at 1125 K. The values obtained for the excess partial molar free energies for Na_2O and V_2O_5 are shown in Table II. The molar properties shown in the table were obtained by the relationship

$$G^{\text{EX}} = G_N^{\text{EX}} \cdot x_N + G_V^{\text{EX}} \cdot x_V \quad [16]$$

Figure 4 shows the activities of Na_2O and V_2O_5 in the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ binary system at 1125 K.

The partial molar enthalpies of V_2O_5 , H_V^M , were obtained by integration of the Gibbs-Duhem equation as follows

$$H_V^M(x_V) = H_V^M(x_V = 1) - \int_{x_V=1}^{x_V} (x_N/x_V) d H_V^M \quad [17]$$

*Uncertainty in excess free energy quantities is as follows: s (G_N^{EX}) = ± 1.5 kJ/mol; s (G_V^{EX}) = ± 1.6 kJ/mol; s (G^{EX}) = ± 1.1 kJ/mol.

As shown in Table I, H_N^M is a linear function of x_v from 0.7 to 0.9 H_v. Extrapolating the line gives a value of -352.6 kJ/mol for H_N^M at N_v = 1. At this composition, H_v^M is 0. The results of the graphical integration of Eq. [17] are shown in Table II. Also shown there are values of H^M obtained by use of the equation for enthalpies that is equivalent to Eq. [16].

Standard free energy of compounds.—The standard free energy of formation of a compound from its constituent oxides at a given temperature was obtained by the relationship

$$\Delta G^\circ = 2.303RT(\log a_N + n \log a_V) \quad [18]$$

The values of log a_N and log a_V were extrapolated from 1125 K to 773 and 873 K by use of the Gibbs-Helmholtz equation (Eq. [9]). It was necessary to assume that H_N^M

Fig. 4. Log a_{Na₂O} and log a_{V₂O₅} in the Na₂O-V₂O₅ binary system at 1125 K.

and H_v^M are constant over this temperature range. The value of the log of the activity for each of the components in Eq. [18] was obtained at the composition on the liquidus envelope of a compound at the two temperatures noted above. Once the standard free energy of formation of the compound was found, the integral molar free energy of mixing for the composition of the compound G^M was then obtained by dividing the standard free energy by n + 1. The enthalpy change for reaction [18] was obtained by applying once again the Gibbs-Helmholtz equation (Eq. [9]) to the standard free energies of formation of the compound that had been obtained at 773 and 873 K. The three compounds of interest in the system are Na₂O · 6V₂O₅, Na₂O · 3V₂O₅, and Na₂O · V₂O₅. The results of the calculations are shown in Table III.

The standard free energy of formation of each of the compounds from the elements, ΔG_f^o, is obtained by adding the standard free energies of formation of the constituent oxides to Eq. [18]. The resulting equation is

$$\Delta G_f^\circ(\text{Na}_2\text{O} \cdot n\text{V}_2\text{O}_5) = \Delta G_{18}^\circ + \Delta G_f^\circ[\text{Na}_2\text{O}(l)] + \Delta G_f^\circ[\text{V}_2\text{O}_5(l)] \quad [19]$$

The results of these calculations for the three compounds are also shown in Table III. Values for the standard free energies of formation of the simple oxides were obtained from the JANAF tables (14).

Discussion

The integral molar free energy of mixing, G^M, was calculated over the composition range studied at the temperatures 773 and 873 K, and the results are shown in Fig. 5 and 6, respectively. According to the Na₂O-V₂O₅ binary phase diagram shown in Fig. 1, at 773 K (500°C), the compounds Na₂O · 6V₂O₅, Na₂O · 3V₂O₅, and Na₂O · V₂O₅ are stable. The stability of the compounds and the liquid phase (at the eutectic) predicted in Fig. 5 are in good agreement with the published phase diagram. Similar agreement is observed between the phase stability predicted in Fig. 6 at 873 K (600°C) and the Na₂O-V₂O₅ phase diagram.

The calculated value of ΔG_f^o(Na₂O · V₂O₅) from the current work is approximately 30 kJ/mol (or 1.7%) less negative than the value calculated by Mah (7) in the temperature range 773-873 K. This difference could arise from the assumption of constant values of H_N^M and H_v^M from 1200 to 773 K for the calculation of ΔG_f^o(Na₂O · V₂O₅) at 773 and 873 K. Mah estimated the values of ΔG_f^o(Na₂O · V₂O₅) up to 1000 K using the solid standard state for Na₂O · V₂O₅. Her values of ΔG_f^o(Na₂O · V₂O₅) have been extrapolated to 1200 K using the heat capacity of the liquid compound as 261.2 J/mol K, and have been corrected to the liquid standard state for Na₂O · V₂O₅ by employing a standard entropy of melting, ΔS_m^o, of 24.7 J/mol K. This value of ΔS_m^o is similar to those for the compounds Na₂WO₄ (14) and Na₂MoO₄ (15) (i.e., ~24.5 J/mol K). The resulting value of the heat of melting, ΔH_m^o, for Na₂O · V₂O₅ is 21.8 kJ/mol. In Fig. 7, the calculated values of ΔG_f^o[Na₂O · V₂O₅(l)] from the current work are compared to those values extrapolated from Mah's data. The difference in the two sets of values for ΔG_f^o[Na₂O · V₂O₅(l)] is less than 10 kJ/mol (0.6%) for the temperature range shown. No data exist in the literature for a comparison of the results for Na₂O · 3V₂O₅ and Na₂O · 6V₂O₅.

*Uncertainties are (14): $s[\Delta G_f^{\circ}(\text{Na}_2\text{O})] = \pm 4.2$ kJ/mol; $s[\Delta G_f^{\circ}(\text{V}_2\text{O}_5)] = \pm 6.5$ kJ/mol.

The $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ melts show extremely large negative deviations from ideality, as seen from the values of G^{EX} and H^{M} in Table II. These values are more than 50% more negative than the values of G^{EX} and H^{M} at $x_N = 0.3$ and 0.4 in the $\text{Na}_2\text{O}\text{-SiO}_2$ system from measurements by Neudorf and Elliott (16) in the temperature range 1055-1200 K. The data of Neudorf and Elliott (1273-1373 K) were extrapolated to the current temperature range (1055-1200 K) by employing the Gibbs-Helmholtz equation. This indicates that V_2O_5 is a more acidic oxide than is SiO_2 , and it would appear that at high concentrations of V_2O_5 nearly all the oxygen anions from the Na_2O react with the :V-O-V: network for form :V-O groups, which would result in a very low activity of Na_2O .

Errors.—There are three principal sources of error in the experiments: (i) error due to reduction of V_2O_5 to V_2O_4 , (ii) uncertainty in the experimental measurements, and (iii) error due to dissolution of the fused-silica electrolyte in the $\text{Na}_2\text{O} \cdot \text{V}_2\text{O}_5$ melt.

Liquid V_2O_5 may be reduced to V_2O_4 by the following reaction

where the values of ΔG_f° for $\text{V}_2\text{O}_4(\text{s})$ and $\text{V}_2\text{O}_5(\text{l})$ are from the JANAF tables (14). The equilibrium partial pressure of O_2 for reaction [20] is 2.6×10^{-3} atm at 1200 K and 4.5×10^{-3} atm at 1055 K. In these experiments, the partial pressure of O_2 in the gas was always greater than 0.40 atm, so no solid V_2O_4 formed from the molten V_2O_5 . Also, according to Block-Bolten and Sadoway (17), there is no nonstoichiometry in liquid V_2O_5 , arising from the presence of V_2O_4 in solution for $p_{\text{O}_2} > 0.06$ atm at 1200 K. Therefore, the error due to nonstoichiometry of the V_2O_5 in the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ binary melts is considered to be unimportant.

A detailed analysis of the uncertainties in the measured and calculated thermodynamic quantities was carried out (18). The estimated random uncertainty in the measurement of the cell temperature was ± 1.0 K and in the measurement of the cell emf was ± 1.0 mV. Combining these errors (18) leads to an uncertainty in $\log \mathcal{A}_N$ of ± 0.014 . In the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ melts, an estimated uncertainty in weighing of $\pm 0.006\text{g}$ (± 1 weight percent [w/o] Na_2O) during melt preparation yields an uncertainty in the concentration of Na_2O of ± 0.25 m/o and an uncertainty in the concentration of V_2O_5 of ± 0.08 m/o for a total sample weight ($\text{Na}_2\text{O} + \text{V}_2\text{O}_5$) of 2.5g. Using the maximum slope of the curve of $\log \mathcal{A}_N$ vs. x_N , an uncertainty in m/o Na_2O of ± 0.25 produces an uncertainty in $\log \mathcal{A}_N$ of ± 0.07 . The uncertainty in the composition of the $\text{Na}_2\text{O}\text{-WO}_3$ reference melt (m/o

Fig. 5. G^{M} in the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ binary system at 773 KFig. 6. G^{M} in the $\text{Na}_2\text{O}\text{-V}_2\text{O}_5$ binary system at 873 K

Fig. 7. The standard free energy of formation of Na₂O · V₂O₅(1) from the elements. Horizontal bars indicate estimated uncertainties in lines.

WO₃ of ± 0.01) causes an error in $\log \mathcal{A}_N$ of ± 0.0013 . Combining all the random errors (19) due to measurement of temperature and emf, and due to uncertainties in melt compositions, results in a total estimated random error in $\log \mathcal{A}_N$ of ± 0.071 . From the least squares line fits to the experimental data, the maximum standard deviation in $\log \mathcal{A}_N$ is ± 0.07 , as shown in Table I. This value (± 0.07) is in good agreement with the total estimated random error in $\log \mathcal{A}_N$ of ± 0.071 . A random error in $\log \mathcal{A}_N$ of ± 0.071 corresponds to a maximum random uncertainty in G_N^{EX} of ± 1.5 kJ/mol at 1125 K. The random errors in H_N^{M} and S_N^{M} are estimated to be ± 9 and ± 2.7 J/mol K, respectively.

A further error in the electrochemical cell experiments arises from the dissolution of the fused-silica electrolyte into the V₂O₅ containing melts. There is a maximum solubility of 2.5 w/o SiO₂ in liquid V₂O₅ at 1200 K according to the V₂O₅-SiO₂ phase diagram (20). However, a fused-silica rod continued to be attacked by a pure V₂O₅ melt even though the saturation concentration of silica of 2.5 w/o was reached (20, 21). This apparently anomalous behavior resulted from silica reprecipitating as quartz or crystalite because the chemical potentials of these crystalline forms are slightly less than that of the silica in the vitreous state. It would appear that the same effect was present with the cell measurements of this study. The apparent solubility of silica in the melt as estimated from the volume of silica removed from the exterior of the electrolyte tube varied with the V₂O₅ content of the melt and the time of operation of the cell. For example, the weight of silica removed ranged from 0.9% to 1.9% of the weight of the melt for times of 6-9.5h exposure and melt compositions of 90, 80, and 70 m/o V₂O₅. For melts containing 50 m/o, the equivalent figure was 5 w/o or less. With a melt of pure sodium sulfate in which the activity of sodium oxide was controlled in the range of 10^{-14} to 10^{-16} , there was no attack of the silica electrolyte for exposures of 15-30h at 1170-1256 K. There was also no attack of these electrolytes by Na₂O-WO₃ melts in which the activity of Na₂O was near 10^{-14} .

The available information on the nature of the Na₂O-V₂O₅-SiO₂ system is much too limited to make a quantitative evaluation of the effect of SiO₂ on the measured values of $\log \mathcal{A}_{\text{Na}_2\text{O}}$. An estimate of the effect can be made, however, on the basis that silica and vanadium oxide, as VO_{2.5} are acids and behave similarly in the Na₂O-VO_{2.5}-SiO₂ system. The actual melt on which the measurements were made is in the ternary system, whereas the results of the study are applied to the Na₂O-VO_{2.5} binary system. In making the correction, the composition of the ternary sys-

tem is calculated on the basis that 2.5 w/o silica was added to the initial binary melt. This addition is 0.033-0.037 mole fraction of silica for the melt compositions studied. It is then assumed that the value of $\log \mathcal{A}_{\text{Na}_2\text{O}}$ is constant along lines of constant concentration of sodium oxide in the ternary system, i.e., for lines of constant SiO₂ + VO_{2.5}. Thus the values of $\log \mathcal{A}_{\text{Na}_2\text{O}}$ are obtained for the binary Na₂O-VO_{2.5} system. Conversion of the compositions in the ternary system back to compositions in the Na₂O-V₂O₅ system provides the estimate of the correction that is to be applied to the lines plotted in Fig. 5. The corrections in $\log \mathcal{A}_{\text{Na}_2\text{O}}$ range from -0.002 to -0.011 in the composition range from 90-50 m/o V₂O₅, respectively. When compared to other sources of uncertainty in the study, this correction is insignificant.

Summary

The activity of Na₂O in the liquid phase of the Na₂O-V₂O₅ system has been measured between 1055 and 1200 K by employing an electrochemical cell. The partial molar thermodynamic quantities for Na₂O and V₂O₅ and the integral molar quantities for the liquid have been evaluated.

The values of ΔG_f° , ΔH_f° , and ΔS_f° for the compounds Na₂O · V₂O₅, Na₂O · 3V₂O₅, and Na₂O · 6V₂O₅ have been calculated in the temperature range 873-773 K. The calculated data on Na₂O · V₂O₅ from the current work is within 1.7% (± 30 kJ/mol) of the data calculated by Mah (7).

The Na₂O-V₂O₅ melts show large negative deviations from ideality which is indicative of the strong chemical interaction between the two components (Na₂O and V₂O₅) in the melt.

The Composite Insertion Electrode

Theoretical Part. Equilibrium in the Insertion Compound and Linear Potential Dependence

S. Atlung,* B. Zachau-Christiansen, K. West, and T. Jacobsen*

Fysisk-Kemisk Institut, The Technical University of Denmark, DK 2800 Lyngby, Denmark

ABSTRACT

The specific energy obtainable by discharge of porous insertion electrodes is limited by electrolyte depletion in the pores. This can be overcome using a solid ion conductor as electrolyte. The term "composite" is used to distinguish these electrodes from porous electrodes with liquid electrolyte. The theoretical basis for such electrodes is discussed and, using a simplified model, equations are derived to describe the distribution of potential and current during discharge/charge operation. Under the assumption that the insertion compound particles are small enough to ensure equilibrium, and that the local electrode potential depends linearly on the degree of insertion, these equations are solved to obtain analytical expressions for the discharge curve. It is shown that the parameters which determine the discharge behavior for a given discharge current are simply related to the effective ionic and electronic conductivities, the thickness of the electrode, the volume fractions, and the slope of the potential curve.

From a specific energy point of view, batteries with insertion electrodes have the advantage that the overall cell process

only includes a minimum of components, and no changes in overall electrolytic composition.

The reaction at the positive electrode

is a topochemical reaction where the monovalent cation M^+ is inserted in the "host compound," H . δ is an infinitesimal increment in the degree of insertion x and the compound HM_x , for $x \leq n$, forms a single phase.

Hence Eq. [2] can take place in both directions with a minimum of structural changes. This should make it possible to design secondary batteries with long cycle life. Li is the metal most used for this type of batteries, but Eq. [2] is known to occur with Na^+ (1), K^+ (2), and Ag^+ (3) as well.

Many insertion compounds are known primarily from the groups of dichalcogenides (4), but lately also oxides, in particular, vanadium oxides, have been studied (5).

Based on the Li/TiS_2 couple, practical battery investigations have shown (6-8) that a specific energy in the range of 100-150 Wh/kg is a realistic goal for moderate temperature batteries. This can be compared with the 50-60 Wh/kg goal for advanced lead acid systems.

The limitations met with in the design of insertion compound batteries originate primarily from the low mobility of the M^+ cation in the electrolytes used (9). Alkali metal anodes dictate the use of nonaqueous electrolytes, either organic solvents with a M salt (10), or solid ionic conductors (7).

The dynamics of insertion cathodes.—Equation [2] is basically a solid-state reaction, whose rate is controlled by diffusion of M^+ into the insertion compound particle. This type of electrode kinetics has been discussed in relation to battery performance in earlier papers (11, 12). It was concluded that insertion cathodes should be made with small particles arranged in a porous structure in order to obtain acceptable specific energies at heavy loads. In a porous electrode, the utilization of the active materials depends on the transport in the active particles, electrode porosity and thickness, and electrolyte properties. By choosing small enough cathode particles, the influence of transport in these can be eliminated without impairing the packing density (11). For example, in the case of the Li/TiS_2 system, a particle size smaller than 1-2 μm ensures that even for 2-4h loads, the Li concentration in the particles is practically uniform.

The impedance for the interfacial charge transfer reaction can be assumed negligible for insertion reactions (13)

*Electrochemical Society Active Member.

Key words: electrode, insertion, solid state, discharge.

and, accordingly, reaction [2], under these circumstances, proceeds close to equilibrium. Hence, the obtainable material utilization in the porous cathode is limited by transport phenomena in the electrolyte in the pores.

These problems were discussed in a previous publication (14), where it was concluded that the utilization of a porous cathode, designed for maximum energy density, was limited by local depletion of electrolyte salt in the cathode. This depletion occurs when the local transfer current consumes more M^+ ions than the amount supplied by diffusion and migration. In Ref. (12) it was indicated that the electrolyte depletion was a consequence of the transport of the anion and could be delayed or suppressed if the anion mobility was low enough. Thus, a low anion and a high cation mobility should be beneficial for material utilization. However, one might fear that the corresponding decrease in conductivity and the appearance of "diffusion potentials" would offset the gain.

A quantitative study was undertaken in Ref. (14) from which Fig. 1 is reproduced. It is obvious from this figure that the electrode performance is dramatically improved by decreasing anion mobility to a low value, regardless of the increase in electrolyte resistance. This points to the use of solid ion conductors with only one ionic species mobile as electrolytes in "porous" electrodes. To indicate the difference between electrodes with liquid electrolytes and solid electrolytes, the term "composite electrodes" is coined to describe these "all solid-state" electrodes.

Composite Electrodes

In experiments with solid ionic conductors it has been the practice to mix the electrode substance with electrolyte powder (15). So far no discussion of this procedure and the expected advantages is found in the literature.

Fig. 1. Calculated discharge curves for porous electrode with liquid electrolyte. Cationic mobility kept constant, different values of t (a, b, c). $a = 0.8$, $b = 0.1$, and $c = 0.01$. For further details see Ref. (14).

For reversible batteries, a composite electrode can hardly be imagined with other electrode systems than insertion compounds because participation of electrolyte compounds in the cell reaction would destroy the structure. Even with insertion compounds the volume changes associated with charge and discharge might cause difficulties. The composite electrode must be made by mixing powders of the insertion compound and the solid electrolyte and consolidating this mixture on a metal grid serving as current collector.

The structure of a composite electrode is shown in Fig. 2. It is essential that the insertion material and the electrolyte form two interwoven contiguous networks with maximum contact area, and that the number of voids or isolated particles is at a minimum. The realization of such a structure is difficult; it can, however, be facilitated using a "soft" electrolyte like $\text{LiI-Al}_2\text{O}_3$ (16) or a small amount of polymeric electrolyte (17) to improve the contact between electrolyte and electrode particles (18).

The composite electrode concept is an imperative prerequisite for the construction of an all solid-state battery system exploiting the advantages associated with electrolytes conducting only the inserted ion.

Such a system can be operated at a moderately increased temperature, 100°-150°C. In the first place, this improves the rather low conductivity of solid electrolytes at room temperature. Assuming an activation energy for ionic transport of 0.3 eV, raising the temperature from 25° to 150°C will improve the battery rate capability by a factor of five. Also, the rate of the insertion process will be improved permitting use of less "active" insertion compounds or larger particles.

Operation of organic electrolyte batteries at increased temperature has until now not been successfully demonstrated, partly from safety considerations, and partly due to the tendency for solvent intercalation in layered materials. It is obvious that the composite electrode should be combined with a layer of solid electrolyte as a separator. The most promising electrolyte materials, Li_3N and $\text{LiI-Al}_2\text{O}_3$, are thermodynamically stable against Li, and this, possibly in connection with the increased temperature, improves the cyclability of the Li electrode considerably (18).

From a construction point of view, the possibility of stacking a number of cells to a high voltage unit without serious containment problems should improve overall specific energy. Hence, the expected advantages associated with the composite electrode concept warrants a closer study of its theoretical and practical aspects.

Theoretical Treatment

Model description.—It is assumed that the electrode is a flat pellet of thickness, l , (Fig. 3). The length coordinate is z , with $z = 0$ at the current collector. The electrode potential, ϵ_c is measured at the current collector with reference to an electrode reversible to M^+ placed at $z = l$. π is the Fermi potential in the electronically conducting insertion compound and ϕ the Galvani potential in the electrolyte. Hence

$$\epsilon_c = \pi_0 - \phi_1 \quad [3]$$

where $\pi_0 = \pi(z = 0)$ and $\phi_1 = \phi(z = l)$.

Due to the equivalence between the electrolyte and insertion compound, it is natural to use the macrohomogeneous model as introduced by Newman and Tobias (19). According to this model, each point is associated with local values of π , ϕ , ionic current density, i_i , and electronic current density, i_e . The electrochemical reaction causes a transfer current, i_t , measured per unit volume electrode. These variables are all functions of position, z , and time, t .

We further ascribe an effective electronic conductivity, κ_e , and a corresponding ionic conductivity, κ_i , to the electrode structure as such. These quantities then include the effect of tortuosity and volume fraction of the insertion and the electrolyte components, respectively. Neglecting volume changes due to charge/discharge, κ_i can be considered constant in time and space, when a true solid

Fig. 2. Composite electrode concept (two dimensional)

ionic conductor is used. This makes all the difference between the treatment of the composite and the porous electrode with liquid electrolyte, where composition and conductance of the electrolyte changes with time and position.

For some insertion compounds, the electronic conductivity of the pure substance, κ_e^0 , can change considerably with the amount of inserted ion. However, the effective value of κ_e in the electrode can be controlled by conducting additives like graphite, etc.

In the following, κ_e is considered constant, the interfacial charge transfer is assumed to be in equilibrium, and the local concentration of inserted ion in each insertion compound particle is uniform. Also, electrical gradients perpendicular to the Z -axis are assumed negligible. Under these assumptions, the transport equations are

$$i_i = -\kappa_i \frac{d\phi}{dz} \quad \text{and} \quad i_e = -\kappa_e \frac{d\pi}{dz} \quad [4]$$

and the conservation of mass and charge requires

$$i_t = \frac{\partial i_i}{\partial z} \quad \text{and} \quad i_i + i_e = i^* \quad [5]$$

i^* is the discharge/charge current density (counted negative for cathodic, i.e., discharge currents). The local single electrode potential is given as

$$\epsilon = \pi - \phi \quad [6]$$

and Eq. [4]-[6] give the porous electrode relation (20)

$$\frac{\partial^2 \epsilon}{\partial z^2} = i_t \left(\frac{1}{\kappa_i} + \frac{1}{\kappa_e} \right) \quad [7]$$

with the boundary conditions for constant current discharge

$$z = 0, i_e = i^*; \quad z = l, i_i = i^* \quad [8]$$

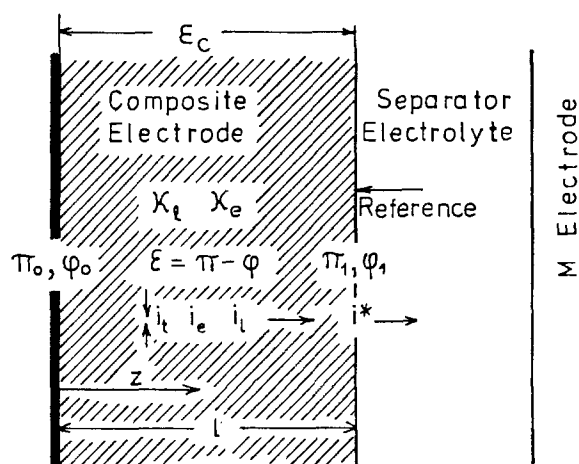

Fig. 3. Specification of composite electrode model

which on the strength of Eq. [4] and [5] can be written as

$$\begin{aligned} z = 0, \partial\epsilon/\partial z &= -i^*/\kappa_e \\ z = l, \partial\epsilon/\partial z &= i^*/\kappa_l \end{aligned} \quad [9]$$

The insertion electrode potential.—In porous and composite insertion electrodes, the reaction is distributed through the electrode, mainly as a result of the change in potential associated with the change in the local degree of insertion caused by the discharge/charge process. A characteristic for insertion compounds is that their equilibrium potential depends strongly on the degree of insertion. One example of this dependence is the relation proposed by Armand (21) for TiS_2/Li

$$\epsilon = \pi - \phi = \epsilon^\theta + RT/F[\ln[(1-X)/X] - f[X - 0.5]] \quad [10]$$

where $X = x/n$ is the degree of insertion, f an "interaction parameter," and ϵ^θ a standard potential for the insertion compound/electrolyte in question.

The interaction parameter, f , expresses approximately the effect of the electrostatic interactions associated with the insertion process (23) and dominates the dependence of the potential on X . The typical range for the linear term is $10 < f < 20$, e.g., 16 for TiS_2 .

A relation of the form Eq. [10] presumes that the insertion takes place in a monophasic region. If, for example, new phases are formed during insertion, the EMF composition relation will exhibit plateaus, and relations like Eq. [10] are only valid within limited regions.

In Fig. 4, we have depicted the TiS_2/Li potential as measured (29) and calculated from Eq. [10]. In this case, it is obvious that a simple linear dependence

$$\epsilon = \epsilon^* - kX \quad [11]$$

is a good approximation. Although other insertion compounds may show this behavior only in a limited range, it is believed that Eq. [11] brings out the characteristic features of insertion electrodes compared with other battery electrodes like HgO , AgCl , and PbO_2 .

The working potential.—The working potential is given by Eq. [3]. In case of a significant contribution from the electronic resistance in the insertion compound network, ϵ_c cannot be identified with the local electrode potential

ϵ_1 at $z = l$. Many insertion compounds have a high electronic conductance as, e.g., TiS_2 , while other compounds interesting from a battery point of view show a rather low electronic conductivity, e.g., some of the vanadium oxides.

Until now there still remains some uncertainty as to the influence of electronic resistivity on battery performance, although it was a main topic in some of the first works on porous electrodes (24).

The following treatment is quite general and based on the local potentials: $\epsilon_1 = \epsilon(z = l) = \pi_1 - \phi_1$ and $\epsilon_0 = \epsilon(z = 0) = \pi_0 - \phi_0$. From Eq. [3], we have

$$\epsilon_c = \pi_0 - \phi_1 = \pi_1 - \phi_1 - (\pi_1 - \pi_0) \quad [12]$$

and from Ohms law (κ_e constant)

$$\pi_1 - \pi_0 = -\frac{1}{\kappa_e} \int_0^l i_c dz \quad [13]$$

and using Eq. [4] and [7]

$$i_c = \int_z^l i_t dz = \frac{\kappa_e \kappa_l}{\kappa_e + \kappa_l} \int_z^l \frac{\partial^2 \epsilon}{\partial z^2} dz \quad [14]$$

Performing the integration and using the boundary conditions in Eq. [9] we obtain

$$\epsilon_c = \frac{1}{\kappa_e \kappa_l} (\kappa_e \epsilon_1 + \kappa_l \epsilon_0 + li^*) \quad [15]$$

At this stage, it is convenient to introduce the parameters ϵ_1^0 and ϵ_0^0 to express the potential difference which would develop across the electrode, if all the current passed through the ionically conducting network or the electronically conducting network, respectively

$$\epsilon_1^0 = -i^*l/\kappa_l; \quad \epsilon_0^0 = -i^*l/\kappa_e \quad [16]$$

As it will appear later, these two parameters and k determine the behavior of the electrode over the entire discharge range. With these ϵ_c can be written as

$$\epsilon_c = \frac{\epsilon_1^0 \cdot \epsilon_1}{\epsilon_1^0 + \epsilon_0^0} + \frac{\epsilon_0^0 \cdot \epsilon_0}{\epsilon_1^0 + \epsilon_0^0} - \frac{\epsilon_1^0 \cdot \epsilon_0^0}{\epsilon_1^0 + \epsilon_0^0} \quad [17]$$

The ratio $\beta = \epsilon_0^0/\epsilon_1^0 = \kappa_l/\kappa_e$ expresses the influence of increasing the electronic resistance for a fixed value of the ionic resistance. Using β , we get

$$\epsilon_c = \frac{1}{1 + \beta} \epsilon_1 + \frac{\beta}{1 + \beta} \epsilon_0 - \frac{\beta}{1 + \beta} \epsilon_1^0 \quad [18]$$

Mathematical treatment.—It is characteristic for porous and composite electrodes that the transport in the two phases is coupled through the local electrode potential $\epsilon = \pi - \phi$. As ϵ is given by the local value of X , which depends on the local degree of discharge, the time dependence of the electrode behavior is introduced. If, as assumed, the insertion compound particles are in equilibrium, then

$$\frac{\partial X}{\partial t} = -\frac{i_t}{Fvc^0} \quad [19]$$

where c^0 is the saturation concentration ($x = n$) and v is the volume fraction of insertion compound. Combining this with Eq. [7] and [16], we get

$$\frac{\partial X}{\partial t} = \frac{i^*l}{Fvc^0(\epsilon_0^0 + \epsilon_1^0)} \frac{\partial^2 \epsilon}{\partial z^2} \quad [20]$$

For convenience, dimensionless variables and groups are introduced. For a battery discharge at constant current, the obvious time unit is the time needed to discharge the battery completely. At equilibrium conditions this is

$$\tau_D = -F l v c^0 / i^* \quad [21]$$

keeping in mind that cathodic currents are negative. τ_D is the "stoichiometric" discharge time and can be consid-

Fig. 4. Insertion electrode potential. (1) measured Ref. (29), (2) approximation according to Eq. [10], and (3) linear approximation ($\epsilon^* = 2.49\text{V}$, $k = 0.67\text{V}$).

ered a measure of the intensity of the discharge. Equivalent terminology is used in the battery industry, e.g., a "5h load." The dimensionless time

$$T = t/\tau_D = -ti^*/F\ell v c^0 \quad [22]$$

is then identical to the degree of discharge.

Introducing dimensionless length, Z , and potential, E

$$Z = z/l; E_j^m = F\epsilon_j^m/RT; \text{ and } K = Fk/RT \quad [23]$$

transforms Eq. [20] and [9] into

$$\frac{\partial X}{\partial T} = -\frac{1}{E_1^0 + E_e^0} \frac{\partial^2 E}{\partial Z^2} \quad [24]$$

$$Z = 0, \partial E/\partial Z = E_e^0; Z = 1, \partial E/\partial Z = -E_1^0$$

where

$$E_j^0 = \frac{F^2 \ell^2 v c^0}{RT\tau_D \kappa_j} \quad (j = e, l) \quad [25]$$

and the potential relation in Eq. [10] into

$$E = E^0 + \ln[(1 - X)/X - f(X - 0.5)] \quad [26]$$

and Eq. [11]

$$E = E^* - KX \quad [27]$$

Equations [24] and [26] or a corresponding potential relation form two simple nonlinear simultaneous second-order differential equations from which E or X can be found as functions of T and Z by well-known numerical methods. Here we will use the linear relation in Eq. [27] to obtain an analytical solution. Equations [24] and [27] give

$$\frac{\partial X}{\partial T} = \frac{K}{E_1^0 + E_e^0} \frac{\partial X^2}{\partial Z^2} \quad [28]$$

Together with the boundary conditions in Eq. [24], this relation shows that the discharge in a composite electrode proceeds in the same way as diffusion (according to Ficks second law) in a bounded domain $0 \leq Z \leq 1$ with constant flux at the two boundaries.

In the dimensionless units used above, the quantity $K/(E_1^0 + E_e^0)$ is equivalent to a diffusion coefficient which in dimensioned units is

$$D_c = \frac{k}{\mathbf{F} \cdot \mathbf{v} \cdot c^0 \left(\frac{1}{\kappa_l} + \frac{1}{\kappa_e} \right)} \quad [29]$$

To describe the discharge characteristics of the electrode at the given load a "load factor," L_c , is introduced

$$L_c = \frac{\tau_c}{\tau_D} = \frac{E_1^0 + E_e^0}{K} = (1 + \beta)E_1^0/K \quad [30]$$

$$= \frac{|i^*| \cdot l}{k} \left(\frac{1}{\kappa_e} + \frac{1}{\kappa_l} \right)$$

where τ_c is the time constant for the electrode: ℓ^2/D_c .¹ The solution of Eq. [28] can be obtained by combining solutions for the equivalent heat conduction phenomena (25) as discussed in the Appendix.

The two solutions below are written using L_c and $E_e^0 = \beta \cdot E_1^0$ to demonstrate the influence of additional electronic resistance

$$X = T + \frac{E_1^0}{K} \left\{ \frac{1 + \beta}{2} Z^2 - \beta Z + \frac{\beta}{3} - \frac{1}{6} + \frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \exp[-n^2 \pi^2 T/L_c] [\beta \cos n\pi Z - \cos n\pi(1 - Z)] \right\} \quad [31]$$

and²

¹In Ref. (11), the reciprocal of L_c was used, called Q .

²ierfc is the first integral of the erfc function. See Ref. (25).

$$X = 2 \frac{E_1^0}{K} \frac{\sqrt{T}}{L_c} \sum_0^{\infty} \left[\text{ierfc} \frac{2n + 1 + Z}{2\sqrt{T}/L_c} + \text{ierfc} \frac{2n + 1 - Z}{2\sqrt{T}/L_c} + \beta (\text{ierfc} \frac{2n + Z}{2\sqrt{T}/L_c} + \text{ierfc} \frac{2n + 2 - Z}{2\sqrt{T}/L_c}) \right] \quad [32]$$

These relations are most conveniently treated by considering "long time" and "short time" behavior separately. To obtain an acceptable battery capacity, L_c should be less than one. For $T > L_c/3$, the sum of exponentials in Eq. [31] vanishes, giving the long time approximation

$$X = T + \frac{E_1^0}{K} \left(\frac{1 + \beta}{2} Z^2 + \beta Z + \frac{\beta}{3} - \frac{1}{6} \right) \quad [33]$$

This concentration profile is a parabola with minimum value at $Z = \beta/(1 + \beta)$. The values of X at the back and front are

$$Z = 0, X_0 = T + (2\beta - 1)E_1^0/6K \quad [34]$$

$$Z = 1, X_1 = T + (2 - \beta)E_1^0/6K$$

Using Eq. [18] and [11], the dimensionless working potential is found as

$$E_c = E^* - KT - (E_1^0 + E_e^0)/3 \quad [35]$$

$$= E^* - KT - (1 + \beta)E_1^0/3$$

For "short time," an approximation can be obtained from Eq. [32] observing that, for small values of T/L_c , all terms except those with $n = 0$ in the summations vanish, (ierfc $1.5 < 0.01$). Also, for Z near zero, only the term with ierfc $(Z/2\sqrt{T}/L_c)$, and for Z near one, only ierfc $((1 - Z)/2\sqrt{T}/L_c)$ remains. Hence, the short time approximation is

$$X = 2 \frac{E_1^0}{K} \sqrt{\frac{T}{L_c}} \left(\text{ierfc} \frac{1 - Z}{2\sqrt{T}/L_c} + \beta \text{ierfc} \frac{Z}{2\sqrt{T}/L_c} \right) \quad [36]$$

showing that the profile is composed of two semi-infinite diffusion profiles starting from $Z = 1$ and $Z = 0$, respectively. They both travel inward and at $Z = \beta/(1 + \beta)$ they meet, building up the parabola given by Eq. [33]. The values of X at the back and front of the electrode are [ierfc(0) = $1/\sqrt{\pi}$]

$$Z = 0, X_0 = 2 \frac{\beta E_1^0}{K} \sqrt{\frac{T}{\pi L_c}} \quad [37]$$

$$Z = 1, X_1 = 2 \frac{E_1^0}{K} \sqrt{\frac{T}{\pi L_c}}$$

Then using Eq. [11] and [18], the dimensionless working potential is

$$E_c = E^* - \frac{2}{\sqrt{\pi}} \frac{1 + \beta^2}{(1 + \beta)^{3/2}} \sqrt{KE_1^0 \cdot T} - \frac{\beta}{1 + \beta} E_1^0 \quad [38]$$

This relation demonstrates the \sqrt{t} dependence, typically for semi-infinite diffusion, but it also contains a constant term for $t = 0$ which is largest for $E_1^0 = E_e^0$, ($\beta = 1$).

Equations [35] and [38] are asymptotic solutions for $T \rightarrow \infty$ and $T \rightarrow 0$, but they are both very good approximations over a large range. Equating dE_c/dT from these two expressions, a transition point is found for

$$T_t = \left[\frac{1 + \beta^2}{(1 + \beta)^2} \right]^2 \frac{L_c}{\pi} = \frac{(1 + \beta^2)^2}{(1 + \beta)^3} \frac{E_1^0}{\pi K} \quad [39]$$

and, at this point, the true value for E_c deviates less than 0.01($E_e^0 + E_1^0$) from the values calculated from Eq. [35] and [38]. Thus, these two relations cover the range $0 < T < 1 - L_c/3$ with a sufficient precision for all practical purposes.

The low potential region.—Physically, X can never exceed 1, and, thus, Eq. [35] or [38] are only valid for $T < T_{sat}$,

where T_{sat} is found by equating X to 1 in Eq. [34] or [37]. For practical batteries, a utilization of more than 50% is usually required and hence, only the use of Eq. [34] is relevant. From this, T_{sat} is

$$\beta \leq 1, T_{\text{sat}} = 1 - (2 - \beta) \frac{E_1^0}{6K} = 1 - \frac{2 - \beta}{6(1 + \beta)} L_c \quad [40]$$

$$\beta \geq 1, T_{\text{sat}} = 1 - (2\beta - 1) \frac{E_1^0}{6K} = 1 - \frac{2\beta - 1}{6(1 + \beta)} L_c$$

For $\beta = 0$ and $\beta \rightarrow \infty$, T_{sat} is $1 - L_c/3$, and for $\beta = 1$, T_{sat} is $1 - L_c/12$. At T_{sat} the insertion compound becomes saturated either at the surface (for $\beta < 1$) or at the current collector ($\beta > 1$). For $\beta = 1$, the saturation occurs simultaneously at the surface and at the current collector.

However, the discharge of the inner parts of the electrode can continue for $T > T_{\text{sat}}$. For $\beta < 1$, due to the transport of M^+ in the ionic conducting network to the non-saturated inner parts, and for $\beta > 1$, correspondingly through transport of electrons in the electronic conducting network of (saturated) insertion compound. In this way the electrode can, in principle, be discharged to 100% utilization.

This part of the discharge is characterized by a boundary between the saturated and still active part of the electrode; the boundary moving inwards for $\beta < 1$. From this boundary on, the electrode reaction proceeds as usual and Eq. [24] will apply. However, the boundary condition $dE/dZ = -E_1^0$ should now be applied to the moving boundary between the saturated and the active part of the electrode. For $\beta > 1$, saturation starts at the current collector. The total current is now carried by the electronic conducting network to the boundary, which is now moving forward but still subjected to the boundary condition $dE/dZ = E_e^0$. For $\beta = 1$, two boundaries starting at each end move against each other. In Fig. 5, we have depicted the development of concentration profiles in the electrode with T for different characteristic values of β .

A simple analytical solution of Eq. [24] with moving boundary conditions has not been found. However, an approximate solution for the position of the boundary can be found if one assumes that the shape of the concentration profile remains parabolic as for $T < T_{\text{sat}}$. This appears reasonable when $1 - T_{\text{sat}}$ is small.

The analytical solutions are only simple for E_e^0 or $E_1^0 = 0$ or in the symmetrical case $E_e^0 = E_1^0$. For $\beta = 0$ let the boundary between the outer saturated and the inner ac-

tive region be at $Z = Z^*$. Then, using the boundary conditions at $Z = 0$ and $Z = Z^*$ and the assumption about a parabolic shape, the concentration profile ($0 \leq Z \leq Z^*$) is found to be

$$X = \frac{E_1^0 Z^2}{2KZ^*} - \frac{E_1^0}{2K} Z^* + 1 \quad [41]$$

As the total inserted amount is T , Z^* can be found from

$$T = \int_0^{Z^*} X dZ + 1 - Z^* \quad [42]$$

resulting in

$$Z^* = \sqrt{3K(1 - T)/E_1^0} \quad [43]$$

For $\beta = 1$ ($E_e^0 = E_1^0$), we have two boundaries, Z_1^* and Z_2^* , symmetrical about $Z = 1/2$. With the same procedure as above, we get

$$Z_1^* = 1/2 + \sqrt{3K(1 - T)/2E_1^0} \quad [44]$$

$$Z_2^* = 1/2 - \sqrt{3K(1 - T)/2E_1^0}$$

At the boundaries, the local electrode potential according to Eq. [11] is $E^* - K$. If $E_e^0 = 0$, we get the working potential directly as

$$E_c = E^* - K - E_1^0(1 - Z^*) \quad [45]$$

And for $E_e^0 = E_1^0$ ($\beta = 1$)

$$E_c = E^* - K - E_1^0(1 - Z^*) - \frac{F}{RT} \int_{Z_1^*}^{Z_2^*} \pi dZ \quad [46]$$

Inserting Eq. [43] in [45] and Eq. [44] in [46] and evaluating the integral as for Eq. [18], we get as a common result

$$E_c = E^* - K - E_1^0(1 - \sqrt{3K(1 - T)/(\beta + 1)E_1^0}) \quad [47]$$

valid for $\beta = 0$ and 1.

The final working potential at $T = 1$ is thus estimated as

$$E_c(T = 1) = E^* - K - E^0 \quad [48]$$

where E^0 is E_1^0 for $\beta \leq 1$ or E_e^0 for $\beta \geq 1$.

Discussion

The basic Eq. [28] demonstrates that in the region where $X < 1$ the composite electrode behaves like a non-porous insertion electrode. The apparent diffusion coefficient depends, according to Eq. [29], on the slope of the EMF curve, on the conductivities, and on the specific capacity ($c^0 \cdot v$) of the electrode.

Using available data for the $\text{TiS}_2/\text{Li}_3\text{N}$ combination,³ a value of $D_c \approx 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ is obtained at 170°C . This relatively high value allows construction of batteries with a high materials utilization and a good packing density even at heavy loads.⁴

To illustrate this further, the discharge curve, i.e., the working voltage, ϵ_c , as a function of degree of discharge, T , can be calculated for an electrode with known values of k , ϵ_1^0 , ϵ_e^0 , and ϵ^* . This can be done using Eq. [38], [35], and [47], successively, observing that the discharge curve can be divided in three regions: the \sqrt{T} region, the linear part, and the low potential region characterized by a $\sqrt{1 - T}$ dependence. The transition points between these regions as given by Eq. [39] and [40] are determined by the load factor L_c defined in Eq. [30]. The case $\epsilon_1^0 \gg \epsilon_e^0$ ($\beta = 0$) is of considerable practical interest and may serve as an illustration of the characteristic course of the discharge curve. Using dimensioned units ($k = RTK/F$, $L_c = \epsilon_1^0/k$), the three regions can be described thus

³ $C^0 = 0.026 \text{ mol cm}^{-3}$, $K = 22$, $\kappa_e \gg \kappa_1 \approx 2.5 \cdot 10^{-3} \Omega^{-1} \text{ cm}^{-1}$ at 170°C , $v = 0.5$.

⁴ It has been experimentally shown that although the $\text{TiS}_2/\text{Li}_3\text{N}$ combination is thermodynamically unstable, it is kinetically stable. Batteries with $\text{TiS}_2/\text{Li}_3\text{N}$ composite electrodes have been cycled more than 500 times (30).

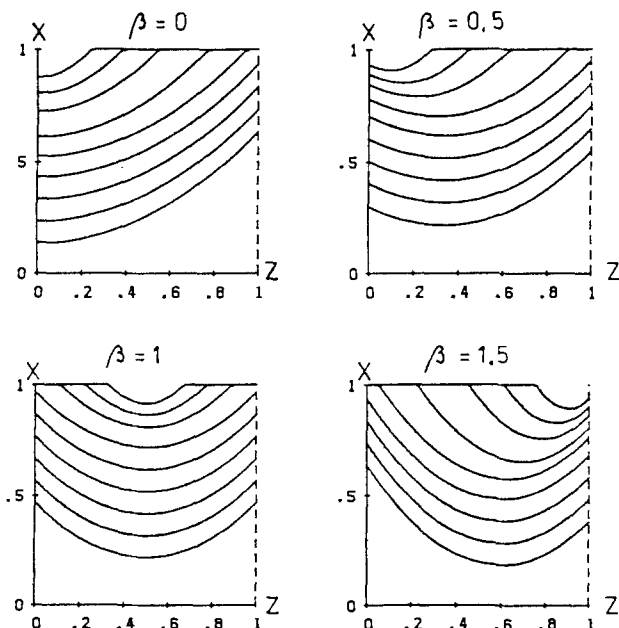

Fig. 5. Calculated concentration profiles in composite electrode. Different values of $\beta = \kappa_1/\kappa_e$ as indicated. E_1^0/K kept constant. Counted from lowest value of X , $T = 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 0.95$, and 0.98 .

$$T < L_c/\pi;$$

$$\epsilon_c = \epsilon^* - \frac{2}{\sqrt{\pi}} \sqrt{\epsilon_1^0 k \cdot T}$$

$$L_c/\pi < T < 1 - L_c/3; \quad [49]$$

$$\epsilon_c = \epsilon^* - \epsilon_1^0/3 - k \cdot T$$

$$1 - L_c/3 < T < 1;$$

$$\epsilon_c = \epsilon^* - k - \epsilon_1^0 (1 - \sqrt{3k(1-T)/\epsilon_1^0})$$

In Fig. 6, discharge curves for $L_c = 1$ and different combinations of k and ϵ_1^0 are depicted. The effect of an additional electronic resistance ($\beta > 0$) is illustrated in Fig. 7. Contrary to the case for $\beta = 0$, there is according to Eq. [38] an initial ohmic voltage drop: $\epsilon_e^0/(1 + \beta)$. In a complete battery, this will be observed in addition to the voltage drop across the separator electrolyte. The \sqrt{T} part of the curve is flattened due to the factor $(1 + \beta^2)/(1 + \beta)^{3/2}$ in Eq. [38] ($= 0.7$ for $\beta = 1$). The linear part is further depressed by $\epsilon_e^0/3$, but the linear range is extended at the expense of the \sqrt{T} and the $\sqrt{1-T}$ regions, delaying the appearance of the more sloping last part of the discharge. The end-point voltage ($T = 1$) is, however, the same as for $\beta = 0$ cf. in Eq. [48].

In general, the course and position of the discharge curve are determined by k and ϵ^* , characteristic for the insertion compound, and by the quantities ϵ_1^0 and ϵ_e^0 , which besides the electronic and ionic conductivities κ_e and κ_i , combine the influence of the discharge current, the thickness of the electrode, and the volume fraction and saturation concentration of the insertion compound.

ϵ^* and k are thermodynamic quantities given by the affinity of the cathode reaction in Eq. [2]. k in particular depends on the interactions associated with the insertion reaction. The ϵ_e^0 's as given by Eq. [16] contain the effective conductivities κ_e and κ_i . The magnitudes of these are critical for the battery performance. It should be realized that these conductivities are effective values, including the effects of volume fraction, tortuosity, contact resistance between particles, and voids in the electrode. All this adds up to a considerable reduction in the effective

Fig. 6. Calculated discharge curves. $\kappa_e \gg \kappa_i$. (1) $E_1^0 = 16, K = 16$; (2) $E_1^0 = 24, K = 6$; (3) $E_1^0 = 16, K = 24$; and (4) $E_1^0 = 24, K = 24$. Transition points indicated by arrows.

Fig. 7. Calculated discharge curves demonstrating the effect of electronic resistance. Parameters as indicated.

conductivities compared with those of the pure substances.

As the electrolyte and insertion compound particles act as nonconducting diluents for each other, some guidance as to the magnitudes of the effective values can be obtained from the study of conductivities of heterogeneous systems as carried out by Meredith and Tobias (26) and later discussed by Newman and Tiedemann (27). According to these authors, κ_i and κ_e can be estimated from the volume fractions and the conductivities of the pure substances κ_i^0 and κ_e^0 by the relations

$$\kappa_i/\kappa_i^0 = (1 - v)^\alpha; \quad \kappa_e/\kappa_e^0 = v^\alpha \quad [50]$$

where the exponent α has a value in the range $1.5 < \alpha < 2.5$. Using Eq. [50], ϵ_e^0 and ϵ_1^0 can be written as

$$\epsilon_1^0 = F \frac{l^2 c_0 v}{\tau_D \kappa_i^0 (1 - v)^\alpha} = - \frac{l}{\kappa_i^0 (1 - v)^\alpha} \cdot i^*$$

and [51]

$$\epsilon_e^0 = F \frac{l^2 c^0}{\tau_D \kappa_e^0 v^{\alpha-1}} = - \frac{l}{\kappa_e^0 v^\alpha} \cdot i^*$$

From these relations, it can be estimated how the different design parameters and the discharge regime influence the course of the discharge curve and thus, the obtainable materials utilization. For example, for different loads it is obvious that the ratio l^2/τ_D should remain constant for a given electrode composition in order not to change the discharge behavior.

Due to the uncertainty present in estimates of the effective conductivities, it is certainly a safer approach to consider the effective κ 's as phenomenological parameters characteristic for a given electrode composition, grain size, and fabrication technique, and to measure them directly on a sample electrode.

This can be done using blocking electrodes for M^+ ions and electrons, respectively, considering the composite as a mixed conductor, and using the methods discussed, e.g., by Rickert (28). It is important in these measurements to observe the requirement of electrochemical equilibrium between the insertion compound and the electrolyte.

Alternatively, estimates of $\epsilon_e^0 + \epsilon_i^0$ and k can be found from the discharge curves when the current is chosen low enough to allow development of the linear region. In these cases, k is the slope of the linear part, while the position of the discharge curve (corrected for the potential difference across the separator) according to Eq. [35] or [49] allows determination of $\epsilon_e^0 + \epsilon_i^0$ for a given current. In cases $\kappa_e \gg \kappa_i$ ($\beta = 0$), the potential difference across the separator can be found from the instantaneous voltage transient when switching the current on or off.

As mentioned above, a consequence of the immobility of the compensating charges in the electrolyte is the possibility to discharge the composite electrode until $T = 1$, as discussed in the derivation of Eq. [47]. However, the predictions which can be made for this part of the discharge are less precise than the predictions for the square root and linear regions. First it must be realized that the assumption about a linear potential/composition relation has limited validity. For $X > 0.95$, a relation like Eq. [10] is a better approximation to the potential dependence, thus causing a steeper slope of the discharge curve and a lower end-point voltage. Also for that part of the discharge, where only a small part of the electrode is active, the assumptions about equilibrium in the insertion compound particles and on the surface of these cannot be maintained because of the high final local current transfer. For $T > 0.95$ the influence of these limitations must be studied using a numerical technique as discussed in our previous paper (14).

Conclusion

The discharge behavior of a composite electrode containing a finely divided insertion electrode material can be adequately described by the ionic and electronic conductivities of the composite and the slope of the EMF/composition curve for the insertion compound.

Using reasonable approximations, the course of the discharge curve for a given electrode can be calculated analytically for a specified constant current load. Due to the immobility of the compensating charges in the solid electrolyte, theory predicts that a materials utilization near 100% can be obtained to an acceptable discharge end point.

The possibility of realizing these advantages depends on the availability of a good solid ion conductor for the inserted ion. The fulfillment of this requirement is facilitated by the possibility of operating this type of electrode at a moderately increased temperature.

Technologically, the realization of the composite electrode concept requires the development of a fabrication technique which results in a structure consisting of two contiguous networks of electrolyte and insertion compounds in intimate contact.

APPENDIX

The heat conduction problem (25)

$$0 \leq x \leq l, V = 0 \text{ for } t = 0$$

$$\frac{\partial V}{\partial x} = 0 \text{ for } X = 0; \frac{dV}{dx} = \frac{F^0}{K} \equiv A \text{ for } x = l \quad [\text{A-1}]$$

$$\frac{\partial V}{\partial t} = \kappa \frac{\partial^2 V}{\partial x^2}; \kappa = \frac{K}{\rho c} \equiv \gamma$$

has (loc.cit.) the solutions

$$V = A\gamma \cdot t/l + A(x^2/2l - l/6) - \frac{2}{\pi^2} \sum_1^{\infty} \frac{(-1)^n}{n^2} \exp[-n^2\pi^2\gamma t/l^2] \cos n\pi x/l$$

and

$$V = 2A\sqrt{\gamma t} \sum_0^{\infty} \left(\operatorname{ierfc} \frac{(2n+1)l+x}{2\sqrt{\gamma t}} + \operatorname{ierfc} \frac{(2n+1)l-x}{2\sqrt{\gamma t}} \right) \quad [\text{A-2}]$$

Equations [24] and [28] can be written

$$U = U(Z, T) \quad 0 \leq Z \leq 1; U(Z, 0) = 0$$

$$\partial U/\partial Z = \alpha_1, Z = 0; \partial U/\partial Z = \alpha_2, Z = 1$$

$$\frac{\partial U}{\partial T} = \gamma \frac{\partial^2 U}{\partial Z^2} \quad [\text{A-3}]$$

Let $R = R(\tau, T)$ and $S = S(s, T)$ be defined by

$$\frac{\partial R}{\partial T} = \gamma \frac{\partial^2 R}{\partial \tau^2}; \quad \frac{\partial S}{\partial T} = \gamma \frac{\partial^2 S}{\partial s^2}$$

$$S = R = 0, T = 0; \quad s = 1 - \tau$$

$$\partial R/\partial \tau = 0, \tau = 0; \quad \partial R/\partial \tau = -\alpha_1, \tau = 1 \quad [\text{A-4}]$$

$$\partial S/\partial s = 0, s = 0; \quad \partial S/\partial s = \alpha_2, s = 1$$

Then, $U = R + S$ is a solution to [A-3]. From Eq. [A-1], for $l = 1$, $x = \tau = 1 - Z$, and $A = -\alpha_1$

$$R = -\alpha_1\gamma T - \alpha_1(1/3 - Z + \frac{Z^2}{2} - \frac{2}{\pi^2} \sum_1^{\infty} \left[\frac{(-1)^n}{n^2} \exp[-n^2\pi^2\gamma T] \cos n\pi(1 - Z) \right])$$

And for $x = s = Z$, $A = \alpha_2$

$$S = \alpha_2\gamma T + \alpha_2 \left(Z^2/2 - 1/6 - \frac{2}{\pi^2} \sum_1^{\infty} \left[\frac{(-1)^n}{n^2} \exp[-n^2\pi^2\gamma T] \cos n\pi Z \right] \right)$$

leading to

$$U = (\alpha_2 - \alpha_1)\gamma T + (\alpha_2 - \alpha_1)Z^2/2 + \alpha_1 Z - \alpha_1/3 - \alpha_2/6 \quad [\text{A-5}]$$

$$- \frac{2}{\pi^2} \sum_1^{\infty} \frac{(-1)^n}{n^2} \exp[-n^2\pi^2\gamma T] [\alpha_2 \cos n\pi Z - \alpha_1 \cos n\pi(1 - Z)]$$

or using Eq. [A-2]

$$U = 2\sqrt{\gamma T} \left[\alpha_2 \sum_0^{\infty} \left(\operatorname{ierfc} \frac{2n+1+Z}{2\sqrt{\gamma T}} + \operatorname{ierfc} \frac{2n+1-Z}{2\sqrt{\gamma T}} \right) - \alpha_1 \sum_0^{\infty} \left(\operatorname{ierfc} \frac{2n+Z}{2\sqrt{\gamma T}} + \operatorname{ierfc} \frac{2n+2-Z}{2\sqrt{\gamma T}} \right) \right] \quad [\text{A-6}]$$

Inserting $\gamma = K/(E_e^0 + E_i^0) = 1/L_c$ and $\alpha_1 = -E_e^0/K = -\beta E_i^0/K$, $\alpha_2 = E_i^0/K$ in Eq. [A-5] and [A-6] gives Eq. [31] and [32].

LIST OF SYMBOLS

c^0	saturation concentration of inserted ion in insertion compound
f	interaction parameter in Eq. [10]
i^*	overall discharge/charge current density
i_e	local electronic current density
i_i	local ionic current density
i_t	transfer current per unit electrode volume
k	slope of linearized Eq. [11]
l	thickness of composite electrode
n	amount of M^+ in HM_x at saturation and also variable in Eq. [31] and [32]
t	discharge/charge time, time coordinate
x	amount of M in HM_x
v	volume fraction of insertion compound
z	length coordinate $0 \leq z \leq l$
D_c	apparent chemical diffusion coefficient for M^+ in composite
H	insertion compound
M^+	inserted ion

T in RT/F , Kelvin temperature

Dimensionless Variables and Groups

E dimensionless potential, $E_i^m = \epsilon_i^m F/RT$ (for significance of superscripts and subscripts see ϵ)
 K $k \cdot F/RT$
 L_c load factor, τ_c/τ_D
 X degree of insertion, $X = x/n$
 T degree of discharge, $T = t/\tau_D$
 Z length coordinate, $Z = z/l$
 Z* boundary between saturated and active part of electrode

Greek Letters

α exponent in Eq. [50]
 β ratio of ionic to electronic conductance and also $\beta = \epsilon_e^0/\epsilon_i^0$
 ϵ insertion compound electrode potential, $\epsilon = \pi - \phi$
 ϵ_θ standard potential in Eq. [10].
 ϵ_0, ϵ_1 ϵ at back and front of electrode, respectively
 ϵ_c working potential of electrode
 ϵ^* electrode potential before discharge
 ϵ_e^0 $-i^* \cdot l/\kappa_e$
 ϵ_i^0 $-i^* \cdot l/\kappa_i$
 ϕ Galvani potential in electrolyte
 κ_e, κ_i effective electronic, ionic conductivities in composite (bulk values)
 κ_e^0, κ_i^0 electronic, ionic conductivities of insertion compound and solid electrolyte
 π Fermi potential in insertion compound ($\pi = -\bar{\mu}_e/F$)
 τ_c time constant for composite electrode = l^2/D_c
 τ_D stoichiometric discharge time = $-F \cdot v \cdot c^0 \cdot l/i^*$

Technical Notes

Rare Earth-Activated Niobates

W. A. McAllister

North American Philips Lighting Corporation, Bloomfield, New Jersey 07003

Alkaline earth niobate phosphors were described some time ago (1, 2), the best materials being calcium and cadmium niobates ($\text{Ca}(\text{Cd})\text{Nb}_2\text{O}_6$) emitting in the blue and having the columbite structure. Other niobates with intrinsic blue emission are based on the fergusonite structure (3), e.g., yttrium niobate (YNbO_6), and have been shown to be good hosts for activation by other rare earths. Energy is transferred from host to activator giving, in the case of Eu^{+3} , emission largely that of the latter species. Since there were no reports of a similar role for the calcium or cadmium niobates, we have investigated the luminescence characteristics of these materials, their

solid solutions, and rare earth activated materials derived therefrom.

Experimental

Phosphors were prepared by reacting SL grade calcium carbonate (GTE) and cadmium oxide (99.99% American Metals and Chemicals) with optical grade Kawecki-Berylco niobium pentoxide; rare earths, when present, were 99.99% Molycorp oxides. Firing was in air or nitrogen (Tb-activated materials only) for 2h at $1100^\circ\text{--}1400^\circ\text{C}$, the higher temperature being required for high calcium [>50 m/o (mol percent)] members of the series. A slight excess of Nb_2O_5 was also required in these latter formulations to suppress formation of the $\text{Ca}_2\text{Nb}_2\text{O}_7$ structure (4).

*Electrochemical Society Active Member.

Fig. 1. Spectral characteristics of $\text{Ca}_{1-x}\text{Cd}_x\text{Nb}_2\text{O}_6$ phosphors.

Product purity was ascertained by x-ray diffraction using a Philips Model APD instrument. Brightness comparisons were made using filtered radiation from a low pressure mercury discharge as the source, a Spectra Brightness Spot meter as the detector. Other spectral characteristics were measured using a Perkin-Elmer MPF44-B instrument with a microprocessor unit for correcting spectra.

Results

Although all phosphors in the solid solution series $\text{Ca}_{1-x}\text{Cd}_x\text{Nb}_2\text{O}_6$ have a broad emission band peaked at 470 nm for excitation peaked sharply at 285 nm, the cadmium-rich members are superior (Fig. 1). The best such material has an emission spectrum similar to "Blue Halo" and with a peak intensity about 75% of that of the latter under 254 nm excitation.

The rare earths were introduced, with sodium as a charge compensating species for substitution on the divalent Ca^{2+} cation site, as activators in the $\text{Ca}_{1-x}\text{Cd}_x\text{Nb}_2\text{O}_6$ series. Only those discussed below gave characteristic

Ln^{3+} emission, excitation being via a charge transfer band of the host at 285 nm and in the 350-500 nm range where the host emits and rare earth f-f transitions occur. The rare earth concentration for best Ln^{3+} emission ranged from 5 to 12%; the brightest generally being noted for the cadmium end member of the series (Table I). The exceptions were in the terbium activated group, the fired group products having tan body colors indicating some (unknown) amounts of Tb^{4+} species and precluding meaningful comparisons.

The emission spectra of the $\text{Ca}_{0.4-2x}\text{Cd}_{0.6}\text{Nb}_2\text{O}_6:\text{Ln}_x\text{Na}_x$ group are depicted in Fig. 2-6. All have considerable host emission except europium which has only the characteristic 612 nm emission.

Discussion

In niobates, excitation is due to transfer of an electron from one of the highest filled molecular orbitals on an adjacent oxygen (O^{2-}) to one of the lowest unfilled orbitals located on the Nb^{5+} ion (5). The columbite structure of these materials is characterized by edge sharing of nio-

Fig. 2. Spectral characteristics of $\text{Ca}_{0.4-2x}\text{Er}_x\text{Na}_x\text{Cd}_{0.6}\text{Nb}_2\text{O}_6$ phosphors.

bate (NbO_6) octahedra, which are further joined at corners to form chains oriented along the C axis; the divalent spe-

cies bridging these chains are in a distorted cubic array of oxygen ions (6). Since all of the $Ca_{1-x}Cd_xNb_2O_6$ phosphors

have the columbite structure, the superiority of cadmium-rich materials must be associated with differences in the divalent ions. Although their orbital radii are similar (7), the three calcium 3p orbitals and five cadmium 4d orbitals differ in directional characteristics. In the poorly defined site symmetry, the latter may overlap with the adjacent oxygen ions, the result being delocalization of the metal d electrons to the oxygens which, in turn, are coupled to the niobium metal ions. The presence of these electrons enables their participation in the $\text{O}^{2-} \rightarrow \text{Nb}^{5+}$ charge transfer and enhancement of the luminescence intensity; the calcium 3p orbitals apparently do not participate to as great an extent in this electron sharing.

This superiority of cadmium-based host materials extends to those in which the divalent metal ions were replaced by $\text{Ln}^{+3}\text{-Na}^{+1}$ combinations. Although the ratio of rare earth/host emission intensities varied with the

lanthanide, phosphors without calcium had the greatest overall intensity for all rare earths. In all cases, the rare earth must compete with niobate for energy to generate the Ln^{+3} emission and only europium is very successful. However, the plaque brightness of the europium-activated niobate is only 35% that of $\text{Y}_2\text{O}_3\text{:Eu}$, indicating considerable energy dissipation in an otherwise efficient host material. This may be due to the electron delocalization implied by orbital overlap. The attendant electron mobility could lead to color center formation by trapping at defects, *e.g.*, sodium vacancies, always present in solids. Evidence for such was noted by exposing plaques of host and rare earth-activated niobates of both calcium and cadmium to the radiation (254 + 185 nm) from a quartz Sterilamp, in an evacuated glass apparatus for 100h. The resulting depreciation was considerably greater for cadmium niobate materials (Table II), and the body

color darkening, which accompanies color center formation, was very apparent.

Use of Plasma-Deposited Si₃N₄ as an Oxidation Mask in the Fabrication of GaAs Shallow-Homojunction Solar Cells

G. W. Turner and M. K. Connors

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173-0073

The optimum junction depth in shallow-homojunction n⁺/p/p⁺ GaAs solar cells is approximately 500Å (1). In the fabrication of these cells, the technique of anodic oxidation and stripping is utilized for thinning the n⁺ layer from its as-grown thickness, which is generally 1000-1500Å, and the final oxidation step is employed to form an antireflection (AR) coating. High efficiency cells have been fabricated with either a tin front contact grid applied before anodic oxidation (1) or a gold front contact grid applied after the final oxidation (2). However, neither metallization scheme is ideal.

Since a passivating oxide layer is formed on Sn during anodic oxidation, Sn contacts can be electroplated on the n⁺ GaAs surface prior to the oxidation process. This procedure is advantageous because it permits the solar cell current and voltage to be monitored after successive oxidation steps, making it convenient to optimize the thickness of the n⁺ layer. However, the bulk electrical conductivity of Sn is only about one-fifth that of Au. Therefore, to obtain comparable series resistance requires the use of thicker Sn layers, which can lead to additional shadowing losses because of the expansion of the contact grid line-width during electroplating. In addition, there is evidence from scanning electron microscopy that an interfacial oxide layer can be formed between the Sn and GaAs during anodic oxidation. Such a layer can increase the contact resistance and therefore decrease the cell fill factor and conversion efficiency.

Unlike Sn, Au does not become passivated during anodic oxidation. Previously, therefore, it has been necessary to deposit Au contact grids after the completion of the thinning process, making it impossible to monitor the cell characteristics after successive oxidations. Furthermore, the reduction in the thickness of the n⁺ layer separating the contacts from the junction increases the risk that extended high temperature operation will lead to junction degradation due to the diffusion of Au into the GaAs.

Plasma-deposited Si₃N₄ has been used in MOS technology as a final passivation layer (3), since it provides an inert barrier to Na and H₂O contamination and can be deposited at a relatively low temperature. In this study, we have found that Au contacts can be protected from dissolution during anodic oxidation by coating them with a film of plasma-deposited Si₃N₄. The use of this technique makes it possible to take advantage of the higher conductivity of Au while retaining the ability to monitor cell performance after the successive oxidation steps. Plasma-deposited Si₃N₄ has been used previously for antireflection coatings on InP solar cells (4), Si solar cells (5), and

InP/InGaAsP light-emitting diodes (6), but not in the fabrication of GaAs solar cells.

Experimental Procedure and Film Properties

The basic solar cell structure was prepared by using vapor-phase epitaxy to grow successive p⁺, p, and n⁺ GaAs layers on p⁺ GaAs substrates, as described previously (2). The Au contacts were formed by either electroplating or evaporation of Au layers 0.3-1.0 μm thick. The protective Si₃N₄ films were deposited at rates of ~160 Å/min in a Plasma-Therm PK1250 multiversion system. The substrate temperatures were in the range of 100°-200°C. The relative flow rates of N₂, SiH₄, and NH₃ were about 30:1.6:1, and the deposition pressure was 0.55 torr. The RF power density was 0.07 W/cm² at 13.56 MHz.

The Si₃N₄ films were characterized by several techniques. Index of refraction and thickness measurements were made at a number of points on each film with a Rudolph Research Auto EL-III automatic ellipsometer. The index of refraction was generally found to be 2.00 ± 0.04, and the thickness uniformity was approximately 5% over 2 in. diam test wafers. The reproducibility of the films was confirmed by wet etch tests in a solution of 20:1 H₂O:HF, which consistently gave etch rates of 1000-2000 Å/min.

Because the n⁺ layer is so thin in shallow homojunction GaAs solar cells, the quality of the n⁺/p junction is very sensitive to damage to the GaAs surface. Any such damage caused by the plasma deposition process or by stress incorporated in the Si₃N₄ film could significantly increase the leakage current, thus degrading the open-circuit voltage and fill factor of the cells. To test the effect of the deposition process, we etched off the anodic oxide layer from a high efficiency solar cell that had been fabricated by our conventional technique (2) and measured the cell I-V characteristics. A film of Si₃N₄ about 2000Å thick was deposited on the n⁺ GaAs surface and then removed, after which the I-V characteristics were re-measured. The open-circuit voltage and fill factor of the cell were found to be unchanged. In contrast, deposition and removal of pyrolytic SiO₂ and PSG generally resulted in degradation of these parameters.

We have demonstrated the low intrinsic stress of the plasma-deposited Si₃N₄ films by using a Tropel 9000 interferometer to examine GaAs and Si wafers before and after deposition of films about 2000Å thick. There was no detectable change in the free-standing radius of curvature of the wafers. To evaluate the intrinsic tensile stress, a membrane deflection technique (7) was used for measurements on films deposited on several Si wafers. The average stress was 9×10⁸ dyn/cm², well below the values of ~4×10⁹ dyn/cm² that were measured by the same tech-

nique for Si_3N_4 films deposited by low pressure chemical vapor deposition.

Solar Cell Results

The optimum thickness of Si_3N_4 to be used for protection masks was determined by experiments on shallow homojunction solar cells fabricated by the procedure shown in Fig. 1. An $n^+/p/p^+$ structure was grown by vapor-phase epitaxy, a 3000Å Au layer was deposited by evaporation on the as-grown GaAs surface and patterned to form a front contact grid, and the entire surface was covered with a layer of Si_3N_4 . Next, a photoresist etch mask was defined over the contact fingers, making certain that there was sufficient overlap for sidewall coverage, and the Si_3N_4 between the fingers was removed with a dilute HF etch. The remaining photoresist was removed, an electrical contact was made to the back of the sample, the sample was mounted face up on a glass slide with a low-melting point wax, and anodic oxidation was performed in the manner described previously (2). Measurements on solar cells fabricated by this procedure showed that a layer of Si_3N_4 2000-3000Å thick is sufficient to protect the Au fingers during anodic oxidation without producing any detectable degradation in the cell parameters.

The Si_3N_4 masking process was then used in fabricating a number of shallow-homojunction solar cells with anodic oxide AR coatings. The I-V characteristic of the best 0.51 cm^2 cell is shown in Fig. 2. The open-circuit voltage V_{oc} is 0.97V, the short-circuit current density J_{sc} is 24.7 mA/cm^2 , and the fill factor is 0.84, giving an AM1 conversion efficiency of 20.1%. This fill factor is higher than the best values that have been obtained for shallow homojunction GaAs cells fabricated using earlier metallization procedures (6). For a 0.0925 cm^2 , 20% AM1 cell fabricated on the same wafer, the diode factor A is 1.1 and the reverse saturation current density J_0 is 1×10^{-17} A/cm^2 . These values were determined from the $\log J_{sc}$ vs. V_{oc} data plotted in Fig. 3 by fitting the straight line shown with the diode equation $J_{sc} = J_0 [\exp(qV_{oc}/kT) - 1]$, where q is the electronic charge, k is Boltzmann's constant, and T is the absolute temperature. These values of A and J_0 are the same as the best values previously obtained (8), confirming the fact that the plasma deposition process does not cause junction degradation.

Conclusion

We have demonstrated a new process that utilizes plasma-deposited Si_3N_4 films for protective masks in the fabrication of high-efficiency GaAs solar cells. The use of gold front contact metallization during anodic oxidation has made it possible to prepare cells with fill factors higher than those previously obtained. Plasma deposition

Fig. 1. Solar cell fabrication procedure using Si_3N_4 protection mask

Fig. 2. Photocurrent density as a function of voltage for GaAs cell with 20% conversion efficiency at AM1.

Fig. 3. Short-circuit current density J_{sc} as a function of open-circuit voltage for a 0.0925 cm^2 cell fabricated on the same wafer as the cell of Fig. 2.

of Si_3N_4 can be used on these shallow-junction GaAs devices with no degradation of junction properties. This process may be useful for other devices that employ anodic oxidation or require deposition of Si_3N_4 in their fabrication.

The Effect of Particle Size on the Electrical Conductivity of CuCl (Al₂O₃) Composites

M. R-W. Chang,¹ K. Shahi,² and J. B. Wagner, Jr.*

Center for Solid State Science and Departments of Chemistry, Mechanical, and Aerospace Engineering and Physics, Arizona State University, Tempe, Arizona 85287

The purpose of this note is to report the effect of dispersoid size on the electrical conductivity, σ , of CuCl containing insoluble Al₂O₃ particles. Enhanced conductivity of electrolytes containing Al₂O₃ was first reported by Liang (1). Subsequently, Jow and Wagner (2) studied the CuCl (Al₂O₃) system but utilized only two particle sizes (0.06 and 0.3 μm Al₂O₃). Shahi and Wagner (3) studied AgI (Al₂O₃) using Al₂O₃ of 0.06, 0.3, 1, 3, 8, and 15 μm size, but only at 24°C. For AgI containing 30 mol percent (m/o) Al₂O₃ they reported an enhancement for all particle sizes; although for samples containing 1, 3, 8, and 15 μm , there was very little change in conductivity (see Fig. 1). In the present work, a similar study was carried out for CuCl (Al₂O₃) between 25° and 390°C.

CuCl, 99.999% pure from Apache Chemicals, Incorporated, was dried at 100°C under vacuum for at least 10h. The particle size of this CuCl was about 3 μm . Alumina, 99.98% pure from Adolf Meller, was dried under vacuum at about 700°C for at least 12h. Weighed amounts of the two powders were mixed, sealed in a quartz tube, and heated at 580°C (mp of CuCl = 493°C) for 8h. The product was quenched to 25°C, pulverized, and pressed at 85 kpsi into pellets, 9.5 mm diam \times 2-3 mm thick. The densities were 90% theoretical. The pellets were sandwiched between 99.999% copper electrodes. Purified argon flowed over the sample, which was annealed at 380°C for 5h prior to onset of measurement using 1 kHz ac.

After measurements, selected samples were thermally etched under vacuum at 350°C for about 7 min and then examined by a SEM which was fitted with an EDAX analyzer. The grain size of the CuCl matrix was 5-15 μm , with \sim 10 μm being the most usual. Agglomeration was not observed for Al₂O₃ of sizes $>$ 1 μm , but did occur for the smaller sizes. Figure 2 shows a plot of $\log \sigma$ vs. $1/T$ for undoped CuCl containing 0.06 and 0.3 μm Al₂O₃. The maximum enhancement occurred at 10 m/o of 0.06 μm Al₂O₃. This is in reasonable agreement with data of Jow and Wagner (2), who found the maximum enhancement at 20 m/o for 0.06 μm Al₂O₃ in CuCl. Jow and Wagner (2) have previously shown that the electronic conductivity of CuCl (Al₂O₃) was negligible compared to the ionic conductivity. In addition to uncertain degrees of agglomeration, the grain size of the matrix plays an important role, as has been shown quantitatively for AgCl (Al₂O₃) by Khandkar (4). Figure 3 shows an Arrhenius plot of $\log \sigma$ vs. $1/T$ for CuCl containing 10 m/o Al₂O₃ of 1, 3, 8, and 15 μm particle size.

We attempted to fit the data for the larger particle sizes to the classical model for a two-phase mixture of an insu-

lator embedded in a conductor (5-7)

$$\sigma(\text{composite}) = \left[\frac{1-f}{1+0.5f} \right] \sigma_0 \quad [1]$$

where $\sigma(\text{composite})$ is the total conductivity of the composite, σ_0 is the conductivity of the matrix CuCl without the Al₂O₃, and f is the volume fraction of the insulator, Al₂O₃. This equation did not adequately represent the data at 100°C. According to the space charge model of Jow and Wagner (2), the enhancement, $\Delta\sigma$, is

$$\Delta\sigma \approx 3 \sum_i e u_i < \Delta n_i > \lambda \left(\frac{1}{r_i} \right) \left(\frac{f}{1-f} \right) \quad [2]$$

where e = electronic charge, u_i = mobility of i th species, Δn_i = change in concentration of i th species, λ = space-charge layer thickness, f = volume fraction, and r_i = radius of insulator particle (assumed spherical). In the present studies for 10 m/o Al₂O₃, the conductivities for all samples (except 15 μm), even those with decreased ionic conductivities, were proportional to the reciprocal of r_i , as shown in Fig. 1. Likewise for AgI for the smaller particle sizes, the plot of $\log \sigma$ vs. \log particle size yields a slope of minus one. These data are consistent with Eq. [2].

At 100°C, the data on CuCl (Al₂O₃) are in good agreement with the report of Shahi and Wagner (3) who showed that Al₂O₃ of 1 μm diam resulted in a very small enhancement of σ for AgI (Al₂O₃) at 24°C. However, Shahi

Fig. 1. Logarithm of conductivity vs. logarithm of particle size for CuCl containing 10 m/o of dried Al₂O₃ at 100°C and for AgI containing 30 m/o of dried Al₂O₃ at 24°C. The slope of the straight lines is -1, in accord with Eq [2].

Fig. 2. Arrhenius plot for CuCl (Al_2O_3) for Al_2O_3 particle sizes of 0.06 and 0.3 μm .

and Wagner found that the larger diameter particles yielded almost no change in σ .

While the smaller particle sizes which result in an enhancement exhibit an Arrhenius behavior such that the conductivity approaches that of CuCl without Al_2O_3 at elevated temperatures ($\sim 250^\circ\text{C}$), the samples with the larger particle sizes (1, 3, 8, 15 μm) do not show such behavior. In these cases, the slopes of the $\log \sigma$ vs. $1/T$ plots are approximately parallel to the CuCl without Al_2O_3 additions. In the case of CuBr (Al_2O_3), the conductivity of a composite containing 10 m/o of 8 μm Al_2O_3 initially was lower than that of CuBr without Al_2O_3 , but for $200 \leq T \leq 300^\circ\text{C}$, σ exhibited a very small enhanced conductivity (8). In the present studies, the experimental error was about one-half logarithm unit for the larger particle sizes (Fig. 3). We attribute the scatter in the data in part to the difference between CuBr (Al_2O_3) and CuCl (Al_2O_3).

In summary, the conductivity of CuCl containing Al_2O_3 of 0.06, 0.3, 1, 3, 8, and 15 μm particle size has been measured between 25° and 390°C . The conductivity is enhanced for the 0.06 and 0.3 size Al_2O_3 for temperatures lower than $\sim 250^\circ\text{C}$, the maximum enhancement being over an order of magnitude for 10 m/o 0.06 Al_2O_3 at 25°C .

A Rotating Disk Electrode Apparatus for the Study of Fuel Cell Reactions at Elevated Temperatures and Pressures

J. McBreen,* W. E. O'Grady,* and R. Richter

Brookhaven National Laboratory, Department of Applied Science, Upton, New York 11973

INTRODUCTION

Much of the recent improvement in performance of phosphoric acid fuel cells has been due to fuel cell operation at elevated temperatures ($\sim 205^\circ\text{C}$) and pressures (8A) (1). Further increases in temperature and pressure are contemplated (1). Apart from increased performance, pressurization minimizes electrolyte loss via vaporization and it significantly increases the volumetric power density as a result of decreases in conduit sizes etc. Performance improvements accrue from an increase in the Nernst potential, and decreases in the activation over-voltages at both electrodes.

All previous studies of oxygen reduction in phosphoric acid have been carried out at atmospheric pressure (2-10). Recent work has confirmed that results on smooth platinum are applicable to carbon supported platinum electrocatalysts in fuel cell electrodes (9,10). This communication describes a rotating disc electrode apparatus for the study of fuel cell reactions at elevated temperatures and pressures. Preliminary data for oxygen reduction in 89.5% H_3PO_4 at temperatures up to 205°C and pressures up to 7.6A are presented.

EXPERIMENTAL

System Design.--The key to a hermetic rotating seal was the use of a ferrofluidic seal (Ferrofluidics Corp.). For this application a water cooled seal with fluorocarbon base magnetic fluid was used. Once the hermetic rotating seal had been achieved the remainder of the design involved provisions for the electrode drive, gas feed, sealed electrical feed-throughs and temperature control of the H_3PO_4 electrolyte. A schematic of the overall system is shown in Fig. 1.

The electrode drive consisted of a DC motor (Indiana General Motor Products) with a motor controller (B&B Motor and Control Corp.). The drive was coupled to the rotating seal via a flexible coupling. The

electrical leads were stainless steel wires that were fed through Conax compression fittings.

Temperature control was achieved through the use of a temperature controller and two cartridge heaters which fitted snugly inside quartz tubes. Uniform heating could be achieved by simply rotating the electrode at 400 rpm during the heating operation. This also resulted in rapid equilibrium between the overhead gas and dissolved gases.

The Cell.--The cell and cover were machined from PTFE. The cell dimensions were 8.5 cm ID x 8 cm H. The cell had a platinum counter electrode and a dynamic hydrogen reference electrode in a quartz Luggin capillary tube.

Experimental Procedure.--The methods for cell cleaning, phosphoric acid purification and platinum disc electrode preparation have been described previously (10). The cell was filled with 300 ml of electrolyte and placed in the vessel. The vessel was evacuated and backfilled with oxygen (5 psi) three times. The electrolyte was heated and runs were started at 150°C . The electrochemical measurements were done in a manner described previously (10). The cell was filled with 300 ml of electrolyte and placed in the vessel. Temperatures were increased in $\sim 25^\circ\text{C}$ intervals and pressures in 1A intervals. Thermal equilibrium could be achieved in 40 min and gas-solution equilibrium (i.e., a stable limiting current) in ~ 15 min. To avoid electrolyte composition changes, no runs were done at less than 3A above 175°C .

RESULTS AND DISCUSSION

Figure 2 shows Tafel plots for oxygen reduction in 89.5% H_3PO_4 . Up to 175°C and at pressures close to atmospheric the Tafel slope was ~ 120 mV/decade and was invariant with temperature. This anomalous behavior has been reported before (5,8,9). However,

on increasing the pressure to 3A at 175°C, the Tafel slope decreased to a value of $\sim RT/F$. At pressures above 3A the current was proportional to the oxygen pressure, indicating a first order dependence with respect to oxygen pressure. The change in Tafel slope indicates a mechanism change with increasing oxygen coverage of the platinum. The reason for this is not understood at this time. However, these results indicate that in addition to the Nernst effect and the oxygen reaction order effect there is a concomitant decrease in the Tafel slope. Thus, the electrochemical reasons for pressurization of phosphoric acid fuel cells are very cogent indeed.

TiSi₂/n⁺Poly-Si Gate Electrode Patterning by Plasma Etching Using CF₂Cl₂O₂

Toshiaki Yachi

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo, 180 Japan

The most generally used gate electrode material in MOS-integrated circuits technology is doped polycrystalline silicon. Recently, with continuously decreasing device dimensions, the relatively high sheet resistance of poly-Si becomes a limiting factor for device performance. This has led to work currently going on to incorporate refractory metal silicides into the device fabrication process (1). In order to keep the well-established quality of the poly-Si gate technology, a double layer of refractory metal silicide on top of doped poly-Si is commonly used (2).

One of the key problems in introducing refractory metal silicide/poly-Si double layers into the fabrication process is an appropriate patterning technique full-filling the demands of LSI circuits. Some reactive ion etching of refractory metal silicide/poly-Si double layers has been reported using CF₂/O₂ for MoSi₂- and WSi₂- based double layers (2, 3), and using SF₆/Cl₂ and CF₄/Cl₂ for Ta-silicide- and TiSi₂- based double layers (4, 5). These techniques, however, require stringent control for obtaining proper etching profile without a poly-Si undercut (3, 4).

The author has carried out an investigation on the plasma etching of TiSi₂/n⁺poly-Si double layers using CF₂Cl₂/O₂. A TiSi₂/n⁺poly-Si pattern with proper etching profile without a poly-Si undercut has easily been produced without pattern width reduction.

Experimental

The etching experiments were performed in a batch-type commercially available planar plasma etching system, as shown in Fig. 1. The rf power (13.56 MHz) was applied to the upper electrode (cathode) via a tuning network. The forward power was held at 400W. The cathode and the anode were also covered by quartz glass. The pumping system consists of a rotary pump and a roots blower. During the etch cycle, the pressure was maintained at 17Pa with a 50 sccm flow of CF₂Cl₂/O₂ gas. The substrate table temperature was also kept 22°C by water-cooling.

The 4 inch Si wafers used for the experiments were prepared in the following way: After growing a thin (50 nm) thermal SiO₂, 0.3 μm phosphorus-doped poly-Si was deposited using chemical vapor deposition. Ti and Si were deposited simultaneously by rf planar magnetron-

sputtering from two independent sources, one a titanium (99.94-percent pure) target and the other a poly-Si (99.999-percent pure) target. Prior to Ti and Si mixed film deposition, a dip in buffered HF removed the native oxide on top of the poly-Si. This Ti and Si mixed film is 0.2 μm in thickness. The Ti concentration is about 50 at. %.

Subsequently, the wafers were annealed at 800°C for 20 minutes in argon using a furnace. X-ray diffraction studies detect only TiSi₂ and Si crystalline phases in the annealed double layers. The sheet resistance of the annealed TiSi₂/n⁺poly-Si double layers is 1 Ω/□. The interface between TiSi₂ and n⁺poly-Si is still clear.

Lithography was accomplished by conventional photolithography in 1.2 μm positive resist AZ1370. Post-baking was performed at 180°C for 10 minutes.

Etch rates were determined by the film thickness decrease in CF₂Cl₂/O₂ plasma, which was measured by creating a step and then using the Taley Step Height Reader. For evaluating the various etch profiles for the TiSi₂/n⁺poly-Si double layers, scanning electron microscope (SEM) analysis has been carried out.

Results

Figure 2 presents the TiSi₂, n⁺poly-Si and resist AZ1370 etch rates as a function of CF₂Cl₂/O₂ gas composition. It was found that the etch rate for the as-deposited Ti and Si mixed film was not reproducible. A TiSi₂ formation anneal for 20 minutes in argon at 800°C was carried out to stabilize the silicide film etch rate. At low O₂ concentrations, the TiSi₂ etches faster than n poly-Si and AZ1370. In the 10-20-percent O₂ concentration range, the TiSi₂ to resist etch rate ratio is 7:1. At low O₂ concentrations, a relatively large etch selectivity of poly-Si over SiO₂, which is necessary for gate electrode patterning, has also been observed (etch rate ratio = 5:1).

Figure 3 shows an SEM micrograph after CF₂Cl₂ (50): O₂(0) etching. It can be seen that the TiSi₂ is etched strictly anisotropically, whereas the n⁺poly-Si shows no undercut and a proper positive slope. At 20-percent and below O₂ concentrations, similar etching profiles were obtained. Moreover, the O₂ addition decreases the residue near pattern edges which is shown in Fig. 3. No undercut of the n⁺poly-Si is consistent with the

Key Words: Films, Integrated Circuits, SEM, Etching

fact that the n^+ poly-Si is also etched perfectly anisotropically in CF_2Cl_2/O_2 at low O_2 concentrations. The proper positive slope of the n^+ poly-Si is consistent with the facts that the n^+ poly-Si to resist AZ1370 etch rate ratio is relatively small, as shown in Fig. 2, and that the resist pattern is semicircular, owing to $180^\circ C$ postbaking. These facts also indicate that the n^+ poly-Si pattern is produced in a pattern width equal to the resist pattern width before etching.

In conclusion, $TiSi_2/n^+$ poly-Si pattern with proper etching profile has easily been produced without pattern width reduction by the plasma etching using CF_2Cl_2/O_2 . This method is very useful for $TiSi_2/n^+$ poly-Si gate electrode patterning in LSI fabrication.

International Trade in Semiconductors: Challenges and Opportunities

William K. Krist

Assistant U.S. Trade Representative for Industrial Trade Policy, Executive Office of the President, Washington, DC 20506

I am pleased to meet with The Electrochemical Society to discuss some of the challenging trade issues that confront the semiconductor industry. Your industry has long been considered the symbol of American inventiveness and ingenuity. Because the products of your industry form the basic building blocks for many high technology industries, increasing numbers of nations are coming to view production of semiconductors as vital to their future. As a result, today you are facing a serious international challenge—a challenge that has led some to question your industry's, and indeed our nation's basic approach to free trade and to our industrial competitiveness.

In many ways, the challenges faced by your industry form the backdrop for the broader trade policy debate now raging in our country. Because your industry's problems are part and parcel of this broader issue of our approach to trade policy, let me talk briefly about our basic trade posture, before describing specific semiconductor issues in more detail.

U.S. Trade Policy Objectives

As you know, since the end of World War II, the United States has led the Western nations in developing a system of international rules to govern world trade, and has fostered a system based on open markets, economic freedom, and interdependence. This fundamental United States objective has been based on recognition that protectionist actions greatly facilitated the descent into the Great Depression and World War II.

This system of open trade has greatly contributed to world growth, and indeed to our substantial economic achievements. World trade grew substantially faster (7.1%) than world commodity production (4.9%) during the last two decades.

For the United States, in just the last 10 years trade has doubled as a percentage of GNP, reaching 13%. Twenty percent of what we manufacture, and 40% of our agricultural output is exported. Most of the new manufacturing jobs created in the United States in recent years have been in industries involved in international trade. Moreover, the economic interdependence that has fomented the spectacular economic growth of the postwar era has also ensured that withdrawal from this process is all but impossible. Even a country with a large and expanding internal market like the United States is increasingly dependent on the international economy for its economic well-being. Never again will the United States be able to confine its economic concerns to its domestic market. We are in international trade to stay, and we believe we have a pressing national interest in seeing this system function and flourish.

The May 30 Summit of Industrialized Nations recognized this stake in the national commitment to "halt protectionism and, as recovery proceeds, to reverse it by dismantling trade barriers." The Summit leaders also

took the courageous step of calling for a new round of trade liberalizing international negotiations in GATT.

Keeping Trade Fair

Although our position is firmly against protectionism, it cannot be over emphasized that, under United States and international rules, countries have agreed to a framework for the conduct of international trade. The purpose of this framework is to ensure that countries benefit from trade equally, and that trade flows are determined by comparative advantage to the greatest extent possible.

If a country deviates from these agreed rules, actions to restore equal competition are not only acceptable but ethically and legally right. These actions, taken in accordance with domestic and international law, must not be confused with protectionism. Through vigorous enforcement of our unfair trade statutes, we must ensure that Americans are not unfairly deprived of their jobs by other governments' trade or market distortions.

However, our target must be unfair competition, not imports in general. Imports provide needed competition for our domestic producers and more choice and lower prices for consumers. They also symbolize an important fact—that we are living in an interdependent world.

In our negotiations for fair and open trade, it is important to produce tangible results. Unless we do, the perception will grow that our trading partners refuse to play by the same rules as we do. Fair and open trade in the Japanese and European markets is important to United States industry because of the current size of these markets and their long-term growth potential.

Market Access for Semiconductors

The semiconductor industry is an area of dynamic growth with a history of intense competition and rapid technological change. The current world market for semiconductors of \$15 billion is projected to grow to \$60 billion by 1990.

Our industry's share of this global market is currently some 55%. However, our share has been declining, and, in fact, is down from 64% in 1975. The Japanese have become our principal competitors, as their share rose from 19.3% to 33%.

The United States Semiconductor Industry Association argues eloquently that this past competition has not been on an even footing. For example, the SIA points out that the Japanese have protected their home market over several decades, relative to our market. The Japanese Government gave substantial aid in the form of financial assistance, research and development, and exemptions from the general antitrust provisions of Japanese law. This assistance enabled Japanese firms to launch an export drive with high products at very low prices.

A historical analysis of Japanese legislation and government policies shows government support commencing as early as 1957, when MITI was authorized to exempt

Z
R

computers and semiconductors from antitrust prosecution and to provide financial assistance. From 1971 to 1978, MITI was authorized not only to instruct firms to take concerted action exempted from antitrust prosecution and to provide financial assistance, but to adopt "rationalization plans" for the industry. This latter step was taken to avoid "excessive" competition among competing Japanese firms.

Although the Japanese protest that these were actions taken in the past, which have since ceased, they are instructive in explaining the concentration of production in six semiconductor manufacturers, each of whom is part of a Japanese industrial conglomerate. This ensures large financial resources are available for necessary capital investment to maintain an increased market share. The Japanese producers also tend to specialize in particular product lines which further tends to reduce head-on competition.

Access to Technology

Another important area of comparison is that of access to technology. Although the United States does control export of some technologies through export administration regulations, export of semiconductors to free-world destinations is essentially free of restriction, and foreign-owned firms are allowed access to patents and technology resulting from United States Government-sponsored research and development. In most cases, United States companies are vested with patent rights and can license the technology flowing from work done under government contract. In contrast, in Japan, there are a number of barriers to technology flow including approval by MITI as to whether Japanese national interests would be served by licensing of technology. Thus, to date, technology flow has been a one-way street in the direction of Japan.

Japanese Success

The success of the Japanese semiconductor effort can be best demonstrated by examining the specific case of the 64K RAM (random access memory). Market protection, government financial assistance, and identification of this product as a priority reduced the costs and risks for Japanese firms of rapid and large-scale investment in 64K RAM production capacity. This capacity buildup resulted in aggressive pricing, and today the Japanese have captured a substantial majority of the world market for the 64K RAM.

Japanese semiconductor successes are not confined only to the 64K RAM. By 1975, Japanese global trade in semiconductors had shifted from a deficit to a surplus. Furthermore, the perennial United States semiconductor trade surplus with Japan had turned into a deficit of close to \$200 million by 1982.

We are understandably concerned with this situation and are working closely with the United States industry to address their primary goal—opening up the Japanese market. In this context, a series of discussions, which we have held with the Japanese Government, resulted in the establishment of a bilateral working group on high technology trade issues. This working group reached an agreement to establish a data base of current information on trade in semiconductors. Monthly data on bookings and billings in the United States and Japanese markets of a selected list of semiconductors is now being collected from nearly all United States and Japanese producers. The participating firms on both sides will be provided with the aggregate figures showing the trends and trade flows. Once aggregated, the data will be reviewed by the working group, which will enable both United States government and industry to monitor trends and respond quickly to problems on the basis of a set of agreed facts.

In response to United States industry's desire to remove barriers to the United States semiconductor sales in Japan, and to establish a trade regime as free as possible from government interference, we have presented the Japanese with a series of proposals for promoting semi-

conductor imports to Japan. The Japanese have agreed to consider these and possibly generate ideas of their own for improving access to sales in the Japanese market. Our objective is to implement an agreed import program by November of this year.

European Community Targeting

In evaluating future international competition in the semiconductor industry, one should also take note of the recent "technological push" implemented by the European Community in order to achieve parity with, if not superiority over, American and Japanese competitors. The program, entitled ESPRIT (European Strategic Program for Research and Development in Information Technology), allots \$1.5 billion (financed on a 50-50 basis by the Community and European Industry) to a five-year research program commencing in 1984. The program aims at establishing a new technological base for the next generation of products in the information technology sector in five key areas: advanced microelectronics, information processing, software technology, office automation, and computer-integrated manufacturing. This EC program is designed to counter a trend in which the Community went from a trade surplus in 1975 to a 1981 trade deficit of \$5 billion, which doubled to \$10 billion in 1982.

Tariffs

As of April 1, 1983, Japan and the United States had cut import duties on semiconductor products from 10.1 and 5.6%, respectively, to 4.2%. This action was five years ahead of the schedule set for the Tokyo Round Tariff Negotiations. In contrast to this, the EC is holding their tariffs at 17%, but are temporarily suspending duties for some products in order to enable downstream users to obtain supplies. The high tariffs have not proved successful to date, since the EC industry capacity is inadequate to fill any gap which might be created by a reduction of imports. In short, in our view, EC input protectionism is hurting, not helping, their own industry.

Government Initiatives

In addition to ensuring fair and open trade in semiconductors with our trading partners, there are other steps that can and should be taken to improve the competitiveness of the United States semiconductor industry.

Antitrust.—We are encouraging more joint research and development within the industry. One leading example is the formation of the Microelectronics and Computer Technology Corporation (MCC), an umbrella organization composed of major United States semiconductor computer firms which will sponsor research and development projects in the field of microelectronics and computer science.

The Administration is proposing amendments to existing antitrust legislation to encourage more joint research and development. We believe this will help the United States' competitive position by promoting efficient use of scarce technical personnel and achieving desirable economies of scale. It will give United States industry the ability to match the collaborative efforts on research and development in high technology areas undertaken by Japanese and European competitors.

The Export Trading Company Act of 1982 is also designed to encourage joint actions to increase competitiveness in world trade.

To further research, the Department of Defense is investing \$300 to \$400 million in a multiyear project related to semiconductors scheduled for completion in 1984.

Need for new relationships.—As we move forward in an increasingly interdependent world economy we simply can no longer afford the types of antagonistic relationships that have all too often existed between management and labor, industry and government. These sectors have historically considered themselves far apart with no common objectives. We simply must move toward a new spirit of cooperation. This can be accomplished if we all

pay more attention to our long-term goals which contain far more similarities than dissimilarities. For example, business labor, as much as needs a motivated and a profitable company that can fulfill its pension obligations. Recognition of this interdependence is critical for all industries in meeting the Japanese challenge.

Education.—The responsibility for ensuring a leadership position in the world economy rests not only with the Federal Government, but with a commitment to excellence on the part of each individual. The general decline of primary and secondary education poses a significant long-term threat to our economic vitality. Evidence of this decline is documented all too clearly by the recent findings of the President's National Commission on Educational Excellence. The Commission reported widespread deficiencies in the fundamentals of English, mathematics, and science.

Proper education is a *sine qua non* in high technology industries. We must consistently reexamine our educational system to ensure that it is doing the job. The Japanese population today is almost completely literate against an estimated 20% rate of illiteracy in the United States. Japanese students score high in mathematics, physical sciences, and other related areas which are important building blocks in later degrees in engineering, chemistry, and other sciences.

America has long been distinguished for the best products of her education system—the scientists, doctors, writers, engineers, and teachers who make possible sustained progress in discovery and invention and who fueled America's technological primacy in the world. Yet even the contribution of these intellectual and scientific leaders is undermined by the lack of financial incentives and social prestige accorded to them. During the seventies, the number of engineers graduating from American universities decreased sharply.

The President is interested in counteracting this trend and has proposed programs to award substantial grants to those undertaking doctoral research. Further, he has proposed measures to increase the number of math and science teachers for elementary and secondary education.

Training

Another implication of the world's rapidly changing economy is that education and professional training must become an on-going process for the many Americans whose jobs will be increasingly affected by evolving technology. The private sector now funds roughly \$30 to \$40 billion each year to update the needed skills of its employees. Such programs are of critical importance, and the President's proposal for a job voucher tax credit should encourage employers to do more on the job training for new employees.

We need to retrain displaced workers as well. The President has proposed a tenfold increase in funds to train displaced workers under the Job Training Partnership Act for which we fought last year. The program should be very promising because of greater private sector participation.

Funding

The long-term view must similarly be incorporated in new and innovative approaches to increasing the availability of low cost capital to fuel the tremendous innovativeness that characterizes yours and other industries. One example is the venture capital area which was extremely healthy through most of the sixties but which evaporated in 1969 following an increase in the capital gains tax from 25 to 49%. When the capital gains tax was reduced to 28% in 1978, venture capital investment doubled in one year and further increased in 1981 when the tax was reduced from 28 to 20%.

With this favorable United States tax policy, we anticipate that the pool of venture capital will continue to grow and will provide favorable conditions for entrepreneurs to increase the cutting edge of technological innovation. Many venture capitalists not only put up the initial funding but help in the development of markets, provide legal and financial services, and then help the company go public at an appropriate stage of development.

Cost of Capital

While today's climate for equity financing is excellent, certain penalties have been attached to this form of funding in the past. Not the least of these is the pressure for short-term profits brought by shareholders. Emphasis on such accounting criteria as earnings per share, which have little relationship to the long-term economic growth and viability of the corporation, have tended to place undue pressures on management for the "quick fix." This same approach has often been used in determining bonuses for managers.

Japanese firms, on the other hand, with their reliance on debt rather than equity financing and with the large financial reserves available to the conglomerates to which they belong, would appear to be better situated to make decisions which will benefit the long-term interests of their companies. Their situation is helped by the government funded research and development for such designated fields as the fifth generation computer, the super computer, new electronic devices, and by Japan Development Bank loans at special interest rates for specific areas of the semiconductor industry.

In addition to increased access to capital in the United States, our cost of capital must be reduced. A major aspect of the reduction of the cost of capital is to bring inflation under control, and this Administration has accomplished that. However, interest rates must be further reduced.

Conclusion

Our free trade position continues to be heavily challenged. Our growing trade deficit (\$76 billion headed toward \$100 billion) will lead to further attacks on the open trade system. On the positive side, the strong economic recovery continues in the United States on a broad basis. Second quarter real GNP growth has now been revised upward from 9.2 to 9.7%. The inflation rate for the 12 months ending in July is 2.4%—the smallest since January 1966.

As the economy continues to recover and industries feel more secure, pressures against an open trade policy should diminish, provided we deal with the deficit.

The immediate future of your industry is an enviable one of having to scramble to meet demand. Clearly, had protectionist measures been taken last year they would seem inappropriate today. We believe as you continue to emphasize the competitiveness of your industry in a better overall economic climate that you will meet the Japanese challenge which is now moving from one of improving technologies imported from the United States to "forward engineering" and the development of original technologies.

To do this, however, you will need to continue your history of innovativeness. No one should underestimate the proven ability of the Japanese to move very quickly into product development in selected areas. United States industry will need to speed up its own reaction time. In this effort, we are prepared to work closely with you to ensure that world competition is fair competition and that the United States regulatory and investment climate is inductive to growth.

A Rotating Disk Study of the Corrosion Behavior of Cu-9.4Ni-1.7Fe Alloy in Air-Saturated Aqueous NaCl Solution

C. Kato¹ and H. W. Pickering*

Department of Materials Science and Engineering, The Pennsylvania State University,
University Park, Pennsylvania 16802

ABSTRACT

Results using a rotating disk electrode (RDE) clarify the mechanism of corrosion of commercial Cu-9.4Ni-1.7Fe alloy in aerated 3.4 weight percent NaCl solution at room temperature. The loosely adherent corrosion product (mainly $\text{Cu}_2(\text{OH})_3\text{Cl}$) formed under rotating conditions consists of two layers. Additional support is obtained for the existence of a third inner layer which is very thin and adherent to the metal surface. The anodic Tafel slope on this corrosion-product-covered sample is $60 \text{ mV decade}^{-1}$ and is independent of rotation speed, consistent with a slow step for the anodic reaction being ionic transport in electrolyte within the porous corrosion-product layer. Results using Pd deposits on the corrosion-product surface show that the rate of the cathodic reaction (oxygen reduction) may be under reaction (charge transfer) control rather than transport control through a corrosion-product inner layer. It follows that the good corrosion resistance of the cupronickels in seawater may be due to a poor catalytic nature of the corrosion-product surfaces for the oxygen-reduction reaction.

Commercial Cu-9.4Ni-1.7Fe alloy (Cu10 Ni) has been used successfully as condenser tubes in saline environments (1-4). Although it is generally believed that the source of corrosion resistance of this alloy is a protective inner layer of the otherwise porous corrosion products which develop on its surface in seawater, results presented herein support an alternative protection mechanism.

In laboratory experiments in aerated 3.4 weight percent (w/o) NaCl solution at room temperature, these corrosion-product layers thickened during the first 10³h (5, 6). Anodic and cathodic polarization curves produced on the corrosion-product-covered alloy surface showed that both the anodic (metal dissolution) and cathodic (oxygen reduction) reaction rates and thus the corrosion rate of the alloy decrease as the corrosion products form. However, the amount of reduction in the cathodic rate is much larger than that of the anodic rate. In a similar experiment conducted in natural seawater, Ijesseling and Kroughman (7) also found rate reductions for both the anodic and cathodic reactions up to a certain stage of the corrosion-product formation. Thereafter, only the cathodic rate decreased, while the anodic-reaction rate held constant. Both of these results suggest that the cathodic reaction is most affected by the formation of the corrosion-product layers in aerated seawater and in 3.4 w/o NaCl solution. North and Pryor (8) also observed reduced anodic- and cathodic-reaction rates and suggested that the reductions are due to the increased anodic (ionic) and cathodic (electronic) resistances during formation of the layer. They and other investigators over the years (9, 10) have suggested that the decreased corrosion rate is correlated with the defect structure of the corrosion product layers: specifically, of a thin inner layer next to the alloy surface. Recently, however, another mechanism

based on reaction control of the oxygen reduction reaction has been suggested by Kato *et al.* (5, 6).

Compositional and structural investigations showed that the corrosion product consists of at least two adherent layers: a relatively thick porous outer layer composed of mainly $\text{Cu}_2(\text{OH})_3\text{Cl}$, and a thin inner layer composed of Cu_2O (6, 7). The alloying elements Ni and Fe were concentrated in the middle portion of the corrosion products where the exact structure is not known (6, 7). In this investigation, as a continuation of our previous work (5, 6), the kinetics of the anodic and cathodic reactions were studied using a rotating Cu-9.4Ni-1.7Fe disk electrode in aerated 3.4 w/o NaCl solution.

Experimental

Materials and specimen preparation.—The composition and mechanical properties of the Cu-9.4Ni-1.7Fe alloy (Cu10 Ni) sheet material (0.17 cm thick) in the solutionized condition (850°C for 30 min, water quench) are given elsewhere (5). Disk specimens were cut from the alloy master sheet, polished successively down to 600 grit, immersed in deaerated 10 volume percent H_2SO_4 for 10 min to remove the air-formed oxide, degreased in acetone with ultrasonic surface cleaner for 10 min, rinsed in methanol and stored (\lesssim 20h) in a desiccator. Then, the alloy disk was soldered to a copper wire and mounted in a plexiglass sample holder which exposed 0.70 cm² of sample surface, and inserted into the solution.

For the open-circuit immersion treatments, the alloy disk was rotated at 800 rpm in 300 ml of an aerated 3.4 w/o NaCl solution. Water-saturated compressed air was bubbled through the solution during immersion. The immersion treatments were conducted for various lengths of time up to 10 days. For the 10 day immersion, the solution was changed at 7 days in order to duplicate a procedure used previously for longer term tests which was designed to avoid an accumulation of Cu and Ni ions (5, 6). The initial pH was ad-

justed to 7.5 using NaOH. It tended to slowly drift upward (few tenths of a pH unit after 7 days).

For the polarization measurement, the Cu10Ni disk electrode was transferred from the open-circuit immersion cell to a conventional three-electrode cell equipped for rotation of the sample. For comparison, polarization measurements were also made on fresh alloy disk electrodes after the above-described sample preparation. Electrical contact was made between the specimen and a stainless steel shaft by a Cu wire. The shaft was supported by two frictionless carbon bearings, mounted in plexiglass, which completed the circuit. Either water-saturated compressed air or purified nitrogen gas was bubbled through the 3.4 w/o NaCl solution during the polarization measurements. A saturated calomel electrode was used as the reference electrode. The potential is reported on the standard hydrogen electrode scale.

Transfer of the sample from the immersion cell to the electrochemical cell was quick enough so that the surface of the specimen remained wet, thereby avoiding crack formation in the corrosion products (5). The potential was preset at -100 mV, so that on contact with the solution the sample was at this value while also rotating at 500 rpm. After about 15 min, by which time a quasi-steady current was reached, a potential scan rate of 0.03 mV s^{-1} was applied in the more noble direction. The anodic polarization curve was found to be the same as for a "steady-state" method.¹ In some measurements, rotations up to 2000 rpm were used to investigate the rotation-speed dependence of the polarization curve.²

Another set of experiments was conducted to study the roles of the outer and inner parts of the adherent corrosion product in the corrosion process. Following immersion and overnight drying in a desiccator, the outer part of the corrosion products was removed with poly-tape. Then, polarization curve measurements in both aerated and deaerated 3.4 w/o NaCl electrolyte solution were conducted on the adherent inner layer. Furthermore, on some specimens, palladium was deposited on the inner-layer surface from an aqueous solution, in order to study the effect of a more catalytic surface on the oxygen-reduction reaction.

Conventional x-ray diffraction SEM methods were utilized to characterize the corrosion products formed during the immersion treatments. The test specimens were always duplicated, so that the freshly made corrosion product was used for each characterization analysis.

Results

Polarization curves on fresh surfaces.—Polarization curves measured on fresh rotating disk electrode (RDE) surfaces are shown in Fig. 1. The intersection of curves B' (anodic metal dissolution) and C (true oxygen reduction) is the corrosion current ($20 \mu A cm^{-2}$) and the corrosion potential ($+5$ mV). The rotation-speed dependence of the anodic (metal dissolution) polarization curves on fresh surfaces are shown in Fig. 2. Above -30 mV, a distinct Tafel line is observed. The anodic polarization curves are less polarized at higher rpm, while the Tafel slope is constant (60 – 62 mV decade⁻¹). At potentials higher than those in Fig. 2 ($+70$ to $+170$ mV), the Tafel slope was higher at ~ 80 mV decade⁻¹. A plot of current density vs. square root of the rotation speed at constant potential (Fig. 3) shows a linear relation with an extrapolation which goes through the origin. The cathodic oxygen-reduction polarization curves are dependent on the rotation speed (Fig. 2); however, the rate decreases rather than increases with increasing rpm.

Fig. 1. Polarization curves on the fresh Cu10Ni surfaces. Curves A and A': measured in air-saturated solution. Curves B and B': measured in deaerated solution. Curve C: calculated true oxygen reduction. Rotation speed is 500 rpm.

Open-circuit corrosion.—SEM examination of corroded Cu10Ni RDE samples following immersion, showed two well-defined corrosion product layers (Fig. 4). Their thicknesses were 2.5 – $5 \mu m$ and approximately $5 \mu m$ for the outer porous and relatively dense (middle) layers, respectively. Otherwise, the corrosion products are as reported for immersion in relatively quiescent solution (6). The total (scraped) corrosion product contained both Cu_2O (in small amount) and $Cu_2(OH)_3Cl$, whereas corrosion product which could be stripped with tape showed only $Cu_2(OH)_3Cl$.

Polarization curves on corroded samples.—For the corroded RDE samples, the rate of reduction of the corrosion products was measured (deaerated solution) at -100 mV and 500 rpm (Fig. 5). The quasi-steady-state value on the 5 day corroded sample was $0.9 \mu A cm^{-2}$ cathodic, which was essentially the same, considering a rather poor reproducibility, as the current on the fresh surface ($1.5 \mu A cm^{-2}$ cathodic), indicating no substantial reduction of the corrosion products. Similar results were obtained at 1200 and 1900 rpm. These experiments also clearly showed that the current is always higher in aerated than in deaerated solution. At -100 mV, there was no visible change in the surfaces of either the 0 or 5 day samples.

Both the anodic and cathodic reaction rates are reduced by formation of the corrosion products, and, hence, the corrosion rate decreases with time (Fig. 6), in agreement with previously reported corrosion rates for this alloy-solution system (5). Both the anodic and cathodic currents for the corroded samples are also independent of the rotation speed. Near the corrosion potential, the anodic curves exhibit Tafel behavior with a slope of about 60 mV decade⁻¹ (Fig. 6 and 7). After stripping the (detachable) corrosion products, a higher anodic rate occurs on the inner layer (curve B in Fig. 7) which approximately equals that on a fresh surface (C), and the anodic reaction main-

¹ Potential was shifted manually every 10 mV, and at each potential a quasi-steady-state current was observed before changing the potential.

² Rotation speeds up to 6000 rpm are expected to produce laminar, rather than turbulent, flow for the size of the disk electrode, $r = 0.5$ cm (11).

Fig. 2. Rotation speed dependence of the polarization curves on the fresh surface. Cathodic curves measured in air-saturated solution, anodic curves in deaerated solution.

tains a Tafel slope of 60 mV decade⁻¹. In addition, an even higher cathodic current can be produced by the application of a Pd coating on the inner layer (curve D in Fig. 7). The anodic curve B (inner layer) in Fig. 7 and the cathodic curve D (Pd-coated inner layer) are rotation-speed dependent, e.g., at -30 mV, the current increases for both reactions by about 20% for an increase from 500 to 1200 rpm. This is virtually the same dependence for the anodic reaction as in Fig. 2 for a fresh surface.

Discussion

Early stage of Cu10 Ni alloy corrosion in 3.4 w/o NaCl solution.—When Cu10 Ni alloy is immersed in 3.4 w/o NaCl solution, visible corrosion products start developing on the alloy surface within 8 min (6). This early stage of the corrosion process was studied by making anodic and cathodic polarization curves on fresh RDE surfaces of the alloy.

The anodic metal dissolution curves on freshly prepared Cu10 Ni surfaces showed a Tafel slope of 60 mV per current decade and a rotation speed dependence which, in a plot of current vs. $\omega^{1/2}$, gives a straight line

Fig. 5. Cathodic current-density transient at -100 mV (SHE) and 500 rpm on freshly polished and 5 day corroded Cu10 Ni in aerated and deaerated 3.4 w/o NaCl solution.

through the origin (Fig. 2 and 3). These features are also seen in the dissolution of pure Cu in HCl (12, 13) and in NaCl (14), although the half-power dependency is not always seen (15). Higher Tafel slopes have been reported for the fresh Cu10Ni alloy in HCl solution, viz., 130 mV decade⁻¹ (13) and 70-80 mV decade⁻¹ (16), as well as at overpotentials higher than those used in the present study (3.4 w/o NaCl solution), where 80 mV decade⁻¹ was obtained instead of the 60 mV decade⁻¹ shown in Fig. 2.

The 60 mV decade⁻¹ Tafel slope for the freshly polished Cu-Ni alloy and the half-power dependency of the anodic dissolution current on the rotation speed (Fig. 3) are indicative of a mass-transfer-controlled anodic dissolution step, which is the same as that already established for copper (12-15). Thus, transport of either Cl⁻ ion to the surface or a copper chloride complex ion away from the surface could be the rate-determining step. If the anodic process at open circuit is controlled by diffusion of CuCl₂⁻ away from the surface, as is most often suggested (12-14), then the concentration of CuCl₂⁻ at the alloy/solution interface can be approximately obtained from

$$[\text{CuCl}_2^-]_s = \frac{i}{D_{\text{CuCl}_2^-} F} \cdot \delta \quad [1]$$

where $[\text{CuCl}_2^-]_s$ is the concentration of CuCl₂⁻ at the alloy/solution interface, i is the current and will be taken as the corrosion current in the following calculation, $D_{\text{CuCl}_2^-}$ is the diffusion coefficient of CuCl₂⁻, F is the Faraday constant, and δ is the diffusion layer thickness, which can be calculated by utilizing the Levich equation

$$\delta = 0.643 \omega^{-1/2} \nu^{1/6} D^{1/3} \text{CuCl}_2^- \quad [2]$$

where ω is the rotation speed and ν is the kinematic viscosity. Using typical values of ω , ν , and $D_{\text{CuCl}_2^-}$ (8.33 Hz, 0.01 cm² s⁻¹, and 0.6×10^{-5} cm² s⁻¹)³, one

³ Taken to be the same as the room temperature diffusion coefficients of CuCl⁺ and CuCl₂⁻ (17).

Fig. 7. Effect of the adherent (inner) and the detachable (outer) corrosion-product layers on the polarization curves: Curves A and A' are 5 day; B and B' are 5 day stripped; C and C' are fresh surface; D is 5 day, stripped, Pd-coated.

obtains the diffusion layer thickness of 18 μm. The corrosion current obtained on a rotating (500 rpm), freshly polished sample is determined by the intersection of the anodic and cathodic polarization curves and is about 20 μA cm⁻² (Fig. 6). Using these values of i and δ , the concentration of CuCl₂⁻ from Eq. [1] is $6.2 \times 10^{-5} M$.

Bacarella and Griess (14) and other investigators (18) suggested that the relatively high concentration of CuCl₂⁻ at the metal surface causes hydrolysis of CuCl₂⁻ and produces Cu₂O by the reaction

It follows from their results that the minimum concentration of CuCl₂⁻ to form Cu₂O for our experimental conditions is $5.5 \times 10^{-6} M$. Thus, the concentration ($6.2 \times 10^{-5} M$) obtained in this study is favorable for the formation of Cu₂O. This is still true, although more marginally so, if a more precise calculation is made in which the Ni and Fe contributions to the corrosion current are taken into account. The x-ray powder diffraction analysis of the corrosion products clearly shows the presence of Cu₂O after the 5 day corrosion. Lesser amounts of Cu₂O, below the detection capability of the technique, were presumably present at earlier stages.

The cathodic current transients in Fig. 5 show an initial drop followed by a quasi-steady state. The initial drop on the 0 day samples may be due to reduction of air-formed oxide, reaction with impurities, and/or formation of Cu₂O or other oxides which have a poorer catalytic nature (as compared to the fresh alloy surface) for the reduction of oxygen or impurities. Resolving these possibilities is difficult because of the typically rather slow rate of reaction (low exchange current density) of oxygen reduction on metal surfaces and the effects of impurities. These factors were less of an issue once the surface was covered with

corrosion products, as indicated by a better reproducibility of the transients on 5 day than on 0 day samples.

The mechanism of oxygen reduction on a Pt electrode has been well documented (19), and its Tafel slope is 110 mV decade⁻¹. However, on the freshly polished Cu10 Ni alloy, the Tafel slope is not well defined and varies between 200-260 mV decade⁻¹. The oxygen reduction rate shows an unusual rotation-speed dependency, decreasing with increase in the rotation speed. Only the last-listed of the above explanations of the initial drop of the current is also consistent with this result, i.e., regarding corrosion-product formation at the immersion potential of -100 mV. As the rotation speed increases, increasing amounts of the corrosion products may form, in accord with the effect of rotation speed on the anodic-reaction rate (Fig. 2). If so, as the rpm increases, the cathodic polarization curves are increasingly measured on the adherent solid corrosion products with their poorer catalytic nature, rather than on the alloy surface. In the same way, the observed decrease in corrosion rate with time (Fig. 6) could occur because of the decreasing catalytic activity of the surface for the oxygen-reduction reaction as the corrosion products form. The possibility of a reaction-controlled corrosion process is further indicated by the results with Pd and also by other results in sulfide-contaminated solutions (see below).

Corrosion mechanism of Cu10 Ni alloy after the 5 day immersion.—After a 5 day immersion of the RDE in the NaCl solution, the corrosion product layers are well developed on the alloy surface. Based on SEM, ESCA, and x-ray diffraction investigations, they consist of three layers (6, 20): a very porous outer layer with high concentrations of Cu and Cl; a relatively porous middle layer which contains a particularly high concentration of Ni; and a very thin inner layer which contains Cu and considerable amounts of Cl and Ni, though it is lower in Cl and higher in Ni than found for a stationary electrode (Fig. 4b). The inner layer is invisible in Fig. 4a; the presence of Cl after 60s of ion sputtering on the inner-layer surface (6, 20) shows that the layer under examination is still within the corrosion products. The detachable outer and middle layers were identified as Cu₂(OH)₃Cl. The thin inner layer was not identified directly, but is probably Cu₂O, since the x-ray diffraction analysis on the total scraped corrosion product showed Cu₂O, whereas the stripped corrosion product layers did not. The approximate thickness of the inner layer is estimated to be between 5 and 500 nm. The lower limit is obtained from the ion sputtering rate of 5 nm min⁻¹. The upper limit is based on the resolution in the micrograph. These results for the rotating alloy samples are similar to those reported for the stationary sample (5, 6), except for the finding of the middle layer which is clearly identified in Fig. 4a.

A well-developed corrosion product produces the following changes in the anodic polarization curves compared to those for a fresh Cu10 Ni surface: (i) they shift to more noble potentials while keeping a Tafel slope of 60 mV per decade current (Fig. 6) and (ii) they become independent of rotation speed. Another set of anodic polarization measurements conducted on the inner layer of the corrosion products (after stripping the loosely adherent corrosion products) showed that the curve on the inner layer (curve B, Fig. 7) is nearly identical to the curve on the fresh surface (curve C) and is rotation-speed dependent. This indicates that the outer loosely adherent layer rather than the inner layer is responsible for the changes found in the anodic polarization curves. The Tafel slope of 60 mV per decade current indicates a mass-transfer-limited anodic-reaction rate (12, 13). Since the anodic polarization curves of corroded samples are independent of the rotation speed, transport

of ions through the solution boundary layer next to the electrode surface cannot be the rate-determining step (rds) of the anodic reaction, in contrast to the situation for the fresh Cu10 Ni surface. Rather, diffusion of these ions in the electrolyte within the porous corrosion-product layer is the likely rds of the anodic reaction for corroded samples.

The important effect of establishing well-defined hydrodynamic conditions at the electrode surface is dramatically illustrated by comparison of the above anodic polarization behavior with prior work which did not employ the RDE (5). For the less well-defined hydrodynamic conditions, the Tafel slope varied from 70 to 110 mV decade⁻¹ with increasing length of the corrosion period. Actually, the 60 mV decade⁻¹ value in the present work is for a lower overpotential region; this region could be examined in the present work because of less current oscillation with the RDE. The 60 mV decade⁻¹ value is taken as a more correct Tafel slope, and is consistent with a particular rds, as discussed above. Another difference is the larger shift with the RDE of the anodic polarization curves (to more noble potentials) in going from a fresh surface to a corroded one. Thus, the anodic reaction plays a somewhat larger role in reducing the corrosion rate in the case of flowing systems than was found for quiescent solution (5), but still is only of secondary importance compared to the cathodic reaction.

Like the anodic curves, the cathodic oxygen-reduction curves were more polarized after the formation of the corrosion-product layer. The polarization measurements conducted on the outer-layer surface (curve A in Fig. 7) and on the inner-layer surface (curve B) showed no dependence on rotation speed. In contrast, with Pd⁴ on the inner layer the oxygen reduction rate was much higher and was rotation-speed dependent (curve D). Thus, neither diffusion of the reactants nor the products in the solution boundary layer is the rate-determining step, except in the presence of Pd. The fact that Pd, a well-known catalyst for oxygen reduction, greatly increases the oxygen-reduction rate supports the theory that the good corrosion resistance of Cu10 Ni alloys in seawater is due to the poor catalytic nature of the corrosion products for the oxygen-reduction reaction. It, nevertheless, is not a decisive result because one cannot rule out the possibility that Pd penetrated to the metal surface, in which case it could have short circuited electron flow through a protective inner layer. Some recent work in this laboratory in a H₂S containing aqueous solution (20), summarized next, yielded data which are, however, consistent only with a reaction, rather than transport-controlled, process.

Corrosion mechanism of Cu 10 Ni alloy in sulfide solution.—The corrosion product formed on the Cu10 Ni alloy during immersion in sulfide-contaminated (~5 ppm) 3.4 w/o NaCl solution was found to be multi-layered. The inner layer has a very small thickness, approximately the same atomic ratio of Cu to Ni to Cl but also containing a small amount of sulfide (2 a/o), and identical anodic polarization curves to that obtained on the inner layer in the sulfide-free solution (curve B, Fig. 7). The cathodic polarization curves obtained on the samples corroded in the sulfide-contaminated solution, however, show a diffusion limiting high rate of reaction similar to that obtained on the Pd-coated inner layer in Fig. 7 (curve D). However, the reaction was found to be very slow on the stripped sample, whereas it should have been unchanged after stripping if the role of the sulfide had been to increase the conductivity of a poorly conducting inner layer. Thus, sulfide increases the cathodic reaction kinetics, presumably by increasing the catalytic nature of the

⁴The exchange current density of oxygen reduction is very high on Pd, about one order of magnitude greater than on Pt (21).

surface of the corrosion products for the oxygen-reduction reaction. The low rate of reaction on the inner-layer surface after stripping could then be attributed to an insufficient level of sulfide on its (fracture) surface to significantly increase the catalytic nature of this surface for the oxygen-reduction reaction.

Conclusions

The loosely adherent corrosion products developed on rotating Cu-9.4Ni-1.7Fe alloy samples immersed in aerated 3.4 w/o NaCl solution have been found to be composed of two layers: a relatively dense middle layer and a porous outer layer. Data obtained on the composition of these loosely adherent corrosion products are largely supportive of earlier data reported for stationary electrodes (6). The presence of an inner corrosion-product layer which is very thin, adherent to the metal, and contains Cu_2O is indicated by the data.

The formation of these layers under rotating conditions produced a greater reduction in the corrosion rate than in the case of their formation under the relatively quiescent conditions of a stationary electrode. Most of the decrease in corrosion rate for either condition is due to a decrease in the rate of oxygen reduction.

For the fresh surface, the Tafel slope is 60 mV decade⁻¹ and is rotation-speed dependent. This indicates that a transport step in the aqueous boundary layer is the anodic rds. In the presence of the corrosion product, the Tafel slope is also 60 mV decade⁻¹ [in contrast to the variable 70-110 mV decade⁻¹ found for stationary electrodes (5)] but is rotation-speed independent. In this case, diffusion of ions in electrolyte within the porous corrosion products is the likely rds of the anodic reaction. Results for the cathodic reaction, though not decisive, support a reaction-control mechanism for the corrosion process. This is a (new) understanding of the good corrosion-resistant character of the CuNi alloys in seawater based on a low exchange current density for the oxygen-reduction reaction, consistent with other results (20) for sulfide-contaminated solutions. The results in sulfide, additionally, appear decisively to rule out transport mechanisms based on a protective inner corrosion-product layer.

ABSTRACT

The effects of sulfide contamination (5 ppm) on the corrosion mechanism of Cu-9.4Ni-1.7Fe alloy were studied in 3.4 weight percent (w/o) NaCl solution at room temperature. Compared to the sulfide-free solutions (i), the thickness of the corrosion products formed in the sulfide solution is much greater, and (ii) the anodic polarization curves measured in clean 3.4 w/o NaCl solution after immersion in the solution containing sulfide are somewhat less polarized but are otherwise similar, whereas (iii) the cathodic polarization curves are very much less polarized (100 times). This much increased cathodic rate is mainly responsible for the increased corrosion rate caused by prior exposure to a solution containing sulfide. After stripping the loosely adherent corrosion products containing sulfide, the corrosion rate fell to a negligible level comparable to that obtained for sulfide-free corroded samples. These results show that sulfide increases the corrosion rate through its effect on the outer corrosion products, rather than on the thin inner layer next to the metal. Since the outer corrosion products are porous, it follows that sulfide's dominant role is that of a catalyst for the oxygen reduction reaction. This explanation is consistent with other results for sulfide-free corroded samples.

Serious corrosive attack of the commercially available Cu-9.4Ni-1.7Fe alloy (Cu10 Ni) has been a problem in naval ships in polluted seawater. Such attack has been attributed to contamination of the seawater environment by sulfide (1-6). Dissolved oxygen is the normal oxidant in unpolluted seawater. In polluted seawater or subsequently in unpolluted (clean) seawater, higher rates of corrosive attack are expected in its presence (1, 5-8).

The usually good corrosion resistance of the Cu10 Ni alloy in seawater is generally attributed to the nature of its corrosion products. These corrosion products have been identified as Cu_2O and $\text{Cu}_2(\text{OH})_3\text{Cl}$ (9-14). They consist of an outer porous layer, a relatively dense middle layer and a very thin inner layer (10-12). The outer and middle layers are loosely adherent and can be removed with adhesive tape. Based on polarization measurements (9, 11), it was concluded that (i) the anodic (metal dissolution) reaction is controlled by diffusion of ions in electrolyte within the porous, loosely adherent corrosion products, (ii) the cathodic reaction (oxygen reduction) may be under reaction control, and (iii) the low corrosion rates of the Cu-Ni alloys in neutral chloride solutions may be due to the mechanism in (ii). Other explanations of the corrosion-resistant character of the cupronickels in seawater which rely on other rate-determining steps and/or are based on the inner layer have been suggested, but these have been questioned based on recent polarization data (9, 11) and are shown to be inconsistent with data in this paper. More generally, our results support the concept of reaction-control as the basis for a corrosion-resistant alloy rather than the classical protective layer concept, *i.e.*, one based on a poisoned surface for charge transfer of the cathodic reaction(s).

In sulfide-contaminated natural or simulated seawater, the corrosion products are modified and the corrosion rate sharply increases. Bates and Popplewell (1) measured the corrosion rate of the Cu10 Ni alloy in sulfide-contaminated (10 ppm) simulated seawater. They used alternating sulfidation and aeration periods in an effort to simulate service conditions involving polluted seawater, and avoided simultaneous sulfidation/aeration since sulfide levels could not be main-

tained due to reaction with the oxygen. They suggested that the higher corrosion rates are due to a highly defective Cu_2O layer containing Cu_2S which permits rapid ionic and electronic transport through it. More recently, Hack and Gudas (5, 6) and Eiselstein *et al.* (8) have shown that very high rates of corrosion, matching those of service failures, occur during simultaneous exposure to sulfide and oxygen. MacDonald *et al.* (2), using deaerated solutions, attributed the effect of sulfide to an increase in kinetics of the anodic reaction, since it changed from cuprous oxide formation in the sulfide-free solution to cuprous sulfide formation in the sulfide-polluted solution. As such, oxygen reduction was not the cathodic reaction, and the corrosion potential shifted in the less noble direction with sulfide addition.

Our previous work (9-11) has focused on the corrosion mechanism of Cu-Ni alloy in simulated unpolluted seawater (NaCl solution). This paper describes the effects of sulfide addition to a 3.4 weight percent (w/o) NaCl solution on the corrosion mechanism of Cu-9.4Ni-1.7Fe alloy.

Experimental

The composition and mechanical properties of the commercial Cu-9.4Ni-1.7Fe alloy, sample preparation, immersion, and polarization procedures are the same as described in previous papers of this series (9-11).

The sulfide-contamination solution was prepared by bubbling a $\text{H}_2\text{S}/\text{H}_2$ gas mixture through a 3.4 w/o NaCl solution which had been first deaerated with purified [anhydrous calcium sulfate (Drierite) and copper at 400°C] nitrogen. The 99.6% H_2S was dried using phosphorous pentoxide, the 99.99% H_2 was dried using drierite and magnesium perchlorate, and oxygen was removed by passing over magnesium at 400°C. The gases were then mixed using conventional flowmeters containing silicon oil (for H_2S) or dibutyl phthalate (for H_2).

For an immersion experiment, a disk sample of Cu10 Ni was rotated at 800 rpm first in the aerated sulfide-free (clean) solution for 23h, and then for 1h in a deaerated solution containing 5-8 ppm sulfide² and a pH between 7.0 and 7.5 at room temperature ($23 \pm 2^\circ\text{C}$).

² Total sulfide, including H_2S , HS^- , and S^{2-} [in the approximate ratio of 1:1:10⁻⁵ (15)], measured using a sulfide ion electrode; oxygen and sulfide were not mixed due to their tendency to react.

For the flow rate used, these values were obtained in about 30 min, see Table I. This cycle was repeated for up to 10 days total time.

Immediately after the immersion tests, some of the samples were rinsed with distilled water and transferred to a conventional three electrode electrochemical cell for polarization curve measurements in sulfide-free 3.4 w/o NaCl solution at 500 rpm, unless otherwise indicated. The 3.4 w/o NaCl solution was either deaerated (with purified N_2 gas) or aerated for some of the cathodic curves using compressed air. The polarization curves were measured from -100^3 to $+150$ mV at a potential scanning rate of 0.03 mV s^{-1} . This immersion/polarization procedure most closely follows that of experiments on sulfide-free corroded samples (9-11) which are used as a basis of comparison, and also may be an encountered corrosion situation in seawater. Corrosion currents were obtained in polarization plots by extrapolation of the cathodic curve (oxygen reduction) in order to obtain the intersection with the anodic curve measured in deaerated solution.

Following established procedures (9, 10), the corrosion products which formed during open-circuit corrosion were analyzed with x-ray diffraction, SEM, and ESCA. Moreover, EDX analyses could be conducted on the cross section of the corrosion products, since they were much thicker than those obtained in the sulfide-free solution.

Results

Compositional and structural analyses.—The corrosion products formed during immersion were separated into an outer loosely adherent and an inner adherent layer, as reported for sulfide-free solution (11). The loosely adherent corrosion products were black and the adherent inner layer was a dull reddish brown. X-ray diffraction analyses of the loosely adherent black corrosion product and of the total corrosion products scraped off the sample both show Cu_2S and $Cu_2(OH)_3Cl$. However, identification is not possible for Cu_2O , whose peaks overlap the Cu_2S and $Cu_2(OH)_3Cl$ peaks. These layers are seen in Fig. 1.

ESCA results are compared in Table II for the sulfide-free (clean) solution and the solution containing sulfide for the surfaces shown in Fig. 2. In all three locations, the Cu to Ni ratio is similar for the solution containing sulfide and the sulfide-free solution: Cu strongly predominates in locations A and C, whereas, Ni is in (slight) majority in location B. The sulfur peak was identified as sulfide (S^{--}). The concentration of S^{--} decreases from position A to C, whereas the concentration of chloride is highest at C and lowest at B for layers formed in the solution containing sulfide, see Table II.

In cross section, the adherent inner layer is too thin to be seen, however, the outer porous layer and multiple lamellae of a middle layer can be seen by SEM, Fig. 3. These loosely adherent outer and middle layers are thicker than those developed after clean corrosion (11); as such they are suitable for EDX analysis. The elemental spectrums obtained at positions D, E, and F (Fig. 3) are shown in Fig. 4 and indicate a unique

^a Electrode potential is reported on the standard hydrogen electrode scale.

experiment may cause reduction of the corrosion products in addition to oxygen reduction. The rate of reduction of the corrosion products was measured by holding a sulfide-corroded sample at a constant potential of -100 mV in the deaerated sulfide-free 3.4 w/o NaCl solution, and the current transient was compared with similar data obtained on a freshly prepared noncorroded (0 day) Cu10 Ni surface, Fig. 6. Initially, a relatively high current (80 μA cm⁻²) is measured on the 5 day sulfide-corroded Cu10 Ni sample in the deaerated (sulfide-free) solution, and this current decreases with time. The charge passed is mainly due to the reduction of the corrosion products, since no other species can be reduced in this inert gas-purged solution at -100 mV, as shown for the fresh sample (bottom curve in Fig. 6). However, the rate of reduction of the corrosion products is between one and two orders of magnitude lower than the rate of oxygen

reduction (top curve in Fig. 6), and was, therefore, ignored in subsequent polarization measurements.

Post-test anodic and cathodic polarization curves (sulfide-free solution) produced on the samples after 3, 5, and 10 day sulfide corrosion tests are compared with those produced after a 5 day sulfide-free corrosion test (11) in Fig. 7. Sulfide corrosion causes about a 100-fold increase in the cathodic current and a slight increase in the anodic current of the respective polarization curves. The corrosion rate increases from ~2 μA cm⁻² for the 5 day sulfide-free (clean) corrosion test to 400 μA cm⁻² for the 5 day sulfide corrosion test, and the corrosion potential shifts from +10 to +160 mV, Table III. The corrosion currents obtained on samples corroded for more than 5 days are not reproducible, varying between 100-500 μA cm⁻², and random detachment of portions of the corrosion-product layer occurs.

A sulfide-corroded sample which has been stripped with tape shows a much reduced cathodic rate and increased anodic rate compared to an unstripped sample (Fig. 8). Both reaction rates on the inner layer are

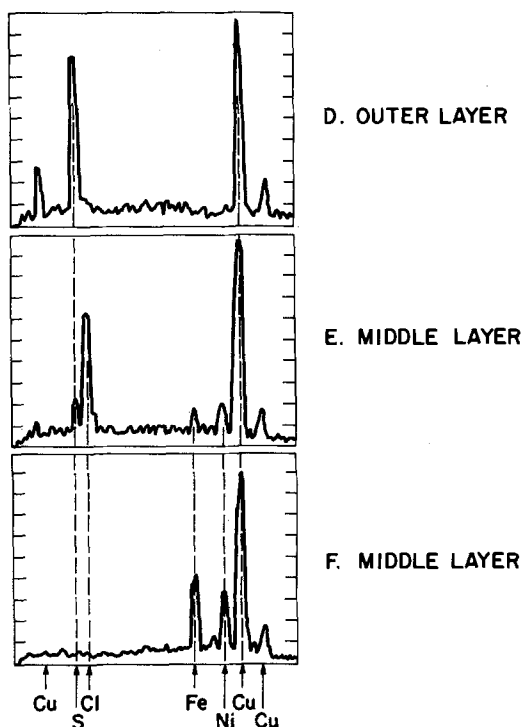

Fig. 4. EDX analyses of locations D, E, and F in Fig. 3 of the corrosion products after a 5 day sulfide corrosion experiment.

Fig. 5. A schematic of the cross section of the corrosion products on the Cu10 Ni surface after a 5 day sulfide corrosion experiment.

Fig. 6. Post-test cathodic current-density transient at -100 mV (SHE) in sulfide-free aerated and deaerated 3.4 w/o NaCl solution on 5 day sulfide-corroded samples. Transient for a fresh (0 day) sample also presented.

similar to those on the inner layer of samples corroded in sulfide-free (clean) solution (11).

Discussion

Comparison of the corrosion products formed in the sulfide corrosion test with those formed in the sulfide-free (clean) test (11) show the following. Those developed in the sulfide-contaminated solution are much thicker ($\sim 70 \mu\text{m}$ vs. $10 \mu\text{m}$ for a 5 day immersion). Both exhibit highly porous and easily detachable outer layers and an adherent very thin inner layer. The thicker sulfide corrosion products are black in color and contain Cu_2S and $\text{Cu}_2(\text{OH})_3\text{Cl}$, whereas those formed in the sulfide-free solution are dull tan and contain Cu_2O and

Table III. Corrosion currents and potentials of sulfide-degraded Cu10 Ni samples measured in sulfide-free 3.4 w/o NaCl solution. Same for Cu10 Ni samples which had been corroded instead in sulfide-free (clean) 3.4 w/o NaCl solution (11).

Time	Sulfide Potential vs. SHE (mV)	Sulfide Current ($\mu\text{A cm}^{-2}$)	Clean Potential vs. SHE (mV)	Clean Current ($\mu\text{A cm}^{-2}$)
1h	—	—	+5	18.0
1 day	—	—	+5	7.0
3 day	+80	100	+5	2.5
5 day	+160	400	+10	2.2
10 day	+100	150	+10	2.0

$\text{Cu}_2(\text{OH})_3\text{Cl}$ (11). The adherent inner layers developed in both solutions are very similar and have the following properties: (i) they are brown in color, adherent to the alloy, and thinner than could be resolved in SEM cross-sectional study, i.e., $\ll 500$ nm. (ii) They contain relatively high concentrations of Cl^- anions [~ 25 atomic percent (a/o)] and Cu and Ni cations [~ 30 a/o] with Cu predominating (ratio of 2-5 to 1).

The corrosion potentials for the sulfide-degraded alloy are more noble (80-160 mV SHE) than in the case of corrosion product formed in sulfide-free solution (5-10 mV SHE), Table III. The reason for the more noble corrosion potential is the greatly improved catalytic nature of the outer corrosion products containing sulfide for the oxygen reduction reaction, as discussed next. A shift of the corrosion potential in the noble direction for aerated solution is in contrast to a shift in the negative direction for deaerated solution (2, 3).

The polarization curves produced on the inner layer after stripping the loosely adherent outer corrosion products actually show a much reduced oxygen reduction rate compared to that on the outer corrosion

Fig. 8. Effect of the adherent (inner) layer and of the detachable (outer) layer of the corrosion products produced in the sulfide-contaminated solution and in the clean solution (11) on the polarization curves.

products containing sulfide (Fig. 8). This reduced rate is about the same (slightly higher) as that obtained on inner layers which had been produced in clean (sulfide-free) solution (Fig. 8). Thus, it is the effect of sulfide on the detachable porous outer layer which totally degrades the normally good corrosion resistant character of the Cu10 Ni alloy in neutral chloride solution. A similar increased rate of oxygen reduction was observed when Pd, a well-known catalyst for oxygen reduction, was applied as a deposit on the inner layer (11). Thus, it is concluded that the porous corrosion-product surface containing sulfide is a good catalyst for the oxygen reduction reaction, whereas normally (in the absence of sulfide incorporation during its formation) it is a poor catalyst for this reaction. This high rate of oxygen reduction ($\sim 500 \mu\text{A cm}^{-2}$) is of the same magnitude as the localized (e.g., pitting) corrosion rate in service failures [$700 \mu\text{A cm}^{-2}$ (16)], and is much larger than service failures when compared on a uniform corrosion or charge-passed, rather than localized corrosion, basis. To maintain this high rate, electron migration must be adequate through the corrosion product to the sites of the pore surfaces where oxygen reduction occurs. Electron migration is, therefore, concluded to be a relatively easy (fast) process. Similarly, the much lower anodic current on the inner layer ($2\text{--}30 \mu\text{A cm}^{-2}$) implies that its surface is a poor catalyst for the oxygen reduction reaction. The polarization data also show that ionic transport in the solid corrosion products is either adequate or not involved to an appreciable extent in the corrosion process; the latter could be the case if the inner, as well as outer, layer is porous so that an aqueous path for ionic transport penetrates to the metal surface.

High oxygen reduction rates on sulfide compounds, such as Co_3S_4 , FeS_2 , and PbS , have been reported by several investigators (17-19). The rate appears to increase with the number of unpaired d electrons per atom. Another interesting phenomenon is an affect of sulfide composition. It was shown that a sulfide of composition $\text{Fe}_{0.5}\text{Ni}_{0.5}\text{S}_2$ is 40 times more active than FeS_2 for oxygen reduction (20). Other catalyzed cathodic processes have also been reported for iron sulfides formed in steel (21). In the present work, the transition metals of Ni and Fe are alloyed with Cu. The ESCA examination revealed that these alloying elements coexist with sulfide in the loosely adherent layers with a relatively high concentration. Therefore, the very high oxygen reduction rate can be expected to be due to a much increased catalytic nature of the corrosion products containing sulfide coupled with normally adequate electronic and ionic conductances.

Conclusions

Corrosion products of Cu_2S and $\text{Cu}_2(\text{OH})_3\text{Cl}$ are developed on Cu-9.4Ni-1.7Fe alloy in sulfide-contaminated 3.4 w/o NaCl solution. Similar to the products developed in sulfide-free solution, the sulfide corrosion products consist of outer porous layers and a thin inner adherent layer. These corrosion products are much thicker (7 times) than those developed in sulfide-free solution (11) and yield a corrosion current in sulfide-free 3.4 w/o NaCl solution, which is much higher ($400 \mu\text{A cm}^{-2}$) than when the corrosion products are formed in the sulfide-free solution ($\sim 2 \mu\text{A cm}^{-2}$). This high corrosion rate, which matches or exceeds that of service failures, is attributed to the much

increased catalytic nature of the porous corrosion products for the oxygen reduction reaction when they contain sulfide.

An explanation of the corrosion-resistant character of the cupronickels in neutral chloride solutions given previously (9-11), i.e., reaction control of the oxygen reduction reaction, was confirmed by a systematic study of the anodic and cathodic polarization behavior of the sulfide-degraded Cu-Ni alloy. A definitive result was the finding that whereas sulfide-degraded Cu10 Ni has a very high corrosion rate, the rate falls to negligible levels when the porous corrosion-product layers are stripped from the sample leaving only the thin inner layer attached to the sample. The salient point is that sulfide causes degradation of the corrosion resistance through its effect on the porous layers, rather than on the adherent inner layer. This result also rules out other mechanisms of protection which involve a slow transport step and/or which postulate that the inner layer is protective in the sense of severely restricting electronic or ionic transport.

The Mechanism of Dealloying of Copper Solid Solutions and Intermetallic Phases

M. J. Pryor* and J. C. Fister

Olin Corporation, Metals Research Laboratories, New Haven, Connecticut 06511

ABSTRACT

Potentiostatic experiments in 0.5N NaCl at $-0.25 V_{SHE}$ show that the kinetics of dealloying of copper base binary alloys fall in the order

For the solutes Al and Zn, the kinetics of dealloying may be expressed by the relationship

$$\text{Log } S_e = K C_s$$

where S_e is the excess solute dissolved and C_s is the atom percent solute. K is related qualitatively to the reversible potential of the solute element. It is shown that dealloying cannot propagate into the alloys by diffusion of solute from the bulk to the surface. Instead, dealloying is maintained by solution intrusion under conditions where continuous solute paths exist in the alloy and where solute removal results in atomic rearrangement of the depleted alloy.

Extensive studies have been conducted on the dealloying of copper base alloys and particularly Cu-Zn alloys. An earlier significant issue was whether dealloying involved selective removal of Zn atoms from the lattice (1-5) or whether zinc and copper dissolved proportionately from the alloy with the copper subsequently being redeposited on the alloy surface (6-10). Except for a few special cases, this does not now appear to be a major issue. Stillwell and Turnipseed (1) succeeded in dealloying ϵ brass in dilute HCl first to γ , then to β , and finally to α brass. Pickering (5) also succeeded in dealloying ϵ and γ brass to more copper-rich intermetallic compounds in deaerated sodium sulfate solution. In these cases, there was no significant doubt that the mechanism of dealloying involved selective removal of Zn atoms from the lattices of the intermetallic phases. More recently, one of the authors (11) has shown that Cu-Mn alloys can be dealloyed in sodium chloride solution without a change in grain size or shape, thereby extending proof of selective removal of solute atoms to the solid solution region.

A second and more fundamental mechanistic issue involves the means by which dealloying is maintained over more than a few atom layers. Pickering and Wagner (12), in a study of the selective dissolution of copper from Au-Cu alloys and zinc from Cu-Zn alloys, proposed that dealloying was supported by solid-state diffusion. Because the diffusion rate of solute at room temperature is much too low to maintain the dealloying kinetics, they suggested that the selective electrochemical dissolution of more electronegative solute atoms from the alloy surface resulted in vacancy injection into the alloy. Diffusion of solute atoms to the surface was believed to be greatly accelerated by rapid divacancy diffusion, thereby permitting propagation of the dealloying process. This concept has been embraced by other investigators (13). In contrast, one of the authors (11) pointed out that the kinetics of dealloying of three copper solid solutions followed the order of

but that the diffusion coefficients did not fall in the same qualitative order. A mechanism involving electrochemical removal of more electronegative solute atoms from the surface, followed by rapid collapse of residual Cu atoms into equilibrium lattice positions, was considered to open up the surface to solution ingress and to maintain dealloying in depth by this

means. A later paper by the same author (14) suggested that diffusion through a segregated surface zone enriched in zinc could also account for the kinetics of dealloying of α brass in sodium chloride solution.

A study of the dealloying characteristics of a Cu-18.7 atom percent (a/o) Al alloy in sodium chloride solution (15) was intended to throw light on whether dealloying kinetics were controlled primarily by electrochemical factors or by diffusion. The study was somewhat inconclusive because of a large difference in a/o solute in the Cu-Al alloy (18.7 a/o) compared with the previously studied Cu-Mn, Cu-Zn, and Cu-Ni alloys (27.8-31.5 a/o solute).

The present study was conducted with the view of being able to compare the dealloying kinetics of Cu-Mn, Cu-Zn, Cu-Al, and Cu-Ni alloys over a broad composition range. In the case of Cu-Zn and Cu-Al alloys, the composition range was extended to encompass most of the intermetallic phases in these systems. Experimental study was largely conducted by a series of mass-balance experiments conducted at a potential of $-0.25 V_{SHE}$. This potential was selected on the basis of previous work on Cu solid solutions (11, 14, 15) conducted over a potential range of -0.5 to $+0.5 V_{SHE}$. At $-0.25V$, the anodic corrosion of Cu in sodium chloride containing dissolved oxygen is not completely suppressed, thereby permitting the selectivity of dealloying to be determined. In addition, the effects of grain size and cold work were investigated on α brass. Extensive diffusion calculations were conducted in an attempt to determine whether enhanced room temperature diffusion could account for dealloying kinetics.

Experimental and Results

Materials.—Three Cu-Zn intermetallic phases and five Cu-Al intermetallic phases were prepared from OFHC copper and high purity Zn or Al additions. The alloys were melted in air in a graphite crucible and poured into a preheated steel mold measuring $1.5 \times 2.5 \times 10$ cm. The phases investigated, together with their chemical compositions, are listed in Table I. The castings were homogenized for 16-18h in dry argon at the temperatures shown in Table I. Selected alloys were water quenched (Table I) to retain the desired phase.

Cu-Zn, Cu-Ni, and Cu-Mn solid solutions were prepared in the form of annealed sheet 0.075 mm thick in the same fashion as was described in earlier publications (11, 14, 16). A Cu-77.6 a/o Mn alloy was solution annealed at 800°C and water quenched (Table I).

Fig. 1. Relationship between corrosion potential and solute content for Cu-Al, Cu-Mn, Cu-Ni, and Cu-Zn alloys in 0.5N NaCl at 25°C.

Cu-29.4 a/o Zn alloy sheet 0.075 cm thick was fabricated with grain sizes of 8.5 μm by annealing for 1h at 420°C, 50 μm by annealing for 1h at 550°C, and 119 μm by annealing for 1h at 650°C.

Cold-rolled Cu-29.4 a/o Zn alloy sheet 0.075 mm thick was fabricated by annealing for 1h at 550°C at a thickness of 0.10 mm and cold-rolling 25% to 0.075 mm and by annealing for 1h at a thickness of 0.150 mm and cold-rolling 50% to 0.075 mm.

Experimental method.—Surface preparation of the cast and rolled specimens was mechanical and involved light unlubricated end milling followed by careful degreasing in benzene. Cast specimens were coated with Microstop to above the water line except for an exposed area of around 3 cm². Sheet specimens were masked with 3M pressure-sensitive tape no. 470. The exposed area was 1 cm² for Cu-53 a/o Mn and 10 cm² for all other alloys.

All corrosion experiments were carried out in 0.5N NaCl prepared from reagent-grade sodium chloride and deionized-distilled water. The solutions contained dissolved air, and experiments were carried out with the solutions freely exposed to the atmosphere. Experiments were conducted for 20h at 25° ± 0.05°C, using 200 ml of solution per specimen. Mass balance experiments were conducted potentiostatically at -0.25 V_{SHE}, where selective removal of electronegative solutes predominates (11, 14, 15). The mass balance experiments together with studies of surface morphology were carried out as described in previous publications (11, 14, 15), except that the microanalyses were performed using an Instrumentation Laboratory Plasma 10D Spectrometer.

Results.—Figure 1 shows the relationship between corrosion potential in 0.5N NaCl and composition for

Table I. Alloy compositions and heat-treatments

Alloy	Phase	Homogenizing temp (°C)	Water quench
Cu-47.3 a/o Zn	β'	600	Yes
Cu-63.3 a/o Zn	γ	600	No
Cu-83.6 a/o Zn	ϵ	500	No
Cu-22.7 a/o Al	δ	800	Yes
Cu-34.1 a/o Al	γ_2	800	No
Cu-39.2 a/o Al	δ	600	No
Cu-48.9 a/o Al	η_2	500	No
Cu-67.7 a/o Al	θ	500	No
Cu-77.6 a/o Mn	γ solid solution	800	Yes

Cu-Al, Cu-Mn, Cu-Ni, and Cu-Zn alloys. Only alloying with Mn results in a substantial depression of corrosion potential at atom percentages of solute less than 50 a/o.

Figure 2 shows the relationship between excess solute dissolved from the alloys¹ and atom percentage of

¹ Obtained by taking the weight of copper removed from the alloy, calculating the associated weight of solute from the alloy composition, and subtracting from the measured weight of solute dissolved from the alloy.

Fig. 2. Relationship between excess solute removed and solute content for Cu-Al, Cu-Mn, and Cu-Zn alloys held at -0.25 V_{SHE} in 0.5N NaCl at 25°C.

solute at a potential of $-0.25 V_{SHE}$. Only the Cu-31.5 a/o Ni alloy was resistant to dealloying. With the exception of the two terminal points on the Cu-Al curves, the results for Cu-Al and Cu-Zn alloys may be expressed by a general relationship

$$\log S_e = KC_s \quad [1]$$

where S_e is the excess solute concentration ($\text{mg}/\text{cm}^2/20\text{h}$) dissolved from the alloy and C_s is the atom percent of solute in the alloy. It is evident from Fig. 2 that, with the exception of the Cu-53 a/o Mn alloy, dealloying kinetics at constant atom percent solute fall in the order

Figure 3 shows that the selectivity of solute removal at $-0.25 V_{SHE}$ as a function of atom percent solute of Al, Mn, and Zn. It is clear that selectivity of preferential dissolution of solute atoms at constant atom percent solute is in the order

Of the various alloys studied from the mass balance standpoint, only θ Cu-Al, ϵ Cu-Zn, and Cu-53 a/o Mn exhibit corrosion potentials more active than $-0.25 V_{SHE}$. Figure 4 shows the current vs. time plot for the Cu-53 a/o Mn alloy over the 20h experiment. Calculation shows that the net anodic current flow only accounts for a Mn weight loss of around $1 \text{ mg}/\text{cm}^2/20\text{h}$, i.e., less than 1% of the total Mn dissolved from the specimen; the preponderance of the weight loss is likely galvanic in nature due to the presence of α Mn in the grain boundaries. The cathodic reaction is the reduction of oxygen dissolved in the electrolyte.

Figures 5-7 shows scanning electron micrographs of dealloyed surfaces of two Cu-Al alloys and one Cu-Mn alloy. Figure 5 is the dealloyed residue of δ Cu-Al. The surface composition² approximates that of β' Cu-Al.

²Surface compositions were determined by SEM microprobe measurements. The values reported are the average solute contents of localized elements of the dealloyed surface and subsurface to a depth of around $1 \mu\text{m}$.

Table II. Effect of grain size and cold work on the dealloying kinetics of Cu-29.4 a/o Zn at $-0.25 V_{SHE}$

Grain size (μm)	Cold reduction (%)	Excess Zn dissolved $\mu\text{g}/\text{cm}^2/20\text{h}$
8.5	0	7.8, 8.6, 5.8
50	0	5.0, 6.9, 3.8
119	0	6.8, 3.6, 4.2
52	25	5.0, 6.5, 3.3
57	50	3.8, 4.6, 6.2

Figure 6 is the dealloyed surface of γ_2 Cu-Al with the residual surface composition being α Cu-Al containing approximately 14 a/o Al. Figure 7 is the dealloyed surface of Cu-53 a/o Mn. The dealloyed residue is γ Cu-Mn containing around 4 a/o Mn. Substantial grain boundary corrosion is evident.

Table II shows the effect of grain size and cold work on the dealloying kinetics of Cu-29.4 a/o Zn in 0.5N NaCl at $-0.25 V_{SHE}$. There appears to be no significant effect of either grain size or cold work on the dealloying kinetics of this alloy.

Discussion

Figure 2 shows that, at constant atomic concentrations of electronegative solutes, dealloying kinetics fall in the qualitative order

i.e., the more active is the standard potential of the solute element, the faster will be the dealloying rate. This conclusion is similar to one made earlier by one of the authors (11), except that the critical data for the Cu-Al system was not known at that time. Figure 1 shows that neither the corrosion potentials of the solute elements nor the corrosion potentials of the alloys themselves relate to dealloying kinetics. Instead, these kinetics are related to the standard potentials of the solute elements with the copper acting as a solvent

Fig. 3. Relationship between percentage of solute dissolved and solute content for Cu-Al, Cu-Mn, and Cu-Zn alloys held at $-0.25 V_{SHE}$ in 0.5N NaCl at 25°C.

Fig. 4. Relationship between time and the anodic current drawn from a Cu-53 a/o Mn alloy held at $-0.25 V_{SHE}$ in 0.5N NaCl at 25°C.

(15). The only deviation from the foregoing relationship is provided by the dealloying behavior of the Cu-53 a/o Mn alloy, which exhibits a very high dealloying rate. At equilibrium, this alloy consists of a γ solid solution in equilibrium with α Mn (17). The present alloy was prepared using a final solution anneal (750°C for 2h) in the γ solid-solution phase field followed by water quenching in the hope of yielding a metastable single-phase alloy (11). There is no doubt from Fig. 7 and also from previous work (11) that, despite the water quenching to room temperature, there was precipitation of α Mn at the grain boundaries, as evidenced by the severe intergranular corrosion. The galvanic corrosion of this more anodic grain boundary phase is believed to account in the main for the unusually high dealloying rate of this alloy. In addition, the γ solid solution in this alloy loses the vast bulk of its Mn content, without the necessity of passing through intermediate phases having progressively slower dealloying kinetics. Indeed, the Mn content of the residual solid solution at $-0.25 V_{SHE}$ is

quite similar to that reported earlier (11) for dealloying at a potential of $0.00 V_{SHE}$.

At around 30 a/o solute, where the complication of decomposition of γ Cu-Mn solid solutions is avoided, calculations from the results in Fig. 2 show that the relationship

$$S_e = Ae \frac{-B}{\eta} \quad [2]$$

is reasonably well obeyed where S_e is the excess solute removed. A and B are constants and η , the approximate overpotential, is the difference between the set potential of the alloys ($-0.25 V_{SHE}$) and the standard potential of the solute atoms.

Figure 3 shows that the selectivity of solute removal is poor in the range of around 20-30 a/o solute for Cu-Al and Cu-Zn alloys. At higher solute contents, the selectivity falls in the order

Fig. 5. Surface of δ phase Cu-Al dealloyed for 20h at $-0.25 V_{SHE}$ in 0.5N NaCl at 25°C ($\times 2000$).

Fig. 6. Surface of γ phase Cu-Al dealloyed for 20h at $-0.2 V_{SHE}$ in 0.5N NaCl at 25°C ($\times 2000$).

Fig. 7. Surface of Cu-53 a/o Mn dealloyed for 20h at $-0.25 V_{SHE}$ in 0.5N NaCl at 25°C ($\times 2000$).

This may be attributed to the higher fields operating on Mn and Al atoms in the lattice than Zn.

Having established that electrochemical factors primarily control the kinetics of dealloying, it remains to determine whether solid-state diffusion plays any role in the propagation of the dealloying process. The fact that dealloying kinetics can be expressed by a general equation

$$\log S_e = KC_s \quad [1]$$

where K is related to E_0 for the various solutes, makes control by solid-state diffusion an unlikely eventuality. Other considerations may be brought to bear to confirm this view. For instance, the presence of vacancies or divacancies as proposed by Pickering and Wagner (12) only serve to increase the chemical diffusion rate in an alloy. Assuming that vacancies or divacancies are present in comparable concentrations in a range of alloys, then, in order for vacancy aided diffusion to be rate determining, the calculated room temperature chemical diffusion coefficients should fall in at least the same qualitative order as the dealloying kinetics. Table III contains calculated chemical room temperature diffusion coefficients for a variety of copper alloys of interest. The high temperature source data from which the results in Table III were calculated were taken from Ref. (18) (Cu-Zn), (19) (Cu-Mn), and (20) (Cu-Al). Of the values calculated, the lowest diffusion coefficient is for Cu-53 a/o Mn, which has one of the highest dealloying rates. A Cu-27.8 a/o Mn alloy dealloys at a substantially faster rate than Cu-18.7 a/o Al alloy, yet the room temperature diffusion coefficients are almost identical. The same Cu-Mn alloy dealloys faster than Cu-29.4 a/o Zn, but has a diffusion coefficient four orders of magnitude lower. Clearly, bulk diffusion coefficients at room temperature in no way correlate with dealloying kinetics.

Pickering and Wagner (12) suggested that divacancies had a sufficient diffusion rate to support the dealloying process in Au-Cu. They suggested an approximate relationship

$$D = D_{\square\square} N_s \square\square \quad [3]$$

where D is the diffusivity in the vicinity of the surface, $D_{\square\square}$ is the diffusivity of a divacancy and $N_s \square\square$ is the mol fraction of divacancies in the vicinity of the alloy surface. If one is to double the solute concentration of a copper alloy susceptible to dealloying, and one removes all the solute atoms from a constant volume in the surface and subsurface region, then the maximum increase in vacancy concentration is a factor of 2 and that of divacancies³ is a factor of 4. This would result at most in a quadrupling of the divacancy-enhanced diffusion rate. Reference to Fig. 2 shows that as the atom percent solute is increased from 30% to 60%, the dealloying rate increases by 2½-3 orders of magnitude, i.e., quite inconsistent with a vacancy-enhanced diffusion model.

The Cu-Al system provides a further check of the lack of influence of diffusion kinetics on dealloying kinetics. Table IV shows the calculated room temperature diffusion coefficients for terminal α phase and for Cu-Al intermetallic phases. There is a sharp 13 orders of magnitude increase in diffusion coefficient on passing from the α to the β' phase field. Thereafter, as aluminum content is increased, there is no large systematic change in diffusion coefficient. Despite this, as one increases the aluminum content from that in the β' phase to that in the θ phase, dealloying kinetics increase by some 4 orders of magnitude without an increase (actually, a modest decrease) in diffusion coefficient. A change of this magnitude is irreconcilable with the modest accelerating effect of vacancies or divacancies described above.

The foregoing considerations argue strongly that there is no relationship between dealloying kinetics and diffusion kinetics, irrespective of whether the solid-state diffusion is vacancy (or divacancy) enhanced, deformation enhanced, or not. The only logical conclusion that can be reached is that solid-state diffusion does not control the propagation of dealloying in copper alloys.

One of the authors had suggested (14) that the kinetics of room temperature diffusion could be rationalized with measured dealloying rates of a Cu-29.4 a/o Zn alloy if it was assumed that surface segregation of solute atoms occurred. Calculations from a treatment of surface segregation by Stüwe and Jager (21) indicated that the surface composition might approach that of disordered β brass. Using the much higher diffusion coefficient of disordered β brass, it was possible in this one case to rationalize diffusion kinetics with dealloying kinetics. A similar treatment is also contained in Table III for some of the alloys in this investigation. Column 2 contains segregated surface compositions in alloys of interest calculated from Stüwe and Jager's treatment (21). Column 4, headed "Surface," shows the room temperature diffusion coefficients in the segregated surfaces. Here, the disagreement between calculated diffusion coefficients and dealloying kinetics is even more pronounced than in the case of the bulk values. The diffusion coefficient for the segregated Cu-29.5 a/o Zn alloy is 10 orders of mag-

³ At very low divacancy concentrations only.

Table III. Calculated chemical room temperature diffusion coefficients

Alloy	Calculated (21) surface composition (300 K)	Diffusion coefficient (\tilde{D}) at 300 K (cm^2/s)	
		Bulk	Surface
Cu-18.7 a/o Al	Cu-15.5 a/o Al	2.58×10^{-34}	3.3×10^{-34}
Cu-27.4 a/o Zn	Cu 35.3 a/o Zn	1.64×10^{-30}	8.5×10^{-34}
Cu-27.8 a/o Mn	Cu-33.1 a/o Mn	1.15×10^{-34}	2.6×10^{-34}
Cu-53 a/o Mn	Cu-43.5 a/o Mn	3.19×10^{-40}	5.14×10^{-38}
Cu-31.5 a/o Ni	Cu-14.3 a/o Ni	2.39×10^{-38}	1.74×10^{-38}

Table IV. Calculated room temperature diffusion coefficients for terminal α phases and Cu-Al intermetallic phases

Aluminum a/o	Phase	\tilde{D} at 300 K (cm^2/s)
18.7	α	2.58×10^{-34}
22.7	β'	1.74×10^{-31}
34.1	γ_2	1.77×10^{-34}
39.2	δ	1.89×10^{-34}
48.9	η_2	2.95×10^{-28}
67.7	θ	3.34×10^{-28}

nitude higher than the other diffusion coefficients, but, with the exception of the Cu-18.7 a/o Al alloy, has the lowest dealloying rate found in this investigation. In summary, neither diffusion coefficients calculated on the basis of bulk composition or on the basis of surface segregation have any qualitative relationship with dealloying kinetics in Fig. 2.

An alternate propagation mechanism based on solution intrusion was suggested earlier by one of the authors (11). At around 50 a/o solute, there are clearly many continuous paths of electronegative solute element throughout a copper alloy susceptible to dealloying. These electronegative atoms in the surface and subsurface region may be easily removed by electrochemical means. Once they are removed electrochemically, the remaining copper atoms find themselves in highly unstable lattice positions. They must collapse rapidly under the influence of electrostatic forces to equilibrium lattice positions, and in so doing will create small copper-rich nuclei and new surfaces.

Forty and co-workers (22-24) in electrooptical studies of the dealloying of Au-Ag alloys containing 50 a/o Au or less in HNO₃ have proposed a mechanism involving growth of Au islands by surface diffusion succeeded by slower tunneling into the alloy. They observed dealloyed residues similar to those observed on Cu-53 a/o Mn [Fig. 9 and 10 from Ref. (11)] and somewhat less similar to the dealloyed residue from δ Cu-Al (Fig. 5). If the Forty *et al.* mechanism is applied to the Cu alloys of this study, it is clear that the surface diffusion of Cu must be rapid enough so as not to be rate limiting for the overall dealloying process. Further, the application of this model to Cu-Zn and Cu-Al alloys containing 50 a/o Cu or less is more problematical, because, under our experimental conditions, dealloying yields more copper-rich intermetallic compounds rather than essentially pure copper. Notwithstanding the difficulties outlined above, surface diffusion represents the most viable explanation for the growth of Cu from the initial nuclei or indeed, from that of the more Cu-rich intermetallic compounds.

As the solute contents of the alloys are reduced to values significantly below 50 a/o, continuous paths of solute atoms tend to be found in increasingly linear arrays, *i.e.*, at grain boundaries, edge and misfit dislocations, etc. This is likely due to these arrays containing an enhanced solute content. As shown in Fig. 6, the morphology of the dealloyed residue changes to one containing discrete channels of fairly large diameter. Similar morphologies have been reported on α Cu-Zn (14) and α Cu-Al (15) dealloyed at more noble potentials.

The nature of the electrolyte is important in the dealloying process particularly at relatively lower solute contents. Pickering and Byrne's work on brass (4) was conducted in deaerated sodium sulfate solution. In this electrolyte, the copper current ceases sharply at around 0.0 V_{SHE}. At more active potentials, only solute atoms were removed. In the sodium chloride electrolyte, a copper current can be maintained at potentials more active than 0.0 V_{SHE} by virtue of the reaction (22)

Under no conditions studies in this work was the re-

moval of solute 100% selective (Fig. 3), and some copper atoms were always removed electrochemically at -0.25 V_{SHE}. The ability to remove some copper atoms electrochemically at -0.25 V puts less of a premium on complete continuity of electrochemically active solute atoms in the alloy lattice, thereby permitting easier propagation of the dealloying process. Indeed, Fig. 3 shows that the dealloying of Cu-Zn and Cu-Al α solid solutions is comparatively nonselective in the range of 20-30% solute.

Acknowledgments

The authors thank the Brass Group of the Olin Corporation for its support of this work. They also wish to thank Dr. L. Lin for conducting the diffusion calculations, together with Mr. A. F. Beck, Mr. J. Conrod, and Mr. E. Olander for assistance with the experimental work.

Rotating Ring-Disk Electrode Studies of Cu-Ni Alloy Electrodissolution in Acidic Chloride Solutions

I. A Commercial Cu-Ni (90/10) Alloy

H. P. Lee* and Ken Nobe**

Department of Chemical Engineering, University of California, Los Angeles, California 90024

ABSTRACT

The electrodissoolution behavior of a commercial Cu-Ni (90/10) alloy with 1.7% Fe in deoxygenated acidic chloride solutions has been studied with rotating ring-disk electrodes. Alloy electrodissoolution was examined at various rotation rates, potentials, and Cl^- and H^+ concentrations. Potentiostatic experiments indicate selective electrodissoolution of Ni in the apparent Tafel region; high rates of Fe electrodissoolution are measured near the rest potential. Formation of a film consisting of mainly CuCl was discerned to begin at about the peak potential. At higher potentials where a current minimum and a current plateau are observed, electrodissoolution is nonselective and under mass-transfer control. In this region, cuprous chloride complexes are the only electro-oxidation product of the Cu component. However, at potentials above the current-plateau region, the Cu component also electro-oxidizes to cupric ions. Above the current-plateau region, electrodissoolution continues to be nonselective but under mixed activation and mass-transfer control.

An understanding of the mechanism of Cu-Ni alloy dissolution requires knowledge of the dissolution kinetics of both pure Cu and Ni. It is known that copper in chloride solutions electro-oxidizes to cuprous chloride complexes. In general, the anodic dissolution of copper in chloride solutions is under diffusion control (1-4) and is independent of pH (1-3). The reaction order with respect to Cl^- is two for low chloride solutions ($< 1M$) and is greater than two for higher chloride concentrations (1-3). Bengali and Nobe (5) have found that the electrodissoolution of Ni in chloride solutions in the active region is under charge-transfer control. The reaction orders are 0.5 for Cl^- and -0.5 for H^+ in solutions in which both H^+ and Cl^- concentrations are less than $1M$, but first order for both Cl^- and H^+ for $1 \leq [\text{H}^+] \leq 5M$ and $1 \leq [\text{Cl}^-] \leq 5M$.

Although the electrodissoolution of copper in chloride solutions has been extensively studied (1-4), the anodic dissolution of copper-based nickel alloys in acidic chloride media has not received much attention. Walton and Brook (6) investigated the electrochemical behavior of (90/10) and (60/40) Cu-Ni alloys in 1/3 to 3M hydrochloric acid at a sweep rate of 5 mV/s. Two current plateaus and a current minimum were observed for the (90/10) Cu-Ni alloy. In the active region, cuprous species were detected as the dissolution product, and at much higher potentials, cupric species were found by means of a rotating ring-disk electrode. Bockris *et al.* (7) studied the electrodissoolution of Cu-Ni alloys in 1N HCl with the electrolyte flowing at a velocity of 0.5 cm³/s. They obtained an anodic Tafel slope of 130 mV/decade for (90/10) Cu-Ni alloy and concluded that the overall dissolution reaction in this region is charge-transfer controlled. Cahan and Hayes (8) reported that Tafel slopes for (30-90% Cu) Cu-Ni alloys 1N HCl are about 80 mV/decade. They concluded from partial current data of a (50/50) Cu/Ni alloy that the overall reaction is controlled by the dissolution of Ni. Kato *et al.* (9) found the anodic Tafel slope to be 70 mV/decade for the dissolution of Cu-9.4Ni-1.7Fe in air-saturated NaCl solution. Current minimum, current plateaus, and film formation were observed.

In this work, electrodissoolution kinetics of Cu-Ni (90/10) alloy (with 1.7% Fe) are studied with a rotating disk and ring-disk electrodes in various pH and chloride concentrations. The selectivity of alloy component dissolution is also investigated using the rotat-

ing ring-disk electrode and atomic absorption spectrophotometry during potentiostatic polarization.

A rotating ring-disk electrode has been specially designed for these studies to permit the disk to be easily changed. Since the electrode design enables rapid disk replacement, acquisition of electrode kinetic data is greatly facilitated.

Experimental

Details of the rotating disk assembly have been described elsewhere (10). The rotating ring-disk electrode design is shown in Fig. 1. Parts A and B of the rotating ring-disk electrode are machined from 3/4 in. diam stainless steel rod (Type 304) into the shape shown in Fig. 1. The lower part of the outer surface of A and the upper part of the inner surface of B are threaded. As Fig. 1 shows, B can be unscrewed from A so that a tight-fitted disk can be easily inserted in or out of B. A 1/16 in. thick pure gold sheet was silver soldered to the bottom steel surface of B and then machined to the ring shape. The disk radius is 0.240 in. (0.610 cm) and the inner and outer radii of the ring are 0.267 in. (0.678 cm) and 0.478 in. (1.214 cm), respectively. This design is convenient for experiments in which the disk electrodes have to be replaced often. A PAR 173 potentiostat was used to control the disk

Key words: electrodissoolution kinetics, mass transfer, Cu-Ni alloy.

Fig. 2. Anodic polarization of Cu in 0.5M HCl + 0.5M NaCl, 1000 rpm.

potential, and a Tacussel potentiostat Type PRT 10-0.5L was used for the ring. In these experiments, the ring potentials were set at +600 mV vs. SCE (saturated calomel electrode) to register the cuprous species current and at -100 mV to detect cupric species. Collection efficiencies, N , for each ring-disk electrode were calculated with the equation developed by Alberly and Bruckenstein (11). Experimental and theoretical values were compared using pure copper disk electrodes and agreed to within 1%.

The disk electrodes were made from a commercial Cu-Ni (90/10) alloy with a nominal composition of 88.8 weight percent (w/o) Cu, 9.4% Ni, 1.7% Fe, and 0.1% others. Electrodes were polished with alumina paper of various grit (no. 240, no. 400, and no. 600) and were rinsed in double-distilled water. The electrodes were then degreased with hot benzene in a soxhlet column and annealed under vacuum (5×10^{-5} torr) at 760°C for 4h. Two types of constant ionic strength electrolytes were used:

1. Constant acid concentrations
 - a. 1M (HClO₄ + HCl) [Cl⁻] = 0.1, 0.2, 0.4, 0.7, 1M
 - b. 4M (HClO₄ + HCl) [Cl⁻] = 1, 2, 3, 4M
2. Constant chloride concentrations
 - a. 1M (NaCl + HCl) [H⁺] = 0.01, 0.05, 0.1, 0.5, 1M
 - b. 5M (NaCl + HCl) [H⁺] = 1, 2, 3, 4M

The hydrochloric acid, sodium chloride, and perchloric acid were Baker-analyzed reagent grade. Water was first deionized and then double distilled from permanganate solutions. All electrolytes were deoxygenated with prepurified nitrogen gas for at least 12h prior to an experiment. The experiments were carried out at about 23°C. Sweep rates were maintained at 0.5 mV/s at the disk for both rotating disk and ring-disk electrodes, while the ring was set at a constant potential. Lower sweep rates indicated the same polarization behavior in the apparent Tafel region and above the current-plateau region. Copper, iron, and nickel solution concentrations in 1N HCl solutions during anodic potentiostatic polarization were analyzed with a Perkin-Elmer atomic absorption spectrophotometer. All potentials were measured relative to a saturated calomel electrode (SCE). Potentials have been corrected for IR drop (unless otherwise noted) and liquid-junction potentials.

Results

Anodic polarization behavior.—Typical anodic polarization of copper in chloride solutions is shown in Fig. 2. The first feature observed as the potential increases above the rest potential is the apparent Tafel region A (this "apparent" Tafel behavior does not represent a charge transfer-controlled process), and it is followed by a current peak B. From that point on, the current decreases as the potential increases

until the current reaches a minimum at C. A current plateau region occurs at D, and then the current increases with potential E.

The rate of cuprous species formation during the anodic dissolution was monitored by the ring electrode. This experiment was first performed using pure Cu as the disk. Figure 3 shows that the Cu disk and the ring current coincide in the Tafel region. This means that cuprous species are the only electro-oxidation products of the Cu disk in this region. Above the peak potential, the ring current stays constant as the potential increases. Cupric ions were detected by the ring electrode above the current-plateau region. However, the cupric-ring current did not correspond quantitatively to the increase in the disk current in the region E. Therefore, separate potentiostatic polarization experiments with the ring-disk electrode and atomic absorption spectrophotometer were performed to determine the rate of cupric ion formation in the higher potential region. This result is also shown in Fig. 3.

For the 90/10 Cu-Ni alloy, the disk and the cuprous-ring currents are shown in Fig. 4. The disk and the ring current do not coincide in the apparent Tafel region as observed for pure Cu due to the dissolution of the Ni component in the alloy (and a small amount of Fe). Above the peak potential, the cuprous current remains constant with increase in potential. Cupric

species are also detected at potentials above the current-plateau region.

Effect of chloride and hydrogen ion concentrations on alloy electrodisolution.—The effect of chloride ions on anodic polarization of the Cu-Ni alloy is shown in Fig. 5. Anodic currents increase, but the depth of the current minimum decreases with increase in chloride concentration. At low Cl^- concentrations ($\leq 0.1M$), the current-plateau region was not observed. Above $[\text{Cl}^-] = 2M$, the current minimum virtually disappears. As chloride concentrations were increased further, peak and minimum currents, as well as the current-plateau region, could no longer be discerned.

As shown in Fig. 5, there is a strong chloride effect on the alloy-dissolution rate. Figure 6 shows that at a constant rotation rate of 700 rpm, the current density in the apparent Tafel region increases tenfold with increase in chloride concentration from 0.1 to 0.7M. The Tafel slope for Cu-Ni alloy dissolution is 70 mV/

decade. At -80 mV, the reaction orders for Cl^- are 1.3 for $[\text{Cl}^-] < 1M$ and 1.6 for $[\text{Cl}^-] > 1M$. Figure 7 shows the dissolution rate of the Cu component (cuprous-ring current) during the alloy dissolution shown in Fig. 6. The Tafel slope for Cu component dissolution is approximately 60 mV/decade. The reaction orders with respect to Cl^- for Cu component dissolution are 1.9 and 2 at low and high chloride concentrations, respectively. The dissolution rate of the Ni component (with a small amount of Fe) has been obtained (Fig. 8) by subtracting the cuprous current (Fig. 7) from the disk current (Fig. 6). The Tafel slope for Ni component dissolution is 100 mV/decade, and the reaction order with respect to Cl^- at both high and low chloride concentrations is approximately one.

The effect of hydrogen ions on alloy and Cu component dissolution is shown in Fig. 9 and 10. At $[\text{H}^+] < 1M$, both the disk and cuprous-ring currents are

Fig. 5. The effect of chloride ions on the anodic polarization of the alloy in (curves a-c) 1M ($\text{HClO}_4 + \text{HCl}$), and (curves d and e) 4M ($\text{HClO}_4 + \text{HCl}$), 700 rpm. Not corrected for IR drop.

Fig. 7. The effect of chloride ions on the electrodisolution of the Cu component (ring current) of the alloy in the apparent Tafel region, 700 rpm.

independent of H^+ concentrations. At $[H^+] > 1M$, an increase in $[H^+]$ increases the anodic currents. However, the magnitude of the increase is not as large as that observed for chloride ions. At $[H^+] > 1M$, the H^+ reaction orders are 0.6 for the alloy-disk dissolution and 0.5 for Cu-component (ring current) dissolution. The Ni-component dissolution was also studied. At low

$[H^+]$, a significant effect of H^+ was not observed. However, at high $[H^+]$, the rate of Ni-component dissolution increases with increase in $[H^+]$ (Fig. 11), and the reaction order with respect to H^+ is 0.6.

Mass-transfer effects on alloy electrodisolution.— Alloy electrodisolution increases with increase in rotation rate. Figure 12 shows that the dependence on rotation rate varies with potential. At potentials slightly above the rest potential, the slope of the log-log plot of the current vs. rotation rate is 0.36. At -100 mV, dependence on rotation rate is greater at rotation rates below 2000 rpm than above 2000 rpm. As shown in Fig. 12, the slope below 2000 rpm is 0.36, but decreases to 0.2 at higher rotation rates. At the current minimum and the current-plateau region, the anodic current varies as the square root of the rotation rate following the Levich relation. However, at potentials above the current-plateau region, where cupric ions are also detected as a reaction product, the slope decreases to 0.4.

Selective alloy electrodisolution.— Selective alloy electrodisolution depends strongly on the applied potential. Selective dissolution of the most active (but minor) component, Fe, is observed at and in the neighborhood of the rest potential (data not shown). However, at higher potentials ($\cong -200$ mV), the rate of

Fig. 9. The effect of hydrogen ions on alloy electrodisolution in the apparent Tafel region, 1000 rpm.

Fig. 10. The effect of hydrogen ions on the electro-dissolution of the Cu component of the alloy in the apparent Tafel region, 1000 rpm.

Fe dissolution is too low to be measured with sufficient accuracy.

Figure 13 shows Cu component electro-dissolution of the alloy at different potentials using data obtained by both the rotating ring-disk electrode and atomic absorption spectrophotometry (the results are obtained by setting the alloy at each potential for about 1h). At -170 mV, only 50 w/o of the alloy dissolved is Cu. As the potential increases Cu electro-dissolution increases. Nonselective dissolution is attained at about the current minimum (≈ 0 mV) when the relative composition of the dissolved species is the same as that of the bulk alloy. In the selective dissolution region (≤ -50 mV); the Cu component electro-oxidizes only to cuprous species. In the nonselective dissolution region above the current plateau (≥ 50 mV), electro-oxidation of Cu to both cuprous and cupric species is obtained. It should be noted that the difference between 100 w/o and the amount of Cu species dissolved (in w/o) is the solution composition of Ni(Fe).

The effect of Fe (1.7%) on alloy electro-dissolution.—Iron has a significant effect on alloy electro-dissolution at low potentials. Figure 14 compares the dissolution rates of 90/10 Cu-Ni alloys with and without Fe at low potentials. At -180 mV, both the disk and cuprous-ring currents for the alloy with Fe are significantly less than that without Fe. Thus, the presence of Fe substantially decreases alloy dissolution and strongly diminishes the propensity of the Cu component for electro-dissolution near the rest potential. As the potential increases, the difference between the alloy and the Cu-component electro-dissolution rates for both alloys is virtually the same.

Discussion

Figure 3 shows that for pure copper electro-dissolution in chloride solutions, cuprous species are the only reaction products from the rest potentials to potentials

Fig. 12. The effect of rotation rate on the electro-dissolution of the alloy in 1M HCl.

Fig. 13. Electrodisso- lution of copper species from the alloy in 1M HCl as a function of poten- tial (≈ 1 h potentiostatic polar- ization at each potential), 700 rpm.

slightly below the potential of the current peak. The reactions are as follows

where

$$E^e = -0.105 - (RT/F) \ln [\text{Cl}^-], \quad \text{V vs. SCE} \quad [1']$$

where

$$K_2 = 6.61 \times 10^{-2} \quad [2']$$

In this region, the CuCl film formation step (Eq. [1]) is slow relative to the film dissolution step (Eq. [2]), precluding buildup of film. Film formation is not discerned until about the peak potential. Moreau *et al.* (12) concluded from their results that the CuCl film begins to form at potentials just below the peak potential. At this point when the film starts to build up, the first step (Eq. [1]) is fast compared to the second step (Eq. [2]).

At the current minimum and in the current-plateau region (Fig. 2 and 3), the cuprous ring current remains constant. In this region, the rate of Cu electrodisso- lution to cuprous-chloride complexes is propor- tional to the square root of the rotation rate following the Levich relation, as shown by Braun (4) and in this study (results not shown). At higher potentials (region E in Fig. 2), cupric ions are detected, as shown in Fig. 3. These results have also been reported by Walton and Brook (6), who suggest that Cu^{++} is formed by electro-oxidation of the CuCl film

where

$$E^e = 0.295 + \frac{RT}{F} \ln [\text{Cu}^{++}][\text{Cl}^-], \quad \text{V vs. SCE} \quad [3']$$

In the apparent Tafel region for pure Cu in chloride solutions, the anodic Tafel slopes of 60 mV/decade are obtained in accord with the results of others (1-4). The chloride reaction order is 2 (data not shown), which is also in agreement with others (1-4). How- ever, at higher chloride concentrations, cuprous tri- chloride and tetrachloride complexes may form in significant amounts, so that chloride reaction orders greater than 2 may be obtained.

For 90/10 Cu-Ni alloy (with 1.7% Fe), the cuprous- ring current and the alloy disk are not equivalent below the peak potential (Fig. 4) as observed for pure Cu (Fig. 3). The reason for this difference between the alloy and pure Cu is that, in addition to the Cu electro- disso- lution reactions (Eq [1] and [2]) for pure Cu, the alloy disk current represents Ni and Fe electrodisso- lution rates

The Fe reaction is especially significant near the rest potential, as shown in Fig. 13. At higher potentials, cupric ions are produced, as observed for pure Cu, probably via Eq. [3].

If the electrodisso- lution of the alloying elements is similar to the pure metals, it is expected that the elec-

Fig. 14. Effect of Fe on Cu-Ni (90/10) alloy and the Cu component electrodisso- lution in 0.5M HCl + 0.5M NaCl, 700 rpm.

trodissolution of both Ni and Fe components is activation controlled (5, 14) and the Cu component is mass-transfer controlled (1-4). The anodic Tafel slopes for the alloy are approximately 70 mV/decade for chloride concentrations of 0.1-4M (Fig. 6), as reported by other investigators (6, 9, 15). The Cl^- reaction orders for alloy electrodisso- lution obtained from the results in Fig. 6 are 1.3 for low Cl^- concentrations and 1.6 for high Cl^- concentrations. These parameters for alloy electrodisso- lution compare with anodic Tafel slopes of 60 mV/decade (Fig. 7) and 100 mV/decade (Fig. 8) for Cu component and Ni component (with Fe) electro- disso- lution, respectively. The Cl^- reaction orders for Cu-component electrodisso- lution are 1.9 and 2.0 for low Cl^- and high Cl^- concentrations (Fig. 7), respec- tively. The Cl^- reaction order for the Ni-component electrodisso- lution is approximately 1 (Fig. 8). The param- eters for the Cu component are essentially the same as those obtained for pure copper (as discussed above). The anodic Tafel slopes for pure Ni in chloride solu- tions have been reported to range from 75 to 120 mV/ decade (5, 16, 17). The Cl^- reaction orders have been reported to be 0.5 (low Cl^- concentrations) and 1 (high Cl^- concentrations) for pure Ni (5). Thus, the param- eters for the Ni component roughly approximate the values obtained for pure Ni.

Mass-transfer dependence of alloy electrodisso- lution is shown in Fig. 12. Complete mass-transfer control of alloy electrodisso- lution is not observed between the rest potential and just below the peak potential where the CuCl film begins to form. This is shown by the slope less than 0.5 for the $\log i$ vs. \log rotation rate plots at potentials of -200 and -100 mV. The slope of 0.36 suggests mixed-activation and mass-transfer control with both Ni and Fe components under activation control and the Cu component under mass-transfer control. At potentials of the current-minimum and current- plateau region ($+20$ mV), alloy electrodisso- lution clearly follows the Levich relation and indicates that the dissolution of the CuCl film (Eq. [21]) is the domi- nant process in this potential region and is under mass- transfer control. Above the current-plateau region, mixed control is again indicated, as shown in Fig. 12 ($+500$ mV), with Eq. [2] the mass-transfer control process and Eq. [3] under activation control. Walton and Brook reported similar mixed mass-transfer and activation-control behavior (6).

Selective electrodisso- lution of Ni is observed at potentials below the peak potentials, as shown in Fig. 13. At potentials near the rest potential, Fe electrodisso- lution, the minor alloying element, is dominant (data not shown). As the potential is increased (Fig. 13), selective electrodisso- lution of Ni is progressively dimi- nished (above -200 mV, the electrodisso- lution rate of Fe is too small to be measured) up to -50 mV. The current-plateau region occurs above 0 mV where electrodisso- lution is nonselective and the cuprous chlo- ride complex is the only electro-oxidation product of the Cu component. As Fig. 13 shows, at potentials

Fig. 15. Electrodisso- lution of the alloy and the Cu and Ni components in 0.6M HClO_4 + 0.4M HCl in the apparent Tafel region, 700 rpm.

Fig. 16. Selective alloy electrodisso- lution at potentials ≤ -50 mV. Data from Fig. 15.

above this region alloy electrodisso- lution continues to be nonselective, but an increasing fraction of the Cu component electro-oxidizes to the cupric state.

Figure 15 provides the basis for a quantitative mea- sure of selective alloy electrodisso- lution at potentials ≤ -50 mV. As the potential is increased, the differ- ence between the currents of the Cu component and the Ni component increases and reaches at -50 mV a Cu:Ni(Fe) weight ratio of 6.46. This ratio compares with the value of 8 for the bulk alloy. The results of Fig. 15 are expressed, in Fig. 16, as the electrodisso- lution rate of the Cu component relative to that of the alloy between -120 and -50 mV. At -120 mV, the relative rate in terms of w/o Cu is 77.5%. There is a steady increase in the relative rate as the potential is increased, and the value of 86.5% is attained at -50 mV. The latter approaches the bulk-alloy composition of 88.8% Cu, which indicates nonselective electrodisso- lution. This point is reached at approximately the potential of the current minimum (> 0 mV), where complete mass-transfer control of the electrodisso- lution process is observed.

ABSTRACT

An examination has been made of the mechanism of breakdown of passive films on iron in borate buffer solution (pH = 8.4) caused by chloride ions. Various electrochemical kinetic criteria were measured. XPS, SIMS, and ISS studies were made of the systems used in the electrochemical work. The rate of breakdown was found to be proportional to c_{Cl^-} and c_{H^+} and exponentially dependent on the electrode breakdown potential and field drop in the oxide film. XPS data showed that when chloride ions caused breakdown, the O_{total}/Fe and H_2O/Fe ratios changed from 2 to 1.5 and 0.5 to 0.1, respectively. SIMS data revealed that heating passive films up to 200°C drove out water from the films and that chloride ions penetrated the whole film thickness on breakdown. ISS data indicated that on changing from a passive to a depassivated film, the O/Fe ratio changed from 2.07 to 1.5. Discussion of the electrochemical kinetic data shows that it is inconsistent with adsorption-displacement models, pore models, and chemico-mechanical models, but is not inconsistent with ion-exchange processes, point-defect models, and hydrated polymeric oxide models. Confrontation of the spectroscopic data with the expectations of the latter three models shows some points of agreement with all these models, but the data taken together is most consistent with the hydrated polymeric oxide model.

Study of the mechanism of breakdown of passive films by anions, and, in particular, chloride ions, presumes a knowledge of the passivation process. Although theories in relation to the chloride effects on passive films abound (1, 2), models with respect to the nature of the latter can, at present, be summarized into two types (3-5).

The crystalline oxide model.—In this model (6-11), the protective nature of the layer which forms upon the surface of a metal under a particular form of oxidation is supposed to be connected with the crystal structure of the film. In the case of iron, the film is considered to be a duplex layer consisting either of an inner layer of Fe_3O_4 and an outer layer of $\gamma-Fe_2O_3$ (6, 10) or of $\gamma-Fe_2O_3$ alone (7, 11). The undeniable presence of water in connection with passive films formed in aqueous environments is interpreted to be due either to hydrogen stabilization of $\gamma-Fe_2O_3$ in the outer regions (12, 13) or to adsorbed water on the surface of the film (14).

The hydrated polymeric oxide model.—Inherent in this model (15-17) is the essential role played by water in transforming the properties of "iron oxide" to those of the protective passive layer. How the water does this varies with the author (15-20).

The essential concept is that the water is supposed to maintain the thin film amorphous, and the word "polymer" is used with the meaning that the bound water (21) "pulls together" the iron oxide in such a fashion that it is difficult for the Fe^{2+} ions from the metal base beneath the film to diffuse to the hydration sites at the oxide/solution interface.

The various theories of passive film breakdown (1, 2, 22) provoke numerous dilemmas, among which the two most in need of resolving are the following: (i) the distribution of hydrogen, or water, within passive

films (13, 15-20, 23), or (ii) the distribution of chloride ions in the bulk of passive films after exposure to chloride containing solutions (2, 24).

The present paper reports the application of both electrochemical and spectroscopic techniques to these problems.

Experimental

Electrodes.—Working electrodes were iron disks approximately 1 mm thick and 6 × 6 mm square (99.99% purity, Alfa Ventron Corporation, Danvers, Massachusetts). They were mechanically polished with 320-, 400-, 500-, and 600-grade silicon carbide paper and then finished with diamond paste of 6-0.25 μ m grain sizes to give a bright mirror surface. After polishing, electrodes were washed with methanol and several times with triply distilled water, dried, and stored *in vacuo*. Each electrode was prepared fresh with a fine-grade diamond paste and washed before use. Electrodes were mounted in a Teflon holder, as described previously (25).

The counterelectrode was a platinum gauze arranged in a half-cylindrical shape opposite the working electrode and had a surface area at least 100 times larger than the iron disk electrode. Its arrangement opposite the iron anode allowed the latter electrode to function unimpeded by depolarization reactions arising from the hydrogen gas evolved during polarization of the large cathode.

The reference electrode was a Hg/HgO, 1N KOH electrode. The calomel electrode was avoided because of the possibility of solution contamination with chloride ions. Potentials in this paper are referred to the normal hydrogen electrode.

Solution preparation.—Solutions were prepared from triply distilled water of conductivity, κ , less than $10^{-6}\Omega$ cm⁻¹ and were made up as buffer solutions consisting of 0.275M analytical-grade sodium tetraborate, mixed

* Electrochemical Society Active Member.

with 0.15M analytical-grade boric acid. The solution pH was 8.4. All solutions were pre-electrolyzed in a separate cell attached to the working cell at a constant current density of about $20 \mu\text{A cm}^{-2}$ using two large platinum gauze electrodes, each about 100 cm^2 in area. The pre-electrolysis time was of the order of 15h.

Removal of air-formed oxide films.—The working electrode was pretreated by cathodic polarization at -0.74V (NHE) (26) for 30 min to remove air-formed oxides. The solution used for this reduction of the electrode, and which contained evolved hydrogen gas, was removed from the main cell by a purified nitrogen gas pressure, and a new pre-electrolyzed solution introduced into the cell in contact with the electrode.

The rest potential of the working electrode prepared under these conditions was -0.5V (NHE).¹ Electrodes prepared in this manner were used as base electrodes in all subsequent experiments, i.e., when an experimental potential pertinent to the passivation experiments was applied, the electrode was prepared as described above, and this new potential was impressed by means of a potentiostatic step onto the resting potential of pure iron.

Formation of the passive layer.—The typical passive film which was used in all experiments was formed at 0.3V (NHE) for a time interval of 50 min, unless otherwise stated. The current decreased continuously during the time of passivation, finally reaching a value of the order of $1 \mu\text{A cm}^{-2}$. Integration of the current/time curve showed that the total charge passed was around 6 mC cm^{-2} . Assuming that the oxide present was Fe_2O_3 , the film thickness would be in the region of 26Å.

Having formed the passive film, the solution present was displaced by purified nitrogen gas, and a solution containing chloride ions was introduced. The solutions which were introduced at this point were either variable in chloride-ion concentration at fixed pH (8.4) or variable in pH at fixed chloride concentration (0.1 or 0.5M) and were of constant ionic strength. Passivated specimens were exposed to these solutions at the potential of film growth (unless otherwise stated) for various times prior to, at, and after breakdown. Induction times (τ)² for breakdown were established under the various conditions used, chloride-ion concentration, pH, passive-film thickness, and the potential at which the electrode was held at in the chloride solutions.

Spectroscopic analyses of passive films.—**Transfer of samples to XPS spectrometer.**—Solutions which had been used in the formation of passive films, or in the depassivation of such films, were pressed out of the cell by means of purified nitrogen gas pressure, the electrode being left in contact with the latter. The cell was then quickly filled with triply distilled water from an attached reservoir and released by nitrogen gas pressure. This was repeated a second time. The cell with the electrode still in place and under a nitrogen gas atmosphere was then removed to a dry box filled with nitrogen gas and opened therein, the electrode being removed, washed again thoroughly with triply distilled water, and transferred to a glass vial filled with nitrogen gas. The vial was sealed, placed in a Dewar containing liquid nitrogen, and then removed from the glove box. The Dewar was transferred to another laboratory in the chemistry building and placed in another nitrogen containing glove box, which was attached to the XPS sample chamber. The electrode

¹The relaxation of the film-free potential to one of -0.5V (NHE) was caused by the needed change of solution. Reference to Wroblowa, *et al.* (27), who studied film formation on iron at the same pH and potential regions as used here, shows that at -0.5V (NHE) a prepassive film of submonolayer thickness is formed.

²The induction time will vary with the age of the film. However, significant effects have been measured only over times in the 100-1000 min range (28).

was once more removed from the original vial and on warming up was placed in the XPS analysis chamber.

The XPS spectra were recorded by use of an HP 5950A ESCA spectrometer, equipped with monochromatized Al $K\alpha$ radiation. The sample probe was encased in a dry box, employing a nitrogen atmosphere filtered with oxisorb cartridge ($\text{O}_2 < 5 \text{ ppm}$). A Surface Science Laboratories Model 259 angular distribution probe was used. The photoelectron detection angle relative to the sample surface, θ , was varied from 8° – 58° (~ 5 – 30Å). A Hewlett Packard 9825A computer was interfaced to the system. A Surface Science Laboratories software package (9825 Data System Rev E) made possible background subtraction and peak deconvolution.

The atomic ratio of O to Fe was calculated according to the relation (29)

$$\frac{N_{\text{O}}}{N_{\text{Fe}}} = \frac{I_{\text{O}} \sigma_{\text{Fe}}}{I_{\text{Fe}} \sigma_{\text{O}}}$$

where N_{O} and N_{Fe} equal the number of atoms of oxygen and iron, I_{O} and I_{Fe} are the corresponding intensities, and σ_{O} and σ_{Fe} are the corresponding cross sections. The relative cross sections, $\sigma_{\text{Fe}}/\sigma_{\text{O}}$, was taken (30) as 1.45.

Transfer of samples to SIMS and ISS spectrometers.—In these cases, analyses were performed in laboratories far from that in which the original experiments had been carried out. Electrodes were treated as described above and were placed in glass vials, the tops of which were carefully sealed using Teflon tape and screw caps. They were opened under inert gas conditions and placed in the respective spectrometer chambers.

The SIMS measurements were performed on a Gatan Model 591C SIMS-SIPS ion microprobe at the Materials Research Laboratory, Pennsylvania State University, Dunmore, Pennsylvania. The ion beam consists of a Colutron ion source, Wein mass filter, and two electrostatic lenses. The ion gun chamber is pumped with a turbomolecular pump. The target chamber can be evacuated to 10^{-10} torr with a second turbomolecular pump and titanium sublimation pump. The secondary ions are detected with an Extranuclear quadrupole mass spectrometer with a Spheric-El energy filter.

The operating parameters were: probe ion beam $^{40}\text{Ar}^+$, beam voltage of 7 keV, beam current of 90 nA, and a sample chamber pressure during analysis of 5×10^{-9} torr. The ion beam of $\sim 70 \mu\text{m}$ diam was rastered over an area of $1.2 \times 1.2 \text{ mm}$. The signal was gated so that the data were collected over a central area of $0.36 \times 0.36 \text{ mm}$. The sputtering rate was determined as 0.3Å s^{-1} , using a $102\text{Å SiO}_2/\text{Si}$ standard.

The ISS analyses were carried out with a Leybold-Heraeus LHS 10 surface analysis system at the Solar Energy Research Institute, Golden, Colorado.

The operating parameters were: probe ion beam $^3\text{He}^+$, primary beam energy 1 kV, beam current of 94 nA, and a sample chamber pressure during analysis of 1.4×10^{-7} torr. The ion beam $\sim 200 \mu\text{m}$ was rastered over an area of $2 \times 2 \text{ mm}$. The signal was gated so that the data were collected over a central area of $1 \times 1 \text{ mm}$. The sputtering rate was determined as 1.3 Å min^{-1} , using as a standard the etch rate for the iron substrate in conjunction with a mechanical profiler.

The atomic ratio of O to Fe was calculated using the equation (31)

$$\frac{N_{\text{O}}}{N_{\text{Fe}}} = \frac{I_{\text{O}} \sigma_{\text{Fe}}}{I_{\text{Fe}} \sigma_{\text{O}}}$$

where N_{O} and N_{Fe} equal the number of atoms of oxygen and iron, I_{O} and I_{Fe} are the corresponding ISS peak intensities, and σ_{O} and σ_{Fe} are the corresponding cross

sections. The relative cross section, σ_{Fe}/σ_0 , taken was the mean of those found in the literature, 6.6 (31) and 8.8 (32), yielding a value of 7.7.

Results

The results of the investigations can be divided into four parts, corresponding to the techniques used.

Electrochemical techniques.—The normal passivation curve for iron is shown in Fig. 1 and corresponds to a sweep rate of 0.2 mV s^{-1} .

In Fig. 2, the log of the breakdown rate (v) is plotted as a function of chloride-ion concentration in the buffered borate solutions to which passivated electrodes were exposed.

It can be seen that

$$\delta \log v / \delta \log c_{Cl^-} = 1$$

where $v (= 1/\tau)$ is the rate of the reaction leading to the breakdown of the passive layer. The process has a reaction order of unity at constant potential [0.3V (NHE)].

The corresponding variation of the log of the breakdown rate with hydrogen ion concentration is shown in Fig. 3. It transpires upon examining this plot that

$$\delta \log v / \delta \log c_{H^+} = 0.66$$

In Fig. 4, the log of the breakdown rate as a function of the electric field across the passive film, for films grown at a constant potential of 0.3V (NHE) for vari-

Fig. 2. Variation of the log of the breakdown rate, v , as a function of chloride-ion concentration. Film growth conditions: 0.3V (NHE) in borate-buffer solution. Breakdown conditions: 0.3V (NHE) in chloride containing borate-buffer solution.

Fig. 3. Dependence of the log of the breakdown rate, v , on hydrogen-ion concentration. Film growth conditions: 0.3V (NHE) in borate-buffer solution. Breakdown conditions: 0.3V (NHE) in solutions of variable pH containing 0.1M NaCl.

Fig. 4. Variation of the log of the breakdown rate, v , as a function of the electric field, E , across the film. Film growth conditions: 0.3V (NHE) in borate-buffer solution for various times and, hence, various film thicknesses. Breakdown conditions: 0.3V (NHE) in borate-buffer solution containing 0.1M NaCl.

ous times is presented. Film thicknesses were estimated by utilizing the charge passed in forming the films and by assuming that the passive layer consists of Fe_2O_3 . The slope of the graph

$$\delta \log v / \delta E = 0.48 \times 10^{-6} \text{ V}^{-1} \text{ cm}$$

The dependence of the log of the breakdown rate on the breakdown potential, V , is given in Fig. 5. It can be ascertained from the figure that³

$$\delta \log v / \delta V = 4.1 \text{ V}^{-1}$$

XPS spectra.—Several analyses were made with XPS. In Fig. 6 is shown the binding energy curve cor-

³The value given here is, of course, not to be taken simplistically, because the V is referenced to other potentials and is only a measure of the potential difference across the film.

Fig. 5. Dependence of the log of the breakdown rate, v , on the breakdown potential, V . Film growth conditions: 1.0V (NHE) in borate-buffer solution. Breakdown conditions: borate-buffer solution containing 0.1M NaCl.

Fig. 6. XPS spectrum for Fe $2p_{3/2}$ for the passive film formed on iron in borate-buffer solution at 0.3V (NHE).

responding to iron (Fe $2p_{3/2}$). It can be seen that after deconvolution metallic iron shows up at a binding energy of 707.4 eV (33), while iron in the oxidized state, Fe^{3+} , is seen at a binding energy of 711.5 eV (34). The passive film prepared at 0.3V (NHE) contains exclusively ferric iron with no ferrous iron content (Fe $^{2+}$ binding energy 708.5-709.5 eV) (34, 35).

In Fig. 7 is shown the O 1s spectra. On deconvoluting the spectra, three peaks were obtained. The peak with binding energy of 530.3 eV is attributed to O $^{=}$ (25, 34, 36), while the peak at 531.8 eV is assigned to OH $^{-}$ (14, 34, 36) and the peak at 533 eV to H $_2$ O (25, 35).

In Table I, XPS results are given for an electron escape angle, θ of 38 $^{\circ}$ ($\sim 22\text{\AA}$), corresponding to passive films prepared at three different potentials. The ratio O_{total}/Fe is about 2 for all potentials, and the H $_2$ O/Fe ratio averages 0.5. The ratios, O/Fe and OH/

Fig. 7. XPS spectrum for O 1s for the passive film formed on iron in borate-buffer solution at 0.3V (NHE).

Fe, are less clear, but if each pair is added together and averaged, a value of approximately 1.5 is obtained.

In Table II, similar results are shown as a function of escape angle, θ , for a passive film prepared at 0.3V (NHE). The ratio of O_{total}/Fe corresponding to an escape angle of 8 $^{\circ}$ ($\sim 5\text{\AA}$) is 2.61, higher than the expected 2.0. The average value of the ratio H $_2$ O/Fe is 0.77. The average of the sum of the ratios, O/Fe and OH/Fe, is 1.46.

The effects of the exposure of passive films to chloride ions for times after breakdown for three escape angles, θ , 18 $^{\circ}$ ($\sim 11\text{\AA}$), 38 $^{\circ}$ ($\sim 22\text{\AA}$), and 58 $^{\circ}$ ($\sim 30\text{\AA}$) are presented in Table III. The ratio O_{total}/Fe has decreased to ca. 1.5. However, more strikingly, the ratio H $_2$ O/Fe is lowered considerably to about 0.1. The average of the sum of the O/Fe and OH/Fe ratios yields 1.53.

ISS spectra.—A typical ISS spectrum of a passive film prepared at 0.3V (NHE) in borate solution (pH = 8.4) is shown in Fig. 8. Two peaks can be seen, the first one at an energy ratio $E/E_0 = 0.53$ corresponds to oxygen and the second one with an energy ratio $E/E_0 = 0.83$ is for iron.⁴

⁴Leybold-Heraeus ISS energy ratio (E/E_0) data for the elements for various bombarding ions applicable to the scattering geometry used.

Table I. O_{total}/Fe , H $_2$ O/Fe, OH/Fe, O/Fe, and (OH + O)/Fe ratios at an electron escape angle $\theta = 38^{\circ}$ ($\sim 22\text{\AA}$) from XPS of passive films on iron formed at various potentials in borate solution (pH = 8.4) for 50 min

Potential V (NHE)	O_{total}/Fe	H $_2$ O/Fe	OH/Fe	O/Fe	(OH + O)/Fe
+0.30	2.1	0.7	0.6	0.82	1.42
+0.065	1.88	0.2	0.77	1.11	1.88
-0.20	1.97	0.5	0.74	0.74	1.58

Table II. O_{total}/Fe , H $_2$ O/Fe, OH/Fe, O/Fe, and (OH + O)/Fe ratios at various electron escape angles, θ , from XPS of passive films formed on iron at +0.30V (NHE) in borate solution (pH = 8.4) for 50 min

Angle, θ	O_{total}/Fe	H $_2$ O/Fe	OH/Fe	O/Fe	(OH + O)/Fe
8 $^{\circ}$ ($\sim 5\text{\AA}$)	2.61	0.91	0.83	0.99	1.82
18 $^{\circ}$ ($\sim 11\text{\AA}$)	2.03	0.84	0.58	0.77	1.35
38 $^{\circ}$ ($\sim 22\text{\AA}$)	2.09	0.69	0.58	0.83	1.41

Table III. O_{total}/Fe , H_2O/Fe , OH/Fe , O/Fe , and $(OH + O)/Fe$ ratios at various electron escape angles, θ , from XPS of passive films after breakdown in an 0.1M chloride containing borate-buffered solution (pH = 8.4) at 0.3V (NHE)

Angle, θ	O_{total}/Fe	H_2O/Fe	OH/Fe	O/Fe	$(OH + O)/Fe$
18° (~11Å)	1.51	0.10	0.6	0.88	1.48
38° (~22Å)	1.52	0.09	0.69	0.91	1.60
58° (~30Å)	1.51	0.12	0.55	0.96	1.51

Plots of the atomic ratio O/Fe , derived from the ISS spectra, as a function of depth, are presented in Fig. 9 for a passive film formed in borate solution at 0.3V (NHE) and for a similar film broken down in a borate-buffered chloride solution at the latter potential. In the case of the film which has not been exposed to chloride solution, the ratio is close to 2, while for the film after breakdown in buffered chloride solution, it is 1.5.

SIMS spectra.—The SIMS data are presented in three aspects.

In Fig. 10, the OH^-/O^- ratios are given as a function of depth for passive films formed in borate solution at 0.3V (NHE) and subsequently thermally treated under a flowing argon gas atmosphere at various temperatures for 15 min. As the temperature increases, the OH^-/O^-

Fig. 8. ISS spectrum of passive film on iron formed in borate-buffer solution at 0.3V (NHE).

Fig. 9. O/Fe ratio as a function of depth, Å, into the passive film on iron from ISS depth profiling: (a) film formed in borate buffer solution at 0.3V (NHE); (b) passive film after breakdown [0.3V (NHE) in borate-buffer solution containing 0.5M NaCl].

Fig. 10. Variation of OH^-/O^- ratio with depth into passive films formed in borate buffer solution at 0.3V (NHE). Annealing temperatures under an argon gas flow were: (■) 25°C; (●) 70°C; (▼) 160°C; (▲) 200°C.

O^- ratio decreases. The ratios of OH^-/O^- for temperatures above room temperature are reduced.

The Cl^- peak height intensities, as a function of depth, presented in Fig. 11 for passive films formed at 0.3V (NHE) in borate solution and subsequently exposed to a borate-buffered chloride containing solution for times of 40, 80, 163, 205, and 420s, i.e., for times before and after breakdown (~160s), show some

Fig. 11. Variation of Cl^- peak height intensities as a function of depth into passive films formed in borate-buffer solution at 0.3V (NHE) and subsequently exposed to a borate-buffer solution containing 0.5M NaCl at this potential for various times.

interesting features: (i) for increasing exposure times (40, 80, and 163s) up to breakdown time, increasing amounts of chloride ions penetrate the passive films, reaching a maximum around breakdown, (ii) for exposure times longer than breakdown, however, namely, 205 and 420s, a decrease in the chloride content of the passive films becomes apparent, the Cl^- concentration within the film being now anomalously lower for the larger exposure time (420s). Chloride ions penetrate passive films right up to the metal/film interface.

The positive SIMS O^+ peak height signals as a function of depth into the same passive films as used in obtaining the data shown in Fig. 11 are given in Fig. 12. The O^+ signals are seen to increase as the depth into the films increases, undergo a constant value for the bulk of the films, and decay as the passive film/metal interfaces are reached.

Discussion

Electrochemically derived kinetic data.—Criteria derived from the data presented in Fig. 2-5, and which are conveniently summarized in Table IV, may now be compared for consistency with leading models for passive film breakdown.

Adsorption-displacement models.—In one approach (37, 38), the events leading to breakdown involve the adsorption of Cl^- and simultaneous displacement of oxygen from the monolayer said to constitute the passive layer in this model. As soon as the chloride ion is adsorbed, dissolution is facilitated (39, 40).

It has been shown that the film breakdown kinetics depend upon the electric field across the film at constant potential (various thicknesses) (41) (Fig. 4) and at constant thickness (with various applied breakdown potentials) (Fig. 5), so that concepts inherent in the Uhlig theory are negated.

In another view (42), adsorption of a small number of chloride ions around an iron cation on the surface of a passive film gives rise to the formation of a complex, which is supposed to dissolve more readily than the corresponding aquo complex.⁵ The local thinning, which would be caused, and the associated stronger local anodic field at the site of removal, will cause further cations to diffuse to the surface, where they will complex with halide ions and dissolve.

A reaction order of unity with respect to chloride ion, found here for the depassivation reaction, appears contradictory; the view demands an order equal to the number of Cl^- ions in the complex.

Ion exchange processes.—Penetration of aggressive ions through passive films by ion exchange processes, e.g., Cl^- for lattice O^{2-} (1), or via cation vacancies (44, 45), has also been considered. A reaction order of unity with regard to chloride ion is consistent with this view. The dependence of lattice-breakdown velocity upon electric-field strength (Table IV) is consistent with the fact that diffusion of chloride ions in the lattice will be exponentially aided by a field. The pH dependence seems anomalous to this view.

⁵ The implied greater stability of the chloride over the aquo complex seems dubious (43).

Fig. 12. Variation of O^+ peak height as a function of depth into passive films utilized in obtaining the data presented in Fig. 11.

Pore models.—The basic supposition is that all passive layers contain flaws or are porous in nature (46, 47). Chloride ions pass through the pores and make contact with the iron lattice. Complexes are formed which diffuse upward to the outer film/solution interface. Pits are formed at the bottom of each pore. Continuation of this process would give rise to greatly increased anodic current densities tantamount to film breakdown.

It is to be expected that this model would be dependent directly on the chloride-ion concentration but that it would not be dependent on the concentration of hydrogen ions.

The point-defect model.—Cation diffusion from the metal/film to the film/solution interface results only in dissolution, a consequence of which is the formation of metal holes at the metal/film interface, which normally tend to disappear into the bulk of the metal (22). However, when the cation diffusion rate is greater than the rate of disappearance of holes into the metal bulk, voids form at the metal/film interface. When a void of sufficient size is formed, local collapse of the passive film occurs, which subsequently dissolves faster than at any other region of the film, leading to pit growth.

The effect of chloride ions on this process would be to increase the potential difference across the film and, therefore, enhance Fe^{2+} diffusion to the surface (22). A consequence of this is seen as increased void formation and breakdown.

Table IV. Summary of data from electrochemical kinetic study of passive-film breakdown

Parameter investigated	Kinetic law followed	Rate dependence
Rate of breakdown dependence on chloride ion concentration at constant potential, thickness, and pH	$v = k c_{\text{Cl}^-}$	$\delta \log v / \delta \log c_{\text{Cl}^-} = 1$
Rate of breakdown dependence upon hydrogen-ion concentration at constant potential, thickness, and Cl^- concentration	$v = k c_{\text{H}^+}$	$\delta \log v / \delta \log c_{\text{H}^+} = 0.66$
Rate of breakdown dependence on electric field, E , across the film at constant potential, pH, and Cl^- concentration	$v = k e^{BE}$	$\delta \log v / \delta E = 0.48 \times 10^{-6} \text{ V}^{-1} \text{ cm}$
Rate of breakdown dependence on breakdown potential at constant thickness, pH, and Cl^- concentration	$v = k e^{BV}$	$\delta \log v / \delta \log V = 4.1 \text{ V}^{-1}$

A model of this kind fits the criteria of Table IV rather well except for the pH dependence, which should be zero on this model.

The chemico-mechanical models.—Adsorption of ions, e.g., Cl^- , on passive film surfaces lowers the interfacial tension at the film/solution interfaces, which results in the formation of cracks or flaws when the repulsive forces between the adsorbed ions are sufficiently large (48). Rupture of passive films can also arise from electrostriction pressure effects (49, 50). The effect of film thickness and reduced interfacial tension, as a result of Cl^- adsorption on the surface of a passive film, on increasing the electrostriction pressure above a critical value to bring about breakdown was considered.

This view does not seem consistent with the linearity of the breakdown rate with chloride concentration. Thus, chloride occupancy of the surface and the corresponding reduction of interfacial tension would depend upon an isotherm. At the higher chloride-ion concentration in solution, a nonlinear region of the isotherm would be reached, and, hence, surface tension would no longer be linear with concentration. A linearity of breakdown rate with chloride-ion concentration (as is observed) would not be expected.

The hydrated polymeric oxide models.—After the Cl^- ion adsorbs on the outside of the passive layer and begins to diffuse inward toward the iron base, it meets with the bound water molecules (17, 51), which, in this model, are the essential cementing elements of the stable passive layer (15-18, 20). The chloride ions displace water molecules (or hydroxyl ions), since chloride ion is a stronger Lewis base than the latter (52), and form chloride containing iron complexes, which then diffuse upward and outward to the solution (53).

As chloride ions displace water molecules, the breakdown rate would be proportional to the chloride-ion concentration. The presence of increasing amounts of protons in solution, which are known (54) to adsorb on oxide surfaces, would give rise to a weakening of $\text{M}-\text{O}-\text{M}$ and $\text{M}-\text{O}-\text{H} \cdots \text{O}-\text{M}$ bonds as a result of conversion to $-\text{OH}$ and $-\text{OH}_2$ groups, respectively. With increasing hydrogen-ion concentration, such processes would lead to a weakened passive-film structure. Thus, the observed rate of breakdown dependence on hydrogen-ion concentration is interpretable qualitatively in terms of interaction of protons with surface hydroxyl groups, surface water molecules, and surface lattice oxygen. The exponential dependence of breakdown rate upon field strength (Table IV) would be consistent with the dependence of the chloride-ion diffusion rate upon field.

Thus, the kinetic data presented in this paper is sharply inconsistent with the adsorption-displacement models proposed by Kolotyrkin (37), Uhlig (38), and Hoar (42), flaw or pore models (46, 47), and chemico-mechanical models (48-50), but is not inconsistent with ion-exchange processes (1, 45, 46), point-defect models (22), or the hydrated polymeric oxide model (15-17, 20).

XPS data.—The spectroscopic data (Fig. 6-12) will be utilized in leading to a distinction between the alternative models mentioned above.

The lack of a ferrous-ion signal on deconvoluting the $\text{Fe } 2p_{3/2}$ spectra (cf. Fig. 6) is not surprising, in view of the potential at which the film was grown, namely, 0.3V (NHE). This is 0.2V more positive than the Flade potential for the solution pH used. This view contrasts with the work of Sato *et al.* (55), who found Fe^{2+} ions at less positive potentials (and at transpassive potentials).

For passive films grown at various potentials, the observed $\text{O}_{\text{total}}/\text{Fe}$ ratio of about 2 and $\text{H}_2\text{O}/\text{Fe}$ ratio of ca. 0.5 at a constant depth for each film (cf. Table I)

are consistent with the model in which the passive film is constituted essentially of $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$. In respect to the O/Fe ratio, the value is not consistent with the model, which requires 1.5, whereas the value observed is around 0.9. However, if one takes the average of the sum of the O/Fe and OH/Fe ratios, a value of approximately 1.5 is obtained. To rationalize this result, it may be taken that the lattice water is bound by means of hydrogen bonding to the lattice O^{2-} ions, so that the XPS sees a pseudohydroxylated structure. The schematic shown in Fig. 13 shows a type of structure which might be consistent with a value of 1.5.

Table II shows the effect of XPS analyzing depth on various relevant ratios. The $\text{O}_{\text{total}}/\text{Fe}$ and the $\text{H}_2\text{O}/\text{Fe}$ ratios are higher than that required by the polymer model near the surface, but they correspond to that required as one goes into the depth of the film. The extra water near the surface may seem reasonable in terms of water adsorbed in the double layer.

In Table III, the effect of chloride ions on the relevant ratios is tabulated. The $\text{O}_{\text{total}}/\text{Fe}$ ratio is down to 1.5 from 2.0. This corresponds to what would be expected if Cl^- ions removed water in the process of depassivation (13, 23). More strikingly still, the ratio of $\text{H}_2\text{O}/\text{Fe}$ goes down to 0.1 after exposure to Cl^- ions, in marked consistence with the model. The average of the sum of $(\text{OH} + \text{O})/\text{Fe}$ is 1.5, after Cl^- addition, in accordance with a dehydrated structure after depassivation. The fact that the OH/Fe ratios of a film after breakdown (Table III) are similar to those of the nonexposed passive films (Tables I and II) is possibly due to residual hydrogen, in the form of hydroxyl groups, remaining in the passive film, or, more probably, due to corrosion product buildup, e.g., $\text{Fe}(\text{OH})_3$, throughout the layer after breakdown.

Ion scattering spectroscopy data.—This is shown in terms of O/Fe ratios (cf. Fig. 9). After the first 5Å, the ratio for a passive film attains a value of about 2, just what is required of the polymer model without chloride exposure. The O/Fe ratio after chloride addition has the constant value of 1.5, as is needed by the polymer model. The constant values obtained also indicate a single oxide phase throughout the thickness of the passive films.

SIMS data.—With respect to depth, it is seen that the OH^-/O^- ratios (Fig. 10) reach a high of 0.5 near

Fig. 13. Schematic representation of the hydrated passive film on iron.

the surface and level off in the bulk of the films at less than 0.1. The modelistic ratio for the polymer structure, e.g., $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, is about 0.3, but SIMS is qualitative, and, therefore, the numerical discrepancy does not seem significant. However, what is significant is the temperature effect. It is seen that, qualitatively, the fall of the OH^-/O^- ratios with increase of temperature is consistent with the removal of water as the key aspect of the effect of temperature on passive films.

The data presented in Fig. 11 establishes chloride penetration into passive films on iron on being exposed to chloride-ion solutions as a result of events leading to breakdown. The requirement of water within passive films to facilitate chloride-ion penetration of the latter has been stressed in the case of the breakdown of passivated titanium alloys (52). With respect to the surprising decrease of chloride ions with time in passive films (cf. Fig. 11), some dissolution of the passive film itself takes place, as is evidenced by the rotating ring-disk work of Heusler and Fischer (53), which showed Fe^{3+} species arising after exposure of passivated iron disks to chloride solution.

From the data presented in Fig. 12, the interfacial passive film region is about 5Å thick, and the region between 10 and 27Å corresponds to films with constant properties. After 27Å, the fall off in the O^+ signal indicates that the interface with the iron substrate is reached. A film thickness of ca. 27-30Å for a growth potential of + 0.3V (NHE) is in excellent agreement with the ellipsometric data of Sato *et al.* (55). It is also possible to conclude from this data (Fig. 12) with regard to the effect of chloride ions that the thickness of passive films clearly remains unchanged for various times of exposure to chloride ions before and after breakdown (41).

It must be pointed out, however, that the data derived from SIMS analyses is qualitative in nature (56, 57). In the SIMS process, complications associated with matrix effects (58, 59), preferential sputtering (60, 61), and knock-on effects (62) in sputtering can arise. Only a general picture, at best, can be deduced from such data.

Conclusion

The electrochemical kinetic evidence excludes adsorption-displacement models (37, 38, 42), pore models (46, 47), and chemico-mechanical models (48-50), but leaves open a choice among ion-exchange processes (1), point-defect models (22), or the hydrated polymeric oxide model (15-17, 20) in the case of the breakdown of passive films on iron in chloride solutions. With respect to the spectroscopic evidence, though none of the data is by itself conclusive, yet, taken together, they point in favor of the polymeric oxide model.

Acknowledgments

Support of this work by the Department of the Interior (DOI) under grant no. 14-34-0001-9446 and to Dr. W. McCoy for discussion is gratefully acknowledged. We greatly appreciate the performance of ISS analyses at Solar Energy Research Institute, Golden, Colorado, and, in particular, acknowledge Dr. A. W. Czanderna, Dr. R. Pitts, and Dr. T. Thomas for this service. We would like to thank Dr. R. P. Frankenthal, AT&T Bell Laboratories, Murray Hill, New Jersey, for pointing out to us the ISS cross-sectional ratio, $\sigma_{\text{Fe}}/\sigma_{\text{O}} = 8.8$. The authors are also grateful to Mrs. Lynn McCartney-Murphy for her editing and typing of this manuscript.

ABSTRACT

A tertiary current-distribution model is developed for predicting two-dimensional shape change during electrodeposition through polymeric masks. The cathode geometry studied consists initially of a parallel array of microscopic, rectangular trenches, the trench bottoms being conductive metal, and the trench walls being formed from insulating mask material. Concentration polarization, activation polarization, and a stagnant diffusion-layer treatment of convective mass transport are incorporated into the model equations. Boundary integral equation methods and Euler-predictor, trapezoid-corrector time integration are used to calculate the deposit-shape history as it depends on geometrical parameters, the level of convection, and the degree of polarization.

Using photolithography techniques and materials developed for the manufacture of integrated circuits, it has become possible to create electroforming molds on a micron- or even submicron-size scale. In the semiconductor industry, these microscopic electroforming molds are termed mask structures, so that the process of electroforming with them is called electroplating through polymeric masks. The individual steps in this process are described elsewhere (1). When metal is electrodeposited through a mask under the proper conditions, the deposit conforms faithfully to the dimensions of the mask pattern. Hence this process can be used to fabricate metal structures that preserve the pattern resolution obtainable with current lithography technology (2).

Romankiw *et al.* (3) have compared this technique to other procedures used to obtain patterned microscopic metal structures. The techniques of wet chemical etching, reactive ion etching, sputter etching, and ion milling cannot etch wholly in one direction. To varying extents they degrade the resolution of the mask pattern by lateral spread of the etching species. Lift-off techniques involving the evaporative deposi-

tion of a metal are more faithful to the mask pattern, but it is only with difficulty that features much taller than they are wide can be obtained. Electroplating through masks does not have this aspect-ratio limitation. In view of its advantages, electroplating through masks is beginning to see use in the fabrication of magnetic bubble memories (2), thin film recording heads (4), masks for x-ray lithography (5), fresnel-zone plates and submicron gratings for x-ray diffraction (6), and interconnection networks for microelectronic circuitry (7).

This work is a theoretical investigation into the mass-transfer aspects of the electrodeposition step of this metallization process. The masked electrode is distinguished by feature sizes that are small relative to the concentration boundary-layer thickness, and by the separated, recessed cathodic areas. We derive a model which emphasizes the importance of diffusional limitations in influencing the evolving shape of the electrodeposit. Other theoretical studies of electrode shape evolution either have not considered tertiary current-distribution effects (8-11), have considered tertiary effects but do not apply to microprofiles (12), or have only considered the limiting current case (13). Among the studies just cited, only Alkire *et al.* (8) have considered a discontinuous electrode geometry.

* Electrochemical Society Active Member.

Key words: current density, moving boundary, boundary element method, electrodeposition.

Theoretical Formulation of the Model Problem

A microprofile is defined as a feature of electrode topography whose size rivals or is smaller than the thickness of the concentration boundary layer adjacent to the electrode surface (14). Microprofiles of an electrode present an uneven surface to mass transfer by diffusion and convection because raised parts of the profile are more accessible to mass transport of the reacting species from the bulk electrolyte. In the process of electrodeposition through masks, the cathode layout is determined photolithographically, so that typical feature sizes are 1-100 μm . The thickness of the concentration boundary layer can be approximated from measurements or calculations of the mass-transfer coefficient. Under conditions of gentle stirring, an effective film thickness of 50-100 μm is typical. Hence deposited features will be within the size domain of the microprofile.

Kardos and Foulke (14) have presented an extensive review of electrodeposition on microprofiles. They present theoretical estimations and experimental results to support the relatively large importance of diffusional and convective effects in determining the distribution of current density on a microprofile. For a microprofile, ohmic influences are negligible as compared to concentration and activation overpotentials in determining the local pattern of current distribution. Neglecting the role of plating bath additives, variation in the current density on a microprofile is primarily due to the variation in mass transfer by diffusion or convection of the depositing species.

We consider the case of a single depositing species in a supporting electrolyte bath. The reduced importance of the potential field in the vicinity of a microprofile electrode feature leads to a simplification of the current-distribution analysis. The portion of the electrode overpotential that is not attributed to changes in the concentration field of the depositing species is assumed constant. The contribution of migration to transport of the minority depositing species is negligible, and solution of the potential field is unnecessary.

The cell geometry considered is illustrated in Fig. 1. At the cathode, where the deposition occurs, a prototypic pattern of evenly spaced, identical rectangular trenches is considered. This might represent a mask for a grating or a group of circuit lines. Since the potential field only influences the deposit growth through its constant contribution to the cathodic overpotential, details of the anode geometry are not considered. Conceptually, the anode is parallel to and located far above the masked-electrode plane.

Convective effects are included in the analysis in an approximate manner by modeling the concentration boundary layer as an equivalent stagnant film adjacent to the electrode surface. The thickness of this film is inversely proportional to the mass-transfer coefficient.

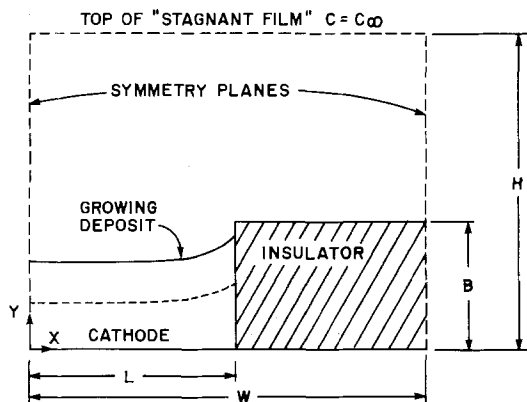

Fig. 1. Two-dimensional model geometry

A thinner film corresponds to greater agitation and a faster rate of deposition. Outside of the stagnant film, all species are assumed to be at their bulk concentrations.

This approximation neglects the effects of the local flow pattern on mass transfer in the trench, a simplification which is valid for small features and moderate rates of agitation. In reality, flow over the top of the trench will induce recirculating motion within the trench. If $\dot{\gamma}$ is the characteristic velocity gradient on the surface of the mask and L is the half-width of the trench, then the characteristic velocity of the recirculating motion is $\sim 0.01\dot{\gamma}L$ (15). Accordingly, the Peclet number that characterizes the importance of this recirculating motion relative to diffusion is $Pe \sim 0.01\dot{\gamma}L^2/D$, where D is the diffusion coefficient of the depositing species. For example, with $L = 10 \mu\text{m}$, $D = 10^{-5} \text{ cm}^2/\text{s}$, and $\dot{\gamma} = 100 \text{ s}^{-1}$ (characteristic of a vigorous, but laminar shear flow), $Pe \sim 0.1$, and diffusion will be dominant.

It is assumed that a single cathodic-deposition reaction occurs and that the current density normal to the cathode surface is described by a concentration-dependent Tafel equation (16)

$$i_{\text{cath}} = -i_0 (C_s/C_\infty)^\beta \exp(-\alpha_c \eta_s F/RT) \quad [1]$$

The surface overpotential, η_s , is found as the sum of the concentration overpotential, η_c , and a constant

$$\eta_s = -\eta_c + \text{const.} \quad [2]$$

$$\eta_c = -(RT/zF) \ln(C_\infty/C_s) \quad [3]$$

As discussed above, the constant corresponds to the level of applied potential, which influences the current level but is much less important than the concentration field in affecting current density uniformity. The expression [3] for the concentration overpotential is valid for a minority reacting species in a supported electrolyte, as shown by Newman (16).

We assume that the bulk concentration and the diffusivity of the reacting species are constant during the deposition and that the rate of shape change of the deposit is slow compared to the establishment of the concentration field. The last assumption is based on an estimated Peclet number for the advance of the cathode of 10^{-5} , using 10^{-6} cm/s as a typical velocity for the cathode surface (7).

With these assumptions the deposit growth is modeled by solving Laplace's equation for the concentration field

$$\nabla^2 C = 0 \quad [4]$$

subject to the following boundary conditions. First, the cathode current density is proportional to the diffusive flux of the reacting species normal to the cathode

$$i_{\text{cath}} = \underline{n} \cdot zFD \nabla C, \text{ cathode surface} \quad [5]$$

Here \underline{n} is the surface normal vector which points into the deposit surface from the electrolyte. Usually the current density is described by Eq. [1]. We are also interested in solving for the limiting current distribution for comparison. For this special case, the concentration of the limiting reactant at the cathode is set to zero

$$C = 0, \text{ cathode surface (limiting current)} \quad [6]$$

The cathode current density also determines the rate of cathode movement. Assuming a current efficiency of unity, and denoting the surface velocity as V_s , the cathode velocity in the direction of the surface normal is given as

$$\underline{n} \cdot V_s = \frac{M}{z\rho F} i_{\text{cath}} \quad [7]$$

The cathode current density is negative, indicating that growth is into the electrolyte. At the bulk solution-

diffusion layer interface, the reacting species is at its bulk concentration

$$C = C_\infty, \quad Y = H \quad [8]$$

Finally, there is no flux across planes of symmetry or insulating surfaces

$$\underline{n} \cdot \nabla C = 0, \quad \text{insulator, symmetry planes} \quad [9]$$

The equation set is recast in nondimensional variables by using the trench half-width as the characteristic length and defining

$$\begin{aligned} x &\equiv X/L & c &\equiv C/C_\infty \\ y &\equiv Y/L & v_s &\equiv V_s t_0/L \\ h &\equiv H/L & \tau &\equiv \frac{DC_\infty Mt}{\rho L^2} \equiv \frac{t}{t_0} \\ \nabla &\equiv L \tilde{\nabla} \end{aligned} \quad [10]$$

Upon substitution, Eq. [1]-[9] become

$$\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial y^2} = 0 \quad [11]$$

$$c = 1, \quad y = h \quad [12]$$

$$\underline{n} \cdot \nabla c = -\xi c^{\beta + (\alpha_c/z)}, \quad \text{cathode surface} \quad [13]$$

$$c = 0, \quad \text{cathode surface (limiting current)} \quad [14]$$

$$\underline{n} \cdot \nabla c = 0, \quad \text{insulator, symmetry planes} \quad [15]$$

$$\underline{n} \cdot v_s = \underline{n} \cdot \nabla c, \quad \tau > 0 \quad [16]$$

where the polarization parameter, ξ , is defined as

$$\xi \equiv \frac{Li_\infty}{zFDC_\infty} \exp[-\alpha_c F(\eta_s + \eta_c)/RT] \quad [17]$$

This use of the term polarization parameter differs from its use in describing secondary-current distributions. Here it is a measure of diffusional mass-transfer limitations compared to electrode-kinetic limitations.

At any time, Eq. [11]-[15] are used to determine the concentration field along the cathode, which is then used to advance the cathode according to Eq. [16]. Repetition of this process results in a history of the deposit shape and its local growth rate starting from the initial condition of a flat profile.

The model equations are sufficiently complex so that numerical solution is required. Prentice and Tobias (17) have recently surveyed numerical methods for solutions to current-distribution problems. Of the methods used to date for moving boundary electrochemical problems, the finite-element method (FEM) (8, 10, 13) and the finite-difference method (FDM) (9, 11, 12) are the most general. In the present study, we have found it advantageous to use an integral-equation technique appropriate for Laplace's equation, referred to as the boundary element method (BEM). The BEM is the method of choice for this investigation primarily for two reasons. First, it incorporates the isoparametric mapping advantage of the FEM. That is, the basis functions that are used to interpolate the concentration field are also used to interpolate the system boundaries. The ability to conveniently represent curved or deforming boundaries is therefore built into the method. Second, by using an integral-equation form of Laplace's equation, it is possible to reduce a problem from a form involving an entire region to a form involving data only along the region's boundary. This reduction in dimensionality of the problem can result in computational savings, especially if only surface values of dependent variables are sought. Unlike the FDM or the FEM, which generate banded, symmetric matrix problems, the BEM results in a matrix problem that is full and asymmetric. The economy of the technique hinges on the reduction of the problem to only the sys-

tem boundaries and the concomitant savings in the number of node points. Its use has been demonstrated by several authors (18-23).

The mathematical formulation of the BEM is derived from the requirement that weighted residual integrals of Laplace's equation vanish over the domain, Ω

$$\int_{\Omega} w_i \nabla^2 c d\Omega = 0 \quad [18]$$

Here $w_i = w_i(x, y; x_i, y_i)$ is a weighting function that is defined with reference to a node point (x_i, y_i) and an observation point (x, y) . By integrating by parts twice and using the divergence theorem, Eq. [18] is reduced to

$$\begin{aligned} - \int_{\Omega} c \nabla^2 w_i d\Omega + \int_{\Gamma} c (\underline{n} \cdot \nabla w_i) d\Gamma \\ - \int_{\Gamma} w_i (\underline{n} \cdot \nabla c) d\Gamma = 0 \end{aligned} \quad [19]$$

where $d\Gamma$ is used to signify integration over the system boundaries, Γ . The first integral taken over the domain is eliminated by choosing w_i to be a Green's function (fundamental solution) for Laplace's equation. The general, two-dimensional BEM formulation is based on using the free space Green's function

$$w_i(x, y; x_i, y_i) \equiv -\frac{1}{4\pi} \ln[(x - x_i)^2 + (y - y_i)^2] \quad [20]$$

which satisfies $\nabla^2 w_i(x, y; x_i, y_i) + \delta(x - x_i) \delta(y - y_i) = 0$. Here δ is the Dirac delta function. Substituting Eq. [20] into Eq. [19] results in the integral form of Laplace's equation

$$\begin{aligned} \theta_1 c_i - \frac{1}{2\pi} \int_{\Gamma} c (\underline{n} \cdot \nabla \ln(r)) d\Gamma \\ + \frac{1}{2\pi} \int_{\Gamma} \ln(r) (\underline{n} \cdot \nabla c) d\Gamma = 0 \end{aligned} \quad [21]$$

where $r \equiv \sqrt{(x - x_i)^2 + (y - y_i)^2}$, and θ_1 depends on the point, (x_i, y_i) , at which the equation is applied. When (x_i, y_i) is outside the domain, $\theta_1 = 0$; when (x_i, y_i) is inside the domain, $\theta_1 = 1$; and when (x_i, y_i) is on the domain boundary, as is the usual case, θ_1 equals the interior angle of the domain divided by 2π . For the usual smooth surface point, $\theta_1 = 1/2$.

A matrix formulation of the BEM is constructed by choosing a set of nodal points along the boundary. The values of the concentration and its normal derivative, $dc/dn \equiv \underline{n} \cdot \nabla c$, on the boundary are interpolated by a set of one-dimensional finite element basis functions $\{\Phi_i(s)\}$. Each function is written in a local coordinate s that accounts for the orientation of the particular segment of the boundary. The concentration and its derivative on the boundary are expressed as

$$c[x(s), y(s)] = \sum_{i=1}^N \Phi_i(s) c_i \quad [22]$$

$$\frac{dc}{dn}[x(s), y(s)] = \sum_{i=1}^N \Phi_i(s) d_i$$

where the coefficients $\{c_i\}$ and $\{d_i\}$ are determined from the solution of the weighted residual equations. The shape of each segment of the boundary is also interpolated by this finite element basis according to the isoparametric mappings

$$x = \sum_{i=1}^N \Phi_i(s) x_i, \quad y = \sum_{i=1}^N \Phi_i(s) y_i \quad [23]$$

The summations in Eq. [22] and [23] are formally over

all nodes on the boundary; however, for the quadratic basis functions used here, only three terms are nonzero at any location.

Substituting the basis functions and boundary conditions of Eq. [12]-[15] into Eq. [21] results in an algebraic equation for each node point (x_i, y_i)

$$\begin{aligned} \theta_i c_i - \frac{1}{2\pi} \int_{\Gamma_d} \underline{n} \cdot \nabla \ln(r) d\Gamma \\ - \frac{1}{2\pi} \int_{\Gamma_i, \Gamma_c} (\Sigma \Phi_j c_j) [\underline{n} \cdot \nabla \ln(r)] d\Gamma \\ + \frac{1}{2\pi L} \int_{\Gamma_d} [\ln(r)] [\Sigma \Phi_j (dc/dn)_j] d\Gamma \\ - \frac{\xi}{2\pi L} \int_{\Gamma_c} [\ln(r)] (\Sigma \Phi_j c_j)^{\beta + (\alpha_c/z)} d\Gamma = 0 \quad [24] \end{aligned}$$

where r measures the distance from the point (x_i, y_i) . The integrals in Eq. [24] are nonzero only along specified boundary segments, as indicated by the notation. The segment types are Γ_c (cathode), Γ_i (insulator or symmetry plane), and Γ_d (top of diffusion layer).

The boundary conditions for a well-posed problem specify either c , dc/dn , or a relationship between them, at every point along the surface. Therefore, application of Eq. [24] using each node as a base point results in a set of simultaneous equations for the unknown nodal values of $\{c_i\}$ and $\{d_i\}$. The matrix formulation for this problem

$$\underline{A} \underline{X} + \underline{F} + \underline{Q} = 0 \quad [25]$$

is obtained by defining

$$A_{ij} \equiv \begin{cases} \int_{\Gamma_i, \Gamma_c} \Phi_j [\underline{n} \cdot \nabla \ln(r)] d\Gamma - 2\pi \theta_i \delta_{ij}, & \text{for } X_i = c_i \\ -\frac{1}{L} \int_{\Gamma_d} \ln(r) \Phi_j d\Gamma, & \text{for } X_i = d_i \end{cases} \quad [26]$$

$$X_i \equiv \begin{cases} c_i & \text{for } \Gamma_i, \Gamma_c \\ d_i & \text{for } \Gamma_d \end{cases} \quad [27]$$

$$F_i \equiv \int_{\Gamma_d} \underline{n} \cdot \nabla \ln(r) d\Gamma \quad [28]$$

$$Q_i \equiv \frac{\xi}{L} \int_{\Gamma_c} [\ln(r)] (\Sigma \Phi_j c_j)^{\beta + (\alpha_c/z)} d\Gamma \quad [29]$$

In Eq. [25], the vector \underline{Q} has a nonlinear dependence on the unknown cathode-surface concentrations. Solution to the matrix equations is accelerated using Newton-Raphson iteration, where the components of the Jacobian are found from the A matrix and from explicit differentiation of Q_i with respect to c_j .

The integrals needed in the above terms are done numerically using a ten-point Gauss-Legendre quadrature rule, except when the base point coincides with the portion of the boundary being integrated. In this case, integrals with $\ln(r)$ singularities result, and a four-point quadrature formula that accounts for the singularity is applied (24). We have found that better numerical accuracy is obtained if θ_i is calculated by difference, as described by Brebbia (22), rather than directly from the interior angle of the domain at (x_i, y_i) . The derivation summarized here for the Tafel polarization expressed in Eq. [1] also applies to the limiting current case, *mutatis mutandis*.

A Euler-predictor, trapezoid-corrector scheme is used to determine the time evolution of the cathode surface, according to Eq. [16]. The method has second-order accuracy in time, with local error being $O(\Delta t)^3$, and therefore offers a similar level of approximation in time to what quadratic basis functions offer in the

spatial representation. Irrespective of the integration scheme used, the error in the calculated position of the deposit surface must increase with time. This is because the problem is physically and mathematically unstable, as will be discussed in the next section.

The calculation procedure is presented in detail elsewhere (25).

Results and Discussion

A definitive analysis of error in the numerical solutions is not possible since analytical solutions are not available. However, an estimate of the solution error was obtained by analyzing the convergence of the solution as the number of nodal points was increased. Figure 2 shows the root-mean-square (rms) differences in the concentration values at the cathode nodes for solutions obtained with varying total nodes, relative to the solution obtained with 240 total nodes. The observed solution convergence rate was slightly less than quadratic for the calculation with the nonlinear Tafel kinetics and somewhat faster than quadratic for the linear limiting current calculation. There was close agreement between the solutions obtained with a small number of nodes and the solutions obtained using 240 nodes.

A strong indication that the solutions obtained were converging to the correct result was the rapid convergence of the overall mass balance, also shown in Fig. 2. The mass balance was obtained by integrating the net current over the surfaces of the domain. This imbalance was expressed as a fraction of the total current at the cathode boundary. The slopes of the mass-balance curves in Fig. 2 indicate that the mass-balance error was proportional to the node spacing raised to the third power, and was comparable to solution error convergence rates for the Galerkin finite-element method applied to Laplace's equation using biquadratic elements (26).

Figure 3 may be used as a guide to estimate computation expense. In Fig. 3, the CPU time needed on a Honeywell 6180 mainframe computer to obtain a concentration field solution at a single time step is plotted as a function of the number of nodes in the solution. The rate of growth of execution time with the number of nodes suggests that formulation of the integral terms dominated the computation expense,

Fig. 2. Convergence of the overall mass balance and of the concentration solution at the cathode surface. Imbalance of the mass flow over the boundaries is expressed as a fraction of the average cathode current. The concentration-field error is the root-mean-square error at the cathode relative to the solution obtained using 240 total nodes. Slopes for the linear regression lines are as indicated.

Fig. 3. Computation time as a function of the number of nodes, for solution of the initial concentration field on a Honeywell 6180 mainframe computer.

since this grows with the square of the number of nodes and the expense of solving the simultaneous equation set scales as the third power of the same number. Given a sufficient number of nodes, the cost of solving the simultaneous equation set will eventually dominate the computation time.

For each time step, the concentration field had to be solved for twice, and for the deposition history of a profile, a sequence of time steps was needed. The results were insensitive to the size of the time step that was used. For most problems a simulation composed of five time steps agreed to within a few percent with simulations that used many smaller time steps. When the current distribution was nearly uniform, even fewer time steps were needed. Simulations that involved filling a deeper trench area, or that involved a less uniform current distribution were more sensitive to the time step and were handled accordingly.

Reaction kinetics, trench geometry, and deposition time are each important in determining the deposit-shape history. The kinetic factors include β , α_c , z and ξ . The values of β , α_c , and z were fixed throughout this study at 0.58, 0.36, and 2, respectively. These values are appropriate for a copper acid-sulfate bath and are based on the statistical study of Caban and Chapman (27). The most important kinetic factor is the polarization parameter (Eq. [17]), ξ . It is a measure of mass-transfer limitations compared to electrode-kinetic limitations. Increasing the Tafel exchange current density corresponds to a more active electrode surface and a higher value of ξ . However, larger diffusivity and bulk concentration of the depositing species decrease mass-transfer limitations and thus decrease ξ . ξ also incorporates the effect of applied cell potential on the electrode reaction; for a higher applied cell potential, ξ will grow exponentially. As ξ becomes infinite, the interfacial concentration becomes zero, and limiting current behavior results.

In Fig. 4, the effect of ξ on the average current density across the initial, flat cathode surface is portrayed. The three curves represent different levels of convection, or thicknesses of the diffusion film, h . Two regimes of electrochemical cell behavior are identified. When $\xi < 0.01$, the kinetic resistance of the electrode reaction controls the rate of reaction, and the current is independent of h . The solution of the concentration field in this low current regime was nearly constant at the bulk value, and the current density was nearly uniform over the cathode surface. At high levels of ξ , mass transfer controlled the electrodeposition. The total current was insensitive to the precise level of ξ ;

Fig. 4. Average initial current density as a function of the polarization parameter and diffusion film thickness, for $b = 0.2$ and $w = 2$.

the cell geometry and the thickness of the diffusion film determined the deposition pattern. Only at intermediate values of ξ were both mass transfer and kinetics important in setting the deposition history.

In Fig. 4, the polarization scale is broken so that the current values from the limiting current calculations are shown on the extreme right. There was a smooth approach of the nonlinear (finite ξ) solutions to the separately calculated limiting current (infinite ξ) solutions. This confirmed the consistency of the underlying calculations.

The value of ξ had a strong influence also on the thickness variations of the deposit shape. In Fig. 5, deposit profiles are drawn to show the influence of ξ after sufficient current has passed to fill either 35% or 70% of the trench area, denoted by $\Lambda = 0.35$ and $\Lambda = 0.70$. Figure 5 shows only the right half of a symmetrical trench deposit, being consistent with the model cell geometry of Fig. 1. For the cases depicted in Fig. 5, the initial trench depth was 20% of the trench half-width. The pattern of nonuniformity depicted in Fig. 5 is in accord with expectation. The right-hand side of the cathode received additional current from the area above the insulating resist material. The deposit on the left-hand side of the diagram corresponds to

Fig. 5. Deposit profiles for two values of the polarization parameter, when the trench area is 35% or 70% full, and $h = 5$, $b = 0.2$, and $w = 2$.

the center of the trench and only received current from the cell area above it. Therefore, as ξ was increased and mass-transfer effects became more important, the deposit grew fastest next to the trench wall. The profile was flat as it approached the left side of the diagram. This was predictable from the symmetry condition that was imposed for the center of the trench.

Except near the limiting current, the deposit profiles calculated for other conditions were similar to those depicted in Fig. 5. The maximum deposit was at the trench wall, and the minimum was at the trench centerline. A smooth curve connected the two extrema, and the curve became flat as it neared the centerline minimum. As the limiting current was approached and the current distribution became less uniform, it was possible to develop rippled deposit shapes. In this case, the predicted node locations along the cathode surface were alternately above or below some average curve.

This rippling is due to an underlying physical instability of the deposition process. A point on the cathode surface that rises above the neighboring surface receives more current because it is more accessible. The enhanced deposition caused by the increased current accelerates the growth of the nonuniformity. The perturbation analysis of Fedkiw (28), for a primary current distribution, indicates that shorter wavelength, sinusoidal electrode profiles will grow faster than longer wavelength ones. Our numerical simulations are consistent with this result in two ways. First, when rippling occurred, it had the periodicity of the node spacing, which is the lowest ripple wavelength that can be accommodated in the boundary-element approximation. Second, refining the approximation by introducing more nodes caused rippled deposits to appear at lower currents, indicating that the shorter wavelength ripples had a faster rate of growth.

In addition to the node spacing, the formation of ripples was influenced to an unknown extent by the accumulation of calculation error. Fortunately, rippled surfaces were found only near the limiting current, and after a substantial degree of deposit growth. Prentice and Tobias (17) report similar instability phenomena which they suppressed, arbitrarily, by numerically smoothing their node locations. No smoothing procedure was employed in the present study.

An effective means of parameterizing the usual deposit shapes as they evolve in time is to express the difference in deposit thickness as a fraction of the maximum thickness. That is, the index of nonuniformity is defined as

$$\Delta Y \equiv (Y_{\max} - Y_{\min})/Y_{\max} \quad [30]$$

The extent of the deposit is described by Δ (deposit area/trench area). Plots of ΔY vs. Δ are used to illustrate the effects of the various geometric parameters on the nonuniformity of the deposit. With reference to Fig. 1, recall that the following geometric factors are defined as dimensionless ratios to the trench half-width, L ; h , the upper limit of the diffusion film; b , the depth of the trenches before deposition; and w , the overall symmetry width. To elicit the effect of these parameters on the deposit formation, it is convenient to define a standard set of parameter values as a reference case. For this purpose we choose $h = 5$, $b = 0.2$, and $w = 2$.

Figure 6 displays the effect of varying the level of convection, as expressed by h , at three values of the polarization parameter, ξ . The other geometric parameters, b and w , are held at their reference values. For a given value of ξ , increased convection (lower h) resulted in a more uniform deposit. With higher levels of convection, the diffusion film was thinner, mass-transfer limitations were lessened, and current from above the insulating resist mask that caused uneven deposition made a smaller contribution to the total current. It is convenient to regard the area above the

Fig. 6. Effect of diffusion film thickness on the development of deposit nonuniformity, for $b = 0.2$ and $w = 2$.

insulating resist mask as a reservoir of the depositing reactant. As mass-transfer limitations become more pronounced, the additional mass flow from this reservoir promotes uneven deposition.

The curves in Fig. 6 fall into groups showing the importance of ξ in setting the nonuniformity of the deposit. At the low value, $\xi = 0.2$, the influence of the trench geometry was only weakly felt and the profiles varied by only a few percent in thickness. One might suppose that the level of current at $\xi = 0.2$ is only a small fraction of the limiting current, in view of the predicted uniformity of profile shapes. It is surprising to note that for the $h = 5$ intermediate case, the current was at 39% of the limiting current level for the unfilled trench. The corresponding figures for $h = 1$ and 10 are approximately 15% and 57% of the limiting current, respectively. When ξ was 2.0, the current level for the $h = 5$ case was at 91% of the limiting current.

In Fig. 7, the effect of varying the overall symmetry width (w) is shown, with h and b held constant. As already noted, the dimensionless cathode half-width is always defined as 1.0. The results were again consistent with the idea of the insulator area functioning as a reservoir of the depositing reactant. When the overall symmetry width approached the cathode width ($w = 1.1$), there was little mass flow available from the vanishing insulator area. If the insulator area were

Fig. 7. Effect of the trench spacing on the development of deposit nonuniformity for $h = 5$ and $b = 0.2$.

eliminated, a uniform one-dimensional current distribution would result. With a larger insulating area, mass flow to the cathode edge was augmented.

The effect of varying trench depth (b) is shown in Fig. 8. As the initial trench was made deeper, the current density became more uniform, since the mass flow from above the insulator was able to diffuse laterally to a greater extent before reaching the cathode surface. With progressively greater amounts of deposition, the deeper trenches became shallower and developed current distributions that were similar to those of trenches that were initially shallow. As any given deposit approached the top of the trench area, it encountered the least uniform current distribution of its history. For a deeper trench, this late growth had a smaller effect on the overall uniformity index (ΔY), because ΔY was normalized by the maximum thickness of the deposit.

A word of explanation concerning the end points of the curves in Fig. 6-8 is in order. The calculations assumed that the deposit height along the insulator wall was always below the top of the insulator. Since the profiles can become sharply curved, the deposit can reach the top of the insulator when there is still a large portion of the trench area unfilled. The different curve lengths in Fig. 6-8 were caused by varied times for termination of the calculations, because of this trench-overrun phenomenon.

Summary and Conclusion

Theoretical predictions have been made for deposit shapes resulting from the use of photolithographically prepared mask structures. The analysis emphasizes the effect of concentration variations in determining the pattern of current nonuniformity on the exposed cathode, represented as a set of parallel, microscopic trenches. We have treated the applied cell potential as a constant contribution to the cathodic overpotential. This analysis is appropriate when ohmic influences on the local variation of current density are negligible compared to concentration and activation overpotentials.

The results show a strong dependence of deposit shape on the polarization parameter, ξ , which expresses the importance of mass-transfer limitations relative to electrode-kinetic limitations. For large values of ξ , where mass-transfer limitations predominate, additional mass flow from the area above the inactive masking material to the cathodic surface causes enhanced deposition rates at the electrode edges adjacent to the mask. This edge effect can be diminished by reducing

Fig. 8. Effect of the trench depth on the development of deposit nonuniformity, for $h = 5$ and $w = 2$.

the fractional area of the substrate that is masked, by increasing the agitation of the bath, or by increasing the thickness of the mask pattern. Reducing the applied cell potential corresponds to reducing ξ . This diminishes mass-transfer limitations and smooths the current distribution but slows the deposition rate. The tradeoff is such that deposit profiles formed at 40% of the limiting current show only a small degree of height variation, for the geometry considered.

The boundary element method was found to be effective for solving this electrochemical current distribution problem, which involves Laplace's equation. The method is especially useful for irregular and deforming domains because it accommodates them in a regular way using isoparametric mapping. Comparatively few nodal points are needed to obtain an accurate current-distribution solution since the problem is only discretized over the boundary surface of the domain. The present analysis can be readily extended to other mask geometries, including nonperiodic and three-dimensional patterns. For the latter case, the relative compactness of the boundary-element method is particularly advantageous. The boundary-element method is also applicable to the unsteady diffusion equation (19), which would allow our analysis to be extended to pulsed cell potentials. However, the boundary-element method only applies to field equations where a Green's function is available, and does not apply directly to current-distribution problems where diffusion and migration are both important.

LIST OF SYMBOLS

A	formulation matrix
b	dimensionless depth of trench before deposition
B	dimensional depth of trench before deposition (m)
c	dimensionless concentration of the depositing species
c_i	dimensionless concentration at the nodal point i
C	concentration of the depositing species (g mol/m^3)
C_s	concentration of the depositing species at the cathode surface (g mol/m^3)
C_∞	bulk concentration of the depositing species (g mol/m^3)
d_i	dimensionless normal concentration gradient, $\underline{n} \cdot \nabla c$, at the nodal point i
D	diffusivity of the depositing species (m^2/s)
F	Faraday's constant (96,500 C/g equiv.)
\underline{F}	vector resulting from matrix formulation
h	dimensionless thickness of the diffusion film
H	dimensional thickness of the diffusion film (m)
i_{cath}	current density normal to the cathode surface (A/m^2)
i_∞	exchange current density corresponding to the bulk concentration of the depositing species (A/m^2)
L	half-width of the cathode trench (m)
M	molecular weight of the depositing species (g/mol)
\underline{n}	normal vector pointing from the electrolyte into the deposit
\underline{Q}	vector of nonlinear contributions
r	radial distance from the point i
R	gas constant (8.32 J/g mol K)
t	time (s)
t_0	characteristic dimensionless time, $\rho L^2 / DC_\infty M$
T	absolute temperature (K)

v_s	dimensionless velocity of the cathode surface
\vec{V}_s	dimensional velocity vector of the cathode surface (m/s)
w	dimensionless symmetry width
w_i	weighting function based at the i th node point
X	dimensional symmetry width (m)
x	horizontal coordinate, dimensionless
x_i	horizontal coordinate of node i
X	dimensional horizontal coordinate (m)
\underline{X}	vector of unknown concentrations and fluxes
y	vertical coordinate, dimensionless
y_i	vertical coordinate of node i
Y	dimensional vertical coordinate (m)
ΔY	deposit nonuniformity index, Eq. [30]
z	valency of the depositing species and the number of electrons in the deposition reaction (g equiv./g mol)

Greek Characters

α_c	cathodic transfer coefficient
β	concentration dependence exponent of the exchange current density
$\dot{\gamma}$	velocity gradient (s^{-1})
Γ	the boundary surface of the model domain
Γ_c	cathode surface contour
Γ_d	diffusion film surface contour
Γ_i	insulator or symmetry plane surface contour
δ	Dirac delta function
δ_{ij}	Kronecker delta function, $\delta_{ij} = 1$ if $i = j$, otherwise $\delta_{ij} = 0$
η_s	surface overpotential
η_c	concentration overpotential
Θ_i	constant related to position of the point i
Λ	trench deposit area/total trench area
ξ	polarization parameter
ρ	density of the cathodic deposit (g/m^3)
τ	dimensionless time
Φ_i	quadratic polynomial basis function centered at nodal point i
Ω	two-dimensional region where Laplace's equation applies
∇	dimensional gradient operator
∇	dimensionless gradient operator

Efficiency of Splitting Water with Semiconducting Photoelectrodes

Michael F. Weber* and Michael J. Dignam*

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A1

ABSTRACT

Solar conversion efficiencies for splitting water with semiconducting photoelectrodes are calculated from basic thermodynamic principles combined with transport properties matching those of the best materials presently available. Assuming no further constraints, we derive in this way "upper limit" estimates of efficiencies achievable via semiconductor photoelectrochemical cells (PEC's), operating with no external electrical bias. Both one- and two-photon configurations are considered. A one-photon PEC is found to have an "upper limit" efficiency of ~7% (AM 1.2 solar energy to chemical potential energy stored as H_2). For two-photon configurations, the "upper limit" for a p-n PEC is ~10%, while for a tandem PEC it is ~18%. The tandem cell configuration is the least sensitive to the choice of materials parameters and transport losses and yields the highest efficiencies. Significant increases in conversion efficiencies result from assuming lower oxygen overpotentials and higher photoelectrode fill factors than have been achieved so far, with the latter being the more important, however.

The free energy required to split water reversibly into H_2 and O_2 gases at room temperature is about

* Electrochemical Society Active Member.

Key words: solar, semiconductor, EMF, energy conversion.

1.23 eV per electron transferred. As a large fraction of solar radiant energy is represented by photons of energy greater than 1.23 eV, one can be misled into believing that reasonable solar energy conversion effi-

ciencies are achievable by splitting water with an electrically unbiased, low bandgap semiconductor. Certain thermodynamic losses, however, are associated with this process. On conversion of photon energy to free energy, there is an entropy price to be paid which is entirely analogous to that associated with heat energy conversion in a Carnot engine (1). In addition to this inevitable loss, there are energy losses associated with bulk and interfacial transport, *i.e.*, with nonradiative recombination, interfacial kinetics (overpotentials), and band bending in the semiconducting element(s) making up the electrode(s). In the following, we show that on choosing transport properties matching those of the best materials presently available, these losses require that a semiconductor of bandgap ~ 2.4 eV be used to achieve the "upper limit" efficiency for conversion of solar energy to chemical free energy as H_2 via an unbiased single-photon photoelectrode. The use of such a large bandgap material for photoconversion excludes most of the solar radiant energy, resulting in a fairly low "upper limit" efficiency. However, much higher efficiencies are possible using multiple photon devices that combine the energies of two or more photons to effect the transfer of a single electron (2).

The aim of this paper is to calculate the "upper limit" efficiencies for splitting water with semiconductor devices. We define the "upper limit" efficiency as that calculated including all essential thermodynamic losses, and transport losses, assuming transport properties matching those of the best materials presently available, but, otherwise, the efficiencies are optimized with no further constraints. Three specific photoelectrochemical cell (PEC) configurations are considered: single bandgap photoelectrode with dark auxiliary electrode, separately illuminated single bandgap photoanode and photocathode, and two-bandgap photoelectrode with dark auxiliary electrode. The first has been widely studied, following Fujishima and Honda's paper on TiO_2 photoanodes (3). In the paper, Fujishima and Honda proposed using a p-type photocathode to replace the Pt auxiliary electrode. This second configuration has since been explored by several workers (4-7). This configuration is commonly called a p-n PEC. Various ways of making devices in the third configuration have been proposed and tested by Wagner and Shay (8), Nozik (9, 10), and Morisaki *et al.* (11). Fan (12) has called this optical series, electrical series arrangement a tandem cell, but has performed calculations for photovoltaic (dry) devices only.

Calculating the thermodynamic maximum open-circuit voltage of a quantum absorbing system is relatively straightforward. Such calculations have been carried out by Ross (13), Ross and Hsiao (14), and Ross and Collins (15). They derived expressions for the maximum power obtainable from such systems as well. Bolton (16) and Bolton and Hall (17) have extended these results to two-photon processes and applied them to several fuel generation reactions and to photobiological systems. The resulting voltage and power maxima are almost twice as high as the efficiencies usually achieved with single-crystal devices. The difference is of course due to the transport losses mentioned above. In photoelectrochemical junctions, a further parameter is involved, namely the flatband potential, V_{FB} , of the semiconductor, as this determines the relative alignment of the semiconductor bands and the redox energy levels of the electrolyte.

We do not make estimates for any particular choice of materials, but have chosen transport properties that are upper limits for any material to date. Bandgap energies, E_g , and V_{FB} , on the other hand, are chosen freely to optimize the conversion efficiencies in the hope that materials can be found with the desired E_g and V_{FB} .

Open-Circuit Potentials

The free energy, $\Delta\mu$, or voltage, $\Delta\mu/e$, available from the electrodes of a PEC cannot be easily measured because ohmic contacts are not made at one or both of the appropriate interfaces. However, the concept is just as useful, and its existence real, as for solid-state devices. The voltage output of a solid-solid junction is derived from the difference between the quasi-Fermi levels for electrons and holes in the space charge region. Similarly, the free energy driving force for an electrochemical junction is determined by the difference between the two quasi-Fermi levels. Gerischer (18-20) has stressed this repeatedly, pointing out that the EMF derived from a doped n-type semiconductor is given by

$$\Delta\mu = kT \ln [(p + \Delta p^*)/p] \quad [1]$$

i.e., by the increase in the hole quasi-Fermi level upon illumination, where p is the hole concentration in the dark, and Δp^* is the change in the hole concentration upon illumination. In the dark, there is only one common Fermi level.

Thus, for a single-photon photoelectrochemical junction to function, bias-free, for the photoelectrolysis of water, it is not a sufficient condition that the energy bandedges of the semiconductor straddle the electrochemical redox energy levels for H^+/H_2 and O_2/OH^- . Rather, the electron and hole quasi-Fermi levels must straddle these electrochemical potential levels, with sufficient extra separation to allow for band bending, overpotentials, and interfacial recombination.¹ In other words, the open-circuit potential, $\Delta\mu_{max}/e$, of a PEC must be considerably larger than 1.23V. The open-circuit potential of either a good single-crystal silicon p-n junction or Schottky barrier is usually ~ 0.6 V, which is considerably less than the bandgap of 1.14 eV. One can then see qualitatively that for a single bandgap device, a bandgap almost twice 1.23 eV will be required for splitting water.

If two semiconductor devices are connected in electrical series, the total $\Delta\mu$ is the sum of the $\Delta\mu$'s for each device. An example of a tandem cell is shown in Fig. 1. In this case, the hole quasi-Fermi level in semiconductor I must lie sufficiently below the O_2/OH^- redox level, and the electron quasi-Fermi level in semiconductor II must lie sufficiently above the H^+/H_2 level, in order to take care of the various free energy losses. It is

¹Redox levels and quasi-Fermi levels are electrochemical potentials for electrons. Net electron flow is forbidden except from higher to lower electrochemical potentials. A common misconception is that net electron flow is determined by the relative alignment of bandedges and redox levels.

Fig. 1. Example of a tandem PEC which divides the solar spectrum into high and low energy photons by sequential irradiance of materials with different bandgaps. An n-n isotype junction is shown here for simplicity, along with the photoelectrochemical junction, but other configurations are possible. Electrons from the high bandgap material enter the valence band of the low bandgap material where low energy photons boost them to the conduction band.

evident that smaller bandgap materials may be successfully used in this device compared to a single bandgap device.

Calculations and Results

We begin by calculating the open-circuit potential, $\Delta\mu_{\max}/e$, obtainable in a semiconductor of bandgap, E_g , in the presence of both radiative and nonradiative recombination. Using a more general formulation than Gerischer, Ross (13) has developed equations for the electrochemical potential difference, $\Delta\mu$, between the lower and upper electronic states of a two-state system. He assumes that all substrates within each band are in thermal equilibrium, *i.e.*, he assumes the validity of the quasi-Fermi level description. Thus, a common chemical potential characterizes all electrons within a single band (13). A more recent formulation of the problem has been given by Ross and Collins (15), upon which we base our present analysis. Ross has shown (13-15) that the gross rate of radiative recombination per unit area is given by

$$[\exp(\Delta\mu/kT)] \int I_{BB}(\nu) \alpha(\nu) W d\nu \quad [2]$$

where $\alpha(\nu)$ is the absorption coefficient and W is the thickness. The net rate is less because of reabsorption of that radiation in other parts of the absorber, and is given by

$$[\exp(\Delta\mu/kT)] \int I_{BB}(\nu) \epsilon(\nu) d\nu \quad [3]$$

where $\epsilon(\nu)$ is the spectral emissivity and I_{BB} is the photon flux of thermal blackbody radiation over all directions

$$I_{BB} = 8\pi n^2 (\nu/c)^2 [\exp(-h\nu/kT)], \quad h\nu \gg kT \quad [4]$$

where n is the refractive index, and all other symbols are conventional. The rate of nonradiative recombination, treated as simply a constant K times the gross rate of radiative recombination given by [2], is given by

$$K[\exp(\Delta\mu/kT)] \int I_{BB}(\nu) \alpha(\nu) W d\nu \quad [5]$$

At open circuit, all carriers recombine, *i.e.*, the rate of photon absorption, I_g , for $h\nu > E_g$, equals the total rate of carrier recombination. Using this condition, we obtain

$$\Delta\mu_{\max} = kT \ln I_g - kT \ln [\int I_{BB}(\nu) \epsilon(\nu) d\nu + KW \int I_{BB}(\nu) \alpha(\nu) d\nu] \quad [6]$$

Equations [2] and [3] were derived for a simple two-state system. Nonradiative recombination requires mid-gap states however, so Eq. [6] is not generally valid. For example, $\Delta\mu_{\max}$ must vanish in the dark, which is predicted by Eq. [6] only if $K = 0$. The error is small at normal illumination intensities, however, as we demonstrate below. For semiconductors, $KW\alpha(\nu) \gg \epsilon(\nu)$ for all ν so the first integral in Eq. [6] can be neglected.

To evaluate the second integral in Eq. [6], we must assume some general functional form for the absorption coefficient $\alpha(\nu)$. The simplest form, a step-function, was found to give considerable error in predicting open-circuit potentials. The integral is heavily weighted for values of $h\nu$ near the bandgap, so a realistic form for $\alpha(\nu)$ must increase more slowly as a function of ν than does a step function. For simplicity, we assume a simple linear dependence on ν

$$\alpha(E) = a(E/E_g - 1), \quad E = h\nu \geq E_g \quad [7]$$

Neglecting higher order terms in kT/E_g , we obtain

$$\Delta\mu_{\max} = E_g - kT \ln [8\pi(kT)^2 n^2 E_g K a L / c^2 h^3 I_g] \quad [8]$$

in which we have replaced the sample thickness W by L where $L = L_m$, the minority carrier diffusion length, if $L_m \leq W$, while $L = W$ if $L_m \geq W$. This last condition was chosen for the following reason. Ross' derivation of $\Delta\mu$ is based on the assumption that the quasi-Fermi levels for both electrons and holes are constant through-

out the semiconductor. This is essentially an assumption of high carrier mobility or long diffusion length. In considering this approximation, he argues (21) that this case produces the highest efficiency, so its use is consistent with our aim of calculating "upper limit" efficiencies. However, the assumption becomes unphysical in the case of thick solids for which $W \gg L_m$. Parts of the solid that cannot communicate via diffusing carriers, cannot affect the separation of quasi-Fermi levels in the illuminated space charge region. Thus, we have limited the region of importance to the smaller of L_m and W .

Other than the bandgap energy, E_g , all material parameters are contained in the product $n^2 K a L$. To test Eq. [8] for silicon, we use the following values for the parameters: $n = 4$, $L = W = 10^{-1}$ cm, $a = 10^3$ cm $^{-1}$ (obtained from the absorption spectrum), $E_g = 1.14$ eV, and $I_g = 2.5 \times 10^{17}$ cm $^{-2}$ s $^{-1}$ for AM 1.2. For good single-crystal silicon, $K \sim 600$ (15). With these values, Eq. [8] predicts an open-circuit potential for silicon of $\Delta\mu_{\max}/e = 0.60$ V. Good single-crystal silicon junctions give $V_{oc} = 0.57$ V (22). The highest reported value for silicon under AM 1.2 illumination is 0.614 V, obtained with $W = 0.03$ cm (23). For $L = 0.03$ cm, Eq. [8] yields $V_{oc} = 0.63$ V. Upper limit values were expected, as we have not considered other minor losses.

Values of n , K , $\alpha(\nu)$, and L are, of course, not available for as yet undiscovered materials with bandgaps chosen to optimize conversion efficiency. Therefore, in all cases, we assume a value of $n^2 K a L = 3.3 \times 10^6$, which gives a value of 0.57 V for $\Delta\mu_{\max}/e$ in silicon. Direct bandgap materials have higher values of a , but lower values of L_m than silicon, leaving $n^2 K a L$ relatively unchanged. Using this value for $n^2 K a L$, we obtain for CuInSe $_2$, with $E_g = 1.0$ eV, a $\Delta\mu_{\max}/e$ of 0.44 V. This agrees quite well with the best observed value of 0.437 V (24). For amorphous silicon, with $E_g = 1.7$ eV, we obtain 1.1 V, which is higher than the best values of 0.9 V. Amorphous silicon undoubtedly has a much higher recombination rate than the value of K used here. Therefore, the values of $\Delta\mu_{\max}$ which we calculate with Eq. [8] can be considered as "upper limit" estimates.

Extracting carriers, *i.e.*, drawing a current to produce power, always reduces $\Delta\mu$. The reduction of $\Delta\mu$ from $\Delta\mu_{\max}$ is due to band bending and interfacial recombination losses. "Lower limits" for these losses are introduced here by taking experimental I-V curves from the best single-crystal devices. For different bandgaps, these response curves are scaled to the appropriate open-circuit voltage and saturation current densities, as described below. The value of $\Delta\mu$ at any operating current can be obtained from these response curves.

For the two-photon tandem cell, we assume that a large bandgap material can be joined physically to a smaller bandgap photovoltaic device such that the latter can provide an electrical bias for the former, for example, by a transparent ohmic contact. The photovoltaic could be a p-n junction, Schottky barrier, etc. We further assume that all radiation not absorbed in the larger bandgap semiconductor can reach the lower bandgap material.

The remaining parameters and transport characteristics necessary to calculate "upper limit" efficiencies are introduced as follows: (i) All photovoltaic I-V curves for different bandgap materials are modeled after that for a silicon single-crystal p-n junction with $V_{oc} = 0.57$ V, $I_{sc} = 37$ mA/cm 2 , $ff = 0.82$ (22). The open-circuit potential for a given bandgap is the $\Delta\mu_{\max}/e$ calculated from Eq. [8], I_s is determined from the AM 1.2 spectrum and the absorption spectrum given below in (iii). (ii) All photoelectrode curves are modeled after that for O $_2$ evolution on one of our thin films of TiO $_2$ at 300 nm. The curve shape is essentially the same as that for single-crystal TiO $_2$ at

330 nm (25) and very close to that for H₂ evolution on Pt-overcoated InP as reported by Heller *et al.* (26). Photocurrent onset is assumed to occur at V_{FB}. An optimum value of V_{FB} is chosen, as described in (iv). (iii) To calculate the saturation current density I_s, the quantum efficiency of all materials was assumed to increase linearly from zero at hν = E_g to unity at hν > E_g + 0.2 eV. This approximation is similar to the one made for α(ν) in calculating Δμ_{max}, but is more convenient for this application. (iv) Various values of flatband are found for different materials, so we have assumed no restrictions here. For an n-type photoanode of bandgap E_g, we choose V_{FB} so that, with AM 1.2 illumination driving a potential of Δμ_{max}/e, the quasi-Fermi level for holes is just far enough below the O₂/OH⁻ level to include the overpotential for oxygen evolution, η_{O₂}. This is illustrated in Fig. 2. For the case shown there, the bandgap is not wide enough for splitting water unless an additional electrical bias is supplied.

Although the overpotential changes with current density, it does so roughly logarithmically, and so is essentially constant over the limited range of current density of interest for these calculations.

Thus, the optimum value for V_{FB} is one that causes the hole quasi-Fermi level to be η_{O₂} below the O₂/OH⁻ level during AM 1.2 illumination. For more cathodic values of V_{FB}, hole transfer is impeded kinetically. However, sufficient band bending will increase the hole concentration at the interface, thus lowering the hole quasi-Fermi level and allowing the reaction to proceed. This could change the I-V response curve and, depending on the kinetics, conceivably either raise, or lower, the efficiency for different cases. For values of V_{FB} more anodic than optimum, a higher bias voltage is required. This latter case is always deleterious and leads to lower efficiencies. (v) For the initial set of calculations, the overpotentials were set at 400 mV for O₂ evolution and 50 mV for H₂ evolution. On most semiconductors and metals, the value of η_{O₂} is much higher than 400 mV at 10 mA/cm². This choice of overpotential, and the possibility of catalytic overcoatings, is discussed later in detail. (vi) All calculations use the AM 1.2, 100 mW/cm² summer total solar spectrum impinging on a flat plate collector as measured by Boer (27). The radiation incident on the photovoltaic ele-

ment is corrected for the light absorbed in the wide bandgap photoanode. No corrections are made for reflection losses. (vii) All efficiencies are determined by a graphical method for each type of PEC configuration.

Tandem PEC

Efficiencies are determined by combining the I-V photoresponse curves of the photovoltaic and the photoanodic junctions. The photovoltaic junction acts to bias the photoanodic junction to the required potential anodic of V_{FB}. The operating current, i_{op}, is given uniquely by the intersection of the photovoltaic I-V curve with that of the photoanode, as this quantity must be equal at both interfaces. Examples are given in Fig. 3 and 4 for different photoanode and photovoltaic bandgaps. Any excess carriers recombine as they normally would for individual operation of either device at the operating current density. The efficiency of

Fig. 3. Current-voltage curves for three cases of a 1.8 eV bandgap photoanode on top of a low bandgap photovoltaic. In each case, the operating current is given by the intersection of the two curves (circled position).

Fig. 4. Current-voltage curves for three cases of a 2.2 eV bandgap photoanode on top of a low bandgap photovoltaic. In each case, the different combinations of bandgaps result in nearly equal efficiencies.

conversion of incident solar radiant energy to stored chemical potential energy (as H_2) is given by i_{op} (mA/cm^2) $\times 1.23V/100$ (mW/cm^2). Obviously, lower bandgap materials give higher photocurrent densities, but the tradeoff is the larger bias voltage needed. In Fig. 3, we see that a bandgap combination of 1.14 (silicon) and 1.8 eV gives nearly equal saturation currents in each, but that the silicon cannot provide the high bias needed to operate a 1.8 eV bandgap photoanode. Recall that the minimum photocurrent onset potential is determined by the requirement that the quasi-Fermi level for holes lie 0.4 eV below the O_2/OH^- level. In addition, we have allowed for the 50 mV of overpotential for H_2 evolution at the metal cathode by shifting the photoanode I-V curves by that amount. The efficiency is markedly improved if a 2.0 eV bandgap photoanode is employed. With still higher bandgaps, such as 2.2 eV, shown in Fig. 4, the efficiency begins to drop because of the smaller saturation photocurrent. The two photojunctions are in electrical as well as optical series, so the efficiency can become limited by the saturation current of either one of them.

Curves of efficiency vs. photoanode bandgap are displayed in Fig. 5 for three photovoltaic bandgaps. The efficiency curve for a photovoltaic bandgap of 1.5 eV is not shown here, but is comparable to that for 1.3 eV. Efficiency contours as a function of both bandgaps are displayed in Fig. 6. The overall maximum efficiency occurs for a photovoltaic bandgap ~ 1.4 eV and a photoanode bandgap ~ 1.95 eV, and is 16.7%. This efficiency is for solar to chemical potential energy as H_2 gas. Photovoltaic solar cells driving an electrolysis cell at 1.68V ($\sim 75\%$ efficiency) must operate at 22.3% to match this performance.

Although the above results were obtained for photoanodes, the same results apply to photocathodes on photovoltaics. With the latter, however, the overpotential for O_2 evolution is easier to reduce, since it involves the dark electrode, and hence could be substantially less than 400 mV. This is discussed in detail later.

p-n PEC

The assumptions and I-V curve shapes used for the tandem PEC are applied here as well. The optimum flatband potential for the photoanode is chosen in the same way. For the photocathode, the flatband is chosen so that the quasi-Fermi level for electrons lies 50 mV

Fig. 5. Conversion efficiency of a tandem PEC as a function of both first (photoanode) and second (photovoltaic) absorber bandgap energies. Smooth curves were drawn through the circled points, which were obtained from Fig. 3 and 4 and others (not shown).

above the H^+/H_2 level during AM 1.2 illumination. Photocurrent onset is assumed to occur at flatband in each case. The operating current of the cell is determined graphically by plotting the absolute values of anodic and cathodic I-V curves and noting the intersecting point. In calculating the efficiency, the operating current must be halved to obtain the current per cm^2 under illumination. Again the trade-off of saturation currents and onset potentials produces a maximum in the efficiency. Examples are shown in Fig. 7 and 8. Efficiency vs. bandgap is plotted in Fig. 9, with a peak efficiency of 9.8% occurring for a bandgap of 1.75 eV. The analysis is for both equal bandgaps and areas for the photoanode and photocathode, but the maximum efficiency does not increase for unequal bandgaps on keeping the I-V curves of the same form.

Single-Photon PEC

Finally, the single-photon photoelectrolysis cell is considered. We graphically analyze the case of a photoanode and dark cathode. The analysis is the same for

Fig. 6. Conversion efficiency contours (in %) for a tandem PEC as a function of first and second absorber bandgaps. These contours were generated directly from the information in Fig. 5 and similar graphs (not shown).

Fig. 7. Current-voltage curves for a p-n PEC with photoanode and photocathode having the same area, and each with a bandgap of 1.6 eV. As for the tandem PEC, the operating current is given by the intersection point.

a photocathode and dark anode if the same overpotentials are assumed. In either case, the operating current density for bias-free operation corresponds to setting $V = 0$ (Fig. 10). As for the tandem PEC, we have included the 50 mV for H_2 evolution by shifting the I-V response curve 50 mV in the anodic direction. The maximum efficiency obtained is seen to be $\sim 4.5\%$ at $E_g \cong 2.6$ eV. For AM 2, or AM 1.2 under hazy atmospheric conditions, the scattering of higher energy photons causes this to drop to about 3%.

Discussion

Considerable attention was given to the choice of oxygen overpotential used in these calculations. Different materials exhibit a wide range of overpotentials, with temperature and electrolyte composition being

important factors. Increasing the temperature lowers the overpotential, but doing so also lowers the voltage obtainable from any semiconductor. The latter is a well-known result, and is born out by Eq. [8]. Running a cell at $100^\circ C$ vs. $25^\circ C$ increases the recombination voltage losses by some 150 mV. This is roughly equal to the resulting decrease in overpotential. Thus, for photoanodes we considered only room temperature values for η_{O_2} , and only for smooth electrodes. Some roughening of photoelectrodes may be possible, but is limited because of the need to maintain a proper internal space charge field for efficient electron-hole separation.

Apart from the simple factor of real surface area, many O_2 evolution catalysts exhibit an abrupt increase in Tafel slope at higher current densities. For example,

Fig. 8. As for Fig. 7, but for a bandgap of 1.9 eV.

Fig. 9. Conversion efficiency of a p-n PEC as a function of the common bandgap energy.

a Pt-black electrode can evolve oxygen at 10 mA/cm², 75°C, 3M KOH, with $\eta_{O_2} = 180$ mV (28); but the overpotential increases to 700 mV at 25°C in 1M KOH on smooth Pt at the same current density (29). For high surface area NiCo₂O₄, η_{O_2} equals 200 mV at 75°C, 10 mA/cm², in 3M KOH (27), but the overpotential increases to 440 mV at 25°C in 1.2M KOH (30).

A new catalyst of lanthanum nickelate (31) exhibits an η_{O_2} of only 270 mV at 25°C, 10 mA/cm², for a sintered powder electrode (surface area not reported). Very low overpotentials of ~ 100 mV at 12.5 mA/cm² have recently been reported, after long term tests, for lead ruthenate catalysts (28). These results were obtained at 75°C, in 3M KOH with heavy catalyst loading of high surface areas. Adding ~ 100 mV for room temperature operation, assuming no change in Tafel slope, and another 100 mV for low surface area electrodes, η_{O_2} is about 300 mV at 10 mA/cm².

Unless the photoanode material itself is highly catalytic, some catalyst such as one of the above must be

deposited on the electrode in a thin film or island configuration without blocking either the incident radiation or interfacial hole transfer, and without increasing surface recombination or delaying the photocurrent onset. As this would be difficult to achieve, we have chosen the value of 400 mV as the lower limit for the oxygen evolution overpotential on a photoanode. For PEC's with a dark anode at 25°C, a value of 200 mV seems entirely possible and will be selected for this case. Repeating the analysis for $\eta_{O_2} = 200$ mV, a maximum efficiency of 18.2% occurs for a photovoltaic bandgap of 1.3 eV and photoelectrode bandgap of 1.87 eV. This is only an increase of 1.5% in efficiency over that for the case of $\eta_{O_2} = 400$ mV.

A p-n PEC of course uses no dark electrode, but repeating the analysis anyway for $\eta_{O_2} = 200$ mV gives a maximum efficiency of 11.5%, with a common bandgap of 1.67 eV. The gain of 1.7% is about the same as for the tandem cell. With a single-photon PEC, the efficiency increases from 4.5 to 7.1% at a bandgap of 2.4 eV, a gain of 2.6%. Since the voltage at which the cells store energy is fixed at 1.23V, the increase in efficiency is due only to the increased rate of photon collection made possible by using materials with smaller bandgaps.

A major source of efficiency loss lies in the slow rate of rise of photocurrent with voltage for photoelectrodes. In the terminology of photovoltaics, photoelectrodes have low fill factors. This high transport loss enters twice for the p-n PEC. If we again use $\eta_{O_2} = 400$ mV, but instead replace the normal photoelectrode I-V curve with one modeled after the photovoltaic curves used above, considerable gains in the maximum efficiency result. The p-n PEC maximum efficiency changes the most; from 9.8 to 14.7% at $E_g = 1.55$ eV. The maximum single-photon cell efficiency increases from 4.5 to 8.4% at $E_g = 2.4$ eV, and the tandem PEC from 16.7 to 20.3% with $E_g^I = 1.85$ eV and $E_g^{II} = 1.25$ eV. These gains are considerably larger than those attained by a 200 mV reduction in overpotential.

For the case of high fill factor and 200 mV oxygen evolution overpotential, the maximum efficiency of 22% occurs for a tandem cell with $E_g^I = 1.8$ eV and $E_g^{II} = 1.15$ eV. A p-n PEC peaks at 16.6% for $E_g = 1.4$ eV, and the single-photon cell peaks at 11.6%, at $E_g = 2.2$ eV. In all cases, we have used the optimum value of the flatband potential, as described above. From Fig. 2, one can see that an anodic shift in the

Fig. 10. Current-voltage curves for a single-photon photoanode for various bandgaps, with inset figure for conversion efficiency vs. bandgap.

Table I. Conversion efficiencies (solar to stored H₂) in percentages as a function of the oxygen overpotential and fill factor* for the solid-electrolyte junction

System	Low fill factor		High fill factor	
	$\eta_{O_2}/400$ mV	200 mV	400 mV	200 mV
Single-photon cell	4.5	<u>7.1</u>	8.4	11.6
p-n PEC	<u>9.8</u>	11.5	14.7	16.6
Tandem PEC	16.7	<u>18.2</u>	20.3	22

* By fill factor we mean the rate of increase of photocurrent from flatband. "Low" refers to values observed for TiO₂ (25) and InP (26). "High" refers to values observed for silicon p-n photocells (22).

flatband can be treated as equivalent to a higher oxygen overpotential. All the cases just described will be treated in more detail in a forthcoming publication (32), where the analysis is extended to include three- and four-photon devices.

Summary and Conclusions

The various cases and resulting efficiencies are summarized in Table I. The underlined values are the "upper limit" efficiencies based on transport properties matching those of the best materials presently available, and hence, represent current realistic goals for these systems. If one includes reflection losses, the efficiency values must be reduced by up to 10% of their value, as the AM 1.2 total, not direct, solar spectrum was used for the calculations. We have not included resistance losses in the electrolyte and separator membrane, but these would be important in an engineering analysis.

We draw three conclusions that are probably of greater significance than the actual calculated efficiencies. First, improving the fill factor would be potentially more rewarding than reducing the oxygen overpotential. Secondly, the single-photon cell efficiency is most sensitive to changes in transport loss factors such as fill factor and overpotential. The p-n PEC efficiencies are less sensitive to these loss factors, followed by the tandem cell efficiencies which are the least sensitive. Thirdly, for equal loss factors, the tandem cell would yield the highest efficiency, followed by the p-n PEC, then by the single-photon device.

Thin Film Photoelectrochemistry: Iron Oxide

K. Itoh[†] and J. O'M. Bockris*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

Fe₂O₃ photoelectrodes offer advantages in respect to simplicity. However, at normal thickness, the efficiency is low. In this paper, the consequences of reducing the thickness of the oxide below that of the space-charge region is investigated. Allowing the light transmitted through the first electrode to be incident on further semitransparent electrodes should give a gain over a normal (ca. 1 μm thick) electrode of ca. three times for ten successive electrodes. The theory is experimentally tested. It is quantitatively in agreement with experiment for values of the hole-solution transfer-rate constant (for water oxidation) of $6 \times 10^{-2} \text{ cm s}^{-1} \text{ M}^{-1}$ and a model in which 1/4 of any change in applied p.d. occurs across the Helmholtz layer.

It is well known that Fe₂O₃ has interesting properties as a photoanode (1-8). However, the efficiency is poor [corresponding to a maximum photocurrent of a few hundred μA · cm⁻² at one sun (6-8)], because of a low absorption coefficient (α) as well as low carrier mobilities (μ) (2, 4). Thus, much light is absorbed outside the space-charge region, and, consequently, many of the corresponding holes are not subject to an effective internal field in transport to the surface. However, if an Fe₂O₃ layer were made with a thickness comparable to or less than that of the space-charge region in a thick electrode, and if the substrate on which Fe₂O₃ is deposited were transparent, light transmitted through the electrode could be utilized by a second electrode. Repetition of this principle should allow most of the incident light to be absorbed within the space-charge regions. Thus, the effect of the disadvantages of Fe₂O₃ could be reduced.

A simple model is used to quantify this concept. It is shown that ten layers of films each with thickness 600Å deposited on SnO₂- and/or In₂O₃-coated glass substrates increase the photocurrent compared with that of a thick electrode by a factor of up to 4.

Photocurrent Electrode-Thickness Dependence for a Thin Film

The photocurrent-potential (*i_p*-*V*) characteristics of thin films is different from that of thick electrodes in a potential range where the space-charge region of thickness $W = (2\epsilon\epsilon_0 V_s / eN_d)^{1/2}$, exceeds the film thickness *d*, where ε represents the dielectric constant of Fe₂O₃, ε₀ is that of vacuum, *V_s* is the Schottky barrier height, *e* is electronic charge, and *N_d* is the donor density (9).

In the potential region in question, the electric field in the Fe₂O₃, $\vec{E} (= -dV/dx)$, is approximately $-V_s/d \equiv -E$, since the SnO₂ substrate employed here is highly conductive (cf. Fig. 1). Then the diffusion equation for holes in the thin layer of Fe₂O₃ can be expressed as follows

$$D \frac{d^2 p}{dx^2} + \mu E \frac{dp}{dx} - p/\tau + I_0 e^{-\alpha x} = 0 \quad [1]$$

Here, *D* represents the diffusion coefficient of holes, *p* is the hole density, μ is the hole mobility, τ the hole lifetime, α the absorption coefficient, *I₀* the light intensity, and *x* the distance from the electrode-solution interface. The lifetime of holes in the film was assumed to be independent of position, i.e., recombination centers (rather than electron-hole collisions) in the film bulk are regarded as the predominant source of loss, since the electron density in a positively biased film is several orders of magnitude smaller than that in the bulk.

These assumptions are reasonable for the situation in which α and μ are small and the film is thin. Otherwise, surface recombination may be the dominating mode of loss.

One boundary condition can be taken for the Fe₂O₃-SnO₂ interface, where a particularly high concentration of surface traps can be taken to imply (cf. Fig. 1)

$$p(d) = 0 \quad [2]$$

Also, at the boundary of Fe₂O₃ with the solution

$$D \left(\frac{dp}{dx} \right)_{x=0} + E p(0) = k_{vH} p(0) = \frac{i_p}{e} \quad [3]$$

Here, *k_{vH}* represents the rate constant of the interfacial reaction between holes in Fe₂O₃ and reactants in solution; the p.d. in the Helmholtz layer is *V_H*.

The solution of Eq. [1], [2], and [3] is given by Eq. [4].

$$p(x) = A \exp(-ax) + B \exp(bx) + C \exp(-\alpha x) \quad [4]$$

Here

$$A = \frac{C[(k_{vH} - aD)e^{-\alpha d} - (k_{vH} + aD - v)e^{bd}]}{(k_{vH} + bD)e^{bd} - (k_{vH} - aD)e^{-\alpha d}} \quad [5]$$

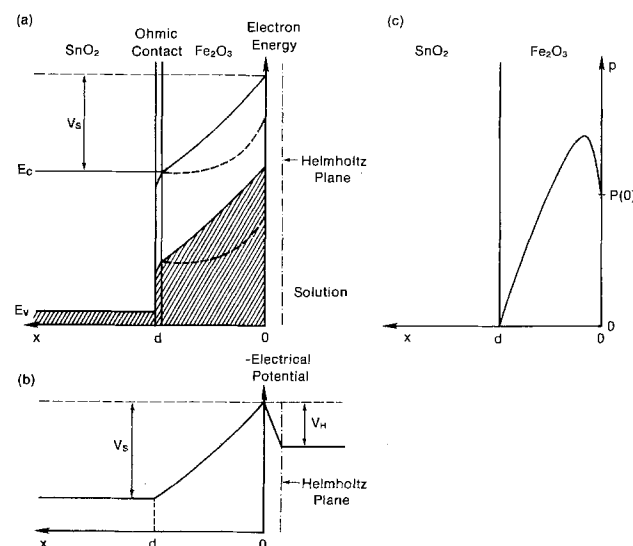

Fig. 1. a: Schematic energy-level diagram for an Fe₂O₃ film-SnO₂ junction. The thickness of the ohmic contact region is regarded as negligible in the text. The dotted line represents a Schottky barrier with a width smaller than *d*. *V_s* is the potential difference (p.d.) across an Fe₂O₃ film. b: Schematic diagram of electrical potential in the electrode and in solution. *V_H* is the Helmholtz layer p.d. c: Schematic diagram of the distribution of hole concentration in the film; *p(d) = 0* was chosen as one boundary condition.

[†] On leave from Department of Chemistry, Faculty of Engineering, University of Tokyo, Tokyo, Japan.

$$B = \frac{C[(k_{vH} + \alpha D - v)e^{-\alpha d} - (k_{vH} + bD)e^{-\alpha d}]}{(k_{vH} + bD)e^{bd} - (k_{vH} - \alpha D)e^{-\alpha d}} \quad [6]$$

$$C = \frac{\alpha I_0}{1/\tau + \alpha v - D\alpha^2} \quad [7]$$

$$a = (\sqrt{v^2 + 4D/\tau} + v)/2D \quad [8]$$

$$b = (\sqrt{v^2 + 4D/\tau} - v)/2D \quad [9]$$

$$v = \mu E(V_s/d) \quad [10]$$

The photocurrent i_p is given by Eq. [3] as $i_p = ek_{vH}p(0)$.

$$i_p = \frac{ek_{vH}CD[a(e^{bd} - e^{-\alpha d}) - b(e^{-\alpha d} - e^{-\alpha d}) - \alpha(e^{bd} - e^{-\alpha d})]}{(k_{vH} + bD)e^{bd} - (k_{vH} - \alpha D)e^{-\alpha d}} \quad [11]$$

It is noteworthy that there are two distinct potential differences at the interface: one, V_s , is the Schottky barrier height; the other, V_H , is the Helmholtz potential difference (p.d.) in solution. In the absence of a high concentration of surface states, the value of V_H is constant with change of external potential. However, with a high concentration of ionized surface states (e.g., 10^{15} cm^{-2} , 1/10 ionized), V_H varies with total applied p.d. (10). The value of V_H at the flatband condition (i.e., $V_s = 0$), V_H^0 , is not necessarily 0 (10). Therefore, the total p.d. V measured from the flatband potential (V_{FB}) can be represented as $V = V_s + (V_H - V_H^0) = V_s + \Delta V_H$. The ratio $V_s/V = \gamma$ is regarded in this paper as a parameter.

Equation [11] is plotted in Fig. 2. It shows i_p as a function of the total potential, V at a thickness of 800Å, with varying γ .

k_{vH} can be represented phenomenologically as (11)

$$k_{vH} = ck_0 \exp[\beta \Delta V_H / (k_B T / e)] \quad [12]$$

where k_B represents Boltzmann's constant, T is the temperature, c is the concentration of reducing species in solution, and k_0 and β ($\beta \sim 0.5$) are parameters.

Deduction of Photocurrent of a Stack of Thin Film Electrodes

The advantage of thin film for electrode materials having properties similar to those of Fe_2O_3 is an enhanced internal field, but the disadvantage is reduced absorption of light, compared with a thick film, respectively. Consequently, increased current density can only be obtained by stacking several electrodes together.

Fig. 2. Calculated i_p - V curves based on Eq. [11] for different values of γ . Parameters used were $d = 800\text{Å}$, $\mu = 0.01 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, $\alpha = 10^4 \text{ cm}^{-1}$, $ck_0 = 10 \text{ cm s}^{-1}$, $\beta = 0.5$, $\tau = 2 \times 10^{-9} \text{ s}$, and $I_0 = 10^{17} \text{ s}^{-1} \text{ cm}^{-2}$.

Here we consider a stack of film electrodes: each electrode is in contact with solution; light from the same source passes through each electrode (cf. Fig. 3). Let the transmittance of an Fe_2O_3 film and that of the conducting substrate be f and g , respectively. Then the light intensity after the m th electrode, I_m , can be represented as follows

$$I_m = fgI_{m-1} = \dots = (fg)^m I_0 \quad [13]$$

The amount of light absorbed by the m th layer equals $(1-f)I_{m-1}$. Hence, the light absorbed by n Fe_2O_3 layers, A_n , is

$$\begin{aligned} A_n &= \sum_{m=1}^n (1-f) I_{m-1} \\ &= I_0(1-f) \sum_{m=1}^n (fg)^{m-1} \\ &= I_0(1-f)(1-f^n g^n)/(1-fg) \end{aligned} \quad [14]$$

Therefore, light absorbed by Fe_2O_3 , increases by a factor of $A_n/A_1 = (1-f^n g^n)/(1-fg) \equiv L_n$. The total photocurrent i_T is obtained as¹

$$i_T = L_n i_p \quad [15]$$

where i_p is given by Eq. [11].

Figure 4 shows the i_T - d relations for a stacked system with varying values of the number of electrodes, n , namely $n = 1, 4, 10, 20$, and ∞ . Here, b was taken as 0.90, a typical value for SnO_2 - and/or In_2O_3 -coated glass (13). The values of μ , τ , α , and V were taken as $0.01 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, $2 \times 10^{-9} \text{ s}$, 10^4 cm^{-1} (2), and 1V, respectively; μ was assumed to be the same as the electron mobility (4), considering that both the conduction band and valence band of Fe_2O_3 are d bands (12). The value of τ is known from the literature (9) on other materials to have the order of magnitude 10^{-9} - 10^{-10} s; it was varied here between 0.1 and 100×10^{-9} s.

It is clear from Fig. 4 and 5 that i_p can be increased by stacking electrodes having an optimal value of thickness. For the conditions chosen for the plots of Fig. 4 and 5, the optimum thickness is 500Å, which value is smaller than the space-charge region width W , which is about 1500Å in a thick electrode at $V_s = 1\text{V}$.

¹ Thus, the value of i_p refers to a fixed potential controlled by an external potentiostat. It represents the current density for the first electrode. The current across the second electrode will be this same i_p (as the potential is held the same at each electrode), multiplied by a fraction representing the light incident upon it, compared with that incident upon the first. The currents for each electrode add. The expression [15] represents this reasoning for n electrodes.

Fig. 3. Schematic diagram of stacked film electrodes, Light intensity after the m th electrode is I_m .

Fig. 4. Dependence of i_T on d for a stack of film electrodes. The numbers of electrodes are shown in the figure, namely, 1, 4, 10, 20, and ∞ . Parameters were taken, $b = 0.90$, $V = 1V$, $\tau = 2.7 \times 10^{-9}s$, $\gamma = 0.75$, $ck_0 = 30 \text{ cm s}^{-1}$, $\beta = 0.5$, and $I_0 = 10^{17} \text{ s}^{-1} \text{ cm}^{-2}$.

Experimental

Fe_2O_3 thin films were deposited onto conducting glass made by coating the glass with SnO_2 and/or In_2O_3 by the use of a spray pyrolysis technique (13). A 0.1M FeCl_3 ethanolic or iso-propyl alcoholic solution containing 0.1M HCl was sprayed onto heated conducting glass substrates (350°C) in air by the use of an all-

Fig. 5. Dependence of i_T on the number of stacked electrodes for different film thickness, d . Parameters chosen are the same as those in Fig. 4.

glass atomizer and N_2 as carrier gas. The substrate temperature was monitored by the use of a thermocouple. The thickness of the films were followed by observing interference colors. Approximately 40\AA of Fe_2O_3 film was deposited by one spraying (i.e., 0.5 cm^3 of the FeCl_3 solution); 1-2 min intervals were taken between each spraying to avoid excess cooling of the substrate.

Figure 6 shows the construction of the thin film Fe_2O_3 electrode. The electrode area exposed to the solution was 1.0 cm^2 ; the other part of the Fe_2O_3 film was covered with silicone sealant, and an ohmic contact was taken at the SnO_2 or In_2O_3 surface.

The electrochemical measurements were performed in a glass cell with a quartz window, and the usual equipment: a potentiostat and a programmer. A 200W Hg-Xe lamp and a solar simulator were used as light sources.

Results

Films deposited on glass as well as onto conducting glass were uniform and hard, having a mirror-like surface. They were transparent and brown in color up to 40 sprayings ($\sim 1600\text{\AA}$). Sheet resistances of Fe_2O_3 films formed on glass substrates were high ($> 20 \text{ M}\Omega$).

Figure 7 shows typical experimental i_p - V curves obtained on 10 and 15 times sprayed films in alkaline solution. No difference in behavior was observed upon change from SnO_2 to In_2O_3 as substrate. Fe_2O_3 deposited onto TiO_2 made from heated Ti foil was also tested, but it gave less photoactivity than did Fe_2O_3 on conducting glass. The 15 times-sprayed film exhibited good photoactivity (curve a in Fig. 7). The photocurrent was stable, and no corrosion was observed. Illumination from the back side of the electrode gave consistent photocurrents with front illumination, except in the wavelength region less than 350 nm where light absorption due to In_2O_3 and SnO_2 occurs. Photocurrents from In_2O_3 and SnO_2 themselves were negligible.

The 10 times-sprayed film showed less photoactivity (curve b Fig. 7) for water oxidation than the 15 times-sprayed film. However, after the addition of 0.5% of H_2O_2 to the electrolyte (5), the 10 times-sprayed films showed a photoactivity as high as for the 15 times-sprayed one [curves c and d in Fig. 7].

The dependence of the photocurrent on the film thickness (i_p - d curve) was examined in the presence and absence of H_2O_2 in the electrolyte. The i_p - d curve for H_2O_2 oxidation (curve b in Fig. 8) was similar to the theoretical curve (Fig. 4), while that for water oxidation showed some quantitative discrepancy (curve a in Fig. 8) in that no current was observed for the first five sprayings, and the i_p number of sprayings, relation tended to an asymptote.

By stacking electrodes, one behind the other, each electrode being in contact with solution, the photocurrent increased, as expected. Figure 9 shows the photocurrent dependence on the number of 15 times-sprayed electrodes for water oxidation (a similar result was

Fig. 6. Construction of a thin film Fe_2O_3 electrode

Fig. 7. Photoactivities of a thin film Fe_2O_3 electrode on conducting electrode. a, c: 15 times-sprayed film. b, d: 10 times-sprayed film. Light intensity was 325 mW cm^{-2} , Hg-Xe 200W lamp without filters. Solution was $0.5M \text{ Na}_2\text{SO}_4 + \text{NaOH}$ (pH 13) for a, b, and $0.5M \text{ H}_2\text{O}_2$ was added for c, d. Corrections for iR drops due to the resistance of SnO_2 and of In_2O_3 films ($0.5V$ at most) were made.

obtained for H_2O_2 oxidation). Simulated solar light was used as a light source.

In Fig. 8, theory and experiment are compared. The circles are the experimental points. The agreement is good ($\tau = 2.7 \times 10^{-9}\text{s}$, $\gamma = 0.75$, $d = 600\text{\AA}$). If the theoretical curve in Fig. 9 (see also Fig. 5) was extrapolated, it reached an asymptotic value of 1.6, 1.9, and $2.0 \text{ mA} \cdot \text{cm}^{-2}$ for a number of electrodes in the stack, $n = 10, 20$, and ∞ , respectively (see Discussion).

Discussion

Films made by the pyrolysis technique, with thickness of less than 1000\AA , give good photoactivities when they are deposited onto suitable substrates. The highly conducting SnO_2 and In_2O_3 act as materials with lower work functions than the n-type Fe_2O_3 film, so that there is an ohmic junction at the Fe_2O_3 -substrate interfaces. Conversely, for Fe_2O_3 - TiO_2 junctions (which give smaller currents), the smaller flatband potential

of TiO_2 compared with Fe_2O_3 implies a nonohmic contact for electrons at the solid-solid boundary.

The difference in i_p - V characteristics between those measured in H_2O_2 and H_2O oxidation can be interpreted by the use of Eq. [11] with appropriate values of k_0 and γ . Figures 10 and 11 show i_p - V curves calculated for typical cases. Figure 10 shows the calculated curves for water oxidation for some values of k_0 ; curves are normalized to unity at $V = 1.2V$. Experimental values fit with the calculated curve quite well at $ck_0 = 3.5 \text{ cm} \cdot \text{s}^{-1}$ ($k_0 = 6.4 \times 10^{-2} \text{ cm} \cdot \text{s}^{-1} M^{-1}$; $c = 55M$) and $\gamma = 0.75$. Figures 11a and 11b show similar curve fittings for H_2O_2 oxidation for different film thickness. The consistency of calculation with experiment is good again. For both the 6 times-sprayed film and the 15 times-sprayed film, the best value of ck_0 was $30 \text{ cm} \cdot \text{s}^{-1}$ ($k_0 = 2.0 \times 10^2 \text{ cm} \cdot \text{s}^{-1} M^{-1}$; $c = 0.15M$). The value of γ was 0.75, the same as for water. These results support the specific model assumptions

Fig. 8. Experimental photocurrent-film thickness dependence for water (a) and H_2O_2 (b) oxidation.

Fig. 9. Photocurrent dependence on the number of 15 times-sprayed electrodes stacked. The solid line is the calculated curve from Eq. [15] $d = 600\text{\AA}$ ($\alpha = 0.95$) and $b = 0.90$. Open circles are experimental values. Experimental condition is pH 13, 0.6V vs. SCE, and light intensity 1 sun from a solar simulator.

upon which the present calculation is based; the electric field in the film can be taken as uniform, and V may be divided into two parts, i.e., V_s and ΔV_H .

The values of γ and k_o can be tested by virtue of those in the literature although only a few experimental values have so far been reported. Theoretically, γ can vary from 1 to 0 (10). A pure Schottky barrier model requires $\gamma = 1$, and complete Fermi-level pinning corresponds to $\gamma = 0$. Vanden Berghe *et al.* observed that a fraction of 0.9 of the applied voltage changes occur over the depletion region of n-type single-crystalline ZnO electrodes ($N_d \approx 10^{18} \text{ cm}^{-3}$) in contact with aqueous solution (14). Considering

that the electrodes we employed are polycrystalline, the value $\gamma = 0.75$ seems acceptable.

Morrison estimated the reactivity (electron-capture rate) of oxidizing agents at n-type ZnO surface (15). Typical results from his work recalculated in terms of k_o , are $1 \times 10^2 - 8 \times 10^3 \text{ cm s}^{-1} M^{-1}$ for $\text{Fe}(\text{CN})_6^{3-}$ for different pH values, $6 \text{ cm s}^{-1} M^{-1}$ for Ce^{4+} , $< 10^{-3} \text{ cm s}^{-1} M^{-1}$ for Cu^{2+} and V^{3+} . In his experiment, the energy differences between the conduction bandedge and E_{redox} 's are 0.7-1.6 eV, which values are of the same order as those between the valence bandedge and E_{redox} in our experiment; $\sim 1.4 \text{ eV}$ for water and $\sim 1.8 \text{ eV}$ for H_2O_2 oxidation. The value of k_o or cK_o which we found consistent with our experiments, $k_o = 6.4 \times 10^{-2} \text{ cm s}^{-1} M^{-1}$ for water and $2.0 \times 10^2 \text{ cm s}^{-1} M^{-1}$ for H_2O_2 oxidation, are reasonably consistent with these.

Charge accumulation may occur in the film when hole consumption is slow, giving rise to an accelerated electron-hole recombination rate. This may be the case with water oxidation in the relatively low bias region. H_2O_2 acts as a strong reducing agent, i.e., a hole scavenger, at the illuminated photoanode due to the less positive potential (0.86V vs. NHE) needed for the reaction

than that of water oxidation (1.23V vs. NHE) (16). Consequently, hole consumption by H_2O_2 occurs faster than by water, and hence electron-hole recombination is suppressed; the charge transfer rate ck_o for H_2O_2 is ca. 10 times that for water in Fig. 10 and 11. The i_p - d relation for H_2O_2 oxidation (curve b in Fig. 8) is consistent with the theoretical one in Fig. 4. However, the experimental results for water oxidation did not show significant currents until 5 sprayings (curve a in Fig. 8). This may arise from the fact that if the film is sufficiently thin, the diffusion length for electrons from the SnO_2 layer extends over a greater portion of the film than when it is thicker, hence causing enhanced recombination. To deal with this, the distance dependence of τ should be taken into account in Eq. [1].

It has been shown above that the experimental results of Fig. 9 showing experiments on stacks of two, three, and four electrodes are consistent with Eq. [15]. This shows that, if some ten electrodes were brought together in the manner suggested, the multiplying

Fig. 10. Theoretical calculation of i_p - V curves for water oxidation based on Eq. [11] for different values of ck_o (cm s^{-1}). Circles are experimental values for a 15 times-sprayed film. The values of parameters, d , τ , β , and γ are the same as those in Fig. 4; note that $d = 600\text{\AA} = 15 \times 40\text{\AA}$. V_{FB} was taken as -0.5V vs. SCE.

Fig. 11. Calculated curves for H_2O_2 oxidation for different values of ck_0 and d . $d = 240\text{\AA}$ ($6 \times 40\text{\AA}$) in a, and $d = 600\text{\AA}$ ($15 \times 40\text{\AA}$) in b. Circles are experimental values for a 6 times-sprayed film in a and for a 15 times-sprayed film in b. Other parameters are the same as those in Fig. 10.

factor over the result for a thin film electrode would be about $5.3\times$. Thin electrodes of the type used here give around 0.3 mA cm^{-2} (0.6V/SCE , $\text{pH} \approx 13$, 1 sun, solar simulator), so that a ten-stack cell should give around 1.6 mA cm^{-2} . A "thick" electrode ($1\text{ }\mu\text{m}$) under similar conditions but prepared by holding an iron foil in a natural gas flame gives about 0.5 mA cm^{-2} . An increase of more than three times may therefore be expected from stacking.

Further increase in i_p could be obtained by improvement of the film. An increase of τ is important. This might be accomplished by changing the spraying condition, including substrate temperature, dopant, and carrier gas, and thus changing the crystallite size. Furthermore, a catalyst introduced on the surface of the films might cause an increase in the k_0 in Eq. [12], and hence make the onset of i_p shift in the negative direction.

The thin films were observed stable for 12h. No stability tests were made for further hours.

Conclusion

If a photoanode has a low value of the carrier mobility and/or the absorption coefficient, an increase in current up to four times can be obtained in a device in which about ten thin (e.g., 600\AA) semiconductor layer electrodes are placed one behind the other.

A New Electrochemical Determination of Potassium Ion Concentration with Immobilized Valinomycin Disk

Minoru Kumakura and Isao Kaetsu

ABSTRACT

A new electrochemical determination of potassium ion concentration in serum with immobilized valinomycin disk was studied, in which the disk having porous structure was prepared by radiation polymerization of hydrophilic monomer at low temperature. The method was based upon the measurement of the current resulting from liberated potassium ion in the disk. The sensitivity varied with the pore size in the porous polymer matrix of the disk, which depends on monomer concentration. Potassium ion concentration ranging from 0.4 to 10 mM/l can be easily assayed with precision of 2% by using 20 μ l of sample. The correlation between potassium ion concentrations in sera measured by flame photometry and by the present method was good ($r = 0.91$).

Determination of sodium and potassium ion concentration in blood serum is important in diagnostic assay, so that various methods have been developed (1-3). The average concentration ranges of sodium and potassium ion in serum of normal humans are 134-143 and 3.5-5.4 mM/l, respectively. Thus, the concentration range is very narrow, so that an analysis method with a high precision is needed. Furthermore, for the diagnostic assay of these ions, a speedy operation is usually necessary. From these points, a flame photoscopic method and electrochemical method with ion-selective electrodes, which have a relatively high sensitivity, have been used (1). However, these methods consist of complicated large apparatus and their response times are relatively long.

In this paper, a new electrochemical determination method with immobilized valinomycin disk, obtained by radiation polymerization, is described. Valinomycin is dissolved in an appropriate organic solvent placed in a convenient liquid-membrane electrode assembly giving rise to an electrode with selectivity ratios of the order of 5000:1 for potassium over sodium; such a selectivity ratio is considerably higher than those of about 8:1 for cation-sensitive glass electrodes (4, 5). The high selectivity of the electrode makes it a very useful sensor for analytical and biomedical measurements in which potassium ion determinations are usually required in the presence of comparable or larger concentrations of sodium ion. Thus, valinomycin has been utilized as the membrane component of ion-selective electrodes capable of *in vitro* or extracorporeal potassium analysis (5-9), in which valinomycin-impregnated membranes using usually polyvinyl chloride (PVC) have been used for the construction of solid-state electrodes. The methods using these sensors based on the diffusion and trapping of potassium ion in the valinomycin-impregnated PVC membranes, in which electrode potentials are measured. We have developed an electrochemical method with immobilized valinomycin disk having a porous structure in which the currents resulting from potassium ions in the disk are measured.

Experimental

Instrumentation.—A regulated dc power supply having current measurement equipment, PAB 350-0.2 (Kikusui Electronics Corporation, Tokyo) was used to supply a constant potential at 20.0V and to measure the current. An Atomic Absorption and Flame Emission

Key words: potassium ion, electrochemical determination, immobilized valinomycin disk.

Spectrophotometer, AA-8200 (Nippon Jarrell Ash Company, Limited, Kyoto) was used for comparison of the assay.

Reagents.—Valinomycin and potassium chloride were obtained from Sigma Chemical Company, St. Louis, Missouri, and Wako Pure Chemical Industries, Limited, Osaka, respectively.

2-Hydroxyethyl methacrylate (HEMA) was obtained from Mitsubishi Gas Chemical Company, Limited, Tokyo.

Preparation of reagents.—Standard potassium solutions were prepared using potassium chloride and doubly distilled water. Freshly centrifuged serum was used throughout. HEMA was purified by base extraction and distillation to remove an inhibitor and impurity prior to use.

Immobilization of valinomycin by radiation polymerization.—Monomer (HEMA), valinomycin (5% w/v), and water were mixed, poured into a 20 \times 0.8 cm (diam) glass tube, and used quickly shaken. Without delay, the tube was frozen at -78°C and irradiated (1 Mrad) by γ -ray from a ^{60}Co source. After irradiation, valinomycin immobilized in the polymer matrix formed was removed from the tube and sliced into thin disks (20 μm thick, 0.8 cm diam) at low temperature with cryostat Model EF-FCS (Bright Institute Company, Limited, England), and then dried with a lyophilizer (Kyowa Vacuum Engineering Company, Limited, Tokyo).

Measurement of potassium ion concentration with immobilized valinomycin disk.—An immobilized valinomycin disk was immersed in the standard potassium solution or serum sample (20 μl) for 10-30 min, and washed with doubly distilled water. The washed disk was placed on a glass plate (18 \times 18 \times 0.15 mm) and heated at 120°C with a heater. After heating, potassium ion with the disk was measured by the instrument as shown in Fig. 1. The disk placed on the plate was put into a sample cell constructed with two platinum electrodes, containing doubly distilled water (2.0 ml). A constant potential of 10V was applied to the electrode with the size of 20 \times 20 \times 0.5 mm. After 1.0 min, the currents based on the liberation of potassium ion from the polymer matrix of the disk were measured at 25°C .

Results and Discussion

Characterization of immobilized valinomycin disk.—The relationship between potassium-ion concentration and current is shown in Fig. 2. The current increased

Fig. 1. Construction of the sample cell for the measurement of potassium ion. A: immobilized valinomycin disk. B: glass plate. C: electrode. D: sample cell.

linearly with increasing potassium-ion concentration, and this indicated that immobilized valinomycin disk reacts efficiently with potassium ion to form a complex, and its disk-potassium complex liberates available potassium ion by heat-treatment. According to the typical current-potassium-ion concentration curve in Fig. 1, it was found that a linear relationship between current and potassium-ion concentration holds up to a potassium-ion concentration of 0 mM/l and the slope of the curve was obtained to be $4.50 \mu\text{A} (\text{mM/l of potassium ion})^{-1}$ with a standard error of $0.20 \mu\text{A} (\text{mM/l of potassium ion})^{-1}$. The detection limit for potassium ion in the present method was found to be 0.4 mM/l. The bond of potassium ion and valinomycin in the polymer matrix of the disk is weak, so that its bond is

Fig. 2. Relationship between potassium ion concentration and current. HEMA monomer concentration: 50% v/v.

broken by heat-treatment and then potassium ion is liberated from the disk-to-water system. The liberated potassium ions act as the carrier of the current. Thus, the heating of the disk on the plate was necessary for the dissociation of the bond in the potassium-valinomycin complex. After heat-treatment, the present method attributed simply to the measurement of conductivity of potassium-ion aqueous solution.

It is known that potassium ion-valinomycin complex is retained with hydrogen bond-stabilized framework, in which all the ester carbonyl groups become involved in ion-dipole interaction with potassium ion (10). Complexation is accompanied by conformational reforming of the molecule in which the three ester carbonyl groups are oriented within the ring to form a hexadentate system of oxygen atoms about the cation. From the situation of such a complex formation, it is proposed that valinomycin immobilized in the polymer matrix of the disk should have a large mobility to react with potassium ion. The polymer matrix of the disk obtained by radiation polymerization of hydrophilic HEMA at low temperature had a soft sponge-like porous structure, as shown in Fig. 3, in which valinomycin is trapped on the surface of the porous polymer matrix. The soft porous polymer matrix having large surface area gives a very convenient situation for the formation of potassium ion-valinomycin complex. The formation of the porous structure was one of the most characteristic features of the polymer matrix obtained by the present method, and its mechanism was due to small ice particles formed at low temperature (-78°C), at which the radiation polymerization was carried out, melting as the temperature rose to room temperature after irradiation. The soft porous polymer matrix of the disk obtained by the present method was different from the rigid, blocky polymer which was developed for ion-selective electrodes resulting from PVC, poly(siloxane), etc. (5-9, 11). Since the porosity of the porous polymer matrix was large (50%-80%) and the pore diameter was 1-10 μm , the diffusion of potassium ion would not be affected by the polymer matrix.

Effect of monomer concentration on the current.—The effect of monomer concentration on the current was studied by varying HEMA concentration in the

Fig. 3. Scanning electron microphotograph of the surface of immobilized valinomycin disk. HEMA monomer concentration: 50% v/v.

Fig. 4. Effect of HEMA monomer concentration on the current. Potassium ion concentration: 10 mM/l.

immobilization of valinomycin. The relationship between the current and HEMA concentration is shown in Fig. 4. The current increased and had a maximum and then decreased with increasing HEMA concentration. From this result, it was found that optimum monomer concentration exists for the sensitivity. The decreases of the current at lower and higher monomer concentrations were probably due to the leakage and the entrapping of valinomycin, respectively, because the nature, such as porosity and flexibility of the disk, depended on monomer concentration. That is, the disks from lower monomer concentrations below 10% gave a very soft polymer matrix having large pore sizes above 10 μm in diameter, while those from high monomer concentrations above 70% a very rigid polymer matrix having small pore sizes below 0.5 μm . The trapping yield of valinomycin in the immobilization at lower monomer concentrations would be low, and then the apparent content of valinomycin in the disk is low, so that the apparent sensitivity of the disk became low. However, valinomycin in the disks from high monomer concentrations was trapped rigidly in the polymer matrix, in which the mobility of valinomycin suffered, and it did not appear to react with potassium ion. Thus, the optimum monomer concentration range giving high sensitivity appeared to be 20%-50%, in which the disk was flexible and gave suitable state for the complex formation of valinomycin with potassium ion.

The porous structure in the disk obtained from such an optimum monomer concentration lead to the increase of the diffusion rate of potassium ion into the disk. After heat-treatment of the disk, potassium ion can be easily released throughout the pore of the porous polymer matrix. In fact, the response time in which the current became constant was very short (<1.0 min).

Reproducibility and precision.—A standard potassium ion solution of 5.00 mM/l was measured ten times using the disks. A coefficient of valinomycin of 2% was obtained.

Fig. 5. Comparison of determinations of the concentration of potassium ion in serum by flame photometry and immobilized valinomycin disk method.

Comparison study with flame photometry.—Figure 5 shows the good agreement between flame photometry and the present method, which is based on different calibration procedures in the two techniques applied. The linear regression analysis of potassium ion gave a correlation coefficient of 0.91.

We conclude from these results that the immobilized valinomycin disks having porous polymer matrix obtained by radiation polymerization at low temperature provides a new simple electroanalytical procedure for the determination of potassium ion in serum samples.

Correlations Between Transport Properties, ¹HNMR Spectra, and Structure of Molten Methylpyridinium Iodides

David S. Newman* and Rex M. Stevens*

Department of Chemistry, Bowling Green State University, Bowling Green, Ohio 43403

ABSTRACT

The equivalent conductance, viscosity, and ¹HNMR spectra of the four molten methylpyridinium iodides were measured as a function of temperature, and correlations between structure, spectra, and transport properties were made. In addition, an interesting new compound was found in the 2-methylpyridinium iodide melt.

In earlier studies of molten pyridinium salts, we found that a melt's transport properties, thermodynamic properties, and ¹HNMR spectrum were affected by the presence or absence of a methyl substituent and by the position of this methyl group on the pyridine ring (1-3). From these observations, we concluded, among other things, that hydrogen bonding between the nitrogenic proton and the halide ion strongly influenced the melt's structure, as well as its transport properties. In the methylpyridinium iodides, hydrogen bonding does not occur (4), so by comparing their transport properties and ¹HNMR spectra with those of the chlorides and bromides, a more accurate assessment of the influence of hydrogen bonding on the chloride and bromide melts can be made.

The suggestion that molten organic salts have relatively weaker repulsive forces between ions than inorganic salts, and also possess the general property that the ratio of the energy of activation for viscosity, E_η , to the energy of activation for equivalent conductance, E_Λ , is about equal to 1.1, is explored further, and the consequences and causes of this ratio are discussed. The existence of an interesting new species present in the 2-methylpyridinium iodide melt is postulated, and the role of complex species in determining the melt's properties is discussed.

Experimental

The methylpyridinium iodide salts were synthesized by methods already described in the literature (3, 5), with the exception that the appropriate methylpyridine was mixed with an equal quantity of petroleum ether rather than benzene. Anhydrous HI gas was bubbled through the solution following a 10 min nitrogen purge that removed air from the system. White crystals of the methylpyridinium salt began to precipitate after about 1 min. All four iodides turned bright yellow upon melting; the yellow color disappearing upon freezing.

Density measurements were made using the modified Lipkin bicapillary arm pycnometer (6), together with a fiber-optic light pipe that greatly facilitated seeing the graduation markings on the pycnometer, which was immersed in a constant-temperature oil bath.

Conductivity measurements were made with a Jones bridge at a frequency of 1000 Hz using a capillary cell with cylindrical platinum electrodes.

Chemical analysis of the salts was done by determining the iodide concentration using a standard KIO₃ solution to titrate the iodide (7).

Viscosities were measured with a Cannon-Fenske viscometer. The ¹HNMR spectra were obtained using the variable temperature probe of a Varian CF¹T 20 NMR machine and external reference standards. Since the salts are hygroscopic, all transfer operations were done in a dry box.

Key words: fused salts, conductance, viscosity, tunneling.

Results

The densities of the four methylpyridinium iodide isomers are listed as a function of temperature in Table I together with each salt's melting point. It should be noted that the 2-methyl iodide is considerably less dense than the other isomers and lies in the density range of the molten bromides (1, 6).

The logs of the equivalent conductances plotted as a function of T^{-1} are shown in Fig. 1, and it is evident that the conductance of 2-mepyr/HI does not fall on the same curve as the conductances of the other three isomers. The logs of the absolute viscosities vs. T^{-1} are shown in Fig. 2. The viscosity values for N-mepyr I differ somewhat from those reported earlier by us (2) and are more accurate.

Table II lists the equivalent conductances and viscosities of the twelve methylpyridinium halides at a common temperature of 425 K. The chloride and bromide data are from earlier studies (1, 2).

This temperature has been selected as the reference temperature because it lies within the accessible liquid range of most of the salts. For the salts whose liquid range does not include 425 K, extrapolated values are used. In the absence of ideal glass-transition temperatures or normal boiling points, which are natural reference states (8), a common temperature is the most valid reference state from which to compare transport properties.

Table I. The densities of the four methylpyridinium iodide salts as a function of temperature

$$\rho = A - B/T \text{ (K)}$$

Salt	A	B ($\times 10^4$)	T _m (°C)	Temp. range °C
4-mepyr/HI	1.995	8.377	171	171-200

Fig. 1. $\ln \Delta$ vs. T^{-1} for each of the four methylpyridinium iodides.

The ^1H NMR spectrum of molten 4-mepyr/HI at 174 K is shown in Fig. 3. The reference here is $(\text{CH}_3)_2\text{SO}_2$ and appears in the spectrum. No temperature dependence was observed for any peak over the temperature range studied. Figure 4 shows the ^1H NMR spectrum of 3-mepyr/HI, and Fig. 5 shows the spectrum of 2-mepyr/HI. DMSO is the reference in both of these melts, but is not shown. Table III lists the chemical shifts, δ , for the three isomers, all corrected to a DMSO reference. DMSO is approximately 2.60

Fig. 2. $\ln \eta$ vs. T^{-1} for each of the four methylpyridinium iodides.

Table III. Proton chemical shifts for 4, 3, and 2-methylpyridinium iodide vs. DMSO (ppm)

Salt	N-H	α	β	γ	CH ₃	Temp. range (K)
4-mepyr/HI	12.1	7.03	6.08	—	0.64	447
3-mepyr/HI	12.32-12.23	6.93	6.10	6.58	0.50	369-418
2-mepyr/HI	12.84-13.10	6.30	5.22	5.75	0.27	369-400

ppm downfield from TMS. The N—H⁺ proton in the 3-methyl melt showed a small upfield shift of the N—H⁺ peak position with increasing temperature, whereas the ring proton chemical shifts were temperature independent. In the 2-methyl salts, the N—H⁺ proton chemical shift showed a rather striking temperature dependence, moving upfield 0.0083 ppm/K. This temperature dependence is larger than any we have yet measured and is in an unexpected direction. Moreover, the integrated area under the N—H⁺ peak was approximately 0.5, rather than 1, as it was in each of the other two spectra.

Chemical analysis of six different 2-mepyr/HI salt samples (each analysis in triplicate) indicated a methylpyridine to iodine ratio of 1.99 to 1.

Discussion

μ-hydrogenbis (2-methylpyridinium) iodide [$(\text{C}_6\text{H}_7\text{N})_2\text{H}^+\text{I}^-$].—These data are compelling evidence for the existence of a dimeric species in the 2-methyl-

Fig. 3. ^1H NMR spectrum of 4-methylpyridinium iodide at 172°C

Fig. 4. ^1H NMR spectrum of 3-methylpyridinium iodide at 134°C

Fig. 5. ^1H NMR spectrum of μ -hydrogenbis(2-methylpyridinium) iodide.

pyridinium iodide melt. In the liquid state, this μ -hydrogenbis(2-methylpyridinium) iodide consists of a dimeric cation, the structure of which is shown in Fig. 6, and an I^- anion. There are two principal reasons why the 2-methyl iodide is different from the

other pyridinium salts studied to date. The $\text{N}-\text{H}^+$

does not hydrogen bond with the I^- , as it does with the Cl^- and Br^- ions, so it is able to form a bond with the partially negative nitrogen (9) on the "second" methyl pyridine ring, and the CH_3 groups on the "2" positions sterically prevent the large I^- from disrupting the

$\text{N}-\text{H}-\text{N}$ bond once it forms. Precedents

for this pyridinium-pyridine type of structure do exist in the literature. X-ray and neutron diffraction studies show $[(\text{C}_5\text{H}_5\text{N})_2\text{H}]^+ [\text{ZnBr}_{3/2}\text{Cl}_{3/2}(\text{C}_5\text{H}_5\text{N})]^-$ to possess a

$\text{N}-\text{H}-\text{N}$ bond (10), and IR together with

neutron diffraction indicate "4-aminopyridine hemiperchlorate ($\text{C}_5\text{H}_5\text{N} \cdot \frac{1}{2} \text{HClO}_4$)" also has a strong

$\text{N}-\text{H}-\text{N}$ bond (11). More importantly, however,

this structure correlates very well with transport properties, ^1H NMR spectra, and density.

The average shielding at a nucleus cannot be measured directly by NMR, so there will be some ambiguity in accounting for the upfield chemical shift of the bridging proton. Nevertheless, it can be said with some certainty that the upfield shift with increasing temperature is caused by the bridging proton becoming more shielded by the bonding electrons, rather than less deshielded by the aromatic ring currents. The average chemical shift difference, $\Delta\sigma_{\text{av}}$, is given by the equation

$$\Delta\sigma_{\text{av}} = \sigma_{\text{av}}(\text{A}) - \sigma_{\text{av}}(\text{B}) \\ = \sigma_{\text{av}}^{\text{p}}(\text{A}) + \sigma_{\text{av}}^{\text{d}}(\text{A}) - \sigma_{\text{av}}^{\text{p}}(\text{B}) - \sigma_{\text{av}}^{\text{d}}(\text{B})$$

where A and B are different magnetic environments and $\sigma_{\text{av}}^{\text{p}}$ and $\sigma_{\text{av}}^{\text{d}}$ are the paramagnetic and diamagnetic contributions, respectively. Employing literature values for the relevant molecular parameters and several plausible assumptions, σ_{av} for the bridging proton can be calculated to a fairly accurate first approximation using a modification of the technique developed by

Fig. 6. Structure of μ -hydrogenbis(2-methylpyridinium) cation

Shuppert and Angell (12). $\Delta\sigma_{\text{av}}$ can then be estimated by comparing this calculation with σ_{av} (TMS) at 10 ppm. The bare proton has a σ_{av} of -20.9 ppm relative to TMS (13). A single electron in a 1s orbital shields this bare proton $+17.7$ ppm (13), but a better shielding value is $+21.4$ ppm because the electrons surrounding a bonded hydrogen are less diffuse than in a hydrogen atom (14). Emsley has calculated a net positive charge of 0.21 units on the nitrogenic proton in an isolated pyridinium ion (9). However, the more recent computation of Goldstein and Ragle placed a net positive charge of 0.32 units on this proton or a net 1s orbital population of 0.68 electrons (4). Using the newer value and assuming, first, that a 2-methylpyridinium "monomer" and a pyridinium ion are not significantly different with respect to the nitrogenic proton's 1s orbital population and, second, that both methylpyridine rings make identical contributions to the bond in the dimeric cation, the 1s orbital population will be $0.68 + (0.32/2) = 0.84$ electrons.

The chemical shift at the bridging proton also depends on the electric field arising from charges on other atoms in the molecule. This dependence is described by the equation (9, 15)

$$\sigma^{\text{E}} = -6.58 \times 10^{-22} \sum_i q_i \cos \theta_i r_i^{-2} \\ - 3.34 \times 10^{-23} \sum_i q_i^2 r_i^{-4}$$

where the coefficients are in coulombs, the q_i are the formal charges, θ_i the angle between the bond, and the vector is r_i . It is obvious that these electric field effects will cancel by virtue of symmetry. For example, the electric field due to the partial negative charge on one nitrogen will exactly cancel the field due to the other nitrogen. This leaves only shielding caused by ring currents to be estimated, and this cannot differ significantly from that in benzene, the extra charge on the nitrogen nucleus being almost exactly canceled by the redistribution of electronic charge (4, 16). We use, therefore, Johnson and Bovey's predicted values of shielding contributions from ring currents in aromatic hydrocarbons (17, 18) to calculate the ring-current contribution to the chemical shift in the cation.

We assume that the $\text{N}-\text{H}-\text{N}$ bond length is 0.27

nm, as measured by Roziere *et al.* for 4-aminopyridine hemiperchlorate (11), that both methylpyridine rings are in the same plane, and that at any intermediate distance between the two nitrogens the ring current contributions are additive. The calculated values are listed in Table IV. These data show that the region, or "box" where the bridging proton has a high probability of being found has a relatively invariant ring current shielding contribution. At a distance of about ± 0.07 nm from the plane of the rings, the negative shielding begins to decrease, but the positive 1s shielding also decreases. Since the electronic shielding is about an order of magnitude larger than the ring current deshielding and since it decreases at least as sharply with distance, it will almost certainly dominate. Consequently, it is highly unlikely that the upfield shift with increasing temperature is caused by decreased

Table IV. Ring current shielding

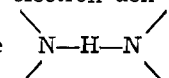

Distance from reference nitrogen (nm)	Shielding in plane of ring (ppm)	Shielding ± 0.05 nm from plane of ring
0.097	-2.47	-2.94
0.111	-2.42	-2.34
0.135	-2.50	-2.46
0.159	-2.42	-2.34
0.173	-2.47	-2.49

deshielding. The only other plausible explanation is the one we offer. Calculating the chemical shift, we obtain (relative to TMS)

$$\Delta\sigma_{av} = [(0.84 \times 2.14) - (2.50) - (20.9)] = -15.42 \text{ ppm}$$

$$\Delta\sigma_{meas} = (-15.44 \text{ to } -15.70) \text{ ppm}$$

The excellent agreement between theory and experiment is no doubt partly fortuitous because of the many assumptions made and because both the CH_3 group and the I^- have unknown, but opposite, contributions to the chemical shift which probably cancel. Nevertheless, the agreement offers strong support for our conclusions. Because the peak moves upfield, the shielding of the proton must increase. Since the bond itself weakens slightly as temperature increases, the only plausible explanation for the increased electron den-

sity about the bridging atom is that the 

bond is asymmetric to begin with, the proton is lying, on the average, closer to one nitrogen than the other, and electron density is being localized around it for longer periods of time. It should be kept in mind that the nonbonding electrons of nitrogen are less delocalized in the pyridinium ion than in the pyridine (9, 16). This means that the bridging proton lies in a double minimum-potential well between the two halves of the pyridinium-pyridine cation and tunnels back and forth between the two minima. The tunneling frequency will be strongly dependent on the relative orientation of one nitrogen to the other. As temperature rises, the nitrogens move away from the appropriate position for maximum tunneling to occur, so that the tunneling frequency diminishes much faster than the frequency of hopping over the barrier increases (19, 20). The proton thus resides in its well for longer time intervals and becomes more and more shielded with increasing temperature. If the proton resided in a deep single-minimum well for a long period of time on the NMR time scale, its resonance peak would be a nitrogen-broadened triplet, as it is in the molten $\text{C}_5\text{H}_5\text{NH}^+\text{Al}_2\text{Cl}_7^-$ spectrum (21, 22), and the proton would become more acidic and less shielded as temperature increased.

Equivalent conductance.—The data in Table II show that at 425 K the conductances of the three N-methyl salts increase in the order $\text{I}^- < \text{Br}^- < \text{Cl}^-$, and that the increase is substantial. This further strengthens our contention that these salts are principally anionic conductors in the molten state. If one assumes that the mobility of the cation is roughly constant in all three melts, the only plausible explanation for the observed increase in Λ between the three salts is that the halide ion's mobility increases from I^- to Cl^- . Consequently, the fraction of the current carried by the anion also increases. In all likelihood, the iodide ion's mobility and the methylpyridinium ion's mobility are somewhat similar, the difference in ionic radius compensating for the difference in ionic mass.

Comparing the Λ 's of the 4-methyl halides with those of the N-methyl salts shows that the percentage differences in conductance, $[(\Lambda_N - \Lambda_4)/\Lambda_N] \times 100$, are 37% for the chlorides, 27.2% for the bromides, and only 2.3% for the iodides. This large difference is almost certainly due to the formation of complexes of the sort

which form in the Cl^- and Br^- melts because of hydrogen bonding. Complex formation reduces the effective number of charge carriers per unit volume at any instant and thus reduces the conductivity. The

larger percentage difference between chloride conductivities than between bromide conductivities is exactly what is expected if the Cl^- ion is both more mobile than the Br^- ion and forms a stronger bond with a $\text{C}_5\text{H}_7\text{NH}^+$ ion. In effect, the hydrogen bonding immobilizes a greater number of faster moving species in the chloride melt and fewer slower species in the bromide melt, thus giving the observed result. This conjecture is confirmed by the fact that at 425 K $\Lambda_{4, \text{meCl}} \approx \Lambda_{4, \text{meBr}}$, but Λ_{NmeCl} is about 14% larger than Λ_{NmeBr} .

The 2.3% difference in conductance between the two symmetrical iodide melts is further confirmation that in iodides hydrogen bonding is not a factor. This is the sort of difference expected from steric considerations only. This small difference in Λ confirms our earlier hypothesis (1) that the 4-methyl pyridinium chloride and bromide conductivities would be about the same as the respective N-methyl conductivities if not for hydrogen bonding. This means our calculated values for the association constants (0.11 for the chloride melt and 0.062 for the bromide melt) based on this assumption are probably fairly accurate.¹

Viscosity.—The iodide viscosities are difficult to explain, especially in context with our other observations. It is evident from the data in Table II that at 425 K each iodide is less viscous than the corresponding bromide and, with the exception of 3-mepyrHI, less viscous than the corresponding chloride. However, each bromide melt is more viscous than its corresponding chloride melt, which implies that something unique is occurring in the iodides to reverse the expected trend. Part of the explanation is the absence of hydrogen bonds, but, obviously, something else must be occurring. The yellow color of the melt and the relatively low electron affinity of iodine are indicative of the presence of complex species, and we suggest these may be charge-transfer complexes having long enough lifetimes to lower each iodide melt's viscosity relative to what it would be if no neutral species were present (23). Since the forces of attraction between neutral molecules and between ions and neutral molecules are much weaker and fall off much more rapidly as a function of internuclear distance than the forces of attraction between ions, the higher the concentration of CT or other neutral complexes, the lower the viscosity, other things being equal.

The apparently "normal" conductivities of the N-methyl melts, i.e., $\text{Cl}^- > \text{Br}^- > \text{I}^-$, in the presence of abnormal iodide viscosities ($\text{I}^- < \text{Cl}^- < \text{Br}^-$) again imply a different iodide melt structure. The formation of relatively stable iodide complexes causes local liquid relaxation (24), which reduces viscosity. These complexes do not contribute to the conductivity, so that charge is being carried at any instant by fewer ions per unit volume than in the other two N-methyl melts, but these ions are fairly mobile.

The explanation for the μ -iodide melt's high conductivity and low viscosity is not at all clear, but it would seem to be directly related to the melt's low density. Because the density is much lower than that of the other iodides, there is a greater probability for "holes" to form, due to local density fluctuations, which an I^- ion can move into. Moreover, the dimer itself contributes to liquid relaxation by shielding the proton's charge, which further reduces viscosity.

Energies of activation.—Table V lists energies of activation for viscosity, E_η , and for equivalent conductance, E_Λ , assuming Arrhenius behavior for all of the iodide melts. Several melts, most notably 2-mepyr-I, deviated slightly from strict Arrhenius behavior, but the limited temperature range and precision of the data did not warrant the use of the three-

¹Table V in Ref. (1) contains several incorrect entries. The correct K_A 's are the ones listed here. The G 's for the Cl^- and Br^- melts are 7.8 and 9.8 kJ/m, respectively.

Table V. Energies of activation for viscosity and conductance

Salt	E_{η} (J/mol)	E_{Λ} (J/mol)	E_{η}/E_{Λ}
N-mepyrI	27.6	26.2	1.05
4-mepyrI	27.6	19.2	1.43
3-mepyrI	30.9	26.7	1.15
2-mepyrI	26.4	18.5	1.42

parameter VTF equation. In any case, the E_{η}/E_{Λ} ratios did not change significantly as a function of temperature. As is true for all other organic salts studied, the ratios are between 1 and 1.5 and considerably less than the ratios for typical inorganic salts, which range between 2 and 5 (25). We consider this difference to be quite significant and indicative of a fundamentally different transport mechanism occurring in organic molten salts. In inorganic melts, repulsive forces dominate, there is a 10%-20% expansion on melting (26), and, as a result, large density fluctuations occur. Therefore, a small positive ion requires considerably less energy to move than an entire molecule or ion pair. In organic melts, repulsive forces are mitigated by attractive forces, there is little, if any, expansion upon melting, and density fluctuations are quite small. Therefore, it takes nearly as much energy for a halide ion to "waffle" by a pyridinium ion as it does for a pyridinium halide ion pair to waffle by another halide or ion pair. Since a given density fluctuation will be still slightly less likely to accommodate the motion of a larger cation than a smaller anion, the E_{η} is always a bit larger than E_{Λ} . The relatively high E_{η}/E_{Λ} ratio of 1.4 for the μ -iodide melt is consistent with our explanation for its unusual transport properties. The reason why the 4-methyl melt's ratio is also 1.4 is not yet clear.

Based on the energies of activation obtained here as well as those measured elsewhere, we suggest classifying those salts whose E_{η}/E_{Λ} ratio is between 1.0 and 1.5 as "soft" salts, and those salts whose E_{η}/E_{Λ} ratio is between 2 and 5 as "hard" salts. This terminology may even be more apt in molten salt systems than in acid-base theory because those salts whose E_{η}/E_{Λ} ratios are 1:1, and therefore considered soft, are easily polarizable and have relatively weak repulsive forces. However, the inorganic salts, particularly at melt temperatures, do behave to a good first approximation as charged hard spheres.

Errors.—We estimate the errors involved in the iodide measurements to be slightly greater than in the chloride and bromide measurements, probably because there are two decomposition pathways, one being photochemical, the other being thermal. This led to a slightly lower precision in our measurements, since it was impossible to exactly duplicate both the thermal and photochemical history of a given melt. With this in mind, we estimate the error in density to be $\pm 1\%$ (the precision was $\pm 0.3\%$ overall, and in the case of 4-mepyrI $\pm 0.1\%$). The error in equivalent conductance $\pm 2\%$ and the error in viscosity $\pm 3\%$.

Conclusion

By obtaining correlations between structure, transport properties, and ^1H NMR spectra of a series of isomeric melts in which no hydrogen bonding occurs, we are better able to assess the contribution of hydrogen bonding to structure and transport properties of those melts in which hydrogen bonding plays an important role. In addition, we have found that by studying a series of compounds in a systematic way, we were able to detect the presence of an interesting new compound that otherwise might have gone unnoticed.

Acknowledgments

We would like to thank Julie Nemeth for performing the iodide analyses. We would also like to thank Dow Corning for contributing the 710 silicon oil for our constant temperature bath.

Determination of Internal Cation Mobilities in the Molten System (Li-K)Cl at 723 K

R. Takagi,¹ H. Shimotake,* and K. J. Jensen

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

Internal cation mobilities of Li^+ and K^+ in the system (Li-K)Cl were determined experimentally using the counter current electromigration method over the temperature range 700-778 K, with initial equivalent fractions of KCl of 0.356, 0.416, and 0.451. The relative difference in internal cation mobilities of Li^+ and K^+ was found to reach as much as 7% in this range.

Lithium-aluminum/iron sulfide cells that contain multicomponent molten salt electrolytes such as (Li-K)Cl mixture are currently under development for energy-storage applications (1). During charge or discharge of such cells, composition gradients of ions, Li^+ and K^+ are induced within the molten salt by the electrode reactions. As a result, the salt compositions are shifted locally from the liquidus range, and precipitation of a solid phase may occur. In lithium/sulfide cells, which are operated at a temperature range of 400°-430°C in (Li-K)Cl eutectic, Askew and Holland (2) noted that the lithium electrode was severely polarized when discharged at high current densities. They conjectured that the polarization was caused by precipitation of LiCl at the lithium electrode. Willars *et al.* (3) found that the cell capacity was inversely proportional to discharge rate, and the result was interpreted in terms of electrolyte phase separation at the iron sulfide electrode. Braunstein and Vallet (4) and Pollard and Newman (5) calculated current-induced composition profiles of LiCl and KCl in lithium/sulfide cells containing (Li-K)Cl electrolyte. Furthermore, Vallet *et al.* (6) predicted a composition profile that indicates an increased KCl concentration near the cathode. More recently, they presented direct evidence of KCl precipitation (7). Furthermore, they have shown that the composition profile depends not only on the initial composition of the electrolyte, but also on the current density and distance between electrodes. The high KCl concentration also favors the formation of J-phase ($\text{LiK}_6\text{Fe}_{24}\text{S}_{26}\text{Cl}$) in the iron sulfide electrode (8). Transition time required for the separation of the components, which was estimated by Braunstein and Vallet (5), is correlated with the transference number and diffusion coefficient. However, transference number is directly related to the emf because the concentration polarization is involved. Thus it is necessary to know the mobilities of the ions at the operating temperature for accurate determination of the transference numbers. At present, the experimental data reported on the mobilities of Li^+ and K^+ in the system (Li-K)Cl are limited to the temperatures at 913 (9) and 1100 K (10), which are much higher than the normal operating temperature of lithium/iron sulfide cells, *i.e.*, 723 K.

In this study, the internal cation mobilities, *i.e.*, the cation mobilities relative to the common anion, were measured in the system (Li-K)Cl at the cell operating temperature range by the counter current electromigration method developed by Klemm (11) and Okada (12).

Experimental

Figure 1 is a schematic diagram of the electromigration cell. The system consists of a sample melt reservoir made of an alumina tube (a), that has a 2.54 cm id and a length of 35 cm, containing a sample

salt mixture (b), a quartz electromigration tube (d) with a main tube that is 0.4 cm id and 20 cm long, which has been packed with quartz powder (80-100 mesh) (g) and sealed with quartz wool (f), an aluminum electrode (j) that is 0.8 cm id and 7 cm long, encased in a boron nitride tube (i) attached to a nickel lead wire (h), and a thermocouple covered with an alumina sheath (e). The electromigration tube, the aluminum electrode, and thermocouple are immersed in an electrolysis vessel (1) that has a 3.8 cm id and is 43 cm long, made of alumina containing (Li-K)Cl eutectic melt (k). The entire system is assembled inside a glove box containing a high purity helium atmosphere. The (Li-K)Cl mixtures were prepared from LiCl and KCl (polarographic grade) supplied by Anderson Physics Laboratory.

¹ Present address: Tokyo Institute of Technology, Tokyo, Japan.

The experimental procedure was as follows: the electromigration tube packed with dry quartz powder was first immersed in the molten salt mixture to be tested in the sample melt reservoir. The tube filled with the sample melt was then transferred into the molten salt bath held in the electrolysis vessel. The electromigration was carried out by passing a current, 100 mA at about 100V for 4-7h supplied by a dc power supply. The transported charge, Q , was determined by a copper coulometer. After electromigration had occurred, the electromigration tube was removed from the salt bath and immediately quenched to room temperature. The upper part of the tube was then cut into eight pieces, each ~ 1.5 cm long. The salt in each piece was dissolved in distilled water and the quantity of Li^+ and K^+ was determined by emission or atomic absorption spectrophotometry. The variation of the composition of Li^+ and K^+ along the electromigration tube allowed the construction of composition profile.

Results and Discussion

The initial equivalent fraction of KCl, p_K , in the (Li-K)Cl mixtures was varied from 0.356 to 0.451, and the temperature was selected in the liquidus region according to the phase diagram (13). The relative difference in the internal cation mobilities, ϵ_{12} , is defined by

$$\epsilon_{12} = (b_{\text{Li}} - b_{\text{K}}) / \bar{b} \quad [1]$$

where \bar{b} is the average value of b 's, and related to the equivalent conductivity, Λ , by

$$\bar{b} = \Lambda / F = p_{\text{Li}} b_{\text{Li}} + p_{\text{K}} b_{\text{K}} \quad [2]$$

where F is the Faraday constant. From Eq. [1] and [2], one can obtain

$$b_{\text{Li}} = (\Lambda / F) (1 + \epsilon_{12} p_{\text{K}}) \quad [3]$$

$$b_{\text{K}} = (\Lambda / F) (1 - \epsilon_{12} p_{\text{Li}}) \quad [4]$$

The values of ϵ_{12} for the different equivalent fractions of K^+ at the different temperatures are calculated from the chemical analysis and the transported charge balances (11, 12) based on the concentration profile along the electromigration tube, an example of which is shown in Fig. 2. The experimental conditions and results are also listed in Table I. The value of ϵ_{12} obtained in this study at $p_K = 0.416$ and $T = 711$ K is estimated to be -0.06 , which reasonably agrees with $\epsilon_{12} = -0.10$ at $p_K = 0.41$ determined by Moynihan and

Laity (9) at the same temperature using the Hittorf method. The point at which the difference in the internal mobilities of Li^+ and K^+ reached zero was designated as the Chemla crossing point (14), which is a function of temperature. The Chemla crossing point at $p_K = 0.356$ was estimated to be at 700 K, extrapolated from experimental values. This extrapolated point is plotted in Fig. 3 together with values for the Chemla crossing point estimated with the reported results (9, 10). In the region represented by the area below the curve obtained by connecting these points, the mobility of Li^+ is greater than that of K^+ .

The internal mobilities, b_{Li} and b_{K} , were calculated from Eq. [3] and [4] using the equivalent conductivity data available in the literature (15). The isotherms of the results at 723 and 772 K are shown in Fig. 4, which indicates that the mobility of Li^+ becomes less than that of K^+ at these temperatures over the concentration range of this study. This interacting phenomenon in which a large cation, K^+ , migrates faster than a small cation, Li^+ , has been known in other systems and was designated as the Chemla effect (12). The other system in which this phenomenon was first observed was (Li-K)Br (16), and later simulated by a model based on the molecular dynamics (17, 18).

It has been experimentally shown that the internal mobility of Li^+ , b_{Li} , is expressed by

$$b_{\text{Li}} = A \exp(-E/RT) / (V - V_0) \quad [5]$$

where E and V_0 are constants, R is the gas constant, and V is the molar volume of the system. The reciprocal value of b_{Li} obtained in this study is plotted in Fig. 5 against the molar volume of the system together with that obtained by Moynihan and Laity (9). This figure shows that within the experimental range the relationship expressed by Eq. [5] holds in the present system. The constants for the solid lines in Fig. 5 are $A = 1.16 \text{ cm}^5 \text{ V}^{-1} \text{ s}^{-1}$, $V_0 = (43.7 - 0.0259T) \text{ cm}^3 \text{ mol}^{-1}$, and $E = 33.1 \text{ kJ mol}^{-1}$. As for the mobility of K^+ , its reciprocal shows similar linear relationships with

Fig. 3. Temperature of crossover composition and of liquidus composition. ●: (10). ○: from Ref. (9). Δ: this work. ----: liquidus temperature (13). - · - ·: 50 K above liquidus temperature. ×: the eutectic composition of 723 K.

molar volume of the system at temperatures 773 and 913 K, as shown in Fig. 6. The parameters for K^+ are $A = 6.18 \text{ cm}^5 \text{ V}^{-1} \text{ s}^{-1}$, $V_o = (75.8 - 0.0743T) \text{ cm}^3 \text{ mol}^{-1}$, and $E = 40.7 \text{ kJ mol}^{-1}$. The curve at 723 K deviates considerably from linearity. Similar non-linearity was observed with large cations such as Rb^+ in the molten nitrates at lower temperatures (14).

The transference number of species i , t_i is related to the mobility of species i , b_i , by the following equation in a binary system

$$t_i = p_i b_i / (p_1 b_1 + p_2 b_2) \quad [6]$$

Fig. 5. The reciprocal of internal mobilities of Li^+ plotted vs. molar volume. \circ : this work. \bullet : from Ref. (9). Δ : the Chemla crossing points.

Fig. 6. The reciprocal of internal mobilities of K^+ plotted vs. molar volume using the same symbols as in Fig. 5.

Therefore

$$t_i/p_i = b_i / (p_1 b_1 + p_2 b_2) \quad [7]$$

When $b_1 = b_2$, one can obtain $t_i/p_i = 1$, which is frequently used as an approximation for the transference number. However, the present study shows the values of t_{Li}/p_{Li} and t_K/p_K to be 0.97 and 1.04 at $T = 723 \text{ K}$ and near the eutectic composition, i.e., $p_K = 0.416$, respectively. The relative difference in internal cation mobilities, which is equal to $(t_{Li}/p_{Li} - t_K/p_K)$, reaches as much as -7% in this system. Since the eutectic composition (x in Fig. 3) is located above the solid line in Fig. 3, where t_K base line is larger than p_K , transition time for phase separation becomes shorter than that estimated from the assumption $t_K = p_K$. For example, the value of $t_K/p_K = 1.04$ determined by this study at $p_K = 0.416$ and $T = 723 \text{ K}$ gives about 8% less transition time than that estimated using the assumption $t_K = p_K$. The discrepancy becomes more pronounced at higher concentration of KCl. However, increased concentration of LiCl lowers t_K and brings t_K to below the value of p_K , resulting in the favorable condition for the cell operation. However, the addition of LiCl to the eutectic salt mixture also results in a higher liquidus temperature, causing the precipitation of the salt component. In such case, the operating temperature of the cell must be kept sufficiently high to maintain the stable cell operation. Usually the cell operating temperature is kept at least 50 K above the liquidus temperature of the salt. For example, changing the electrolyte composition from $p_K = 0.415$ to $p_K = 0.36$ raises the liquidus temperature of salt to 673 K. A cell containing this salt requires an operating temperature of 723 K for the stable operation.

EMF, ϕ , due to the concentration polarization can be calculated by

$$\phi = \frac{1}{F} \int_0^{\Xi} \frac{1 - t_{Li}}{1 - p_{Li}} \frac{d\mu_{LiCl}}{dx} dx \quad [8]$$

where μ is chemical potential and Ξ is the separation distance between electrodes (4). With the boundary conditions $p_{Li} = 0.52$ at $x = 0$ and $p_{Li} = 0.72$ at $x = \Xi$ and assuming $t_{Li} = p_{Li}$ and an ideal solution, one can obtain $D = 20.4 \text{ mV}$. A similar calculation can be carried out, using t_{Li} , estimated from Eq. [6], and $\phi = 20.7 \text{ mV}$ is obtained. Therefore, as far as EMF of this system is concerned, the assumption of $t_i/p_i = 1$ seems to be satisfactory.

Conclusion

The internal cation mobilities of Li^+ and K^+ in the system (Li-K) Cl were determined experimentally over

the temperature range 700–778 K, with initial equivalent fractions of KCl of 0.356, 0.416, and 0.451. The Chemla effect was observed in this system.

The transference numbers calculated from the internal mobilities showed a discrepancy from the relationship $t_i/p_i = 1$, which is frequently used as an approximation for transference number.

Porous Electrodes

I. Numerical Simulation Using Random Network and Single-Pore Models

Michael Kramer and Micha Tomkiewicz*

Department of Physics, Brooklyn College of the City University of New York, Brooklyn, New York 11210

ABSTRACT

A random network model is introduced to simulate the porous metal-electrolyte interface. This is the first time that an attempt has been made at defining a model for this system that maintains the random nature of the rough topology. A previously utilized model for this system, the single-pore model, is explored and extended. The models are compared, and the results of the random network model are found to be in qualitative agreement with the single-pore models.

The porous metal electrode is a subject of intense theoretical and applied interest. Although widely utilized in electrochemical systems, especially in battery technology, very little is known in detail about the porous interface from first principles, aside from a general knowledge of how the porous electrode's behavior deviates from flat-electrode behavior. Specifically, it would be useful to know how the complicated topology of the porous metal electrode contributes to the electrical properties of the interface. Previous attempts at modeling the porous electrode are presented in the review article by DeLevie (1). The macroscopic model (2) treats the electrode-electrolyte system as a superposition of two continua, one of the electrode matrix and one of the solution matrix that fills all the unoccupied space. The solution is assigned an effective conductivity, and the interface is considered to have an effective capacitance per unit area. The single-pore model is based on a one-dimensional representation of

a pore as a transmission line (see Fig. 5) which represents a pore of "average pore length." These models, however, do not account for the random distribution of pores in a true porous solid, nor for a complicated surface topology. We have chosen to introduce a three-dimensional model of the rough interface based on the random-network lattice that has proven to be so useful in representing conduction in inhomogeneous materials and related percolation problems (3-5). AC impedance measurements are widely used experimentally for the *in situ* characterization of electrochemical systems under equilibrium conditions. In conducting these measurements on porous electrodes, the complex topology of the electrode in various states of charge yields ambiguous data, not subject to a unique interpretation. The computer simulation allows us to examine the impedance of the system as a function of given charge accumulation modes at the electrode-electrolyte interface. The model is not intended to portray the dc operation of the electrode, but rather to provide a means for understanding the interface. Using an IBM/

Key words: electrode, impedance, battery, topography.

370 computer, we construct our model and calculate its complex impedance, $Z(\omega)$, in the frequency range of 1 Hz to 1 MHz. Based on this impedance spectrum, we model the system in terms of passive elements (6).

In this paper, we will present our model in detail, discuss preliminary results, and compare these results with the "DeLevie model." We will also discuss further work being done to utilize this model for a more detailed characterization of the interface.

The "Random" Network Model

We consider a simple system, in which a 1 cm³ porous metal electrode is immersed in electrolyte, along with a counterelectrode. Only the bottom (1 cm²) surface of the electrode is exposed to the electrolyte. The electrode is allowed to discharge, allowing for a buildup of a semiconductor on the metal surfaces exposed to the electrolyte. To explore the electrical behavior of this system, we note that we may define a local conductivity, $\sigma(\vec{r})$, the bulk conductivity at point \vec{r} in our system. Rather than attempt to solve for the current distribution using the electrostatic equations for the continuous case, we transform the problem into one requiring the solution of a discrete set of Kirchoff's law equations (a finite difference approximation to the continuum problem (3)). We subdivide our bulk system into a regular cubic mesh of points $\{r_i\}$ ($i = 1, S$) and assign to each branch of the mesh a conductivity that represents the conductivity of the surrounding bulk in that region of space. Let the conductance of the circuit branch that connects node i and j be denoted as g_{ij} , the voltage at node i be V_i , and the net current into node i be I_i . We then have $(S-1)$ equations of the form

$$\sum_j g_{ij}(V_i - V_j) = I_i \quad [1]$$

or in matrix notation

$$G \cdot V = I$$

where G is the conductance matrix ($G_{ii} = \sum_j g_{ij}$ and $G_{ij} = -g_{ij}$), V is a vector containing the voltages on each node with respect to ground, and I is a vector containing the net current inputs to each node. We may solve these simultaneous equations for the V 's on all the nodes, and for the total impedance of the system. A detailed presentation of the algorithm that we have employed follows.

We define a three-dimensional cubic lattice, $A(i, j, k)$, where i, j , and k range from 1 to N , and $N^3 = S$, the total number of nodes. N is chosen so that it is sufficiently large to approximate an infinite system. Construction of the electrode is simulated using a random

number generator to place "metal" at various points in the lattice, until the desired porosity is reached. A check is made of the resulting electrode to insure that it is continuous and that no pieces of metal are "hanging" in midair. Any disjointed pieces of metal are removed, and are randomly replaced on the remaining available lattice points. This process is repeated until a continuous electrode of the desired porosity is obtained. Lattice plane $k = 1$ is defined as electrolyte, to represent the solution; the electrode itself begins at lattice plane $k = 2$. The electrolyte is allowed to "seep" into the pores in the electrode until all accessible pores are filled, by searching for continuous electrolyte paths from the $k = 1$ plane throughout the electrode. Any point on the lattice which has been left empty (i.e., no metal was placed there, and electrolyte was precluded from penetrating to that site) is considered to be "air."

Each lattice point represents a node in a three-dimensional circuit network, (see Fig. 1), and each pair of nodes defines a circuit branch in the network. The impedance of each branch is determined by the characteristics of the two surrounding nodes. Thus, for example, if $A(1, 1, 1)$ is electrolyte and $A(1, 2, 1)$ is also electrolyte, the circuit branch defined by those nodes will consist of two series resistors of resistance R_e (the resistance of a microscopic section of the electrolyte). If $A(1, 1, 2)$ is metal and $A(1, 2, 2)$ is metal, then the circuit branch defined by those two nodes will be two series resistors of value R_m (the resistance of a microscopic section of the metal). Finally, the branch defined by $A(1, 1, 1)$ -electrolyte, and $A(1, 1, 2)$ -metal, is represented by an R_m and an R_e resistor in series, with the addition of a parallel R-C element in series with them to represent the semiconductor-electrolyte interface that results (see Fig. 2). Any circuit branches leading into nodes that are defined as "air" are taken to be of infinite resistance.

The values that we have chosen to use as our unit impedances for the individual components of metal, electrolyte, and semiconductor are presented in Fig. 2. These values were obtained by taking the values of bulk impedance for a 1 cm³-sized sample (we chose numbers characteristic of Zn and ZnO) and scaling them down to the magnitude of a unit pore size: approximately 10 μ diam. We define a characteristic time constant of the interface, $\tau = R_p C$. These components are assembled into a system, as described above (see Fig. 3), and the total impedance of the system is calculated. The total impedance is then rescaled by an appropriate factor that normalizes the whole system to a 1 cm³ size. Thus, an attempt is made to obtain im-

Fig. 1. Representation of the three-dimensional lattice in terms of circuit elements. Figure 1b shows our model in terms of a checkerboard pattern of bulk components of metal, electrolyte, semiconductor, and air. Figure 1a depicts our representation of a corner of Figure 1b in terms of a network of circuit elements. Z_{sc} is the impedance of the semiconductor layer on the interface (see Fig. 2).

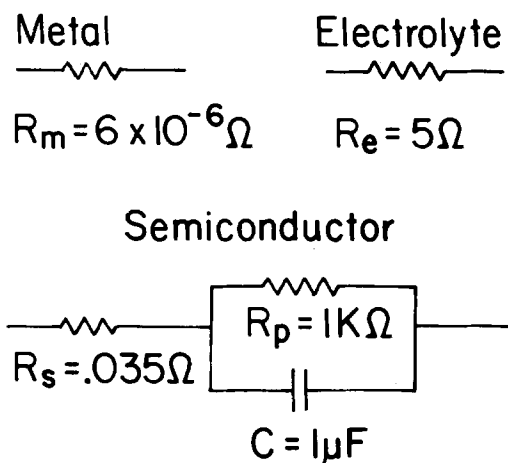

Fig. 2. Equivalent circuits used to represent the microscopic components of the system (metal, electrolyte, semiconductor, etc.).

pedance data with numbers representative of that which might be encountered in a real system.

Once the electrical network has been defined, the computer sets up the Kirchoff's law equations. Due to the fact that our model includes reactive circuit elements, the quantities G , V , and I in Eq. [1] are complex, and may be represented as 2S-1 equations of the form

$$\begin{pmatrix} G_r & -G_i \\ G_i & G_r \end{pmatrix} \begin{pmatrix} V_r \\ V_i \end{pmatrix} = \begin{pmatrix} I_r \\ I_i \end{pmatrix} \quad [2]$$

Fig. 3. The random network lattice used to generate the data for Fig. 4. At this porosity of 0.3, the electrolyte does not fully penetrate the lattice. (Actually, the penetration of the electrolyte into the pores seems to conform to classical percolation theory. At porosities above 0.35, the liquid starts to penetrate through the electrode).

where the subscripts r and i stand for the real and imaginary components, respectively.

A known current is sent uniformly into all the bottom nodes (so as to eliminate the "edge effects" that would result if the current were sent only into one node), and the impedance of the system is calculated between one node on the electrolyte plane (1, 1, 1) and one node of the top electrode plane (N, N, N) by solving for the V 's on all the nodes.

For a system of $N = 15$ (a lattice of size $15 \times 15 \times 15$ with 3375 nodes) there are up to 6748 equations to be solved. This is a formidable computer problem. Indeed, the task would be prohibitive without taking advantage of the fact that the conductance matrix, G , is a sparse-symmetric coefficient matrix.

A number of techniques exist for the solution of this class of problems. A widely used method for solving the simultaneous equations in the random resistor lattice is the Gauss-Seidel iteration procedure with over-relaxation (5). This is a very economical method, in both execution time and storage space. A serious drawback of this technique is the relatively strict requirements that it places on the coefficient matrix in order for convergence to be achieved, namely, that the matrix be either diagonally dominant, or at least positive definite (7). For Kirchoff's law problems with purely resistive components, diagonal dominance is assured, since the diagonal elements of the conductance matrix are simply the sum of the off diagonal elements. In our problem, with complex impedances, we find that at frequencies for which the real conductance approaches the same order of magnitude as the imaginary conductance, the Gauss-Seidel procedure does not converge. This is due to the form of the equation in Ref. (2) where there are many more off diagonal elements due to the G_i values. When these imaginary components are large, the matrix is no longer diagonally dominant nor positive definite.

For most of our computations, we have resorted to the use of a Gaussian elimination routine which takes advantage of both the sparseness and the symmetry of the G coefficient matrix (8). Only the nonzero elements in the upper half-triangle of the matrix are stored, and an efficient pivoting strategy is chosen to minimize nonzero matrix fill during the pivoting and to minimize the number of multiplications required in the solution. In practice, the technique is approximately an order of magnitude more expensive to use than Gauss-Seidel in both speed and storage requirements. The advantage of using the Gaussian elimination technique is that a solution is guaranteed for almost any problem. The solutions obtained from the Gauss-Seidel procedure (in the range in which convergence is reached) are in complete agreement with the results obtained using the modified Gaussian elimination technique.

Figure 3 presents a system constructed with a porosity of 0.30, and the resulting impedance of the system as a function of frequency is plotted in Fig. 4. We have identified three basic regions of interest in the frequency range spanned by our results. Region I is the low frequency range, in which our system seems to behave as a parallel RC combination (see Fig. 4). Region II is in the mid-frequency range, with an impedance spectrum that cannot be represented using passive elements, and Region III is representative of a series RC combination. The variation of the impedance data as a function of system size is presented in Fig. 5 from size $N = 5$ to $N = 15$. For the results presented here, $N = 15$ was used to ensure proper statistical representation of an infinite system.

The Single-Pore Model

It is interesting to compare, at least qualitatively, the results from our three dimensional model with the results obtainable from the single pore model previously mentioned (1).

Fig. 4 Impedance spectrum from the random network model at a single porosity (0.3), and a single random number. Three frequency regimes are identified, and we have modeled two regimes with a simple passive-element model. The bars on each curve represent the variations in the data when various random-number seeds are used to construct the lattice. For each random-number seed, the shape of the impedance spectrum is almost identical.

DeLevie, following on the heels of other researchers [Daniel-Bek (9) and others], suggested that each pore in a porous electrode may be thought of as having a uniformly distributed electrode and electrolyte resistance throughout its length. As such, the single pore may be modeled as in Fig. 6a, where R is the resistance per unit length of the electrolyte solution in-

side the pore and Z is the impedance of the electrode-electrolyte interface. The current voltage relationships of this circuit may be expressed as a differential equation, and a solution may be obtained for the total impedance of the circuit as (1)

$$Z_o = (RZ)^{1/2} \coth(\rho L) \quad [3]$$

where R and Z are defined above, $\rho = (R/Z)^{1/2}$, and L is the length of the pore. This is the main, and currently utilized (10), result from this model. The main characteristics of the calculation are: (i) although flat electrode impedances vary as a function of Z , porous surface impedances will be dependent on $(RZ)^{1/2}$, and (ii) the contribution of the electrode surface deep inside the pore is negligible, $1/\rho$ becoming the characteristic "penetration depth." If $\rho L \gg 1$, the pore behaves like a semi-infinite one.

In order to utilize these results for comparison with the random network model, we must introduce a value for Z , and we must also combine the single-pore transmission-line impedances to form a complete rough electrode. The former is accomplished by defining the electrode-electrolyte interface as a standard parallel RC model, as depicted in Fig. 6b. We have used the same numerical values for the individual components as those in the random network model (here they are shown already normalized to the $10 \mu\text{m}$ single-pore size). As a result

$$Z = r_s + \frac{R_p}{1 + \omega^2 \tau^2} - j \frac{\omega \tau R_p}{1 + \omega^2 \tau^2} \quad [4]$$

where $\tau = R_p C$. Substituting Eq. [4] into Eq. [3] and simplifying, we get

$$Z_o = \sqrt{\frac{RP}{2}} \frac{e^{2x} - e^{-2x}}{e^{2x} + e^{-2x}} \times \left\{ \left[(\beta + \alpha)^{1/2} + \frac{2 \sin 2\theta}{e^{2x} - e^{-2x}} (\beta - \alpha)^{1/2} \right] + j \left[(\beta - \alpha)^{1/2} - \frac{2 \sin 2\theta}{e^{2x} + e^{-2x}} (\beta + \alpha)^{1/2} \right] \right\} \quad [5]$$

where we have defined the following quantities

$$P = \frac{R_p}{1 + \omega^2 \tau^2}$$

$$\alpha = 1 + \frac{r_s}{P}$$

$$\beta = (\alpha^2 + \omega^2 \tau^2)^{1/2}$$

$$x = L \left(\frac{R}{P} \right)^{1/2} \frac{1}{\sqrt{2}\beta} (\beta + \alpha)^{1/2}$$

$$\theta = L \left(\frac{R}{P} \right)^{1/2} \frac{1}{\sqrt{2}\beta} (\beta - \alpha)^{1/2} \quad [6]$$

A log-log plot of the relationship between Z and f (for a single pore) is presented in Fig. 7. It is interesting to note the similarity in shape between the impedance spectrum of the single-pore model (even though we are only considering a single pore) and that of our random network model (Fig. 4). The advantage of considering a single pore at the present stage is that it is the only system for which we have an analytic result (Eq. [5]), which may be used to derive expressions for the impedance in different frequency ranges.

We define three frequency regimes:

1. The low frequency range ($\omega \tau \ll 1$)

$$\text{Re}(Z_o) \simeq K$$

$$\text{Im}(Z_o) \simeq K\omega\tau$$

[7a]

Fig. 5. The impedance in the random network model as a function of system size. All values are normalized to the impedance of lattice size $15 \times 15 \times 15$ ($N = 15$).

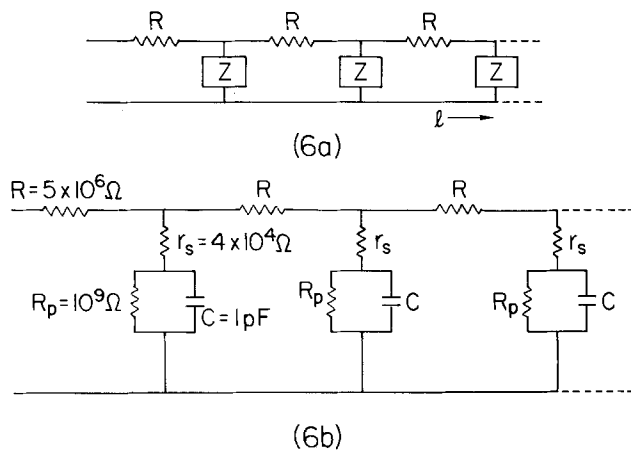

Fig. 6. The DeLevie model of a single pore. Figure (6a) presents the general transmission-line model. (6b) presents the value we have chosen for R , the electrolyte impedance, and our specific model for Z , the electrode-electrolyte interface inside the pore.

Fig. 7. Impedance spectrum from the DeLevie model, single pore. The sections of the curve labeled 1 are areas in which the imaginary impedance plot is of slope = 1 on the log-log plot, and the impedance in these ranges may be modeled by the two passive elements models shown. The section of the curve labeled 2 has a slope of 1/2 (see Eq. [7a]-[7c]).

where K (independent of frequency) is given as

$$K = \sqrt{RR_p} \frac{e^{2x} - e^{-2x}}{e^{2x} + e^{-2x} + 2}$$

and x is

$$x \approx L(R/R_p)^{1/2}$$

The notable features of Eq. [7a] are the frequency independence of the real part and the slope 1 dependence (on the log-log plot) in the imaginary part of the impedance (see Region I on Fig. 7).

2. The intermediate frequency range ($\omega\tau \gg 1$, but $r_s\omega\tau/R \ll 1$)

$$Re(Z_o) = Im(Z_o) = \sqrt{\frac{RR_p}{2}} \frac{1}{\sqrt{\omega\tau}} \quad [7b]$$

This results in the slope $-1/2$ line in Region II of Fig. 7.

3. The high frequency range ($\omega\tau \gg 1$ and $r_s\omega\tau/R_p \gg 1$)

$$Re(Z_o) = \sqrt{Rr_s}$$

$$Im(Z_o) = \frac{1}{2} \sqrt{\frac{R}{r_s}} \frac{R_p}{\omega\tau} \quad [7c]$$

which results in a frequency independent real impedance, and the slope -1 line in the imaginary impedance, as can be seen in Region III of Fig. 7.

In addition to the frequency limits, it was also assumed that $R_s/R_p \ll 1$, and that $R > r_s$ by at least an order of magnitude (which is usually the case).

To combine the single pores into a unified metal-electrolyte system, we extend DeLevie's model slightly. We define an X-Y plane and divide it into N^2 squares, and randomly place a rectangular-width pore on the X-Y plane with its length extending in the Z direction. The length of the pore, L , is also randomly chosen to be from 1 to N , and the pore width, W , is selected so that there is a Gaussian distribution about $W = 2$ (to prevent a few very wide pores from "taking over" the whole electrode). More random-sized pores are randomly placed on the X-Y plane until the desired porosity is reached. We may then solve for the total impedance of the system by adding up all the parallel impedances due to the individual pores, using Eq. [5] to represent the impedance of each pore. The impedances of the nonporous sections of the electrode are also added on to the total impedance.

The results, for a porosity of 0.3 and $N = 40$, are presented in Fig. 8. The criteria for choosing N was based on considerations similar to those used to choose N in the random network model, namely, that the results be independent of N and statistically independent of the random number. This phase of the calculation was performed on an IBM PC.

Discussion of Results

There is a qualitative agreement between the random network model and the single-pore model. A comparison of the passive elements representation of the two systems (Fig. 4 and Fig. 8) also yields order-of-magnitude quantitative agreement. One discrepancy between the two models is the definite shift in the location of the "mid-frequency peak" in Fig. 8 as compared to the random network and single-pore results. A major difference between the two models in construction, is the fact that in the random network the pores interact with each other as in a true porous electrode, while in the DeLevie model each pore is kept separate from the others, and is a separate channel. The favorable comparison of the two models would seem to bear out DeLevie's assertion that "the disregard of crosslinks [between the pores] presumably does not introduce a significant error" (1). Nevertheless, this

Fig. 8. Impedance data from DeLevie model, randomly distributed pores. Porosity = 0.3, $N = 40$.

can be a useful starting place for an explanation of a discrepancy between the two.

The behavior of the system impedance in the random network model may be somewhat inferred from the values of the constituent components that make up the system. The low frequency (real and imaginary) impedance in Fig. 4 reflects the values of R_p and C of the unit (semiconductor) interface, although the 300Ω value of $Re(Z)$ is noticeably lower than the $1\text{ k}\Omega$ R_p . In the high frequency regime, C dominates, totally shunting out R_p , the only contribution to the real impedance being R_e . This provides us with an indication that the total behavior of the porous-metal system may be inferred from the values of the components that make up the complicated surface topography. Our ultimate goal is to generate a detailed picture of the macroscopic interface from the impedance data of the microscopic components that make up the system. This will be considered further in a subsequent paper, along with an exploration of the physical significance of the passive elements model of the entire system.

We will also examine the correlation between the single-pore analytic results (in the various frequency limits) and the random network model. Only a single porosity has been considered thus far, but an exploration of the random network model at different porosities is in order. Although some rough surfaces may exhibit a conduction percolation threshold (11, 12), we do not expect to see any classical percolation in our system. This is due to the fact that we have constrained the system to be above the percolation threshold by the requirement that the metal electrode be continuous. We would, however, expect to see some less dramatic system dependence on porosity.

Acknowledgments

We would like to express our special gratitude to Dr. Philip E. Seiden from IBM, Thomas J. Watson Re-

search Center, for helping us to formulate the Random-Network problem. We would also like to thank Dr. Itzhak Webman from Exxon, for helpful discussions during the initial phases of the project. This work was supported by the Office of Naval Research under Contract N00014-81-K-0339.

Study of the Initial Stages of Anodic Oxidation of Polycrystalline Silver in KOH Solutions

Maria Hepel* and Micha Tomkiewicz*

Department of Physics, Brooklyn College of the City University of New York, Brooklyn, New York 11210

ABSTRACT

Growth of the anodic Ag_2O film on a polycrystalline silver disk electrode in 1 mol dm^{-3} KOH solution at ambient temperature has been examined using a variety of electrochemical techniques. On the basis of the experimental results, a solid-state model of silver electrode covered by a thin semiconductor film with a finite ionic conductivity has been proposed. It has been found that under potentiostatic control, thickness of the oxide film adjusts very quickly to the hydrodynamic conditions by a deposition/dissolution process, and the steady-state oxidation currents fulfill the Levich equation for RDE, despite the fact that the electrode is covered by a thin Ag_2O film. In the case of thicker films, after completion of nucleation and growth, changes in the hydrodynamic conditions do not influence the oxidation current, and adjustment of the thickness of the oxide film to new hydrodynamic conditions proceeds at slower rate because of the slowness of the solid-state diffusion step. The Ag_2O nucleation and growth peak has been observed in chronoamperometric transients above potential of $+240\text{ mV}$ (vs. Ag/AgCl). It has been observed that the nucleation and growth peak decreases as the convective diffusion is accelerated by the rotation speed of the RDE. The dependence of the oxidation current upon the rotation speed vanishes gradually during the Ag_2O nucleation and growth process.

Porous silver oxide electrodes in conjunction with zinc, cadmium, iron, or hydrogen electrode serve as cathodes in various batteries (1). The silver electrodes offer excellent cycle life when used in rechargeable cells (1-4). In spite of development of commercial rechargeable silver-zinc batteries and the numerous investigations on the electro-oxidation of silver in alkaline solutions, the basic electrochemical processes involved are still not well understood. Apparently simple, consecutive oxidation

scheme

is complicated by adsorption processes, nucleation overvoltages, solid-state diffusion, and dissolution of Ag(I) in form of hydroxy complexes. The resulting cyclic voltammogram for polycrystalline smooth electrode consists of five anodic peaks (see Fig. 1), of which only two are associated with the formation of bulk Ag_2O and Ag_2O_2 .

Fig. 1. The CV characteristic for the polycrystalline silver electrode (geometric area $A = 0.385 \text{ cm}^2$) in 1 mol dm^{-3} KOH solution at 22°C . Potential cycles 6-8 between -650 and $+900 \text{ mV}$ vs. Ag/AgCl, $\nu = 10 \text{ mV/s}$, quiet solution, $E_{\text{cond}} = -1240 \text{ mV}$.

Our present objective is to study the initial stages of the oxidation of smooth polycrystalline silver electrode.

Commencement of silver oxidation has been ascribed by Giles *et al.* (5, 6) on the basis of impedance measurements, to its dissolution in form of $\text{Ag}(\text{OH})_2^-$ complexes. According to Brezina *et al.* (7), the multilayer surface oxides are formed in the region of peak A_1 (see Fig. 1), while Giles *et al.* (5, 6) proposed a mechanism in which a monolayer of Ag_2O is completed in the region of the first oxidation peak. Droog *et al.* (8) and Ambrose *et al.* (15) treated their peak as A_1 on the basis of the recalculation of the electrode-potential scale, but, previously (5, 9, 10), this peak was compared to the peak A_2 of other authors (11-14). Ambrose and Barradas (15) conclude on the basis of ring-disk study that in the A_1 region the dissolution of silver(I) as $\text{Ag}(\text{OH})_2^-$ occurs, giving linear Koutecky-Levich plots, $i^{-1} = f(\omega^{-1/2})$. However, no further conclusions could have been drawn from the potential dependence of the determined values of the anodic current at $\omega \rightarrow \infty$. Earlier, the ring-disk technique has been applied by Miller (16). In this study, the supersaturation in the vicinity of the electrode surface has been observed at the foot of the A_3 peak; the peaks A_1 and A_2 have not been observed on his freshly polished electrodes. Tilak *et al.* (9), Perkins *et al.* (10), and Stonehart (11) have treated the peak A_1 as an artifact (carbonate impurities, electrode etching, etc.). Droog *et al.* (8) attribute it to a complex situation in which at least two reactions are involved. They have proven that the change in carbonate concentration does not influence the A_1 peak potential. On the basis of the combined electrochemical and ellipsometric studies, the same authors (8) conclude that the A_1 peak is due to the silver dissolution and the formation of a surface monolayer. The peak A_2 has been identified by Dirkse and de Vries (12) as AgOH . To similar conclusions came Stonehart (11), neglecting dissolution of adsorbed and volume films of AgOH . Other hypotheses have also been proposed: oxidation of adsorbed hydrogen (13), preferential oxidation of surface silver atoms of low coordination number (16, 17), and electrodisolution of silver with eventual formation of a surface of Ag_2O monolayer (9, 10). The latter point of view has been associated (10) with the fact that no photoeffects were observed in the A_2 region. It has been found that the onset of the photocurrent on voltammetric characteristics for semiconducting $n\text{-Ag}_2\text{O}$ film electrode takes place after the peak A_2 is completed (10, 18).

The aging effects in the initially formed oxide film have been considered by Arvia and co-workers (19). The electrochemistry of silver in KOH solutions at elevated

temperatures has been studied by Macdonald and co-workers (25-28).

In this study, we examine the initial stages of the electro-oxidation of silver and growth of the semiconducting oxide films on polycrystalline silver electrodes in alkaline environment. The aim of this work is to describe the solid-state transport processes across the thin Ag_2O anodic film starting from first monolayers. The influence of different parameters on the total oxidation current is discussed. On the basis of the performed experiments, we propose a steady-state model of the Ag/ Ag_2O electrode in the region of the space-charge buildup in the growing film. The linear scan voltammetry (LSV), linear potential scan coulometry (LPSC), cyclic voltammetry (CV), and rotating disk electrode (RDE) techniques have been used in measurements.

Experimental

A standard plexiglass electrolytic cell of about 100 cm^3 capacity was used in this study. A fritted glass tube was used to separate the Pt-foil counterelectrode from the main cell compartment. A silver rod (Johnson-Matthey) pressed into a Teflon holder was used as a working electrode; its active surface area was 0.385 cm^2 . A Model EC-219 rotating disk electrode (IBM Instruments, Incorporated) was also used in experiments with controlled hydrodynamics. The potentials were measured against the double-junction silver/silver chloride electrode (Sargent-Welch Scientific Company) with internal saturated KCl solution and external 1 mol dm^{-3} KNO_3 solution. The latter one was exchanged each day to avoid contamination of the main solution (KOH) by chloride ions.

An EG&G Model 173 potentiostat, equipped with a Model 179 digital coulometer and Model 175 universal programmer, was used for voltammetric and chronocoulometric measurements. The experimental plots were recorded on a Hewlett-Packard Model 7044 A XY-plotter.

All the chemicals used were of analytical-grade purity. The solutions were prepared with deionized water ($18 \text{ M}\Omega$) obtained using a Milli-Q purification system. Before the measurements, silver electrode was polished with $0.05 \mu\text{m}$ alumina (Fisher Scientific Company), washed with deionized water, and dried in a vacuum. The solutions were deoxygenated by nitrogen bubbling.

Results

A well-developed full CV characteristic for polycrystalline silver electrode in 1 mol dm^{-3} KOH solution can be obtained after approximately six cycles between -650 and $+900 \text{ mV}$ vs. Ag/AgCl reference electrode. Such a voltammogram is presented in Fig. 1 for the potential scan rate of 10 mV/s . All the faradaic activity start at potentials positive to -300 mV vs. Ag/AgCl. In consecutive cycles, only small changes (increase) in the peak heights are observed, and they are due to increasing real surface area of the electrode. It is seen, that in the anodic scan, five current peaks are observed and they are designated A_1 through A_5 . The current increase at the positive limit of the voltammogram is associated with the oxygen-evolution reaction.

The formation of bulk Ag_2O and Ag_2O_2 can be ascribed (5, 6, 8-10, 12-21) to peaks A_3 and A_4 , respectively. In the potential region of the peak A_3 , at the foot of the oxygen-evolution wave, the highest silver oxide, Ag_2O_3 , is formed, as has also been reported in Ref. (22, 23, 25, 29-32). The peaks A_1 and A_2 correspond to the initial stages of the silver oxidation.

When the electrode is conditioned in solution at open circuit for a long time (*e.g.*, 24h) significant changes are seen in the LSV peak structure (Fig. 2). The peak A_2 is not observed, and the peak A_3 is much sharper than normally obtained on freshly polished electrode and also is higher than the peak A_4 corresponding to the nucleation and growth of the argentic oxide. Furthermore, upon successive cycles, large changes are observed in the relative amplitude and the position of the various peaks. After about

Fig. 2. Consecutive runs (1-4) of the cyclic voltammogram for a stationary silver electrode conditioned for 24h in 1 mol dm⁻³ KOH solution. Scan rate: 10 mV/s. Potential limits: -650 and +900 mV. $A = 0.385$ cm².

four cycles, a stable voltammogram emerges. This evolution is shown in Fig. 2.

Potential region of the peak A₁.—The current prewave A₁, hardly seen in Fig. 1, is presented in enlarged scale in Fig. 3 for a set of potential scan rates ranging from 10 to 200 mV/s. When the anodic inversion potential E_i is equal +180 mV (as in Fig. 3), a full anodic wave is developed only at $v \leq 10$ mV/s. In the reverse scan, the peak C₁ is observed for all values of v . The half-peak width increases with v and approaches approximately 60 mV at $v = 200$ mV/s. The dependence of the peak height upon the potential scan rate is presented in Fig. 4.

The amount of charge consumed during LSV experiment can be calculated by integrating the voltammetric

Fig. 3. The LSV characteristics for the Ag electrode in 1 mol dm⁻³ KOH solution in the region of peaks A₁ and C₁, for the potential scan rate v [mV/s]: (1)10, (2)20, (3)40, (4)60, (5)80, (6)100, (7)120, (8)140, (9)160, (10)180, (11)200, $A = 0.385$ cm².

Fig. 4. The dependence of the cathodic peak current (C_1) upon the potential scan rate (curve 1) and the square root of the scan rate (curve 2). Solution: 1 mol dm⁻³ KOH.

characteristic. The charge Q plotted vs. the electrode potential gives then the LPSC characteristic. The same result can be obtained by the use of an electronic digital coulometer with analog output. Typical LPSC characteristics obtained in this way for the initial stage of silver oxidation are presented in Fig. 5. The experimental conditions are similar to the LSV curves shown in Fig. 3, except that E_i is now equal to +200 mV, and the scan rates down to 1 mV/s are applied. Despite a fall of the LSV currents, the total anodic charge increases significantly as v decreases. The total cathodic charge Q_c does not compensate the anodic one Q_A and is always lower by about 1.2-1.5 times. The slower the potential scan, the larger the unrecovered charge.

Note, that all the charge peaks on the LPSC curves in Fig. 5, appear exactly at the same potential. It corresponds to the isopotential point E_x in the family of the respective LSV characteristics. In this case, $E_x = 175$ mV.

As shown by Droog *et al.* (8), the cathodic peak C_1 increases as the anodic potential limit E_i is shifted toward more positive values. We have observed the same effect

Fig. 5. The LPSC curves for the initial stage of silver oxidation and reduction in 1 mol dm⁻³ KOH solution. Potential scan rates v [mV/s]: (1)200, (2)180, (3)160, (4)140, (5)120, (6)100, (7)80, (8)60, (9)40, (10)20, (11)10, (12)5, (13)2, (14)1, $A = 0.385$ cm².

on a stationary polycrystalline silver electrode. It is interesting now to compare this effect with the LSV curves obtained under different hydrodynamic conditions. A set of LSV characteristics with changing E_i obtained on the rotating silver disk electrode (RDE) is presented in Fig. 6. No effect of E_i is observed up to $E_i = 220$ mV, unless fast potential scans are applied. The significance of this observation is discussed in the Discussion section.

Dissolution effects in the formation of a thin Ag_2O film.—The steady-state anodic oxidation currents measured on silver RDE at different angular velocities, in the potential range 180–250 mV, fulfill the Levich equation

$$i = 0.62nFAD^{2/3}\nu^{-1/6}\omega^{1/2}(C_s - C^*) \quad [3]$$

where D is the diffusion coefficient of the diffusing species, ν is the kinematic viscosity of the solution, C_s and C^* are the concentrations of the diffusing species at the electrode surface and in the solution bulk, respectively, ω is the angular velocity of the rotating disk, and the other symbols have their usual meaning.

The plot of the linear relations $i = f(\sqrt{\omega})$ for different electrode potentials under steady-state conditions is presented in Fig. 7. (The rotation speed $\bar{\omega}$ is expressed in rpm; $\bar{\omega} = [60/2\pi]\omega$). It is evident from Fig. 7 that the surface concentration C_s increases with increasing potential up to approximately +250 mV. Above +250 mV, the situation is much more complex because of commencement of the growth of the bulk Ag_2O film. This process proceeds via the nucleation and growth mechanism (21) with the control by a solid-state transport through the underlying basal layer.

The chronoamperometric curves presented in Fig. 8 illustrate the nucleation and growth of Ag_2O film at $E = +260$ mV on RDE at 5990 rpm and on a stationary electrode. Note that the charge under the nucleation and growth peak is much greater for the stationary electrode than for the RDE. It is not unreasonable to assume that a thicker film is formed in the former case. The problem then arises what is the dependence of the oxidation current upon the hydrodynamic conditions in different stages of the Ag_2O film growth and what is the role of the oxide dissolution processes. From many experiments per-

Fig. 6. The slow-scan, LSV characteristics for a rotating polycrystalline silver disk electrode in 1 mol dm^{-3} KOH solution for different values of the anodic inversion potential E_i [mV]: (1)185, (2)182, (3)190, (4)200, (5)210, (6)220. Conditions: $\nu = 1$ mV/s, $\omega = 5990$ rpm.

Fig. 7. Dependence of the steady-state oxidation current i_a upon the square root of the rotation speed $\sqrt{\omega}$ [in: (rpm) $^{1/2}$] of the silver RDE for different electrode potentials E [mV vs. Ag/AgCl]: (1)260, (2)250, (3)230, (4)200, (5)180. Solution; 1 mol dm^{-3} KOH.

formed to answer these questions, we present below three typical examples which explain the results in terms of the relaxation of the oxidation current after the perturbation of the transport rate in solution.

The current-time curve shown in Fig. 9 was obtained after anodization of the silver disk electrode at constant potential $E = +260$ mV and $\omega = 0$ for 10 min until the nucleation and growth peak had been completed. This curve is a continuation of the curve 1 from Fig. 8. A very small response to the change of the hydrodynamic conditions is then observed (compare branch A obtained at $\omega = 0$ with branch B at $\omega = 5990$ rpm in Fig. 9), and the current returns to the previous value after stopping the disk rotation (branch C, $\bar{\omega} = 0$). However, a longer rotation at $\bar{\omega} = 5990$ rpm (branches D and E) causes a gradual increase in the oxidation current which finally approaches a steady-state level. If now the disk is stopped again, the current falls down, but the nucleation and growth process start again, leading to the transient similar to that presented in

Fig. 8. Typical chronoamperometric transients obtained on a stationary (1) and rotating (2) silver disk electrodes at $E = +260$ mV (vs. Ag/AgCl) in 1 mol dm^{-3} KOH solution. Curve 2: $\omega = 5990$ rpm. Current scale: right for curve 1, left for curve 2.

Fig. 9. The current-time transient obtained on a silver disk electrode after depositing of the Ag_2O film for $\tau_d = 600\text{s}$. The branches A-E of the transient correspond to the rotation speed of the disk ω : (A,C)0 and (B,D,E)5990 rpm. Solution: $1\text{ mol dm}^{-3}\text{ KOH}$; $E = +260\text{ mV}$ (vs. Ag/AgCl), $A = 0.192\text{ cm}^2$.

Fig. 10. The transients shown in Fig. 10 illustrate the short-term rotation-speed dependence of the oxidation current in different stages of the Ag_2O film growth. Approximately steady-state anodic current at $\omega = 5990\text{ rpm}$ is observed after about 2 min ($E = +260\text{ mV}$). At the point A, disk rotation was stopped. The $i - \omega$ relations at different times (points B through G) are represented by the arrow whose length is equal to the difference Δi between the current at $\omega = 5990\text{ rpm}$ (measured after 25s) and the current at $\omega = 0$. Each arrow represents a separate experiment because the disk rotation for 25s influences the nucleation and growth peak at $\omega = 0$, which becomes more expanded in time. As seen in Fig. 10, the dependence of the oxidation current upon ω vanishes gradually during the Ag_2O nucleation and growth process.

At the potential $E = +230\text{ mV}$, the nucleation and growth of the Ag_2O film is not observed, and adjustment of the anodic current after changing rotation speed of the disk electrode proceeds faster. This situation is illustrated in Fig. 11 and can be compared to those described above.

Discussion

The voltammetric characteristics of silver electrodes in alkaline solutions are influenced by many factors, of which the following seem to be the most important: (i) pretreatment of the electrode surface, (ii) roughness fac-

tor and surface structure, (iii) hydrodynamic conditions, (iv) solution impurities, (v) illumination, and (vi) electrode history (i.e., conditioning potentials, cycling, potential programs of previous experiments, etc.). Most of the present literature contradictions concerning silver oxidation can be explained when specific experimental conditions and procedures are taken into account.

The general oxidation path at the silver electrode in the potential range -300 through $+900\text{ mV}$ is shown in Fig. 1 (cycling between -650 and $+900\text{ mV}$). There are five anodic peaks, A_1 through A_5 . On the basis of our experiments, we list the conditions under which A_1 and A_2 peaks can be observed: unstirred solution, electrode roughened by strong oxidation and oxide stripping, solution not saturated with Ag(I) -hydroxy complexes. Similar peak structure has recently been reported by Droog *et al.* (8) and Teijelo *et al.* (except the feature A_5).

It is clear from our measurements (Fig. 2, 6) that the first two peaks A_1 and A_2 do not appear on the voltammogram for polycrystalline silver electrode conditioned for a long time or when the solution is stirred and is not saturated with Ag(I) . The surface restructuring processes are evidently involved in the conditioning step. The reconstruction of the surface monolayers and formation of the thermodynamically more stable atomic configurations with some preferential crystallographic orien-

Fig. 10. The short-term effect (marked by the length of arrows) of changing the rotation speed of the filmed silver disk electrode from 0 to 5990 rpm in different stages of the Ag_2O film growth. The current-time transients were obtained at $\omega = 5990\text{ rpm}$ (branch A) and 0 rpm (branch B). Each arrow represents a separate experiment in which the transient was interrupted at the time (marked by arrow) by turning the rotation on ($\omega = 5990\text{ rpm}$) and reading the value of current after 25s. $E = 260\text{ mV}$ (vs. Ag/AgCl), $A = 0.192\text{ cm}^2$.

Fig. 11. The current response on the change in the rotation speed of the filmed polycrystalline silver disk electrode at $E = 230$ mV (vs. Ag/AgCl) in 1 mol dm^{-3} KOH solution; ω [rpm]: (1) 10, (2) 5990, (3) 0, (4) 100, (5) 400, (6) 900, (7) 1600, (8) 2500, (9) 3600, (10) 4900, (11) 5990. Dashed curve: initial current-time transient at 5990 rpm (current scale $\times 2$).

tations on a polycrystalline material can be considered. Eventually, it may concern even a few monolayers. Note, that some authors (14, 17) identify the peak A_2 with the preferential oxidation of surface atoms of low coordination number. Also, in this case (Fig. 2, curve 1) the peak A_3 has a different shape than that seen in Fig. 1; it is sharp and much higher than the peak A_4 for the Ag_2O_2 nucleation and growth.

This indicates that Ag_2O nucleation process (A_3) is highly retarded on reconstructed surfaces and starts spontaneously when the solution becomes supersaturated at the electrode surface and the potential reaches sufficiently positive value. Before the first monolayer of Ag_2O film starts to grow, the reaction of silver dissolution according to Giles and Harrison (5) can be represented by the equation

assumed also by other authors (15).

The initial stage of Ag_2O formation proceeds via the net electrochemical reaction [5] which in our opinion is presumably composed from a few elementary steps

or by the precipitation mechanism which is generally accepted for thicker Ag_2O films (9, 15, 16, 21, 22). In the latter case the reactions that might be involved are the following

The subscript (i) was used at Ag_2O in the reaction Eq. [5]-[18] to denote differences between consecutive monolayers (at least between the first, adsorbed layer and the bulk Ag_2O layers). The complexes $\text{Ag}(\text{OH})_2^-$ and AgO^- are prevailing Ag(I) species in the solution (16, 32). The reaction Eq. [5] has been proposed for the formation of the adsorption Ag_2O film (5). For the next monolayers, the same equation can be used as a total reaction for the film growth, but it has been found on the basis of the RRDE experiments (15, 16), that the important step in the mechanism is precipitation of Ag_2O from the supersaturated solution via the nucleation and growth process. Dignam *et al.* (33) and other authors (9, 21, 34) pointed out the significance of the solid-state transport in the Ag_2O film formation.

Initial stages of silver oxidation.—Determination of the contributions of the initial silver-dissolution process and the Ag_2O adsorption reaction to the total current is difficult because no mechanistic studies have been performed which could give a better insight into the reactions involved.

Comparison of our LSV characteristics for the region of peak A_1 (Fig. 3 and 6) shows a significant influence of the dissolution processes at the RDE, where the effect of the increasing inversion potential E_i on the cathodic currents is not observed. The results of the LPSC measurements (Fig. 5) at a stationary electrode can be explained by loss of charge due to the dissolution at $E_i < 200$ mV.

On the basis of the RDE experiments (Fig. 7 and other data), we can calculate the surface concentration C_s of the Ag(I) species at different potentials using Levich Eq. [3]. For a reversible electroreduction of metallic silver, one can expect a linear relation $\log C_s$ vs. potential E with a slope $(\delta E / \delta \log C_s) = 59.16$ mV. However, in our case (Fig. 12), the slope is 73 mV at higher potentials and about 90 mV at lower potentials. The potential region where the slope 73 mV is observed corresponds to the region of the change in optical parameters ($\delta\Delta$) in the ellipsometric studies of Droog *et al.* (8) and can be associated with the influence of the adsorption process.

Effect of the solid-state transport and nucleation and growth phenomena on the potentiostatic transients under different hydrodynamic conditions.—At potentials $E > 250$ mV, the bulk Ag_2O is formed, however, the Ag(I) surface concentration C_s maintains the saturation value. The dependence of the steady-state oxidation currents vs. $\sqrt{\omega}$ is still similar to that represented by the curve for $E = 250$ mV, although adjustment of the film thickness during the change in the rotation speed takes place (Fig. 9-11). This fact seems to be a natural consequence of the interrelations between the varying rate of convective diffusion in the solution and the mass transport within the solid film. The electrical conductivity of Ag_2O is very low [$\sigma = 10^{-8}$ S/cm (33)], and, basically, one might assume a constant field approximation

$$E = -\frac{d\phi}{dx} = \text{const.} \quad [9]$$

for the potential distribution across the Ag_2O film, similarly to that, for example, for niobium oxide (35) or iron oxides (36). In consequence, adjustment of the film thickness to the changed hydrodynamic conditions would require in this case a change in the potential drop across the film. But, because of the observed constancy of $C_s = C_s^{\text{sat}}$

Fig. 12. Plot of the electrode potential vs. the logarithm of the surface Ag(I) concentration calculated from experimental steady-state oxidation currents using Levich Eq. [3]. Solution: 1 mol dm^{-3} KOH.

at varying ω (i.e., linearity of the Levich plot) under steady-state conditions, it seems that constant potential drop rather than constant field is maintained in the oxide film. Work is underway in our laboratory to address this question, using impedance measurements, and the results will be reported in the forthcoming publications.

Finally, we would like to emphasize one characteristic feature of the system behavior: the invariance of the LSV peak currents A_2 and A_3 with respect to the rotation speed ω as was reported by Tilak *et al.* (8) and Hampson *et al.* (17), as compared to the rotation speed dependence of the oxidation currents at constant potentials in the potential region of the LSV peak A_2 that is reported here (Fig. 8-11). A possible explanation of this fact is that in the LSV experiments ($v = \text{const.}$), the film thickness increases following the continuous changes in the electrode potential. In the case of the nucleation and growth, the current peak is determined by the increasing real surface area. An acceleration of the rotation speed causes a longer delay before the commencement of the nucleation and growth process, and this is manifested by a shift of the peak potential. The peak currents, however, remain undisturbed by the dissolution processes. The nucleation and growth peaks seen in Fig. 8 and 10 correspond probably to the same processes as those at the LSV peak A_3 because a further potential scan applied in the direction of positive potentials shows only peak A_4 (Ag_2O formation).

Conclusion

The steady-state oxidation currents measured on the polycrystalline silver RDE fulfill the limiting Levich equation, despite the fact that the electrode is covered by a thin Ag_2O film. When the hydrodynamic conditions are changed by the change of the rotation speed of the disk, the anodic current adjusts to the new value. The rate of this adjustment indicates that the solid-state transport processes and changes in the film thickness are involved. However, the final value of the current indicates that the saturation of the solution with respect to Ag(I) is maintained. A steady-state model of the metal/semiconductor electrode undergoing dissolution is thus proposed. In the case of thick Ag_2O films, the solid-state diffusion control of the anodic processes can occur. At the same constant electrode potential, thicker films are obtained under conditions of slower mass transport in the solution. This conclusion follows from the proposed model and is consistent with the experimental results.

The Ag_2O nucleation and growth peak has been observed in chronoamperometric transients above the potential of +240 mV (*vs.* Ag/AgCl). The height of this peak decreases as the convective diffusion is accelerated by the rotation speed of the RDE.

In case of the monolayer Ag_2O films, which can be obtained in the potential region of the first LSV peak (A_1), the surface concentration of Ag(I) in solution is lower than the equilibrium value corresponding to the reversible Ag/Ag(I) electrode, and the slope ($\delta E/\delta \log C_s$) is greater than 59.16 mV. The results of the LPSC measurements obtained on a stationary silver-disk electrode show a large unrecovered charge during the potential cycle (starting from the negative potential limit at the conditioning potential). The dependence of the peak currents A_1 and C_1 upon the potential scan rate is not linear. All these observations indicate a complex behavior of the system in the region of peak A_1 which cannot be simply described by the equilibrium silver dissolution with the formation of a reversible adsorption layer of Ag_2O .

Application of a Magnetohydrodynamic Generator-Detector Electrode to Hydrodynamic Voltammetry

Ryoichi Aogoki*

ABSTRACT

Utilizing a fluid motion induced by electromagnetic force, a new method of voltammetry under forced convection was developed. The electrolytic cell was composed of two pairs of electrodes, *viz.*, generator and detector pairs embedded on the bottom and top innerwalls of a rectangular channel. An intermediate produced on the surface of one of the first generator pair of the electrodes was swept downstream by the induced liquid flow to the neighboring electrode of the second detector pair and measured as a current. Examination of the mechanism between the induced flow of the electrolyte solution and the diffusion process of the intermediate permitted deriving the several expressions of electrolytic current for each pair of the electrodes as functions of bulk concentration of reacting species and externally applied magnetic field. It was also predicted that the detecting current interacts with the generating current, which can be depicted in terms of the collection efficiency of the intermediate. Observed results in experiments were in good agreement with these predictions.

It has been known that when a magnetic field is externally imposed on an electrolytic cell system, electromagnetic force is induced to move the solution and thus promotes the mass-transport process (1-4). Such a liquid motion becomes laminar flow in viscous or boundary layer mode for well-defined electrode cell geometry. The kinetics of the diffusion current in the viscous and boundary layer flows of electrolyte solution have already been established (5-7). The characteristics of the phenomenon are essentially attributable to the fact that the electrode itself acts as a kind of fluid pump. Thus, as a consequence of the coupling of electrolytic current and magnetic field, the electrolyte solution acquires fluid motion along the electrode surface. Therefore, in view of the application to studying the kinetics of electrochemical reactions, the electrode system has some advantages in contrast to other static electrode systems containing mechanical moving parts (8), *i.e.*, the cell dimension becomes stable and compact, and the whole system is easy to seal under arbitrary atmospheres. In this paper, we will aim at the application of this electrode system to voltammetry under forced convection, as represented by the rotating ring-disk electrode (RRDE), important for studying intermediates of electrode reactions.

The experimental setup of this magnetohydrodynamic generator-detector electrode system is two neighboring pairs of parallel electrodes; the first, a generator pair (one being a working electrode and the other its counterelectrode) yields intermediates and acts as a pump to carry the species downstream to the neighboring electrode, which is the working electrode of the second detector pair, capturing the intermediates in the form of electrolytic current.

In order to establish this method, it is important to know the mechanism between the generating and detecting currents and to obtain the expression for the collection efficiency of the detector electrode. We will, therefore, examine the behavior of the flowing of electrolyte solution induced by electromagnetic force, and then deduce the expressions of the diffusion currents at the generator and detector working electrodes as functions of the bulk concentration of reactants, the external magnetic flux density, and the collection efficiency. Finally, the predicted expressions are verified in experiments by comparing them with the observed results for the redox reaction in aqueous CuCl_2 solutions containing KCl as a supporting electrolyte.

Theoretical

Figure 1 shows the schematic configuration of the electrolytic cell used for this study. The cell is made of a relatively short channel with two open ends. Inside the channel, two pairs of electrodes are embedded in the top and bottom innerwalls; the first pair comprises the working and counterelectrodes to generate reaction intermediates, and the second pair is the working and counter-electrodes for detecting the intermediates. Each electrode of the same pair possesses equal area. Consequently, the electrolytic cell is characterized by the following five zones: the first zone is the inactive entrance section, $0 \leq x < x_1$; the second zone is the region of generator electrode pair, $x_1 \leq x < x_2$; the third zone is the inactive gap, $x_2 \leq x < x_3$; the fourth zone is the region of detector electrode pair, $x_3 \leq x < x_4$; and the fifth zone is the inactive exit section, $x_4 \leq x \leq l$. The reference electrodes, as mentioned in the

Fig. 1. Electrolysis cell. Magnetic flux density \vec{B} is applied vertically to the electrolytic currents, and the cell is placed horizontally in a large vessel. (a) Generating electrode section, (b) detecting electrode section, (c) Luggin capillary, and (d) streamline.

previous papers (5-7), are inserted into small holes drilled behind the working electrodes through conical Luggin capillaries so that the tips of the capillaries come to the levels of the electrode surfaces. The whole electrode cell is horizontally immersed in a large vessel ($25 \times 30 \times 5$ cm) filled with an electrolyte solution. When a dc current flows between the first generator electrode pair in the y -direction, the motion of the electrolyte solution is produced in the channel in the x -direction due to the electromagnetic force. Simultaneously, the reaction intermediate formed at the generator working electrode is conveyed downstream to the neighboring detector working electrode for measurement. As a result of the fluid motion, friction exerted over the whole channel walls by the liquid entering the channel gives rise to hydrodynamic boundary layers which develop with the distance from the inlet section. With assumptions of small channel length and/or comparatively large Reynolds number ($\gg 1$) referring to the channel width, the boundary layers do not fully develop. Thus, the fluid motion consists of two types of flows, *viz.*, main and thin boundary layer flows (14). Within the layer, another type of thin diffusion layer is occurring as a consequence of the mass transfer of active ionic species accompanying the electrode reactions. This was actually observed by means of laser interferometry (9). Figure 2 schematically illustrates the characteristics of the relation mentioned above.

The main flow part of the electrolyte solution is regarded as nonviscous and incompressible. It is essentially the same as in the previous paper (5); the main flow velocity, U , in the channel is given by

$$U = \sqrt{\frac{2\gamma B(I_g + I_d)}{\rho w}} \quad [1]$$

where γ is the cell constant of value nearly equal to unity (5), I_g is total generating current, I_d is total detecting current, w is the electrode width, B is the magnetic flux density, and ρ is the fluid density.

Then, the x and y components of the velocity in the boundary layer can be expressed as (6)

$$v_x = \frac{1.33}{4} \frac{U^{3/2}}{\nu^{1/2} x^{3/2}} y \quad [2]$$

and

$$v_y = \frac{1.33}{16} \frac{U^{3/2}}{\nu^{1/2} x^{3/2}} y^2 \quad [3]$$

where ν is the kinematic viscosity.

Diffusion current for active species reacting on the generator working electrode.—As the electrolytic current flows between the working and counter-electrodes of the generator section, the intermediate is formed on the surface of the generator working electrode following an electrode reaction represented by

where S_1 and S_2 are the species participating in the electrode reaction and n_1 is the number of electrons exchanged in the reaction. The transport of the active species will take place through the diffusion layer, which is due to the motion of the species entrained by the fluid motion induced by the electromagnetic force and to the diffusion of the species resulting from the concentration gradient, since any migration contribution is negligible owing to a large excess of an inert electrolyte. The diffusional equation for convective diffusion of species S_1 in steady state is simplified in consideration of sufficiently small thickness of the diffusion layer compared with the representative length of the electrode, *i.e.*, channel width (6). Subsequently, the equation is written as

$$v_x \frac{\partial C}{\partial x} + v_y \frac{\partial C}{\partial y} = D_1 \frac{\partial^2 C}{\partial y^2} \quad [5]$$

The diffusion problem for the species S_1 at the generator working electrode ($x_1 \leq x \leq x_2$) is solved with the following boundary conditions; (i) $C_1 = C_1^s$ (surface concentration) at $y = 0$, and (ii) $C_1 = C_1^0$ (bulk concentration) as $y \rightarrow \infty$.

The total generating current I_g solved in the same manner as before (6), is expressed as

$$I_g = 0.68 n_1 F D_1 (C_1^0 - C_1^s) \left(\frac{\nu}{D_1}\right)^{1/3} \left(\frac{U}{\nu}\right)^{1/2} (\sqrt{x_2} - \sqrt{x_1}) w \quad [6]$$

where D_1 is the diffusion coefficient of S_1 .

Detecting current and collection efficiency.—The intermediate S_2 formed on the surface of the generator working electrode is carried downstream to the neighboring detector working electrode surface by the resulting fluid flow. The reaction product S_2 is afterwards reduced or oxidized at the detector electrode section, yielding the species S_3 according to the reaction

where n_2 is the number of the electrons participating in the reaction. In the case when the intermediate S_2 can be regarded stable enough not to be decomposed on the way

Fig. 2. Schematic profile of the cell and the solution flow. (A) Luggin capillary, (B) generating electrode, (C) detecting electrode, (D) diffusion layer formed at the generating pair of electrodes, (E) diffusion layer at the detecting pair of electrodes, (F) hydrodynamic boundary layer, (G) streamline, (I_g) generating current, (I_d) detecting current, and (B) magnetic flux density.

to the detector working electrode, it can be collected with a certain collection efficiency as will be mentioned later. The collection efficiency is defined according to Matsuda (13) as the absolute ratio of the total generating current to the total detecting current, N

$$N = \left| \frac{I_d}{I_g(\text{DE on})} \right| \quad [8]$$

or as the absolute ratio of the mass flux at the generator working electrode to the amount reaching the detector working electrode, N' , as follows (16)

$$N' = \left| \frac{J_d}{J_g(\text{DE on})} \right| \quad [9]$$

where $I_g(\text{DE on})$ and $J_g(\text{DE on})$ denote the total generating current and mass flux of S_1 , respectively, when the detector electrode pair is employed, and I_d and J_d are the total detecting current and mass flux of S_2 , respectively. N and N' have a relation of $N = (n_2/n_1)N'$, where N' should be a function of only electrode geometry in consideration of the equation, Eq. [10] below.

For the double-channel electrode comprising two neighboring rectangular electrodes, the diffusion problem of the intermediate S_2 with a half-life long enough for it to be carried by the liquid flow to the detector working electrode surface is solved from Eq. [5] with the following boundary conditions; (i) the amount of the product S_2 leaving from the surface of the generator working electrode per unit time is equal to that of the species S_1 entering from the bulk per unit time, i.e., $D_2(\partial C_2/\partial y)_{y=0} = -D_1(\partial C_1/\partial y)_{y=0}$ for $x_1 \leq x < x_2$. (ii) The product S_2 does not react at the inactive gap, $D_2(\partial C_2/\partial y)_{y=0} = 0$ for $x_2 \leq x < x_3$. (iii) S_2 is detected as a limiting current at the detector working electrode, $C_2 = 0$ at $y = 0$ for $x_3 \leq x < x_4$. (iv) S_2 does not exist in the bulk of the solution, i.e., $C_2 \rightarrow 0$ as $y \rightarrow \infty$ for all zones.

These boundary conditions correspond to those already treated for geometric systems such as a rotating ring-disk electrode (12). According to Matsuda (13), the collection efficiency expression for the two neighboring plane electrodes exposed to the solution flow with two-dimensional boundary layer and the conditions mentioned above is

$$N = \frac{n_2}{n_1} \left\{ \left(\frac{x_4^{3/4} - x_3^{3/4}}{x_2^{3/4} - x_1^{3/4}} \right)^{2/3} G \left(\frac{x_2^{3/4} - x_1^{3/4}}{x_3^{3/4} - x_2^{3/4}} \right) + G \left(\frac{x_3^{3/4} - x_2^{3/4}}{x_4^{3/4} - x_3^{3/4}} \right) - \left(\frac{x_4^{3/4} - x_1^{3/4}}{x_2^{3/4} - x_1^{3/4}} \right)^{2/3} G \left(\frac{x_2^{3/4} - x_1^{3/4}}{x_4^{3/4} - x_1^{3/4}} \cdot \frac{x_4^{3/4} - x_3^{3/4}}{x_3^{3/4} - x_2^{3/4}} \right) \right\} \quad [10]$$

where

$$G(\theta) = \frac{\sqrt{3}}{4\pi} \ln \left\{ \frac{(1 + \theta^{1/3})^3}{1 + \theta} \right\} + \frac{3}{2\pi} \arctan \left(\frac{2\theta^{1/3} - 1}{\sqrt{3}} \right) + \frac{1}{4} \quad [11]$$

Interference effect and diffusion currents.—The total diffusion currents, I_g and I_d , in Eq. [6] and [8] are identified with the electrolytic currents coupled with the external magnetic field in Eq. [1]. Therefore, the following two experimental conditions are considered.

1. The case when the detecting current does not flow ($I_d = 0$).

This situation is furthermore divided into two cases; the first is that no intermediate collected by the detector working electrode is formed at the generator working electrode, and the second is that from the beginning, the detector electrode pair is not employed. In these cases, the usual diffusional generating current flows at the generator section according to the equation in the previous report (6). Namely, in view of $I_d = 0$, elimination of the main flow velocity from Eq. [1] and [6] leads to the following equation

$$I_g(\text{DE off}) = H(C_1^0 - C_1^s)^{4/3} B^{1/3} \quad [12]$$

where

$$H = 0.753(n_1 F D_1)^{4/3} (\nu/D_1)^{4/9} \nu^{-2/3} \rho^{-1/3} \gamma^{1/3} \omega (\sqrt{x_2} - \sqrt{x_1})^{4/3} \quad [13]$$

2. The case when the detecting current flows ($I_d \neq 0$).

When an intermediate is formed on the generator working electrode surface, it diffuses into the solution to be carried downstream by convection to the detector working electrode. At the electrode surface, the species reacts immediately, and, simultaneously, a detecting current flows between the working and counterelectrodes of detector section. Since both generating and detecting currents participate in the formation of the electromagnetical force inducing fluid motion, they become dependent on each other, and are obtained by eliminating the variable, U , from Eq. [1], [6], and [8]

$$I_g(\text{DE on}) = (1 - N)^{1/3} H(C_1^0 - C_1^s)^{4/3} B^{1/3} \quad [14]$$

$$I_d = -N(1 - N)^{1/3} H(C_1^0 - C_1^s)^{4/3} B^{1/3} \quad [15]$$

where the sign of the current is determined according to the direction of the electrolytic current. Consequently, the generating current $I_g(\text{DE on})$ is influenced by the detecting current, decreasing in comparison with $I_g(\text{DE off})$ in the case of $I_d \neq 0$. Such an interference effect is introduced through the collection efficiency of the intermediate, N . The electromagnetical forces induced by $I_g(\text{DE on})$ and I_d are opposite in sign, so that the blocking effect of I_d on fluid flow increases with increasing N , which implies that the large value of N is not applicable to actual systems because the fluid motion slows down with increasing N . In the extreme case, viz., $N = 1.0$, as derived from Eq. [14] and [15], $I_g(\text{DE on})$ and I_d become zero since the fluid is prevented from flowing by the two electromagnetical forces which are equal in quantity but opposite in sign; thus, the thickness of the diffusion layer increases toward infinity.

Experimental

Theoretical Eq. [12], [14], and [15] were experimentally examined by measuring the relation of the limiting diffusion current corresponding to $C_1^s = 0$ against the concentration of active species in the bulk of the solution and the externally applied magnetic field. Moreover, the collection efficiencies observed for the electrode cells with several dimensions were compared with the values calculated by the theoretical equations, Eq. [10] and [11]. The detailed dimensions of the cells are described in Table I.

The working electrodes for generation and detection were made of Pt sheets and each counterelectrode was a copper sheet with the same area as its corresponding working electrode. The solutions used in the experiments were aqueous CuCl_2 solutions containing 1M KCl which is one of the conventional electrolyte systems to measure the collection efficiency of RRDE (12). Figure 3 represents the current-potential curves for the cell 4 in which cupric ion was reduced under a uniform magnetic flux density of 0.6 Wbm^{-2} , and SCE was used as a reference electrode. When increasing potential was at first applied to the generator working electrode, the reduction, $\text{Cu}^{2+} + e \rightarrow \text{Cu}^+$, started on the surface and at the same time, the generating current $I_g(\text{DE off})$, when the detector electrode pair was not employed, began to flow between the working and counterelectrodes of the generator pair. As soon as the detecting electrodes were switched on, the detecting current, I_d , began to flow in the opposite direction of I_g , corresponding to the oxidation, $\text{Cu}^+ \rightarrow \text{Cu}^{2+} + e$. As a result, the generating current $I_g(\text{DE on})$ in the case of $I_d \neq 0$ decreased in contrast to the initial value, $I_g(\text{DE off})$ by the interaction of I_d . Therefore, in this area, three different curves emerged.

Further, as the potential was increased, eventually copper metal deposition, $\text{Cu}^{2+} + 2e \rightarrow \text{Cu}$, took place and the generating current rose on the second wave, as shown in Fig. 3. In this region, since the reaction product was deposited as an insoluble substance, the detecting current

channel width, $w = 1.0 \times 10^{-2}$ m

ceased. Thus, the generating current was no longer affected and $I_g(\text{DE on})$ was the same as $I_g(\text{DE off})$, the separated curves becoming one. In addition, referring to the reactions occurring in the two regions, the ratio of the second limiting value of $I_g(\text{DE off})$ to the first current value of $I_g(\text{DE off})$ was $32 \text{ mA}/89 \text{ mA} = 0.36$, which is caused by the change of electrons transferred from 1 to 2. This is nearly equal to the value, $1/2^{4/3} = 0.4$, theoretically predicted. The usual RRDE method gives the theoretical ratio, $1/2 = 0.5$ to this CuCl_2 system. The experimental data by Nekrasov and Berezina (15) give it as $46 \mu\text{A}/102 \mu\text{A} = 0.44$.

Then, the experiments to measure the three total limiting currents, $I_g(\text{DE off})$, $I_g(\text{DE on})$, and I_d were carried out with the cell 3. Each observed value is plotted in Fig. 4 against various magnetic flux densities in an aqueous $7.14 \times 10^{-2} \text{ M}$ CuCl_2 - 1 M KCl solution. The plot of each current vs. the $1/3$ -power of magnetic flux density follows a good straight line. Figure 5 shows the results obtained by observing I_d against various concentrations of CuCl_2 in the bulk at a fixed magnetic flux density. Good linearity can be seen between the current and the $4/3$ -power of the concentration.

Finally, the dependence of the collection efficiency N for the cell dimensions listed in Table I was investigated. The experimental data of N were then compared with the

Table II. Collection efficiency of detecting electrode (N_{obs} : observed value, N_{pred} : theoretical prediction)

Cell no.	N_{obs}	N_{pred}
1	0.185	0.184
2	0.261	0.263
3	0.309	0.302
4	0.395	0.368

calculations as shown in Table II. For cells 1-4, the observed and theoretical values of the collection efficiency fall, except for cell 4, within a limiting error of about 2%: cell 1, $N_{\text{obs}} = 0.185$ and $N_{\text{pred}} = 0.184$; cell 2, $N_{\text{obs}} = 0.261$ and $N_{\text{pred}} = 0.263$; and cell 3, $N_{\text{obs}} = 0.309$ and $N_{\text{pred}} = 0.302$, where N_{obs} and N_{pred} are the observed and predicted collection efficiencies, respectively. The disagreement between the evaluated and measured values, that is, the evaluated value 0.368 and the observed value 0.395, for cell 4 may be because the relatively long channel, in comparison with the other cells makes the flow mode more viscous-like (7).

The interference effect between the generating and detecting currents is illustrated in Fig. 6. In the figure, solid lines indicate the theoretical results deduced from Eq. [14] and [15], and circles are experimentally observed data; here $I_g(\text{DE on})$ and I_d are divided by $I_g(\text{DE off})$ for normalization. Observed values are in good agreement with the theoretical curve. However, the whole range of the collection efficiency theoretically predicted cannot be realized in the actual situations. For the range nearly equal to 1.0, it is difficult to carry out the experiments. In the extreme case of $N = 1.0$, where $I_g(\text{DE on})$ and I_d have the same magnitude and opposite signs in direction, the net flow of the solution falls to zero, and this device be-

comes useless for studying electrode kinetics. In most cases of RRDE geometry, efficiencies ranging from about 0.2 to 0.4 are employed (17). For this electrode system, the same range of the efficiency is also available for operation.

Discussion

The strength of the magnetic field we used was unfortunately not high enough to have the flow velocity induced by the electromagnetical force very high. The magnitude of the main flow velocity can be easily estimated by Eq. [1], i.e., $U \sim \sqrt{2\gamma B I_d / \rho w}$. Using the data, $\gamma \sim 1$, $B \sim 0.5 \text{ Wbm}^{-2}$, $I_d \sim 10^{-2} \text{ A}$, $\rho \sim 10^3 \text{ kg m}^{-3}$, and $w \sim 10^{-2} \text{ m}$, we can obtain $U \sim 3 \times 10^{-2} \text{ ms}^{-1}$. Thus, the Reynolds number in this case becomes $\text{Re} = Uw/\nu \sim 3 \times 10^2$. Therefore, the induced flow is concluded to be laminar, not turbulent. The sensitivity to detect unstable intermediates is chiefly limited by the main flow velocity. But, in the case of rectangular electrode, it is comparatively easy to make the gap between the generator and detector electrode sections quite narrow up to the order of magnitude of 10^{-4} m . The time for the intermediates to reach the detector working electrode from the generator working electrode is estimated as about $10^{-4} \text{ m} / 10^{-2} \text{ ms}^{-1} = 10^{-2} \text{ s}$. Hence, we can approximately say that the species of which lifetime is up to 10 ms can be detectable under usual laboratory conditions. This situation can be improved if we use a stronger magnet such as a superconducting magnet with a magnetic flux density of the order of 10 Wb m^{-2} . Species having a lifetime up to 0.1 ms will then be detectable. Such a strong magnet will also make available a much wider range of flow velocities for this device.

Another limitation may exist in the approximate nature of the fluid flow, which is based on the built-in assumptions, not only that the current distributions are uniform on both the generator and detector electrodes but also that the externally applied magnetic field is homogeneous in the whole region of the electrodes. Such uniformities may not be completely realized since the edge effect of electrolytic current at the ends of electrode cannot be neglected. However, this difficulty can be modified by introducing the cell constant γ as shown in Eq. [1], which can be easily obtained according to the experimental procedures in the preceding papers (5, 6). The introduction of γ gives satisfactory results supported by the good agreement between the observed and predicted values of the collection efficiency in Table II.

The relative advantages of this method may be stressed in the following; there is no mechanical moving part so that the cell dimension is stable and compact, and the whole cell system can be completely sealed under arbitrary atmospheres. This suggests that some troubles associated with nonaqueous or fused salt systems will be reduced. In addition, one should bear in mind that the range of application of this device can be extended not

only to boundary layer flow discussed in this paper, but also to other flow modes like viscous flow. This fact seems to indicate the possibility of the application to quite small electrode geometries. The multiple possibilities concerning practical applications are likely to bring bright prospects to this kind of voltammetry. From another point of view, this system may be the most useful when the effect of magnetic field on electrochemical reactions is investigated.

Photointercalation and Photodeposition of Copper in P-Type Lamellar InSe

C. Levy-Clement* and B. Theys

Laboratoire de Physique des Solides, CNRS, 92195 Meudon France

ABSTRACT

We report here, as an example of actual photointercalation, the light-induced intercalation of copper into p-type InSe from an organic medium ($\text{CH}_3\text{CN} + 0.1\text{M TBA-BF}_4 + 0.1\text{M CuCl}$). The two types of InSe electrodes used had their exposed surfaces parallel or perpendicular to the cleavage surface [(001) plane]. From the photovoltages, short-circuit currents, current *vs.* potential characteristics, photocurrent spectra, and SIMS measurements, it is shown that metallic copper is photoelectrodeposited on the cleavage surface whereas copper is photointercalated when the surface perpendicular to the cleavage face is in contact with the electrolyte. Deintercalation of copper does not take place spontaneously in the dark.

One of many photoelectrochemical effects that can occur at the semiconductor-electrolyte interface (1) is photointercalation. This effect has been theoretically predicted (2), but no experimental evidence has been published. In a classical semiconductor-liquid Schottky barrier, photogenerated minority carriers are ejected from the semiconductor to the electrolyte where they react with the redox system in solution. Majority carriers flow through the semiconductor and the external load to the counterelectrode. In a p-type photocathode whose crystal structure allows the insertion of guest atoms, oxidized species of the redox couple may penetrate into the semiconductor and trap *in situ* the photogenerated electrons, while holes flow to the counterelectrode. This process, is known as photointercalation. Lamellar compounds are very suitable materials, because of the existence of weak Van der Waals bonds between some adjacent planes. The layers are easily separated and a variety of atoms or organic molecules can be intercalated into the Van der Waals gaps (3). This process will occur spontaneously when thermodynamically favorable. When the intercalated species is a cation (M^+) and an electron is provided by the lamellar compound (Lc) the following reaction may proceed: $x\text{M}^+ + xe^- + \text{Lc} \rightarrow (\text{M})_x\text{Lc}$. When the lamellar compound is a metal or an n-type semiconductor the electrons can be introduced electrochemically (4-5) (Fig. 1a). Such a reaction cannot proceed in a p-type semiconductor in the dark because of the lack of electrons. The electrons can however be photogenerated (Fig. 1b).

For photointercalation to take place, one must find a suitable semiconductor plus cation pair. The p-type semiconductor must meet following conditions: (i) adequate carrier mobility, (ii) favorable thermodynamics for reaction of the reduced species with the lattice, (iii) fast diffusion of the reduced species in the lattice, (iv) stability against corrosion and photocorrosion, and (v) the redox potential of the intercalated cation must be located inside the bandgap of the semiconductor.

Indium selenide InSe is a III-VI lamellar semiconductor which meets the criteria for photointercalation. Depending on the growth conditions and on doping, this material exhibits n or p-type behavior (6). From a preliminary photoelectrochemical study of InSe in aqueous electrolytes, the position of the bandedges was estimated as -0.45V vs. NHE for the conduction band and as $+0.75\text{V vs. NHE}$ for the valence band (7-9). Copper (I) with a

Cu^+/Cu^0 redox potential at -0.38V vs. NHE in acetonitrile (10) is very suitable for intercalation. One can also easily see when it is reduced to red metallic copper (0). InSe has two crystalline surfaces exhibiting very different physical properties. One, the cleavage surface perpendicular to the \vec{c} axis, consists of selenium atoms bonded together with covalent forces. The other surface, parallel to the \vec{c} axis, is made of selenium and indium atoms, the selenium atoms of adjacent layers being bonded by Van der Waals forces (Fig. 2).

We report an example of demonstrated photointercalation, the light-induced topotactic reaction with p-type InSe and show how the structure of the surface in contact with the electrolyte plays a major role in this effect.

Experimental

Preparation of the electrodes.—p-type InSe single crystal was grown by the Bridgman-Stockbarger method (6) and has 500 ppm zinc doping. In the direction perpendicular to the \vec{c} axis, the bulk resistivity was $240 \Omega\text{-cm}$ and the mobility $40 \text{ cm}^2\text{v}^{-1}\text{s}^{-1}$. The number of carriers was $6.8 \cdot 10^{14}\text{cm}^{-3}$, assuming a one carrier model. Two types of

Fig. 2. Crystal structure of a polytype for InSe (a) packing of the layers, (b) perspective view, the unit cell extends over three layers.

crystalline surfaces were used. Crystals were cleaved perpendicular to the *c* axis or carefully cut parallel to the *c* axis. The electrode was named \perp electrode when the cleavage surface was exposed to the solution and \parallel electrode when the surface parallel to the *c* axis was exposed. The two surfaces were used without pretreatment. Optical properties of InSe are well known (11). In the direction \perp to the *c* axis there is an indirect gap of 1.187 eV and a direct gap, weakly allowed by spin-orbit coupling in the valence band, at 1.352 eV. In the direction \parallel to the *c* axis there is only the direct transition gap. Ohmic contacts at the back of crystals were made with conductive silver paint. Crystals were encapsulated in resin (Epoxy-patch, the Dexter Corporation) with only the chosen surface left exposed to the electrolyte.

Choice of the electrolyte.—The redox couple Cu^+/Cu^0 is not stable in noncomplexing aqueous solutions; therefore an organic electrolyte was used. The electrolyte was highly pure and dry acetonitrile in which 0.1M tetrabutylammonium tetrafluoroborate (TBA- BF_4 , Sigman Chemical Company) supporting electrolyte was dissolved with 0.1M CuCl (Johnson Matthey). TBA- BF_4 and CuCl were dehydrated under a 10^{-6} torr vacuum at 150° and 110°C, respectively, for 24 hr. The electrolyte was kept out of the light to avoid the photo-oxidation of copper (I).

Measurements.—A special cell was built with a Pyrex optical flat window and three watertight passages. A three electrode system was used. The counterelectrode was a copper wire and the reference electrode was Ag/0.1M AgNO_3 (dissolved in CH_3CN). Details of the photovoltage, short-circuit current, current/voltage characteristics [I-V] in the dark and under illumination, photocurrent spectroscopy measurements and the electronic equipment have been reported previously (12). The electrode was illuminated by a 6.5 mW 632.8 nm helium neon laser, or by a 250-W tungsten-iodine lamp; white light and laser light had comparable incident intensities in milliwatts per square centimeter. Either direct or chopped white light or monochromatic chopped light was used.

Results

The redox system.—The oxidation-reduction potentials of Cu^+/Cu^0 and $\text{Cu}^{2+}/\text{Cu}^+$ in $\text{CH}_3\text{CN} + 0.1\text{M TBA-BF}_4$ electrolyte were deduced from the cyclic voltammetric characteristics, obtained using two platinum electrodes. In Fig. 3 two oxidation-reduction waves are visible. The reduction of Cu^+ starts at -290 mV vs. Ag/AgNO₃ and the oxidation of Cu^0 takes place at $+600$ mV. The large peak that appears when the potential is scanned negative to positive corresponds to the oxidation of metallic Cu^0 deposited on the surface of the platinum cathode.

Fig. 3. Voltammetric behavior at Pt electrodes of CuCl in CH_3CN containing 0.1M TBA- BF_4 .

Photoelectrochemical experiments are done with either a \perp or \parallel electrode in contact with the electrolyte containing Cu^+ .

Behavior of the \perp electrode.—Figure 4 shows the variation of the open-circuit voltage of the \perp InSe photocathode vs. the reference electrode. In the dark the open-circuit voltage is -210 mV. Under the laser illumination it increases promptly to $+180$ mV and reaches $+250$ mV after 1 min. When the illumination is discontinued the open-circuit voltage drops rapidly to $+70$ mV, then slowly over a period of 20 min, to the initial value of -220 mV. Similar results are obtained under white light illumination. The very long period necessary for the open-circuit voltage to reach back the initial value is an indication of an important modification of the InSe surface under illumination. Further information will be obtained under short-circuit conditions.

Figure 5 shows the variation of the short-circuit current between \perp InSe and the counterelectrode in the dark and under the laser illumination. The current equals $0.1 \mu\text{A}/\text{cm}^2$ in the dark. Under the laser illumination, the current rises rapidly to $4 \text{ mA}/\text{cm}^2$ then starts to decline. When the illumination is discontinued, the current drops instantaneously to the background level. After a 5 min illumination the photocurrent drops to a quarter of the initial value and a copper spot, the shape of the laser illuminated area, appears. When the entire surface is illuminated with the white light the photocathode is completely

Fig. 4. Variation of the open-circuit voltage of \perp InSe cathode vs. the Ag/Ag⁺ reference electrode in the electrolyte. ----- In the dark, — under He-Ne laser illumination.

covered with a metallic layer of copper. The very fast variation of the current between dark and light conditions shows that the photoelectrochemical effect at the semiconductor/electrolyte interface (photoelectrodeposition of copper 0) occurs with, or stops instantaneously without, the light.

Figure 6 shows the I-V characteristics. In the dark \perp InSe shows the expected p-type diode behavior (curve a). Under white light illumination a cathodic photocurrent appears, corresponding to the reduction of the copper (I). A residual photocurrent of 0.05 mA/cm^2 maintained under anodic polarization up to 1V is due to the presence of an InSe/Cu⁰ Schottky junction formed by the photodeposition of the metallic copper (curve b). When a +0.7V bias is applied for 5 min, the copper deposited at the surface of the photocathode is oxidized; as it is dissolved, a thin yellow film appears at the surface and the residual photocurrent disappears.

Figure 7 shows the photocurrent spectrum of the \perp InSe electrode with the copper deposited at the surface after 10 min white light illumination at -1V vs. Ag/Ag^+ . The photoresponse is in agreement with the photocurrent spectrum of p-type InSe in contact with aqueous solutions (7).

Behavior of the // electrode.—Figure 8 shows in the dark and under the laser illumination the variation of the open-circuit voltage of the // InSe photocathode vs. the reference electrode. In the dark the open-circuit voltage equals -305 mV and under the laser illumination it increases to -200 mV in 30s. Three minutes later it reaches an equilibrium value of -100 mV . When the illumination is discontinued, the open-circuit voltage declines slowly

Fig. 6. Current voltage characteristics of \perp InSe electrode in the electrolyte. ----- Curve a in the dark, — curve b under direct white light. Light source, 250W tungsten-iodine.

Fig. 7. Photocurrent spectrum of \perp InSe electrode, in the electrolyte at $-1\text{V vs. Ag/0.1 AgNO}_3$.

and regularly over a period of 2 min to the initial value. Identical results are obtained under white light illumination and the value of the photovoltage is the same. When the experiment is repeated, the photovoltage value decreases, and, on successive trials, the photovoltage continues to decrease.

Figure 9 shows the variation of the short-circuit current between InSe and the counterelectrode in the dark and under the laser illumination. The dark current is $1.7 \mu\text{A/cm}^2$. Under the laser illumination it increases slowly and regularly; it takes 4 min to reach the steady-state value at $90 \mu\text{A/cm}^2$. The value of the photocurrent stays stable for at least half an hour. When the illumination is discontinued, the intensity of the current decreases regularly and after 2 min is back to its initial value. The same steady-state value for the photocurrent is obtained under direct white light illumination. Even after a 2h illumination period, no metallic copper was visible at the surface of the photocathode. The shapes of the photopotential and the short-circuit photocurrent vs. time curves are an indication that the effect occurring at the semiconductor-

Fig. 9. Variation with time of the short-circuit current between // InSe electrode and the counterelectrode in the electrolyte. ----- In the dark, — under He-Ne laser illumination.

electrolyte interface is diffusive in nature. The intercalation effect is such an effect. We believe that under short-circuit conditions, the intercalation of copper (I) is photoinduced.

Figure 10 shows the current/voltage characteristics using the three electrode system. After a previous white light illumination under short-circuit conditions for 10 min, InSe no longer shows p-type diode behavior in the dark (curve a). Strong hysteresis of the curve depending on the scan direction is observed. Under direct white light illumination both anodic and cathodic photocurrent are observable (curve b). This effect is more readily visible on curve c where the photocurrent is measured with a lock-in amplifier, the white light being chopped, after a 3h white light illumination period, under a $-0.7V$ bias. Both dark current and photocurrent curves indicate that the \parallel electrode InSe is no longer a simple p-type semiconductor but has now n and p domains, coexisting on the same surface. A similar coexistence has been reported for the tungsten diselenide photoelectrode (13). The intercalation of copper is believed to be responsible for the appearance of the n-type domains.

Figure 11 shows the photocurrent spectra of the \parallel InSe electrode. Curve (a) corresponds to the beginning of the photointercalation when InSe is biased at $-1V$ vs. $Ag/AgNO_3$. Spectrum (b) also obtained with a $-1V$ bias applied to this InSe electrode (but after a previous 3h white light illumination period at a $-1V$ bias) corresponds to an advanced step of the photointercalation. Curve b indicates that the intercalated copper introduces recombination centers in the semiconductor. From the fact that the maximum of the photocurrent spectrum is at 1030 nm, one can deduce that less copper is intercalated in the bulk than near the surface of the semiconductor.

Figure 12 shows the concentration profile of copper in InSe after a 20h white light illumination period at a $0.15V$ vs. Ag/Ag^+ bias. The measurement was made with an IMS 300 CAMECA measuring the $126Cu_2^+$ and the $78Se^+$ peaks. The copper was detected to a depth of $55\mu m$.

Discussion

The results reveal drastically different photoelectrochemical behavior for the \perp face and the \parallel face of InSe in contact with the organic electrolyte. Previously we have shown that in $0.1M H_2SO_4$ the photopotentials of \perp and \parallel electrodes are limited to 280 and 230 mV, respectively, by the presence of states which pin the surface Fermi level. These values decrease by less than 50 mV when the pH is increased from 1 to 12 (14). In acetonitrile, the photopotential of the \perp electrode is no longer limited by surface states and a photopotential of 450 mV is developed. Such

Fig. 10. I-V curve of \parallel InSe in the electrolyte. Curves a and b after a 10 min white light illumination under short-circuit conditions. ----- In the dark, — under direct white light. — Curve c under white chopped illumination and after a 3h white light illumination period at $0.7V$.

Fig. 11. Photocurrent intercalation spectra of \parallel InSe electrode, in contact with the electrolyte at $-1V$ vs. $Ag/0.1M AgNO_3$. a high photopotential, however, cannot be reached even in acetonitrile with the \parallel electrode.

Under illumination, metallic copper is electrodeposited at the \perp surface whereas it is intercalated in the \parallel electrode. In both cases photogenerated electrons reduce the Cu^+ at the surfaces of the electrodes. Because intercalation of Cu^+ in InSe is a thermodynamically downhill process, less energy is needed to intercalate the metal than to deposit it at the surface. Since Cu^+ (or Cu^{2+}) cannot diffuse in a direction perpendicular to the Van der Waals plane, intercalation can physically take place only when the Van der Waals gaps are in contact with the electrolyte. Because the potential for intercalation is less negative than the potential for electrodeposition, no electrodeposition takes place as long as copper is being intercalated. Indeed, at the \parallel electrode, intercalation of copper occurs spontaneously under short-circuit condition. After a half-hour illumination period, the $90\mu A/cm^2$ maximum photocurrent starts to decrease and, after 20h, it drops to half of its initial value. At the \perp electrode where intercalation cannot take place even under illumination, Cu^+ is simply photodeposited on the surface. After 5 min illumination at short circuit, a metal (Cu^+)-semiconductor (p-type InSe) Schottky junction is formed. Figure 6 shows the I-V characteristics of this Schottky junction when immersed in the organic electrolyte. The small photocurrent that persists under anodic polarization is the leakage current across the Schottky barrier.

Both dark and light I-V characteristics of the \parallel electrode indicate that, upon photointercalation of copper, the p-InSe acquires n-type regions, with both n- and p-type regions coexisting on the same surface.

The observed decrease in photocurrent with time is due both to photodeposition and photointercalation of copper. Photodeposited copper absorbs the light and, as its thickness grows, the photocurrent declines. Photointerca-

Fig. 12. SIMS measurement. Concentration profile of copper in \parallel InSe electrode after a previous 20h white light illumination period at $-0.15V$ bias in the electrolyte.

lation of copper in InSe does not prevent photons from being absorbed but introduces electron-hole recombination centers. These also cause the photocurrent to decline.

Copper photodeposited at the surface of the cleavage face can be anodically oxidized at +1V vs. Ag/Ag⁺, becoming a thin yellow film visible at the surface of the electrode.

Intercalation is a reversible reaction. From the theoretical study (2) it has been predicted that if intercalation of cations occurs by photoelectrochemical process, the deintercalation of these cations should take place spontaneously in the dark, while electrons flow to the counterelectrode, giving an external current of direction inverse to the one observed during photointercalation. Such a behavior is not observed in Fig. 9. We conclude that in our experiment the deintercalation of copper does not take place spontaneously in the dark.

In a classical lithium layered chalcogenide cell the host material is deintercalated upon charging the cell, *i.e.*, by driving electrons from the host to the metal electrode where lithium is electroplated. Similar deintercalation should be observed in InSe/Cu when an anodic bias is applied. Our results do not allow us, however, to conclude at this time that under anodic polarization copper is indeed deintercalated. More experiments have to be done in this direction with new p-type semiconductors, considering the important implication of the deintercalation process for *in situ* energy storage.

Conclusion

Evidence for the photointercalation of a metal into a layered semiconductor is presented. Under illumination copper is intercalated into p-type InSe only when the Van der Waals gaps are in contact with the electrolyte. This phenomenon occurs at more positive potential than the deposition potential of copper at the surface because intercalation is a thermodynamically favored process. For this reason deintercalation of copper does not occur spontaneously in the dark under short-circuit conditions. On the cleavage face only the photoelectrodeposition of metallic copper occurs.

Selectivity Changes in Electrochemical Reaction Sequences by Modulated Potential Control

Peter S. Fedkiw* and William D. Scott, Jr.

Department of Chemical Engineering, North Carolina State University, Raleigh, North Carolina 27695

ABSTRACT

Electro-organic reactions typically involve the electrochemical generation of a reactive intermediate which may participate in further chemical or electrochemical reactions. It is possible to effect the product distribution in such branched reaction networks by modulating the electrode potential. Reaction rate calculations under electrokinetic-controlled conditions for four reaction mechanisms, each involving an electrogenerated intermediate, are presented for step- and sinusoidal-potential modulation. The results show that reactor operating conditions unobtainable under steady potential control are possible. The cycle-averaged selectivity and yield of selected products may be significantly increased at the stationary state in comparison to those at an identical production rate but under dc conditions. The effect of modulation is frequency dependent; for some reaction sequences, the reaction trend at low frequency may be opposite than that at high frequency. The relative rates of a chemical reaction in parallel with an electrochemical reaction, both involving the intermediate, are more sensitive to potential modulation than either two parallel chemical or electrochemical reactions. Mass transfer limitations dampen the results of modulation. Reactor performance increases under modulated potential (or current) control possibly may be significant enough to make an electrochemical processing route economically viable.

In a branched-reaction sequence involving both chemical and electrochemical steps, the electrochemical reaction rates may be modified by a change in the electrode potential during the course of the reaction. Thus, it is conceivable to manipulate, by modulation of the potential,

*Electrochemical Society Active Member.

the outcome of a reaction to enhance the formation of desired products and simultaneously retard the formation of undesired products. The yield (percent of reactant consumed to form the desired product) and selectivity (ratio of desired product to all other side products) may be favorably increased by modulated potential control such

that an otherwise inefficient reaction may possibly become economically viable due to decreased capital costs (yield improvement) and reduced separation costs (selectivity increase).

The possible beneficial effects of modulated potential control have been qualitatively noted in the literature (1), but quantitative guidelines as to when modulated potential may be useful have not been presented. This paper presents calculated yields and selectivities of several branched-reaction sequences, typical of electro-organic processes, under two modes of potential control: sinusoidal and step modulation. Simple kinetic expressions and isotherms have been used to focus the results on the modulation effect. In this vein, the discussion is directed mainly at electrokinetic-controlled reactions occurring on electrodes with a uniform secondary-current distribution. It is shown that modulation can significantly enhance the selectivity of some products or can be detrimental to other products or even entire reaction sequences.

A brief review of modulated control of a chemical reactor and the use of modulated potential (or current) in electrochemical reactors is presented first. The example reaction sequences used in the calculations and their kinetic expressions are presented next, followed by the results and discussion.

Periodic Control of Reaction Rates

Chemical reactions.—It has been recognized that reaction rates and selectivities may be significantly effected in ordinary chemical reactors by periodic control of some external forcing function. Theoretical and experimental studies of both homogeneous and heterogeneous reactions have been performed. Temperature (2-6), reactant concentration (7-16), and heat-addition rate (17) have been modulated and have been shown to change the reaction rate and yield from that at the cycle-averaged value. Depending upon the particular reaction sequence under consideration, periodic control may be better or worse than steady-state operation. Reviews of periodic control for ordinary chemical reactors are available (18, 19). It is not very practical in an industrial context to modulate the reactant concentration into a reactor. In addition, the large thermal inertia associated with the reactor wall, catalyst support, and solvent can significantly dampen temperature fluctuations. Consequently, periodic forcing control of a reactor has not been practiced by the chemical industry.

Inorganic electrochemical reactions.—Periodic reaction control has been recognized to be of benefit by the inorganic electrochemical industry. In particular, electroplating characteristics may be significantly altered by periodic reaction control (20). The morphology of an electrodeposit may be controlled under periodic potential or current manipulation (21-28), and electrodeposited alloy composition may be changed by periodic reaction control (29-31). Electrodeposition under periodic reaction control at mass-transfer-limited conditions has also received attention (32-37). In addition, it has been shown that electrodisolution efficiency may be increased under periodic current control (38, 39) and corrosion characteristics may be modified (40, 41).

Electro-organic reactions.—Electro-organic reactions should be particularly sensitive to potential or current modulation, since they typically involve a sequence of electrochemical and chemical steps in a parallel or series arrangement. Electrolysis of organic substrates under periodic current modulation was first studied by Ghosh (42). Modulation of potential and current has been used mainly to ascertain reaction mechanisms in electro-organic-reaction sequences. Most studies on ac electrolysis are concerned with the determination of current efficiency and its dependence on frequency and do not explicitly consider the most interesting aspect of ac control, which is the ability of periodic operation to alter the course of complex reactions and the nature of the resulting products.

Wilson and Lippincott (43) used step current modulation to study the oxidation of propionic acid and acetate. They found the production of ethylene from oxidation of propionic acid decreased sharply with increasing frequency, while only a slight decrease in ethane formation from the oxidation of acetate was observed. They reasoned that the first reaction was second order in an adsorbed intermediate, while the second was first order. The realization that the pulse frequency has different effects on reactions of different orders has important consequences for reaction sequences in which competing reactions are of different order. Fleischmann *et al.* (44) studied the kinetics of the Kolbe electro-synthesis of ethane on Pt from aqueous acetate solutions under pulse-potential control. They observed that with short pulses acetate ions were completely oxidized to carbon dioxide; however, with increasing pulse time, the formation of ethane increased to its steady-state value. Hickling and Wilkins (45) investigate the anodic electrolysis of aqueous potassium ethyl malonate solutions and acetate solutions using step current modulation. By applying small cathodic currents between the anodic pulses, they observed a sharp minimum in current efficiency at a characteristic frequency. This frequency corresponded to the passage of a critical quantity of charge sufficient to destroy conditions for dimerization, thereby permitting oxygen evolution to become an effective side reaction. Fleischmann and Goodridge (46) and Atherton *et al.* (47) studied the decarboxylation kinetics of acetate ions in alkaline solution using square-wave potential modulation. Cycle time, amplitude, and duty ratio of the potential pulse were varied. Production of methanol, ethane, methane, and oxygen were measured. Oxygen evolution exhibited a maximum with pulse duration, while both ethane and methanol yields decreased. The ratios of ethane and methanol production to oxygen production (and, to some extent, ethane production to methanol production) were changed by varying the pulse length while holding the amplitude and duty ratio constant. Fleischmann *et al.* (1, 48) studied the reduction of nitrobenzene and the Kolbe synthesis of ethane under pulse potential control. They concluded that for the reduction of nitrobenzene, the product distribution could be altered by pulsing the electrode potential. Their work is the first clear qualitative statement that periodic control can selectively produce certain reaction products in cases where there are competitive reactions. Nadebaum and Fahidy (49, 50) developed a model for the reaction kinetics in the Kolbe synthesis and were able to predict the observed maximum production of oxygen with varying pulse time as seen by Fleischmann *et al.* Scrivastava and Shukla (51) studied the ac electrolysis of sodium salts of aliphatic acids. The reaction products were the same for both constant current and ac, but the relative distribution of the products exhibited a marked dependence on current density and frequency. Bhadani (52) studied the electropolymerization of styrene under ac control and noted that the yield and molecular weight of the resulting polymer decreased with frequency. Alkire and Tsai (53) examined the alternating current electrolysis of propylene oxide and reported a decrease in current efficiency with increasing frequency.

Electro-Organic Reaction Sequences

In electro-organic reactions an intermediate species is usually generated by a one- or two-electron transfer. This intermediate may then participate in further chemical or electrochemical reactions. Table I illustrates the reaction sequences which were studied in this work. [Other, more complex reactions have been discussed by Scott (54).] The intermediate concentration may be manipulated by modulation of the initial electrochemical-reaction rate, and, hence, any reaction which depends upon its concentration. Consider the E-C,E reaction sequence shown in Table I. If the electrode potential is modulated between a high driving force for the production of R_1 and a low value where this rate is negligible, the production of R_2 and R_3 will consequently vary periodically. The questions

Table I. Coupled electrochemical-chemical reaction sequences

Reaction designation	Mechanism

 C² = second-order chemical reaction.

addressed here are: how does the cycle-averaged production of R_2 or R_3 or their ratio (selectivity) increase or decrease under the modulated conditions, and what is the basis for this decision; what are the control conditions (e.g., frequency, modulation waveform, etc.) which result in higher production rates and reaction selectivity?

Electrode kinetics.—Since the focus of this work is the effect of modulated electrode potential on the outcome of reaction sequences, simple, yet representative kinetic expressions have been used in the calculations and are shown in Table I. The rate expressions used are consistent with those given by Sakellaropoulos (55). For presentation purposes, all electrochemical reactions are assumed to be reductions. No side reactions (such as solvent electrolysis) take place, and the electrode-electrolyte potential difference is assumed to be spatially uniform. Furthermore, for the majority of the calculations, mass-transfer limitations are neglected; i.e., electrokinetic-controlled reaction conditions exist. Additional assumptions are listed below.

1. All concentrations appearing in Table I are on an area basis, and the adsorbed species are assumed to follow a linear adsorption isotherm. (Scott has also presented calculations for a Langmuir isotherm.) The concentration of the intermediate R_1 in the bulk solution is assumed to be zero, and the net rates of all chemical and electrochemical reactions which consume R_1 are assumed to occur at a large enough value such that no R_1 escapes the vicinity of the electrode.

2. The electrochemical reactions are assumed to be irreversible, first order in the concentration of their reactant, and obedient to Tafel behavior with potential. The potential is assumed to be displaced sufficiently from the open-circuit potential of the initial electrochemical reaction and any follow-up electrochemical reaction.

Within the limitations of the above assumptions, the rates of reaction, for example, in the E-C,E reaction sequence, are written as

$$\begin{aligned} r_1 &= K1R_0 \exp(-a_1fE) \\ r_2 &= K2R_1 \\ r_3 &= K3R_1 \exp(-a_3fE) \end{aligned}$$

where the rate constants $K1$ are independent of the potential E , which is measured with an arbitrary reference electrode, a_1 is a cathodic transfer coefficient, and $f = F/RT$.

Solution Procedure

Production rates for the products R_2 and R_3 in the various reaction schemes shown in Table I were calculated by solving the governing equation for the intermediate concentration $R_1(t)$ and substituting into the appropriate rate expression. The Appendix shows the differential equation which governs the intermediate concentration for the various reaction sequences. The solution depends upon the waveform of the imposed voltage, $E(t)$; sinusoidal and step potential modulation as shown in Fig. 1 were used. Since the differential equation cannot be solved analytically, a numerical integration scheme useful

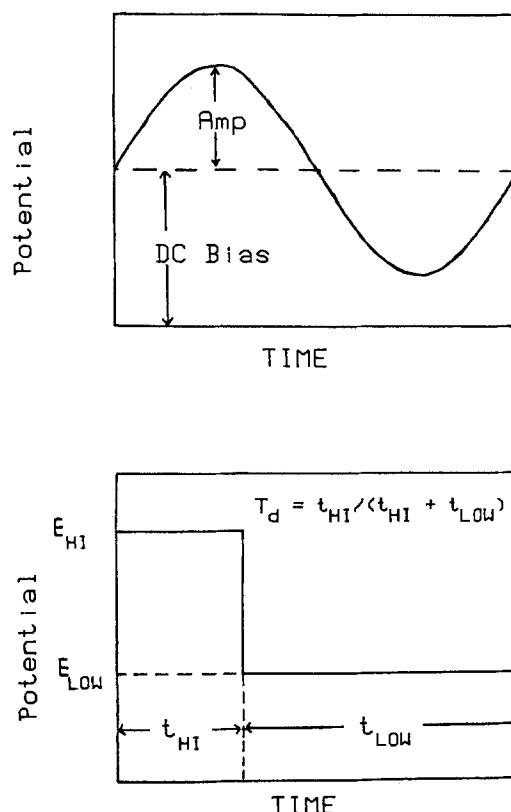

Fig. 1. Electrode potential waveforms used in calculations (a) sinusoidal (b) step. The definition of duty cycle is indicated in Fig. 1b.

for stiff ordinary differential equations was used (56). The integration was continued until the stationary state of the intermediate concentration was found. The reaction rates were then averaged over a period; only cycle-averaged quantities are reported here. The yield and selectivity of the reaction are of interest, and it is only necessary to report one of the two, since they are related for the reactions shown in Table I; for example, in the E-C,E reaction, the yield, Y , of the chemical product R_2 ($Y = \langle r_2 \rangle / \langle r_0 \rangle$) is related to its selectivity, S ($S = \langle r_2 \rangle / \langle r_3 \rangle$), as $Y = S/(1 + S)$, where $\langle \rangle$ designates a cycle-averaged quantity.

Results and Discussion

Basis of comparison.—At the stationary state, the cycle-averaged production rate and selectivity should be compared to some reference values to determine if the reaction modulation is beneficial. The dc reaction rates evaluated at the average potential of the modulation appear to be a logical choice, but are inappropriate bases, however, for two reasons. The first is a practical limitation due to the nature of the kinetic expressions used in the calculations. Step potential manipulation when the electrochemical reactions are completely eliminated during the “off” cycle is a limiting case of interest. Since the reactions are assumed irreversible, an infinite positive voltage, fE_{Low} , will be required to eliminate completely the electrochemical reactions. Hence, in this case, an average potential for a step potential manipulation has no meaning. The second objection is more fundamental. Because the electrochemical reactions depend exponentially upon the electrode potential, the cycle-averaged reaction rates under sinusoidal modulation will always be greater than that of a steady-state reaction evaluated at the cycle-averaged potential. It can be argued that, if the goal is larger production rates, then the reaction need only be operated at a higher, steady polarization instead of modulating the potential.

A given product-production rate is the basis chosen in this work for comparison of the modulated to steady-state reactor. It is assumed that there is a given requirement of the desired product, e.g., Z kg/hr of R_2 . At this given production rate, selectivities are calculated under steady-state and stationary-state conditions. With the results presented in this manner, it is clear if cyclic operation is beneficial or harmful to the net outcome of a reaction sequence.

E-C,E reaction sequence.—There are four intrinsic dimensionless variables which effect the outcome of the E-C,E reaction sequence: a_1 , a_2 , $K1/K2$, and $K3/K2$. In addition, the results depend upon the waveform of the imposed potential. For step potential modulation, the characteristics of the waveform are the duty cycle, T_d , the most cathodic and least cathodic voltage, fE_{Hi} and fE_{Low} , respectively, and the cycle time or frequency, w . Under sinusoidal potential modulation the control variables are the frequency, amplitude, $f\Delta E$, and bias voltage, fE_{dc} .

Calculations have been performed for a range of the rate constants (54). The magnitude of the reaction rates at any potential will, of course, depend upon the value of the rate constants; however, the trend of either increased or decreased selectivity under modulated potential control was found to be independent of the rate constants examined. The results are much more sensitive to the value of the transfer coefficients. Consequently, one set of reasonable values of the rate constants are used in the calculations presented, with emphasis placed on the effect of the transfer coefficients.

Figure 2a presents the cycle-averaged selectivity of the chemical product R_2 as a function of its dimensionless cycle-averaged production rate for constant and step potential modulation. Figure 2b presents analogous results for sinusoidal modulation with both figures calculated with $a_1 > a_3$. The center curves in Fig. 2a and 2b, labeled with “+,” are the selectivity under steady potential control. The potential becomes increasingly cathodic as more

of the product R_2 is produced, and three values of the steady-state potential are indicated in Fig. 2a and 2b.

The limiting case of $fE_{Low} = +\infty$ is used for step potential modulation. Under this polarization condition, all electrochemical steps are eliminated during the “off” portion of the cycle; hence, the intermediate may decay only via the chemical-reaction pathway. The largest selectivity for the chemical product can be anticipated under these conditions.

The asymptotic behavior for low and high frequency is shown on each figure for three fE_{Hi} for step potential modulation and three fE_{dc} for sinusoidal potential control. Each point on the modulated potential control curves in Fig. 2a represents operation at a different duty cycle. All curves originate on the dc line on which the duty cycle is one. Table II is an index for the duty-cycle value for all results graphically reported; e.g., the fourth symbol from the dc curve at any frequency represents a 50% duty cycle. Under sinusoidal potential control, the amplitude is varied at any frequency, and Table II also presents an index for all these results; e.g., the third point from the dc curve represents a dimensionless voltage amplitude of 5 imposed upon the dc bias.

The results show that selectivities not obtainable under dc operation are possible with modulated potential control, and an improvement in reactor performance is possible. Both an increase or decrease in selectivity is obtainable for both waveforms at any given production rate of R_2 depending upon the frequency; high frequency improves selectivity, while low frequency always decreases it for sinusoidal operation and, except at very low duty cycles, also for step potential control. Figure 3a and 3b show results at a number of intermediate frequencies for step and sinusoidal control, respectively. The dependence on frequency may be understood by examining the behavior of the intermediate concentration R_1 over a cycle. Under sinusoidal control at low frequency, a pseudo-steady state is obtained, and the intermediate concentration is maintained at a high value, which is effectively consumed by the electrochemical reaction during the potential oscillation. At high frequency, however, the intermediate concentration cannot follow the potential oscillations and is maintained at a lower value than that expected from the average calculated under steady conditions at the cycle-extreme potentials. Under step potential control at low frequency, the intermediate concentration and, hence, selectivity depend upon the duty cycle. A pseudo-steady state in the intermediate concentration during the “on” cycle may be obtained at low frequency. Since the intermediate concentration is its largest value then, the selectivity decreases because of its consumption in the electrochemical reaction. However, if the duty cycle is decreased to a small enough value, a pseudo-steady state of R_1 will not be obtained, and the selectivity will increase as T_d is decreased further, since the intermediate is consumed only by the chemical reaction during the “off” period.

The sign of the slope of the modulated-potential-control curves in Fig. 2 is different for the step and sinusoidal

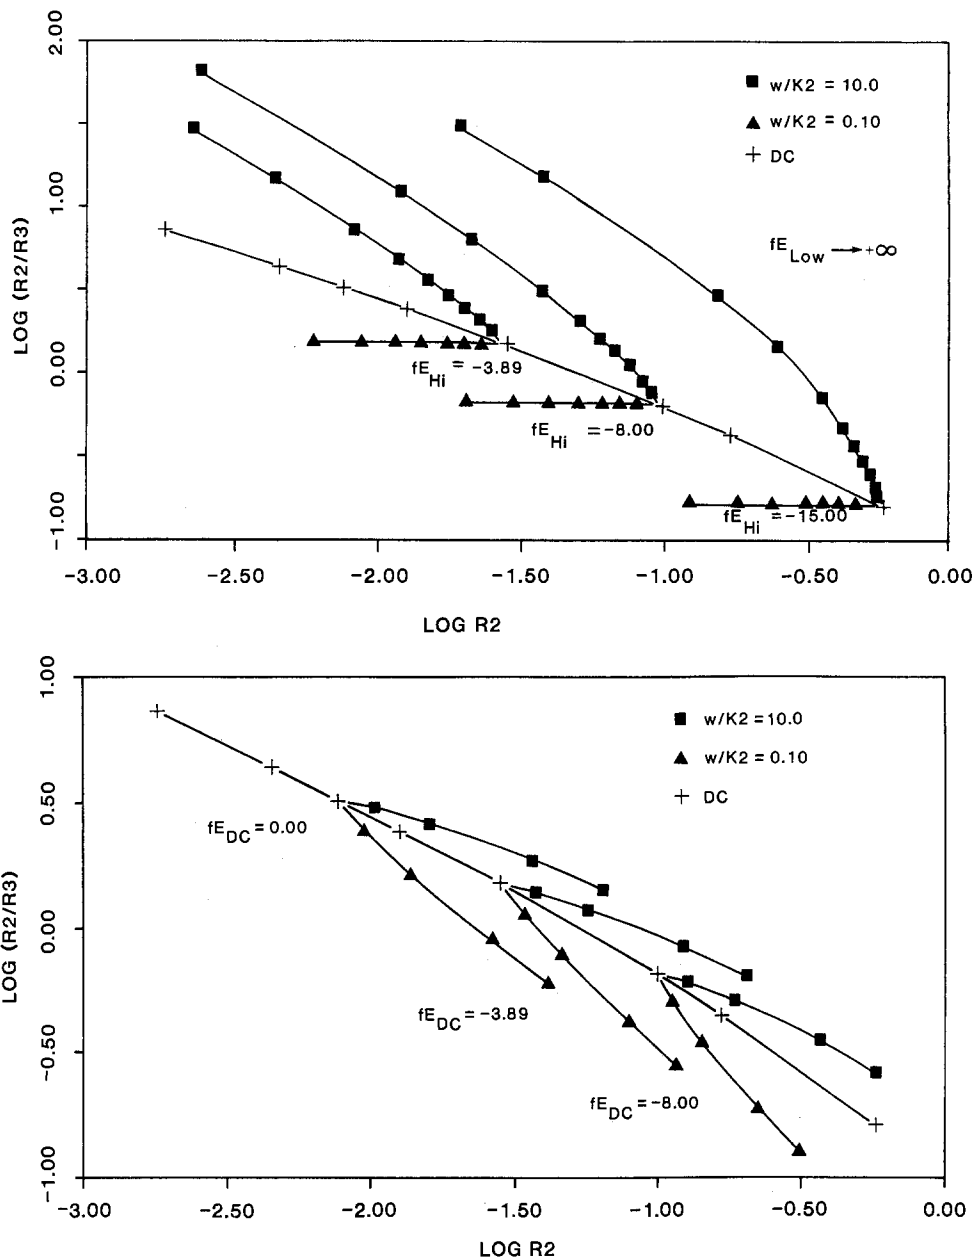

Fig. 2. Selectivity of the chemical product of the E-C,E reaction sequence as a function of its dimensionless production rate ($R_2 = r_2 K_2 R_0$): $a_1 = 0.4$, $a_3 = 0.2$, $K_1/K_2 = 0.01$, and $K_3/K_2 = 0.3$. A, top: step potential modulation. B, bottom: sinusoidal modulation.

waveform. This is due to the exponential dependence of the electrochemical reactions on potential. Under sinusoidal modulation the cycle-averaged production of R_1 increases with amplitude; hence, the curves slope downward to higher R_2 -production rates. Under step potential modulation, however, the cycle-averaged production of R_1 decreases with a drop in the duty cycle, and, hence, the opposite behavior is observed. Examination of Fig. 2 shows that the step potential modulation is a better control strategy in that larger increases in selectivity can be obtained than with sinusoidal control.

If fE_{Low} for step potential control is set to a less anodic value than that used in the calculations in Fig. 2, the increase in selectivity as T_D is lowered, with all other conditions remaining constant, goes through a maximum since the selectivity approaches the steady-state value at $fE_{Low} \rightarrow 0$.

The dramatically different behavior when the transfer coefficient of the second electrochemical step is larger than that of the first is shown in Fig. 4. In this situation at constant potential control of the reactor, a maximum in the production rate of the chemical product is observed. At low cathodic polarizations R_1 is generated at a rate sufficient to supply both the electrochemical- and chemical-follow-up reaction. As the potential becomes more cathodic, however, the second electrochemical reac-

tion effectively consumes more of R_1 than the chemical step and, eventually, consumes all of the R_1 produced. In this case, neither step or sinusoidal potential modulation was beneficial; either a decrease in selectivity was observed under varying potential or a steady potential existed which would meet the given production-rate requirement and yet result in a higher selectivity. (The case in which $a_1 = a_2$ was also examined, and the same conclusions may be stated.)

E-C²,E reaction sequence.—There are four intrinsic dimensionless variables which govern the outcome of this reaction sequence: K_1/K_2R_0 , K_3/K_2R_0 , a_1 , and a_3 . Calculations are presented for one set of rate constants, since the trend of increasing or decreasing reaction selectivity was found to be insensitive to these parameters. The relative values of the transfer coefficients effect whether there is a positive or negative result of the potential modulation. Four cases arise: (i) $a_1 = 2a_3$, (ii) $a_1 > 2a_3$, (iii) $2a_3 > a_1 > a_3$, and (iv) $a_1 < a_3$. Case (i) is a degenerate case in that the dc selectivity is independent of potential. Both high and low frequency modulation enhance the selectivity at any given production rate of the chemical product for both waveforms; the enhancement is more pronounced at the higher frequency. For case (ii), the dc selectivity increases with an increase in the production rate of the chemical product, while for case (iii) the dc selectivity decreases.

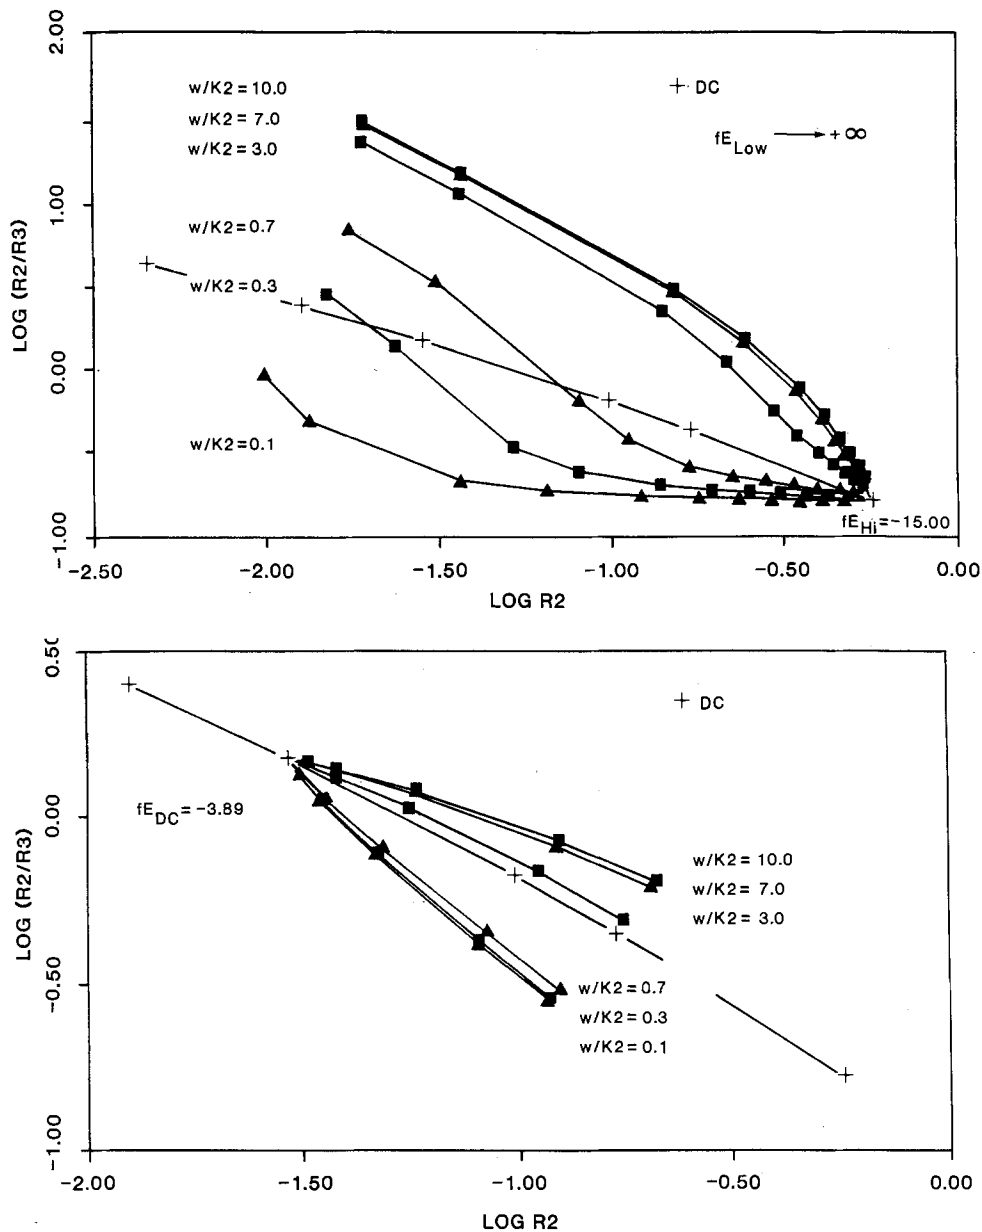

Fig. 3. Effect of frequency on the selectivity of the chemical product of the E-C,E reaction sequence as a function of its dimensionless production rate ($R2 = r_2 K2 R_0$): $\alpha_1 = 0.4$, $\alpha_3 = 0.2$, $K1/K2 = 0.01$, and $K3/K2 = 0.3$. A, top: step potential modulation. B, bottom: sinusoidal potential modulation.

Figure 5a and 5b and 6a and 6b illustrate the effect of step and sinusoidal potential modulation for cases (ii) and (iii), respectively. Again, ranges of reactor operation are possible which cannot be obtained under steady-state condi-

tions. The modulation effect on the selectivity for case (iii) in Fig. 6 is much like that for the first case discussed of the E-C,E mechanism: high frequency increases the selectivity, while low frequency decreases it. For case (ii),

Fig. 4. Selectivity of the chemical product of the E-C,E reaction sequence as a function of its dimensionless production rate under step potential modulation ($R2 = r_2/K2 R_0$): $\alpha_1 = 0.2$, $\alpha_3 = 0.4$, $K1/K2 = 0.01$, and $K3/K2 = 0.3$.

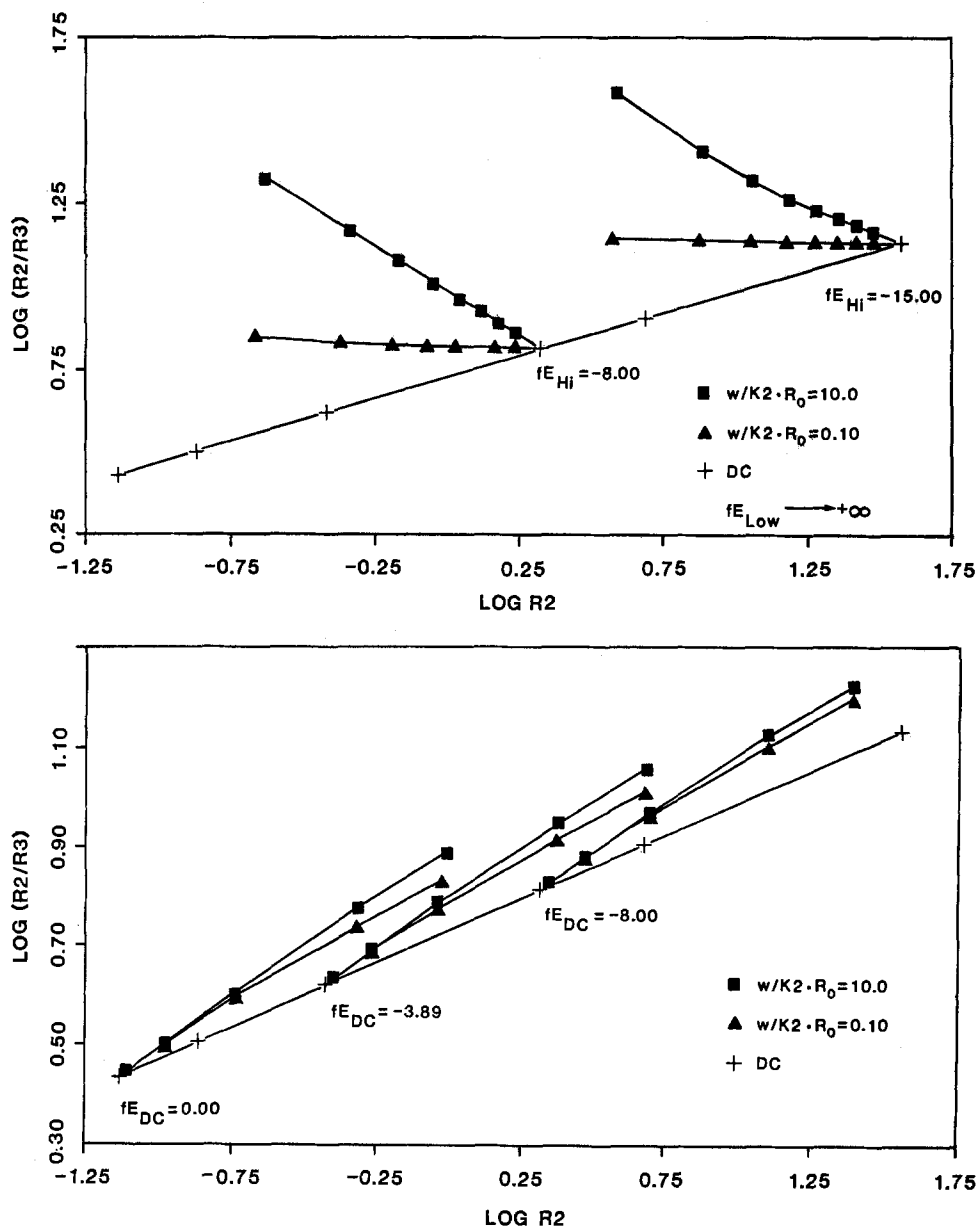

Fig. 5. Selectivity of the second-order chemical reaction product of the E-C²,E reaction sequence as a function of its dimensionless production rate ($R2 = r_2/K_2R_0^2$): $a_1 = 0.4$, $a_3 = 0.1$, $K_1/K_2R_0 = 0.1$, and $K_3/K_2R_0 = 0.1$. A, top: step potential modulation. B, bottom: sinusoidal potential modulation.

both high and low frequency modulation increase the selectivity. This may be attributed to the higher sensitivity of the second-order chemical reaction to the intermediate concentration than the first-order electrochemical reaction. In case (iv), a maximum-production rate of the chemical product is obtained under dc conditions as seen in Fig. 7, which shows the results of step potential modulation. No advantage of either step or sinusoidal potential control over steady potential control was found in this case. As in the E-C,E sequence, the step potential waveform appears to be better than sinusoidal when modulation is beneficial.

E-C,C² reaction sequence.—There are three dimensionless parameters which effect the outcome of this reaction sequence: K_1/K_2 , K_3R_0/K_2 , and a_1 . Figures 8a and 8b illustrate typical results for the selectivity of the second-order chemical product as a function of its production rate for step and sinusoidal potential modulation, respectively. Reactor operating conditions are again possible at the stationary state which are unobtainable at the steady state. The results at high frequency modulation approach those of dc operation; however, the low frequency modulation results for both waveforms illustrate an increase in selectivity at any given production rate of R_0 . At the low frequency, an increase in the intermediate concentration is obtained over that at higher frequencies; thus, the second-order chemical reaction is favored. The selectivity

of the first-order product is decreased by potential modulation.

E-E,E reaction sequence.—Five dimensionless kinetic parameters determine the outcome of this reaction sequence: K_1/K_2 , K_3/K_2 , a_1 , a_2 , and a_3 . Under dc conditions, the steady-state selectivity of the product with the smaller transfer coefficient decreased with an increase in its production rate, while the selectivity of the product with the larger transfer coefficient increased with its production rate. Modulation always decreased the selectivity in the first case and always increased it in the second case. Figures 9a and 9b illustrate typical results under step and sinusoidal potential control. Results using two different values of the lower potential, fE_{Low} , are shown in Fig. 9a. High frequency is better than low frequency in increasing selectivity for both waveforms, but note that the increase above the dc selectivity is considerably smaller for this reaction sequence than those for the previous three.

Comments.—Clearly, orders of magnitude increase in reaction selectivity can be obtained by modulation of the potential for some of the reaction sequences studied. The calculations have shown that modulation is most effective when a chemical-reaction step competes in parallel with an electrochemical step for the same intermediate. Such large increases in selectivity and yield may make an elec-

Fig. 6. Selectivity of the second-order chemical reaction product of the E-C²,E reaction sequence as a function of its dimensionless production rate ($R2 = r_2/K2R_0^2$): $a_1 = 0.4$, $a_3 = 0.3$, $K1/K2R_0 = 0.1$, and $K3/K2R_0 = 0.1$. A, top: step potential modulation. B, bottom: sinusoidal potential modulation.

trochemical processing step competitive with alternative chemical processing schemes. Of course, an increased energy cost must be paid if the potential is modulated. Capacitive double-layer charging, which was not considered

here, would be an energy loss which could become important for large-surface-area reactors. There is no reason to expect that either step or sinusoidal potential modulation is the best waveform. On the contrary, if an objective

Fig. 7. Selectivity of the second-order chemical reaction product of the E-C²,E reaction sequence as a function of its dimensionless production rate under step potential modulation ($R2 = r_2/K2R_0^2$): $a_1 = 0.2$, $a_3 = 0.4$, $K1/K2R_0 = 0.1$, and $K3/K2R_0 = 0.1$.

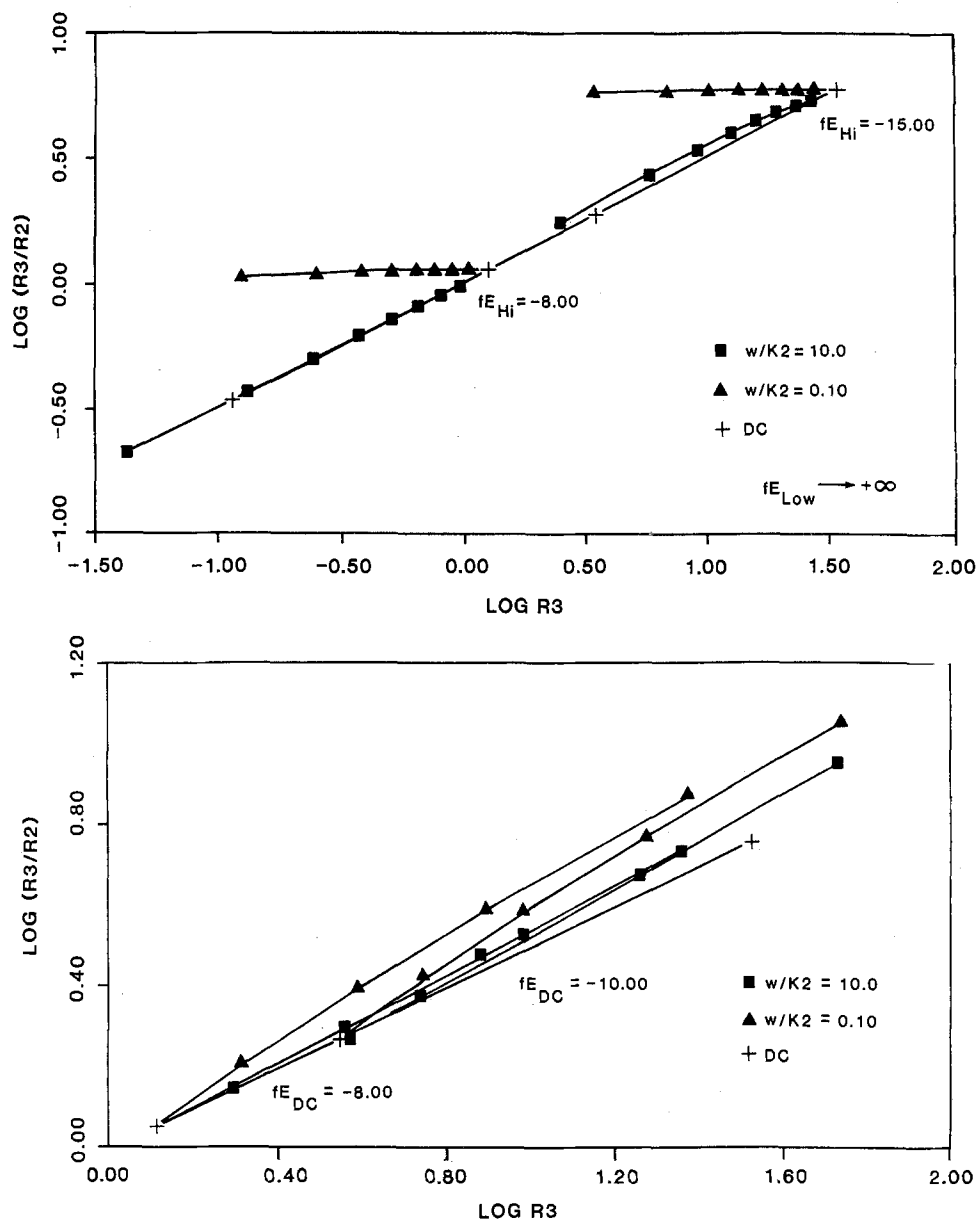

Fig. 8. Selectivity of the second-order chemical reaction product of the E-C, C² reaction sequence as a function of its dimensionless production rate ($R3 = r_3/K3R_0^2$): $\alpha_1 = 0.4$, $K1/K2 = 0.1$, and $K3R_0/K2 = 1.0$. A, top: step potential modulation. B, bottom: sinusoidal potential modulation.

function can be defined, mathematical techniques developed in control theory (57, 58) can be used to construct the optimal waveform to establish the maximum or minimum of the objective function.

If mass-transfer limitations are present, the degree to which the modulated potential changes the outcome of the reaction sequence is dampened. This can be expected, since mass transport is independent of potential in a well-supported electrolyte. Indeed, Scott has shown that a maximum production rate exists for some of the products in the reaction sequences of Table I when the mass-transfer rate of the initial reactant R_0 to the electrode becomes important. Figure 10 illustrates this effect for the E-C,E sequence at three values of the mass-transfer coefficient KM . Thus, the calculations presented here may be thought of as the "best case" example for the positive effect of potential modulation on reaction outcome. A simulation of an actual operating reactor must also consider the effect of nonuniform potential distribution, as well as possible mass-transfer limitations.

If the intermediate R_1 is soluble in the bulk solution, the beneficial effect of potential modulation may be either increased or decreased, depending upon the desired product and reaction sequence involved. For example, if the follow-up chemical reaction may occur homogeneously in the E-C,E reaction sequence, the increase in selectivity under modulated reaction control should be greater than that calculated here. This would be expected, since the

competing electrochemical reaction is heterogeneous and cannot consume that R_1 , which enters the bulk electrolyte. However, the selectivity of the second-order product in the E-C, C² reaction sequence if both chemical reactions occur homogeneously will be lower than that calculated here. This occurs because of the dilution effect and the higher sensitivity of the second-order chemical reaction to concentration than the first-order reaction.

The detailed understanding of reaction sequences and their characterization by appropriate rate expressions may limit the utilization of modulated potential control of a reactor. The results show how dramatically different the effect of modulation is on a reaction product depending upon how that product is formed. The waveform of the imposed potential strongly affects the reaction outcome. If experiments are performed on the wrong reaction system, or with the wrong waveform, or at the wrong frequency, the unfortunate conclusion may be drawn that modulation is not effective in enhancing reactor performance.

Finally, current to the reactor may be modulated instead of the potential. The outcome will be consistent with some periodic modulation of the potential but with a different waveform from that of the current. Care must be taken, if the reactor is operated in this mode, that the potential does not oscillate into secondary reaction regimes such as solvent electrolysis.

Fig. 9. Selectivity of the product with the larger transfer coefficient for the E-E reaction sequence as a function of its dimensionless production rate ($R_2 = r_2/K_2R_0$): $\alpha_1 = 0.2$, $\alpha_2 = 0.4$, $\alpha_3 = 0.3$, $K_1/K_2 = 0.1$, and $K_3/K_2 = 1.0$. A, top: step potential modulation. B, bottom: sinusoidal potential modulation.

Summary

Under electrokinetic-controlled conditions for the simple reaction sequences shown in Table I and subject to

the assumed rate expressions, substantial increases in reaction selectivity are possible by modulation of the electrode potential in comparison to steady-state operation. Step potential modulation was found to be more effective

Fig. 10. Selectivity of the chemical reaction product of the E-C,E reaction sequence as a function of its dimensionless production rate in the presence of mass-transfer resistance under step potential modulation ($R_2 = r_2/K_2R_0$): $\alpha_1 = 0.4$, $\alpha_3 = 0.2$, $K_1/K_2 = 0.01$, and $K_3/K_2 = 0.3$.

Table A-1. Dimensionless intermediate concentration equations

Mechanism	Governing equation for intermediate
E-C ² ,E	$\frac{dI}{d\tau} = \frac{K_2 \cdot R_0}{w} \frac{K_1}{K_2 \cdot R_0} \exp(-a_1 fE) - \frac{K_2 \cdot R_0}{w} I^2 - \frac{K_3}{K_2 \cdot R_0} \frac{K_2 \cdot R_0}{w} I \exp(-a_3 fE)$
E-C, C ²	$\frac{dI}{d\tau} = \frac{K_1}{K_2} \frac{K_2}{w} \exp(-a_1 fE) - \frac{K_2}{w} I - \frac{K_3 \cdot R_0}{K_2} \frac{K_2}{w} I^2$
E-E,E	$\frac{dI}{d\tau} = \frac{K_1}{K_2} \frac{K_2}{w} \exp(-a_1 fE) - \frac{K_2}{w} I \exp(-a_2 fE) - \frac{K_3}{K_2} \frac{K_2}{w} I \exp(-a_3 fE)$

than sinusoidal modulation, although neither of the two is necessarily the best waveform. The effect is highly frequency dependent; the reaction outcome may show opposite behavior at low vs. high frequency. Mass transfer effects dampen any changes in reaction outcome caused by modulating the potential. By operating an electrolysis reactor in a modulated control mode, the combination of decreased capital cost for the reactor (increased yield) and decreased operating cost of downstream mass-separation devices (increased selectivity) may possibly make an electrolytic production route economically favorable.

APPENDIX

In the E-C,E reaction sequence, the intermediate concentration R_1 is governed by the rate equation

$$\frac{d}{dt} R_1 = r_1 - r_2 - r_3$$

The transport rate of the initial reactant from the bulk solution to the electrode surface may be characterized by a pseudo-mass-transfer coefficient, KM , times the concentration difference between the surface and bulk concentration. The concentration driving force must be expressed on a surface concentration to be consistent with Table I. After simple manipulations and nondimensionalization of the resulting equation, the following equation which governs the dimensionless intermediate concentration $I (R_1/R_0)$ may be derived

$$\frac{dI}{d\tau} = \frac{(K_1/K_2)(K_2/w)\exp(-a_1 fE)}{1 + (K_1/KM)\exp(-a_1 fE)} - (K_2/w)I - (K_3/K_2)(K_2/w)I\exp(-a_3 fE)$$

where $\tau = wt$, w is the fundamental frequency of the potential oscillation ($w = 2\pi \cdot \text{cycle time}$), and R_0 is the surface concentration of the initial reactant.

Similar equations in the absence of mass-transfer limitations may also be derived for the other reaction mechanisms and are shown in Table A-1.

Formation and Reduction of Anodic Sulfide Films on Antimony Electrodes

Alfred Viehbeck^{*1} and Norman Hackerman^{**}

Department of Chemistry, Rice University, Houston, Texas 77251

ABSTRACT

The growth and reduction of anodic Sb_2S_3 films on antimony electrodes in alkaline sulfide solutions has been investigated using potentiodynamic, galvanostatic, and potentiostatic techniques. The sulfidation mechanism and the efficiency of charge storage in the sulfide film are dependent on the electrode potential and current density. The initial stages of film formation follow a high field growth process involving ionic transport through the sulfide film. The growth of thicker films is controlled by coupled electrochemical and chemical reactions involving mass transport and nucleation. Metal dissolution accompanies film formation under most growth conditions. The anodic and cathodic behavior of these films is consistent with their rectification or n-type semiconductor properties.

The formation and reduction of anodic surface films has a major influence on the overall electrochemical reactivity of a metal. The growth of an anodic film usually occurs by the migration of cations or anions (or both) through the film phase and across the interfaces and is often described using either Verwey's (1) or Cabrera-Mott's (2) high field model. Recently, Chao *et al.* (3) proposed a point-defect model for the growth of a passive layer. While most of the information concerning anodic film growth and the basic mechanistic models have been derived from studies of oxide formation on metals, the development and behavior of anodic sulfide films has received relatively little attention (4, 5).

The growth of some metal sulfides was examined by Miller and Heller (6) in connection with their possible use as photoanodes. Peter (7, 8) has correlated the anodic formation of CdS and Bi_2S_3 to a high field process and on Hg electrodes examined the initial underpotential deposition of a sulfide monolayer (9). Anodic Ag_2S formation reportedly occurs in a manner similar to the mercury system (10). Recently, the anodic oxidation of sulfide on a Pt electrode in alkaline solutions was found to result in the formation of a sulfide containing surface layer that passivated the electrode (11). Preliminary investigations have also demonstrated the semiconductor properties of anodically formed antimony sulfide films (12).

In the work reported here we discuss the growth and reduction of anodic sulfide films on polycrystalline antimony electrodes (13). The electrode behavior and kinetic parameters determined experimentally have been used to correlate various growth models to this system. The results of ESCA analysis of the anodic films are discussed.

Experimental

All experiments were carried out in 0.1M Na_2S + 1.0M NaHCO_3 (pH 9.0) solutions, prepared using conductivity water (resistivity $> 5 \times 10^6 \Omega\text{-cm}$) and reagent-grade chemicals. Antimony electrodes were made from disks cut from a polycrystalline rod (6.615 g/cm³) having a purity of 99.998% (Alfa Products). These were cemented to nickel wire and mounted in epoxide resin. The electrode surface was polished to 0.05 μm alumina finish.

The electrochemical cell was a conventional three-compartment Pyrex design. The reference electrode was

Key words: antimony sulfide, anodic films, sulfidation, Sb_2S_3 film reduction.

a mercury/mercuric sulfide (red) slurry in contact with the sulfide solution (-0.513V vs. NHE) to which all potentials are referred.

The electrochemical measurements were carried out under an N_2 atmosphere on fresh electrodes that were first cathodically polarized (-1.00V) in the sulfide solution to remove any reducible surface films. Current densities were determined using a roughness factor of 1.7 as estimated from capacitance measurements (13).

Results and Discussion

Potentiodynamic conditions.—A typical current vs. potential (*i/E*) curve for an antimony electrode in the solution described and subjected to a triangular potential scan is shown in Fig. 1. The polarization profile is strongly dependent on the electrode surface preparation, solution composition, scan rate (ν), and the number of previous scanning cycles. With a fresh electrode, a positive potential scan usually exhibits four major anodic peaks which are represented as Peaks I, II, III, and IV (Fig. 1). The electrode surface also becomes yellow near the onset of Peak III turning to an orange color as the sulfide film thickens at higher potentials. The multiple anodic peaks are interpreted as the nucleation and spreading of successive sulfide layers where the overall surface process can be summarized by the following reaction

Similar *i/E* behavior has been seen for oxide nuclei spreading on an electrode surface (14, 15). Oxygen evolution does not occur even at potentials to +4.00V.

On the return negative (cathodic) scan there is a net anodic current response throughout most of the potential region of film formation. Depending on the sweep rate an anodic current peak is seen in the region 0.60 to 0.10V. This behavior might be due to the time dependent dissolution of some outer surface phase (*e.g.*, a sulfur layer) that is formed at the more noble potentials, thus reactivating the electrode to further sulfidation or metal dissolution. Surface film reduction on the Sb electrode occurs between -0.70 and -1.00V with a loss of the yellow-orange coloration.

The "development" of the surface is demonstrated in the *i/E* profiles in Fig. 2, made by repetitive triangular potential scans (RTPS). In each successive cycle, the anodic potential limit ($E_{\lambda,a}$) was progressively increased. As $E_{\lambda,a}$ is made more positive, the corresponding reduction charge increases, and there is a negative shift in the reduction

Fig. 1. Current vs. potential profile for an Sb electrode in a 0.1M Na₂S + 1.0M NaHCO₃ solution. $\nu = 20$ mV/s.

peak potential. This negative shift in the reduction peak with an increase in $E_{\lambda,a}$ might be associated with an increase in film stability due to a field-assisted growth process in which the free energy of the phase increases with potential, thus requiring a larger cathodic overvoltage to reduce the phase (16).

From coulometric measurements of the RTPS above (Fig. 3) the charge associated with Peak I is calculated to

Fig. 2. Repetitive triangular potential scans for an Sb electrode in the sulfide solution with varied $E_{\lambda,a}$ at $\nu = 20$ mV/s.

be ≈ 0.30 mC/cm². Taking the sulfide film density (ρ) as that of bulk Sb₂S₃ (4.12 g/cm³) this charge value corresponds to approximately a monolayer of film with an estimated thickness of 0.52 nm. The charge passed in Peak II accounts for approximately two monolayers, while in Peak III the film grows to above 15 nm. However, the efficiency of anodic charge stored as film (*i.e.*, the ratio between Q_c and Q_a in Fig. 3) rapidly decreases for potentials positive of -0.30 V.

The current response under RTPS in the potential region between -1.00 and -0.20 V displayed an overall current increase with each successive cycle. This behavior is due to an increase in surface area by roughening. The reduction of the sulfide film leads to the formation of a porous layer of Sb metal, since the Sb₂S₃ phase occupies nearly twice the volume than the Sb metal from which it forms (17).

The sweep rate (ν) data for some of the anodic peak current maxima (i_m) and anodic peak potentials (E_m) are plotted in Fig. 4 and 5. The kinetic parameters derived from the voltammetric experiments are summarized in Table 1.

The potential of Peak I ($E_m = -0.74$ V or reversible potential, E^0) is not dependent on ν , while i_m and ν are linearly related (Fig. 4a). This is consistent with a deposition process involving a one-electron transfer, assuming Langmuir adsorption conditions and negligible solution diffusion effects (18). The initial reaction is considered to involve the adsorption of hydrosulfide ions (HS⁻) to form a monolayer deposit as in Eq. [2]

A similar process yielding an adsorbed sulfide intermediate prior to bulk sulfide film formation has been discussed for the sulfidation of Hg (9), Ag (10), and Pt (11).

The sweep-rate characteristics of Peak II (Fig. 4a and 5) correspond to a multistep consecutive mechanism in which the initial electron-transfer reaction is followed by a chemical reaction (19). A proposed scheme for the processes represented by Peak II is

yielding a hydro-sulfo Sb complex as an intermediate.

Fig. 3. Measured anodic (Q_a) and cathodic (Q_c) charge vs. $E_{\lambda,a}$.

This complex could then either dissolve or participate in a rapid electron-transfer reaction resulting in bulk antimony sulfide film formation

A similar mechanism has been proposed for the anodic formation of an oxide film on antimony (20, 21). It was re-

ported that the current efficiency for oxide formation is nearly 100% in acidic media, whereas extensive metal dissolution occurs during oxidation in alkaline solutions.

In the proposed sulfide film formation process, Eq. [4] is taken as the rate-determining step (RDS). The quasi-equilibrium hypothesis assumes that for an activation controlled process, all steps prior to the RDS are in equilibrium (18). Under potentiodynamic conditions (*i.e.*, $E = E_i + \nu t$, where E_i is the initial potential) the resulting expressions for the peak current and potential maximum as a function of ν are

$$i_m = Q_f(1 - \theta_m)(F/RT)\nu \quad [7]$$

$$E_m = G + 2.303(RT/F) \log \nu \quad [8]$$

where Q_f is the total film charge, θ_m is the fraction of surface covered by $(\text{HS})_{\text{ads}}$ at the maximum peak response, G is a constant, and R , T , and F have their usual meanings (22). These equations demonstrate the linear i_m vs. ν and ca. 59 mV/decade E_m vs. ν relations found for Peak II.

The effect of ν on Peak III (Fig. 4b and 5) corresponds to an irreversible process involving both an electrochemical and chemical reaction under diffusion control (23, 24). According to Delahay (23), the expressions for the peak current and potential as a function of ν are given by

$$i_m = (3.01 \times 10^5) n(\alpha N_a D_a \nu)^{1/2} C_0 \quad [9]$$

$$E_m = E^\circ + (RT/\alpha N_a F) [0.78 - \ln(K_0/D_a^{1/2}) + 0.5 \ln(\alpha N_a F \nu / RT)] \quad [10]$$

where α is the transfer coefficient, N_a is the number of electrons in the rds, n is the total number of electrons transferred in the sequence, C_0 is the concentration of diffusing species, and K_0 is the electrochemical rate con-

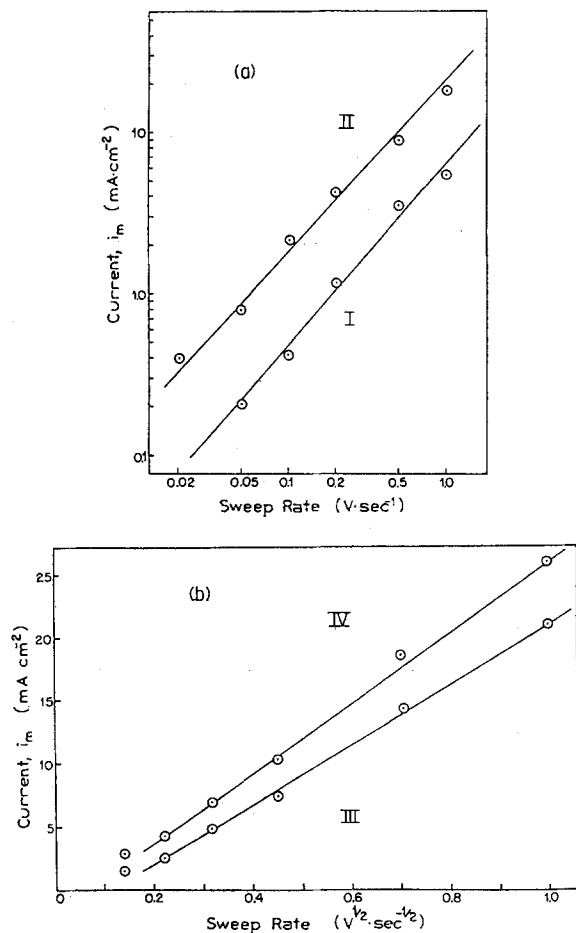

Fig. 4. A, top: sweep rate dependence of the current maximum for Peaks I and II. B, bottom: sweep rate dependence of the current maximum for Peaks III and IV.

Table I. Experimental kinetic parameters for anodic peaks

Peak I	$(\partial \log i_m / \partial \log \nu) = 0.88 \pm 0.01$ $(\partial E_m / \partial \log \nu) = 0$ $E_{1,\nu}^\circ = -0.74\text{V}$
Peak II	$(\partial \log i_m / \partial \log \nu) = 1.19 \pm 0.10$ $(\partial E_m / \partial \log \nu) = 55 \text{ mV/decade}$ $E_{2,\nu}^\circ = -0.57\text{V}$
Peak III	$(\partial \log i_m / \partial \log \nu) = 0.63 \pm 0.02$ $(\partial E_m / \partial \log \nu) = 28 \text{ mV/decade}$ $E_{3,\nu}^\circ = -0.31\text{V}$
Peak IV	$(\partial \log i_m / \partial \log \nu) = 0.57 \pm 0.05$ $E_{4,\nu}^\circ = +0.20 \text{ to } +0.40\text{V}$

Fig. 5. Sweep rate dependence of the potential for Peaks II and III

stant. Thus, the slope of the experimental E_m vs. $\log \nu$ plot yields a value that is one-half of the Tafel slope, which in this case gives a 56 mV/decade value for Peak III, and therefore $\alpha N_a = 1$. The value of the diffusion coefficient (D_a) as calculated from the i_m vs. $\nu^{1/2}$ plot, and Eq. [9] is 5.4×10^{-7} cm²/s, assuming HS⁻ as the diffusing species. This value is lower than expected for such a solution process, which is usually 2×10^{-5} cm²/s. This discrepancy suggests that the presence of sulfide film influences the charge transport kinetics. Similar deviations have also been found for the anodic growth of metal oxides and sulfides (10, 11, 25). Since the quantity of charge represented by Peak III is much greater than the charge in Peak II, this process is not merely due to the transformation of the Sb₂S₃ phase to a higher oxidation state; rather, it involves additional oxidation of Sb metal to Sb (III).

The current maximum of Peak IV (Fig. 4b) is linear with respect to $\nu^{1/2}$, which again indicates a mechanism having a diffusion-controlled rds. However, the dependence of the Peak IV potential on ν was difficult to establish due to the broad current response.

Although neglected in the above scheme, the anodic sulfidation process probably involves hydration effects, and at the more positive potentials oxide (hydroxide) incorporation into the sulfide film. Miller *et al.* (26) demonstrated the influence of sulfide film breakdown and hydroxide incorporation on the photoelectrochemical activity of anodic CdS and Bi₂S₃ films.

Galvanostatic conditions.—Under a controlled anodic current density (i_a), the electrode potential must compensate for the rate of film formation and dissolution. In Fig. 6, the potential vs. anodic charge (E/Q_a) transients are shown for the initial passage of 8 mC/cm² under different i_a . Within the first few tenths of a millicoulomb, there is a rapid potential increase which approaches a nearly constant value after ≈ 3 mC/cm². The constant potential represents a stationary state, when the anodic current is no longer consumed by film formation (*i.e.*, constant film thickness) (27).

Figure 7 shows plots of $\log i_a$ vs. E at various constant anodic charge. The resulting Tafel slopes exhibit an in-

Fig. 6. Dependence of electrode potential on the anodic charge under galvanostatic conditions. Curves a through j: 8, 20, 40, 50, 75, 100, 150, 200, 250, and 500 μ A/cm², respectively.

crease with film thickness and are consistent with the values determined from the scan-rate dependence of Peaks I and II. This behavior indicates that a constant potential drop is maintained across the film during its growth. The growth of an anodic film involving ionic charge transport is described by an exponential function of the field strength, H , given by

$$i = A_0 \exp(BH) \quad [11]$$

where A_0 and B are electrolytic parameters and negligible ionic movement in the direction opposite the field is assumed (1, 2, 28).

The (E/t) transients for sulfidation show an extended initial linear response and lower slopes with a lower i_a . The slopes of the charging curves are related to the rate of film formation where the film thickness is represented by the following expression (29)

$$L = L_0 + mi(t - t_0)/r \quad [12]$$

where L_0 is the initial film thickness, m is the coulometric volume of Sb_2S_3 ($m = 2.85 \times 10^{-4} \text{ cm}^3/\text{C}$), and r is the roughness factor. Extrapolating the linear potential traces to $t = 0$ gives an intercept at $E_f^0 = -0.55\text{V}$, which is the minimum potential required for film formation. This value corresponds to the potentiodynamic film-formation potential E_{f0}^0 . The minimum current necessary for initiation of film growth is estimated to be $i_0 = 10 \mu\text{A}/\text{cm}^2$ for $dE/dt = 0$ and E_f^0 .

The slopes (log) of the linear charging transients are plotted vs. i_a (log) in Fig. 8. The steady-state rate of sulfidation is related to i_a by the empirical equation

$$(dE/dt) = a(i)^b \quad [13]$$

where a is the formation rate at unit current density. From the slope of the plot in Fig. 8, b has a value of 1.29, which compares favorably with values reported for the anodization of other value metals (29, 30).

Under a fixed i , the potential drop across the film (E_f) can be considered constant with a field strength

$$H = E_f/L \quad [14]$$

Using the high field approximation and Eq. [12] and [14], the electrode potential can be expressed as

$$E = \phi + (L_0/B) \ln(i/A_0) + (mi/rB) \ln(i/A_0) \quad [15]$$

and the film formation rate by

$$(dE/dt)_i = (Mi/rB) \ln(i/A_0) \quad [16]$$

where ϕ is the sum of the potential differences at all the interfaces. In a limited range the $\log(i/A_0)$ term in Eq. [16] is insignificant, which is in agreement with the experimentally observed linearity in Fig. 8. Using Eq. [16], the calculated values for B are between $2.11 \times 10^{-6} \text{ cm/V}$ and $4.78 \times 10^{-6} \text{ cm/V}$. The activation or "half-jump" distance (γ) can be obtained from the relation

$$B = \frac{Z\gamma F}{RT} \quad [17]$$

where Z is the charge of the migrating ion. The value calculated for γ ranges between 0.18 and 0.41 nm. The estimated electric field strength varies from $3.2 \times 10^5 \text{ V/cm}$ for the lowest currents to $6.4 \times 10^5 \text{ V/cm}$ for the highest currents applied. This variation in the field strength with current illustrates the effect of the film-

Fig. 8. Plot of sulfidation rate vs. current density.

Fig. 9. Dependence of cathodic charge on anodic charge under the galvanostatic condition $i = 50 \mu\text{A}/\text{cm}^2$.

formation potential under the applied current. The film-growth parameters determined above correlate reasonably well with the growth model based on a field-assisted ionic conduction, in spite of the fact that the following have not been accounted for: (i) the small changes in potential during film growth, (ii) not all anodic charge is stored as film, and (iii) the polycrystalline and nonstoichiometric nature of the sulfide film.

Figure 9 illustrates the relation between the anodic charge and corresponding cathodic reduction charge under a constant $50 \mu\text{A}/\text{cm}^2$. The quantity of charge stored as film or Q_c was determined as the amount of charge consumed while at the reduction potential under chronopotentiometric conditions. The results of the galvanostatic measurements coincide with the potentiodynamic results which indicate a $<100\%$ anodic film-production efficiency (i.e., charge-storage efficiency) after the passage of $\approx 2 \text{ mC}/\text{cm}^2$. Atomic absorption analysis of the electrolyte solution for Sb ions confirmed that more than 95% of the charge not residing in the film is due to film dissolution. This observation supports a cationic migration scheme according to the Cabrera-Mott model for film growth.

The amount of charge stored in the film, plotted as reciprocal Q_c vs. $\log t$ is linear, as shown in Fig. 10. During galvanostatic sulfidation, the electrode potential is taken as nearly constant, and thus the growth process follows the Cabrera-Mott model, where the integrated form of the rate equation yields the inverse logarithmic rate law

$$\frac{1}{L} = C - D \ln t \quad [18]$$

where C is a constant and $D = RT/Z\gamma F E_t$ (2).

Figure 11a shows a typical E/t transient for an Sb electrode at $250 \mu\text{A}/\text{cm}^2$. Two potential steps are exhibited with the second arrest having an initial potential peak. Discontinuing the current at any time in either step results in a potential drop to the same open-circuit potential ($E_{oc} = -0.45 \pm 0.01 \text{ V}$). The peak prior to the second arrest is attributed to a fast nucleation process in the solution phase involving a dissolution/precipitation mechanism (31). The inflection between the transition from the first to second potential arrest, and the peak is produced when a species such as a hydro-sulfo antimony complex (e.g., HSbS_2) in reversible equilibrium is consumed by nucleation and deposition, causing a lowering of the concentra-

Fig. 10. Dependence of sulfide film charge on growth time under (a) $50 \mu\text{A}/\text{cm}^2$ and (b) $250 \mu\text{A}/\text{cm}^2$.

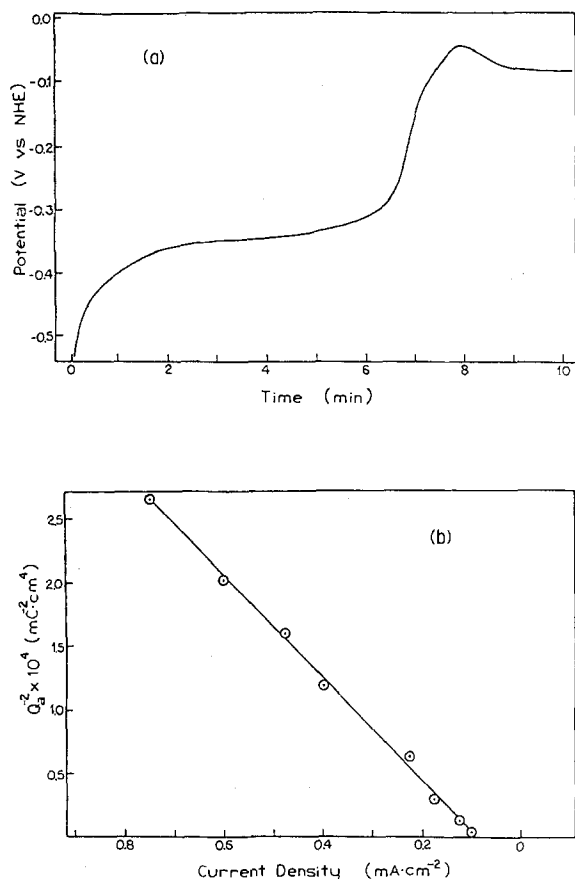

Fig. 11. A, top: potential transient under constant anodic current, $i = 250 \mu\text{A}/\text{cm}^2$. B, bottom: relation between anodic charge passed as $(1/Q_a^2)$ at the time of the potential inflection and current density.

tion polarization until a steady-state condition is reached. This diffusion-controlled process is also consistent with the results from the potential-scan experiments. In addition, processes involving sulfide film breakdown and oxide formation are also possible (26).

The transition from the first to second potential arrest assumed to be a change from a solid-state to a diffusion-limited growth process is dependent on the applied current density and the potential acquired. The quantity of charge required to induce the transition shown in Fig. 11b is represented by

$$1/Q_a^2 = i_{\min} + i_a \quad [19]$$

where i_{\min} is the minimum current needed to initiate the transitions. As extrapolated from the plot (Fig. 11b) $i_{\min} = 90 \mu\text{A}/\text{cm}^2$ at infinite time. In the equilibrium condition, the film thickness remains constant while the anodic current flow is consumed by film or metal dissolution.

ESCA analysis was used to further investigate the anodic sulfide films. The spectra ($\theta = 8^\circ$ and $\theta = 58^\circ$) of a film grown at $250 \mu\text{A}/\text{cm}^2$ to the second potential-arrest region revealed the presence of both a hydrated Sb_2O_3 outer layer and sulfide. The S_{2p} response showed two sets of doublets corresponding to S_2^{-2} and S^{-2} species. From the sulfur ratios, the structure of the sulfide component at the outer surface is a sulfide-polysulfide $\text{Sb}_2(\text{S}_2)_2\text{S}$ or Sb_2S_5 . The trend for the outer 30 Å of film indicates a compositional increase toward Sb_2S_3 and decrease in the Sb_2S_5 and hydrated Sb_2O_3 away from the outer surface.

From these results, it is inferred that the bulk of the film is present as Sb_2S_3 . The existence of polysulfide units in Sb_2S_3 is manifested by previous Mössbauer studies showing Sb in Sb_2S_3 exists only in the Sb (III) state (32, 33). Thus, the sulfidation at higher potentials probably results in the additional oxidation of sulfide to polysulfide during film growth and oxide (hydroxide) incorporation without oxidation of Sb to the (+5) state.

Photoelectrochemical spectral measurements of these semiconducting sulfide films gave the same bandgap for films grown at low and high potentials. The value of 1.7 eV is consistent with that of bulk crystalline Sb_2S_3 (12).

Potentiostatic conditions.—Analysis of the time dependence of the current response to a potential step can be used to investigate film-formation processes. Current transients (i/t) for an electrode subjected to a positive potential pulse exhibit high currents during the initial few milliseconds due to the charging of the double layer. The current decay thereafter is in response to the buildup of film on the surface until a steady-state condition is reached. Under potentiostatic conditions, the expression which relates the current to the charge accumulated in the film (Q_f) is given by

$$i = K \exp(cE - Q_f/d) \quad [20]$$

where K , c , and d are potential-independent constants (28). In this model, it is assumed that film growth occurs through a cation/anion place exchange in the film where the activation energy for growth increases linearly with film thickness. Integrating Eq. [20] yields the following equation relating i , t , and E

$$1/i = (t/d) + (1/K) \exp[(Q_0/d) - cE] \quad [21]$$

where Q_0 is the charge associated with the film at the time of the potential step. The integrated form of Eq. [21] gives a direct logarithmic growth-rate law.

For antimony sulfide film formation, the initial state of electrode surface is taken as film free or $Q_0 = 0$ at $t = 0$. Figure 12 shows the resultant current transients at different potentials plotted as reciprocal i vs. t . In the plots shown, the zero-time intercept decreases with E , as predicted by Eq. [21]. The value of d as determined from the slopes depends exponentially on E with a 195 mV/decade gradient. However, the parameter d is supposedly related to the chemical-activation energy and is therefore only a function of temperature. Such a dependency of d on E has also been found for the growth of oxides on Sn (29) and Fe (30), and is still a matter for debate.

Fig. 12. Relation between reciprocal current and time under the potential steps. a through d: -0.43 , -0.39 , -0.34 , and -0.14V , respectively.

Fig. 13. Repetitive triangular potential scans with varied $E_{\lambda,c}$ at $\nu = 20$ mV/s. $E_{\lambda,a} = -0.20$ V.

The plots in Fig. 12 also deviate from linearity in the initial few seconds. The current is linearly related to $t^{-1/2}$ at short times. One explanation for this behavior is that since d is a time-independent constant, the initial deviation is due to the exponential term in Eq. [21] where $c = F/2\Phi RT$ cannot be assumed constant. In other words, the term $(1/K) \exp(-cE)$ must initially decrease with time until it reaches the value at the $1/i$ vs. t intercept. This can be explained on the basis that Φ , representing the ratio between the occurrence of the rate-determining step to that of the overall reaction, might be comparatively small when there is little or no film on the surface, but then increases with time until a steady-state value is attained.

The potentiostatic film-growth data can also be successfully described using the "point-defect model" (3). In this model, the initial current transient associated with very thin films varies inversely with the square root of time. At longer times, the current varies inversely with time, leading to a logarithmic rate law for film growth. The model also assumes that the migration of anion vacancies through the film results in film growth, while the migration of cation vacancies results in metal dissolution. The metal cations at the film/solution interface are also considered to be in equilibrium and can result in film growth through reprecipitation.

Potentiodynamic film reduction.—Further information concerning the growth and properties of the sulfide films can be obtained by studying voltammetric film-reduction behavior. The influence of the cathodic scan potential limit ($E_{\lambda,c}$) on the anodic current profile is shown in Fig. 13. In each case, the potential is first held at -0.20 V for 30 s then scanned in the negative direction. On the positive going return scans, the anodic response is negligible for $E_{\lambda,c} > -0.68$ V. As $E_{\lambda,c}$ is made more negative, the subsequent positive scans exhibit anodic current over much of the same potential region, and with increased film removal the magnitude of the response is greater.

The most commonly used reduction model involves the transport of cations through the film and reduction at the metal/film interface (34). This model is the reverse of the high field anodic-growth mechanism. According to the ionic conduction mechanism, the anodic-

current response during a positive potential scan for the case where there is some film present on the electrode should remain small until the anodic field across the film can support ionic transport (35).

The reanodization profiles in Fig. 13 suggest that sulfidation and growth proceeds at potentials positive of the critical formation potential at a reduced rate on a partially removed film. Therefore, it is assumed that reduction to Sb metal occurs at the outer surface, as opposed to being formed at the metal/film interface. Instead of an ionic mechanism, the reduction can be expressed as an electronic migration process, where

It is further assumed that electron injection occurs over a low energy barrier at the metal/film interface (35). This mechanism is in agreement with the rectification properties (n-type semiconductor) of these anodic films, in which electronic current is not easily passed under anodic conditions, but can readily flow under cathodic bias (12).

The reduction of the anodic Sb_2S_3 films is usually observed as a single cathodic peak prior to H_2 evolution. The reduction response is dependent on both film thickness and sweep rate. Figure 14 illustrates the influence of scan rate on the reduction response for both a thin film (curve a) and a thick film (curve b). The thin sulfide films ($\approx 10 \text{ \AA}$) were potentiodynamically grown at 20 mV/s to -0.40 V, while the thicker films ($\approx 500 \text{ \AA}$) were formed at 100 mV/s to $+0.65$ V.

The sweep-rate effect on the reduction-peak parameters for the thin film case is depicted by the plots in Fig. 15a. The linear relations, i_m vs. ν and E_m vs. $\log \nu$ (25 mV/decade slope) are consistent with a reduction mechanism involving consecutive electrochemical reactions in which the third electron-transfer step is rate determining. Accordingly, the Sb ions in the thin film grown to -0.40 V are reduced from the (+3) state to Sb metal. The results correlate with the proposed mechanism involving the formation of an Sb_2S_3 phase at Peak II.

Figure 15b shows the $\nu^{1/2}$ dependence of the reduction-peak parameters for a thicker sulfide film. These characteristics for the peak parameters can be explained by a dissolution/precipitation process under ohmic-resistance control (36, 37). Assuming that the Sb_2S_3 film

Fig. 14. Potentiodynamic reduction profiles for (a, right) thin sulfide film and (b, left) thick sulfide film

reduction occurs through electronic transport from the underlying metal to the film/solution interface, metal from the freshly reduced film would initially appear at discrete surface positions where electrons are likely to be trapped, e.g., anion vacancies. Such centers could act as nucleation sites which collect the Sb atoms diffusing across the surface. The newly formed Sb deposit occupies less volume than the sulfide. Thus, as the sulfide phase continues to be reduced at discrete locations, the reduction process can be envisaged as resulting in the development of channels in a dendrite fashion extending through the film to the metal substrate, where now the newly formed Sb metal accumulates at the base of the channels (35). This concept is substantiated by the

voltammetric-reduction results discussed above, where the current flow upon resulfidation of a partially reduced film depends mainly on the area of the film removed, rather than showing a threshold-voltage dependence, which would prevail for a uniform thinning of film.

It is believed that in the latter stages of film reduction the fresh metal deposits grow and spread to cover the base substrate. The reduction of the thicker films is then limited by the resistance in the pores between the Sb deposits given by

$$R = L_d/\delta A(1 - \theta) \quad [23]$$

where L_d is the deposit thickness, δ is the specific conductivity of the solution, A the surface area, and θ is the fraction of surface occupied by the newly deposited metal. Under potentiodynamic conditions, the following equations describe the sweep rate dependence of the peak maxima

$$i_m = (nF\rho\delta/M)^{1/2} A(1 - \theta_m)\nu^{1/2} \quad [24]$$

$$E_m = (nF\rho\delta/M)^{1/2} [(L_d/\delta) + R_s A(1 - \theta_m)]\nu^{1/2} \quad [25]$$

where R_s is the bulk solution resistance, θ_m is the coverage at the peak maximum, and M is the molecular weight of Sb (36, 37). Using Eq. [24], θ_m from Fig. 15b was estimated to be 0.9991, assuming the physical properties for Sb metal. This θ_m value is in good agreement with the model, which assumes that the layer-pore resistance is relatively small until the surface is beyond 99% covered (36).

Conclusions

The electrochemical investigation of antimony in alkaline sulfide solutions has demonstrated that anodization results in the formation of an antimony (III) sulfide film. The first anodic process possibly involves the adsorption of hydrosulfide onto the surface, followed by the nucleation of an Sb_2S_3 phase and its lateral spread across the electrode. The growth kinetics follow different rate laws, depending on whether film growth is produced by an applied current or an applied potential. However, considering the approximations made in the inverse and direct logarithmic rate models, they are nearly equivalent when considering small changes in the film thickness such as the situation during initiation of film formation.

The initial stage of film thickening has been interpreted as a high field-assisted ionic-migration process with, possibly, the rate-limiting energy barrier being at

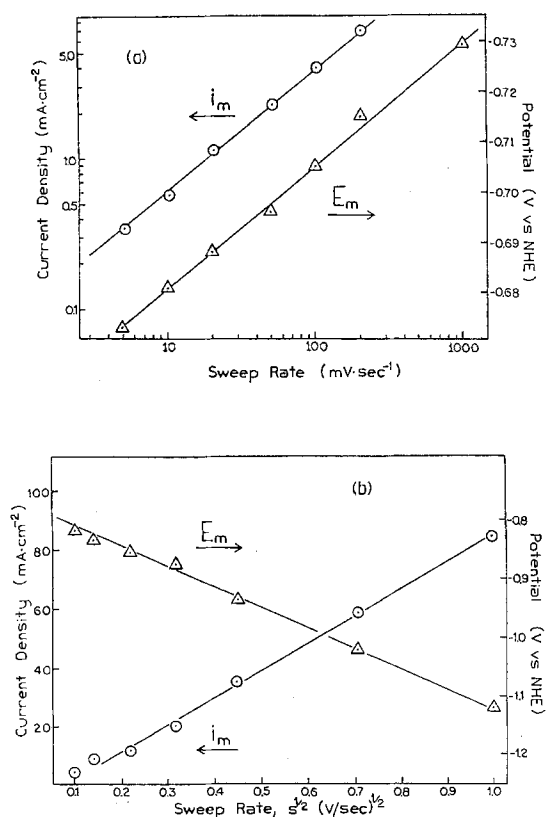

Fig. 15. Dependence of the reduction peak i/E maxima on ν for the (a, top) thin film and (b, bottom) thick film

the film/solution interface. The nature of the films is nonstoichiometric, which might be due to the differences in the cationic and anionic conductivities. A simple electrostatic approach has been taken in discussing the anodic films. Under anodic conditions, the films exhibit resistance to electronic transport, in accordance with their n-type semiconductor properties (12). For thicker films grown positive of -0.40V , the growth mechanism is controlled by a dissolution/precipitation process resulting in a porous antimony sulfide layer with some hydrated oxide incorporated into the film.

The reduction behavior of the sulfide ($E^\circ = -0.76\text{V}$) has been found to be dependent on the film thickness and sweep rate. For films a few monolayers thick, reduction proceeds through three consecutive electron transfers from Sb(III) to Sb(0). The reduction of thicker films is limited by resistance in the pores between the deposited-metal sites. Under cathodic conditions, charge transport through the films is predominantly due to electronic conductivity. Reduction occurring at the film/solution interface results in the deposition of a porous metal surface layer.

N_a	number of electrons in rds
Q_0	initial film charge
Q_a	anodic charge
Q_c	cathodic charge
Q_t	total film charge

R_s	bulk solution resistance
rds	rate-determining step
r	roughness factor
t	time
Z	charge of migrating ions

Greek Symbols

α	transfer coefficient
γ	activation distance
δ	solution specific conductivity
θ	fraction of surface covered by Sb deposit
θ_m	fraction of surface covered at i/E peak maximum
ν	potential scan rate
ρ	density
Φ	ratio of the rds to overall reaction occurrence
ϕ	sum of all interfacial potential differences

An Ionized Air Reference Electrode

I. Principles of Operation

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

A novel ionized air electrode (IAE) has been investigated for use as a reference electrode in electrochemical systems. The IAE employs a low level source of ionizing radiation (Am-241) to ionize an air gap, thereby establishing electrical contact with the electrolyte of an electrochemical system without introducing a liquid junction potential and its associated uncertainties, such as contamination of the test solution. Other advantages of the IAE include operation over an extremely large temperature range, long life, high durability, low cost, simple design, and freedom from maintenance. Studies of the effects on electrode behavior of factors such as electrode configuration and materials of construction are presented. Preliminary measurements indicate that it may be possible to use the IAE to replace conventional reference electrodes, such as the saturated calomel electrode, in electrochemical measurements such as the electrometric determination of pH.

Commonly used reference electrodes, such as the saturated calomel electrode, suffer from limitations resulting from the direct physical contact made with the test solution by way of a liquid junction. Diffusion contamination of the test solution and the internal solution of the reference electrode is troublesome. In addition, the liquid junction potential (LJP) is often difficult to evaluate. In aqueous solutions, such LJP's generally are in the order of ± 10 mV (1). Ionic activities in nonaqueous media can vary so much from the values in aqueous solutions that LJP's between aqueous and nonaqueous solutions can be as large as several hundred millivolts. In such cases, commonly used reference electrodes often do not function very well because the unknown LJP can comprise a large fraction of the total measured electrode-potential difference. Furthermore, because of hysteresis effects, thermal disproportionation reactions, decomposition reactions, and the presence of a volatile aqueous phase, familiar reference electrodes such as the calomel electrode or the Ag/AgCl electrode are not very amenable to use at elevated temperatures.

In view of the above problems, a reference electrode that functions through a mechanism that differs from those encountered in the above-mentioned conventional systems might, under certain circumstances, serve as a useful alternative that suffers from fewer, or less severe, limitations. In the present paper, we describe a secondary reference electrode that is based on the use of an ionized air gap to contact the surface of the test solution (2-4). Such an electrode eliminates ionic contamination and permits use over a wide temperature range, including use with molten salts.

Ionized air electrodes (IAE) have been used in conjunction with standard reference electrodes since 1924 as indicator electrodes to study the surface potentials (χ) of solutions (5-7). The technique employed by all the early workers suffered from the major drawback of the very short half-life (138 days) of the Po-210 that was used to ionize the air. This required the frequent preparation of fresh electrodes from a stock solution of radium bromide. In 1960, Kamienski and co-workers (8) began using plutonium-239 as the ionizing source. Pu-239 has a much longer half-life than Po-210 (24,000 yr vs. 138 days), and decays with mono-energetic alpha particles of an energy about equal to that of Po-210 alpha particles. Using a 2 μ Ci source above a 0.1M potassium chloride solution, it was found that the time required to attain a steady potential varied from about 3 to 25 min. In 1964, Kamienski and Czarnecki (9) greatly reduced the time required to obtain a steady potential by increasing the activity of the alpha particle source to 20 μ Ci, permitting the use of electrode-solution separations of up to 1.5 cm to protect the elec-

trode from wetting. In more recent work americium-241 has been used as the ionizing source by Volthardt and Wustneck (10) and by Costa and co-workers (11, 12).

In spite of the previous use of the IAE as an indicator electrode to measure solution surface potentials, it would appear that, prior to the present work, such an electrode has not seriously been tried as a reference electrode. Possibly this oversight has resulted from concern about the variation of the surface potential from solution to solution or from concern about the reproducibility of the surface potential in seemingly identical solutions.

The magnitude of the surface potential that exists at a pure water/air interface is believed to be of the order of 0.13 ± 0.02 V, as a consequence of a net alignment of water molecules in the first few monolayers of the liquid phase (12-16). Experiments have demonstrated that the aqueous phase is positive relative to the air, indicating that the hydrogen ends of the water dipoles are directed inwards towards the bulk of the liquid phase (17-21). Insofar as this surface potential is reproducible and constant, it poses no impediment to the use of the IAE as a reference electrode. Unfortunately, the surface potential of water is shifted by the presence of dissolved solutes, so that such a variation poses a limitation on the use of an IAE as a reference electrode. Conversely, the LJP that is established between most conventional reference electrodes and a test solution also varies from solution to solution, giving rise to a similar limitation on the reproducibility and constancy of the reference potential.

In general, simple electrolytes such as the alkaline metal hydroxides, fluorides, chlorides, and sulfates exert only a small effect ($\Delta\chi$) on the surface potential of water (22, 23). At 0.1M concentration, aqueous solutions of the majority of common electrolytes exhibit surface potentials within ± 2 mV from the value for pure water. Furthermore, except in the presence of surface-active agents [which can alter the surface potential drastically (19, 20)], or at very high concentrations of solute, the shifts from the value for pure water are seldom greater than ± 10 mV (12, 22-24).

Similarly, the effect of solution pH on the surface potential of an aqueous solution does not seem to be significantly worse than the corresponding effect on a LJP. Kamienski (25), for example, has shown that dilute hydrochloric acid exerts negligible effect on solution surface potential over the pH range of 2 to 12. He also has shown that over the pH range of about 6 to 10 even certain surface active agents such as 0.025M p-hydroxybenzoic acid do not change the surface potential of the solution by more than about 10 mV (20). Admittedly, as is evident from Table I, in more concentrated acid solutions, the surface potential does change quite significantly from the value for pure water (22). However, as can be seen from Table II (1), LJP's also undergo large changes at extreme values of pH.

A preliminary design for an ionized air reference electrode employed a single element consisting of a 100 μCi source of americium foil, which served both as ionizing source and current collector (2). The element was kept suspended about 1 cm above the liquid in a shielded glass tube. This electrode was used to replace the SCE as reference electrode in a series of glass-electrode pH measurements in aqueous solutions of widely varying pH and ionic strength and in methanol-water systems.

Although this preliminary reference electrode performed well, producing pH measurements of good quality, the time required to reach a steady-state potential was long (10 ~ 15 min) and a slow potential drift about $5 \text{ mV} \cdot \text{h}^{-1}$ was observed. In the present study, the electrode design has been modified to reduce the response time and potential drift by using the Am-241 foil only as an ionizing source and by providing a separate, electrically isolated collector element.

In order to determine the suitability of the IAE for various proposed applications, design parameters such as ionization build-up time, potential, and resistance, as functions of source height, composition of ionized gas, and composition of collector metal have been studied.

Experimental

Electrode construction.—The design of the Am-241 ionized air reference electrode (IAE) is shown in Fig. 1. The electrode housing (B) is constructed in two parts, the upper containing the source (A) and the lower containing the collector (D). The upper housing is a double layer of Pyrex glass tubing closed at the top with the layers being separated by 0.002 cm thick lead foil, which serves as an electrostatic shield around the ionized air. The lower housing is constructed of a single layer of Pyrex glass tubing. Five lower housings were constructed, each with a different collector metal. The gas inlet (C) is 5 mm id glass tubing that connects directly to the gas supply via a short length of Tygon tubing. The two-part housing was constructed to allow the source-to-collector spacing to be easily varied from about 0.5 to 6.0 cm and to facilitate the use of the same Am-241 source for each of the different collectors.

Fig. 1. Details of Am-241 ionized air reference electrode. A = Am-241 source; B = housing; C = gas inlet; D = collector electrode; E = connection to electrometer; F = surface of electrolyte.

The americium-241 alpha-particle source (A) is a disk (approximately 0.83 cm diam) of 100 $\mu\text{Ci}/\text{cm}^2$ Am-241 foil with an activity of approximately 57 μCi . Am-241 has a half-life of 433 yr and emits alpha particles at an energy of 5.5 MeV. The 2 μm thick gold covering on the foil, required to keep structural integrity of the Am-241 layer, somewhat reduces the average alpha particle energy.

The collector element (D) is constructed of 50-mesh screen and is of approximately 1 cm diam. Collectors were constructed from platinum, copper, nickel, iron, and brass. Electrical connection to the collector is by the center conductor of RG 58/U coaxial cable with the braid connected to the Am-241 source and the internal shield of the upper housing.

Measurements.—Voltage measurements were made using a Keithley 610 C electrometer. A Keithley 370 strip chart recorder was used with the electrometer for the measurement of voltage-time behavior. A Corning Model 7 pH meter was used in the millivolt mode for pH measurements. The conventional electrodes employed consisted of a Beckman Model 40498 glass electrode and a Fisher Model 13-639 saturated calomel reference electrode, both of which were new at the start of the work.

Reagents and materials.—Reagent grade chemicals dissolved in doubly distilled water were used for all aqueous solutions. Fisher Certified Buffer Solutions of pH 1, 2, 4, 6, 8, and 10 were used in the pH measurements. Laboratory grade gases (H_2 , He, Ne, Ar, CO_2 , CH_4 , O_2 , and air) supplied from gas cylinders were used without further purification in the experiments dealing with the electrode performance in different gaseous environments.

Temperature regulation.—The temperature was held constant using a water bath controlled by a Philadelphia Roto-Set adjustable mercury-switch temperature controller, which was connected to a 50W electric immersion heater through an electronic relay. Temperatures below 25°C were obtained by adding ice to the water bath to stabilize the heater at the lower temperatures. To reduce the possibility of electrical interference, the water bath was circulated around the experimental electrode assembly from outside the Faraday cage used to contain the cell, using a $50 \text{ ml} \cdot \text{s}^{-1}$ pump. For each experiment, an equilibration time of about 2h was allowed to ensure that the test assembly was at the desired temperature.

Experimental Results and Discussion

Potential gradient profiles.—If the americium ionized air electrode (IAE) is to be used in applications such as voltammetry, which involve making measurements in an applied electric potential field, the electrode must maintain a constant potential in the applied field. This property of the electrode was tested by constructing the device shown in Fig. 2. By passing a constant current through the platinum electrodes in the aqueous KCl solution, a potential gradient is established between the electrodes that is linear over most of the separation distance. By recording the potential of the test electrode (T) vs. the stationary electrode (R) at various distances (x) along the slider, the voltage-distance profile in the KCl solution can be obtained. If the profile is linear with a slope equal to the product of the solution current density and the solution resistivity, then the potential of the test electrode is constant in the applied electric field.

Figure 3 shows the results of such an experiment, during which an applied potential difference of 3.0V was placed across the two Pt electrodes (spaced 20 cm apart in 0.1M KCl at 22°C), driving a constant current of 1.3 mA through the cell. With an electrolyte resistivity of $78 \pm 2 \Omega\text{-cm}$ and an electrolyte cross-sectional area of $3.8 \pm 0.2 \text{ cm}^2$, the theoretical slope of the profile is $26.5 \pm 2 \text{ mV} \cdot \text{cm}^{-1}$ (95% confidence limits). Using a SCE as the stationary reference electrode (R), the lower line shows the profile obtained using a SCE as test electrode ($24.9 \pm 2.5 \text{ mV} \cdot \text{cm}^{-1}$), while the upper line shows the profile obtained using the IAE as test electrode ($24.5 \pm 2.2 \text{ mV} \cdot \text{cm}^{-1}$). The IAE employed a Pt collector at 0.5 cm above the solution with a 57 μCi source at 4.0 cm above the collector.

Both experimental slopes deviate by less than 10% from the theoretical value and by less than 2% from each other. A statistical test at the 97% confidence level indicates no significant difference between the theoretical and experimental slopes.

Response time.—In measuring the potential developed between a SCE previously placed in 0.1M KCl solution at 22°C and the IAE, the initial rise time of the IAE, *i.e.*, the time taken to fully build up the ionized air gap from $t = 0$ when the glass shell of the IAE is first placed adjacent to the solution surface, is in the order of 20 ~ 60s. When used in conjunction with a glass electrode in a pH meter application, the effect of this response time is unimportant, since it is less than the time required for the glass electrode to stabilize in the solution. If desired, the response time probably could be shortened by narrowing the tip of the IAE, possibly to capillary dimensions, thereby better maintaining trapped ionized air within the electrode shell.

The longer time-response stability of the potential developed by the IAE over pH 4.00 buffer solution at 25°C also was determined. The drift in the potential difference between the IAE and the SCE over a period of 8h was only $1.5 \cdot 10^{-4} \text{ V} \cdot \text{h}^{-1}$. In the same solution the drift in the potential difference between the IAE and the glass elec-

trode was equivalent to approximately 0.15 pH units over the same 8h period. An analogous study using a SCE vs. a glass electrode showed a drift similar to that using the IAE vs. glass electrode system, indicating either that the drift was attributable primarily to the particular glass electrode used or that the IAE and SCE used both exhibited about the same amount of drift.

Electrode resistances.—The IAE consists of two parallel conduction paths: collector to ground via the source (R_s), and collector to ground via the solution and external circuitry (R_g). Unless the resistance of the collector-to-source path is much higher than that of the collector-to-solution path, its presence can cause an error in the IAE potential measurements. A source-to-collector resistance of 100 times that of the collector-to-solution path can be expected to produce a measured error of about 1%.

The electrical resistances R_s and R_g were measured using the Keithley electrometer in the high impedance ohmmeter mode. As can be seen from Fig. 4, R_s increased rapidly with increasing source-to-collector separation (h). R_g was measured with the collector at a height of 0.5 cm above the 0.1M KCl solution. Electrical connection to the solution was made via a platinum wire with the end placed in the solution approximately 1 cm directly below the collector. The resistance of the 0.1M KCl solution was negligible compared with that of the air gap.

The high magnitude of R_g ($10^{10} \sim 10^{11} \Omega$) indicates the need for a very high impedance voltmeter to be used with the IAE. Electrometers and good-quality pH meters have comparable and suitable input impedances in the order of $10^{14} \Omega$.

Alpha particles of 5.5 MeV energy that are emitted into air ionize the air, producing a maximum number of ion pairs per centimeter at a distance of about 4 cm from the source, with the rate of ionization decreasing rapidly at distances greater than this (26). As discussed below, the metal collector interacts with these ionized air particles; therefore, it was deemed optimal to locate the collector at a distance of $h = 4$ cm from the Am-241 source. With regard to the collector-to-solution distance, it was found

Fig. 4. Variation of source-to-collector resistance (R_s) and collector-to-solution resistance (R_g) with source-to-collector separation distance (h). 0.1M KCl solution.

that when this distance was made less than 0.5 cm, the reproducibility of the IAE was hampered by the condensation of water vapor on the surface of the collector. Conversely, if the collector-to-solution distance was increased to beyond 0.5 cm, in order to maintain a sufficiently high ratio of R_s to R_g it would have become necessary to increase the collector-to-source distance (h) to greater than 4 cm, which was considered undesirable. For these reasons, a collector-to-solution distance of 0.5 cm was considered to be the optimum practical distance. Consequently, most of the subsequent experimental work was performed with the collector 0.5 cm above the solution and the source 4.0 cm above the collector. Under these conditions the collector-to-solution resistance is about $10^{11}\Omega$, and the error in the measured voltages due to the voltage drop across the voltmeter is about $10^{11}/10^{14}$ or 0.1%. The R_s/R_g ratio of approximately 100 leads to a measurement error of less than 1%.

IAE potential vs. source height.—In Fig. 5, the potential of the IAE is plotted as a function of the source-to-collector distance, the platinum collector being fixed at a height of 0.5 cm above the 0.1M KCl solution. It can be seen that the potential becomes more positive as the source height is increased, indicating that it is possible to change the potential of the IAE by altering the source height. The practicality of this change is, however, limited by the restrictions on the electrode resistances discussed in the previous section.

Influence of the gas used for ionization.—It has been known since 1897 (27) that the voltage generated at an ionized gas electrode is affected by the nature of the gas ionized. To investigate this design parameter an experimental cell consisting of an ionized gas electrode, an

Fig. 5. Potential of IAE vs. source-to-collector separation distance (h). 0.1M KCl solution.

aqueous 0.1M solution of KCl, and a SCE was used with various gases as the absorbing medium. The results, shown in Fig. 6, indicate that a wide variation in the voltage of the IAE results from variation in the gas ionized and that the molecular weight of the gas is a property of major influence.

Alpha particle energy loss occurs mainly through ionization and excitation of the absorbing medium. Inelastic collisions of α -particles with loosely bound outer elec-

Fig. 6. Potential of IAE vs. molecular weight of gas used for ionizing medium. 0.1M KCl solution. Source-to-collector distance = 4 cm; collector-to-solution distance = 0.5 cm.

trons in the atoms or molecules of the absorbing gas result in the ejection of the struck electrons, *i.e.*, primary ionization of the atoms or molecules (28). The ejected electrons (delta particles) may possess sufficient kinetic energy to cause secondary ionization of the gas molecules, with the result that the total ionization may be several times larger than the primary ionization (29). A simple calculation (see Appendix) for the IAE used in the present study indicates that, when the absorbing medium is air, the steady-state concentration of ions will be about 2×10^8 ions/cm³.

To explain the effect of different gases, it appeared reasonable to postulate that the potential established at the IAE might be related to the average specific ionization of a given gas, *i.e.*, the average total number of ions produced by an α -particle per unit path length traversed. This is given by

$$-\frac{(dE/dx)_{AV}}{W} \quad [1]$$

where $(-dE/dx)_{AV}$ is the average rate of α -particle energy loss with distance and W is the mean energy expended to form an ion pair in a given gas. Since W is constant over a wide energy interval, the average specific ionization is approximately proportional to the average rate of energy loss (28). This, in turn, is related to the properties of the gaseous medium through the terms N , Z , and I in the well-known Bethe equation (28-33), which, when expressed in SI units takes the form

$$-\frac{dE}{dx} = \frac{e^4 z^2 N Z}{4\pi\epsilon_0^2 m_e v^2} \ln \left(\frac{2m_e v^2}{I} \right) \quad [2]$$

where E = energy of the α -particle (J), x = distance (m), e = electronic charge (C), z = valence of the α -particle ($2 \geq z \geq 0$), N = number of atoms in the absorbing medium (m⁻³), Z = atomic number of the absorbing medium, ϵ_0 = permittivity of free space (C · V⁻¹ · m⁻¹), m_e = rest mass of the electron (kg), v = velocity of the α -particle (m · s⁻¹), and I = effective ionization potential of the absorbing medium (J).

The valence, z , of an α -particle is a function of its (kinetic) energy, ranging from $z = 2$ at energies greater than

3 MeV (4.8×10^{-13} J) to $z = 0$ (corresponding to a neutral helium atom) when the particle essentially has been "stopped" by the absorbing medium. By substituting an expression for $z = f(E)$ (34) into the Bethe equation, the equation can be numerically integrated for each gaseous medium [the Bragg Additivity Rule (35) being used for compound gases] to yield a reasonably accurate value for the average "stopping power" $(-dE/dx)_{AV}$ for each gas

$$(-dE/dx)_{AV} = E_0/l \quad [3]$$

where E_0 is the initial energy of the α -particle and l is its range in the given medium, given by

$$l = \int_0^{E_0} \left(-\frac{dE}{dx} \right)^{-1} dE \quad [4]$$

Figure 7 shows a plot of the voltage of the ionized gas electrode *vs.* the average specific ionization for each gas, as calculated using Eq. [1]-[4]. It is evident that, with the exception of argon and helium, the correlation is somewhat better than that obtained by plotting the voltage *vs.* the molecular weight (*cf.* Fig. 6). The deviations for helium and argon are readily explained by the so-called "Jesse Effect" (36), which refers to the marked increase in the total amount of ionization of noble gases when very small amounts of certain other gases are added. Thus, when less than 1% of nitrogen is added to helium, the value of W drops from 46 eV/ion pair to about 30 eV/ion pair, resulting in a 50% increase in specific ionization. Similarly, in argon, the presence of small amounts of carbon dioxide, for example, greatly increases the specific ionization of the argon. These marked increases in the observed ionization of noble gases, which may be brought about by only a few hundred parts per million of various gases, can be explained in terms of the transfer of excitation energy from the main gas component to the minor gas component. Since only cylinder-grade gases were used and no special precautions were taken to exclude small amounts of contaminant gases, it is likely that the actual values for the specific ionization of argon and helium are much greater than indicated by the calculated values shown in Fig. 7, which would have the effect of

Fig. 7. Potential of IAE vs. average specific ionization. 0.1M KCl solution. Source-to-collector distance = 4 cm; collector-to-solution distance = 0.5 cm.

shifting the relevant data points to the right to fall in line with the behavior of the other gases.

The results shown in Fig. 7 indicate that the mechanism by which a potential is generated at the IAE depends more on the number of ions present in the ionized gas than it does on the particular gas ionized. This might mean that the potential-determining ionized species is the same for all the gases employed. In pure air, for example, it is known that initially almost all the species are ionized with equal probability; but that within nanoseconds these ions transform into certain dominant species (37). In air, the dominant positive ions are $(\text{H}_3\text{O})^+(\text{H}_2\text{O})_n$ and $(\text{NH}_4)^+(\text{NH}_3) \cdot (\text{H}_2\text{O})_n$, whereas the dominant negative ions are $(\text{O}_2)^-(\text{H}_2\text{O})_n$ and $(\text{CO}_4)^-(\text{H}_2\text{O})_n$, with n ranging from 2 to 6. A common species present in all the gases employed was water, present to the extent of about 3% (assuming saturation at 25°C from the aqueous electrolyte). This implies that the ions $(\text{H}_3\text{O})^+(\text{H}_2\text{O})_n$ and/or $(\text{O}_2)^-(\text{H}_2\text{O})_n$ might be the potential-determining species.

Although air is preferred because of the simplicity of the electrode system, other gases may be useful under special circumstances.

Influence of the collector metal.—It also has long been known that the potential of an IAE is influenced by the metal chosen for the collector element (27). To investigate this aspect, collector screens made from several different metals were used with air as the ionizing gas in a configuration similar to that used for the previous section. As can be seen from Fig. 8, the potential generated by the IAE increases linearly with an increase in the electronic work function (Φ) of the metal used for the collector element (38). This dependence confirms that the voltage-determining mechanism involves electron exchange at the collector/gas interface. A metal with a high electronic work function has a strong affinity for electrons. This means that it has more electron energy states than does a metal with a low electronic-work function, so that electrons are readily accepted without conferring a negative charge to the surface of the metal. Conversely, a metal with a low electronic-work function accepts electrons with an accompanying tendency to acquire a nega-

tive surface charge. The above reasoning accounts for the variation of potential with Φ . The data plotted in Fig. 8 also confirm the constancy and reproducibility of the surface potential at the electrolyte/air interface, since, if any variation in this quantity from experiment to experiment were greater than a few millivolts, such variation would show up in Fig. 8 as additional scatter.

With regard to the potential-determining species at the collector/air interface, early work by Townsend (39) proved that negatively charged ions in air not only were more mobile than positively charged ions, but also had a greater affinity for water. It is thus suggested that the potential-determining reaction for the IAE might be

Use in pH measurements.—In order to test the IAE as a reference electrode for practical pH measurements, measurements were made under a variety of conditions using a commercial glass electrode pH meter with the SCE reference electrode replaced by the IAE. The IAE used for this practical application consisted of a 57 μCi source set at 4.0 cm above a 50-mesh Pt collector in air, the collector in turn being 0.5 cm from the solution surface. The IAE system was found to give a relatively rapid response and to be reasonably free from drift or instability, although it was somewhat less rapid and stable than the SCE reference system. In general, the values of pH measured in aqueous solutions at room temperature were indistinguishable from the values obtained using a SCE reference both in magnitude and precision as shown, for example, in Fig. 9, plot A. Plot B illustrates the magnitude of the errors introduced by the use of a small source-to-collector distance. The slope of the $h = 4.0$ cm line (plot A) is -0.059 ± 0.002 V/pH unit while that of the $h = 2.0$ cm line (plot B) is -0.0185 ± 0.003 V/pH unit, both by least squares linear regression. The theoretical slope of these lines at 25°C is -0.05915 V/pH unit. For plot A, the resistance ratio is $R_s/R_g = 100$. Therefore there is negligible error caused by the parallel conduction path error. For plot

Fig. 8. Potential of IAE vs. work function of collector metal. 0.1M KCl solution. Source-to-collector distance = 4 cm; collector-to-solution distance = 0.5 cm.

Fig. 9. pH response: use of IAE in combination with a glass electrode and a pH meter. 25°C. (●) Source-to-collector distance = 4.0 cm, (▲) Source-to-collector distance = 2.0 cm. Collector-to-solution distance = 0.5 cm.

B, $R_s/R_g = 2.33$. The large error caused by this low ratio was as expected. This error could be reduced by increasing the source-to-collector distance, but this also would cause an increase in the electrode response time. A suitable trade-off among these factors has to be established for a given application and incorporated into the electrode design. The 0.5 cm collector height combined with the 4.0 cm source-to-collector separation was found to be practical for the experimental work reported here.

Similar satisfactory results were obtained at various temperatures in the range 10°-50°C. Preliminary pH measurements in methanol-water systems using the IAE reference electrode also were without significant difference from SCE measurements. These, and other practical applications of the IAE will be reported in detail in the subsequent paper.

Areas for further study.—One problem area encountered with the IAE is the great care required in providing adequate electrical shielding to the system. To achieve reproducible measurement, it was found necessary not only to provide electrical shielding to both the IAE and all the leads, but also to place the complete assembly (cell, electrometer, temperature bath, etc.) in a Faraday cage and to stand back from the assembly while taking readings. Apparently, capacitance effects from the human body are strong enough to influence the electrometer readings.

A second problem is voltage drift from what appears to be moisture condensation on the collector element. This was encountered if the collector was closer than about 0.5 cm from the surface of the aqueous test solution or if the air temperature was permitted to drop several degrees over a short period of time. Methods of circumventing this problem might be the provision of a small heating element in the electrode casing, continuous flushing with relatively dry ionizing gas, or the provision of a hydrophobic microporous plastic cap over the tip of the IAE. This problem is unlikely to occur in nonaqueous or high temperature applications.

A third concern, more of theoretical than practical significance, is how to correlate the potential of the IAE with the Standard Hydrogen Scale. The data plotted in Fig. 3, for example, indicate that the potential of the IAE is +0.108V vs. that of the SCE, which gives a "standard" value of +0.35V on the Standard Hydrogen Scale. As discussed earlier, however, the potential of the IAE depends on a number of factors, such as the composition of the ionizing gas, the collector material, the placement of the electrode elements, the source strength, and the composition of the electrolyte. For any given set of values for the above parameters, the potential of the IAE appears to be constant and reproducible; hence, the electrode can be calibrated against a conventional reference electrode, making it a type of secondary reference electrode, albeit at the present time one for which the mechanism of operation is not completely understood. This in no way detracts from its usefulness in measuring things such as electrode polarization or as a monitor electrode in various difficult environments. Furthermore, as discussed earlier, the potentials of even conventional electrodes such as the Ag/AgCl electrode or the calomel electrode involve uncertainties owing to liquid junction potentials (especially in nonaqueous media), disproportionation and/or oxidation reactions, hysteresis, heat effects, aging, and contamination (1).

In conclusion, although it is unlikely in the near future that the IAE is going to displace more conventional electrochemical reference electrodes, it would appear possible that with more development it could play a valuable role as a secondary reference electrode for use in special situations for which conventional reference electrodes with liquid junctions are inappropriate. Applications that come to mind include high temperature corrosion monitoring, use with fused-salt or solid-electrolyte systems, contaminant-sensitive systems, situations involving long-term storage with only intermittent use, and embedded *in situ* systems that are not readily accessible for servicing.

Acknowledgments

The authors wish to acknowledge their gratitude to Dr. P. Sivenas and Professor F. Beales of the Department of Geology, University of Toronto, and to Professor S. N. Flengas of the Department of Metallurgy and Materials Science, University of Toronto, for early discussions that led to the development of the ionized air reference electrode. Financial assistance from the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

APPENDIX

Calculation of Extent of Air Ionization

Strength of ionizing source

$$= 57 \mu\text{Ci}$$

$$= (57 \times 10^{-6} \text{ Ci})(3.7 \times 10^{10} \text{ s}^{-1} \cdot \text{Ci}^{-1})$$

$$= 2.109 \times 10^6 \alpha\text{-particles/s}$$

$$\text{Volume of contained air} = (4.5)(\pi \times 0.75^2) = 7.952 \text{ cm}^3$$

Number of air molecules present at 25°C and 1 atm

$$= \frac{PVN_A}{RT} = \frac{(1.013 \times 10^5)(7.952 \times 10^{-6})(6.022 \times 10^{23})}{(8.314)(298.15)}$$

$$= 1.957 \times 10^{20}$$

E_0 = Total energy of each α -particle at point of emission = 5.48 MeV

Number of ion pairs formed per α -particle

$$= \frac{E_0}{W} = \frac{5.48 \times 10^6 \text{ eV}}{35 \text{ eV/pair}} = 1.565 \times 10^5$$

Total number of ion pairs formed per second

$$= (1.565 \times 10^5)(2.109 \times 10^6) = 3.302 \times 10^{11}$$

Total number of ions formed per second

$$= (2)(3.302 \times 10^{11}) = 6.604 \times 10^{11}$$

Rutherford (40) showed that for the irradiation of air with α -particles, the rate of recombination of the ionized particles is given by

$$\frac{dn}{dt} = -\alpha n^2 = -1.60 \times 10^{-6} n^2 \quad [\text{A-1}]$$

where n is the number of ions/cm³ and t is seconds.

If N_0 is the constant rate of ion production, then

$$N_0 = \frac{6.604 \times 10^{11}}{7.952} = 8.305 \times 10^{10} \text{ ions} \cdot \text{s}^{-1} \cdot \text{cm}^{-3}$$

and

$$\frac{dn}{dt} = N_0 - \alpha n^2$$

i.e.

$$n = (N_0 - \alpha n^2)t$$

$$\alpha n^2 + n - N_0 t = 0 \quad [\text{A-2}]$$

Solving Eq. [A-2] gives

$$n = (-1 + \sqrt{1 + 4\alpha N_0 t^2})/2\alpha t$$

For large t

$$n = \sqrt{\frac{N_0}{\alpha}} \quad [\text{A-3}]$$

Therefore, from Eq. [A-3], the steady-state concentration of ions is $\sqrt{8.305 \times 10^{10}/1.60 \times 10^{-6}} = 2.278 \times 10^8 \text{ ions/cm}^3$, and the total number of ions present is $(2.278 \times 10^8 \text{ ions/cm}^3)(7.952 \text{ cm}^3) = 1.812 \times 10^9$.

Percentage of air molecules ionized

$$= \frac{1.812 \times 10^9}{1.957 \times 10^{20}} \times 100\% = 9.26 \times 10^{-10}\%$$

An Ionized Air Reference Electrode

II. Applications

D. W. Kirk* and F. R. Foulkes*

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

A novel ionized air electrode (IAE) that utilizes a low level source of ionizing radiation (Am-241) to ionize an air gap in order to establish electrical contact with an electrolyte was tested for use as a reference electrode in a number of electrochemical measuring systems. Experimental results indicated that it may be possible to use the IAE to advantage to replace conventional reference electrodes, such as the saturated calomel electrode, for use in pH meters. This use was shown to be especially promising in the case of pH measurements made in nonaqueous solvents such as methanol. The IAE also was tested in a binary molten carbonate electrolyte at 525°C and was found to give results comparable with those obtained using a platinum-wire reference electrode.

An ionized air reference electrode (IAE) has been described in a previous report (1). This reference electrode has a number of features that would be useful particularly for applications in which temperature, contamination, corrosion, or ill-defined liquid junction potentials create difficulties for conventional reference electrodes. An essential feature of the ionized air reference electrode is that contact with the electrolyte is achieved through an ionized air gap. Thus, contamination and liquid junctions are eliminated, while corrosion problems are much reduced. The details of the operation and design of this electrode have been discussed in Part I of this work (1).

All reference electrodes have the function of providing a stable reference voltage against which voltage changes at another electrode may be measured. Difficulties in the use of reference electrodes arise in a number of ways. Dif-

ferences in the electrolytes surrounding the reference electrode and working electrode cause liquid junction potentials to be set up, as well as causing cross-contamination problems. This is particularly serious for nonaqueous electrolytes where liquid junction potentials of several hundred millivolts can be generated. In high temperature work, reference electrodes with aqueous electrolytes are unsuitable, so that bare silver or platinum wires frequently are used (2). Corrosion and the build up of corrosion products on the electrode surface often severely limit the useful life of these electrodes. In the case of a solid electrolyte, no satisfactory reference electrode has been found.

The ionized air reference electrode makes contact with the electrolyte only through an air gap. With the use of suitable materials for the collector and housing, potential measurements can be made at almost any temperature and with any electrolyte. Although liquid junction poten-

tials are eliminated with this arrangement, surface potentials are generated. In most cases, the magnitude of the surface potential will be comparable with that of the liquid junction potential. For most inorganic electrolytes in aqueous solutions, the surface potential is within the range ± 15 mV from that of pure water (3) and is not very dependent on electrolyte concentration at concentrations of less than one molar (3-6). In organic electrolytes, liquid junction potentials are often as large as 100 mV (7), and in most cases are difficult to calculate because of the lack of activity and conductivity data for these electrolytes. In contrast, the corresponding surface potentials may be small, and may not pose a problem in operating with an ionized air electrode. In this study, the use of the ionized air electrode will be compared with that of the saturated calomel electrode in aqueous and nonaqueous electrolytes and with a platinum wire in a molten salt electrolyte.

Experimental

A detailed description of the electrode design and the arrangement of the measuring system for use with aqueous systems has been given previously (1). For the high temperature work, the electrode housing was constructed of high temperature vycor glass (structurally stable to $\sim 1000^\circ\text{C}$). An americium-241 foil of strength $100 \mu\text{Ci} \cdot \text{cm}^{-2}$ was used as the ionization source. The collector element was a 50-mesh platinum screen placed 4 cm from the americium source. Platinum wire was used to make electrical connections to the collector and to ground the source. Nickel foil was wrapped around the electrode to serve as an electrostatic shield. Asbestos tape was used for insulating the wire leads within the furnace. A Keithley electrometer (Model 610 C) was used for all the measurements. A schematic of the arrangement is shown in Fig. 1.

Results and Discussion

Aqueous measurements.—The ionized air reference electrode (IAE) was first tested as a reference electrode for pH measurements. Buffered solutions were prepared with pH values from 2 to 10. At room temperature, the theoretical voltage response of the glass electrode with a standard reference electrode such as the saturated calomel electrode (SCE) is -0.059V per pH unit, with the absolute voltage being standardized at a particular pH. The voltage response of the IAE depends on the ratio of the resistance between the source and the collector (R_s) to that between the collector and the solution (R_g). With a source-to-collector distance of 4 cm and a source-to-solution distance of 4.5 cm, $R_s/R_g = 100$. With $R_s/R_g = 100$, the slope of the line is $-0.059 \pm 0.002\text{V}$ per pH unit, as reported earlier (1).

The effect of temperature on the potential response of a reference electrode is an important operating characteristic of the electrode. Large potential variation is undesirable, since this creates more stringent requirements for accurate temperature control and the measured voltage must be corrected for the potential change. If the reference electrode has an isopotential point with the glass electrode (*i.e.*, a potential at which the glass/reference electrode couple does not change with temperature), then automatic temperature compensators can be used. Most pH meters using a glass/SCE electrode couple have this feature.

The changes in potential measured at three temperatures for the glass/IAE couple and the glass/SCE couple are shown in Fig. 2 as a function of pH. The rate of change of potential with pH is greater with increase in temperature for both electrode couples. Both the glass/SCE and the glass/IAE electrode couples have well-defined isopotential points.

In Table I, the theoretical and measured potential/pH responses for the glass/SCE and glass/IAE electrode couples are given for 10° , 25° , and 50°C . The deviation of either electrode pair is less than 1% from the theoretical value.

10	-0.05618	-0.0563 ± 0.0015*	-0.0560 ± 0.0014
25	-0.05916	-0.0592 ± 0.0018	-0.0591 ± 0.0015
50	-0.06412	-0.0643 ± 0.0012	-0.0642 ± 0.0017

* 95% confidence interval.

A plot of the electrode voltage vs. that of the SHE as a function of temperature is shown in Fig. 3. Data for the SCE were taken from Dobos (9), whereas the points for the IAE represent averages over the pH range 2-10, taken from the experimental data. The temperature coefficient for the SCE is $-0.51 \text{ mV} \cdot ^\circ\text{C}^{-1}$, while the experimentally determined temperature coefficient for the IAE was $-0.75 \pm 0.15 \text{ mV} \cdot ^\circ\text{C}^{-1}$. The temperature coefficient for the IAE is sufficiently close to that of the SCE that the IAE could be substituted for the SCE in pH measurements without recalibration over the temperature range $0^\circ\text{-}50^\circ\text{C}$.

Some pH measurements could be more accurate with the IAE. Polybasic acid electrolytes generate liquid junction potentials with the SCE of 30-40 mV (3), which is equivalent to over 0.5 pH units at 25°C . In many cases, the surface potential error for the IAE for these solutions is smaller and more constant (3-6).

Organic electrolytes.—The effect of organic electrolytes on the magnitude of the liquid junction potential can be difficult to estimate because of the lack of activity and conductivity data. One electrolyte solution for which data are available for the calculation of liquid junction potentials with the SCE is aqueous methanol (7). Therefore, methanol, water, and sodium citrate/citric acid combinations were used to study the behavior of the IAE relative to that of the SCE. For these solutions the liquid junction potential is $\approx 5 \text{ mV}$ (7)

A plot of measured potentials for the glass/SCE and the glass/IAE electrode couples as a function of the percent of methanol is given in Fig. 4. Both electrode pairs show

Fig. 3. Temperature variation of electrode potential vs. SHE. \circ = IAE; \bullet = SCE.

Fig. 4. Voltage response of the glass/IAE and glass/SCE electrode couples in aqueous methanol solutions. 25°C . $V(\text{glass}) - V(\text{IAE})$: \blacksquare = experimental, \times = calculated. $V(\text{glass}) - V(\text{SCE})$: \bullet = experimental, \circ = calculated. $V(\text{IAE}) - V(\text{SCE})$: \blacktriangle = experimental.

very similar behavior. With increase in methanol concentration, the measured potential decreases. In aqueous electrolytes, this potential decrease would correspond to an increase in alkalinity. With organic electrolytes, the pH scale ceases to be well defined. The prerequisite that pK for water = $-\log [\text{H}^+][\text{OH}^-] = 14$ at 25°C is no longer appropriate. Thus, for methanol $\text{pK} = 16.7$. A method of calculating the pK value for a methanol-water mixture has been given by Ohtaki and Tanaka (7). These values have been converted to the voltage scale and plotted in Fig. 4. The calculated values have the same voltage trends as the measured values. The differences between the experimental and calculated values can be attributed to liquid junction potentials in the case of the SCE and to surface potentials in the case of the IAE. In both cases the measured values are $\approx 5 \text{ mV}$ more positive than the calculated values. The differences between the two electrode couples also are plotted in Fig. 4, and reflect the effect of the solvent on the two half-cell potentials of the SCE and IAE without the effect of the glass electrode. Both electrodes either are not affected greatly by the change in methanol concentration or change in a similar manner.

The behavior of the glass/SCE and the glass/IAE electrode couples also was studied with the addition of citric acid or sodium hydroxide to various methanol-water mixtures. The results are shown in Fig. 5. At a concentration of 0.1 M citric acid, the measured potentials of both electrode couples decrease with increase in methanol concentration. The effect is similar to that of the methanol-water behavior in Fig. 4. The total potential change from pure water to pure methanol is about -0.088 V , while with 0.1 M citric acid the total change is about -0.080 V . In the case of the addition of a strong base (0.1 M NaOH), also shown in Fig. 5, the potential of both glass/reference electrode couples remains constant. The activity of the hydroxide ion apparently remains constant and dominates the response of the glass/reference electrode couple. The difference between the glass/SCE and the glass/IAE remains constant over the entire methanol concentration range for both weak acid and strong base additions. Thus, the IAE functions as a well-behaved reference electrode in these

Fig. 5. Electrode response to aqueous methanol solutions containing 0.10M citric acid or 0.10M sodium hydroxide. 25°C. 0.10M citric acid: ● = $V(\text{glass}) - V(\text{SCE})$, ■ = $V(\text{glass}) - V(\text{IAE})$, ▲ = $V(\text{IAE}) - V(\text{SCE})$; 0.10M NaOH: ○ = $V(\text{glass}) - V(\text{SCE})$, × = $V(\text{glass}) - V(\text{IAE})$, △ = $V(\text{IAE}) - V(\text{SCE})$.

solutions, and the surface potential effects do not pose a serious problem to the operation of the electrode.

Molten salt electrolyte.—High temperature measurements were conducted at 525°C using a binary molten carbonate electrolyte consisting of 62 mol percent (m/o) Li_2CO_3 and 38 m/o K_2CO_3 , having a melting point of 500°C. A constant current was passed through the melt via two platinum working electrodes spaced 6 cm apart. The potentials of each working electrode were recorded relative to the reference electrode (IAE or Pt wire) situated 3 cm from either electrode.

Initial measurements with the IAE partially inside the furnace gave poor reproducibility. The cause of the problem was traced to two effects. First, the cooler surfaces of the IAE not in the furnace were subject to condensation of the melt vapors. Second, the temperature gradient affected the ionization of the air gap in the IAE and was difficult to control. By inserting the IAE completely into the furnace and increasing the collector-to-solution distance to 1 cm, reproducible readings were obtained.

In order to obtain an estimate of the ionization rise time and the stability of the potential generated at the IAE, the electrolysis cell was run at a steady cell voltage and cell current of 2.15V and 15 mA, respectively. At $t = 0$, the IAE was brought adjacent to the melt surface, and its potential vs. the anode and cathode monitored as a function of time. The results, shown in Fig. 6, indicate that the behavior of the IAE stabilizes after about 1 min. Similar measurements made using a Pt wire reference electrode stabilized within a few seconds.

The change of potential of both the IAE and the platinum wire reference electrode is shown in Fig. 7 as a function of cell current. Both reference electrodes show essentially the same potential change with current in the measurement of the cell anodic and cathodic polarization, although it is evident that there is somewhat more scatter with the IAE than with the platinum wire reference electrode. The cause of this scatter has not yet been determined, but may be related to CO_2 gas from the cell reaction mixing with the ionized air in the IAE housing and

affecting the ionization process. Regression analysis of the data shows that there is no statistical significance at the 95% confidence level between the anode and cathode slopes obtained using either the IAE or the Pt wire reference electrode. It is clear that the IAE can operate as a reference electrode in molten salt electrolytes. The response time is relatively rapid (1 min) and direct contact of the electrode with the melt is avoided. Further work is being carried out to demonstrate the application of the IAE with solid electrolytes.

ABSTRACT

The anodic behavior of polycrystalline, some deliberately oxidized, and amorphous Ti_xCu_{1-x} alloys has been investigated in 1N H_2SO_4 (0-2.5V SCE). In addition, some of the polycrystalline electrodes were characterized by means of ESCA before and after electrochemical treatment. Two types of alloys exist: Ti-rich alloys ($Ti \geq 0.84$) which passivate and behave like pure Ti, and Cu-rich alloys ($Cu \geq 0.33$) which corrode and show oxygen evolution. Nonpassivation behavior of the electrodes is related to a stationary copper concentration (≥ 0.01) at the surface.

The interest in the electrochemistry of titanium has grown during the last years due to the electrochemical properties of titanium and the potential applications of the metal (1). The discovery of photoelectrochemical water splitting at the TiO_2 /electrolyte interface (2) has prompted a great number of investigations about doped and undoped titanium oxide electrodes prepared mainly by thermal or anodic oxidation of a titanium substrate (3). The electrochemistry of titanium alloys, to the contrary, is hardly established except for some Ti alloys with Pd and Pt (1). Corrosion of Ti_xCu_{1-x} (x up to 0.33), for example, has only been investigated in detail in 1N H_2SO_4 between -600 and -10 mV (SCE) (4).

It was our idea to use the stability of TiO_2 layers in preparing an electronically conducting, noncorroding surface layer which could sustain the current densities of technical electrolysis processes (e.g., 250 mA/cm²). Such layers should be prepared by anodic or thermal treatment of a titanium alloy, for which we chose Ti_xCu_{1-x} with different compositions. Results, to be presented below, show that for our experimental conditions, two types of alloys exist: type I, with low Cu content, passivating like pure titanium; and type II, with higher Cu content, not forming an electrically blocking film, but corroding. Interestingly, strong oxygen evolution is observed at the type II alloys, a feature not found for the pure constituents. But our more detailed investigations showed that surface layers with the desired properties could not be prepared from TiCu alloys by the applied methods.

Experimental

Alloy preparation and characterization.—Polycrystalline Ti_xCu_{1-x} alloys were prepared by arc melting the respective mixtures of metal powders (reagent grade) in argon atmosphere. For homogeneity, the alloy buttons were remelted two times. After cutting, the samples were polished to a mirror finish.

The microstructure of each alloy was investigated using optical microscopy after a chemical etching process and scanning electron microscopy after electrochemical treatment. X-ray powder diffraction patterns were recorded in a Guinier camera with Cu $K\alpha$ radiation. The phases deter-

Key words: alloy, electrode, ESCA, oxidation.

mined, which are shown in Table I, are in agreement with the recently published phase diagram (5). The hexagonal solid solution of Ti_2Cu in α -Ti is present in the samples containing 92 and 84 atomic percent (a/o) Ti. Alloys $Ti_{0.67}Cu_{0.33}$ and $Ti_{0.50}Cu_{0.50}$ are essentially single phases of Ti_2Cu and TiCu, respectively. Both of these intermetallic compounds have been formed congruently. The microstructure of $Ti_{0.50}Cu_{0.50}$ is shown in Fig. 1. Alloy $Ti_{0.25}Cu_{0.75}$ consists mainly of the $TiCu_3$ phase.

Samples of $Ti_{0.92}Cu_{0.08}$ and $Ti_{0.50}Cu_{0.50}$ were also oxidized for 1h at 350°C in air, and samples of $Ti_{0.67}Cu_{0.33}$ were oxidized at the same temperature for 1h and 16h, to see the influence of thermal pretreatment on electrochemical behavior.

Amorphous Ti_xCu_{1-x} alloys with $x = 0.46, 0.57,$ and 0.67 were prepared by melt spinning.¹ These samples were 0.05 mm thick, 1 cm wide, and self-supporting.

Electrochemical measurements.—Electrochemical measurements were performed with a Princeton Applied Research Electrochemical System in standard electrochemical cells. Nonde-aerated 1N H_2SO_4 was used as electrolyte at room temperature (20°C). All potentials refer to the saturated calomel electrode (SCE).

Potentiodynamic scans were run between 0 and 2.5V (SCE) with scan rates of 2 mV/s. Galvanostatic measurements were conducted at 250 mA/cm².

The surface of some anodically oxidized samples was characterized by XPS. After electrochemical treatment under specific conditions, the samples were cleaned with distilled water, dried with purified nitrogen, and immediately introduced into the vacuum system.

XPS measurements.—XPS measurements were carried out in a Kratos ES 300 Electron Spectrometer with an overall resolution of ~1.3 eV. Binding energies have been measured using a gold standard. Polycrystalline Ti_xCu_{1-x} samples ($x = 0.25, 0.67,$ and 0.92) have been investigated. Samples polished outside the XPS machine could not be used for reference spectra owing to the formation of oxide films of various thicknesses. Therefore, samples were ground *in situ* in ultrahigh vacuum ($p < 10^{-8}$ torr) within

¹We thank Professor Günterodt, University of Basel, for kindly supplying these alloys.

Table I. Composition and x-ray analysis

Composition a/o	Structure
Ti _{0.92} Cu _{0.08}	Ti(α) and other weak lines
Ti _{0.84} Cu _{0.16}	Ti(α) + Ti ₂ Cu
Ti _{0.67} Cu _{0.33}	Ti ₂ Cu
Ti _{0.50} Cu _{0.50}	TiCu and other weak lines
Ti _{0.25} Cu _{0.75}	TiCu ₃ and other weak lines

the preparation chamber by allowing the tip of the rotating diamond end mill to abrade the sample in such a way as to clean the area that would be illuminated by the x-ray during analysis (6). The spectra of the samples ground *in situ* can be considered as reference spectra which, for large take-off angles of the electrons, reflect the composition of the bulk material.

In separate experiments, samples ground *in situ* were thermally oxidized in the preparation chamber at different temperatures and an oxygen pressure of 5×10^{-5} torr. After thermal oxidation, qualitative depth profiles have been obtained by sputtering with Ar ions (4 keV, 16 μ A/cm²). Samples with a surface area of 3×16 mm² were used in order to guarantee an approximately uniform sputter efficiency over the sample surface. These areas had been determined by sputter experiments of opaque films on glass substrates; they are also approximately uniformly illuminated by the x-ray beam. Sputter rates of TiO₂ and Ti_{0.67}Cu_{0.33} have been calibrated with films of known thickness deposited on glass by reactive sputtering in a Balzers Sputron RF/DC machine. Thicknesses have been measured by an Alpha-Step Tencon instrument. The sputter yield was about 30 Å/min for Ti_{0.67}Cu_{0.33} and 27 Å/min for TiO₂. From these calibration measurements, the thickness of the oxide layer on the bulk sample of Ti_{0.67}Cu_{0.33} prepared by *in situ* thermal oxidation has been estimated.

Some information about the depth profile of Cu, Ti, and O within the information depth of XPS (~20Å) has also been obtained by measuring the angular dependence of the intensities (7-9).

Results

Electrochemical measurements.—Polycrystalline alloys.—During the first anodic scan the corrosion current at potentials lower than 1.6V is always approximately one order of magnitude higher than for the second and the following scans, probably because of preferential copper dissolution from the surface (see XPS results) and oxidation of Ti. Cycling (2 mV/s) the electrodes between 0 and 2.5V for 2h leads to the voltage-log current plots displayed in Fig. 2.

In analogy to Ti, the current in the oxygen evolution region of the alloys Ti_{0.92}Cu_{0.08} and Ti_{0.84}Cu_{0.16} is slightly lower in each consecutive scan even after 2h. The oppo-

Fig. 1. Microstructure of an arc-melted Ti_{0.50}Cu_{0.50} sample. The structure contains only congruently formed TiCu with traces of other phases at the grain boundaries.

Fig. 2. Potentiodynamic (2 mV/s) voltage-log current plots for Ti_xCu_{1-x} electrodes recorded after 2h cycling in 1N H₂SO₄.

site is observed with the other three alloys on account of an increase in surface area because of copper and titanium corrosion. This can be seen in Fig. 3 for Ti_{0.50}Cu_{0.50} (galvanostatically polarized), where corrosion occurs preferentially at the grain boundaries. Copper redeposition at the counterelectrode is seen after some time. Titanium can be detected in solution by the specific yellow color produced when adding H₂O₂.

Common features are observed for all five alloys. First, the corrosion starts at approximately +50 mV in non-deaerated 1N H₂SO₄. Second, the current increases only slightly in the voltage range from 200 mV to 1.6V. Third, a steep increase in slope in the log current-potential plot is observed starting at approximately 1.6V; it is due to oxygen evolution. Generally, while the shape of the curves remains more or less the same, the currents increase with increasing copper content of the alloy.

The curves for Ti and Cu are also sketched in Fig. 2 for comparison. While Ti is totally passivated after a few cycles, Cu is corroding with a constant current density within the investigated potential range. It is interesting to note that neither of the two metals alone shows oxygen evolution.

Potentiodynamic current-voltage curves were also measured under the same conditions with deliberately ox-

Fig. 3. SEM micrograph of an anodically polarized Ti_{0.50}Cu_{0.50} sample (1h, 250 mA).

dized samples of $Ti_{0.92}Cu_{0.08}$, $Ti_{0.67}Cu_{0.33}$, and $Ti_{0.50}Cu_{0.50}$ in order to see the influence of an oxidized surface on the electrochemical performance. Oxidation at $350^{\circ}C$ for 1h in air causes only minor changes in the electrochemical behavior. Oxidation of $Ti_{0.67}Cu_{0.33}$ for 16h leads to significant changes. The corrosion current (0.2-1.6V) decreases by a factor of five, and the current at 2.5V drops by more than two orders of magnitude.

Under galvanostatic conditions (250 mA/cm^2), alloys with $x = 0.92$ and 0.84 passivate within a few seconds, the potential rising up to 50V (limited by the power supply) and the current dropping to $\sim 5\text{-}10\text{ mA}$. Alloys with $x < 0.67$ exhibit strong oxygen evolution and corrosion of the two alloy components at steady state. No reasonable correlation of the corrosion potential at 250 mA/cm^2 with composition could be observed. A gravimetric determination of the dissolved copper from $Ti_{0.50}Cu_{0.50}$ showed that less than 1% of the total current is consumed for copper corrosion, oxygen evolution being the predominant electrode reaction.

As mentioned above, corrosion of alloys with $x < 0.67$ leads to a strong roughening of the surface (Fig. 3). Alloys with $x = 0.92$ and 0.84 on the contrary, show a smooth surface (SEM) after electrochemical treatment.

Amorphous alloys.—Potentiodynamic voltage-log current plots for amorphous Ti_xCu_{1-x} with $x = 0.46, 0.57,$ and 0.67 are shown in Fig. 4. The shape of the anodic curves is very similar to the ones of the polycrystalline alloys. Within the entire potential range, the currents are shifted to higher values with decreasing Ti concentration. A characteristic difference exists between the polycrystalline and amorphous $Ti_{0.67}Cu_{0.33}$ sample, the current of the amorphous sample being approximately one order of magnitude higher within the entire potential range. This result is in contrast to the anodic behavior reported for an amorphous and a polycrystalline $Ti_{0.50}Cu_{0.50}$ alloy (10). However, the preparation conditions may play an important role in corrosion behavior, as could be shown with differently prepared TiCu alloys (11).

Contrary to what was seen with the polycrystalline alloys, a nice linear dependence of the potentials at 250 mA/cm^2 on alloy concentration is observed for these three amorphous samples. This very probably reflects the single-phase behavior of these alloys (12).

Fig. 4. Potentiodynamic (2 mV/s) voltage-log current plots for amorphous Ti_xCu_{1-x} electrodes in $1N\text{ H}_2\text{SO}_4$.

XPS.—An XPS spectrum of an *in situ* ground $Ti_{0.67}Cu_{0.33}$ sample is displayed in Fig. 5a. The residual oxygen level of the alloy is reflected by the O1s line observed near 950 eV kinetic energy and is at least four times lower than at the surface of an air exposed sample. This demonstrates the necessity of *in situ* preparation of a "clean" surface to characterize the true bulk composition of these samples.

Anodic polarization of the sample for 1h at 250 mA/cm^2 changes the surface composition of the alloy. These changes are shown in Fig. 5b. Electrochemical treatment increases the intensity of the O1s line more than four times while decreasing the copper lines (see below). In addition, three weak sulfur lines near 1258 eV ($S2s_{1/2}$), 1322 eV ($S2p_{1/2}$), and 1323 eV ($S2p_{3/2}$) appear which very probably originate from the electrolyte.

The Ti2p doublet of the same sample is shown in more detail in Fig. 6. That for the air-exposed sample is displayed in Fig. 6a, that for the *in situ* ground in Fig. 6b. The differences emphasize the statement about surface preparation made above. The air-exposed sample contains metallic Ti and TiO_2 . The binding energies of metallic $Ti2p_{1/2}$ and $Ti2p_{3/2}$ are 461.0 and 454.9 eV, respectively, while the corresponding energies for TiO_2 are 464.7 and 458.9 eV (13, 14). Thus, the chemical shift component of $Ti2p_{3/2}$ overlaps with the $Ti2p_{1/2}$ line. Grinding the sample *in situ* removes the TiO_2 layer (Fig. 6b). After anodic polarization, TiO_2 is the only detectable Ti species at the surface (Fig. 6c).

The influence of anodic polarization on superficial copper concentration is shown in Fig. 7 with the Cu2p doublet. After anodic oxidation, the intensities decrease by a factor of 40 ($\sim 1\text{ a/o Cu}$). The chemical shifts and the satellite structures indicate the presence of CuO and possibly Cu_2O (15).

The big difference between the air exposed and the *in*

Fig. 7. XPS spectrum of $Cu2p_{1/2}$ and $Cu2p_{3/2}$ lines of $Ti_{0.67}Cu_{0.33}$. (a) Ground *in situ* (Al 75W, 10^4 Hz); and (b) after anodic polarization during 1h at 250 mA/cm².

situ ground sample was also observed with $Ti_{0.92}Cu_{0.08}$. Anodic oxidation leads to total conversion of the surface to TiO_2 . In contrast to $Ti_{0.67}Cu_{0.33}$, very little copper (< 0.2 a/o Cu) can be detected at the surface of this alloy after electrochemical treatment (10 mA/cm² for 2h). Anodizing the sample with 250 mA/cm² leads to immediate passivation. (Limited by the voltage output (50V) of the power supply, ~10 mA/cm² can be passed through the electrode.) Hence, the XPS results demonstrate that, within the information depth, very little copper or copper oxide is present at the surface of a passivating Ti_xCu_{1-x} alloy, the surface consisting essentially of pure TiO_2 .

The contrasting result for a corroding and heavily oxygen evolving alloy is displayed in terms of the Cu2p doublet for $Ti_{0.25}Cu_{0.75}$ (Fig. 8). Anodic oxidation (250 mA, 1h) again leads to a decrease in the copper concentration by a factor of 25 (Fig. 8b) compared to the copper surface concentration of the *in situ* ground sample (Fig. 8a). As with the $Ti_{0.67}Cu_{0.33}$ sample, the chemical shifts and satellite structures indicate the presence of CuO and possibly Cu_2O . After electrochemical treatment, Ti again is completely converted to TiO_2 , as with type I alloys.

The electrochemical results for oxidized Ti_xCu_{1-x} demonstrate that oxidation for 1h at 350°C in air did not significantly change the anodic behavior. To characterize the surface of oxidized Ti_xCu_{1-x} alloys, *in situ* ground surfaces of $Ti_{0.92}Cu_{0.08}$ and $Ti_{0.67}Cu_{0.33}$ were exposed for 10 min to an oxygen pressure of 5×10^{-3} torr at 350°C. The result for $Ti_{0.67}Cu_{0.33}$ is shown in Fig. 9 for the two Cu2p lines. The intensity decreased by a factor of about 12. The corresponding factor for $Ti_{0.92}Cu_{0.08}$ is more than 20. Additional oxidation of the former sample leads to a gradual increase in intensity of the O1s line and a further decrease in the intensities of the Cu lines. After 160 min of oxidation, the surface consists essentially of TiO_2 as can be judged from the chemical shifts of the Ti2p lines. Very small amounts of copper can, however, still be detected, indicating that the segregation between Ti and Cu is not complete. In contrast to anodic oxidation (Fig. 7), thermal oxidation leaves copper predominantly in its metallic state beneath the TiO_2 film; this is indicated by the binding energies of the Cu2p lines (Fig. 9). It should be mentioned, however, that the Cu3p line does show a chemical shift component in the form of a weak shoulder, indicating small amounts of CuO and/or Cu_2O .

Fig. 8. XPS spectrum of $Cu2p_{1/2}$ and $Cu2p_{3/2}$ lines of $Ti_{0.25}Cu_{0.75}$. (a) Sample ground *in situ* (Al 75W, 10^4 Hz); and (b) after anodic polarization (Al 105W, 3×10^3 Hz).

Fig. 9. XPS spectrum of $\text{Cu}2p_{1/2}$ and $\text{Cu}2p_{3/2}$ lines of $\text{Ti}_{0.67}\text{Cu}_{0.33}$. (a) Sample ground *in situ* (Al 130W, 10^4 Hz); and (b) after thermal oxidation during 10 min at 350°C and $p(\text{O}_2) = 5 \times 10^{-5}$ torr (Al 120W, 10^4 Hz).

A similar result is obtained when the depth profile of such an oxide film is determined by angular resolved XPS. Here the surface sensitivity can be considerably enhanced by measuring the spectra at small take-off angles θ of the photoelectrons (insert of Fig. 10) (7-9). Thin oxide films of less than 50Å have been formed by exposing a $\text{Ti}_{0.67}\text{Cu}_{0.33}$ sample first ground *in situ* to oxygen at $p = 5 \times 10^{-5}$ torr for 8 min at room temperature in the preparation chamber of the XPS system. Figure 10 shows the angular variation of the intensity ratios $R_1 = I(\text{O}1s)/I(\text{Cu}2p_{3/2}, \text{met.})$, $R_2 = I(\text{Ti}2p_{1/2}, \text{oxide})/I(\text{Cu}2p_{3/2}, \text{met.})$, and $R_3 = I(\text{Ti}2p_{3/2}, \text{met.})/I(\text{Cu}2p_{3/2}, \text{met.})$. The strong angular variation of the $R_1(\theta)$ and $R_2(\theta)$ curves suggests that the first surface layers consist of pure TiO_2 . On the other hand, the small variation of $R_3(\theta)$ confirms the fact that both metallic Cu and Ti exist below the oxide film.

The depth profile obtained by argon sputtering of the $\text{Ti}_{0.67}\text{Cu}_{0.33}$ sample after 160 min of oxidation is shown in Fig. 11. The intensity of the $\text{Cu}2p_{3/2}$ line increases continuously and reaches a maximum near $t \approx 30$ min corresponding to a film thickness of about 900Å. The concentration of oxygen decreases, as can be seen from the intensity of the O1s peak. Steady-state values are reached after about 70 min sputtering time. The origin of the weak oscillations in the copper and oxygen intensities is not known; we believe, however, that they do not reflect the true concentration profile but are, rather, sputter-induced effects.

Discussion

Anodic passivation behavior.—The potentiodynamic and galvanostatic measurements demonstrate that with respect to anodic corrosion two types of $\text{Ti}_x\text{Cu}_{1-x}$ alloy exist: type I, Ti-rich, with Cu concentrations going up to at least 16 a/o, which passivate and behave like pure Ti electrodes; type II, Cu-rich, with Cu concentrations going down to at least 33 a/o, which do not passivate but corrode and exhibit rather strong oxygen evolution.

The anodic passivation mechanism of titanium in H_2SO_4 has been carefully investigated (16, 17). Passivation starts with the growth of discrete patches of titanium oxide-hydroxide, which coalesce (17). Depending on the final applied voltage, two different passivation layers occur. Below 50V, the passivation film shows a quasi-amorphous structure, and above 50V, the layer is poly-

Fig. 10. Ratios of the intensities $I(\text{O}1s)/I(\text{Cu}2p_{3/2})$, $I(\text{Ti}2p_{1/2}, \text{oxide})/I(\text{Cu}2p_{3/2}, \text{met.})$, and $I(\text{Ti}2p_{3/2}, \text{met.})/I(\text{Cu}2p_{3/2}, \text{met.})$ as a function of the emission angle θ for the $\text{Ti}_{0.67}\text{Cu}_{0.33}$ sample. The dashed curve refers to the left-hand scale.

crystalline and of anatase modification. For both voltage ranges, a characteristic value of 25 Å/V has been determined (16). Auger measurements combined with noble gas ion sputtering showed a rather constant Ti/O ratio within the film and a relative sharp transition of the oxygen concentration at the metal oxide/metal interface (18).

XPS measurements of $\text{Ti}_{0.92}\text{Cu}_{0.08}$ after galvanostatic treatment demonstrated that the surface consists of more or less pure TiO_2 . Copper has been preferentially dissolved from the alloy (4). Considering the anodic passivation of $\text{Ti}_{0.84}\text{Cu}_{0.16}$ the same may be expected for this alloy. Both alloys essentially consist of $\text{Ti}(\alpha)$ with some amount of Ti_2Cu (Table I). The influence of foreign atoms on the passivation of Ti has been discussed as distortion of the TiO_2 lattice (19). Hence, a certain concentration of foreign component is necessary to bring about this distortion and hinder the build up of a "long range" order of TiO_2 . For the two investigated alloys, this would imply that bulk concentrations of 8 or 16% Cu are not enough to sustain the required surface concentration (at least > 0.2 a/o) which is balanced by preferential dissolution and bulk diffusion of Cu within the alloy, and necessary for preventing the formation of the passivation layer. For the surface of $\text{Ti}_{0.975}\text{Cu}_{0.025}$ passivated for 1 or 10 min, it has been found that the setting up of a long-range order is shifted from $\sim 50\text{V}$ (the value for pure Ti) to higher voltages (19). Also, from the appearance of a quadratic term in the growth law, it had been concluded that these films do not behave as barrier films.

Fig. 11. Depth profile obtained by Ar ion sputtering of Ti_{0.67}Cu_{0.33} after thermal oxidation during 160 min at 350°C and $p(\text{O}_2) = 5 \times 10^{-5}$ torr. (Beam voltage 4 keV, ion current density 10 $\mu\text{A}/\text{cm}^2$, sputter yield $\approx 30 \text{ \AA}/\text{min}$.)

These qualitative assumptions about the influence of Cu on the passivation behavior of Ti are in agreement with the observations made with type II alloys. After anodic treatment, a stationary copper concentration can be detected at the surface for type II with the highest Ti concentration (Ti_{0.67}Cu_{0.33}).

The surface concentration of copper is reduced to approximately 1% through the preferential dissolution process. Hence 1% of copper at the surface is enough to prevent passivation. A similar result has been obtained with Ti_{0.25}Cu_{0.75}, where, after anodic treatment, a surface concentration of 3% Cu has been measured. In both cases, Ti is completely oxidized to TiO₂, no metallic-titanium peaks are observed.

The question remains how high the copper surface concentration has to be to start preventing passivation behavior. The metallographic results show that the two type I alloys are essentially two-phase alloys containing (Ti(α) and Ti₂Cu. Alloy Ti_{0.67}Cu_{0.33}, more or less 100% a single phase of Ti₂Cu, already belongs to type II. Therefore, nonpassivating behavior has to start at the particular Ti₂Cu/Ti(α) ratio where the surface portion of "Ti₂Cu" (taking into account the surface depletion of Cu) is large enough to prevent the coalescence of passivating TiO₂ patches. It would be interesting to determine the exact concentration where the break in passivation behavior occurs, and relate it to a model as done for Ti6Al4V (20).

The polarization behavior of the deliberately oxidized samples (1h 350°C, air) was not significantly different from that of the nonoxidized samples, except for Ti_{0.50}Cu_{0.50} oxidized for 16h. Even if the conditions for the two oxidation procedures were different (a stronger oxidation may be expected in air than at 5×10^{-5} torr O₂), the XPS results for the oxidized samples should give some information useful to understand the polarization behavior of the air-oxidized alloys. XPS shows that preferential oxidation of Ti to TiO₂ occurs and that Cu segregates towards the bulk. But after 160 min of oxidation, Cu still can be detected within the information depth of XPS in Ti_{0.67}Cu_{0.33} samples. In contrast to anodic oxidation, Cu is not oxidized at these temperatures but remains in the metallic state, which can be explained by the different standard free energies of oxide formation for the two metals (21). This is also confirmed by angle-resolved XPS of Ti_{0.67}Cu_{0.33} oxidized for only 8 min (Fig. 10). Only a very few surface layers of this sample consist of essentially pure TiO₂, leaving metallic Ti and Cu beneath. Hence oxidation under these conditions produces a few angstroms thin TiO₂ layer on top of a mixture of Ti oxide and metallic Cu (see also below). For the electrochemical behavior

it may be concluded that at least for the chosen oxidation conditions (1h, 350°C, air), the TiO₂ layer is not thick enough to behave passivating. In other words, the Cu concentration beneath this TiO₂ layer is high enough to still distort the TiO₂ layer under electrochemical conditions. An effect of the metallic state of Cu below this TiO₂ layer on the diffusion properties of Cu in TiO₂ may be speculated to be present. The fact that anodic oxidation leads to anatase while thermal oxidation yields a mixture of anatase and rutile may also have some influence.

The distribution of Cu within the Ti oxide layer can also be seen from the sputter profile² of the Ti_{0.67}Cu_{0.33} sample oxidized for 160 min (Fig. 11). The Cu concentration systematically increases from the surface to the bulk. The thickness of the mixed Ti oxide-Cu layer is estimated to be about 900 \AA . This value is much higher than the value for an oxide layer of pure TiO₂ prepared under comparable oxidation conditions ($\sim 200\text{\AA}$) (22). This is in qualitative agreement with results obtained from marker experiments, where Au doping of the Ti surface impedes the dissolution process of the oxide layer into the bulk and therefore causes an increase in oxide layer thickness (23).

Oxygen evolution.—An interesting feature of type II Ti_xCu_{1-x} alloys is the strong oxygen evolution starting at around 1.65V (Fig. 2). This is even more surprising because neither of the two components show oxygen evolution at these potentials. At 2.5V, for example, a current density on the order of 10^{-5} to 10^{-6} A/cm² can be passed through a passivated Ti electrode. On the other hand, Cu exhibits a constant corrosion current (~ 0.1 A/cm²) with no oxygen evolution up to potentials of at least 10V. This potential-independent current in H₂SO₄ comes about owing to a surface layer of CuOH which impedes passivation

² It is interesting to compare the intensity ratios $R(\text{Ti}/\text{O}) = I(\text{Ti}2p_{3/2})/I(\text{O}1s)$ and $R(\text{Ti}/\text{Cu}) = I(\text{Ti}3p)/I(\text{Cu}3p)$ observed at steady state with the corresponding bulk ratios. The latter values have been obtained from independent measurements with the same sample ground *in situ* before sputtering. We find $R(\text{Ti}/\text{O}) = 1.60$ after sputtering and $R(\text{Ti}/\text{O}) = 1.1$ for the bulk, indicating a rather strong preferential sputtering of the residual oxygen compared with Ti. For $R(\text{Ti}/\text{Cu})$, we find a value of 0.42 after sputtering and 0.51 for the bulk, reflecting a slight sputter-induced enrichment of Cu. This observation is in agreement with the general result obtained for many binary alloys; that the target develops a surface layer enriched in the heavier constituent, copper in our case (24, 25). Using the relation for the steady-state concentration ratio (25) we estimate a sputter yield ratio $S_{\text{Cu}}/S_{\text{Ti}}$ of about 1.1 for the alloy in the steady state. On the other hand, the corresponding ratio for the individual elements is about 3.2 at 1 keV (26). This demonstrates that the preferential sputtering behavior of the alloy cannot be predicted according to the sputter yields of the individual elements, a fact which has also been established for other alloys such as Al/Pd and Si/Pd (27).

as well as oxygen evolution, as could be demonstrated with freshly scratched copper electrodes (28).

Obviously, oxygen evolution at these electrodes is correlated to nonpassivation. The surface sites of the electrode where oxygen evolution occurs remain a matter of speculation. We could see above that nonpassivation is due to a stationary Cu surface concentration causing Cu, and some Ti, corrosion. Hence, a more or less fresh surface composed of Cu oxide and Ti oxide is exposed to the electrolyte under steady-state conditions. One can assume that the Cu component in the alloy should behave like a pure Cu electrode, implying that O₂ evolution does not take place on Cu sites. Oxygen evolution rather should take place at the titanium part of the electrode. It is tentatively assumed that at type II alloys, Ti is oxidized to TiO₂ only within the first layers. It has been shown that surface layers do not alter electrode behavior as long as they are less than 20Å thick (29). Furthermore, fresh titanium electrodes exhibit an activity orders of magnitudes higher than electrodes already passivated (30).

Conclusions

Our results demonstrate that passivation of Ti_xCu_{1-x} alloys is related to a critical copper surface concentration. Alloys either passivate or corrode, hence the desired properties of a stable and conducting surface layer could not be obtained. Nevertheless, Ti_xCu_{1-x} seems to be an interesting system to study passivation of titanium and should deserve further attention.

Effect of Nonstoichiometry and Solvent on Discharge Property of Li/TiS₂ Battery

T. Yamamoto,^{*,1} S. Kikkawa, and M. Koizumi

The Institute of Scientific and Industrial Research, Osaka University, Osaka 567, Japan

Intercalation into TiS₂ has been extensively investigated and was applied as cathode reaction of lithium secondary battery (1). There have been many publications on this topic (1). However, it was not easy to obtain stoichiometric TiS₂ due to its variable compositional range and the presence of higher sulfide, TiS₃ (2). Thompson *et al.* verified the existence of stoichiometric TiS₂ (3). Its fine powder was then prepared from a titanium sponge between 450° and 600°C in a temperature gradient which fixed the sulfur pressure (4). Nonstoichiometry affects the discharge property of lithium battery. Winn *et al.* prepared single crystals of Ti_xS₂ ($x = 1.002, 1.01, 1.02$) and electro-intercalated lithium and sodium in propylene carbonate (5). They measured open-circuit voltages and chemical diffusion coefficients of alkali metals as a function of alkali content. Whittingham reported discharge curves of lithium battery in 70% tetrahydrofuran and 30% dimethoxyethane mixed solution using TiS₂ and Ti_{1.1}S₂ as cathodes (6). They also found that excess titanium reduced the diffusibility of intercalated lithium (6). Selection of solvent is important for the development of an ambient temperature secondary battery. 2-Methyltetrahydrofuran-LiAsF₆ was found to be superior to the electrolytes based on propylene carbonate, methyl acetate and tetrahydrofuran for the lithium electrode cycling efficiencies (7). However, the effect of solvents has not yet been comparatively investigated on intercalation battery using TiS₂ having various Ti/S ratios.

In the present study, samples having compositions of Ti_xS₂ ($1.00 \leq x \leq 1.13$) were prepared and the discharge properties of lithium batteries were galvanostatically investigated using lithium perchlorate as the electrolyte in several kinds of organic solvent. The discharged products were characterized using powder x-ray diffractometry.

Titanium sulfides were prepared by heating mixtures of titanium and sulfur having various mixing ratios at temperatures of 500°, 600°, and 800°C for several days in evacuated silica tubes. The tubes were 8 mm in diam and 10 cm long. The temperature gradient was within 3°C/cm in the furnace. The products were characterized by x-ray diffractometry and thermogravimetry. They had compositions of Ti_{1.00}S₂, Ti_{1.03}S₂, Ti_{1.06}S₂, and Ti_{1.13}S₂. Average particle sizes were ca. 13 μm for Ti_{1.00}S₂ and 9 μm for the others. Electrochemical properties were investigated several times on the sample belonging to the same batch. The samples of ca. 2 mg were pressed to disks of 5 mm diam at 700 MPa. Lithium perchlorate was dried in vacuum at 150°C. Tetrahydrofuran (THF), dimethylsulfoxide (DMSO), formamide (FA), and propylene carbonate (PC) were dried using 3Å molecular sieves. 1M solutions of LiClO₄ were prepared using the respective solvents. Bottle-type lithium batteries were set up using these electrolytes and discharged in He atmosphere. The Hokuto Denko Limited HJ-201 charge/discharge testing system was used for the galvanostatic discharge. The discharged

products were sealed in a capillary, and they were investigated by x-ray diffractometry using CuKα radiation.

Discharge properties were investigated using THF, DMSO, FA, and PC as the respective solvents of electrolyte on the sample having composition of Ti_{1.03}S₂. Galvanostatic discharge curves at 1.5 mA/cm² were presented in Fig. 1. The utilization in the figure was calculated as a quantity of discharged electricity from Li/TiS₂ cell against the amount of TiS₂ used as cathode. 100% utilization means that the discharged electricity corresponds to the amount necessary to obtain LiTiS₂ by lithium intercalation into TiS₂. Cell EMF was ca. 2.2V at the beginning. It gradually decreased to 1.5V with the discharge. Utilizations were 80% in DMSO, 75% in THF, 55% in FA, and 45% in PC when 1.5V of cell EMF was attained. Thereafter, the potentials rapidly decreased with the discharge in the solvents of THF, DMSO, and PC. However a plateau was observed at about 1.2V on the discharge curve in FA.

The discharged products were investigated using powder x-ray diffractometry. The cathode materials were taken out from the following two points; (i) 1.5V of cell EMF was attained, and (ii) the rapid potential decrease was finished. They were sealed in capillary tubes to prevent reactions with humidity. The diffraction results are summarized in Table I. The products discharged in THF showed only the basal spacing of about 6.2Å, which was the value of lithium intercalated TiS₂ (1). The products in DMSO or PC had the same spacing of 6.2Å and additionally very weak diffraction lines around 8.8Å, which could be assigned as the basal reflection of hydrated lithium intercalated phase by a monolayer of water (8). A small amount of water might remain in these solvents even after the drying on molecular sieves. The assignment is difficult for the spacing of 13.6Å observed in DMSO. This phase may correspond to the one detected on TaS₂ intercalated alkali ions solvated by DMSO (8). Basal spacing of ca. 13.2Å was observed on the discharged products in FA with 6.2Å phase. The intensity of x-ray diffraction lines

Fig. 1. Effect of solvents on discharge of Li/Ti_{1.03}S₂ cell with 1M LiClO₄. Current density was 1.5 mA/cm².

Table I. X-ray diffractions of the discharged cathodes in $\text{Li}/\text{Ti}_{1.03}\text{S}_2$ at $1.5 \text{ mA}/\text{cm}^2$

Solvent	Utilization (%) (final voltage, V)	Basal spacings (Å) of the additional phases observed with Li_xTiS_2 having 6.2Å spacing
THF	70 (1.7)	—
	94 (0.2)	—
DMSO	68 (1.6)	13.6, 8.8
	95 (0.2)	13.6, 8.8
FA	49 (1.6)	13.2
	100 (0.9)	13.5
PC	45 (1.6)	8.8
	69 (0.2)	8.8

for 13.2Å phase was comparably strong as that for 6.2Å. Spacings of 13Å had been reported for FA intercalated complexes of metal disulfides (9). Thus the 13.2Å spacing was estimated as that of the intercalated TiS_2 with lithium ions solvated by FA. Cointercalation of solvent reduced the amount of lithium which can be intercalated into TiS_2 .

It may be associated with solvation energy whether lithium alone is intercalated or incorporated with solvent molecules. According to Born's model, solvation energy ΔG can generally be related to the dielectric constant of solvent as follows

$$\Delta G = - \frac{L(Ze)^2}{8\pi\epsilon_0\gamma} \left(1 - \frac{1}{\epsilon} \right)$$

where L is Avogadro's number, Z is the number of ionic charge, ϵ_0 and ϵ are dielectric constants of vacuum and of solvent, and γ is ionic radius. Dielectric constants are 7.39 for THF, 48.9 for DMSO, 64.4 for PC, 78.5 for water, and 111.5 for FA (10). THF probably has the smallest solvation energy because of the smallest dielectric constant in these solvents. Thus, cointercalation of solvent was not observed in THF. THF might be the most favorable solvent in the present study.

Current pulse technique (11) was applied to investigate whether the solvent effect simply be due to ionic conductivity and/or lithium ion transport in the solution phase. 0.05 ~ 0.3 mA current was supplied to the batteries using $\text{Ti}_{1.03}\text{S}_2$ for the periods of 15s. The variation of the transient voltage (ΔE) with time (t) was plotted against $t^{-1/2}$. The linear region was observed in the period of 2 ~ 400s when THF was used as the solvent. The initial nonlinearity which was attributed to an "electrolyte effect" (11) was not observed for the duration less than 2s. Diffusivity around $2.5 \times 10^{-8} \text{ cm}^2/\text{s}$ was calculated from the slope of the linear region. The value is comparable to lithium diffusivity (11), but it changed with the amount of intercalated Li. In the case of PC, two kinds of slope were observed when more than 10% utilization was attained. The diffusivity calculated from the slope for the period between 2 and 25s was about $2.5 \times 10^{-8} \text{ cm}^2/\text{s}$. Much smaller values of $4 \times 10^{-9} \text{ cm}^2/\text{s}$ was obtained from the slope in the period between 25-400s. It may correspond to the diffusivity of hydrated lithium. Intercalation using FA as solvent showed linear region in ΔE vs. $t^{-1/2}$ plot in the utilization above 20%. The calculated diffusivity was about $1 \times 10^{-9} \text{ cm}^2/\text{s}$, which was probably the value for Li solvated with FA molecules. Thus, the ionic conductivities of lithium itself and/or of solvated lithium are apparently important for the observed solvent effect. The electrolyte effect can probably be observed in the initial period until 2s. Our equipment does not have enough capacity to resolve such transient phenomena.

Discharge properties were studied on the samples having various compositions, $\text{Ti}_{1.00}\text{S}_2$, $\text{Ti}_{1.03}\text{S}_2$, $\text{Ti}_{1.06}\text{S}_2$, and

Fig. 2. Effect of nonstoichiometry on discharge of $\text{Li}/1\text{M LiClO}_4\text{-THF}/\text{TiS}_2$ cells at $1.5 \text{ mA}/\text{cm}^2$.

$\text{Ti}_{1.13}\text{S}_2$ at the constant current density of $1.5 \text{ mA}/\text{cm}^2$ in THF. Excess titanium reduces the discharge rate as previously reported (6). The utilizations at 1.5V were 75% for $\text{Ti}_{1.00}\text{S}_2$ and $\text{Ti}_{1.03}\text{S}_2$, and 71% for $\text{Ti}_{1.06}\text{S}_2$ and 62% for $\text{Ti}_{1.13}\text{S}_2$, as shown in Fig. 2. Summations of the amount of excess titanium and the utilization percent were about 75% for all samples. Excess titanium probably sits in the site which the intercalated lithium should occupy. It reduces the number of sites which can accommodate the intercalated lithium.

Intercalation of lithium into TiS_2 reduces the anisotropy of thermal expansion in the TiS_2 lattice (12). Excess titanium in the interlayer region also plays similar role to the intercalated lithium and binds the host TiS_2 layers to each other. Thus, the diffusion constant of about $10^{-7} \text{ cm}^2/\text{s}$ was reported for sodium in $\text{Na}_x\text{Ti}_{1.00}\text{S}_2$, but it was only about $10^{-9} \text{ cm}^2/\text{s}$ in $\text{Na}_x\text{Ti}_{1.02}\text{S}_2$. The present discharged products of $\text{Ti}_{1.06}\text{S}_2$ and $\text{Ti}_{1.13}\text{S}_2$ in THF showed only the basal spacing of 6.2Å, which is the same as that for Li_xTiS_2 , as shown in Table II. However, the discharged product of stoichiometric TiS_2 was accompanied by a small amount of 12.8 and 8.8Å phases. These two spacings probably correspond to those of the hydrated phases having bi- and monolayers of water (1). The stoichiometric TiS_2 partially intercalated the bulky hydrated lithium due to its weak bonding between the TiS_2 layers.

Discharge curves in FA are given in Fig. 3. $\text{Ti}_{1.00}\text{S}_2$ showed the initial voltage of 2.5V. The voltage rapidly decreased at around 25% of utilization. Only the expanded basal spacing of 13.2Å was observed just before and after

Table II. X-ray diffractions of the discharged cathodes in lithium battery at $1.5 \text{ mA}/\text{cm}^2$ prepared by using various compositional titanium disulfides

Solvent	Cathode	Utilization (%) (final voltage, V)	Basal spacings (Å) of the additional phases observed with Li_xTiS_2 having 6.2Å spacing
THF	$\text{Ti}_{1.00}\text{S}_2$	96 (0.2)	12.8, 8.8
	$\text{Ti}_{1.06}\text{S}_2$	95 (0.2)	—
	$\text{Ti}_{1.13}\text{S}_2$	80 (0.2)	—
FA	$\text{Ti}_{1.00}\text{S}_2$	26 (2.0)	13.2*
	$\text{Ti}_{1.00}\text{S}_2$	49 (1.0)	13.2*
	$\text{Ti}_{1.06}\text{S}_2$	100 (0.9)	8.8
	$\text{Ti}_{1.13}\text{S}_2$	100 (0.8)	8.8

	$\text{Ti}_{1.13}\text{S}_2$	55 (0.1)	8.8

* Diffraction lines of Li_xTiS_2 having 6.2Å spacing were not observed.

Fig. 3. Effect of nonstoichiometry on discharge of Li/1M LiClO₄-FA/TiS₂ cells at 1.5 mA/cm².

the rapid decrease of potential. The discharged product of Ti_{1.03}S₂ also showed the expanded spacing of FA cointercalated phase. However, the discharged products of Ti_{1.06}S₂ and Ti_{1.13}S₂ showed the spacing of ca. 6.2Å accompanied by a very weak 8.8Å line of the hydrated phase as shown in Table II. The variation of discharge property seems to suggest that the interlayer bonding of TiS₂ is strengthened with nonstoichiometry as observed on the discharge in THF. The final discharge voltage is ca. 1.0V, which is quite different from the value observed in other solvents. This peculiar behavior may correspond to the formation of formamide complexes with titanium sulfides whatever their nonstoichiometries are.

The utilizations at 1.5V in PC was seriously decreased with the degree of nonstoichiometry as illustrated in Fig. 4. The values were 55% for Ti_{1.00}S₂, 45% for Ti_{1.03}S₂, 38% for Ti_{1.06}S₂, and 28% for Ti_{1.13}S₂. Only the discharged product of Ti_{1.00}S₂ to 100% utilization showed a basal spacing of 18.8Å which might be a PC-cointercalated phase (1). The expanded basal spacing could not be observed on other discharged products.

In summary, excess titanium reduced the utilization of Li/TiS₂ battery due to the reduction of available interlayer sites for lithium as reported earlier (6). However, it is effective for pinning TiS₂ layers to each other to prevent the cointercalations of solvents. Polar solvent was sometimes cointercalated and this reduced the cell utilization for stoichiometric TiS₂. In this respect, THF was the most favorable solvent in the present research.

Fig. 4. Effect of nonstoichiometry on discharge of Li/1M LiClO₄-PC/TiS₂ cells at 1.5 mA/cm².

Composition of Chromate Passivation Films on Aluminum-Zinc Alloy-Coated Sheet Steel

H. E. Townsend and R. G. Hart

Bethlehem Steel Corporation, Sheet Steels and Coated Products Division, Research Department, Bethlehem, Pennsylvania 18016

Galvanized coatings, that is, zinc coatings applied by a hot-dip process, are widely used to protect steel against corrosion (1). Even greater protection is afforded by a new coating comprising (by weight percent): 55 Al, 43.5 Zn, and 1.5 Si (2, 3). Steel sheet with the Al-Zn alloy coating is marketed in the United States under Bethlehem Steel Corporation's trademark Galvalume. The Al-Zn alloy coating generally provides greater than two times the life of a zinc coating of equivalent thickness.

Although Zn and Al-Zn coatings have good durability during bold atmospheric exposure, both are susceptible

Key words: x-ray photoelectron spectroscopy, wet storage stain, galvanized.

to accelerated attack when exposed to moisture in the crevice-like conditions which are created when sheet is stored in coiled or stacked form. This attack is known as wet-storage staining, and its effects vary from mere superficial discoloration of the surface to total destruction of the coating.

Chromate passivation is the usual method of providing temporary protection against wet-storage stain during shipment and storage of Zn- and Al-Zn-coated sheet. This passivation treatment typically involves immersion of the sheet in an acid chromate bath to deposit a thin film containing roughly 6-25 mg of chromium per square meter. In an earlier study, we found that the degree of protection

against wet-storage stain imparted by a given amount of chromium deposited during chromate passivation is greater for the Al-Zn coating than for the Zn coating (4). The present study was conducted to determine whether differences exist in the passivation films that could account for the difference in performance.

Experimental

Al-Zn- and Zn-coated steel sheets were produced on commercial continuous hot-dip coating lines. The usual mill-applied chromate treatments were omitted to enable surface analyses before and after chromate treatment, which was done in the laboratory. For comparative purposes, we also studied wrought zinc (99.9%) sheet and Al-clad 3003 aluminum sheet.

Materials were passivated in the laboratory according to the following procedure: (i) vapor degrease, (ii) heat to 66°C, (iii) immerse in a chromate bath at 66°C for 5s, (iv) rubber roll squeegee to remove excess solution, and (v) dry in 52°C air. The chromate bath was a 3 v/o solution of Iridite 9L6, a proprietary fluoboric acid-activated chromate passivation treatment supplied by the Richardson Company, Des Plaines, Illinois. In the case of the zinc sheet, we found it necessary to abrade the surface prior to chromating in order to ensure uniform reaction in the chromate bath.

To remove most of the water soluble, unreacted portion of the film remaining on the sheet after passivation and thus facilitate spectroscopic analyses, the chromate-treated materials were washed in distilled water at 91°C for 1 min. Water-insoluble chromium on the surface after washing (Table I) was determined by stripping the remaining film in dilute phosphoric and sulfuric acids and analyzing the solution by atomic absorption.

X-ray photoelectron spectroscopy (XPS) analyses were performed in a Perkin-Elmer, Physical Electronics Model 548 spectrometer at pressures generally less than 10^{-9} torr. A magnesium x-ray source was used to excite photoelectrons which were detected over an area of 4 mm² with a pass energy of 50 eV. X-ray excited photoelectrons used in these analyses are listed in Table II. Depth profiles were obtained by argon ion (5 keV) sputtering. The ion beam was rastered over a 25 mm² area to give a Ta₂O₅ sputtering rate of 2 nm per min.

Results and Discussion

XPS provides information on the identity of elements present, relative quantities, and oxidation states. In Fig. 1-3, we give depth profiles for cationic species present in the film, expressed in atomic percent of cations. Oxygen and a small amount of fluorine also present in the films are omitted for simplicity. In general, oxygen was detected in direct proportion to the amount of trivalent cation.

Prior to chromating, the surface of the Al-Zn coating is covered with a thin layer of trivalent aluminum oxide (Fig. 1a). We attribute the paucity of zinc in the oxide

film to preferential oxidation of the more active aluminum component during solidification of the hot-dip coating in air.

After chromating (Fig. 1b), a passivation film is observed that comprises chromium in three oxidation states. At the outer surface of the film, chromium is present in the hexavalent form that we associate with a thin residue of the wet film that was dragged out of the chromate bath during processing, dried on the surface, and incompletely removed during subsequent working. Following sputter removal of the hexavalent chromium, the major components of the film are trivalent oxides of aluminum and chromium. With continued sputtering, the trivalent components diminish, and a peak in metallic chromium occurs. Thus, in simplest terms we can picture the passivation film on the Al-Zn surface as consisting of three layers as shown in Fig. 5.

Fig. 2. XPS analysis of aluminum sheet. a, top: before chromating. b, bottom: after chromating.

Fig. 3. XPS analysis of zinc sheet. a, top: before chromating. b, bottom: after chromating.

Analysis of aluminum sheets prior to chromating (Fig. 2a) shows the surface is initially covered with an aluminum oxide film. After chromating (Fig. 2b), a three-layer film is observed that, except for the lack of zinc, is qualitatively similar to that formed on the Al-Zn coating.

Corresponding analyses of the zinc surface before chromate treatment (Fig. 3a) show an initial film of zinc oxide. After chromating (Fig. 3b), we see only two chromium containing layers: an outer layer of hexavalent chromium and an inner layer of trivalent chromium oxide.

Additional XPS analyses comparing galvanized and Al-Zn-coated sheet steel, typified in Fig. 4, confirm the absence of metallic chromium on the zinc-coated sheet.

The above results, which we summarized schematically in Fig. 5, indicate that the chromate passivation films formed on the Al-Zn alloy and aluminum differ from that

on zinc in two significant ways. They exhibit: (i) an intermediate layer containing aluminum oxide and (ii) an inner layer of metallic chromium. Either or both of these additional features could account for the greater degree of protection afforded by chromate passivation to Al-Zn coatings as compared to zinc coatings.

Our results for zinc surfaces are in reasonably good agreement with those of earlier work (7). However, our results differ from those of earlier studies of aluminum (8, 11) and aluminum-zinc coated steel (9) in that metallic chromium was not reported in the previous work. A probable explanation for the difference between our results and those of Ref. (8) and (9) is that we used ion sputtering to remove the outer layers of the passivation film and thus we were able to detect the underlying metallic chromium. Ion sputtering was employed in the work reported in Ref. (11), and, while the authors do not explicitly note

Fig. 4. XPS chromium spectrum comparing zinc-coated (upper curve) and Al-Zn alloy-coated (lower curve) sheet steel.

Fig. 5. Schematic of chromate passivation film on 55% Al-Zn-coated steel sheet.

it, there may be evidence in these results [compare Fig. 5 of our work to Fig. 7 of Ref. (11)] of chromium metal.

Aluminum oxide is thermodynamically more stable than chromium oxide. Greater thickness or stability of the aluminum containing oxide is suggested by the fact that twice the sputtering time was needed to remove the passivation film on aluminum even though the amount of chromium deposited on the zinc was over three times greater. For a given amount of chromium, an oxide film containing both aluminum and chromium should be a thicker or more dense barrier than one containing only chromium.

A layer of metallic chromium could also provide additional barrier protection. Indeed, metallic chromium found in the passivation film on CDC (cathodic deposited chromate) treated tinplate is believed to enhance re-

sistance to tarnishing (5, 6). In the case of aluminum and Al-Zn-coated steel, the metallic chromium may result from complete reduction of chromic acid in the passivation bath according to

Another explanation is that the metallic chromium detected in our work is a sputtering artifact. Although it has been reported that chromium oxide is not reduced by argon-ion bombardment in the vacuum of a spectrometer (10), we cannot rule out the possibility that aluminum may reduce chromium oxide when activated by an ion beam according to

Metal/Flame-Sprayed-Aluminum Interface as Studied by Emission Mössbauer Spectroscopy

Henry Leidheiser, Jr.,* Svetozar Musić, and Attila Vértes

Department of Chemistry and Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

Herbert Herman and R. A. Zatorski

Department of Materials Science, State University of New York, Stony Brook, New York 11794

Two of the authors of this article (H. L. and H. H.) served on a National Academy of Sciences Committee to review the application of flame-sprayed aluminum to corrosion protection of components of naval vessels. A report on this subject has recently been issued by the Acad-

emy (1). As a result of the discussions of the committee, it became apparent that the type of bonding between a steel substrate and the aluminum was not known, although the low bonding strength, typically 2000-4000 lb/in², and the necessity of having the proper degree of roughness of the

** Gamma ray emission is from Fe-57 species. There is not necessarily a 1:1 relationship between the originating Co-57 species and the Fe-57 atom that emits the gamma ray.

substrate, suggested that the adherence was primarily mechanical in nature. The following model experiments were carried out in order to explore this point.

The technique selected-emission Mössbauer spectroscopy has been used previously in studies of the interfacial region between a cobalt substrate and a polybutadiene coating (2). The method requires the use of cobalt because Co-57 is the precursor for the excited state of Fe-57, which actually emits the gamma ray that is detected by the Doppler effect conventionally utilized to obtain a Mössbauer spectrum. The method is very simple in concept. Metallic cobalt is electrocoated with a very thin deposit of cobalt containing Co-57. A reference Mössbauer spectrum is obtained. The cobalt is spray coated with aluminum, and another spectrum is obtained. Differences in the spectrum before and after spray coating with aluminum are indicative of chemical changes at the interface. A description of the experimental details will now be given.

The cobalt sheet in the form of a square, approximately 2 cm on a side, was sandblasted, scrubbed gently with a nylon brush under running distilled water, and immediately immersed in a plating bath containing $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$ doped with Co-57, 0.31 g/l; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ 100 g/l; H_3BO_3 30 g/l; pH = 4.0. A current density of 0.01 A/cm² was used. Two samples were prepared. One deposit was estimated to be approximately 5 nm thick, and the other was estimated to be approximately 10 nm thick. The resulting cobalt electrodeposit consisted of an ionic component (presumably the surface oxide) and a ferromagnetic metallic

component (the unoxidized metal). A computer evaluation of the spectrum of the thicker deposit is given in Table I, in which it is noted that the metallic component composed 56% and the ionic component composed 44% under the assumption that the recoil fraction was the same for all components.

After the original spectra had been obtained, the samples were maintained in a desiccator for approximately 2 weeks before being transported to Stony Brook for the flame spraying process. Both samples retained their clean appearance between the time of preparation and flame spraying. The samples were maintained in a vertical position through use of a magnetic holder and were flame sprayed in two passes with the gun pointing in a direction normal to the specimen surface. The resulting coating was approximately 0.01 cm thick. Adherence of the coating was poor at the edges, but the coating on the major fraction of the surface exhibited satisfactory adherence. The adherence was not measured quantitatively because of the difficulty in working with a radioactive sample.

The spectra for the thicker electrodeposit are given in Fig. 1 for the cobalt surface immediately after preparation and in Fig. 2 for the sample after the application of the aluminum. Superposition of the two spectra indicated that they were identical in all respects. The following conclusions can be drawn.

1. The amount of oxide film on cobalt remained constant before and after flame spraying. Thus, aluminum did not reduce the oxide film, and the oxide film did not thicken.

2. There was no evidence of a change in the chemical nature of the oxide film on cobalt. The 37:7 ratio of the trivalent:divalent species was the same before and after flame spraying.

In summary, it can be concluded that a flame-sprayed aluminum coating has no significant effect on the chemical nature of a cobalt surface such as normally exists during exposure to air at room temperature. The bonding between cobalt and flame-sprayed aluminum does not involve a chemical reaction and is largely, or perhaps exclusively, mechanical in nature. It appears reasonable that this conclusion in the case of cobalt can be extended to steel because there are many similarities in the chemical behaviors of the surface oxides on cobalt and iron.

Solubility Characteristics of Perfluorinated Polymers with Sulfonyl Fluoride Functionality

G. H. McCain and M. J. Covitch¹

Diamond Shamrock Corporation, T. R. Evans Research Center, Painesville, Ohio 44077

Functionalized perfluorocarbon polymers such as Nafion (E. I. du Pont de Nemours & Company) are of significant commercial importance as membranes in brine electrolysis cells (1), as well as fuel cells. The excellent chemical and thermal stability of these materials in the presence of harsh oxidizing electrolytes, such as chlorinated brine, make this class of polymers uniquely suited for electrochemical applications. A number of other electrochemical processes and components have utilized functionalized perfluorocarbon polymers including, for example, novel-coated electrodes (2) and water electrolysis cells (3).

Membranes are fabricated into sheet form by extrusion of the sulfonyl fluoride (or alkylcarboxylate) form. They are then saponified (4) in caustic to generate the hydrophilic sulfonate form which, unlike the sulfonyl fluoride precursor, swells in aqueous electrolytes and exhibits transport behavior typical of a cation exchange membrane. This fabrication method applies only to the manufacture of sheet and tube membranes (or other geometries of constant cross-sectional area). Martin *et al.* (5) published the first procedure to solubilize commercially available perfluorosulfonate polymers having equivalent weights of 1100-1200 for use in preparing chemically modified electrodes. Their procedure involves heating the polymer (presumably in the potassium sulfonate form) in an alcohol/water solution up to 250°C in a stirred pressure reactor. Stable solutions are obtained up to solid concentrations of 1 weight/volume percent (w/v). Above this concentration, the polymer can be well dispersed, but it partially settles out with time (6). Thus, this method is particularly useful for the preparation of very thin (<20 μm) film structures. Baczek and McCain (7) reported another procedure for solution processing of these materials. They found that solutions of up to 20 weight percent (w/o) solids can be prepared by dissolving the sulfonyl fluoride precursor form of the polymer in perhalogenated solvents at temperatures in excess of 220°C at atmospheric pressure. For the preparation of thick solvent cast separators (>100 μm thick) such as those which are useful as stand-alone membranes for many electrochemical processes, the latter procedure provides a fabrication method which is both convenient and suitable for the preparation of membranes with complex geometries. This paper describes the solubility characteristics of sulfonyl fluoride-type perfluorinated polymers in detail, including several new solvents which are useful for dissolving the polymer at temperatures as low as 143°C.

Experimental

The 1100 equivalent weight (EW) perfluorinated sulfonyl fluoride polymer was prepared from Nafion 511 or Nafion 117 by the following procedure. The as-received polymer has converted to the sulfonic acid form by continuous extraction with 18% HCl under reflux for 16h followed by thorough water washing and finally vacuum drying at 80°C for 24h. The polymer was then contacted with SF₆ and HF at 30°-50°C under autogenous pressure in either a 1-liter Monel bomb mounted on a shaker rack or a 1-liter stirred Parr Monel reactor according to the procedure described elsewhere (8). The reaction product was stirred in methanol for several hours and vacuum dried at 40°-60°C for 24h. 1200 EW sulfonyl fluoride polymer was prepared as above from Nafion 501.

¹Present address: The Lubrizol Corporation, Wickliffe, Ohio 44092.

Key words: membrane, solvents, separators, solvation.

All solvents were used as-received from commercial suppliers without further purification. Polymer dissolution was performed in Pyrex (Corning Glass Works) vessels under a blanket of dry nitrogen. The vessel was heated in either an oil or a sand bath and was periodically removed and shaken to promote dissolution.

Swelling measurements were performed on the sulfonyl fluoride form of Nafion 117. The dry membrane was submerged in a given liquid at 20°-24°C and removed, blotted, and weighed daily until it reached constant weight. Reported weight gain values represent averages of at least three days' equilibrium data. Cloud point measurements were made as follows: the sulfonyl fluoride polymer and a 50/50 mixture by weight of Halocarbon Oils 11-14 and 11-21 (Halocarbon Products Corporation) were heated in a test tube to 250°C in an oil bath until dissolution occurred. The test tube was then allowed to cool in ambient air, and the temperature (measured by a thermocouple probe inserted in the solution) at which the solution first became turbid was recorded as the cloud point temperature.

Results and Discussion

Ambient temperature swelling studies.—A number of organic liquids varying in solubility parameter² from 6.8-12.1 Hb were chosen as swelling agents in order to provide clues which would lead to the identification of a suitable solvent for the sulfonyl fluoride fluoropolymer. This solubility parameter range was suggested by Yeo (10) to include the solubility parameter of the "organic part" of the "Nafion precursor" (SO₂F form). The results of these swelling experiments are summarized in Table I and Fig. 1. The only significant weight increase is observed in the solubility parameter range from 7.3-9.1 Hb, which is within the lower range of Yeo's "envelope I" (10). There does not appear to be a good correlation between hydrogen bonding strength of the swelling agent and polymer weight gain since there are examples of high weight gain for both poorly and strongly hydrogen bonding solvents.

Within the class of poorly hydrogen bonding solvents, the perhalogenated compounds all induce polymer weight gains greater than 1.5%, whereas the nonhalogenated liquids swell the polymer to less than 0.7%. Among the perhalogenated liquids, there are two suggested trends. First, as the relative volatility (defined as the ratio of the temperature of the experiment to the boiling point in K) of the solvent increases, the weight gain increases (see Table II). Second, within the solubility parameter window of higher polymer weight gain (7.3-9.1 Hb), fluorinated liquids are more effective swelling agents than chlorinated compounds. Within the class of strongly hydrogen bonding liquids, all of the amines act as effective swelling agents. Piperidine, a secondary amine, may have reacted with the sulfonyl fluoride group of the polymer; thus, the weight gain of 27.45% in piperidine may be misleadingly high. The two tertiary amines probably are not quaternized by the sulfonyl fluoride group under the conditions of this experiment; thus, the weight gain values in these liquids are considered to be representative of the sulfonyl fluoride fluoropolymer *per se*. As was the

²The solubility parameter (δ) is defined as $(\Delta E/V)^{1/2}$ where ΔE is the energy of vaporization to infinite molecular separation and V is the molar volume. The dimension of the solubility parameter used in this paper is the Hildebrand, where 1 Hb = 1 (cal/cm³)^{1/2}. When the solubility parameters of the solvent and solute are very close in value, mutual solubility is thermodynamically favored.

Table I. Swelling data for Nafion 117 (SO₂F form) in various liquids grouped according to hydrogen bonding strength

Swelling agent	Solubility parameter, Hb	Weight gain of Nafion 117 (SO ₂ F) at 20°C, %
Poorly hydrogen bonding

* See text.

case of the poorly hydrogen bonding solvents, the relative volatility of these strongly hydrogen bonding liquids correlates with polymer weight gain (Table II).

Note that triethylamine swells the fluoropolymer more than tributylamine by a factor of two. Since the tertiary nitrogen is less shielded by the alkyl component in triethylamine than in tributylamine, the tertiary nitrogen group may play a significant role in polymer swelling.

Tetrahydrofuran is the only moderately hydrogen bonding liquid that swells the sulfonyl fluoride fluoropolymer to any great extent. This may be due to its high relative volatility (0.867), although diethylether has a larger relative volatility (0.951) but is far less effective as a swelling agent.

In summary, the room temperature swelling experiments suggest that compounds with high relative volatility, fluorine atoms, tertiary nitrogens, and/or cyclic ether oxygens may prove to be effective solvents for the sulfonyl fluoride fluoropolymer.

Polymer solubility.—As pointed out by Gierke (12) and Starkweather (13), these fluoropolymers are partially crystalline at equivalent weights greater than about 910. Therefore, dissolution of the fluoropolymer may be impeded by the presence of crystallinity. It is known (14) that these polymers are soluble in polar organic liquids such as alcohols below about 950 EW but are insoluble in these same solvents above 1000 EW except at elevated pressure (5). This is an analogous situation to the dissolution of other semicrystalline polymers such as polyethylene which require heat to break up the crystalline domains by solvent action. Therefore, compounds with high boiling temperatures which contain the chemical constit-

Fig. 1. Swelling data for Nafion 117 (SO₂F form) in various liquids grouped according to hydrogen bonding strength (see Table I for data). Solid line represents Yeo's "envelope I" (10).

uents suggested by the swelling experiments were chosen for study as potential solvents for the fluoropolymer. In order to maximize the possibility for dissolution in a given compound, the dissolution temperature was chosen to be within 10°C of the boiling temperature of the solvent.

A list of compounds which were successful in dissolving 1100 and 1200 EW Nafion sulfonyl fluoride fluoropolymer is found in Table III. Although at room temperature Halocarbon Oil barely swells the fluoropolymer, at high relative volatility it completely dissolves the material, resulting in a clear free-flowing liquid. As this solution cools, it becomes turbid at a temperature which is dependent upon both equivalent weight and solids content

Table III. Solubility of the sulfonyl fluoride forms of Nafion 501 and 511 at solids concentrations >2 w/o

Fig. 2. Effect of solids content on cloud point temperature for fluoropolymer solutions in Halocarbon Oil.

(see Fig. 2). Below this temperature, the cloud point temperature, the polymer forms a translucent gel and exudes a portion of the solvent (syneresis). The other solvents also form gels as they cool, although most other gels are relatively transparent. The solutions which form solids at room temperature do so by virtue of the melting points of their respective solvents. The driving force for gelation during cooling is most probably related to the energy barrier for dissolution during heating, polymer crystallization.

Examination of Table III confirms several predictions which resulted from the room temperature swelling experiments. First, the solvent must be totally halogenated and preferably fluorinated. The only hydrogens which may be present are carboxylic acid and hydroxyl protons. Aliphatic, aromatic, aldehydic, and sulfonic acid hydrogens are undesirable. Second, the perfluorotertiary amines are good solvents for the sulfonyl fluoride fluoropolymer. Third, relative volatility seems to play a role in the solvation process since the temperature which is necessary for dissolution depends largely upon the boiling point of the solvent. For example, the 1100 EW sulfonyl fluoride fluoropolymer forms a clear 2 w/o solution in pentafluorophenol at 143°C; however, it does not go into solution in Halocarbon Oil at this concentration at temperatures less than 224°C.

Membrane formation from these solutions can be accomplished by standard casting techniques (7). Close control of the solution temperature, the substrate temperature, and the coating speed are required for reproducible results. Since these solutions form gels upon cooling, the solution must be maintained at a temperature within about 10°C of its boiling point during casting. If a cool substrate is dipped into the hot solution, a dense gel layer will form on the substrate. The solvent can then be extracted by leaching in a miscible liquid such as methylene chloride, or it can be driven off in a vented oven. It is often useful to fuse the membrane at 150°C for several hours following solvent extraction to ensure that the sep-

arator is free of pinholes or other imperfections. Flat sheets, thimbles with one closed end, fabric reinforced membranes, and complex shapes have all been formed by this process.

Now that the dissolution of sulfonyl fluoride containing perfluorocarbon polymers has been demonstrated, a number of fundamental investigations aimed at elucidating the molecular architecture of these materials are suggested. High temperature light scattering can reveal molecular weight and chain conformation information. Mechanisms of network formation (crystallinity, side chain aggregation?) could be elucidated by conducting x-ray diffraction and/or light scattering (clear gel systems only) experiments both above and below the gelation temperature. The dynamic mechanical and dielectric response of these gels as a function of temperature would complement similar studies (15) of these materials in the dry state and could provide direct evidence for dipole-dipole interactions between sulfonyl fluoride groups and/or the entire perfluoroether side chains. These are only several of a myriad of fundamental studies which are made possible by the identification of methods to solubilize sulfonyl fluoride containing fluoropolymers.

ABSTRACT

Oxygen reactive ion etching of the planarizing photoresist layer in a three-layer resist system is described. The vertical and lateral etch rates of the thick resist layer, as well as the degree of isotropy of the resist profile, are reported as functions of RF power and oxygen pressure. The optical emission spectra are recorded and interpreted for oxygen plasmas used in etching, revealing the presence of oxygen atoms (O) and ionized oxygen molecules (O_2^+). It is demonstrated that trends in the degree of isotropy which occur with changes in RF power and oxygen pressure can be predicted by monitoring the O/O_2^+ emission intensity ratio.

A three-layer resist system has been developed for use in a variety of applications (1). Some of these applications, such as electron-beam lithography, require the planarizing resist to be etched with vertical walls. In the processing of GaAs devices, on the other hand, lift-off is used to define small metal features. A three-layer resist used for lift-off requires the planarizing layer to be undercut from the edge of the transfer layer. In order to achieve both vertical and undercut profiles reproducibly in the same material requires accurate control of the etch step. Reactive ion etching can be made reproducible when there is some understanding of the etching process. Emission spectroscopy is an unobtrusive technique for gaining information about the chemical species present in the plasma, as well as their relative concentrations. This paper describes how emission spectroscopy can be employed to study oxygen reactive ion etching of photoresist used as the planarization layer of a three-layer system. The spectral data are used to determine and monitor the chemical species in the plasma as functions of gas pressure and RF power. It is then demonstrated how emission spectroscopy can be used as a process development tool to predict and control the degree of isotropy in the profile of the planarization layer.

Experiments

The three-layer resist system developed at the Sperry Research Center employs positive photoresists and plasma deposited silicon nitride. Two micron thick AZ[®] 2430 is used as the planarizing layer, and one-tenth micron silicon nitride is plasma deposited over the resist, which has been hard-baked to prevent wrinkling. Details of this process are reported elsewhere (1). The imaging layer is generally 0.5 μm of a positive resist which can be either electron-beam or optically exposed and then developed. Once developed, the imaging resist acts as a mask for plasma etching the silicon nitride layer in CF_4/O_2 . The

patterned silicon nitride layer then serves as a mask for reactive ion etching of the AZ 2430 layer.

Etching of the AZ 2430 layer is accomplished with 13.56 MHz RF power applied to the bottom electrode of a planar system with a chamber volume of 13.5 liters. The input power to the 25.4 cm diameter electrode is varied between 50 and 450W. MOS purity oxygen is used as the etch gas and the flow of gas into the chamber is controlled by mass flowmeters. The chamber pressure is held constant by an automatic venetian blind valve controlled by a capacitance manometer, where pressures between 5 and 1000 mtorr are studied. During the etching both the top and bottom electrodes are maintained at 40°C.

Samples are etched for varying time periods but never long enough to completely remove the planarizing resist. After the specified etch time, the sample is cleaved and examined in the SEM, where measurements of the etch depth and the amount of undercut from the mask are made from SEM photographs. These data, taken from several locations on the sample, are used to calculate the average vertical and lateral etch rates. The lateral etch rate divided by the vertical etch rate is defined as the degree of isotropy, which is a quantitative way to describe the etched profile of the planarizing resist. The degree of isotropy is calculated for several oxygen pressures and RF input powers, and the average value is reported for each set of conditions.

Emission spectra are taken through a quartz window in the etching chamber using an optical multichannel analyzer. The spectrum between 300 and 800 nm is integrated on a 1024 channel linear diode array detector for 16s, which gives a good signal-to-noise ratio. The relative concentration of a species is determined by computing the area under the peak due to emission by that particular atom or molecule. These areas are corrected by subtracting the background spectra due to stray light and detector noise.

Results

The vertical etch rate of hard-baked AZ 2430 in an oxygen plasma is plotted in Fig. 1 for several values of the

machine parameters. Figure 1 shows the vertical etch rate as a function of RF power at constant pressure values. It can be seen that the etch rate increases linearly with increasing power when the oxygen pressure is 5, 20, 200, and 1000 mtorr. At a chamber pressure of 100 mtorr, the etch rate increases with increasing power, but the dependence is not linear.

The lateral etch rates for the same samples are plotted in Fig. 2 as a function of power at constant pressure. The power dependence of the lateral etch rate is similar to the power dependence of the vertical etch rate. Lateral etch rates increase with increasing power, the dependence being linear except for pressures near 100 mtorr.

Optical emission spectra are recorded of oxygen plasmas under the conditions used for etching. The spectra are recorded without wafers in the chamber to determine which chemical species are generated in the plasma and are available in the gas phase as possible etchants. Figure 3 shows the emission spectrum of a 20 mtorr oxygen

Fig. 2. Lateral etch rates for hard-baked AZ 2430 in an oxygen plasma. Etch rates as a function of RF power for several system pressures.

plasma excited at 300W. The wavelength of a peak or line in the spectrum is used to identify the chemical species responsible for the emission. Most of the emission peaks can be assigned to electronic transitions of oxygen atoms (O) and ionized oxygen molecules (O_2^+). The prominent oxygen atom lines are in the quintet and triplet systems (2). The oxygen molecular ion transitions observed are in the first negative $4\Sigma_g^- \rightarrow 4\Pi_u$ and second negative $2\Pi_u \rightarrow 2\Pi_g$ systems (3). Even though most of the gas in the system is molecular oxygen, the emission from O_2 is too weak to observe, a common occurrence in low pressure discharges (3).

Discussion

The electron-molecule reactions which occur in an oxygen discharge are listed in Table I. The number of ions or

atoms produced from an electron-oxygen reaction depends on the density of oxygen, the cross section for the process (Table I), the number of electrons, and the electron energy distribution within the plasma. To dissociate O₂ into O atoms (reaction 3) requires an electron energy above 4.5 eV (5); ionization of O₂ to O₂⁺ (reaction 1) requires 12.2 eV (5); and ionization of O atoms to O⁺ (reaction 7) requires 13.6 eV (2). From other data it is expected that the electron energy distribution function peaks near 5 eV (6, 7), so to ionize O₂ and O requires electrons in the high-energy tail of the distribution. Other studies have found that oxygen atoms can make up approximately 10% of the plasma (8), but the degree of ionization of O₂ in the type of low temperature plasmas used for etching is of order 10⁻⁷ – 10⁻⁴ (9, 10). Spectral data of the plasmas studied in this work show emission from only O atoms and O₂⁺ ions. No emission is observed due to O⁺ ions, but since the lowest allowed transitions have excitation energies in excess of 25 eV, this does not preclude the presence of O⁺ (the highest energy O and O₂⁺ transitions observed are excited at less than 15 eV). However, Thompson reports that in the positive column of a DC discharge the O⁺/O₂⁺ ratio is equal to 1/70 (11). Therefore, the density of O⁺ is small enough that O⁺ can be neglected as an etchant. Oxygen is a very electronegative element, so electron attachment (reactions 4 and 5) is a likely reaction. However, the reverse of reaction 4 is very rapid (4), so any O⁻ formed would recombine quickly and very little O⁻ would be available for etching. In addition, O⁻ is negatively charged and would be repelled from the cathode, where etching is taking place.

Thus it can be concluded that there are three species present in the oxygen discharge which could possibly be responsible for the etching which occurs: O₂, O, and O₂⁺. It is known that O atoms will etch photoresist, but O₂ molecules will not etch photoresist under the same conditions (12). It is also likely that O₂⁺ ions will etch photoresist; these ions will be accelerated in a direction perpendicular to the wafer surface by the plasma sheath electric field. These ions may be directly responsible for etching photoresist in the vertical direction as proposed by Namatsu *et al.* (13), or these ions may participate in an ion-enhanced mechanism to promote vertical etching. In either case, the vertical etch rate would be proportional to the flux of O₂⁺ ions to the wafer surface. The O atoms produced in the oxygen plasma are unaffected by the sheath electric field, so the atoms will etch in both the lateral and vertical directions.

The degree of isotropy is defined to quantitatively compare etch profiles of the planarizing resist under different plasma conditions. This parameter is defined as the lateral etch rate divided by the vertical etch rate. For completely isotropic etching the degree of isotropy is one, while for anisotropic etching it equals zero. The degree of isotropy is plotted as a function of RF power and oxygen pressure in Fig. 4. The degree of isotropy is seen to increase with increasing pressure. At constant pressure, the degree of isotropy decreases for increasing RF power, but only at low values of power. At high RF power values the degree of isotropy remains constant as the power is increased. This information is valuable for process development. For completely anisotropic etching the oxygen pressure must be below 5 mtorr. Then any power value between 150 and 400W will yield anisotropic etching, but the power value determines the etch rate (Fig. 1). For

Fig. 4. Degree of isotropy of hard-baked AZ 2430 after oxygen RIE. The ratio of lateral to vertical etch rate is shown as a function of RF power for several system pressures. Error bars represent 1 σ uncertainties.

some processing techniques a controlled undercut is desired; this can be reproducibly achieved by using the etch rate and degree of isotropy data in Fig. 1 and 4 (1).

Assuming a model using first-order kinetics, both the vertical and lateral etch rates will be proportional to the density of the reactant species in the etching reaction. By this model the lateral etch rate will be proportional to the number of O atoms present in the plasma and the vertical etch rate will be proportional to the number of O₂⁺ ions. The oxygen atoms also contribute to the vertical etch rate, but at low pressures this contribution can be neglected because the lateral etch rate is small compared to the vertical etch rate (see Fig. 1 and 2). The emission intensities of these species can be used to monitor their relative concentrations in the plasma.

For an observed spectral line, the emission intensity has the form

$$I \propto n_e n_i f(\chi, T_e) \exp(-\chi/kT_e)$$

where n_e is the electron density, n_i is the density of the ions or atoms responsible for the emission, χ is the excitation energy to the upper state, and T_e is the electron temperature. The Boltzmann factor, $\exp(-\chi/kT_e)$, naturally appears in the rate of excitation due to electron collisions (14); the remaining temperature dependence has been written as $f(\chi, T_e)$. Since the Boltzmann factor dominates the temperature dependence for $kT_e \sim \chi$, the ratio of emission intensities for O atoms and O₂⁺ ions is given approximately by

$$\frac{I_o}{I_+} \propto \frac{n_o}{n_+} \exp(-\Delta\chi/kT_e)$$

Here n_o and n_+ are the densities of O and O₂⁺, respectively, while $\Delta\chi = \chi_o - \chi_+$ is the difference in excitation energies for the two spectral lines chosen.

Assuming that the degree of isotropy is proportional to the ratio n_o/n_+ , it is also proportional to I_o/I_+ multiplied by a temperature-dependent factor, $\exp(\Delta\chi/kT_e)$. This correction term is a decreasing function of electron temperature. At low temperatures ($kT_e < \Delta\chi$) corresponding to low power and high pressure in the plasma, the correction term is a strongly varying function. At high temperatures ($kT_e > \Delta\chi$) corresponding to high power and low pressure, this term varies slowly.

The intensity ratios of various oxygen atom lines to the 558 nm O₂⁺ band are plotted in Fig. 5. The ratios are plotted as a function of RF power for a 20 mtorr O₂ plasma. The ratio of oxygen atom lines at 394, 437, 533, 615, and 645 nm to the 558 nm O₂⁺ band changes very little as the power is increased. The ratio of the O atom lines at 777 and 844 nm (latter not shown in the spectrum or plot) to the O₂⁺ band decreases sharply as the power is increased. Similar plots have been made for plasmas produced at O₂ pressures of 5 and 100 mtorr; similar results are observed. The differences between the longer wave-

Fig. 5. Relative emission intensities of several oxygen atom lines compared to the O_2^+ band peaking at 558 nm. The intensity ratio of the 777 nm O line to the O_2^+ band is reduced by a factor of 20 in this plot. Chamber pressure is 20 mtorr.

length lines and the other five O atom lines are not presently understood but are being explored further. Spectra have also been compared to an O_2^+ band at 523 nm and a band in the second negative system of O_2^+ at 383 nm. All of these results show the same dependence of the ratios on machine parameters as observed in Fig. 5.

The ratio of the O atom emission line at 615 nm to the 558 nm O_2^+ band is plotted as a function of power at several values of oxygen pressure in Fig. 6. The ratio of the oxygen atom emission to the ionized oxygen molecule emission decreases as the pressure is lowered. At 5 and 20 mtorr chamber pressure, the ratio increases as the power is raised from 50 to 200W; between 200 and 400W the ratio of emission intensities is constant. For an oxygen pressure of 100 mtorr the curve of intensity ratios falls slightly as the power is raised over the range 50-400W. At oxygen pressures of 200 mtorr the emission curve falls sharply as the power increases.

The emission data in Fig. 6 and the degree of isotropy data in Fig. 4 show important similarities in their dependence on pressure and power. At a fixed pressure of 100 mtorr or below, both graphs flatten for powers above 200W. In addition, at a fixed power, decreasing the pressure decreases both the emission ratio and the degree of isotropy. The lowest degree of isotropy occurs at the lowest pressure, where the ratio of O/ O_2^+ emission is also at a minimum.

Application of the temperature correction term [$\exp(\Delta\lambda/kT_e)$] to the emission intensity data helps to understand the small differences between Fig. 4 and 6 at low power. Consider the data at fixed low pressure (5 or 20 mtorr) where the degree of isotropy is small. At high RF powers, the correction term varies slowly with power and the data shown in Fig. 4 and 6 are in substantial agreement. As the power is decreased, the electron tempera-

Fig. 6. Ratio of O emission at 615 nm to O_2^+ emission at 558 nm. This ratio is plotted against power for several pressures values.

ture decreases and the correction term increases, explaining the apparent discrepancy between the degree of isotropy and the emission data.

Conclusions

It has been shown that the degree of isotropy obtained in oxygen reactive ion etching of the planarizing layer of a three-layer resist system is a strong function of pressure, but a much weaker function of RF power. Emission spectra of oxygen plasmas revealed that O atoms and O_2^+ ions are present and available to etch photoresist. It was demonstrated that the parameter dependence of the degree of isotropy can be predicted by monitoring the O/ O_2^+ emission intensity ratios as functions of the same parameters. The effect that changes in the pressure and power have on the planarizing resist profile can be predicted from changes in the emission ratios.

Low Temperature Plasma-Enhanced Epitaxy of GaAs

K. P. Pande*

Bendix Advanced Technology Center, Columbia, Maryland 21045

A. C. Seabaugh

National Bureau of Standards, Semiconductor Materials and Processes Division, Washington, DC 20234

ABSTRACT

Low temperature ($\leq 450^\circ\text{C}$) deposition of single-crystal GaAs using a new plasma-enhanced MO-CVD technique is reported. In this technique, plasma is created by a dc potential and the substrate is not directly exposed to the plasma. Deposition of GaAs was achieved at extremely low plasma power ($0.3\text{--}0.5\text{ W/cm}^2$) using trimethylgallium (TMGa) and arsine (or trimethylarsenic) reactants. The resulting epitaxial films show excellent surface morphology and thickness uniformity over a large area substrate. A linear dependence of growth rate upon TMGa concentration was observed with a typical growth rate of $0.1\ \mu\text{m/min}$ for a TMGa flow rate of 15 ml/min . Undoped films were found to be n-type with a room temperature mobility in the range of $5200\text{ cm}^2\text{ V}^{-1}\cdot\text{s}^{-1}$. Measurements on Schottky barrier devices fabricated on n/n⁺ layers show uniform impurity doping profiles. Temperature dependence of the diode capacitance indicates a density of deep trapping centers as low as $6.2 \times 10^{13}\text{ cm}^{-3}$.

Significant advances have been made in the preparation of high purity GaAs for microwave and optoelectronic device applications using a number of epitaxial growth techniques (1). These techniques include liquid phase epitaxy (LPE), vapor phase epitaxy (VPE), metal-organic chemical vapor deposition (MO-CVD), and molecular beam epitaxy (MBE). With the exception of MBE, all of these techniques require high growth temperatures, typically $600^\circ\text{--}800^\circ\text{C}$. These high temperature growths can lead to thermally generated defects, interdiffusion, and autodoping in the epitaxial layer. While high quality MBE layers can be grown at lower temperatures ($\geq 500^\circ\text{C}$), this technique requires an expensive ultrahigh vacuum unit, and the epitaxial growth rate is extremely slow. Plasma-enhanced deposition offers the advantage (2) of low temperature growth with comparable or higher growth rates than those achieved with conventional epitaxial techniques. In addition, plasma-enhanced deposition should result in efficient utilization of reactant, high reactivity among constituent atoms, increase in the number of nucleation sites, residual impurity gettering, and high doping efficiency. This paper describes a novel growth system utilizing a plasma-enhanced MO-CVD process. In order to minimize any substrate damage due to radiation and ion bombardment, the substrate is not directly exposed to the plasma. Moreover, deposition of single-crystal GaAs is achieved at extremely low plasma power ($0.3\text{--}0.5\text{ W/cm}^2$) using metal-organic reactants. The use of metal-organic reactants facilitates the use of a simple one-zone reaction chamber, and the grown layers are highly uniform over a large area substrate (50 mm diam).

Experimental Details

Epitaxial GaAs layers were deposited using a reactor configuration shown schematically in Fig. 1. The T-shaped stainless steel pedestal was used as the active plasma electrode on which a dc bias was applied via an electrical feedthrough enclosed in a ceramic sheath. The substrate was placed on the top of the pedestal. The pedestal contains a resistive heater to heat the substrate and a thermocouple to monitor its temperature. The second plasma electrode (passive), placed approximately 2-3 in. below the pedestal, was made of a 1/4 in. diam stainless steel tube bent at 90° , as shown in Fig. 1. Arsine (AsH_3 , 10% in H_2) gas or trimethylarsenic ($[\text{CH}_3]_3\text{As}$) was introduced into the reaction chamber through a row of holes in the horizontal arm of this electrode. All the results reported here were obtained for epitaxial layers grown using arsine, since in using a trimethylarsenic source, high quality layers were not readily achieved. The passive

electrode was kept at ground potential, while a negative dc bias in the range of $300\text{--}350\text{V}$ was applied to the active pedestal electrode to create a plasma in the region shown in Fig. 1. This arrangement prevents the substrate from being directly exposed to the plasma.

For the deposition of epitaxial GaAs, trimethylgallium (TMGa) was introduced from the top of the reaction chamber by bubbling hydrogen through the TMGa source (at 0°C). Dopants [hydrogen sulfide (H_2S) or trimethylsilicon ($[\text{CH}_3]_3\text{Si}$)] can be introduced as needed through the TMGa port. Provisions were also made to etch the substrate *in situ* using gaseous HCl and to cover the substrate with a shutter (not shown in Fig. 1) during initial plasma excitation.

The epitaxial layers were deposited on highly polished Cr-doped GaAs substrates oriented 2° off the (100) direction, toward the (110) direction. Some samples were also

Fig. 1. Cross section of the plasma-enhanced MO-CVD reaction chamber.

Key words: plasma CVD, MO-CVD, low temperature epitaxy, GaAs epitaxy.

grown on highly doped (n^+) GaAs substrates for device application. Prior to the growth, the substrates were cleaned in organic solvents and etched in $H_2SO_4:H_2O_2:H_2O$ (3:1:1 by volume) to remove the surface damage due to polishing.

Before a typical growth run, the system was evacuated to a few millitorr pressure and purged with nitrogen gas. This sequence was repeated at least three times. A plasma was then generated in argon or nitrogen gas to clean the reaction chamber. During this period, the substrate was covered with the shutter to minimize any hydrocarbon deposition on the substrate. After cleaning, the shutter was opened and the substrate was etched (3) *in situ* with gaseous HCl at 200°C (as desired) using a flow rate of 2 ml/min. As soon as the desired growth temperature was stabilized, the reactants were introduced to begin the epitaxial layer growth.

Results and Discussion

Materials.—Epitaxial growth was carried out over the temperature range 250°–500°C with TMGa flow rate varied between 5 and 35 ml/min at constant arsine flow rate of 15 ml/min. During the growth, the pressure in the reaction chamber was maintained between 0.8 and 1.5 torr. Typically, SEM micrographs of the epitaxial layers were highly uniform and featureless (4). Typical epitaxial layer thicknesses were between 1 and 10 μm . The films exhibit excellent thickness uniformity (within 3 to 4%, as measured in an SEM after cleaving and staining) over a large area (50 mm diam) substrate. Films can be grown at temperatures as low as 250°C, but films grown at such low temperatures show gallium inclusions (identified by energy dispersive x-ray analysis using an SEM) and hillock formations (4). By using an SEM in the specimen current mode, electron channeling patterns (ECP) (5) were recorded for films grown at 425°C. The electron channeling patterns for these layers are sharp with fine lines, angular details, and high band contrast (4), showing features very similar to those observed in high quality VPE layers.

To study the growth kinetics, the films were deposited at different TMGa flow rates at a constant arsine flow rate of 15 ml/min. Figure 2 is a plot of growth rate *vs.*

Fig. 2. Variation of growth rate with TMGa flow

TMGa flow. The linearity of the plot indicates that the growth is mass-transport-limited, as reported previously (6). The growth rate was found to be independent of growth temperature in the range 300°–500°C (Fig. 3), with all other deposition parameters constant. Note that below 300°C, the growth rate decreases rapidly, and a significant departure from linearity is observed. Below 300°C, incomplete growth, which may be caused by incomplete pyrolysis of the arsine, occurs.

Without intentional doping, all the epitaxial layers were found to be n -type. Net carrier concentration for undoped layers was found to decrease with decreasing growth temperature, as shown in Fig. 4. At a growth temperature of 350°C, the net impurity concentration derived from Hall-effect measurements was found to be $\sim 5 \times 10^{15} \text{ cm}^{-3}$. Undoped films grown at 400°C show a room temperature Hall mobility of $5200 \text{ cm}^2 \text{ V}^{-1} \cdot \text{s}^{-1}$ (Fig. 4). Films grown below 350°C show a decrease in mobility, which may be due to increased scattering as a result of hillock formation, as reported previously (7).

In order to assess the doping density in typical epitaxial layers, capacitance-voltage measurements were performed on Schottky-barrier diodes fabricated on two undoped n -type layers grown on (Te-doped) n^+ substrates. Both layers were grown at 425°C with a TMGa flow rate of 12 ml/min. Layer B1 was grown with an arsine flow rate of 15 ml/min, while layer B2 was grown with flow rate of 20 ml/min. Both of these layers showed a flat doping profile with net background impurity concentra-

Fig. 3. Dependence of growth rate on growth temperature, with TMGa flow rate of 12 ml/min and AsH_3 (10% in H_2) flow rate of 152 ml/min.

Fig. 4. Dependence of net room temperature carrier concentration and Hall mobility on growth temperature.

doping profile with net background impurity concentration of roughly $5 \times 10^{16} \text{ cm}^{-3}$ (layer B2 is shown, Fig. 5).

To estimate the trap concentration in these films, capacitance-temperature measurements were performed after the method of Sah *et al.* (8). The plots of measured reciprocal capacitance squared as a function of voltage at 77 K and room temperature are given in Fig. 6 for layers B1 and B2. Assuming all the deep traps are ionized at room temperature and deionized at 77 K, the difference in the ionized impurity concentration (measured from the slopes of the two lines) at these two temperatures is equal to the trap density. The lines drawn are least squares fits to the data points. The trap densities for layers B1 and B2 were 6.2×10^{13} and $3.0 \times 10^{14} \text{ cm}^{-3}$, respectively. It is not

Fig. 6. Reciprocal capacitance squared vs. voltage at 77 and 300 K (a) for layer B1 and (b) for layer B2. Upper solid line corresponds to 77 K measurements.

known at present if low trap density in layer B1 is the result of reduced arsine flow rate during growth.

Devices.—The I-V characteristics of a Schottky-barrier device fabricated on an n/n^+ GaAs layer with gold as the rectifying contact exhibited 0.6V forward voltage drop and $\sim 55\text{V}$ reverse breakdown voltage (4). A device ideality factor of 1.02, indicating a thermionic emission transport mechanism, and a saturation current density in the range of 10^{-9} A/cm^2 were determined. A few Schottky-barrier solar cells were also fabricated by evaporating 7.5-10 nm of gold on the active n/n^+ layer. The response of the cells was measured under AM1 illumination. The photovoltaic response of these cells (4) without antireflective (AR) coatings showed an efficiency of 5.7% with high current collection (17.8 mA/cm^2) and fill factor (0.82), although open-circuit voltage was low (0.39V).

Conclusions

A new plasma-enhanced MO-CVD technique for the growth of epitaxial GaAs has been demonstrated. Using this technique, low temperature growth of device-quality GaAs layers with room temperature mobility of $5200 \text{ cm}^2 \text{ V}^{-1} \cdot \text{s}^{-1}$ has been achieved. The films show excellent surface morphology when grown between 350° and 500°C. It is the first time, to the authors' knowledge, that single-crystal epitaxial layers of GaAs have been grown at $\leq 400^\circ\text{C}$ with good electrical properties and device characteristics. Undoped n -on- n^+ epitaxial layers grown at 425°C showed a flat dopant profile with a shallow impurity concentration of approximately $5 \times 10^{15} \text{ cm}^{-3}$. The deep trap content in the epitaxial layers was in the range 6×10^{13} - $3 \times 10^{14} \text{ cm}^{-3}$. Schottky barrier devices show excellent performance with characteristics comparable to those fabricated on VPE- and MBE-grown samples. Solar cells without an AR coating showed an AM1 efficiency of over 5%. Optimization of this growth technique should lead to epitaxial layers with excellent electrical properties for high performance microwave and optoelectronic devices.

Acknowledgments

The authors would like to thank Dr. J. M. O'Connor and Dr. J. Coleman for helpful discussions, D. Ulrich for the SEM work, and Dr. G. P. Carver and Dr. R. A. Wachnik, National Bureau of Standards, for their assistance in the impurity profiling measurements.

Manuscript submitted Oct. 24, 1983; revised manuscript received Feb. 6, 1984.

The National Bureau of Standards assisted in meeting the publication costs of this article.

Fluorescence and Nonradiative Relaxations of Rare Earths in Amorphous Media and on High Surface Area Supports: A Review

Renata Reisfeld

Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel 91904

ABSTRACT

The origins of the electronic levels of rare earths in the condensed phase and the influence of the glassy matrix on the position of the energy levels and factors responsible for radiative and nonradiative transitions are discussed. Examples are given of rare earth intensity parameters and nonradiative transitions in oxide, chalcogenide, and fluoride glasses. The spectral behavior of rare earth ions adsorbed or incorporated into high surface porous materials are discussed.

The main difference between optical spectra of inorganic ions in amorphous materials and crystalline media of comparable composition is the inhomogeneous broadening due to the variety of sites in the former (1, 2). This is due to the fact that the dopant ions in glasses reside in a variety of environments and experience different perturbing local fields. Thus, instead of identical electronic energy levels, there is a distribution of spectroscopic parameters which depend on the host glass composition and result in different radiative and nonradiative transition probabilities. These variations are evident in absorption and fluorescence spectra as inhomogeneously broadened lines when conventional light sources are used. The decay times of fluorescence from excited states of different sites normally exhibit a nonexponential behavior. However, if fast diffusion of excitation energy occurs among the different sites, then the decay will become exponential with the fastest time constant available among the sites.

Laser-induced fluorescence line narrowing (FLN) enables, in some cases, the excitation of a subset of ions having the same energies. In the absence of accidental coincidence of electronic levels, a tunable pulsed laser can be used for determining the electronic levels and transition probabilities of a selected subset of the total ensemble of sites. The intraconfigurational 4f-4f transitions of rare earth ions are especially suitable in this type of investigation because of small electron phonon coupling. The degree of selectivity of the FLN technique depends on the ratio of homogeneous to inhomogeneous widths (3), which is of the order of 10^{-3} for rare earths at low temperatures. Figure 1 (4) provides an example of FLN on Eu^{3+} in phosphotungstate glasses at 4 K, the excitation being performed into the ${}^5\text{D}_0$ level of the different sites. The three-line ${}^5\text{D}_0 \rightarrow {}^7\text{F}_1$ emission is shown as a function of excitation frequency of the ${}^7\text{D}_0 \rightarrow {}^5\text{D}_0$ transition and corresponds to the different sites.

Modeling the atomic arrangement in glass is often done using molecular dynamics. In this technique the position of the ions is calculated by numerical integration of Newton's equations of motion using a model interatomic potential function. This method so far has been applied to SiO_2 , B_2O_3 , BeF_2 , ZnCl_2 , and KCl and multicomponent sodium silicate, sodium borosilicate, and fluoroberyllate glasses (3). While the method is very elegant and promising, its validity is still being tested by comparison with experimentally measured physical properties such as thermodynamic and transport characteristics.

Radiative Transitions

For most practical purposes, the oscillator strengths and the connected radiative-transition probabilities obtained from the absorption spectra correspond to some average values due to the total number of sites. This is also true for the nonradiative-transition probabilities, which are obtained from the measured average lifetimes and average quantum efficiencies of fluorescence.

The positions of the spectra of the rare earth ions which are due to intraconfigurational f-f transitions in amor-

phous materials are only slightly dependent on the host. However, a small shift of the free-ion levels to lower energies, the nephelauxetic effect, can be observed as a result of covalency between the rare earths and the matrix. This is evident especially in chalcogenide glasses (5). The intensity of the transitions can be calculated to a good approximation by the Judd-Ofelt theory, in which the calculated matrix elements of the transition are combined with the experimentally obtained intensity parameters (6).

The optical transitions of rare earths in solids are predominantly of electric dipole character and their spectral intensities can be described using the treatment of Judd and Ofelt. In this approach, the line strength S of a transition between two J states is given by the sum of products of empirical intensity parameters Ω_t and matrix elements of tensor operators $U^{(t)}$ of the form

$$S(J, J') = \sum_{t=2,4,6} \Omega_t \left| \langle aJ || U^{(t)} || bJ' \rangle \right|^2 \quad [1]$$

The values of Ω_t are obtained from a least squares fit of measured and calculated absorption line strengths and typically have an experimental uncertainty of $\sim \pm 10\%$. The integrated intensities of the absorption bands yield Ω_t 's which are an effective average over the different rare earth environments in the glass.

The most significant factor determining the Ω values is the strength of the odd-order terms in the expansion of the local field at the rare earth site. These in turn are affected by the nearest neighbor anion(s) and cations. For a given glass, former systematic changes of Ω_t have been observed with changes in the size and charge of network modifier ions (7).

Intensity parameters of Nd^{3+} , Ho^{3+} , and Er^{3+} are given in Tables I, II, and III.

It has been shown recently (8) for Er^{3+} that the Judd-Ofelt parameters have also a physical meaning, so that the Ω_2 parameter is indicative of the amount of covalent bonding, while the Ω_6 parameter is related to the rigidity of the medium in which the ions are situated.

Nonradiative Transitions

Excited electronic levels of rare earths (RE) in solids decay nonradiatively by exciting lattice vibrations (phonons) (9). When the energy gap between the excited level and the next electronic level is larger than the phonon energy, several lattice phonons are emitted in order to bridge the energy gap. It was recognized that the most energetic vibrations are responsible for the nonradiative decay, since such a process can conserve energy in the lowest order. In glasses, the most energetic vibrations are the stretching vibrations of the glass-network polyhedra, and it was shown that these distinct vibrations are active in the multiphonon process (10) rather than the less energetic vibrations of the bond between the RE and its surrounding ligands. Later (11), it was demonstrated that these less energetic vibrations may participate in cases when the energy gap is not bridged totally by the high energy vibrations. The experimental results reveal that the logarithm of the multiphonon-decay rate decreases linearly with the energy gap, or the number of phonons bridging the gap. The theory of nonradiative decay by multiphonon mechanism was first proposed by

Kubo and Toyozawa (12), who proposed that the basic mechanism allowing such transitions is the correction in the Born-Oppenheimer (BO) approximation due to vibrational motion of ions which admixes the electronic wave function and causes transitions that represent stationary states in the zero-order BO approximation. For multiphonon processes, one has to proceed to higher order being $\Delta E/\hbar\omega$ to get real transitions between the electronic states (13). It should be noted that in contrast to the smallness of the radiative processes of high order, the nonradiative high order processes are quite high.

From the point of view of theoretical treatment, it is extremely difficult to calculate accurately the perturbation of a high order. However a considerable part of ΔH_{vibr} can be eliminated as a perturbation by including it exactly in the wave function by a "renormalization." The part of ΔH_{vibr} which still remains after renormalization is the non-adiabaticity of the BO correction operator. At the end of the calculation, an approximation is made of the interaction with only one phonon mode (14-18). For small coupling and low temperature, a Poisson-like function is obtained (17) for the distribution of the multiphonon relaxation rate with the number of phonons. The nonradiative transition probability W_p is given by

$$W_p = \exp(-S) S^p/p! \quad [2]$$

where S is the Huang-Rhys-Pekar number (13), and

$$S(T=0) = 1/2 \Delta^2 \quad [3]$$

(S is the measure of electron phonon coupling strength.)

The displacement Δ measures the horizontal shift of the electronic state potentials in units of the zero-point amplitude. In the case of an isolated RE ($S \ll 1$), S can be incorporated in the exponential formula of Dexter

$$W = \beta \exp(-\alpha \Delta E) \quad [4]$$

with

$$\alpha = (\hbar\omega)^{-1} [\ln(p/S) - 1] \text{ for low temperature} \quad [5]$$

and

$$\alpha = (\hbar\omega)^{-1} [\ln(p/S)(n+1) - 1] \text{ for } T > 0 \quad [6]$$

n being the phonon occupancy number or

$$n = (\exp(-\hbar\omega/kT) - 1)^{-1} \text{ as explained in Ref. (19)} \quad [7]$$

Application of the multiphonon theory to glasses requires the knowledge of the structural units forming the glass. Similar to the electronic spectra in glasses, the vibrational frequencies show inhomogeneous broadening due to the variation of sites. Table IV shows the average frequencies of the network formers. The vibrations involving the network modifiers are lower by a factor of 2 to 4. The lack of symmetry in a glass and the molecular character of the high energy vibration were taken into account by Layne *et al.* (20) in developing the theory of multiphonon relaxation in glass using higher order terms in the perturbation theory. The dependence of a multiphonon rate on the energy gap to be bridged results then from the ratio of p-phonon process to that for a p-1 phonon decay. Assuming the average matrix elements to be the same for p- and p-1-order processes, the ratio of W_p

to W_{p-1} is

$$W_p/W_{p-1} = (\hbar/2M\omega) (n+1) 4m^2 | \langle a|V|b \rangle |^2 / (\hbar\omega)^2 \quad [8]$$

Since the perturbation is weak

$$W_p/W_{p-1} = \epsilon \ll 1 \quad [9]$$

This result leads to the following exponential dependence of the rate on the energy gap

$$W_p = W_0 \epsilon^p = W \exp [\ln(\epsilon)/\hbar\omega] \Delta E \quad [10]$$

Considering the dependence of W_p on the phonon occupation number from Eq. [7], the rate for a p-order multiphonon decay is at temperature $T > 0$

$$W_p = W_0 [n(T) + 1]^p \exp(-\alpha \Delta E) \quad [11]$$

where

$$\alpha = -\ln(\epsilon) \hbar\omega \quad [12]$$

and $W_0 = \beta$ of Eq. [4] is dependent on the host but independent of the specific electronic level of RE from which the decay occurs.

Struck and Fonger have treated the nonradiative decay processes by a numerical matrix method (21) and found that in the case of rare earth ions where there is a small offset in the configurational coordinates the multiphonon transition rate can be treated by the Kiel formula of the type which is consistent with Eq. [11] presented in Eq. [4], [10], and [11].

In calculating theoretically the multiphonon relaxation Siebrand (22) has used the Condon approximation in which the electronic matrix elements are separated from the vibrational ones and assuming that the transition is dominated by a small number of promoting modes which consume the energy $\hbar\omega$. The accepting modes provide only for the remaining energy difference $\Delta E_0 - \hbar\omega_{\max}$.

The theoretical results arising from this theory are

$$W_{NR} = \exp(-\Delta E_0 - 2\hbar\omega_{\max}) \alpha \quad [14]$$

By developing this theoretical expression further, van Dijk and Schuurmans (23) have shown that the pre-exponential factor in the nonradiative relaxation expression does not vary by more than one order of magnitude for the various compounds studied, and is due to the electronic factor.

The multiphonon decay rate from a given level to the next lower level decreases with the lowering of energy of the stretching frequencies of the glass former. Since a large number of phonons is needed in fluoride glasses and more so in chalcogenide glasses in order to reach the same energy gap, the nonradiative relaxations are smallest in these hosts. Dependence of the multiphonon transition rate on the number of phonons from the emitting to the next lower level for a number of glasses and crystal hosts are presented in Fig. 2.

The parameters α and β of Eq. [4] and ϵ of Eq. [12] of glasses and crystals are presented in Table IV together with the phonon frequencies.

Chalcogenide and Fluoride Glasses

Chalcogenide and fluoride glasses have been found to be highly efficient phosphors with several activators. These glasses have also low absorption in the infrared part of the spectrum because of the high order multiphonon absorption in this region, lower than that for the oxide glasses.

Rare earth sulfides with Ga_2S_3 and Al_2S_3 were prepared by Flahaut and his group, who have studied in detail the phase diagrams of these materials (24). The glass of composition $3Al_2S_3 \cdot La_2S_3$ (ALS) is transparent from 1,500-25,000 cm^{-1} , and the glass of composition $3Ga_2S_3 \cdot La_2S_3$ (GLS) from 1,500-20,000 cm^{-1} . These may prove important materials for fiber optical waveguides.

Laser emission cross sections of the 1077 and 1370 nm emissions of Nd^{3+} in $3Ga_2S_3 \cdot 0.85 La_2S_3 \cdot 0.15 Nd_2S_3$ (GLS) and $3Al_2S_3 \cdot 0.872 La_2S_3 \cdot 0.128 Nd_2S_3$ (ALS) were obtained from the calculated matrix elements in the glasses, exper-

Fig. 2. Dependence of multiphonon transition rate on number of phonons in different glasses.

imentally measured intensity parameters, emission half-widths, and lifetimes. The laser threshold power for side-pumping in the chalcogenide glasses is much lower than for ED-2 glass.

The peak cross sections of Nd^{3+} in GLS are $7.95 \times 10^{20} cm^2$ at 1077 nm and $3.60 \times 10^{-20} cm^2$ at 1320 nm; $8.20 \times 10^{-20} cm^2$ at 1077 nm and $4.10 \times 10^{-20} cm^2$ at 1370 nm in ALS, as compared to $2.90 \times 10^{-20} cm^2$ at 1060 nm and $0.72 \times 10^{-20} cm^2$ at 1300 nm for ED-2 glass (25).

A new family of fluoride glasses was obtained in 1975 by Poulain *et al.* (26) in Rennes. They are called fluorozirconate glasses containing large amounts (above 50 mol percent [m/o]) of ZrF_4 (which can be replaced by HfF_4 or ThF_4) along with lesser amounts of alkaline-earth, rare earth, or uranium IV fluorides. Miranday *et al.* (27, 28) prepared another type of new fluoride glasses based on PbF_2 and 3d-group fluorides.

Because of the low relaxation of the rare earth luminescent ion in fluoride glasses, they can provide an ideal medium or host for various devices. The high infrared transmittance and good chemical stability makes them suitable for integrating the laser light source and the waveguide itself. The spectroscopic and fluorescent properties of Nd^{3+} containing fluorozirconate glasses have been reported by Weber in work with the Lucas-Poulain group in Rennes (29).

The low multiphonon relaxation in fluoride glasses is also evidenced by the luminescence arising from the 3D_3 , 5D_2 , and 5D_1 levels of Eu^{3+} in addition to the 5D_0 fluorescence in fluoride glasses (30). An example of such fluorescence is presented in Fig. 3 for Eu^{3+} in a glass of composition $57ZrF_4 \cdot 34BaF_2 \cdot 4AlF_3 \cdot 3LaF_3 \cdot 2EuF_3$.

The luminescence characteristics of Er^{3+} in fluoride glasses were studied recently (31). Because of low nonradiative relaxation, emission of Er^{3+} in these glasses can be observed from the first, second, fourth, and fifth electronic levels when excited into the $^2H_{11/2}$ level (see Fig. 4). In all these cases, the energy gap is lower than $2800 cm^{-1}$ to the next lower excited level.

Since the undoped materials are excellent candidates for fiber optic waveguides due to their high transmittance in the infrared and their chemical stability, it was suggested that erbium-doped materials having the desired laser emission wavelengths, which can be selected from Table V, be used as light sources for fiber optic systems. They could be integrated into the waveguide providing integrated fiber optic systems (31).

Fig. 3. Emission spectrum of Eu^{3+} in the glass $57\text{ZrF}_4:34\text{BaF}_2:4\text{AlF}_3:3\text{LaF}_3:2\text{EuF}_3$ under 395 nm excitation.

Fig. 4. Comparison of emission spectra of Er^{3+} in two fluoride glasses (1) 2.00 w/o $\text{ErF}_3:46\text{PbF}_2:22\text{ZnF}_2:30\text{GaF}_3:2\text{LaF}_3$ m/o, and (2) 2.66 w/o $\text{ErF}_3:57\text{ZrF}_4:34\text{BaF}_2:3\text{LaF}_3:4\text{AlF}_3$ m/o.

The emission of Er^{3+} in fluoride glasses can be additionally intensified by the process of energy transfer from Mn^{2+} to Er^{3+} (32).

Luminescence of Rare Earths Adsorbed on Porous Glasses

When porous glasses are dipped into a rare earth solution, the ions are adsorbed into the glass pores and exhibit fluorescence similar to that obtained for ions in the bulk of a glass (33).

Vycor porous glass, Corning no. 7930, has an average pore diameter of 40-70Å, sufficiently large for the penetration of rare earth ions or complexes. The surface area of such glasses is about 200 m²/g, as obtained by the nitro-

Fig. 5. Emission spectrum of Eu^{3+} adsorbed on Vycor

gen BET method. Also compressed pyrogenic silica gel Cab-O-Sil Aerosil, yields porous transparent disks (34). The disks are totally transparent in near-ultraviolet and visible light.

The relative intensities of fluorescence in the various rare earth ions adsorbed in Vycor and fumed silica disks are: $\text{Tb} > \text{Eu} > \text{Dy} > \text{Tm} > \text{Pr} > \text{Ho} > \text{Er}$ (35).

Figure 5 presents the fluorescence spectrum of Eu^{3+} adsorbed on Vycor. The hypersensitive transition $^5\text{D}_0 \rightarrow ^7\text{F}_2$ is much higher than the $^5\text{D}_0 \rightarrow ^7\text{F}_1$ transition due to magnetic dipole. Such a picture corresponds to the well-known behavior of the Eu ion in a low symmetry site.

We believe that a chemical bond is formed between Eu^{3+} and the glass support since the adsorbed ion cannot be washed out by liquids.

The ratio between the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ transition to the $^5\text{D}_0 \rightarrow ^7\text{F}_1$ transition is even greater when Eu-benzoylacetonate is adsorbed on Vycor glass. The introduction of fluorescent complexes into porous glasses opens a possibility of using inorganic species with organic ligands, and thus increasing the luminescence by several orders of magnitude (36).

Energy transfer between dyes and rare earth ions can also be performed on various types of glass (37).

Application of Luminescence of Rare Earths in Luminescence Solar Concentrations

While the luminescence of rare earths for lasers (Nd-glass laser) and phosphors has been well established during the last two decades, their use in luminescent solar concentrators has been proposed only recently (38-40).

The first attempt to use neodymium ions for solar collectors was made by Levitt and Weber (41), who measured devices consisting of Owens-Illinois ED-2 Nd-doped laser glass. The efficiency of this glass for solar collection is rather low because of the low absorption of Nd^{3+} in this glass. The problem can be circumvented by incorporating Nd^{3+} into tellurite glass. Calculated plate efficiencies of Nd^{3+} in tellurite glass based on optical measurements of absorption and emission spectra and quantum efficiency

Table V. Selected possible laser transitions of erbium(III) in the glass $57\text{ZrF}_4:34\text{BaF}_2:3\text{LaF}_3:4\text{AlF}_3:2\text{ErF}_3$

of Nd^{3+} are 12%, which is three times higher than in conventional silicate glass (42).

Reisfeld and Kalisky have shown that a combination of UO_2^{2+} with Nd^{3+} or Ho^{3+} in glass (39) extends the spectral sensitivity range of luminescent solar concentrators due to efficient energy transfer from the $20,500\text{ cm}^{-1}$ excited level of the uranyl ion. Both energy transfer and direct excitation to the Nd^{3+} levels provide the well-known laser transition ${}^4\text{F}_{3/2} \rightarrow {}^4\text{I}_{11/2}$ (1060 nm) with a branching ratio around 0.5, as well as the transition to the ground state ${}^4\text{F}_{3/2} \rightarrow {}^4\text{I}_{9/2}$ (880 nm) (6). The latter transition is a resonant one and repopulates the ${}^4\text{F}_{3/2}$ level, and thus no appreciable amount of energy is lost by reabsorption. Both transitions lie in the spectral range in which silicon solar cells have high spectral sensitivity.

ABSTRACT

Phosphor depreciation due to physical damage has been studied. The effects of ion bombardment on luminescence, lattice disorder, and affinity for Hg atoms are investigated. The following results are obtained for $Zn_2SiO_4:Mn$ polycrystal: An amorphous layer of about 3000Å in depth is produced at the surface bombarded by Ar^+ ions with an energy of 200 eV. Hg atoms are adsorbed more easily at the ion bombarded surface than the nonbombarded surface. It is also found for 16 kinds of phosphor powders that the deterioration characteristic caused by ion bombardment is similar with that of lumen depreciation of a fluorescent lamp composed with the same phosphor. The possibility of the lumen depreciation of a fluorescent lamp arising from the ion bombardment is discussed.

Since the advent of the fluorescent lamp in the middle nineteen-thirties, many technical efforts have been expended for improvements in the fluorescent lamp. Nevertheless we have little information concerning the phosphor depreciation in a burning fluorescent lamp. In the investigation of the depreciation mechanism of a fluorescent lamp, the possibility of phosphor depreciation due to ion bombardment has not been denied completely. For example, Lehmann (1) proposed that phosphor depreciation is caused by energetic ion bombardment in the fluorescent lamp, although the generation mechanism of the energetic ions is not still clear. However, studies of the effects of ion bombardment on the properties of fluorescent phosphors are few. In this work we investigated the influence of ion bombardment on phosphor depreciation. First, physical damage of $Zn_2SiO_4:Mn$ polycrystal by ion bombardment is presented. An amorphous layer of about 3000Å in depth is produced at the surface bombarded by Ar^+ ions with an energy of 200 eV. The amorphous layer is nonluminescent under UV light excitement, but absorbs UV light. Hg atoms are adsorbed more easily at the amorphous layer than the nonbombarded polycrystal surface. Next ion bombardment test for phosphor powders and burning test for fluorescent lamps were carried out concerning 16 kinds of phosphors. The results show that the depreciation characteristic of phosphor powders induced by the ion bombardment is similar with that of lumen depreciation of fluorescent lamp. Finally the possibility of the lumen depreciation of fluorescent lamp arising from ion bombardment is discussed.

Experimental

Preparation of $Zn_2SiO_4:Mn$ polycrystalline disk.—To investigate the influence of ion bombardment on the properties of phosphor, it is desirable to use a large crystal surface rather than powders. Using the floating zone method (2), we prepared $Zn_2SiO_4:Mn$ polycrystals. Appearances of as-grown $Zn_2SiO_4:Mn$ polycrystal rod and its cross section (8 mm in diameter) normal to growth direction are shown in Fig. 1. The interior part of the cross section is composed of polycrystalline grains of about 0.5 mm in diameter, and the crystal axis [111] of each grain is uniquely parallel to the growth direction. The interior part was used for the experiment.

Apparatus for ion bombardment.—A schematic diagram of an apparatus used for the ion bombardment is shown in Fig. 2, which is a usual RF (radio frequency) diode sputtering apparatus. When RF voltage is applied on the target holder, glow discharge occurs and the phosphor placed on the target holder is bombarded by energetic positive ions. In the present experiment, the glow discharge was made in pure Ar or a mixed gas of Ar and

Hg vapor. Hg vapor was evaporated naturally from a glass vessel containing Hg. During the ion bombardment, gas pressure of Ar or Ar-Hg gas was maintained at 0.03 torr and the RF voltage was at 200 or 400V.

Phosphor powders used in this experiment.—An ion bombardment test for phosphor powders and a burning test for fluorescent lamps were carried out concerning the following 16 kinds of phosphors: (i) $(LaCe)PO_4:Tb$, (ii) $3.5MgO \cdot 0.5MgF_2 \cdot GeO_2:Mn$, (iii) $Y_2O_3:Eu$, (iv) $CaWO_4:Pb$, (v) $MgAl_{11}O_{14}:CeTb$, (vi) $CaO_{10}(PO_4)FCl:Eu$, (vii) $BaMg_2Al_{16}O_{27}:Eu$, (viii) $(SrCa)_5(PO_4)_3Cl:Eu$, (ix) $Y_2O_3:S:Eu$, (x) $Sr_5(PO_4)Cl:Eu$, (xi) $Sr_2P_2O_7:Sn$, (xii) $Y(PV)O_4:Eu$, (xiii) $Ba_2P_2O_7:Ti$, (xiv) $(SrMg)_3PO_4:Sn$, (xv) $YVO_4:Eu$, (xvi) $Zn_2SiO_4:Mn$. Correlation between the phosphor depreciation by ion bombardment and the lumen depreciation of fluorescent lamp was investigated.

Results and Discussion

Damage of phosphor surface by Ar^+ ion bombardment.—In the following experiments, we used the $Zn_2SiO_4:Mn$ polycrystalline disks indicated in Fig. 1, which were polished and etched by diluted HF solution. Then half the region of the disk surface was bombarded by Ar^+ ions with an energy of 200 eV using the apparatus illustrated in Fig. 2. Hg^+ ion bombardment gave a similar result, so we show only the results for the Ar^+ ion bombardment to make clear the influence of physical damage.

Amorphous layer by ion bombardment.—Residual damage on the $Zn_2SiO_4:Mn$ surface by the Ar^+ ion bombardment has been investigated by high energy electron diffraction (RHEED). The RHEED pattern for original nonbombarded surface is indicated in Fig. 3(a). Sixfold symmetry spots and extra spots are observed. But after the Ar^+ ion bombardment, all these spots vanished and the pattern changed to hollow pattern as shown in Fig. 3(b). This result indicates that most atoms at the $Zn_2SiO_4:Mn$ surface are microscopically displaced from the regular position, that is, the surface becomes amorphous by the ion bombardment.

Depth of amorphous (damaged) layer.—Depth of amorphous layer was estimated as follows. After the ion bombardment, a thin layer was removed chemically by diluted HF solution (0.03N), and cathodoluminescence was measured at each surface. In this case, the mean etch rate for $Zn_2SiO_4:Mn$ was determined to be 230 Å/min from the scanning microscope views of the cross sections of etched samples. Figure 4(a) shows the cathodoluminescence spectra at different etching time. Figure 4(b) indicates the peak intensities of the spectra as a function of the etching time or the etched depth. It is found that the defects which deteriorate the cathodoluminescence range to the depth of about 3000Å from the surface. At the surface there is a heavily damaged layer whose depth is be-

Fig. 1. Appearances of the as-grown $Zn_2SiO_4:Mn$ polycrystal rod and its cross section. The growth direction is parallel to the crystal axis [111]

low 100Å. Similar defect distribution monitored by photoluminescence intensity was obtained for ion-bombarded GaAs by Kawabe *et al.* (3). Since direct atom displacement by ion bombardment is thought to be much smaller than the depth of 3000Å, the heavily damaged layer will be the region corresponding to the direct atom displacement and the diffusion of defects will be responsible for the following damaged layer. The presence of this kind of diffused defects was assumed by Lehmann (1) in the investigation of phosphor depreciation. Our result confirms his assumption experimentally, although our bombarding ion energy (200 eV) is larger than that in Lehmann's report (100 eV).

Mercury adsorption on phosphor.—Fluorescent lamp phosphors originally have strong resistance against mercury adhesion. However ion bombardment changes this character. This will be understood from the following two experiments. The $Zn_2SiO_4:Mn$ polycrystalline disks were treated following processes (I), (II), and (III) indicated in Fig. 5(a), where process (I) is the bombardment by 200 eV Ar^+ ions, process (II) is the dipping process accompanying the stirring of Hg pool by ultrasonic vibrator, and process (III) is annealing at 400°C in air.

(i) Using electron probe microanalysis, we first measured the Hg signal on the $Zn_2SiO_4:Mn$ surface. In this

case, ion bombardment [process (I)] was carried out for only a part of the disk surface, and then the disk was dipped into Hg pool [process (II)]. The Hg signal at boundary area between the bombarded and nonbombarded parts is shown in Fig. 5(b). Almost all large signals are observed at the bombarded part. This result indicates that ion bombardment promotes the adsorption of Hg on the $Zn_2SiO_4:Mn$ phosphor.

(ii) To detect the adsorbed Hg atoms by another method, the samples were annealed abruptly at 400°C [process (III)]. In this case, the adsorbed Hg atoms will amalgamate with phosphor, and recovery of photoluminescence intensity will be hindered. Figure 5(c) shows the change in photoluminescence intensity during the above three processes. A curve (I-III) indicates that the ion bom-

(b) Hg distributions on the bombarded and nonbombarded parts measured by electron probe microanalysis. (c) Photoluminescence intensity with respect to the above processes (I), (II), and (III).

bombarded sample is completely recovered by the annealing process (III). For the case of the nonbombarded sample, too, the photoluminescence intensity becomes 100% after the dipping and annealing processes as shown by a curve (II-III). However, when the bombarded sample is dipped into the Hg pool and then annealed, the photoluminescence intensity does not return to 100% as indicated by a curve (I-II-III). This depreciation is thought to be due to an amalgamation of the amorphous layer with Hg atoms, so we can say that Hg atoms are adsorbed mainly on the bombarded phosphor surface. This is the same result as that by electron probe microanalysis. Both results in Fig. 5(b) and (c) indicate that Hg adsorption is enhanced by ion bombardment, that is, the amorphous layer is more reactive in the adsorption of Hg atoms than crystalline surface.

Depreciation characteristic and annealing effect.—First we carried out the ion bombardment test for the $\text{Zn}_2\text{SiO}_4:\text{Mn}$ phosphor powder. The powder was put into a small stainless steel box and bombarded by Hg^+ or Ar^+ ions. Figure 6 shows the change in the logarithm of normalized photoluminescence intensity, $\ln P_t$, with respect to the square root of the bombarding time, \sqrt{t} . In both cases for the ion bombardments by Hg^+ and Ar^+ , the depreciation characteristic is the same. Data for 200 eV ion bombardment lie on a straight line as shown in Fig. 6, which indicates that P_t is expressed by an exponential function of \sqrt{t} . This time dependence is the same as that reported by Lehmann (1) for lower ion bombardment. Data for 400 eV ion bombardment are also indicated in Fig. 6. In this case, the data are approximately expressed by the two straight lines. At the initial stage of ion bombardment, the phosphor depreciates at a higher speed and thereafter the decreasing rate becomes slow. According to Lehmann's consideration (1), the photolumines-

cence intensity should be proportional to $\exp(-\alpha c \sqrt{t})$, where α is the optical absorption constant for UV light of the damaged layer, c is a constant, and I is the intensity of bombarding ion flux. The above expression explains the results in Fig. 6 at the initial stage at least, because the increase of RF voltage means the increase of the bombarding ion flux according to diode sputtering theory (4). Therefore we can understand the results in Fig. 6 by the same model mentioned by Lehmann (1), which assumes that the damaged (nonluminescent) layer opti-

Fig. 6. Depreciation curves of the photoluminescence intensity P_t for ion-bombarded $\text{Zn}_2\text{SiO}_4:\text{Mn}$ powder at RF voltages of 200 and 400V.

cally absorbs exciting UV light and the thickness of damaged layer can be expressed by $c\sqrt{t}$.

Next we investigated the annealing effect on the photoluminescence after ion bombardment. Damage by ion bombardment vanishes by heating the sample. Figure 7 shows the recovery characteristic of photoluminescence by thermal annealing for $\text{Zn}_2\text{SiO}_4:\text{Mn}$ powder. The decreased photoluminescence by Ar^+ ion bombardment is perfectly recovered by annealing at a temperature of 400°C in air under atmospheric pressure. The same phenomenon was observed by annealing in H_2 gas, which indicates that the photoluminescence recovery is due to thermal rearrangement of the displaced atoms at the nonradiative layer, but not to some oxidation. However the damage by Hg^+ ion bombardment does not recover perfectly by the annealing. This residual damage is thought to be induced by the amalgamation of phosphor with Hg atoms.

The relatively low annealing temperature in this experiment is not so exceptional a condition. For example, in annealing experiments for ion-bombarded Ag, Ge, and GaAs, the annealing temperature ranged from 300° to 500°C , and sufficient annealing effect was obtained for the recovery of lattice disorder and luminescence (3, 5, 6). These low annealing temperatures react as follows; Defects generated by ion bombardment are easily movable at a room temperature as indicated in the diffusion of defects in Fig. 4, and so these defects conversely are removed by annealing at a relatively low temperature.

Relation between phosphor depreciation by ion bombardment and lumen output drop of fluorescent lamp.—Figure 8 shows lumen output L_t of fluorescent lamps of $(\text{LaCe})\text{PO}_4:\text{Tb}$ and $\text{Zn}_2\text{SiO}_4:\text{Mn}$ as a function of burning time t . The time dependence of L_t is the same as that of the photoluminescence intensity P_t in Fig. 6, although the scale of burning time in Fig. 8 is much longer than that of bombarding time in Fig. 6. Similar time dependence of L_t and P_t was observed for the remaining 14 kinds of phosphors. To investigate the relation between L_t and P_t , the intensities of L_t after 100, 500, and 1000h during the burning test run were plotted in Fig. 9(a), (b), and (c), respectively, with respect to the intensity of P_t after the Hg^+ ion bombardment for 1h. According to a regression analysis, a regression line of L_t on P_t is indicated as a solid line. In this case, the regression line was expressed by the relation $(100 - L_t) = \beta(100 - P_t)$, where β is the inclination of the line. Two dashed lines corresponding to two inclinations $\beta(1 \pm 0.3)$ are also described in Fig. 9. Most data points enter the region surrounded by the two dashed lines. These results indicate the tendency that the phosphor depreciated easily by ion bombardment also degrades rapidly in a fluorescent lamp during the burning test.

Fig. 7. Annealing characteristic of the photoluminescence of $\text{Zn}_2\text{SiO}_4:\text{Mn}$ powder bombarded by Ar^+ or Hg^+ ions.

Fig. 8. Maintenance of two fluorescent lamps with thin coatings of phosphors, $(\text{LaCe})\text{PO}_4:\text{Tb}$ and $\text{Zn}_2\text{SiO}_4:\text{Mn}$.

It has been said that there is a correlation between Hg content in a depreciated lamp phosphor and lumen drop of its fluorescent lamp, and so the contamination of Hg atoms at the phosphor surface is responsible for the long-term depreciation of the lamp. For example, Froelich (7) proposed a photochemical depreciation process where the excited Hg atoms react with phosphor atoms such as oxygen. From this point of view, a criterion is deduced that a phosphor which has a long life in a burning lamp is the phosphor which resists the adsorption of Hg atoms. At the present stage, however, the content of Hg in the

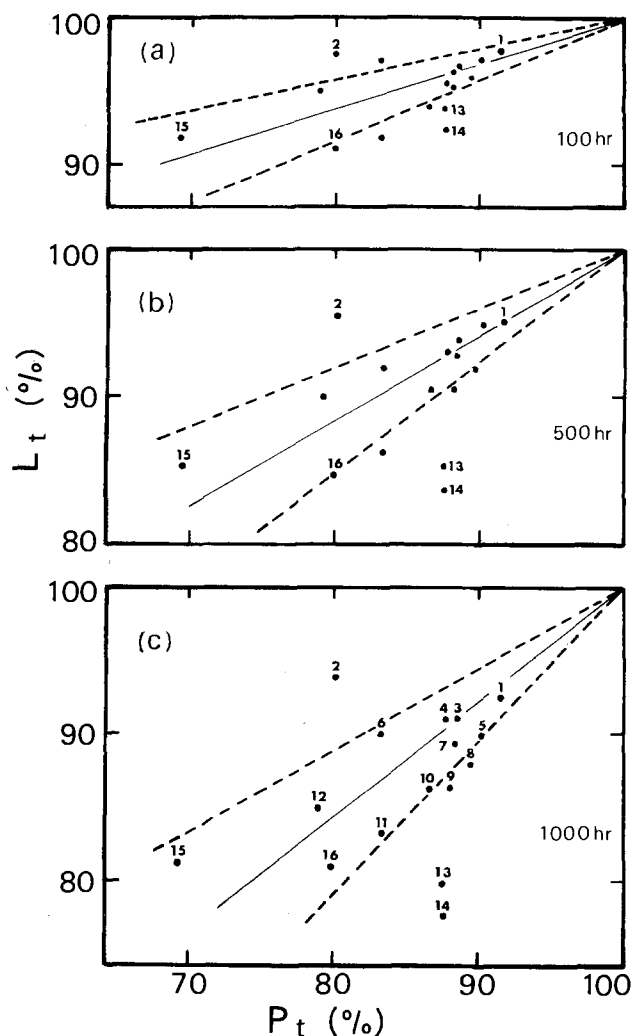

Fig. 9. Relation between the photoluminescence of the phosphors bombarded by Hg^+ ions for 1h and the lumen output of fluorescent lamp after the burning time for (a) 100, (b) 500, and (c) 1000h. The data for the 16 kinds of phosphor powders mentioned in the experiment are plotted. The solid line is a regression line which is expressed by the relation $(100 - L_t) = \beta(100 - P_t)$, where β is the inclination. Dashed lines are expressed by the relations $(100 - L_t) = \beta(1 \pm 0.3)(100 - P_t)$.

depreciated lamp phosphor depends on the different phosphors and the criterion to estimate the affinity of Hg atoms for phosphor is not known as pointed out by Narita (8). We can obtain another criterion to improve the phosphor maintenance. The results indicated in Fig. 6, 8, and 9 show that there is a close relation between the susceptibilities of the lumen drop of a fluorescent lamp and the phosphor depreciation by ion bombardment, and that the phosphor which has a long life in a fluorescent lamp is also stable for the Hg⁺ ion bombardment. Therefore the influence of ion bombardment on the phosphor depreciation by physical damage in a fluorescent lamp is supposed. However, for phosphor depreciation in a lamp, the presence of energetic ions to produce an amorphous layer is not demonstrated explicitly, so precise experimental works are necessary further for this point. Furthermore, taking into account that the adsorption of Hg atoms is enhanced by ion bombardment as indicated in Fig. 5, we think that the influence of ion bombardment on phosphor depreciation by Hg adsorption should be also taken into consideration for the depreciation mechanism of a fluorescent lamp.

Conclusions

In this experiment we obtained the following results:

1. Under energetic ion bombardment, the phosphor surface becomes amorphous. The depth of the amorphous layer is about 3000Å for ion bombardment by Ar⁺ ions with an energy of 200 eV. This amorphous layer is non-radiative under UV light excitement and absorbs UV light.
2. Adsorption of Hg atoms on the phosphor surface is enhanced by ion bombardment.
3. The depreciation characteristic of phosphor induced by ion bombardment is similar to that of lumen depreciation of a fluorescent lamp.

4. One of the criteria to produce the phosphor which has a long life is to prepare the phosphor which is strong for ion bombardment.

5. The results obtained in this experiment suggest that the influence of ion bombardment on phosphor depreciation should be taken into consideration for the lumen drop of a fluorescent lamp.

A Simple Pre-Exposure Treatment to Improve Post-Develop Photoresist Step Coverage

Robert Carlson

Honeywell, Incorporated, Solid State Development Center, Plymouth, Minnesota 55441

ABSTRACT

In this study, a pre-exposure treatment to AZ-type photoresist that helps post-develop step coverage is reported. Using the present-day standard technique, the photoresist is coated and baked. This is followed by an immersion of the wafers in a dilute alkaline base such as 5:1 AZ351 developer for a short time. The wafers are then rinsed, dried, exposed, and developed using standard techniques. By this procedure, a significant improvement in step coverage has been observed. A possible reaction mechanism is proposed.

In semiconductor device fabrication, step heights of the order of 1 μm are not uncommon. Photoresist deposited on such surfaces by spin coating technique gives rise to nonuniform thickness of the photoresist layer in the vicinity of the steps. Postpatterning linewidth variation near the steps in the form of notching has been reported by several authors (1, 2). Nonuniform photoresist linewidths on metal layers result in nonuniform conductor linewidths, which in turn lead to electromigration failure and nonuniform electrode spacing in CCD. In extreme cases, discontinuities in the conductor due to poor step coverage have been observed. Increased usage of dry etching to produce small features adds to the step-

coverage problem by leaving vertical feature walls and cusped upper edges. The PCM technique (3) is one of the few solutions to this problem. In this study, a simple pre-exposure treatment has been investigated by the authors which gives improved step coverage without making the lithography process more complex.

Experimental

A pattern was etched in a 1.25 μm thick thermally grown SiO₂ layer on the wafer surface to produce steps of height about 1.25 μm . The wafers were primed with HMDS and coated with Shipley's AZ1350 photoresist to an average thickness of about 1.5 μm . After air drying for 10 min, the photoresist-coated wafers were baked at 90°C for 30 min in a convection-type bake oven. At this point,

Fig. 1. Wafer processed with pre-exposure treatment

Fig. 2. Wafer processed by standard method. Note the resist line thinning over the step.

the wafers were divided into two groups. One group of wafers (Group A) were immersed in a 5:1 solution of AZ351 developer at room temperature for a short time

(typically 15-30s), rinsed in DI water for 10 min, spin dried, and sent on for exposure. The other group (Group B) went directly to exposure.

The projection aligner used was a Canon mask aligner which uses 405 and 436 nm wavelength UV light for exposure. After determining the optimum focus on a flat wafer, step exposure was performed on a test wafer from Group A and on one from Group B. The wafers were developed in 5:1 AZ351 developer for 60s. The minimum exposure required to clear a 4 μm pitch grating was determined in both cases. It was observed that the Group A wafers which went through the pre-exposure treatment required about 10% higher exposure than the Group B wafers. The wafers were then examined for the step coverage using the SEM.

Results

A remarkable increase in photoresist step coverage was observed in the case of the Group A wafers that went through the pre-exposure treatment. In the case of Group B wafers, the photoresist going over the 1.25 μm steps was found to thin down or disappear entirely. When the experiment was repeated using a new set of wafers and a different operator the results were the same.

The authors believe that the improved step coverage of the Group A wafers is the consequence of the dissolution rate of unexposed photoresist's being considerably lower than that of the conventional processing used in Group B. It was also observed that the surface of the photoresist of the pre-exposure-treated wafers was considerably smoother than that of Group B wafers. The image quality of Group A wafers were as good as that of Group B, if not better. The results are shown in SEM pictures (Fig. 1-6).

Explanation

The nature and chemistry of AZ-type positive resists has been extensively studied and reported by several authors (4-6). The AZ1350 formulation is composed primarily of PAC (Fig. 7) in a phenolic resin (Fig. 8). Imaging results from UV exposure of the resist in desired areas. The

Fig. 5. Wafer processed with pre-exposure treatment

resulting photolysis mechanism (Fig. 9) was first proposed by Süs in 1944 and is now well recognized. The base-soluble material produced by UV exposure of PAC

Fig. 7. Photoactive component in AZ1350 photoresist

has been presumed to be an indenecarboxylic acid formed from a reactive ketene intermediate. In the alkaline base, the exposed areas undergo the reaction shown in Fig. 10.

As the basic developer is also a solvent for the resin, the slower rate of dissolution in the unexposed area was postulated by DeForest (4) to result from a base-induced aZ_o coupling between the PAC and the resin (Fig. 11). It was proposed by DeForest that the coupling reaction takes place "instantaneously," producing a cross-linked structure that reduces the solubility of the unexposed region.

The observed slow dissolution rate of the unexposed photoresist of Group A wafers in the present study can be explained if we assume that coupling is a slow, diffusion-dependent reaction rather than an instantaneous reaction. The development and the coupling rates of resists depend on diffusion of the developer in the polymer film, the molecular configuration, and strain in the polymer film. At a given temperature, many parameters may affect the

diffusion mechanism. Gel formation, free volume in the film, and solvent retention may all play a role in the developing of photoresist films (7). It is conceivable that in the conventional developing method, the coupling does not take place instantaneously to completion in the unexposed areas. Since the developer is amply used up in developing the exposed resist, fresh developer is not locally available to the unexposed resist in order that coupling may effectively take place.

In the method the authors have tried, the coupling takes place prior to exposure. Although this method desensitizes the resist a little bit, the compound is still photoactive. The study of Hiraoka and Pacansky (8) indicates that after development and rinsing there is some residual developer left in the resist. The authors believe that in their investigation, the residual developer has adequate time to be able to diffuse into the bulk of the resist and so the coupling reaction takes place to completion before the wafers go into the developer for the second time. The completion of the coupling reaction is responsible for preserving the photoresist thickness over the steps. In addition to inhibiting the dissolution rate of the unexposed portions of the resist, the authors believe that the pre-exposure treatment hardens the surface of the photoresist, which explains the smoother photoresist surface of Group A wafers as compared to Group B. This effect is similar to the technique used by Canavello *et al.* (9), in which the resist is soaked in chlorobenzene to alter the local development rate of the resist near the surface.

Summary

A simple pre-exposure treatment of wafers coated with AZ-type photoresist has been described. It improves the step coverage after development by inhibiting the dissolution rate of unexposed photoresist. The pre-exposure treatment involves immersing the photoresist-coated and baked wafers in a mild alkaline base such as 5:1 AZ351 developer for a short time. The phenomenon is explained as a consequence of the slow diffusion-dependant coupling reaction in which the diazo joins with other compounds to form aZ₀ linkage.

Carrier Saturation in Tin-Doped InP Films Grown by Liquid Phase Epitaxy

B. H. Chin, R. E. Frahm, T. T. Sheng, and W. A. Bonner

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We have investigated tin doping at high concentrations in InP films grown on <100> InP by liquid phase epitaxy. Contrary to previously published work, our Hall measurements show that the carrier concentration saturates at $\sim 6 \times 10^{19}/\text{cm}^3$ for a mol fraction of tin in liquid ≥ 0.08 . Measurements of actual tin concentrations in the solid by secondary ion mass spectroscopy indicate that a solid solubility limit is reached. Transmission electron microscopy reveals no precipitate formation.

Liquid phase epitaxy (LPE) in InP from indium-rich solutions has become a major technique for the growth of optoelectronic device structures. When n-type layers are needed, tin is the usual dopant. Although there have been many studies (1-8) of tin doping in LPE InP, they have mainly concerned doping levels of $(N_D - N_A) \leq 5 \times 10^{19}/\text{cm}^3$, corresponding to a mol fraction of tin in solution of $\chi_{\text{Sn}}^l \leq 0.1$. Higher doping levels, however, have been less thoroughly investigated; furthermore, studies of doping in the $10^{19}/\text{cm}^3$ range have often involved atypical LPE growth conditions. Under the usual conditions for optoelectronic structures, *i.e.*, growth from indium solution on an InP substrate at 600°-700°C, we are aware of only two studies reporting doping levels in the $10^{19}/\text{cm}^3$ range. Rosztochy *et al.* (1) measured $(N_D - N_A) \approx 1.5 \times 10^{19}/\text{cm}^3$ at $\chi_{\text{Sn}}^l \approx 0.4$; Williams *et al.* (2) and Astles *et al.* (3) found $(N_D - N_A) \approx 8.5 \times 10^{19}/\text{cm}^3$ at $\chi_{\text{Sn}}^l \approx 0.5$. We would like to emphasize that, in both instances, only a single data point with $(N_D - N_A)$ in the $10^{19}/\text{cm}^3$ range was given. Other work reporting very high doping levels has utilized atypical growth conditions. Shay *et al.* (4) deposited an InP film on an InP substrate from a tin solution at $\sim 510^\circ\text{C}$; the resulting $(N_D - N_A)$ was $5 \times 10^{19}/\text{cm}^3$. Jacobs *et al.* (5, 6) studied doped, strongly lattice-mismatched layers of InP grown on GaAs substrates from either indium solution at 785°C or tin solution at 580°C. Values of $(N_D - N_A)$ as high as $9 \times 10^{19}/\text{cm}^3$ were measured.

In this study, we have grown InP, under typical LPE conditions, with χ_{Sn}^l up to 0.14. Contrary to previous work, we find that $(N_D - N_A)$ saturates at $\sim 6 \times 10^{19}/\text{cm}^3$ for $\chi_{\text{Sn}}^l \geq 0.08$. In addition to Hall measurements, the epitaxial layers were examined by secondary ion mass spectroscopy (SIMS) and transmission electron microscopy (TEM).

Crystal Growth

The epitaxial layers were grown on semi-insulating substrates from two-phase solutions (9); a graphite horizontal slider boat was used. The <100> oriented, Fe-doped InP wafers were first cut from a boule grown by liquid-encapsulated Czochralski (LEC) and then polished with bromine-methanol. Immediately prior to a LPE run, a substrate was freshly etched in 3 methanol:1 H_3PO_4 :1 H_2O_2 , rinsed successively in methanol and running DI water, and, finally, blown dry with high purity helium gas. During the period needed to homogenize the growth solution, the substrate was protected with an InP coverpiece (10) to reduce surface thermal decomposition.

To reduce variations in background doping levels, special precautions were observed for preparing the source materials—vacuum-baked indium rod (six 9's purity), tin shot (six 9's purity), and undoped $[(N_D - N_A) \approx 5 \times 10^{16}/\text{cm}^3]$ polycrystalline InP slices. The indium rod was first etched in 1 HNO_3 :1 H_2O , rinsed in running DI water, rinsed in methanol, and blown dry with helium. After the rod had been cut up into pieces weighing 5.00g, the pieces were loaded into the wells of the growth boat and baked

out overnight at 700°C in flowing hydrogen. The boat was then cooled, and the indium ingots were removed and stored for future use. Since high concentrations of tin are used in this study, impurities in the tin may be significant. Hence, the tin shot was also purified by the same procedure (except that concentrated HCl was the etchant). Just before a growth run, the source materials were freshly re-etched and weighed (the poly InP was also etched in concentrated HCl). Two melts were loaded into the boat: (i) a pure In "wash" melt (11) for *in situ* etching of the substrate surface and (ii) the growth melt, consisting of 5.000g In, the proper amount of Sn, and poly InP in excess of the solubility limit at the growth temperature.

An LPE run proceeded according to the following schedule. After the melts had been homogenized at 660°C for 1h, the furnace temperature was ramped down at 0.7°C/min. At 648°C, the substrate was pushed under the In "wash" melt for 10s and then pushed under the growth melt. Growth continued at a ramp rate of 0.7°C/min until 640°C was reached. The wafer was then wiped off, and the boat was rapidly cooled down. (Surface terraces became increasingly pronounced at high doping levels; however, clean wipe-off was achieved on all samples.) Since the distribution coefficient of tin may vary with temperature, the growth temperature was deliberately held to a narrow range (8°C). This growth interval was sufficient to produce a film thick enough ($\sim 5 \mu\text{m}$) for subsequent characterization.

Before discussing the characterization results, we must first clarify one point. Quantities will be plotted as a function of χ_{Sn}^l , the mol fraction of tin in liquid. Strictly

$$\chi_{\text{Sn}}^l = M_{\text{Sn}} / (M_{\text{In}}^0 + M_{\text{In}}^1 + M_{\text{P}} + M_{\text{Sn}}) \quad [1]$$

where M_{Sn} and M_{In}^0 are, respectively, the number of mols of pure Sn and In, whereas M_{In}^1 and M_{P} are the contributions from the dissolved InP. If

$$(M_{\text{In}}^1 + M_{\text{P}}) \ll (M_{\text{In}}^0 + M_{\text{Sn}}) \quad [2]$$

then

$$\chi_{\text{Sn}}^l \approx M_{\text{Sn}} / (M_{\text{In}}^0 + M_{\text{Sn}}) \quad [3]$$

We directly verified that condition (ii) was satisfied over the entire range of doping used in this study. The solubility of InP in the most highly doped melt was determined in the following way. A melt consisting of 5.000g In and 0.875g Sn was homogenized at 648°C. An InP wafer, which had been accurately weighed, was then slid under the melt. After a 1h homogenization, the wafer was pushed clear. From measurements of the weight gain in the melt and of the weight loss in the substrate, we determined the solubility to be 0.055g InP, a negligible amount compared to the initial 5.875g charge. Thus, Eq. [3] was used for χ_{Sn}^l .

Characterization

The epitaxial layers were characterized by Hall measurements, SIMS, and TEM. The net carrier concentra-

Key words: Hall measurements, secondary ion mass spectroscopy, transmission electron microscopy.

tion ($N_D - N_A$) was determined by Hall measurements in the van der Pauw configuration; a fully computer-controlled apparatus (12) was used for rapid and accurate measurements. To monitor the actual tin concentration, samples were analyzed by SIMS¹, a Cs ion source was used for depth profiling, and the mass 120 tin peak was monitored. Conversion of the SIMS signal levels to atomic concentrations was achieved by comparison with signals from ion-implanted standards. For TEM analysis, a 3 mm diam disk was ultrasonically cut from a wafer. After the substrate had been polished down to $\sim 25 \mu\text{m}$ with bromine-methanol, a number of small holes were opened up near the center of the disk with a jet polish of bromine-methanol.

Hall measurements of several nominally undoped layers gave a reproducible background doping level of ($N_D - N_A$) $\approx 1 \times 10^{17}/\text{cm}^3$, which was an order of magnitude less than the lowest intentional doping level. The values of ($N_D - N_A$) at room temperature as a function of χ_{Sn}^1 are plotted in Fig. 1. For $\chi_{\text{Sn}}^1 \lesssim 0.08$, there is a linear dependence of ($N_D - N_A$) on χ_{Sn}^1 ; in this regime, the calculated distribution coefficient is $k \approx 2.7 \times 10^{-3}$, in good agreement with values measured by other workers (8) [Two definitions of k exist (8); here, we use the common one: $k = (\text{mols Sn/gram of solid})/(\text{mols Sn/gram of liquid})$ (3, 8).] Contrary to previous work (1-3), however, we find that ($N_D - N_A$) saturates at $\sim 6 \times 10^{18}/\text{cm}^3$ for $\chi_{\text{Sn}}^1 > 0.08$.

Since Hall measurements yield only the net electrically active concentration, they do not unambiguously determine the doping behavior. Saturation of ($N_D - N_A$) as a function of χ_{Sn}^1 may be consistent with the following scenarios: (i) the mol fraction of tin in the solid, χ_{Sn}^s , saturates; i.e., a solubility limit of tin in the solid is reached. (ii) χ_{Sn}^s increases as a function of χ_{Sn}^1 with constant ($N_D - N_A$). In this case, some of the tin may be incorporated into neutral or acceptor sites. Alternatively, ($N_D - N_A$) may also remain constant if the concentration of acceptor impurities increases with χ_{Sn}^1 .

To clarify the situation, the concentration of tin in the solid, c_{Sn}^s (atoms/cm³), was determined by SIMS; the results are plotted in Fig. 1 as a function of χ_{Sn}^1 . Within the accuracy of the SIMS calibration (a factor of 2), the values of c_{Sn}^s measured by SIMS agree with the values of c_{Sn}^s expected from the Hall measurements (assuming that all tin is incorporated as ionized donors). We see clearly in Fig. 1 that c_{Sn}^s saturates; hence, a solid solubility limit is reached.

The following additional analyses were taken to support this result. The background doping of three samples, with $\chi_{\text{Sn}}^1 = 0, 0.06$, and 0.14 , respectively, was monitored by wide-field SIMS scans. Since the mass spectra of all three layers were essentially identical, there was no significant increase in background doping with increasing χ_{Sn}^1 . Furthermore, TEM analysis of the sample with $\chi_{\text{Sn}}^1 = 0.14$ revealed no precipitates (at a magnification of 50,000 \times), indicating that all tin was in solid solution.

Discussion

For $\chi_{\text{Sn}}^1 > 0.08$, we have shown that the carrier concentration in tin-doped InP saturates at ($N_D - N_A$) $\approx 6 \times 10^{18}/\text{cm}^3$; furthermore, the carrier saturation arises because a solubility limit of tin in the solid is attained. We emphasize that this result holds under the specific conditions employed, namely, growth from indium solution on a $\langle 100 \rangle$ -oriented InP substrate at 648°-640°C; however, these conditions are the common ones for optoelectronic device structures. Our results differ from those reported by Rosztochy *et al.* (1) and Astles *et al.* (2, 3), who found no evidence of carrier saturation. Although the exact rea-

¹SIMS analysis performed by C. A. Evans and Associates, San Mateo, California.

Fig. 1. Plot of room temperature carrier concentration and tin concentration as a function of mol fraction tin in liquid.

sons for this difference are not clear, there are two possibilities. First of all, dopant incorporation may depend on substrate orientation (13, 14) Rosztochy *et al.* used $\langle 111 \rangle \text{B}$ substrates throughout. In the case of Astles *et al.*, the situation is more vague because $\langle 111 \rangle \text{A}$, $\langle 111 \rangle \text{B}$, and $\langle 100 \rangle$ substrates were used. The authors mentioned that the doping behavior did not depend strongly on orientation; however, it is not clear whether the one very high value of ($N_D - N_A$) reported ($8.5 \times 10^{19}/\text{cm}^3$) was attained on all orientations. Secondly, at high χ_{Sn}^1 , impurities in the tin may be significant. Thus, the higher values of ($N_D - N_A$) measured by other workers may have been due to a strong donor impurity present in the tin. To resolve these issues, the incorporation of tin as a function of orientation and the presence of impurities in tin need further investigation.

Acknowledgments

ABSTRACT

The electronic properties of silicon-on-sapphire were investigated as a function of selected heat-treatment sequences between 900° and 1100°C, similar to certain processing steps used in device fabrication. Employing photovoltage spectroscopy and laser scanning photovoltage microprofiling, it has been found that heat-treatments significantly change deep and shallow levels and the minority-carrier lifetimes. Detectable changes of the amorphization factor and of the magnitude of inhomogeneities were also observed, but only upon annealing at the highest temperature investigated (3h at 1100°C).

Silicon-on-sapphire (SOS) (1), in addition to bulk silicon (2), is a well-recognized material for applications in the electronic industry, especially for the fabrication of radiation hard devices. It has been previously demonstrated that macro- and microscopic electronic properties of as-grown SOS films are closely related to film crystallinity (3, 4), and that surface photovoltage spectroscopy can be used successfully to characterize their electronic properties (3-5). The properties of bulk silicon change during processing (6, 7). By analogy, it is anticipated that the electronic properties of as-grown SOS films also change during various heat-treatments, and that these changes are a strong function of the temperature of the processing steps. The various processing cycles used for the fabrication of conventional circuits and radiation-hard CMOS circuits could influence material characteristics differently, and could be reflected in circuit performance. In this work, we present systematic studies of ion-implanted and nonimplanted SOS films subjected to heat-treatments typical of the conventional CMOS fabrication and radiation hard processes. In addition, we also investigated the effects of a high temperature preannealing (which could be applied prior to processing) on the electronic characteristics of SOS films.

Experimental

Commercially available SOS wafers 0.6 μm thick were preselected according to their crystallographic quality (A type according to UV reflection) (8) and were subjected to processing treatments listed in Table I. Two processing sequences were used, one involving no ion implantation (sequence I), and another involving ion implantation as follows: $1 \times 10^{12}\text{cm}^{-2}$ boron implanted at 150 keV plus 1.1

$\times 10^{12}\text{cm}^{-2}$ boron implanted at 35 keV (sequence II). After implantation, the SOS films were oxidized in steam at 900°C for 23 min. The wafers were sectioned by cleaving. Sections A, B, and C were thermally treated according to a specification given in Table I. The processing temperatures used for the sequence A were typical for the radiation hard process, while those used for the sequence B are for the conventional process. The untreated section D was used as a reference.

The study of sections A, B, C, and D was carried out utilizing photovoltage-related techniques (5): (i) photovoltage spectroscopy measurements for determination of localized levels and the degree of amorphization, (ii) measurements of the temperature dependence of photovoltage for assessment of the role of trapping centers, and (iii) laser scanning photovoltage microprofiling for determination of the homogeneity of silicon-on-sapphire. A detailed description of these approaches and their application to silicon-on-sapphire was given elsewhere (5, 9).

Photovoltage measurements were carried out utilizing the metal-semiconductor (MS) configuration. Photovoltage generated by a chopped monochromatic light was measured between a semitransparent gold film and a second electric contact (made with a silver paste) which was kept in the dark. Two sets of samples ($3 \times 10\text{ mm}$), 1A, 1B, 1C, and 1D and 2A, 2B, 2C, and 2D, were cleaved from wafers treated according to process simulation sequence I and II, respectively (see Table I). They were simultaneously prepared for measurements (evaporation of gold and silver-paste contacts). Four samples (1A-1D and 2A-2D) were placed on the cold finger of the variable-temperature cryostat. They were simultaneously measured in an effort to optimize the reliability of comparative study.

Results and Discussion

Magnitude of photovoltage.—The most significant quantitative difference between the various SOS films was in the magnitude of photovoltage in the region of intrinsic excitation ($h\nu > E_g$). As shown in Table II, the photovoltage was smallest for untreated film D and had higher values for films subjected to thermal treatments. This seems to be the observation for implanted and unimplanted films. The simplest interpretation of this effect is that it is associated with the enhancement of excess carrier lifetime. This would lead to a tentative conclusion that the highest temperature annealing steps (the heat-treatments B and C) are most beneficial in improving the lifetime value.

Temperature dependence of photovoltage.—In our previous studies, we utilized the temperature dependence of photovoltage as a means for the determination of thermal-activation energies of trapping centers (3-5). Such typical photovoltage vs. $1/T$ dependence is shown in Fig. 1. It exhibits, in the high temperature region, the photovoltage

Fig. 1. Typical temperature dependence of the photovoltage of silicon-on-sapphire containing deep traps of thermal activation energy 0.5 eV.

quenching with a characteristic activation energy, $E_A \approx 0.5 \text{ eV}$, which has been observed in most of the SOS films studied previously (3-5). Exemption from this rule was observed only in films with the lowest density of deep levels, such as, for example, hydrogenated films of SOS (10).

The temperature dependence of photovoltage of the unimplanted films discussed here is only partially consistent with this tendency. As seen in Fig. 2, these films exhibit a photovoltage maximum at a temperature of about 220 K, and also photovoltage quenching with an activation energy approximately equal to 0.5 eV. However, this photovoltage quenching does not extend to room temperature. Instead, the photovoltage increases near room temperature for thermally treated films A, B, and C, and at a slightly lower temperature for the untreated film D. It is very likely that the differences, in comparison with previous results of Ref. (3) and (5), are due to surface effects. The SOS films discussed in Ref. (3) and (5) were covered with a protective SiO_2 layer (for example, 100 min steam oxidation at 900°C), while the films described here were subjected to oxide removal as the final preparation step. A silicon surface covered with a thin native oxide and with thermal oxide is known to exhibit different electrical properties (11).

Photovoltage vs. $1/T$ for a series of ion-implanted films treated according to process simulation sequence II is presented in Fig. 3. It is evident that all ion-implanted samples exhibit basically similar temperature dependence to the oxidized samples studied in Ref. (3) and (5). Thermal quenching with 0.5 eV activation energy is also clearly visible. The photovoltage quenching of unimplanted films did not extend up to room temperature, most likely because of surface effects. In ion-implanted material with much higher carrier concentration, the surface effects can generally be expected to be less pronounced; thus, the boron-implanted films analyzed in Fig. 3 did not show this surface-related effect.

Fig. 2. Temperature dependences of the photovoltage of unimplanted silicon-on-sapphire heat-treated according to Table I (processing sequence I).

Fig. 3. Temperature dependences of the photovoltage of ion-implanted silicon-on-sapphire treated according to the processing sequence II (see Table I).

Spectral dependence of photovoltage.—The photovoltage spectra normalized to photovoltage values at $h\nu = 2.0$ eV are given in Fig. 4 for the two extremes of heat-treatments C and D. The normalization of photovoltage eliminates the differences in magnitude discussed above, and thus permits the observation of other differences occurring in particular spectral regions. Two regions, $h\nu < E_g$ and $h\nu \approx E_0$, are of primary importance here, as they correspond at lower energy to photoionization transitions involving localized levels and the higher energy reflect a degree of amorphization of SOS films (3)¹. It is seen from Fig. 4 that the heat-treatment at 1100°C suppresses both of them, although the effect is much stronger in the case of subbandgap photoionization transitions. The photovoltage spectra of films A and B, which received an intermediate heat-treatment (not shown in Fig. 4) also showed a noticeable suppression of deep level photoionization transitions in comparison with the untreated film D. However, no significant change was found for these films regarding the degree of amorphization (as judged from photovoltage increase around $h\nu \approx E_0$). It should be emphasized that the effects of heat-treatment were very similar for unimplanted and ion-implanted films (sequence 1 and 2).

For a quantitative analysis of the effect of heat-treatment on deep levels, we have attempted here a procedure discussed in Ref. (3) based on the subbandgap photoionization transitions in silicon-on-sapphire involving deep levels of energies, $E_1 \approx 0.6 - 0.7$ eV below the conduction band. The strength of this photoionization transition can be estimated from the photovoltage value normalized to the photovoltage value at the maximum (2 eV). As discussed in Ref. (3), they can be treated as a rough indication of the concentration of the deep levels. The relative concentration of deep levels E_1 in the processed samples, normalized to the concentration observed in as-grown samples (D), is given in Table III. The

¹Note that the amorphous-like shoulder at E_0 (Fig. 4) originates from defects in SOS affecting long-range interaction (dangling bonds and lattice strains), rather than from amorphous domains (12).

Fig. 4. 170 K photovoltage spectra (normalized to photovoltage value at $h\nu = 2.0$ eV) for unimplanted SOS films 1C and 1D and ion-implanted films 2C and 2D. Spectra were averaged in order to eliminate interference extrema.

lowest concentration of deep level E_1 is consistently observed in sample C, which received the highest temperature heat-treatment (1100°C); the highest concentration of E_1 levels is in the unannealed sample D.

A degree of amorphization can be conveniently analyzed by introducing the amorphization factor η (3)

$$\eta = \frac{\Delta V}{V} \cdot \frac{\alpha}{\Delta \alpha} - 1$$

where $\Delta V/V$ is the relative photovoltage increase taking place in the vicinity of $h\nu = E_0$, and $\Delta \alpha/\alpha$ is the corresponding change of the absorption coefficient of the bulk (single-crystalline) silicon. Estimated values of η normalized to values observed in the unannealed films D are listed in Table III for all films under study. It seems that only the films annealed at 1100°C show a systematic reduction in the value of the amorphization factor η , compared to the as-grown films D. Also, the value of the minority-carrier lifetime, determined from the photovoltage magnitude and normalized to values obtained from as-grown films D, is shown in Table III. The largest improvement is also observed in the films 1C and 2C, which were exposed to the highest temperatures.

Comments on Deposit Homogeneity

As discussed in Ref. (9), the laser scanning photovoltage in the MS configuration provides an effective means for revealing the electrical inhomogeneities of a thin semiconducting film. The relative change of the magnitude of photovoltage, ΔV , with respect to an average photovoltage signal, V_{av} , was used in our previous study as a quantitative measure of the homogeneity of silicon-on-sapphire. The central portion of the best SOS films analyzed by this technique exhibited $\Delta V/V_{av}$ as low as $\pm 3\%$, while the inferior quality films of D-F category exhibited $\Delta V/V_{av}$ even as high as $\pm 50\%$ (9, 10). Values of $\Delta V/V_{av}$ for the presently studied unimplanted films, with the exception of the edge of the wafers, were estimated to be between $\pm 10\%$ and $\pm 15\%$. The lowest value corresponds to film C,

Table III. The effect of heat-treatment on electrical properties of SOS

Property	Processing schedule							
	Implant	A		B		C		D*
		No implant	Implant	No implant	Implant	No implant	No implant	As grown

* Note that all properties are referred to corresponding property of silicon-on-sapphire film not subjected to thermal annealing.

** Estimated from the magnitude of photovoltage under intrinsic excitation ($h\nu = 2$ eV), which at low temperature minimizes effects of surface recombination.

which received the highest temperature heat-treatment, and the highest value to the as-grown film D. Typical He-Ne laser photovoltage scans along the radial direction for a short distance in the central portion of the films 1D and 1C are shown in Fig. 5. The homogeneity of films 1A and 1B seems to fall between those of films 1C and 1D; however, the differences were too small for unambiguous correlation of homogeneity with a given heat-treatment. The peripheral regions of the films exhibited large inhomogeneities (photovoltage changes by as much as a factor of 3) confined within about 1 cm from an edge of the wafer.

Ion implanted wafers exhibited measurable inhomogeneities only in peripheral regions. It should be noted that the presence of inhomogeneous peripheral regions, and improvement of homogeneity upon ion implantation, is consistent with our previous study of silicon-on-sapphire (4, 9, 10). This indicates that a uniform implant of shallow ionized impurities tends to overshadow electrical inhomogeneities present in as-grown films with localized potential barriers.

Summary

It has been shown that the electronic properties of SOS films are affected by high temperature annealing. Improvement of the lifetime, a decrease of deep level concentration, and reduction of inhomogeneities have been observed in both ion-implanted and nonimplanted SOS

films after annealing. The annealing was designed to simulate processing steps used in the fabrication of radiation-hard and conventional SOS circuits. The largest improvement in electronic properties has been observed for SOS films subjected to the highest temperature treatment: 1100°C for 3h. These SOS samples also showed a reduction in the degree of amorphization. It seems that the smallest improvement of electronic properties has been observed for simulation of the radiation-hard process which has the lowest processing temperatures. Very similar changes in electrical properties have been observed for ion-implanted and nonimplanted samples.

It can be speculated that an increase of the minority-carrier lifetime is caused by a decrease in the deep level concentration, which is caused by the gettering action of the interfacial region between the silicon film and the sapphire substrate.

The efficiency of gettering introduced by interfacial strain should increase with increasing temperature due to the increase of strain and the mobility of defects. Therefore, one can expect that the defect density will be lower for the highest processing temperature. It can be speculated that high temperature annealing could also affect redistribution of aluminum near the silicon-sapphire interface, which could be reflected in the reduction of amorphization and interfacial inhomogeneities, as observed in the photovoltage scans.

Acknowledgments

The authors would like to thank M. T. Duffy and R. A. Soltis for supplying them with SOS samples selected according to crystallinity, and R. Soydan for his assistance.

Application of Low Angle Beveling for Thin Film Thickness Measurement by SEM or AES

G. Riga*¹ and B. Horblit²

Fairchild Camera & Instrument Corporation, Mountain View, California 94039

ABSTRACT

The feasibility of measuring the thickness of very thin films (<1000Å) by using a low angle beveling technique in conjunction with a scanning electron microscope (SEM) or an Auger electron spectroscopy (AES) has been demonstrated. The thin film thickness has been magnified in two steps, 200 times with low angle beveling, and an additional 5000 times with the SEM or AES. The accuracies of measurements performed on two SiO₂ films having thicknesses of 740 and 194Å were found to be 4.2% and 13.4%, respectively, when compared to ellipsometric measurements. This technique has also been used on MOS gate oxide and Si-Cr thin film resistor samples. With better control of the variables involved, it is reasonable to expect that films on the order of 20Å could be measured.

In many cases, conventional techniques cannot be used to measure the thickness of very thin films. This is because the required accuracies cannot be achieved under the restrictions imposed by sample size and structure (1-3). By using a combination of angle beveling with scanning electron microscopy (SEM) or Auger electron spectroscopy (AES), it is possible to measure the thickness of a large number of thin films in a wide variety of structures. In the case of insufficient SEM image contrast, the AES provided spatial and chemical resolution to determine the film boundaries.

Description of the Technique

A technique that uses two stages of magnification has been employed to measure the thicknesses of very thin films. The first magnification is obtained by beveling the sample at a small angle (4, 5, 9). The second is provided by the SEM or AES (6).

The technique consists of the following steps: (i) sample preparation; that is, mounting and beveling, (ii) measurements of bevel angle, film thickness by SEM or AES, and film width on the photo, and (iii) calculation of the film thickness.

The sample is mounted on a beveled mounting block using a low temperature melting wax. The block consists of a metallic disk that has the top surface precision machined at a known small angle with respect to the bottom surface of the disk. The beveling is achieved by polishing the specimen on a frosted-glass plate. The final polishing medium is a 0.1 μm diamond particle in oil. The surface of the specimen is cleaned with trichloroethylene (TCE). The bevel angle is then measured using the small angle measurement (SAM) technique (7).

The SAM technique requires a microscope in which the rotation of the specimen can be accurately determined. The detection of the layer can be accomplished by using the SEM or AES. The SEM can be used in all cases where the secondary or backscattered electrons provide sufficient material contrast to distinguish the edges of the layer. The AES can be used for all specimens, and is particularly useful in distinguishing layers that differ only

slightly in composition. The image obtained is in the form of an Auger elemental map (8). It is important to note that the minimum detection limit of the AES is about 1 weight percent (w/o). In either case—SEM or AES—care must be taken that the sample is mounted perpendicular to the electron beam. After the image of the layer is obtained, the width of the layer is measured from the photomicrograph and the actual layer thickness is calculated using

$$T = A \cdot \sin \alpha \cdot M^{-1}$$

where T is the actual film thickness, A the film width measured from the photomicrograph, α the bevel angle, and M the photomicrograph magnification.

Test to Determine Accuracy

The accuracy of the technique described above has been determined by comparison to ellipsometric measurements. Silicon dioxide films of about 200 and 700Å were thermally grown on silicon wafers. The films were carefully measured with an ellipsometer. The averages and ranges of the measurements are reported in Table I.

The thin oxide films were covered with 2500Å of polysilicon for edge delineation and simulation of typical device structure. After the samples were beveled, an SEM photomicrograph and an AES elemental dot map of the SiO₂ films were obtained (Fig. 1-4). The width of the layer measured from the photomicrograph is reported in Table I along with the calculated film thickness. The error with respect to the thickness value obtained from the ellipsometric measurement is 4.2% and 13.4% for the 700 and 200Å samples, respectively.

Source of Errors

Three orders of errors have been identified. Errors of first order include (i) edge definition of the film, (ii) determination of the bevel angle, and (iii) SEM or AES magnification. Errors of second order include (i) length measurements from the photomicrographs, and (ii) sample position in the SEM or AES. The error of third order is spatial resolution of the SEM or AES.

The sharpness of the interface between the film and the surrounding material determines how well the edge of the film can be defined and therefore how well its width can be measured. The edge definition of the film is a strong function of the quality of the beveled surface,

Table I. Summary of experimental data

Sample id	T_{ref} (Å) avg/range	Sin α	M (1000×)	A (mm)		T (Å)		ϵ %	
				SEM	AES	SEM	AES	SEM	AES
700	740/2	0.0094	5	38	41	714	771	-3.5	+4.2
200	194/7	0.0044	4	20	20	220	220	+13.4	+13.4
SiO ₂ gate	NA	0.0100	6	41	42	683	700	—	—
SiCr resistor	NA	0.0083	2	*	24	—	996	—	—

* Difficult to measure.

T_{ref} = thickness from ellipsometric measurements.

ϵ (%) = $(T - T_{ref}/T_{ref}) \cdot 100$.

Fig. 1. SEM photomicrograph of 700Å SiO₂ film at 5000×

Fig. 4. AES oxygen dot map of sample shown in Fig. 3 at 5000×

Fig. 2. AES oxygen dot map of sample shown in Fig. 1 at 5000×

Fig. 3. SEM photomicrograph of 200Å SiO₂ film at 5000×

which is influenced by the particular lapping technique used. For the 200Å film, the edge definition was the main source of error in the determination of thickness.

The error introduced by the measurement of the bevel angle which was performed by the small angle measurement technique is on the order of $\pm 5\%$, and it can be further reduced if an interferometric technique is used.

The SEM or AES magnification error, which directly influences the width of the film observed from the photomicrograph, is generally less than 10%. The error can be reduced to less than 3% with the use of appropriate calibration standards.

After the edges of the film are defined on the photomicrograph, the error introduced in measuring the film width is on the order of ± 0.5 mm. The error in percent is therefore a function of the film width on the photomicrograph.

Applications

To demonstrate the applicability of the technique to a device structure characterization, the gate oxide of a MOS transistor and a Si-Cr thin film resistor have been measured (see Fig. 5-8). The film thicknesses have been found to be 700 and 996Å.

The Cr dot map of the Si-Cr film illustrates the effectiveness of the AES in delineating the film boundaries in cases of low material contrast. The Si-Cr resistor lies on and is covered by silicon dioxide.

Conclusions

It has been demonstrated that very thin films can be measured by appropriately combining the well-known techniques of angle beveling with scanning electron microscopy or Auger electron spectroscopy. Regardless of the film nature (*e.g.*, conductor or insulator), this technique can be used and is limited only by the AES detection limit.

Fig. 5. SEM photomicrograph of a SiO₂ gate at 6000×

Fig. 6. AES oxygen dot map of sample shown in Fig. 5 at 6000 \times

Fig. 8. AES chromium dot map of sample shown in Fig. 7 at 2000 \times

Fig. 7. SEM photomicrograph of Si Cr resistor at 2000 \times

By improving the beveling techniques (smoother surface) and increasing the accuracy in determining the bevel angle (by interferometry), it is reasonable to expect that films on the order of 20 \AA thick and covering small areas (e.g., $1 \times 10 \mu\text{m}$) might be measured (9, 10).

Acknowledgments

The authors express their appreciation to R. Razouk, M. Sklar, and B. Cairns of Fairchild Advanced Research and Development Laboratory for the help received in preparing the standards, and to W. Jansen of Perkin Elmer Physical Electronic Laboratories for the AES analysis.

Our thanks are also extended to Mr. R. Smith, General Manager of Fairchild Linear Division, for giving us permission to publish this paper.

The Thermodynamic Effects of Using an Inert Gas in the Hydride VPE Growth of InP

C. W. Tu and K. A. Jones*

Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

Substituting an inert gas for hydrogen as the carrier gas in the VPE growth of InP and other III-V compounds has the negative effects of reducing the growth rate and the HCl concentration in the growth zone. This results from a decrease in the supersaturation for the deposition reaction. These effects are quantified for the hydride growth of InP under equilibrium conditions. The thermodynamic growth rate and the equilibrium InCl, HCl, P₂, P₄, and PH₃ partial pressures are computed as a function of the inert gas/inert gas + H₂ pressures.

Hydrogen is an excellent carrier gas because it can be highly purified at a relatively low cost using a hydrogen purifier. It also getters oxygen. Recently, some people have suggested using N₂ as the carrier gas because it can be highly purified by first liquifying it (1), and because it suppresses the silicon contamination and reduces the degree of compensation (2). One should consider the possibility of forming nitrides if he chooses to use N₂, but he should also consider how substituting an inert gas for the H₂ affects the thermodynamics of the growth process. The latter consideration is the topic of this paper.

The parameters considered in this paper are the thermodynamic growth rate and the equilibrium PH₃ and HCl concentrations in the growth zone. Clearly, reducing the H₂ partial pressure will reduce the PH₃ pressure. This is important since it has been suggested that the growth rate is higher when more PH₃ is present due to the fact that InCl more readily reacts with PH₃ than with P₂ or P₄ (3). [It should be noted that PH₃ decomposes rather slowly (4), so that more PH₃ is present in the growth zone than is computed from thermodynamic data. Thus, the calculations that follow can only be used to indicate the trends.] The HCl concentration is important because it is thought that increasing the HCl concentration reduces the activity of silicon in the quartz reactor (5).

From the deposition reaction

one can see that reducing the H₂ pressure will reduce the deposition rate, and this, in turn, will reduce the HCl partial pressure, since it is formed during the deposition reaction. In this equation, x is the ratio of the amount of phosphorus in the P₂ form to the amount of phosphorus in the P₂ and P₄ form and is given by the equation

$$x = \frac{P_{\text{P}_2}}{P_{\text{P}_2} + 2P_{\text{P}_4}} \quad [2]$$

y is the fraction of the phosphorus in PH₃ and is given by

$$y = \frac{P_{\text{PH}_3}}{P_{\text{PH}_3} + xP_{\text{P}_2} + (1-x)P_{\text{P}_4}} \quad [3]$$

First, the output pressures from the source zone, designated by the superscript 1, must be determined for the source zone reaction

The output InCl pressure is, from a chlorine balance

$$P_{\text{InCl}^1} = P_{\text{HCl}^0} - P_{\text{HCl}^1} \quad [5]$$

where P_{HCl^0} is the input HCl pressure. P_{HCl^1} can be found from the equation

$$P_{\text{HCl}^1} = \frac{P_{\text{HCl}^0} (1 - P_{\text{HCl}^0})^{1/2}}{(1 - P_{\text{HCl}^0})^{1/2} + K_5} \quad [6]$$

where K_n is the equilibrium constant for the reaction in equation n .

$$P_{\text{H}_2} = 1 - P_{\text{HCl}^0} \quad [7]$$

was used in deriving Eq. [6].

For the deposition zone, first a value of P_{P_4} is assumed, and then it is used to determine P_{P_2} after the equilibrium constant for the reaction

has been found. P_{PH_3} can be found from the phosphorus balance

$$P_{\text{PH}_3} = P_{\text{PH}_3^0} - 2P_{\text{P}_2} - 4P_{\text{P}_4} - (P_{\text{HCl}} - P_{\text{HCl}^1}) \quad [9]$$

where $P_{\text{PH}_3^0}$ is the input phosphine pressure and $P_{\text{HCl}} - P_{\text{HCl}^1}$ is the amount of phosphorus consumed by the deposition of InP. Again, P_{InCl} is found from the chlorine balance

Fig. 1. The equilibrium HCl, PH₃, P₂, P₄, InCl, and H₂ partial pressures in the deposition zone plotted as a function of the inert gas partial pressure when $P_{\text{HCl}^0} = P_{\text{PH}_3^0} = 0.01$ atm, $T_s = 750^\circ\text{C}$, and $T_D = 650^\circ\text{C}$.

$$P_{InCl} = P_{InCl}^I + P_{HCl}^I - P_{HCl} = C_1 - P_{HCl} \quad [10]$$

The total pressure is 1 atm, so that

$$\begin{aligned} P_{H_2} &= 1 - P_{InCl} - P_{P_2} - P_{P_4} - P_{PH_3} - P_I - P_{HCl} \\ &= 1 - P_{InCl}^I - 2P_{HCl}^I + P_{P_2} + 3P_{P_4} - P_{PH_3}^o - P_I + P_{HCl} \\ &= C_2 + P_{HCl} \approx C_2 \end{aligned} \quad [11]$$

where P_I is the partial pressure of the inert gas. Now, P_{PH₃} can be computed from

$$P_{PH_3} = P_{P_2}^{x/2} P_{P_4}^{(1-x)/4} P_{H_2}^{3/2} / K_{13} \quad [12]$$

where K₁₃ is the equilibrium constant for the dissociation reaction

P_{HCl} can be calculated from

$$P_{HCl} = \frac{C_1 K_1 Q}{1 + K_1 Q} \quad [14]$$

where

$$Q = P_{P_2}^{(1-y)x/2} P_{P_4}^{(1-y)(1-x)/4} P_{PH_3}^y P_{H_2}^{1/2(1-3y)} \quad [15]$$

K₁ is the equilibrium constant for the deposition reaction, and R is defined in Eq. [10]. Finally, P_{PH₃} computed from Eq. [9] is compared with the value found from Eq. [13]. If they are not the same, a new value of P_{P₂} is assumed. The process is repeated until the two P_{PH₃} values are equal.

The thermodynamic growth rate, R, is

$$R = \frac{P_{InCl}^I - P_{InCl}}{P_{InCl}^I} \times \frac{\text{no. of InCl}^I \text{ atoms crossing unit area per unit time}}{\text{no. of In atoms per unit volume in InP}}$$

Therefore

$$R \propto P_{InCl}^I - P_{InCl} \quad [16]$$

Using the thermodynamic data collected by Shaw (6), the equilibrium partial pressures of HCl, PH₃, H₂, P₂, P₄, and InCl were computed and are plotted as a function of the inert gas partial pressure in Fig. 1, and there it is seen that the growth rates are qualitatively similar to the experimental curves of Ihara *et al.* (1). For these calculations, the source temperature was, T_S = 750°C, the deposition temperature was, T_D = 650°C, and both P_{HCl}^o and P_{PH₃}^o were 0.01 atm. P_{HCl} decreases by about a factor of 10 as P_I increases from 0 to 0.98 atm. This reduction is due to less hydrogen being available to form HCl during the deposition reaction. Because there is less InP deposited with in-

Fig. 2. The thermodynamic growth rate plotted as a function of the inert gas pressure for (a) the standard conditions, (b) P_{HCl}^o = 0.01/3, (c) P_{HCl}^o = 0.03, (d) P_{PH₃}^o = 0.01/3, (e) P_{PH₃}^o = 0.03, (d) T_D = 600°C, and (e) T_D = 700°C.

creasing P_1 , P_{InCl} increases. P_{PH_3} decreases two orders of magnitude over the range of P_1 , since there is less hydrogen available, and, as a result, P_{P_2} and P_{P_4} increase. They also increase because there is less InP deposited.

That there is less deposition when P_1 increases is shown in Fig. 2 where the ideal growth rate is plotted vs. P_1 . R decreases continuously until at $P_1 = 0.975$ atm there is no deposition. The effects on the growth rate of decreasing P_{HCl^0} or $P_{\text{PH}_3^0}$ by one third, increasing P_{HCl^0} or $P_{\text{PH}_3^0}$ by a factor of three, or increasing or decreasing T_D by 50°C are also shown in Fig. 2. The effects are largest when $P_1 = 0$, and all of the curves tend to converge on the point $R = 0$ and $P_1 = 0.97$.

Reducing P_{HCl^0} by one-third reduces the initial growth rate by one-third, and tripling P_{HCl^0} triples the initial growth rate. $R \propto P_{\text{HCl}^0}$ in this range, because $P_{\text{InCl}^1} \propto P_{\text{HCl}^0}$ and $R \propto P_{\text{InCl}^1}$. The effect of tripling or tripling $P_{\text{PH}_3^0}$ is smaller, as it only changes the initial growth rate by 30%. Adding to or reducing the PH_3^0 concentration has a smaller effect because the free-energy change for the deposition reaction is much more sensitive to the HCl concentration. Lowering the deposition temperature by 50°C doubles the initial growth rate, and raising it by 50°C halves the growth rate. These effects reflect the temperature dependence for the deposition reaction.

How changing HCl^0 , PH_3^0 , and T_D affects the equilibrium HCl and PH_3 concentrations for different values of P_1 is illustrated in Table I.

That decreasing the hydrogen partial pressure decreases the growth rate has been verified experimentally for the chloride growth of GaAs, InAs, GaP, and InP (7). The investigators also found that there were kinetic, as well as thermodynamic, effects, such as the growth rate being reduced more by a heavier inert gas.

Chemical Vapor-Deposited Boron Nitride Film on Silicon as a Boron Diffusion Source

Chol Kim,* Byung-Ki Sohn,¹ and Katsufusa Shono**

Faculty of Science and Technology, Sophia University, Tokyo 102, Japan

ABSTRACT

CVD-BN films deposited onto silicon have been investigated as a diffusion source. The concentration ratio of boron to nitrogen C_B/C_N in the as-deposited BN film could be controlled in the range from 1.4 to 2.5 by changing the depositing temperature with the $\text{B}_2\text{H}_6/\text{NH}_3$ ratio of 1/140. The boron concentration at the silicon surface depends mainly on the concentration ratio C_B/C_N and remains constant during the heat-treatment for diffusion, but decreases with diffusion temperature. The concentration ratio of boron nitride to excess boron $C_{\text{BN}}/C_{\text{Bx}}$ in the film has been empirically formulated in the Boltzmann form as a function of the deposition temperature. The boron surface concentration has also been described in the Boltzmann form, in terms of the diffusion temperature and the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$. The excess boron atoms in the BN film cause boron diffusion into the silicon. The activation energy for excess boron diffusion in the BN film is approximately proportional to the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$.

A chemical vapor-deposited boron nitride (CVD-BN) film² has been used as a solid source of boron for diffusion into a silicon crystal (1). The encapsulation over the BN surface with a thin Si_3N_4 film very effectively produces good uniformity and good reproducibility of the sheet resistance of the boron-diffused layer.

The chemical and physical properties of the CVD-BN films are strongly dependent on the deposition parameters, such as the flow rates of the reactant and carrier gases, the flow-rate ratio of reactant gases, and the substrate temperature during the deposition (2). An example is that the electrical resistivity of the BN film deposited in the temperature range from 400° to 600°C under a fixed gas-flow condition increases from 10^{11} to 10^{15} Ω-cm with increasing deposition temperature (3). The strong dependence of the properties of BN film on the deposition parameters is mainly attributed to the composition and structure of the BN layer.

In this paper, the chemical composition of BN films is analyzed as a function of the deposition temperature. The

boron concentration at the silicon surface is discussed as a function of the film composition and the heat-treatment temperature for diffusion.

Experimental

BN and Si_3N_4 films were deposited with the CVD system described in a previous paper (4). The fused silica reaction chamber was 35 mm wide, 400 mm long, and 20 mm high. A graphite plate, 30 mm wide, 50 mm long, and 5 mm thick, was used as the susceptor with RF heating. The reactant gases used were 1% B_2H_6 in N_2 , 5% SiH_4 in N_2 and NH_3 , and the carrier gas was nitrogen.

Phosphorous-doped silicon wafers, having the resistivity of 3-5 Ω-cm and (100) orientation, were used as the substrate. The BN films were deposited under the gas-flow conditions: 50 cm^3/min of 1% B_2H_6 , 70 cm^3/min of NH_3 , and 2000 cm^3/min of nitrogen carrier gas. The volume ratio of B_2H_6 to NH_3 was kept constant at 1/140. The above conditions were maintained constant for all deposited films. The deposition temperature was varied from 440° to 830°C. The resultant thickness of the BN films grown over the silicon surface was about 1000Å. An Si_3N_4 film was successively deposited over the surface of the BN under the gas-flow conditions: 70 cm^3/min of NH_3 , 20 cm^3/min of 5% SiH_4 , and 2000 cm^3/min of nitrogen carrier gas, and a substrate temperature of 720°C. The thickness of the Si_3N_4 film was approximately 300Å.

Key words: CVD, solubility, and integrated circuits.

²In this study and in the work of Ref. (2), the obtained film is nonstoichiometric. We customarily call the film "BN," which involves excess boron in boron nitride.

Boron diffusion into silicon from the BN film was carried out by heat-treatment performed in the temperature range from 1050° to 1200°C for 15-400 min in a nitrogen atmosphere. After the heat-treatment, the Si_3N_4 was removed in HF and the BN film in hot H_3PO_4 (1).

The boron diffusion depth was measured by spherical drilling and staining, and the sheet resistance with a four-point probe. The boron diffusion profile was obtained by use of spreading resistance. In obtaining the profile for the surface region, there were some errors which probably arose from using the angle lapping technique, or the corrective function to calculate the boron concentration from spreading resistance (5). Therefore, the surface concentration and the profile in the surface region were determined by the differential conductivity technique. The chemical composition of the BN film was determined by Auger electron spectroscopy (AES).

Results

Composition of the CVD-BN film.—The boron concentration C_B in the as-deposited CVD-BN film as a function of the deposition temperature T_D is shown in Fig. 1. For increasing deposition temperatures from 440° to 830°C, the boron concentration C_B decreased from 2.25×10^{22} to $1.05 \times 10^{22} \text{ cm}^{-3}$.

Figure 2 shows the concentration ratio of boron to nitrogen C_B/C_N in the as-deposited BN film as a function of the deposition temperature T_D . Under the gas-flow conditions, the concentration ratio C_B/C_N decreased from 2.5 to 1.4 with increasing deposition temperature in the temperature range from 440° to 830°C. In all the cases investigated, the as-deposited BN films were boron-rich and had an amorphous form, which was confirmed by observing reflection electron diffractor patterns.

Boron concentration at the silicon surface.—The boron profiles in silicon are shown in Fig. 3, where the deposition temperature T_D was (a) 440°C, (b) 600°C, and (c) 720°C, the diffusion temperature T_H was 1200°C, and the diffusion times were 15, 30, and 60 min. As the deposition temperature increased, the boron surface concentration C_s at silicon decreased. The BN films deposited at 440°, 600°, and 720°C gave boron surface concentrations of (a) 2×10^{20} , (b) 5.6×10^{19} , and (c) $0.9\text{--}1.2 \times 10^{19} \text{ cm}^{-3}$, respectively. These were kept constant during the heat-treatment for boron diffusion.

The boron surface concentration as a function of the deposition temperature is shown in Fig. 4 for the diffusion temperatures of 1050°, 1100°, and 1200°C. The maximum boron surface concentration, which was obtained for the BN deposited at temperatures lower than 500°C,

Fig. 1. Boron concentration of the as-deposited BN film vs. deposition temperature.

Fig. 2. C_B/C_N ratio of the as-deposited BN film vs. deposition temperature.

Fig. 3. Boron profiles in the silicon. The groups a, b, and c show the profiles for the deposition temperature 440°, 600°, and 720°C, respectively. The three curves in each group stand for the three different diffusion times 15, 30, and 60 min.

was $2.2 \times 10^{20} \text{ cm}^{-3}$. The boron surface concentration C_s decreases from 2.2×10^{20} to $2 \times 10^{18} \text{ cm}^{-3}$ with increasing deposition temperature T_D from 500° to 800°C and with decreasing the diffusion temperature T_H .

Discussion

As a result of the study of the deposition rate and the composition of BN films as a function of the flow rate and the flow-rate ratio of reactant gases, Murarka *et al.* concluded that, during the deposition, two nearly independent reactions occurred, leading to the simultaneous deposition of boron nitride and boron. They also concluded that the resulting films contained both BN and B in an intimate amorphous mixture (2). In other words, they concluded that the properties of the as-deposited BN films depend on the composition in terms of the concentration ratio of boron nitride to excess boron $C_{\text{BN}}/C_{\text{Bx}}$ in

Fig. 4. Boron surface concentration vs. deposition temperature

the film, where C_{BN} is the BN concentration defined as equal to C_N , and C_{Bx} is the excess boron concentration given by $C_{Bx} = C_B - C_N$.

From the results shown in Fig. 2, the concentration ratio of boron nitride to excess boron C_{BN}/C_{Bx} in the as-deposited CVD-BN film can be plotted in Fig. 5 as a function of the reciprocal of the deposition temperature T_D . In the range of deposition temperature, given in Fig. 5, the concentration ratio C_{BN}/C_{Bx} can be written as

$$\frac{C_{BN}}{C_{Bx}} = R_0 \exp\left(-\frac{\Delta E}{k T_D}\right) \quad [1]$$

where $R_0 = 24.40$, $\Delta E = 0.225$ eV, and k is the Boltzmann constant. If the concentration ratio C_{BN}/C_{Bx} corresponds to the deposition rate ratio of BN to B, ΔE may stand for the difference between the activation energies for the simultaneous deposition of BN and B. Under the conditions in this investigation, both the reference concentration and the activation energy for the formation of the BN are larger than those for the B.

From Fig. 4 and Fig. 5, the boron surface concentration C_s can be plotted, as shown in Fig. 6, as a function of the

Fig. 5. C_{BN}/C_{Bx} ratio vs. the reciprocal of deposition temperature

Fig. 6. Boron surface concentration vs. C_{BN}/C_{Bx} ratio

concentration ratio C_{BN}/C_{Bx} of the as-deposited BN film. The boron surface concentration C_s is an exponential function of the concentration ratio C_{BN}/C_{Bx} , and the slope β of the straight line on the semilogarithm graph varied approximately linearly with the diffusion temperature T_H , as shown in Fig. 7. The slope β is thus seen to be

$$\beta = 1 + \frac{E_0}{k T_H} \quad [2]$$

where $E_0 = 0.38$ eV. Then, the boron surface concentration C_s can be written, in Boltzmann form, as

$$C_s = C_x \exp\left(\frac{E_x}{k T_H}\right) \quad [3]$$

where

$$C_x = C_0 \exp\left(-\frac{C_{BN}}{C_{Bx}}\right) \quad [4]$$

$$E_x = E_0 \frac{C_{BN}}{C_{Bx}} \quad [5]$$

where $C_0 = 9.5 \times 10^{21}$ cm⁻³. E_x , the activation energy, is a function of the concentration ratio C_{BN}/C_{Bx} and increases

Fig. 7. β vs. the reciprocal of heat-treatment temperature

linearly from 0.25 to 0.95 eV with an increase of $C_{\text{BN}}/C_{\text{Bx}}$ over the range from 0.6 to 2.5.

The excess boron concentration C_{Bx} in the as-deposited BN film, which was shown as a function of the deposition temperature T_{D} in Fig. 1 and 2, is compared in Fig. 8 with the reference concentration C_{x} in Eq. [3]. The solid line in Fig. 8 is 2.6 times the value of C_{x} which was calculated from Eq. [1] and [4]. It closely fits the curve for C_{Bx} , the excess boron concentration. This means that, in the temperature range considered, the excess boron concentration C_{Bx} is approximately equal to 2.6 times C_{x} . The boron surface concentration C_{s} increases with the increasing excess boron concentration C_{Bx} , and must be zero if there are no excess boron atoms in the BN film. This formulation leads to the conclusion that only the excess boron atoms in the BN films act as a boron diffusant into the silicon.

According to Eq. [3], the boron surface concentration C_{s} in silicon should increase exponentially with the decreasing concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$ and finally reach the value C_{v} . However, in the region at deposition temperatures lower than 500°C in Fig. 3 or at concentration ratios $C_{\text{BN}}/C_{\text{Bx}}$ less than 1.0 in Fig. 5, the experimental results do not agree with the trend of Eq. [3], but for a diffusion temperature of 1200°C, the boron surface concentration C_{s} is limited to $2.2 \times 10^{20} \text{ cm}^{-3}$, which corresponds to the solid solubility of boron in silicon (6).

A general description of impurity diffusion from a thin film source into a semi-infinite sink has been presented by Barry and Olofson (7). In their model, when the film thickness is larger than the diffusion length of impurity in the film, the impurity concentration at silicon surface C_{s} is independent of diffusion time but depends on an initial concentration of the impurity C_{i} in the film, a ratio of the impurity diffusivity D_{x} in the film to that D_{B} in the silicon, and a segregation coefficient m of the impurity. The relation is given as

$$C_{\text{s}} = \frac{C_{\text{i}} \sqrt{D_{\text{x}}/C_{\text{B}}}}{1 + \sqrt{D_{\text{x}}/D_{\text{B}}}} \quad [6]$$

The experimental results of Ref. (1) give the excess boron diffusivity D_{x} in the BN film less than $10^{-16} \text{ cm}^2/\text{s}$ at the diffusion temperature of 1200°C, which is much smaller than the boron diffusivity D_{B} in silicon. Therefore, Eq. [6] can be simplified as

$$C_{\text{s}} = C_{\text{Bx}} \sqrt{D_{\text{x}}/D_{\text{B}}} \quad [7]$$

where the initial impurity concentration C_{i} was replaced by the initial concentration of excess boron C_{Bx} in the

film. It can be found that the activation energy E_{x} of Eq. [3] is a difference of the activation energy for the excess boron diffusion in the film and for the boron diffusion in silicon. The former is approximately proportional to the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$ and the latter is still constant. The exponential relation of the surface concentration C_{s} on the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$ can be referred to the exponential dependence of the excess boron diffusivity D_{x} on the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$.

The boron profiles of Fig. 3 show significant characteristics. For the boron surface concentration $C_{\text{s}} = 2 \times 10^{20} \text{ cm}^{-3}$, the boron concentration in the silicon decreases linearly with increasing distance from the silicon surface. The diffusion profiles for the boron surface concentration $C_{\text{s}} = 0.9$ to $1.2 \times 10^{19} \text{ cm}^{-3}$ fit well on the complementary error function curve without the tail region where the boron diffusion was retarded. The detailed analysis of this will not be discussed here.

The boron diffusion technique presented has been employed in source and drain formation for PMOS IC fabrication and in the simultaneous formation of base and isolation regions in bipolar IC's. After the deposition of the BN, the film thickness has been inspected by the ellipsometric technique and the refractive index of the film calculated.

The refractive index of CVD-BN is shown in Fig. 9 as a function of the reciprocal of deposition temperature. The refractive index n can be written as

$$n = n_0 \exp\left(\frac{\Delta E'}{k T_{\text{D}}}\right) \quad [8]$$

where $n_0 = 1.17$ and $\Delta E' = 0.032 \text{ eV}$. By combining Eq. [1] and [8], an empirical relation between the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$ and the refractive index n can be written as

$$\frac{n}{n_0} = \left(R_0 \frac{C_{\text{Bx}}}{C_{\text{BN}}}\right)^{\Delta E'/\Delta E} \quad [9]$$

or

$$n = 1.83 \left(\frac{C_{\text{Bx}}}{C_{\text{BN}}}\right)^{0.14} \quad [10]$$

Equation [10] shows that the refractive index n depends only weakly on the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$ and that incorporation of boron into the films leads to a higher refractive index.

Using the relation of Eq. [10], the concentration ratio $C_{\text{BN}}/C_{\text{Bx}}$ can be determined from the refractive index n , instead of by direct measurement of the composition using the AES technique. This provides a convenient way of checking the boron diffusion source during the process.

Fig. 9. Refractive index vs. the reciprocal of deposition temperature

Conclusions

Boron-rich BN films were deposited on silicon by CVD with the B_2H_6/NH_3 ratio of 1/140. When the deposition temperature increased from 440° to 830°C, the concentration ratio of boron to nitrogen C_B/C_N in the as-deposited film decreased from 2.5 to 1.4. The CVD-BN films deposited over the silicon wafer can be effectively used as a boron diffusion source. For diffusion heat-treatment at 1200°C, the boron surface concentration decreased over a range from 2.2×10^{20} to 2×10^{18} cm^{-3} as the deposition temperature of the BN film was increased from 440° to 830°C. The surface concentration remained constant during the diffusion heat-treatment, but decreased with decreasing heat-treatment temperature.

The concentration ratio of boron nitride to excess boron C_{BN}/C_{Bx} in the film was empirically formulated in the Boltzmann form as a function of the deposition temperature. The boron surface concentration has also been described in the Boltzmann form, in terms of the diffusion temperature and the concentration ratio C_{BN}/C_{Bx} . The excess boron atoms in the BN film constitute a source of boron diffusion into silicon. The activation energy for excess boron diffusion in the BN film is approximately proportional to the concentration ratio C_{BN}/C_{Bx} .

Characterization of Metallic Precipitates in Epitaxial Si by Means of Preferential Etching and TEM

C. J. Werkhoven,^{*,1} C. W. T. Bulle-Lieuwma, B. J. H. Leunissen, and M. P. A. Vieggers

Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

ABSTRACT

Microdefects in epitaxial silicon have been studied by means of preferential etching and transmission electron microscopy. Wafers with a high density of etch pits contained a high density of very small (≤ 10 nm) defect clusters, as revealed by transmission electron microscopy. A good correlation between defect clusters and etch pits could be established. In a larger type of defect, occurring at lower density, the precipitating material was identified as being Cu. In wafers showing a low etch pit density, only a low density of another type of larger defects was found containing Fe or Ti. Processing conditions and gettering treatments only affected the density of the smallest and the Cu containing particles.

Preferential etching is widely used as a rapid method to characterize defects in semiconductor materials. Among the many etching features of silicon, the so-called shallow etch pits or S-pits (1) have been attributed to microdefects which usually develop after high temperature treatments, and which have been correlated with precipitates of transition metals (2). At high etch pit densities, *i.e.*, about 10^6 cm^{-2} , the appearance of the wafer surface is referred to as "haze."

At various instances, the characterization of microdefects was reported. Cullis and Katz (3) found relatively large (~ 2 μm) rod-like $FeSi_2$ precipitates, sometimes associated with Cu. Ward (4) observed iron disilicide precipitates in the emitter regions of ion-implanted bipolar transistors. Gleichmann *et al.* (5) found large precipitates in power devices after prolonged high temperature processing. Augustus (6) reported small precipitates in epitaxial silicon wafers, which were shown to contain either Ni or Fe. In wafers with gross contamination, larger Ni-containing defects were identified and it was concluded that Ni precipitated as $NiSi_2$. Earlier, Augustus *et al.* (7) reported the contamination of bipolar transistors with large rod-like precipitates of α -Fe, which were found in the boron diffused base regions. Stacy *et al.* (8) identified Ni as an impurity decorating oxidation-in-

duced stacking faults in wafers contaminated by metallic tools, and Cu as an impurity precipitating in nonintentionally contaminated wafers. Recently, Pearce and Kannon (9) reported precipitation phenomena of various metallic and nonmetallic impurities after high temperature processing.

The present work is part of a study on microdefects in nonintentionally contaminated epitaxial layers. In the first part (10), the characterization of a larger type of defect observed in wafers processed in an RF-heated reactor was described. The precipitated impurities were identified as Fe and Ti, which, as radioactive tracer experiments showed, originated from the susceptor. The present report focuses on a smaller type of defect which was unidentified at that time, and which appears to have a good correlation with preferential etching features.

Experimental Procedures

Epitaxial layers were grown in a radiantly heated barrel-type reactor at 1080°C using dichlorosilane as the Si source material. A prebake at 1150°C in H_2 was used to remove the native oxide. The substrate wafers were of 3 in. diam, boron-doped in the range 7-21 Ωcm , and of (111) orientation. Prior to high temperature processing, the wafers were cleaned in H_2O_2 - H_2SO_4 for 10 min at 110°C.

Defect characterization of the near front surface region was performed by preferential etching and transmission electron microscopy (TEM). In the former case, the wafers were immersed in the Wright etchant for 1 min at

*Electrochemical Society Active Member.

¹Present address: Philips Research Laboratories Sunnyvale, c/o Signetics Corporation, Sunnyvale, California 94086.

Key words: semiconductor, defects, epitaxy, contamination.

room temperature. The etching features were examined by optical microscopy and scanning electron microscopy (SEM). For TEM investigations, samples of the wafers were thinned from the rear side surface to a thickness of 300 nm by wet chemical etching. The specimens were studied in a 120 kV Philips EM400T microscope, equipped with an energy-dispersive x-ray spectrometer. The TEM work was done on the part of the wafer which was not preferentially etched. Some samples were also prepared with wafers which were etched for only 15s in order to investigate the development of etch pits at defect sites.

Preferential Etching

The density of etch pits as observed by optical microscopy ranged between 10^3 and 10^7 cm^{-2} . An accurate figure in the low density regime was difficult to obtain because of the small size and the shallowness of the etch pits. Even in the SEM, good contrast was not readily achieved in most cases. At higher densities the etch pits tended to be larger and deeper. A first indication of the density and the distribution of etch pits across the wafer surface could be obtained by visual observation using high intensity light.

A SEM micrograph of an etched wafer surface showing a high density of etch pits is presented in Fig. 1. The typical triangular-shaped pits vary in size from almost indistinguishable to about $1 \mu\text{m}$. It is evident that optical microscopy can significantly underestimate the defect density. A reduction of the etch-pit density by more than an order of magnitude was noticed after removal of a thin (200-300 nm) surface layer, indicating the presence of a near surface region significantly enriched with defects. The size distribution of etch pits as visible in Fig. 1 probably represents the depth distribution of the corresponding defects (about 700 nm is etched off during 1 min preferential etching).

In anticipation of the TEM investigations, we wish to remark that the lateral distribution of defects even on a submicron scale could be very inhomogeneous (see Fig. 1). Hence, large variations in defect density from one area to the other can be expected in high magnification TEM micrographs.

Transmission Electron Microscopy

The samples investigated by TEM were selected according to the etch pit density observed on separate parts of the wafers. Two extreme cases were considered, *viz.* a very high density of etch pits (10^6 - 10^7 cm^{-2}) and a low density of etch pits (10^3 - 10^4 cm^{-2}). In addition, we examined wafers whose initially high etch pit density was reduced to a low value by means of a phosphorus-diffusion gettering treatment at the rear side of the wafers from a POCl_3 source (3).

In samples with a high density of etch pits, three types of defects could be distinguished:

Type 1: very small defects, which were not resolved under dynamical two-beam imaging conditions. They

Fig. 1. SEM micrograph of a preferentially etched epitaxial wafer showing a high etch pit density. Scale mark is $1 \mu\text{m}$.

showed only a spherically symmetric tensile strain field typically extending about 10-nm. Faceting could be observed on somewhat larger defects. X-ray analysis failed to yield reliable results, probably owing to the small dimensions. The density varied markedly within a given sample and could be locally as high as 10^{10} cm^{-2} . A detailed study of the contrast phenomena (11) indicated increasing density towards the surface. A typical micrograph is shown in Fig. 2.

Type 2: faceting features similar to those present on the type 1 defects were also observed on a larger type of defect ranging in size between 30 and 200 nm. Many of these particles showed fringe contrast (see also Fig. 2), which indicates a specific orientation and misfit of the defect lattice in the Si matrix. Locally, the density could be 10^7 cm^{-2} (larger defects), but it could also be as low as 10^4 cm^{-2} (larger defects). The larger particles were accessible to x-ray microanalysis, showing Cu significantly above the background signal of the microscope. Attempts for a microdiffraction analysis were unsuccessful, due to the very small volume of the particles involved.

Type 3: the largest type of defect, with dimensions between 100 and 200 nm and densities between 10^4 and 10^5 cm^{-2} . These precipitates had a characteristic elongated or spherical shape and contained either Fe or Ti, respectively [see Fig. 3 and Ref. (10)]. The low densities involved hampered a reliable estimate of differences in density between different samples. In the earlier report (10), we related these defects with impurities in the susceptor.

Considering the TEM results on wafers with a low etch pit density, the absence of type 1 and 2 defects can be seen as a striking difference in comparison to wafers with a high etch pit density. The same applies to the wafers which received the gettering treatment. We therefore conclude that the smallest type 1 defects also leave distinct etch pits in the surface upon preferential etching. This was verified by examination of slightly etched (15s) wafers in the transmission electron microscope. As illustrated in Fig. 4, well-defined etch pits were observed, which showed a black, a white, or a black-and-white fringe contrast, depending on their depth. Under some

Fig. 2. Bright field TEM micrograph showing dynamical diffraction contrast of a higher density of small type 1 defects and one larger, type 2 defect containing Cu. The operative reflection: $g = 220$.

Fig. 3. TEM micrographs and x-ray spectra of type 3 defects containing Fe and Ti.

Fig. 4. Dark field TEM micrograph of a slightly etched wafer showing the various stages of development of etch pits at defect sites. The operative diffraction vector: $g = 220$.

etch pits, showing very weak contrast, a small type 1 defect was still present. Other defects, situated at a larger distance below the surface, had not yet developed etch pits with sufficient depth to cause a noticeable contrast effect. Larger and less regular contrast features were also observed, and because of their much lower density, we attributed these etch pits to type 2 and 3 defects.

In relation to the impurities identified in some of the defects, it is of interest to note the difference in sensitivity to the gettering treatment between type 1 and 2 defects on one hand and type 3 defects on the other. The trend observed here is in good agreement with the RBS results of Buck *et al.* (12), *i.e.*, rapid gettering of Cu with respect to Fe, and suggests that the type 1 defects, like the type 2 defects, also contain Cu. Some morphological resemblance between types 1 and 2 supports this as well.

Regarding the source of the metallic contamination, we have already mentioned (10) the role of the susceptor in the case of Fe and Ti. The same report also pointed out that Cu was consistently detected in substrate wafers by means of neutron activation analysis and confirmed earlier results obtained by the same technique (13). As reported by Stacy *et al.* (8), Cu is a major background impurity decorating oxidation-induced stacking faults. Hence, there are strong indications for suspecting the substrate wafer of being a source of the Cu on the defects observed after various high temperature processes.

A general phenomenon of Cu appears to be its tendency to form a high density of very small precipitates (3). In contrast with most transition metals, Cu has a relatively high solid solubility, so that supersaturation is reached at relatively low temperatures. The limited range of diffusion at low temperatures favors the formation of a high density of nuclei. The extremely weak x-ray signals obtained from the precipitates containing Cu point to a low metal content, suggesting a heterogeneous nucleation mechanism which may involve intrinsic point defects.

Summary

Depending on process conditions, preferential etching of (111)-oriented epitaxial wafers revealed a wide range of etch pit densities. When a high density of etch pits was found, TEM showed a high density of very small isolated defects which are not accessible for x-ray microanalysis. A good correlation was established between these defects and the etch pits. In addition, two types of larger precipitates containing Cu and Fe or Ti, respectively, were present in much lower densities. Apart from the etch pit density, only the density of the smallest defects and that of the somewhat larger precipitates containing Cu varied with deposition conditions and postgrowth gettering treatments. Both the etch pit density and the defect density decreased rapidly below the surface.

Reduction of Electron-Beam-Induced Damage in MOS Devices Using Three-Layer Resist with Heavy Metal Interlayer

Masakazu Shimaya, Osake Nakajima, Chisato Hashimoto, and Yutaka Sakakibara

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, Kanagawa, 243-01, Japan

ABSTRACT

A three-layer resist with a heavy metal interlayer is proposed to remove the electron-beam-induced damage in MOS devices. The three-layer resist with 280 nm thick platinum interlayer can decrease positive charge and neutral traps in the gate oxide to about one-fifth of those for direct exposure. This effect is equivalent to reducing exposure dosage about two orders of magnitude. The saturation effect of damage reduction is found with increasing the Pt interlayer thickness to above 280 nm, due to the damage generation by secondary electrons or x-ray. The dissipation energy calculation by Monte Carlo technique indicates that the saturation threshold for damage removal corresponds to about 1×10^{21} eV/cm³ dissipation energy in the gate oxide. This critical value for the dissipation energy provides an optimum metal interlayer thickness T_m in the three-layer resist, which is given as $T_m = 30E^{1.75}/\rho$ (nm), where E is the electron energy (keV) and ρ is the metal mass density (g/cm³). Considering the restriction of interlayer thickness and the dry etching capability in the lithography and patterning process, tungsten is suitable for the metal interlayer in the three-layer resist.

Direct writing electron-beam lithography provides the high resolution pattern delineation necessary to fabricate high density and high performance VLSI's. However, energetic electrons can create radiation damage in the gate oxide in MOS devices, due to the fact that they ionize materials as they pass through the surface layer. The radiation-induced positive charge and neutral traps in the oxide and interface traps at the Si-SiO₂ interface degrade MOSFET characteristics severely (1). Therefore, the radiation damage in the gate oxide has been studied extensively (2, 3). Of particular importance is the annealability of that damage with the temperature-time limits imposed by the device processing. The most restricted annealing process is postmetallization annealing, in which annealing temperatures are limited by either metal penetration or contact resistance degradation problems associated with the contact metallurgy. Typical postannealing at 400°-450°C in N₂ or forming gas, however, is not sufficient to remove positive oxide charge and neutral traps. Above 700°C, annealing has been reported necessary to remove these traps completely (4). Therefore, more efficient postmetallization annealing procedures have been investigated recently to remove radiation damage, such as annealing in pure hydrogen gas ambient (5), annealing in high pressure (50 atom) forming gas (6), and in the RF plasma (7). These methods are effective to some extent, compared to conventional forming gas annealing, but are not sufficient to remove radiation damage completely.

In this paper, the approach proposed is the suppressing or stopping of electron penetration into the gate oxide in the lithography step, using three-layer resist (8) with a heavy metal interlayer. We have evaluated residual damage in the gate oxide after electron-beam exposure and after annealing in N₂ at 450°C, as a function of the thickness of platinum interlayer in the three-layer resist. We also compare the experimental results with the dissipation energy in the gate oxide, calculated by Monte Carlo simulation. The optimum metal interlayer thickness is determined for some heavy metals, according to the electron energy.

Key words: radiation damage, neutral trap, MOS devices, three-layer resist, dissipation energy.

Experimental Procedure

MOS devices used in this work were polysilicon gate MOS capacitors fabricated on p-type (100) silicon substrate with a resistivity of 0.1-0.2 Ω · cm. All MOS capacitors were fabricated with conventional photolithography and chemical etching. After forming thick field oxides and removing oxides in the 2.5×10^{-3} cm² gate area, a 30 nm thick gate oxide was grown in dry oxygen at 950°C. Phosphorous-doped polysilicon electrodes 450 nm thick were fabricated by CVD, followed by annealing in dry N₂ at 1000°C so as to reduce the resistivity. After etching off polysilicon outside the gate area, CVD SiO₂ was deposited for surface passivation, followed by contact hole etching. Finally, the capacitors were annealed in a forming gas ambient at 450°C for 30 min.

The three-layer resist was formed as follows. AZ® resist 1.0 μm thick was spun on MOS capacitors and baked at 200°C for an hour. A platinum interlayer, 0-500 nm thick, was deposited on the AZ resist by RF sputtering. Finally, an electron-beam-exposed resist CMS 400 nm thick was spun on the Pt interlayer.

Electron-beam exposure to some capacitors in a wafer was carried out through the three-layer resist by an electron-beam lithography system (9). The gate area for individual capacitors was scanned by a 20 keV electron-beam. Dosages were between 2 and 2000 μC/cm². Annealing was carried out at 450°C in an N₂ ambient for 30 min after electron-beam exposure and taking off the three-layer resist.

High frequency C-V curves were measured to determine the radiation-induced flatband voltage shift. The density of neutral traps, as well as positively charged traps, were determined by avalanche injection technique, which injects hot electrons from the silicon substrate to gate oxides and measures the flatband voltage shift (10). By analyzing the characteristics of flatband voltage shift vs. the number of injected electrons, the effective density and the cross section of electron traps can be obtained.

Results and Discussion

Radiation damage after exposure.—Figure 1 shows the relation of the V_{FB} shifts vs. Pt interlayer thickness in

Fig. 1. Flatband voltage shift from pre-irradiation state for electron-beam-irradiated MOS capacitors as a function of Pt interlayer thickness in the three-layer resist.

three-layer resist after electron-beam exposure. Negative V_{FB} shift, indicating positive charge buildup in the oxide, decreases with an increase in the metal thickness, and tends to become constant when Pt layer is more than 280 nm thick. The V_{FB} shift for capacitors on which a three-layer resist was applied with 280 nm thick Pt interlayer decreases drastically to about one-fifth of that for direct exposure. This indicates that the application of three-layer resist in the lithography step is very effective in reducing radiation damage, and equivalent to reducing exposure dosages by about two orders of magnitude.

Figure 2 shows the results of electron injection measurements for MOS capacitors exposed at $20 \mu\text{C}/\text{cm}^2$. In this figure, the change in V_{FB} , which occurs as injected electrons are captured, is plotted against the number of injected electrons per unit gate area. This clearly shows that electron beam exposure substantially increases the trapping in the oxide and that the three-layer resist is very efficient to reduce the traps in the oxide. For unexposed capacitors, V_{FB} shift occurs after injecting above $10^{16}/\text{cm}^2$ electrons. This V_{FB} shift is thought to be due to electron trapping by water-related defects in the oxide (11), which exist in as-made state. Analysis of the curve for capacitors exposed directly, without the three layer resist, shows that two distinct kinds of traps are being filled as electron injected. The first kind of trap is positively charged and is completely filled after $10^{14}/\text{cm}^2$ electrons have been injected. This saturated V_{FB} shift coincides to the negative V_{FB} shift in the magnitude, observed after electron beam exposure, as shown in Fig. 1. The

Fig. 2. Flatband voltage shift due to avalanche hot electron injection into the gate oxide for irradiated MOS capacitors.

electron capture cross section for positively charged traps is 10^{-13} - 10^{-14} cm^2 . The additional V_{FB} shift, observed after saturation of positively charged traps, is due to filling of neutral electron traps introduced by electron beam exposure. Its capture cross section is 10^{-15} - 10^{-16} cm^2 .

Noticeably, application of the three-layer resist is very effective in reducing neutral traps, as well as positively charged trap. The V_{FB} shift for capacitors with 280 nm Pt interlayer thickness after injection of $2 \times 10^{16}/\text{cm}^2$ electrons is only 330 mV and about one-seventh of that for direct exposure, where this injection level corresponds to the filling of positively charged traps and neutral traps. This damage reduction effect is accounted for by the suppression of electron penetration in the oxide through the three-layer resist. However, the decrease in positively charged traps and neutral traps is found to be constant with increasing interlayer thickness to above 280 nm. This constant phenomenon is believed to be due to the damage generation by secondary electrons or x-ray, which is produced by electron scattering within a high density metal layer in the three-layer resist.

Residual radiation damage after annealing.—Figure 3 shows V_{FB} shifts after annealing in a N_2 ambient at 450°C , as a function of Pt layer thickness. V_{FB} shift decreases extremely with increasing metal thickness. When exposure dosage is $20 \mu\text{C}/\text{cm}^2$, V_{FB} shift for capacitors with a 280 nm thick Pt interlayer is about 40 mV and is one-ninth of that for direct exposure. This ratio is smaller than that before annealing. When exposure dosage is $2 \text{ mC}/\text{cm}^2$, V_{FB} shift for capacitors with 280 nm Pt interlayer thickness is about 0.2V. This shift is smaller than the V_{FB} shift for direct exposure with $20 \mu\text{C}/\text{cm}^2$ exposure dosage. This result indicates that, after annealing in N_2 at 450°C , the application of three layer resist is equivalent to reducing exposure dosage more than two orders of magnitude.

Figure 4 shows the electron injection measurement results for capacitors annealed in N_2 at 450°C . The V_{FB} shift after injecting $2 \times 10^{16}/\text{cm}^2$ electrons is only 90 mV for capacitors with 280 nm thick Pt interlayer. The V_{FB} shift due to filling of neutral traps is approximately 50 mV. Neutral traps as well as positive charge are found to be removed sufficiently by annealing in N_2 at 450°C for capacitors with 280 nm Pt interlayer thickness.

These experimental results show that three-layer resist application with a heavy metal layer suppresses the generation of damages and furthermore enhances the removal efficiency of positive charge by low temperature annealing.

Dissipation energy in gate oxide.—The dissipation energy in the gate oxide is calculated and compared with the experimentally observed radiation damage.

Fig. 3. Flatband voltage shift from pre-irradiation state for annealed MOS capacitors after EB exposure, as a function of Pt interlayer thickness.

Fig. 4. Flatband voltage shift due to avalanche hot electron injection into the gate oxide for annealed MOS capacitors after EB exposure.

The Monte Carlo technique for the electron trajectories calculation has been applied by several authors to study the backscattered electrons, energy dissipation, and secondary electron emission (12, 13). We also use this method to calculate the dissipation energy in each layer of the multilayered structure.

In electron free path calculation, a few free path model is used, which takes into account not only the scattering probability in the layer involving the initial scattering point, but also that in other layers along the scattering direction (14). The multilayered structure shown in Fig. 5 is employed to calculate dissipation energy, where point electron beam is exposed. For detailed dissipation energy calculation, the multiple layer is divided into 50 layers. The calculation is accomplished for 10,000 electrons in order to obtain meaningful results.

The AZ resist thickness (0.4 μm) in Fig. 5 is thinner than that used in the experiment (1 μm). This is caused by the restriction in calculation depth. However, an estimated error in the dissipation energy in the gate oxide due to inadequate AZ resist thickness is negligible, since the density of AZ resist is low.

Figures 6a and 6b show examples of the dissipation energy profile for the multilayer structure, where metal interlayers are formed by 320 nm thick platinum and 600 nm thick platinum, respectively. In Fig. 6a, the dissipation energy in SiO_2 is about 3×10^{20} eV/cm³, which indicates that incident electrons penetrate the three-layer resist and reach the gate oxide. In Fig. 6b, the dissipation energy decreases drastically in the Pt layer and the dissipation energy in SiO_2 cannot be estimated. This result shows that incident electrons cannot penetrate the three-layer resist with 600 nm thick Pt interlayer.

Fig. 5. Multilayered structure for dissipation energy calculation

Fig. 6. An example of dissipation energy profile for the multilayered structure. (a, top) Platinum layer is 320 nm thick. (b, bottom) Platinum layer is 600 nm thick.

Optimum metal layer thickness.—Figure 7 shows the relation of the experimentally observed effective density for the positive oxide charge after electron-beam exposure and the calculated average dissipation energy in SiO_2 . As shown in the experiment, radiation damage cannot be reduced to less than a certain level, which will be determined by secondary electron or x-ray, even if the metal interlayer in the three-layer resist is sufficiently thick. A thinner metal interlayer is better with regard to the dry etching process. In Fig. 7, the effective positive charge density is found to become constant with a decrease in the dissipation energy below 1×10^{21} eV/cm³. Therefore, the optimum thickness of metal interlayer can be determined to be a thickness where the dissipation energy in the gate oxide is about 1×10^{21} eV/cm³.

Figure 8 shows the dissipation energy in the gate oxide as a function of several kinds of metal interlayer. The thickness corresponding to the 1×10^{21} eV/cm³ dissipation energy is about 260 nm for Pt, about 280 nm for W, and about 570 nm for Mo. These thicknesses correspond to about 65% of the experimental penetration distance for the metal layer, called gruen range R_G (15), which is represented by

$$R_G (\text{nm}) = 46 E^{1.75} / \rho \quad [1]$$

where E is electron energy (keV) and ρ (g/cm^3) is the den-

Fig. 7. Relation between effective density of radiation-induced positive charge and the average dissipation energy in the gate oxide.

Fig. 8. Average dissipation energy in the gate oxide for various kinds of metal, as a function of metal interlayer thickness in the three-layer resist.

sity of metal. Thus, the optimum metal interlayer thickness in three-layer resist (T_m) can be given by a simple formula

$$T_m \text{ (nm)} = 30 E^{1.75}/\rho \quad [2]$$

Using this formula, the metal interlayer thickness is easily estimated without the complicated calculation of the dissipation energy. In Table I, T_m values are shown for various metals as a function of electron energy. For the three-layer resist technology, the metal interlayer thickness is restricted by dry etching tolerance of electron-exposed resist. Its thickness is normally less than 600 nm. When electron energy is 20 keV and metal thickness is assumed to be 600 nm, required metal density is calculated to be more than 9.5 g/cm³, using Eq. [2]. Considering this condition and the dry etching process, tungsten ($\rho = 19.3$ g/cm³) is suitable for the metal interlayer in the three-layer resist.

On the other hand, it seems that the use of the three-layer resist with a heavy metal interlayer may degrade the patterning resolution, because of the increase in the backscattered electrons. However, after careful consideration, no degradation in patterning resolution was obtained by thinning the electron-beam-exposed resist and selecting the appropriate exposure dosage. Moreover, the

Table I. Optimum thickness (nm) of metal interlayer for reducing damage.

METAL	ELECTRON-BEAM ENERGY (keV)		
	10	20	50
Mo	164	550	2743
Ta	102	342	1700
W	87	294	1461
Pt	78	265	1318

use of this resist has several advantages, for instance, the reduction in irradiation dosage. The work relating the patterning characteristics for the three-layer resist with a heavy metal interlayer will be published in detail elsewhere.

Although a three-layer resist with heavy metal interlayer has been discussed here, there is another scheme, such as a thick monolayer resist and a two-layer resist with the thick bottom layer for blocking incident electrons. These schemes are usually done by applying an organic material which has an excellent step coverage and high RIE resistance. However, a thickness of more than 5 μ m needs 20 keV electrons for blocking. Using such a thick resist, it is not easy to get a high pattern resolution. Therefore, the three-layer resist with heavy metal interlayer is a better technique than other resist schemes, with regard to the damage reduction and the high patterning resolution.

Conclusion

The three-layer resist with a heavy metal interlayer in the electron beam exposure step has been proposed to reduce electron-beam-induced damages in MOS devices.

Applying this resist with a 280 nm thick Pt interlayer, damages decreased drastically to about one-fifth of that for direct exposure and were removed sufficiently by annealing in N₂ at 450°C. The application of three-layer resist with 280 nm Pt interlayer is equivalent to reducing exposure dosages about two orders of magnitude. However, the decrease in damages is found to become constant with increasing Pt interlayer thickness to above 280 nm, because of the damage generation by secondary electrons or x-ray.

Applying the Monte Carlo method to the dissipation energy calculation, it is clear that the constant phenomenon for the damage decrease begins when the dissipation energy in the gate oxide is about 1×10^{21} eV/cm³. According to these results, the optimum metal interlayer thickness in the three-layer resist can be extracted by $T_m = 30E^{1.75}/\rho$. Tungsten is suitable as the interlayer metal in the three layer resist, because of its high mass density and its dry etching capability.

Siltec Corporation, Mountain View, California 94043

ABSTRACT

The warpage of laser-damaged P-type (111) and (100) silicon wafers subject to thermal cycles which simulate processing sequences was found to be less than that produced by mechanical abrasion damage. Both warpage and laser damage depth in wafers from the tail-end of crystals were found to be different from that in wafers from the middle or seed-end. These differences cannot be explained on the basis of the total interstitial oxygen content in the wafer and suggest that the state of the oxygen has an important influence on the mechanical properties of silicon.

In recent years, one of the major aims of VLSI technology has been the fabrication of large area devices free of lattice defects. For this reason, efforts have been concentrated on the suppression of process-induced defects in silicon. The effectiveness of back-side damage gettering in the reduction of process-induced defects has been widely investigated and reported in the open literature (1-3). Back-side damage gettering uses a dislocation network on high stress regions created on the wafer back surface, which acts as an effective source of vacancies or a sink of interstitials. This dislocation network also acts as a sink of fast-diffusing metallic impurities and reduces their decoration on oxidation-induced stacking faults near the front surface, which is an important cause of structure-related device failure in silicon devices.

Key words: semiconductor, integrated circuit, warpage, gettering.

Fig. 1. Axial oxygen concentration distribution of two ingots used for this investigation.

Although various other methods of inducing back-side damage for gettering have been studied, for example lapping, sandblasting, phosphorous diffusion, ion implantation, Si_3N_4 deposition, polycrystalline silicon deposition, and laser irradiation, laser damage gettering has many advantages and has received some attention from a number of research groups (4, 5). Laser damage gettering utilizes laser irradiation to generate gettering sites where a variety of point defects, such as impurities and interstitials, gather. The technological advantages of this method are (i) the damage is induced at room temperature, (ii) the damage can be precisely controlled, and (iii) the damage is more permanent during common IC fabrication thermal cycles. Laser back-side damage gettering has the additional advantages that it is a clean and reproducible process, and throughput rates are compatible with wafer fabrication requirements.

One of the major obstacles to the development of a laser back-side damage gettering process is wafer distortion due to lattice damage generated by high power pulsed laser irradiation (6). Warped wafers are difficult to handle in automatic processing equipment. The generation of complex circuit patterns by photolithography on a warped or bowed wafer is difficult to perform due to a

varying focal plane. This problem is especially serious with projection printing, during which wafer flatness is no longer improved by the application of mechanical pressure to a wafer with a mask, as occurs during contact

printing. In addition to wafer handling and photolithographic problems, warpage can also affect the electrical characteristics of devices and circuits. Dislocations introduced into processed wafers as a result of plastic deformation are known to cause excessive leakage currents in processed circuits when located in the active device volume. Due to a change of lateral dimensions on the wafer by warpage, an exact device geometry (e.g., a channel length) cannot be realized due to the misalignment which can cause degradation of device characteristics.

The purpose of the present work is to examine how the lattice damage caused by laser irradiation affects the mechanical properties of silicon wafers during simulated high temperature device processing. In addition, an attempt is made to quantify the laser damage from measurements of the depth of damage using etching of polished sections.

Experimental

vestigation. The P(111) silicon crystal was grown under the following conditions: flat top shoulder, pull speed during body growth 3-3½ in./hr, seed rotation 15 rpm CCW, crucible rotation 8 rpm CW with a 3-phase ac powered Siltec 860D furnace. The growth parameters for the P(100) crystal were: slow shoulder, pull speed during body growth 3 1/2-4 in./hr, seed rotation 20 rpm CCW, crucible rotation 7 rpm CW with 3-phase ac powered Siltec 860D furnace. Both ingots had the same size of 100 mm diameter and 580 mm effective length and were doped with boron. 50 wafers of 625 μm thickness were cut from

mination of interstitial oxygen contents was 9.63 from ASTM F121-79. The longitudinal distribution of $[O_i]$ along the pulling direction for both crystals is shown in Fig. 1. The radial distribution of $[O_i]$ from three portions for both crystals is summarized in Table I. Carbon contents ranged from less than 0.05 ppm to 1.0 ppm for both crystals.

Laser damage was induced on the rear surface of the caustic-etched wafers by a Quantronix 610 Epitherm Q-switched Nd:YAG laser system. Various levels of energy density were used for back-side damage gettering as follows: 20, 24, 34, and 45 J/cm² for P(111) and 20, 24, 30, 35, and 50 J/cm² for P(100) wafers. The dot spacing of 150 μ m and row spacing of 250 μ m were fixed for all the different laser parameters. The pulse repetition rate varied between 0.9 and 8.5 kHz (which depends upon the desired energy density). The pulse duration time was 150 nsec, and the focused 1/e spot size of the pulses was about 65 μ m. The mechanical back-side damage process was carried out by a direct surface abrasion technique (DSAT). In this process, the wafer was rotated on a vacuum chuck, and an abrasive-coated paper (grit size 400), placed in line contact with the wafer, was moved radially, leaving a series of concentric damage sites. Simulated multiple high temperature thermal cycles used for P(111) warpage studies are shown in Fig. 2. Three multiple oxidation cycles at 1000°C for 3 hr with or without ramp-up and ramp-down schedules were used for P(100) warpage studies. For these experiments the wafers were stacked in the vertical position in a boat with 2.5 mm distance between wafers with at least five "dummy" wafers at both ends to ensure the same cooling kinetics for all the test wafers. Warpage during simulated thermal cycles was measured by an ADE 3046A gauge.

For measurements of laser damage depth, the wafers were cleaved and polished, initially with diamond grit and then with three different submicron alumina powders with appropriate felt pads. The polished surfaces were then Sirtl etched.

Results and Discussion

Laser damage depth measurements were made only on P(111) wafers. This method of characterizing the damage was suggested by Yang and Schwuttke (7) who used P(100) wafers and reported that the threshold energy density for Nd:YAG laser irradiation was about 6 J/cm².

Each laser spot gives rise to a bundle of dislocations, and the resulting pits were observed on Sirtl etching points where each dislocation (or similar defect) intersected the polished surface. The distance from the silicon surface to the center of the etch pit was measured for a number of etch pits. The depth of damage was then taken

Fig. 9. Warpage of laser back-side damaged and mechanically back-side damaged P(100) wafers during multiple oxidation cycles without ramping.

as the tail of the resulting histogram of the number of pits observed at a certain distance from the wafer surface vs. that distance. A typical histogram is shown in Fig. 3; this was obtained for 232 individual damage depth counts.

It can be seen that occasional etch pits appear well beyond the normal tail of the distribution plot. These have been ignored in calculating the depth of damage, although they may be important in practice. The laser damage depth obtained as the mean of the cluster of data points at the tail of the distribution is plotted in Fig. 4 for the series of samples investigated. The accuracy of measurement is about $\pm 10\%$ but error bars have been omitted for clarity.

The damage depth for a laser beam intensity of 20 J/cm² was found to be only 1-2 μ m so the threshold intensity for detectable damage is 19 ± 1 J/cm². This value depends on the surface roughness as well as on the orientation. The dependence of damage depth on laser intensity has been indicated by joining up the data points in Fig. 4; the real behavior may be on a curve or show a step, but more data points would be necessary to resolve this question.

Within experimental error the damage depth is the same for wafers taken from the seed end and from the middle of a crystal. However, the average damage depth in wafers cut from the tail end is consistently a little higher than from the other regions.

Warpage

Due to rather subtle differences of warpage variation and related phenomena between P(100) and P(111) type materials during simulated multiple high temperature thermal cycles, we believe they warrant a separate discussion in this section.

P(111) materials.—The warpage of various energy density laser damaged and mechanical back-side damaged P(111) wafers is shown in Fig. 5. These data clearly demonstrate that back-side damage generated by pulse laser irradiation of energy densities less than 45 J/cm² have shown no adverse effects on warpage during subsequent oxidation cycles, compared with that of mechanical back-side damaged wafers. Based on the depth of damage measurements, the warpage of wafers damaged at 20 J/cm² is expected to be similar to that of undamaged wafers.

During the course of this investigation it was observed that P(111) materials from the seed-ends of the ingot generally exhibit higher resistance to warpage, regardless of the back-side damage techniques applied (mechanical or laser). A typical example is shown in Fig. 6. Recently,

Fig. 10. Warpage ratio of 20 J/cm² laser back-side damaged P(100) wafers from seed-ends or middle section over those from tail-ends.

Eggermont *et al.* (8) have demonstrated that as-irradiated P(111) materials show a dramatically lower fracture strength than virgin wafers. It also has been reported by Schwuttke (9) that silicon materials from the seed-end are

stronger than those from the tail-end. As shown in Fig. 1, interstitial oxygen content differences between seed-end and tail-end materials are about 5 ppma, at the most. Also, oxygen diffusivity at room temperature is so low that it is

Fig. 11. Cross-section optical micrograph of (a, top left) nondamaged (b, top right) mechanically back-side damaged (c, bottom left) and (d, bottom right) laser back-side damaged ($E_d = 30$ and 50 J/cm^2) P(100) wafers after multiple oxidation cycles with ramp-up and ramp-down schedules. Stained by Wright etchant for 5 min. (magnification: 110X).

highly unlikely for oxygen impurities inside the bulk to interact with laser-irradiated defects. Therefore, we believe that this phenomenon cannot be explained by interstitial oxygen content differences alone.

The state of oxygen that gives the dislocation pinning effect is of technical importance. Hu and Patrick (10) established that precipitates are not the cause of pinning and proposed that clusters were. Other explanations (such as Cottrell atmospheres) fit the known data. Since, inside the Czochralski crystal pullers currently available, materials from seed-ends have been known to experience much faster cooling rates ($\sim 100^\circ\text{C/hr}$) than those from tail-ends, it can be expected that the state of oxygen from seed-ends might differ from that near tail-ends. The complexing of oxygen with carbon and other impurities could also vary from seed-end to tail-end. It should be pointed out that the difference in mechanical properties between material from the seed- and tail-end of a crystal could be associated with microcracks (or "microsplittings") as suggested by Schwuttke (9). He found more saw damage in wafers cut from the tail-end, and this residual damage is not completely removed from the back surface by the etching procedure. Recently, Eggermont *et al.* (8) have proposed that back surface laser damage depends strongly on the presence of microcracks and the seed- vs. tail-end microcrack concentration would explain the differences seen in Fig. 4 and 6.

It has been also reported that the presence of the oxygen precipitation induced by heat-treatment can increase the amount of nucleation sites for dislocations and decrease the upper yield point (11). The first half of the final thermal cycles used for P(111) material testing involved a Sb subcollector diffusion drive-in step (no predeposition) for about 3 hr at 1270°C under dry oxygen ambient. It has been well recognized that 1270°C is a sufficiently high temperature to dissolve grown-in micro-precipitates and process-induced oxide precipitates during the first oxidation cycle (1150°C) shown in Fig. 2. Therefore, we should not expect any significant contribution toward overall warpage variations due to the oxygen precipitation. Optical microscopic analysis of cleaved but unpolished laser back-damaged wafers by Sirtl etchant revealed that there were, in fact, very few precipitates inside the bulk of the finished wafers [Fig. 7 (a) and (b)]. These pictures also clearly demonstrate that damage generated by conventional mechanical means tends to propagate much deeper towards the front surface than that produced by laser irradiation of energy density less than 45 J/cm^2 during the high temperature thermal cycles used, and this leads to more pronounced warpage degradation.

P(100) materials.—Warpage data for P(100) materials based upon simulated multiple high temperature thermal cycles with or without ramp-up and ramp-down schedules are displayed in Fig. 8 and 9. The data clearly demonstrate that warpage variations of the wafers subjected to pulsed laser irradiation processes with energy density less than 35 J/cm^2 , regardless of the thermal cycles used, compare very favorably to those produced by the mechanical damage process. As in the case of (111) wafers, irradiation at 20 J/cm^2 appears to produce very little damage. Materials from seed-ends and middle sections were found to be more resistant to warpage than those from the tail-ends. This phenomenon is more pronounced under the thermal cycles without the ramping schedule. A typical example is shown in Fig. 10. Since interstitial oxygen concentration differences between seed-ends and tail-ends are less than 4 ppm, interstitial oxygen differences are not enough to explain this phenomenon, as in the case of P(111) wafers.

One interesting aspect of P(100) materials is that the laser irradiation process does not degrade warpage characteristics of materials from tail-ends significantly, whereas the opposite is true for P(111) materials. Why this rather subtle difference in warpage behavior between wa-

fers of the two different orientations occurs under high energy density pulsed laser irradiation is not obvious at the present time.

The finished wafers were cleaved and decorated by Wright etchant. Cross-section optical micrographs shown in Fig. 11 (a)-(d) reveal very limited numbers of noticeable precipitates. This is another clear indication of the rather insignificant role that oxygen precipitation plays in explaining the overall warpage variation phenomena observed during the course of this investigation.

Conclusions

Etching of polished sections to reveal the point of emergence of dislocation etch pits is a simple method of quantifying the initial back-side damage produced by laser irradiation. The damage threshold for P(111) silicon is $19 \pm 1\text{ J/cm}^2$.

From warpage variation studies of laser back-side damaged P(100) and P(111) material subjected to simulated bipolar and n-MOS high temperature thermal cycles, the following conclusions were reached:

1. Laser irradiation with energy density less than 45 J/cm^2 for P(111) materials and energy density up to 35 J/cm^2 for P(100) materials has shown no adverse effect on warpage variations during their respective simulated bipolar and n-MOS high temperature thermal cycles, compared with a conventional mechanical back-side damage process.
2. Materials from seed-ends are generally more resistant to warpage than those from tail-ends. This phenomenon cannot be explained by the total interstitial oxygen content alone. The state of the oxygen, which is a strong function of thermal history inside the Czochralski crystal puller, should be considered in addition to the total oxygen content.

Ion Bombarded-Enhanced Etching of Indium Phosphide

T. Inada,* S. Taka,¹ and K. Kodama

College of Engineering, Hosei University, Kajino-cho, Koganei, Tokyo 184, Japan

ABSTRACT

The effect of ion bombardment on the enhancement of the etch rate of InP has been investigated. The damage creation in InP due to ion bombardment has also been examined by Rutherford backscattering techniques. It has been shown that a highly enhanced etch rate of 800 Å/min in an HF solution is obtained from the ion bombardment-induced amorphous InP layer, which can be easily produced by room temperature ion bombardment with light mass ions such as Mg ions. The experimental results obtained have shown that the ion bombardment-enhanced etching can be used as a rapid precise tool for selective sectioning of InP.

Recently, there have been increasing requirements for the development of a precise tool for sectioning Si and compound semiconductors. Ion bombardment-enhanced (IBE) etching would be one of the most promising tools because this etching process can be characterized by ion species, incident ion energy, and ion dose used. In addition, this technique has a potential advantage of maskless selective etching of semiconductors if combined with a fine ion beam technology.

The possibility of the IBE etching for Si has been reported by Gianola (1) and then clearly demonstrated by Mazey *et al.* (2) and by Gibbons *et al.* (3). No report, however, has been published on the IBE etching of III-V compound semiconductors. This paper will present the results on the IBE etching of InP. We have investigated the introduction of lattice damage into InP, bombarded with Mg ions, using Rutherford backscattering techniques. Etch rates of InP bombarded under various conditions have been measured. Results clearly indicated the etch rate in an HF solution is highly enhanced for ion-bombarded amorphous InP layers.

Experimental

The substrates used in the present work were (100)-oriented, Fe-doped semi-insulating commercially available InP wafers. The substrates were degreased in several organic solvents, dipped in an HF solution, rinsed in deionized water, and then dried in an N₂ flow. The substrates were bombarded with Mg ions at room temperature and at incident energies in a range from 40 to 200 keV. During ion bombardment, the substrate was tilted by 7° from the incident ion beam to reduce channeling effects. The incident ions were scanned along the X- and Y-directions to introduce uniformly distributed damage in the InP substrate. A part of every sample was masked from the incident ion beam with a metal plate to get an unbombarded area on the sample. For some of the substrates, a mask of SiO₂ with various configurations was formed on the substrate prior to ion bombardment by a chemical vapor deposition technique combined with a conventional photoresist technique. Note that no damage was introduced in the InP surface layer during the SiO₂ deposition process within the detection limits of the Rutherford backscattering system used. The thickness of the SiO₂ mask was chosen so that almost all of the incident ions stop within the mask film. After ion bombardment, the mask patterns were printed in the InP substrate surface layer in a form of damage. If the etch rate of the ion-bombarded area is enhanced as compared with that of the unbombarded area, the printed mask patterns will be developed after etching. Such surface structures as developed by selective IBE etching were examined with a scanning electron microscope (SEM).

The damage incorporated into InP substrates due to ion bombardment was examined by Rutherford backscattering techniques using a collimated beam of 1.5 MeV He

ions from the Van de Graaff accelerator of Hosei University. The scattering angle used in the Rutherford backscattering measurement was 150°. Chemical etching of ion-bombarded InP was carried out by dipping the substrates into solutions with different HF contents. The etching time ranged from 40 to 10,000s. The variation of the thickness of the damaged surface layer with etch time was examined by successive Rutherford backscattering measurements followed by the chemical etching process. The height of a step, which appeared after etching between the ion-bombarded and unbombarded areas on the sample, was also measured using either an interferometer or a step-meter.

Results and Discussion

Figure 1 shows the Rutherford backscattering spectra obtained from an InP sample before and after ion bombardment with 200 keV Mg ions to a dose of $5 \times 10^{14}/\text{cm}^2$

Fig. 1. Rutherford backscattering spectra obtained from an InP sample, bombarded with Mg ions to a total dose of $7 \times 10^{14}/\text{cm}^2$ ($200 \text{ keV } 5 \times 10^{14} + 40 \text{ keV } 2 \times 10^{14}/\text{cm}^2$), before (curve a) and after successive etching in an HF (50%) solution at room temperature (curve b-h). The curve (virgin) was obtained from an unbombarded area of the InP sample.

Key words: InP, ion-assisted etching, ion bombardment damage.

at room temperature. The sample was additionally bombarded with 40 keV to a dose of $2 \times 10^{14}/\text{cm}^2$ to achieve a uniformly distributed damage profile. The curves (virgin) and (a) in Fig. 1 show the channeling spectra from an InP sample before and after ion bombardment, respectively. The channeling yields reached the random levels after ion bombardment, indicating that the surface layer was transformed to an amorphous state. The thickness of the amorphous layer formed was estimated to be about $0.38 \mu\text{m}$ as calculated from the channeling data shown with the curve (a). After ion bombardment, the sample was successively dipped in an HF (50%) solution at room temperature. The curves (b)-(h) were obtained from the sample after each etch step. These channeling data clearly show that the thickness of the amorphous layer remaining after etching was decreased with increasing etch time. After etching for 320s, the entire amorphous layer was removed from the substrate, as indicated with the curve (f) in Fig. 1. The channeling yields of this sample were found to be still higher than those from the un-bombarded area, indicating that there was a transition layer which contained a high concentration of damage between the ion-bombarded amorphous layer and the underlying single-crystal substrate. It was also found that the thickness of the transition layer was decreased with increasing etch time as shown with the curves (f)-(h) in Fig. 1. These results showed that the etching still proceeded in the transition layer.

The thickness of the InP layer removed at each etching step is potted in Fig. 2 as a function of etch time, which is calculated from the channeling data shown in Fig. 1. In Fig. 2, the etched depths are also given, which were measured using either an interferometer or a step-meter. The etched depth was defined as a height of a step which appeared after etching between the ion-bombarded and un-bombarded areas on the sample, as illustrated with the insertion in Fig. 2. Note that there was a good coincidence between the data of the etched depth obtained by the channeling and step measurements within the experi-

mental errors, indicating that the etching proceeded only in the damaged region and not in the unbombarded area of the InP sample. This is based upon the idea that if the unbombarded area was stripped in the etchant used, the thickness of the removed InP layer in the bombarded area obtained by the step measurement should be thinner than that by the channeling measurement. From these results it was concluded that the etch rate of InP in the HF solution was enhanced by the introduction of damage in the substrate by ion bombardment.

As shown in Fig. 2, the etched depths were monotonically increased with increasing etch time in a range from 40 to 320s. The enhanced etch rate, defined as the inclination of the depth vs. etch time curve, was estimated to be about $800 \text{ \AA}/\text{min}$ in the ion-bombarded amorphous layer. It was also found that the etch rate was still enhanced in the highly damaged (not amorphous) InP layer but it was much reduced as compared with that of the amorphous layer.

The IBE etch rate was found to depend on both the concentration of HF in the etchant and its temperature. Figure 3 shows an etched depth vs. etch time curve, where etching was carried out on an ion-bombarded amorphous InP sample using a low HF content (25%) etchant. In addition, the etchant was cooled at 0°C during etching procedure. In this case, a reduced IBE etch rate of $45 \text{ \AA}/\text{min}$ was measured. This rate is a factor of 17 slower than that for the etching in the high HF content solution at room temperature. These results showed that the IBE etching is a thermally activated process. Figure 4 shows the dependence of the thickness of InP, removed after etching in the high HF content (50%) solution, on bombardment energy. The etching was done at room temperature for a given time, 1500s. The solid line in this figure shows the energy dependence of the sum of $(Rp + \Delta Rp)$ for Mg ions in InP, calculated from the LSS range-energy theory (4), where the Rp and ΔRp are the projected peak range and standard deviation, respectively. As can be seen in Fig. 4, there is a clear relationship between the

Fig. 2. The thickness of InP layers removed after etching in an HF solution as a function of etch time, calculated from the Rutherford backscattering data shown in Fig. 1. The data shown with open circles and squares reveal the height of steps, appeared after etching, as determined by a step-meter and an interferometer, respectively.

Fig. 3. The thickness of InP layers removed after etching in low HF content (25%) solution held at about 0°C as a function of etch time, calculated from Rutherford backscattering spectra. The data shown with open circles and squares reveal the height of steps, appeared after etching, as determined by a step-meter and an interferometer, respectively.

Fig. 4. Relationship between ion energy and the thickness of InP layers that can be removed after Mg ion bombardment at room temperature and dipping them in an HF (50%) solution for 1500s.

thickness of InP that can be removed by the IBE etching and the incident ion energy. This result shows that the depth of the region to be etched off from an InP substrate can be determined by incident ion energy rather than etch time, which is the striking feature of the IBE etching.

About $2 \mu\text{m}$ width SiO_2 strips were formed on InP substrates and used as a mask against the incident ion beam for achieving selective ion bombardment. These samples were bombarded at room temperature with 200 keV Mg ions to a dose of $5 \times 10^{14}/\text{cm}^2$ and then additionally with 40 keV Mg ions to a dose of $2 \times 10^{14}/\text{cm}^2$. After ion bombardment, these samples were submerged in the high HF content (50%) solution. As a result, steps were developed on the surface of the sample. Figure 5 is a SEM photograph showing a typical side view of the step developed by the IBE etching. The side of the step was found to be very sharp as shown in Fig. 5. We believe that this is due to the fact that the boundary between the ion-induced

Fig. 5. SEM photograph showing the surface structure of InP, formed by selective ion bombardment-enhanced etching.

amorphous region and the unbombarded single-crystal region is clearly defined not only at the surface but also inside of the substrate, and the IBE etching stops at the boundary. These results indicate that the IBE etching is useful as a precise sectioning technique for submicron InP devices.

Summary

In summary, it has been demonstrated that the etch rate of InP in an HF solution is enhanced by the introduction of damage in the substrate by ion bombardment. The results obtained clearly show that the IBE etching of InP is controlled by physical parameters such as ion energy and dose. The highest rate of 800 Å/min is obtained in ion-induced amorphous InP layers. This etch rate is sufficiently high enough for the practical use of sectioning fine structures of InP devices. Such fundamental characteristics of the IBE etching as revealed in InP might be applied to other III-V compound semiconductors. Similar experiments on GaAs are now in progress and the results will be reported in the near future.

ABSTRACT

Radiation damage to 35 nm gate insulators of n-channel silicon IGFET's was investigated using direct exposure by x-rays from aluminum and copper targets in the dose range 10^4 - 10^8 rads (SiO_2). In addition, direct electron-beam damage at 3×10^6 rads (SiO_2) and 3×10^7 rads (SiO_2) was studied using an electron-beam direct write exposure system at 10 keV accelerating voltage, and incident electron doses of 20 and 200 $\mu\text{C}/\text{cm}^2$. The extent of damage was estimated using hot electron trapping in conjunction with device threshold determination via source-drain current-voltage measurements. It was found that the extent of x-ray induced damage is essentially the same for Al K α and Cu K α irradiation, and that the damage levels were the same when different dose rates at a constant total dose was employed. Positive charge levels were observed to begin leveling off above 10^6 rads, while neutral trap levels continued to increase monotonically. These levels at 10^8 rads are of the order of 2.3V positive charge threshold equivalent, and 4.2V of neutral traps using Al K α irradiation. Electron damage appears to be considerably higher at equivalent dosages. Apparent negative charge generation by x-rays is low, even at 10^7 rads, and appears to become significant (ca. 0.4V) at 10^8 rads. Apparent negative charge generation by electrons is noticeably greater, ca. 0.3V at 3×10^6 rads and 1.1V at 3×10^7 rads. The above, together with the results of an earlier report, indicate that it is important to keep ionizing radiation insulator dosage levels at 10^6 rads or less in processing steps. This can be best accomplished by using the lowest energy radiation possible to increase energy absorption in the films overlaying the gate insulator.

A variety of fabrication and analytical processes of potential, use in semiconductor chip manufacturing, subject the devices to low energy ionizing radiation in the range ≤ 25 keV. These processes include x-ray or E-beam lithography, E-beam metallization, plasma-assisted etching and deposition, plasma-assisted oxidation, and scanning electron microscope voltage contrast testing, to name several. The primary impinging radiation can, in turn, generate secondary ionizing radiation. Because of its lower energy, the absorption of this secondary radiation may be greater per unit of film thickness than that of the primary radiation.

This will, in fact, be the case if either the type of the secondary emission is of the same kind as that of the primary impinging radiation, e.g., primary x-rays give rise to secondary x-rays, or if photon primary radiation gives rise to electron secondary radiation. If electron primary radiation gives rise to secondary x-radiation of similar energy, this secondary radiation may penetrate more deeply than would the primary radiation (1). As a result of ionizing radiation exposure, it is also known that the gate insulator of an insulated gate field effect transistor, IGFET, may exhibit damage in the form of fixed positive charge and interface states immediately following irradiation (2, 3). In addition, so-called neutral traps are simultaneously generated during exposure to such radiation (4, 5). In the as-fabricated device, such neutral traps are not electrically active. The fixed positive charge and interface states can alter the time zero threshold and transconductance, respectively, of the IGFET, while as a function of time, all three of these defect types can be either annihilated or trap charge, thereby affecting the longer term device threshold stability. If electrons are captured, the instability is evidenced by an upward drift of the threshold voltage. These defects can, in large measure, be removed in all stages of device fabrication up to the device metallization step by elevated temperature annealing. If they are introduced during the metallization process via the use of E-beam metal deposition, x-ray or E-beam lithography, or plasma-based etching techniques, they cannot be removed completely using conventional annealing procedures. This is because metallized shallow junctions (0.5 μm or less) cannot be subjected to temperatures much in

excess of 400°C for time intervals much in excess of 30 min without incurring the possibility of metal penetration through the junctions. At atmospheric pressure, it has been found that in ambient atmospheres containing hydrogen, temperatures in excess of 550°C are required to remove neutral traps and fixed positive charge, while interface states can be removed at somewhat lower temperatures (5, 6). In nitrogen, it has been reported that fixed positive charge and neutral traps require temperatures in excess of 700°C, while the interface states can be eliminated at 450°C (7). It is argued in Ref. (7) that when the gate insulator is cyclically damaged and reannealed, it becomes more difficult to remove the damage with each successive damage cycle. This result is, however, debatable, since it has been shown that inert gas is not effective in removing fixed positive charge and neutral traps (8). When such removal is observed to a degree, it appears to be due to the presence of water vapor present as a contaminant in the inert gas.

In two recent studies (8, 9), it has been reported that essentially all of the generated fixed positive charge, almost all of the excess neutral traps, and all of the interface states and apparent negative charge can be removed by annealing at 50 atm and 400°C in a 10% H_2 -90% Ar ambient atmosphere. For these elevated pressure annealing studies, damage was introduced via a simulated E-beam metallization process using 10 keV electrons to evaporate aluminum from a hearth. First, the IGFET wafers were fabricated via a conventional polygate process using nonionizing radiative processing. The completed metallized patterned wafers were then coated with photoresist, and E-beam-evaporated aluminum was deposited on the photoresist as described in Ref. (8, 9). During this blanket metal deposition, the surface of the photoresist-covered wafer was bombarded by reflected primary electrons, secondary electrons from the aluminum melt, aluminum K α , and white radiation, as well as additional secondary electrons and x-rays when the hearth radiation impacted the device wafer surface. At the conclusion of the process, the photoresist and deposited aluminum were stripped off, and the devices were analyzed. Using 10 keV primary radiation, it is obvious that the energy range of the bombarding radiation, E , lies in the interval $0 < E \leq 10$ keV. The dosage range examined was approximately 10^4 - 10^7 rads (SiO_2). As a reference point, for the metallization sys-

*Electrochemical Society Active Member.

Key words: x-rays, electrons, MOSFET's, gate insulators.

tem employed, a 10 min evaporation at 0.5A beam current, during which 50 nm of aluminum was deposited, resulted in a composite x-ray/electron dose of about 5×10^6 rads (SiO_2).

It was found that the damage process resulted in the generation of fixed positive charge and neutral traps, as expected. What was unexpected were the observations that the fixed positive charge level saturated with increasing dose, and that "apparent" negative charge was generated. This apparent negative charge could be due to interface state generation as defined by the Deal Committee (3), or to an analog of fixed positive charge. The latter is believed to be the more likely explanation, since very little transconductance degradation was detected from I-V measurements. Recently, such fixed negative charge was observed as a result of hot carrier injection in encapsulated IGFET's (10). It is proposed in Ref. (10) that such fixed negative charge is due to the formation of SiO^- bonds.

Ning (11) had examined IGFET damage following E-beam metallization at 6.8 keV and 210 mA for 100s in a nonscanned hearth which deposited 1.2 μm of Al. Ning did note differences between ΔV_T (threshold shifts) and ΔV_{FB} (flatband shifts) which he attributed to interface states. He did not, however, verify this speculation, and this effect may be similar to the one we have attributed to fixed negative charge. Further, as he used only a single aluminum thickness, he could not have observed the fixed positive charge saturation effect we reported on.

The present study was stimulated by a desire to understand better (i) the radiation(s) responsible for the negative charge, (ii) whether the fixed positive charge saturation phenomenon can be generated using a single type of radiation, (iii) what the effects are of varying photon energy at fixed total dose, (iv) what the effects are of varying photon flux for a fixed total dose, (v) what the effects are of a large variation in electron dose with electron energies in the 10 keV range, and (vi) the similarities and differences between photon and electron damage.

Experimental Procedure

Devices.—The devices examined in the present study were 350 nm thick polysilicon electroded IGFET's fabricated as described in Ref. (8). They employed a lift-off Ti contact metallurgy, Al-3% Si interconnection metallurgy, 35 nm gate insulators, and 0.5 μm phosphorous junctions. The threshold of these devices, fabricated in 0.5 Ωcm Si, was $1.2 \pm 0.1\text{V}$ using -1V substrate bias. The specific devices employed in the present study were 20:1 width/length ratio devices with 50m channel lengths and gate insulator areas of $5.0 \times 10^{-4} \text{cm}^2$. This gate area is suitable for precise measurement of injected electron trapping by positively charged and neutral traps. As in the early study (8), only traps with cross sections $\geq 10^{-15} \text{cm}^2$ were examined since these are of greatest interest. The devices were examined using the hot electron injection technique of Ning (11) as used in Ref. (8).

X-ray damage.—Because of the nature of the process, in the simulated E-beam metal evaporation process employed in Ref. (8), the IGFET's were exposed to all x-ray wavelengths up to 10 keV. Because normal x-ray sources employ beryllium windows, they do not provide much energy less than 1 keV. Consequently, using an aluminum target x-ray source, as we did in the present study, is not a complete representation of the aluminum radiation experienced by a device wafer in an E-beam metallization process. What we could do, however, was to compare radiation of different energies to see if, at constant total dose, qualitative or quantitative differences in damage could be detected. This would give some indication of wavelength effects pending studies in the ≤ 1 keV range via other means. Such a comparison was run between aluminum $K\alpha$ radiation (1.49 keV) and copper $K\alpha$ radiation (8.03 keV). In addition, these two energies span the white radiation range encountered in the E-beam metallization process in question. While the present approach to exposure

with aluminum radiation does not fully duplicate conditions in an E-beam metallization system, it does approximate exposure conditions from a synchrotron ring source. The latter offers potential in x-ray lithography applications, and the energy range employed would be in the 1-2 keV vicinity. For a given target, the photon output above and below the characteristic wavelength range is small. For example, measurements of the high output aluminum target x-ray source available to us showed an aluminum $K\alpha$ photon output/total photon output at 15 kV of 0.8. Because of this, dosages were calculated based only on the $K\alpha$ output. For example, if it is assumed that the average wavelength of the white radiation centered near the $K\alpha$ value, the maximum energy error would be 20%. If it centered at higher wavelengths, the error would be much less since the absorption of this higher wavelength in a given film thickness would be roughly proportional to the cube of the energy ratios. Comparing the $K\alpha$ with an average energy of white radiation of 5 keV, for example, leads to the conclusion that the absorption in a unit of film thickness is given approximately by the ratio $(1.5/5)^3 = 0.03$. Thus, only $0.03 \times 0.20 = 0.006$ of the white radiation photons are absorbed in the same film thickness as is the characteristic radiation, a negligible amount. The calibrated aluminum $K\alpha$ x-ray source was operated at 15 keV for all exposures. The target was 40 cm from the sample providing uniform radiation over a 1 in. diam. Five of six pie wedge-shaped sections on each of two device wafers were irradiated using a 1.02 mm thick stainless steel template as a mask. The sixth wedge was used as a control. During irradiation, calculated Si rad dosages absorbed in the insulator, target beam current, and exposure times, respectively, were: 10^4 rads 10 mA 36s; 10^5 rads 100 mA 36s; 10^6 rads 200 mA 3 min; 10^7 rads 200 mA 30 min; and 10^8 rads 200 mA 300 min. The wafers were unbiased, as would be the case during device processing. The same experiment was repeated on a wafer overcoated with 0.4 μm photoresist and on another wafer overcoated with 0.4 μm of photoresist and 30 nm of aluminum to examine the effects of these coatings, since such layers could be present in a metal lift-off process and were present in the studies described in Ref. (8, 9). On an additional device wafer, the effect of dose rate at constant total dose was examined since the above-described exposures were made at different dose rates for practical reasons. In addition to a control wedge, one wedge was irradiated at 3.3 krad/min and another at 330 krad/min, both to a total insulator dose of 1.5×10^6 rads (SiO_2).

Copper radiation exposures were conducted somewhat differently than those with aluminum to assess the effects of photon energy, and to see if differences in target spectral content at different excitation voltages would affect defect generation levels. The yield of characteristic radiation is known to increase markedly with excitation voltage. For example, the output from a copper target increases in the ratio 1:2:10 (12) when the excitation voltage is increased from 15 to 20 to 40 kV, based on extrapolation of the data in Ref. (12) for a 15 kV target operating at 200 mA and a target to sample distance of 40 cm. The copper $K\alpha$ 20 kV irradiations, all at 50 mA, and a sample to source distance of 36 cm were conducted at: 10^4 rads 118s; 10^5 rads 19 min 46s; 10^6 rads 3h 17 min; and 2×10^7 rads 64h 48 min. The 40 kV exposures all at 100 mA were at: 10^4 rads 12s; 10^5 rads 119s; 10^6 rads 19 min 46s; 10^7 rads 3h 17 min; 7.2×10^7 rads 24h. The copper source, of course, had a similar low energy cutoff problem as did the aluminum source, because of the presence of a beryllium window.

Al $K\alpha$ x-ray dosages were calculated assuming mass absorption coefficients for SiO_2 and Si of 1.268×10^3 and $0.5428 \times 10^3 \text{cm}^2/\text{g}$, respectively. Copper $K\alpha$ x-ray dosages were calculated assuming mass absorption coefficients for SiO_2 and Si of 28 and 48 cm^2/g , respectively. The absorption in the SiO_2 was calculated at an incident flux of 2.8 $\text{mJ}/\text{cm}^2/\text{min}$. For 10 and 100 mA, rates were assumed to vary linearly. Thus, at 200 mA and 15 kV, the SiO_2 rad

rate was $0.33 \times 10^6/\text{min}$; at 100 mA and 15 kV, it was $0.165 \times 10^6/\text{min}$, etc. For copper, the data were calculated at 200 mA target current, then recomputed for 50 mA at 20 kV and 100 mA at 40 kV using the data in Ref. (12).

Electron damage.—Electron irradiation was conducted in an electron-beam lithography system. Chen *et al.* (13) had reported on E-beam lithography damage to 38 nm gate insulators in submicron IGFET's. They did not specify their device layer thicknesses, nor beam accelerating voltages, and they did not quantify defect concentrations using electron injection methods, but simply measured threshold shifts at rad doses up to 10^4 . This made it impossible for us to compare our results with theirs. For the present study, the E-beam system was operated at 10 keV to simulate the process being examined. The damage introduced at 20 and 200 $\mu\text{C}/\text{cm}^2$ incident fluxes was examined. The maximum penetration depth for these electrons was calculated using the Terrill equation (14). This equation, Eq. [1], is reported to be applicable to electrons with accelerating potentials in the range 10^3 – 10^5V . For the calculations

$$X_e = \frac{2.5 \times 10^{-12} V^2}{\sigma} \quad [1]$$

where V is in volts, σ is the density in g/cm^3 , and X_e is in cm. σ was assumed to be $2.32 \text{ g}/\text{cm}^3$ which approximates the values for SiO_2 ($2.32 \text{ g}/\text{cm}^3$) and Si ($2.33 \text{ g}/\text{cm}^3$). The dosage in the gate insulator was then calculated assuming (i) the penetration depth was 1.08 μm , (ii) the absorption is essentially linear, and (iii) none of the incident electrons is reflected. Based on these assumptions and the incident electron flux of 20 and 200 $\mu\text{C}/\text{cm}^2$, the dosages were calculated to be approximately 3×10^6 rads (SiO_2) and 3×10^7 rads (SiO_2), respectively. For the electron-beam studies, 15–18 devices were measured for each experimental condition.

Experimental Results and Discussion

Aluminum and copper $K\alpha$ irradiation.—Table I shows for an uncoated wafer and 15 kV target voltage, the threshold voltages, V_T , of devices before and after irradiation following injection of $2.5 \times 10^{13} \text{ e}/\text{cm}^2$ to annihilate positive charge and $1.25 \times 10^{16} \text{ e}/\text{cm}^2$ to label neutral traps. Positive charge, neutral trap, and apparent negative charge concentrations in terms of volts of threshold shift are also given in Table I. The thresholds were all measured at a substrate bias of -1.0V and a source drain voltage of 0.1V . An average of five devices were injected and measured on each pie wedge.

It is seen from Table I that the control wedge was unaffected by the irradiation sequence and the device thresholds varied by less than 0.05V for the 30 or so unirradiated devices measured on the different wedges. On all wedges, the same devices were measured before and after irradiation. The effects at $\leq 10^5$ rads are small with no negative charge detected, positive charge showing about a 0.2V shift, and generated neutral trap content at only 0.06V or thereabouts. At 10^6 rad dosages, the positive charge generation rate appears to begin slowing down while the neutral trap concentration rises dramatically. For the first time, a small quantity of negative charge appears to have been generated at the 10^7 rad dosage level. At 10^8 rads, which is a greater dosage than used in Ref. (8), the positive charge generation rate is slowing down further while the neutral trap generation rate continues to increase.

Negative charge increases significantly but is still at a lower value than observed in Ref. (8) at lower doses.

From the above, we may conclude that the negative charge observed in Ref. (8) is not due to the Al $K\alpha$ radiation, at least not when it is the sole type of ionizing radiation. Further, while the positive charge level does not saturate, its rate of generation on a percentage basis decreases markedly with increasing dose. The most important conclusions that can be drawn from Table I relate to the neutral trap picture, because these traps are the most difficult to remove. It is seen that their concentration does not become significant until a dose of 10^6 rads is absorbed. In Ref. (8) it was pointed out that unlike positive charge, neutral trap removal is related directly to its concentration before annealing; the larger the concentration, the more that will remain following annealing. Thus, it would argue for tailoring process steps, when possible, to keep the absorbed dose in the gate insulator to $\leq 10^6$ rads (SiO_2).

In an E-beam metallization process, for example, it would indicate that the hearth (the target in effect) should be kept as small as possible and that the molten scanned region should be as small as possible to keep the energy as localized as possible to obtain the maximum amount of evaporation in the shortest time. As we shall see below in discussions of negative charge generation due to electron damage, this would argue for using magnetic or electrostatic removal of reflected or secondary electrons from the hearth before they can impinge on the sample. In x-ray lithography, it would argue for employing the longest wavelengths possible to minimize penetration depth. This would require working in the energy range 0.5–1 keV, rather than using radiation in the 1–2 keV range since the absorption would be greater by approximately the cube of the ratios, e.g., $0.5^3/1.0^3 X$, where X is the absorption depth of a 1 keV photon. This is about 12.5% of X . Further, as the incident energy is confined to a thinner layer, it is very likely that much smaller incident doses would be required for exposure.

This raises another question as to whether traps are created during irradiation or merely made visible. It could be argued, for example, that the 2.30V equivalent of positive charge seen at a dosage of 10^8 rads in Table I was present in the insulator, prior to irradiation, and that the traps were electrically inactive because they had been annihilated by electrons, that all irradiation did was to empty these traps of their electrons. It would, however, be difficult to advance such an argument in the case of neutral traps for the following reason. The neutral traps are not visible electrically before or after irradiation. If the quantities seen after irradiation were already present before irradiation, they would have been detected in the neutral trap measurements of the control samples prior to irradiation. However, they are not seen and, therefore, they could not have been present initially. It is not unlikely that positive and negative charge defects are also created, and not simply made visible during the irradiation process.

Tables II and III represent the results obtained when device wafers were employed to simulate an E-beam metallization process using only the aluminum $K\alpha$ photon output of a hearth in such a process. Thus, in Table II, the data were obtained when the wafer was coated first with 0.4 μm of a positive photoresist; in Table III the data are those obtained when the wafer was coated with a bottom

layer of 0.4 μ m of photoresist, and a top layer of 30 nm of aluminum was then deposited by resistance heating. To a first approximation, the results are, within experimental limits, identical to those shown in Table I. This indicates that no cooperative phenomena occur that affect the damage behavior induced by the low energy aluminum K α radiation due to the presence of these films. No absorption corrections were made in arriving at the total dose experienced by the gate insulator due to absorption in these top coatings.

Table IV shows the results obtained when the device gate insulators absorbed the same aluminum K α dose, 1.5×10^6 rads (SiO₂) at two different rates: 3.3 krad/min and 330 krad/min. It is seen that the results are the same for the two cases and consistent with the results shown in Tables II and III. This demonstrates that the insulator damage is reasonably independent of the dose rate and a function only of the total dose. It also indicates that the damage arises as a function of microscopic interaction of the ionizing radiation, e.g., bond-radiation interaction as opposed to a macroscopic effect, e.g., macroscopic heating. These data, obtained at doses of 1.5×10^6 rads, together with the data of Table I show the rapid increase in damage when the dosage reaches the 10^6 rad range. It indicates again, the necessity of keeping the insulator dosage below this value in processing. From a practical point of view, e.g., in a lithographic exposure using x-rays, or in an E-beam metal evaporation, it indicates that there is no advantage in reducing the dose rate of ionizing radiation in order to minimize damage; that as long as the total insulator dose is the same, the damage will be the same.

Tables V and VI show the effects of Cu K α radiation at constant total dose based on K α content, when the spec-

tral output from the target was varied significantly by employing 20 and 40 kV target beam accelerating voltages. Within experimental limits, the results are the same, indicating that basing the energy content calculation on K α output is a reasonable one. As with the Al K α exposures, the primary damage introduced appears to be in the form of positive charge and neutral traps. Thus, at the 10^6 - 10^7 rad levels, while volts of positive charge and neutral traps are detected, only tenths of volts of negative charge is in evidence.

The data in Tables I-VI are depicted graphically in Fig. 1 and 2. Figure 1 shows the positive charge situation, while Fig. 2 depicts the neutral trap behavior for Al and Cu x-ray damage. The graphs need no further discussion.

Electron beam irradiation.—Table VII shows the damage levels obtained at 3×10^6 rads (SiO₂) and 3×10^7 rads SiO₂ using 20 μ C/cm² and 200 μ C/cm² incident electron doses, respectively, at 10 keV accelerating voltage. Positive charge levels appear to be somewhat higher than obtained using x-rays as can be seen in Fig. 1, e.g., 1.8V vs. 1.3V at the 20 μ C level, and 2.9V vs. <2V at the 200 μ C level. By comparing the results of the present work to those obtained in Ref. (8), it can be seen that the positive charge level due to x-rays alone is lower than the combined x-ray and electron damage obtained in the earlier study in the 10^6 - 10^7 total rad dosage range, while the positive charge level due to electrons alone in the same dosage range is greater. This appears to be reasonable.

Neutral trap differences are even more pronounced than positive charge effects. At 3×10^6 rads electron dose, about 3.5V of threshold equivalent are generated, while x-rays at the same dose generate only 1V of equivalent

threshold voltage. With the 3 \times 10 7 rad electron dosage, > 5V are generated. The limit of our measuring capability for V $_T$ is 5V. The comparable x-ray figure is 4V. Apparent negative charge generation for the electrons at 3 \times 10 6 rads is some three times greater than that generated by x-rays at the 10 7 level. Similarly, at the 3 \times 10 7 electron dose level, approximately three times as much negative charge is generated than that at the 10 8 level for x-rays.

Conclusions

Based on the results of studies of gate insulator damage in IGFET's due to x-rays alone, or electrons alone, it appears that apparent negative charge observed in earlier work (8) is due almost entirely to electrons, with x-rays

yielding low levels of such damage until the 10 8 rad (SiO $_2$) range is reached. It was found also that when using different x-ray dose rates, the extent of damage at constant total dosage is essentially the same. It also appears that the damage level with x-rays is relatively insensitive to the x-ray energy employed using aluminum and copper radiation, again the total dose being the determining factor. The positive charge saturation effect observed in the earlier work appeared to occur using x-rays alone, at about the same total dosage level as in the earlier study. However, even at the 10 8 dosage level, there is still some increase in positive charge level observed. A possible explanation is that positive charge saturation is coupled in some way to the simultaneous generation of apparent negative charge, such charge requiring electron irradiation for generation at lower dosage levels.

While x-rays and electrons appear qualitatively to generate the same type of damage, electrons are much more effective, *i.e.*, at given dosages, the concentrations of the generated defects are considerably greater with electrons than with x-rays. The effect is most obvious with negative charge formation.

With x-ray exposure, the damage to the gate insulator, in the form of both positive charge and neutral traps is relatively minor at the 10 4 rad (SiO $_2$) level, but becomes significant in the 10 5 -10 6 range. In fact, the rate of damage increase of neutral traps is considerably greater above 10 6 rads than below it. An opposite effect is observed in positive charge formation. However, as the rate of positive charge generation is greater below 10 5 rads and smaller above this value, positive charge and neutral traps achieve similar damage levels around the 10 6 rad value.

Since high levels of neutral traps are difficult to remove, it appears that processes involving ionizing radiation should be adjusted to keep dosage levels below 10 6 rads (SiO $_2$). In a lithographic process, for example, this can be done by using lower x-ray or electron energies for photoresist exposure. If this is done, then two effects will lead to lower damage levels being introduced into gate insulators of IGFET's. First, since absorption will be greater in the photoresist, penetration to underlying films will be less. Second, since absorption in the desired layer is more efficient, lower incident doses will be required to achieve the desired dose in the photoresist.

Acknowledgments

The authors are indebted to T. H. Ning and J. Aitken of IBM for their many stimulating discussions, to R. F. Boehme for conducting the copper irradiations, and to T. P. Donohue for conducting the electron-beam exposures. They also wish to thank C. K. Williams of North Carolina State University for computer plotting the data.

ABSTRACT

Phosphorus and boron implantation studies of laterally seeded silicon on silicon dioxide recrystallized by a scanning graphite strip heater are presented. Hall profiling has been used to obtain carrier concentration and mobility as a function of depth. The recrystallized silicon layer contains subgrain boundaries which slightly reduce dopant activation and carrier mobilities compared with bulk silicon values.

Composite structures consisting of laterally seeded recrystallized polysilicon films on insulating layers such as silicon dioxide grown on bulk silicon substrates have a tremendous potential in device applications. Such structures may, in principle, be used to make three-dimensional integrated circuits, dielectrically isolated high speed devices, solar cells, and other thin film devices. These films have certain advantages over silicon-on-sapphire (SOS) or conventional dielectrically isolated silicon. This technology is potentially less expensive than traditional dielectric isolation methods. Compared with SOS or silicon-on-quartz, these silicon-on-insulator (SOI) films are under less mechanical stress, which commonly results in a high density of stacking faults and in drastically altered carrier mobilities. Various directed energy sources such as scanned laser and electron beams have been employed to recrystallize the silicon films on insulating substrates (1). A particularly simple alternative is the use of a thin heated graphite strip swept mechanically across the surface (2).

Ion implantation is an extremely important method of selectively doping these films, as required in forming the source and drain regions in MOS transistors, for example. Although some structural and electrical properties of SOI layers have been reported (3), there have been few studies of ion implantation into such regrown films. The electrical activation and carrier mobilities for phosphorus and boron implants into silicon films regrown by a scanning graphite strip system are reported here as a function of dopant concentration and isochronal furnace anneal temperature. It is found that electrical activation and carrier

mobilities are comparable to those in bulk silicon and are much superior to those in the unrecrystallized films. Transmission electron microscopy (TEM) and selected area electron diffraction studies have been performed on the as-implanted and furnace annealed films. Residual implantation damage is observed, including dislocation loops and defect clusters. Segregation of implanted atoms along the subgrain boundaries is also observed.

Experimental Procedure

A recessed oxide 9100Å thick was grown on (100) Czochralski silicon wafers, with windows in the oxide exposing the underlying single crystal silicon. This step employed a modified LOCOS technique, which avoids "bird-beaking." An essentially planar surface of oxide and exposed crystalline silicon resulted, which was then covered by a 5000Å layer of polycrystalline silicon in a low pressure chemical vapor deposition (CVD) system (4).

The recrystallization technique is essentially the same as that described by Fan *et al.* (2). The samples were covered by a composite encapsulation layer to improve the stability of the liquid zone during zone melting and recrystallization. The cap consisted of a 500Å thermal oxide layer, covered by a 2 μm atmospheric pressure CVD silicon dioxide layer, and a final covering by 500Å of RF plasma-deposited silicon nitride. The thermally grown oxide appears to provide a smooth interface between the cap and the polysilicon and thereby improves the smoothness of the regrown film. The samples were placed on a stationary graphite strip which was resistively heated in a flowing argon ambient to approximately 1300°C in about 30s. A narrow graphite strip about 1 mm wide, placed 0.5 mm above the sample, was then heated

*Electrochemical Society Active Member.

up to produce a narrow molten region in the polycrystalline film over one of the "window" regions. The upper strip was then scanned over the sample surface at 1 mm/s using a motor driven system. In this procedure, the polysilicon over the window region is recrystallized first, with the underlying single crystal silicon substrate acting as a seed. This recrystallized region then assists in the lateral seeding of the silicon film as the melt zone is propagated over the silicon dioxide layer.

After completion of the recrystallization step, the encapsulant was removed using 1HF: 1H₂O. Electron channeling patterns using a scanning electron microscope (SEM) and selected area electron diffraction spot patterns using a TEM showed that the regrown films were (100) single crystal silicon. The surfaces were studied using SEM and Nomarski contrast optical microscopy. The roughness of the regrown films is about 200Å. The films contain large single crystal grains about 1 mm wide and extending indefinitely along the scan direction. There are a few small protrusions along some of the grain boundaries. The crystal grains contain low angle grain boundaries at about 25 μm intervals (5). These subgrain boundaries have been delineated by Seeco etching and have been examined by Nomarski optical microscopy. Cross-sectional SEM pictures were obtained to verify that the integrity of the underlying isolation oxide was maintained after the recrystallization of the polysilicon films.

Room temperature ³¹P+ (¹¹B+) implants were performed at 150 keV (70 keV) with the samples tilted 7° with respect to the ion beam normal to reduce channeling effects. The LSS peak for P (B) lies at 1888Å (2188Å) which is near the center of the 4500Å Si film. The amorphization threshold for P (B) room temperature implants is 6 × 10¹⁴ cm⁻² (8 × 10¹⁶ cm⁻²) (6). To study the concentration dependence of annealing, low (10¹³ cm⁻²), medium (10¹⁴ cm⁻²), and high (10¹⁵ cm⁻²) dose implants were studied. The 10¹⁵ cm⁻² ³¹P+ dose produces a surface amorphous layer (~3000Å) as determined by etching experiments (7). Thirty-minute conventional furnace anneals of the implanted samples were performed at various temperatures to study the temperature dependence of annealing. The anneals were performed in flowing forming gas (4% H₂, 96% N₂), using a 1000Å Si₃N₄ encapsulant layer to inhibit impurity out-diffusion during annealing.

Differential resistivity and ac Hall effect measurements in conjunction with successive layer removal were used to obtain the electrically active dopant profile and the carrier mobility variation with depth (8). Au-Sb (Au-B) contacts were deposited in a Van der Pauw geometry by evaporation and alloyed at 370°C for 10s in flowing hydrogen to produce ohmic contacts for these measurements. The layer removal was accomplished by chemical etching (750 HNO₃: 250 CH₃COOH: 1HF), providing an etch rate of ~300Å/min. The layer thicknesses removed were measured by a Sloan Dektak profilometer. For comparison, similar studies were performed on the unrecrystallized polysilicon films, and on bulk single crystal silicon. Secondary ion mass spectrometry (SIMS) was used to obtain the atomic profiles.

TEM and selected area electron diffraction studies were performed on the as-implanted and the annealed samples after thinning by chemical etching from the back of the wafers. Residual implantation defects and grain boundary segregation effects were studied in order to compare the structural information with the electrical data. For P, anneals at 500°, 700°, 900°, and 1000°C cover the entire range of temperatures for which there is significant annealing without appreciable redistribution of the P atoms (9).

Isochronal furnace annealing studies of B-implanted bulk Si by Seidel and MacRae (10) reveal three annealing temperature ranges. Below 500°C, activation increases because of annealing out of compensating damage centers, the fraction of substitutional B atoms remaining fixed, and mobilities being low. Between 500° and 600°C, a reverse annealing effect is observed with substitutional B atoms being replaced by Si interstitials, thereby improv-

ing hole mobilities. There is a high temperature annealing range between 700° and 1000°C where B atoms occupy substitutional sites by a mechanism involving the creation of Si vacancies and the movement of these vacancies to combine with B interstitials. In the present study, 30 min isochronal furnace anneals have been performed at 700°, 800°, 900°, and 1000°C for each dose to cover the high temperature annealing range described by Seidel and MacRae (10).

Results and Discussion

Temperature and dose dependence.—The donor concentration profiles and the electron mobility variation with depth in the recrystallized SOI layers are shown in Fig. 1-3 for P fluences in the range 10¹³-10¹⁵ cm⁻². The theoretical Irvin mobility (11) curve corresponding to a donor concentration profile after a 900°C, 30 min anneal is also shown. The sheet carrier concentrations for the various P doses and anneal temperatures are shown in Fig. 4. For low doses and slight lattice damage, there is appreciable activation even at 500°C, but for higher doses and lattice damage there is a considerable increase in electrical activation between 500° and 900°C. The greater redistribution for the higher doses, especially at 900° and 1000°C (Fig. 2 and 3), is consistent with the concentration and defect dependence of P diffusion observed in bulk Si implantation (12). A notable feature is that the electrical profile extends throughout the regrown film thickness, thereby attesting to the excellent crystalline quality of the regrown film even near the Si-SiO₂ interface. From the sheet concentration data in Fig. 4, the peak activation for the 10¹³ cm⁻² dose is seen to be at 700°C, while for the higher doses a 900°C anneal appears to be optimum. Also, the peak electrical activation for the 10¹⁴ cm⁻² dose is less than for a lower (10¹³ cm⁻²) or a higher (10¹⁵ cm⁻²) dose.

The mobility profiles are consistent with the electrical activation data. In ion-implanted Si, there is mobility degradation due to residual damage after annealing. There is a dip in the mobility profile corresponding to the peak of the electrical profile due to ionized impurity scattering, as seen from the Irvin curves. However, residual damage is also apparent in that the measured mobilities are lower than the Irvin mobilities. This discrepancy is greater for higher doses and for lower anneal temperatures, as expected. For donor concentrations of about 5 × 10¹⁶ cm⁻³, electron mobilities as high as 600 cm²/V-s are observed.

Similar studies have been performed for B with doses between 10¹³-10¹⁵ cm⁻² and anneal temperatures between 700°-1000°C. The results are essentially similar to those for P implants. The electrical profiles for a 10¹⁵ cm⁻² implant are shown in Fig. 5, and the sheet carrier concentration data are summarized in Fig. 6. The annealing and redistribution of B implants in bulk silicon have been extensively discussed by Hofker (13). The redistribution of B during annealing in Fig. 5 can be explained using the three-stream diffusion model of Chu and Gibbons (14). The model is valid for ion fluences below 10¹⁵ cm⁻² and anneal temperatures above 900°C. The model considers substitutional, electrically active B which diffuses slowly, B-vacancy pairs which are electrically inactive but diffuse fast, and positively charged vacancies. It may be noted that 100% activation is never achieved. This is consistent with observations in bulk Si, where amorphization is a prerequisite for complete activation of B. Tsai and Streetman (15) have shown that complete B activation in bulk Si is achieved by annealing at low temperature (550°C) if the Si is pre-amorphized by Si self-implants. This involves solid phase epitaxial regrowth from the underlying single crystal Si substrate. In order to examine if a similar technique could be applied to the SOI films, the recrystallized films were amorphized by low temperature (-110°C) multiple Si implants (4 × 10¹⁵ cm⁻² at 200 keV, 2 × 10¹⁵ cm⁻² at 150 keV, 1 × 10¹⁵ cm⁻² at 100 keV, 6 × 10¹⁴ cm⁻² at 50 keV) to produce a continuous 3500Å amorphous layer in a 4500Å thick regrown film. A 60 min 550°C anneal for a 70 keV, 10¹⁵ cm⁻² B implanted sample resulted in 100% activation with a sheet carrier mobility

Fig. 1. Net donor concentration and electron mobility profiles obtained from differential sheet resistivity and Hall effect measurements for $^{31}\text{P}^+$ (10^{13} cm^{-2}) implanted silicon-on-oxide, after various isochronal anneals. The LSS distribution for the as-implanted $^{31}\text{P}^+$ is shown. The theoretical Irvin mobility profile in bulk Si is shown for the donor distribution measured after a 900°C anneal.

The mobility results suggest that the films are relatively free of stress. For example, compressive strain in the regrown silicon would lead to electron mobility degra-

Fig. 5. Net acceptor concentration and hole mobility profiles for isochronal furnace annealed, $10^{15} \text{ cm}^{-2} \text{ }^{11}\text{B}^+$ implanted silicon-on-oxide.

dation and enhancement of hole mobilities (16). Conversely, a tensile stress in the films would cause electron mobility enhancement and a decrease of hole mobility. Since no such effects are observed, we conclude that the films are essentially stress-free. It may be noted that SOS films are under tremendous compressive stress, which causes a large density of stacking faults. Conversely,

Fig. 6. Sheet carrier concentrations for $^{11}\text{B}^+$ implanted silicon-on-oxide, bulk silicon, and polysilicon for 30 min furnace anneals. The doses are as indicated in parentheses. The x marks indicate the total $^{11}\text{B}^+$ atomic concentration in the films as determined by SIMS.

silicon-on-quartz films are under tensile stress, which tends to cause cracking. In contrast, relatively stress-free films such as silicon-on-oxide have a high potential for device applications.

Structural properties of implanted SOI.—TEM and SEM studies of the P implanted films have been used to

Fig. 7. Selected area electron diffraction pattern from as-implanted (10^{15} cm^{-2} , 150 keV, $^{31}\text{P}^+$) SOI film (left) and after a 30 min, 900°C furnace anneal (right).

Fig. 8. Transmission electron micrograph of as-implanted (10^{15} cm^{-2} , 150 keV, $^{31}\text{P}^+$) SOI film (left) and after a 30 min, 900°C furnace anneal (right)

correlate their structural and electrical properties. For a 10^{14} cm^{-2} implant, electron channeling patterns can be observed in the as-implanted samples, indicating that the single crystal structure of the regrown films is retained. In contrast, for the 10^{15} cm^{-2} implant channeling patterns are not obtained from the as-implanted sample. However, upon annealing at 900°C for 30 min, the channeling pattern reappears. Selected area electron diffraction patterns obtained from the 10^{15} cm^{-2} implanted sample before and after annealing are shown in Fig. 7. For the as-implanted (10^{15} cm^{-2}) sample, the diffraction pattern is a superposition of a single crystal spot pattern and a diffuse ring pat-

tern, which indicates the presence of a highly damaged amorphous layer. Upon annealing, the ring pattern disappears, and the spot pattern alone is seen. There is solid phase epitaxial regrowth of the top amorphous layer from the underlying damaged but single crystal Si. TEM micrographs of an as-implanted and an annealed sample are shown in Fig. 8. Implanted P ions produce defect complexes and clusters during room temperature implantation. Upon annealing at high temperatures, these clusters coalesce into dislocation loops and networks. These residual defects cause the mobilities to be lower than would be expected from the Irvin mobilities. Since similar results

Fig. 9. Transmission electron micrograph of as-implanted (10^{15} cm^{-2} , 70 keV, $^{11}\text{B}^+$) SOI film (left) and after a 30 min, 1000°C furnace anneal (right)

have been observed in bulk silicon (7), the observed mobility degradation is apparently due to the implantation and annealing process and not because of the crystal growth technique. For 10^{13} cm $^{-2}$ implants, there is so little lattice damage that complete activation can be achieved at 700°C. For 10^{15} cm $^{-2}$ implants, complete activation is again achievable, although at a higher temperature because the epitaxial recrystallization of amorphized Si is accompanied by activation of the P in the regrown layer. It is for the intermediate dose (10^{14} cm $^{-2}$), which is insufficient to cause amorphization, that the residual defect density after annealing is rather high, leading to incomplete activation.

The B implantation produces point defects in Si such as vacancies and self-interstitials which have a high mobility at room temperature. Room temperature annealing causes these Frenkel type defects to coalesce into defect complexes including clusters such as those seen in Fig. 9 for a 10^{15} cm $^{-2}$ implant into the regrown Si. However, since B is a very light atom, the amorphization threshold for room temperature implants is very high (8×10^{16} cm $^{-2}$). The electron channeling pattern obtained from the as-implanted (10^{15} cm $^{-2}$) sample shows that the film is still single crystal. The defect clusters produced during a 10^{15} cm $^{-2}$ implant coalesce to form dislocation loops which remain even after annealing at 1000°C (Fig. 9). For anneals at 700° and 800°C, B precipitates along these dislocation networks, thereby leading to extremely poor activation, especially for the higher doses (Fig. 6). At higher temperatures, precipitated B atoms are released from the dislocation loops and occupy substitutional sites.

Comparison with bulk Si and polysilicon.—Since a 900°C anneal is optimal for implantation into the regrown Si, 900°C anneals were also performed for implanted polysilicon and bulk Si. For polysilicon, no profiles could be obtained for the 10^{13} cm $^{-2}$ and 10^{14} cm $^{-2}$ doses because of

the extremely high resistivity of the samples. Typical electrical profiles for 10^{15} cm $^{-2}$ P and B implants are shown in Fig. 10 and 11, respectively. SIMS atomic profiles are also shown for comparison. The sheet carrier concentration data for bulk Si and polysilicon are shown in Fig. 4 and 6 for P and B implants, respectively. B and P activation in the regrown Si films approaches bulk Si values for all doses. There is good agreement between the atomic and electrical profiles. At high anneal temperatures there is substantial dopant redistribution in the regrown Si films, accompanied by segregation effects along the subgrain boundaries (18). This becomes apparent in Fig. 12, which shows a typical subgrain boundary before and after a 1000°C, 30 min furnace anneal of a 10^{15} cm $^{-2}$ B implant. The subgrain boundaries become broader and darker after annealing, presumably because of B segregation along these boundaries. For the as-deposited polysilicon, the density of grain boundaries is so large that the electrical profiles lie significantly below those in bulk Si and recrystallized Si (Fig. 10 and 11). Trapping of carriers in a disordered region near the grain boundary can also contribute to lowering the sheet carrier concentration (18).

The variation of sheet carrier concentration with temperature in the regrown films can be understood in terms of two dominant mechanisms. Ion implantation damage is annealed out better at higher temperatures, leading to increased electrical activation. However, the increased redistribution at higher temperatures causes increased segregation at grain boundaries. This explains why for the 10^{14} cm $^{-2}$ and 10^{15} cm $^{-2}$ implants, the sheet carrier concentration is lower after annealing at 1000° than at 900°C. For the 10^{13} cm $^{-2}$ implant, the peak concentration occurs at a lower temperature (700°C) because the implantation damage is more easily annealed out. It is unlikely that the decrease in sheet carrier concentration after 1000°C anneals,

Fig. 12. TEM micrograph of a subgrain boundary in a 10^{15} cm^{-2} , 70 keV, $^{11}\text{B}^+$ implanted SOI sample before (left) and after (right) a 1000°C , 30 min furnace anneal.

relative to the 900°C anneals, is due to outdiffusion of impurities into the SiO_2 because the integrated SIMS atomic profiles indicate that there is little loss of dopants even at 1000°C .

The mobility profiles in Fig. 10 and 11 exhibit the general trend that mobilities are highest in bulk Si and extremely poor in the unrecrystallized polysilicon. A conduction model has recently been proposed by Wu and Yang (19) for polysilicon which includes scattering of majority carriers by grain boundaries and subgrain boundaries. In this model a potential barrier is created at grain boundaries along with a depletion region because of trapped charge and this causes majority carrier scattering. Such scattering at subgrain boundaries is apparently responsible for lower mobility in the recrystallized Si than in bulk Si. One can write the mobility in these SOI films, μ_{SOI} , as

$$\mu_{\text{SOI}}^{-1} = \mu_{\text{B}}^{-1} + \mu_{\text{GB}}^{-1} \quad [1]$$

where μ_{B} is the mobility in implanted bulk Si and μ_{GB} is the contribution of subgrain boundary scattering. The difference in mobility values for the regrown Si and bulk Si is most pronounced for the lowest dose, where ionized impurity scattering is least significant. Figure 13 shows the B electrical profiles for a 10^{13} cm^{-2} implant in recrystallized SOI and bulk Si. The acceptor concentrations at 1200Å are the same in bulk and regrown Si. Therefore, we expect the same ionized impurity scattering. We observe $\mu_{\text{B}} = 240 \text{ cm}^2/\text{V}\cdot\text{s}$ and $\mu_{\text{SOI}} = 180 \text{ cm}^2/\text{V}\cdot\text{s}$. Therefore, the subgrain boundary contribution to mobility is found to be $\mu_{\text{GB}} = 720 \text{ cm}^2/\text{V}\cdot\text{s}$. In polysilicon, the hole mobilities are extremely poor because of the high density of grain boundaries. The further degradation of mobilities close to the Si-SiO₂ interface (Fig. 10 and 11) is attributable to a high density of defects near the interface in the as-deposited films.

Summary

Lateral epitaxy by seeded solidification using a moving graphite strip heater has been used to produce single crystal silicon films on silicon dioxide. Electron channeling patterns, TEM micrographs, and selected area electron diffraction patterns all show that the regrown films are single crystal. However, the films contain low angle

grain boundaries, as determined by SEM and Seeco etch techniques. Donor concentrations and electron mobilities measured as a function of depth by the double ac Hall effect method show that a 30 min furnace anneal at 700°C is optimum for low (10^{13} cm^{-2}) phosphorus doses, while for

Fig. 13. Net acceptor concentration and mobility profiles in silicon-on-oxide and in bulk silicon for 10^{13} cm^{-2} $^{11}\text{B}^+$ implants. The theoretical Irvin mobilities in bulk silicon are shown corresponding to the acceptor distributions in the regrown silicon films and in bulk silicon. SIMS atomic profiles are shown for comparison.

higher doses, a 900°C anneal gives the highest activation. Phosphorus atoms are activated throughout the entire film thickness, with no mobility degradation near the silicon-silicon dioxide interface. TEM micrographs reveal the presence of residual implantation damage such as dislocation loops even after annealing at 900°C. These recrystallized films have electrical activation and mobilities comparable to bulk silicon, and are considerably superior to that in unrecrystallized polysilicon films. The slightly lower activation in the recrystallized films compared to that in bulk silicon is apparently due to phosphorus segregation and carrier trapping effects at subgrain boundaries in the regrown films, and grain boundary scattering causes slightly lower electron mobilities in these films compared with bulk silicon. Thus the subgrain boundaries in the silicon on silicon dioxide films have a slightly deleterious effect on carrier transport and electrical activation.

The annealing behavior of boron acceptor implants into silicon-on-insulator films recrystallized by seeded lateral epitaxy has been studied for doses of 10^{13} - 10^{15} cm⁻². A 30 min furnace anneal at 900°C is optimum. Complete activation at low temperatures (550°C) is achievable if the boron profile lies in an amorphized layer not extending throughout the entire regrown film thickness. In all cases electrical activation is observed throughout the entire regrown film thickness. TEM studies reveal clusters and dislocation loops as residual implantation damage even after annealing at 1000°C. This residual damage leads to mobility degradation and incomplete activation. The presence of subgrain boundaries in the regrown silicon films decreases carrier mobilities by introducing grain boundary scattering, and reduces sheet carrier concentrations by causing impurity segregation and carrier trapping. However, the effect of the residual subgrain boundaries on mobility is not severe, indicating that relatively stress-free device quality films are obtained. Hole mobilities and electrical activation values in the regrown film approach bulk silicon values. In the as-deposited polysilicon films, by contrast, electrical activation and hole mobilities are extremely poor.

Crystal Damage during CV Profiling

J. van de Ven

Faculty of Science, R.I.M., Department of Solid State III, Catholic University, Toernooiveld, 6525 ED Nijmegen, The Netherlands

ABSTRACT

After CV measurements of GaAs and highly doped Si, using mercury as a Schottky contact, crystal damage on the diode electrode sometimes occurs as can be made visible by selective etching techniques. The presence of this damage appears to be related to the magnitude of the applied bias voltage and to a slight contamination of the mercury with dust particles. The penetration depth has been observed to be in the order of a few hundred nanometers.

CV measurement of semiconductor structures has become a very important technique for fast profiling of carrier concentrations. It has been shown by various authors that for silicon and gallium arsenide mercury can be applied as cathodic as well as anodic Schottky contact (1-3). This method always has been considered as being nondestructive, but the present results point out that care has to be taken as to this assumption because it appeared rather

easy to create surface damage on the crystal during the CV measurement. This is not evident by normal inspection, but by using sensitive defect revealing methods the damage can be made visible.

Experimental

Measurements were mainly performed on n-type Si-doped GaAs with doping levels ranging from 5×10^{16} to 2

$\times 10^{18} \text{ cm}^{-3}$, but also some Sb- and P-doped Si samples were used. Various surface pretreatments were used: For GaAs, anodic polishing followed by a 4 w/o HCl/H₂O dip (4) or a H₂SO₄/H₂O₂/H₂O (vol. 3:1:1)-etch. Si crystals received a final 10 w/o HF dip. After CV measurement the samples were also cleaned in different ways, e.g., with a HCl or HF dip, ultrasonic acetone bath, etc.

The CV measurements themselves were performed using either the Hg-1 single mercury probe from MSI-electronics or a homemade double mercury probe. In both cases contact with the crystal was made by evacuating the vacuum channels on the probe head. The mercury used was "suprapur" from Merck and was regularly refreshed.

To reveal possible defects on the crystal surface DS and DSL etchants (5) have been used as well as anodic dissolution in EDTA electrolyte of pH ~ 8.5 (6).

Results and Discussion

It was found in several cases after CV measurements of GaAs and Si, that the reverse-biased diode contact could be made visible by selective etching methods. Usually this crystal damage appeared in the form of a ring on the surface, whereas inside as well as outside the ring the surface morphology was similar (Fig. 1). As revealed with a step profiler, the ring appears as an elevation on the surface after DSL or anodic defect revealing, but as a depression after DS etching. The formation of the ring has been observed on GaAs samples, Si doped in the range 5×10^{16} - $2 \times 10^{18} \text{ cm}^{-3}$, and on some heavily doped n-type Si samples. A condition for this turned out to be that the maximum applied bias voltage during profiling should at least have approached the breakdown voltage for the anodic diode contact. It was found that for highly doped material the ring could be revealed more easily. After using the double mercury probe, the large contact could only be made visible when the voltage was reversed during the CV measurement, thereby actually turning this contact into the reverse-biased diode contact. Similar results were obtained when a thin, $\sim 100\text{\AA}$, oxide layer on top of the GaAs sample was present. In some cases it was also noticed that after etching, the reverse-biased diode showed up as a rough area delimited by a ring, but this

Fig. 1. Nomarski interference microscopy picture of the diode ring after CV measurements on 10^{18} cm^{-3} Si-doped GaAs. Selective etching has been performed with $D_{1:4}S_{1/1}$ [notation defined in Ref. (5)], etch depth $\sim 2 \mu\text{m}$. The ring is a depression of 500-1000 \AA .

kind of damage could be attributed to incomplete cleaning of the sample after CV measurement. Recommended in this respect is an ultrasonic acetone bath followed by a 4 w/o HCl dip and extensive rinsing with water.

In order to study the penetration depth of the crystal damage, electrochemical sequence etching on GaAs was performed. First thin layers of the sample were anodically polished off, followed by anodic defect revealing (6). For a 10^{18} cm^{-3} Si-doped GaAs sample which had been at the breakdown voltage of $\sim 2\text{V}$ for about 30s (which in itself is no extreme condition), the rim of the reverse-biased diode could still be observed after removal of $0.2 \mu\text{m}$ of material, but it had disappeared after anodically polishing off $0.5 \mu\text{m}$ of material. This shows that in this case the penetration depth of the effect is at least several tenths of microns, which lies in the same order of magnitude as the depletion width at breakdown for this sample.

Closer inspection of the ring, produced after anodic defect etching, with SEM showed a twisted structure (Fig. 2). This structure corresponds with the microstructure of the (perspex) probe head.

Careful inspection of the contacts showed that small dust particles contaminate the mercury and gather at the contact edges when vacuum is applied. These contaminations cannot be removed by simply replacing the mercury, but require extensive cleaning of the entire probe head. After such cleaning they will rapidly gather again, however, even when working under dust poor conditions. The presence of these particles proved to be a critical factor in the appearance of the ring.

From the former observations we can conclude about the origin of the crystal damage, that:

1. It is not merely mechanical, for then the applied bias voltage would not be critical and defects should be seen directly on the surface without defect etching,
2. It is not a simple matter of an amalgamating reaction, for then it cannot be explained (i) that only the edge of the contact would be visible, (ii) that when a thin oxide layer is left on the surface it looks undamaged after profiling, whereas on the crystal itself the reverse-biased diode ring can be made visible, and (iii) that the damage could not be seen on the polished surface before defect revealing. In addition, neither Si nor As have any tendency to dissolve in Hg, whereas pure elementary Ga only dissolves slightly (7, 8),
3. It is related to the presence of dust particles at the surface of the mercury diode biased up to breakdown conditions.

Therefore the conclusion is that at breakdown voltages an "avalanche effect" takes place at the diode edge, most probably supported by the presence of dust particles. The precise nature of the defect is unknown. It may be either caused by local introduction of impurities from the contact into the crystal lattice, possibly supported by a local heating up during the avalanche period, or it can be

Fig. 2. Detail of Fig. 1; SEM photograph

formed by a local disordering of the lattice under the avalanche conditions. Anyhow, the appearance of an elevated ring on GaAs after DSL and anodical defect etching indicates an increased recombination center density in the damage region. The fact that a depression is found after DS etching indicates that a strong change in chemical potential has also taken place, because otherwise this defect revealing method would be expected to produce an elevation on the defect as well.

Summary

As under normal working conditions voltages may easily approach breakdown values and because small contamination of the mercury contacts will normally appear as well, crystal damage during CV profiling always may occur, especially when dealing with higher doped samples. Therefore, special attention to this effect should be given when dealing with highly doped epilayers which have to be used for further processing. As a positive side effect it can be mentioned that the contact surface area of the reverse-biased diode contact can be evaluated accurately after measurement. It should be stressed here that the CV results themselves are not influenced noticeably by the crystal damage.

The Influence of High Pressure Oxidation on Boron Redistribution in LOCOS Structures

P. Deroux-Dauphin

ABSTRACT

As device dimensions approach 1 μm , narrow channel effects are becoming more and more critical. In a LOCOS structure, these effects are essentially due to lateral diffusion of the field threshold implant during oxidation. EBIC, SIMS, and preferential chemical etching have been used to investigate the effects of high pressure oxidation on lateral and in-depth diffusion of boron. It has been found that lateral and vertical diffusion of boron is reduced by 0.20 and 0.33 μm , respectively, when the pressure increases from 1 to 20 bar. For a 3 μm linewidth test device, the observed reduction of the lateral diffusion of boron with increased pressure is shown to correspond to a 22% increase in the width of the active regions. The actual shape of the boron-doped region under the bird's beak has been deduced from EBIC measurements and preferential chemical etching within 0.06 μm accuracy. In addition, the boron segregation coefficient at the Si/SiO₂ interface is given as a function of pressure.

MOS devices in integrated circuits are becoming ever smaller in an aim to achieve higher device density and lower cost. However, many difficulties have arisen from the reduction of device size (1). One of these difficulties emanates from lateral diffusion of boron, which is used as a channel-stop implant in coplanar structures (2). Redistribution of the boron field implant plays an important role in narrow-channel effects (3) and influences the capacitance value between the n⁺ sidewall region and the P region at the field edge (4). Circuit designers require knowledge of such phenomena to draw up valid design rules.

Lee and Dutton have presented a 2-D approach to boron impurity profiles after oxidation at atmospheric pressure (5).

This paper presents measurements of the actual extent, both lateral and vertical, of the boron-doped region under

Key words: bird's beak, electron beam induced current, secondary ion mass spectroscopy.

the bird's beak in samples oxidized under high pressure. Test devices were fabricated, and three main characterization techniques used: electron-beam-induced conductivity (EBIC), secondary ion mass spectroscopy (SIMS), and preferential chemical etching. According to our measurements, lateral diffusion of the boron implant is reduced by 0.20 μm and vertical diffusion by 0.33 μm when the pressure is increased from 1 to 20 bar. The segregation coefficient of boron at the Si/SiO₂ interface has also been investigated as a function of pressure.

Experimental

Sample preparation.—Test devices for determining the lateral diffusion of boron were fabricated according to the classical coplanar process outlined in Fig. 1. CZ, n-type <100> silicon wafers of 10 $\Omega \cdot \text{cm}$ resistivity were used. The wafers were oxidized at 950°C in dry ambient to grow a 0.025 μm pad oxide. A silicon nitride film, 0.1 μm thick, was deposited by LPCVD. The wafers were subsequently

Fig. 1. Fabrication sequence of the test device investigated in this work

coated with photoresist, and the nitride film was selectively plasma etched so that a repetitive pattern of nitride stripes of width W_n was obtained (see Fig. 1a).

The samples were then implanted with boron at a dose of $3 \cdot 10^{12} \text{ cm}^{-2}$ and an energy of 80 keV. The photoresist was removed, and, after cleaning, the wafers were oxidized in a wet O_2 ambient at a constant temperature of 920°C and under various time-pressure conditions, as summarized in Table I.

For each pressure, P_{ox} , the corresponding oxidation time, t_{ox} , was chosen so that a $0.6 \mu\text{m}$ thick SiO_2 layer was grown. The nitride film was then etched off in orthophosphoric acid at 180°C , and the thick oxide was completely removed in buffered HF. Following that, a $0.1 \mu\text{m}$ film of low temperature oxide (LTO) was deposited, intended to reduce the reverse current of p-n junctions. Finally, aluminum electrodes were defined, yielding the structure shown in Fig. 1c.

Experimental details.—The distances to be measured were W_n (see Fig. 1a) and W_e (see Fig. 1c). The lateral diffusion of boron is then deduced from these measurements using the relation

$$X_{j1} = \frac{1}{2} (W_n - W_e) \quad [1]$$

In other words, our X_{j1} measurements are based on the exact values for W_n and W_e derived according to the methods described below.

SEM measurement of W_n .—Special precautions had to be taken in this measurement. First, we must point out that W_n represents the actual width of the nitride stripes, as shown in Fig. 1a, and not the width of the photomask used for etching the resist. Thus, W_n was measured just after etching of the resist film. Second, we had to be sure that W_n and W_e referred to the same nitride stripe on our test devices; otherwise, confusion could result from possible fluctuations of W_n on a given chip or from chip to chip. To get around this problem, a linewidth optical sys-

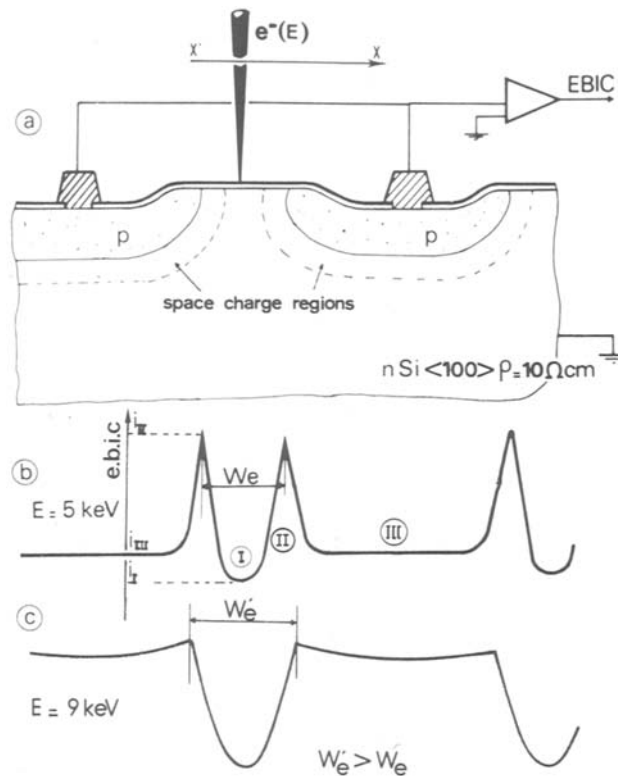

Fig. 2. a: Cross-sectional drawing of the sample structure investigated by EBIC. b and c: EBIC signal induced by the electron beam swept along $x'x$ in Fig. 2a and corresponding to beam energies of 5 and 10 keV, respectively.

tem measurement from Leitz was used to delineate an area on each wafer in which variations in linewidth are less than $0.05 \mu\text{m}$. The wafers were then cleared in this area and subsequently observed in a calibrated scanning electron microscope to check the optical measurement.

EBIC measurement of W_e .—The width W_e was measured using the EBIC technique in a Jeol 35C microscope operated in the line-scan mode. As shown in Fig. 2a, an electron beam of energy E is swept along $x'x$ perpendicular to the surface of the sample. The current induced by the electron beam in the p-n junctions is collected in an external circuit via a 10^7 - 10^8 V/A preamplifier.

Figure 2b shows the EBIC response of the p-n junctions at a beam energy of 5 keV. This signal exhibits three distinct areas.

Area I.—This is located between two adjacent p-type regions, i.e., outside the space-charge regions, and gives rise to a low induced current i_I corresponding to the diffusion part of the EBIC signal.

Area II.—This is characterized by a maximum induced current i_{II} and corresponds to the nearly vertical space-charge region at the edge of the p-n junctions.

Area III.—This corresponds to the EBIC response i_{III} in the p-n horizontal junction.

In order to explain the dependence of the EBIC signal on the beam energy E , we shall consider both the range of electrons in silicon given by (6)

$$R = 0.01837 E^{1.75} \frac{R(\mu\text{m})}{E(\text{keV})} \quad [2]$$

and the junction depth X_{jv} , equivalent to a few tenths of a micrometer, as will be seen below.

In Fig. 2b, the beam energy is set so that $R \approx X_{jv}$, i.e., the limited excitation volume and the very small diffusion length for minority carriers in the p^+ region produce a low i_{III} intensity. The EBIC signal is maximum in area II, where the space-charge region comes up to the sample surface (Fig. 2a).

The distance W_e between two adjacent boron-doped regions can then be deduced from the distance between two EBIC peaks, as shown in Fig. 2b. If E is now increased (case c in Fig. 2), the electron-hole pairs will be mainly generated in the horizontal space-charge region of the junction (area III), thereby increasing both i_{III} and W_e . Indeed, this increase in W_e can be accounted for by the curve of the space-charge regions as drawn in Fig. 2a. Relation [1] can then be written as

$$X_{ji}(E) = \frac{1}{2} \{W_n - W_e(E)\} \quad [3]$$

or, in terms of R , given by [2]

$$X_{ji}(R) = \frac{1}{2} \{W_n - W_e(R)\} \quad [4]$$

Finally, after measuring W_n and $W_e(R)$, we plot $X_{ji}(R)$ given by Eq. [4] to obtain a 2-D representation of the p-n junction. We have measured $W_e(E)$ by varying E from 3 to 9 keV and using electron-beam intensities from 2 to 20 pA. Low intensities were deliberately chosen to avoid fast charge effects in the top oxide layer. The following experimental procedures were likewise introduced: (i) to enhance the EBIC signal, the background level was counterbalanced by injecting an adjustable opposite dc current in the preamplifier, and (ii) to improve the accuracy of measurement, the EBIC signal was recorded on a plotter monitored by the line scan mode of the SEM.

SIMS analysis.—To complete our EBIC results, we used a Cameca IMS 300 ion microprobe for SIMS measurements of boron depth profiles in our samples. From these profiles, the segregation coefficient of boron at the Si/SiO₂ interface was deduced. Flat-bottomed, sharp-edged craters were created by using a large defocused primary beam (7).

The in-depth resolution obtained in these craters was better than 5 nm. To obtain the same secondary ion yield for boron in both silicon dioxide and silicon, an oxygen flow was set to saturate the surface with respect to our uniform sputtering rate (0.2 nm s⁻¹).

Preferential chemical etching.—Preferential chemical etching of silicon was used to reveal the p-n junctions in the LOCOS structure. The test devices were cleaned, preferentially etched in a 1:3:20 HF/HNO₃/CH₃COOH solution (9) and subsequently observed in a SEM.

Results

Bird's beak measurement.—Figure 3 is an SEM cross-sectional view of the LOCOS structure obtained at $P_{ox} = 15$ bar. In this micrograph, the bird's beak and the edge of the Si₃N₄ mask are clearly delineated. The lateral bird's beak parameter (L_{BB}) is defined as the distance between

the edge of the nitride mask and the tip of the bird's beak. SEM examination showed that L_{BB} is equal to 0.70 ± 0.003 μm for all the sample conditions given in Table I, i.e., L_{BB} is constant within the accuracy of our measurements. The ratio L_{BB}/E_{ox} where E_{ox} is the oxide thickness, is found to be 1.16 in each case. Therefore, high pressure oxidation has no significant effect on the shape of the bird's beak.

Two-dimensional representation of p-n junction, as deduced by SEM-EBIC.—Figure 4 shows the plots of $X_{ji}(R)$ derived from relation [4] for $P_{ox} = 1, 10,$ and 20 bar, and Fig. 5 gives those for $P_{ox} = 1, 5,$ and 15 bar. In these figures, the bird's beak, as seen in the micrograph in Fig. 3, has been drawn for purposes of clarity. The experimental points have been determined with an uncertainty of ± 0.06 μm, which is mainly due to the difficulty in determining the EBIC maxima.

Figures 4 and 5 illustrate that: (i) the reductions of X_{ji} and X_{iv} are about 0.2 μm and 0.33 μm, respectively, when P_{ox} increases from 1 to 20 bar, and (ii) the junction profile does not vary significantly between 10 and 20 bar oxidation pressure. In the case of our 3 μm linewidth test device and taking into account the lateral extension of the bird's beak, this reduction of X_{ji} with pressure leads to a relative increase of the width of the active regions of about 22%.

Also given in Fig. 4 and 5 (lower left-hand corner) are the junction depths X_{iv} for each P_{ox} as deduced from SIMS measurements. These values satisfactorily fit the $X_{ji}(R)$ plots. Finally, our EBIC measurements suggest a modification in the curvature of the junction profile beneath the bird's beak. The solid lines of the $X_{ji}(R)$ plots represent the actual shape of the junction, and the dashed lines those which might be expected. This surprising result is also found in the following.

Junction delineation by preferential chemical etching.—Figures 6a and 6b show our results for $P_{ox} = 1$ bar and 15 bar, respectively. For both pressures, the junction has been revealed. The junctions are drawn schematically in Fig. 6c. A reduction of X_{ji} and X_{iv} occurs when P_{ox} is increased. However, quantitative measurements can not be made by direct comparison of Fig. 6a and 6b. The sample structures in these figures issued from two distinct areas of the wafer. Hence, variations may exist in the linewidth measurement W_n not taken into account in this experiment. Nevertheless, the modification of the curvature of the junction profile under the bird's beak, as revealed by EBIC, appears again here. This result will be discussed next.

SIMS results.—The boron depth profiles measured by SIMS are plotted in Fig. 7 for $P_{ox} = 1, 10,$ and 20 bar. The

as-implanted profile prior to oxidation is given for comparison purposes (dashed line). The data are summarized in Table II.

When P_{ox} increases from 1 to 20 bar, the following can be observed: (i) the in-depth diffusion of boron decreases from 0.47 to 0.14 μm , (ii) the surface concentration C_s increases by a factor of 2, and (iii) the maximum concentration C_{max} also increases and is located close to the Si/SiO₂ interface.

The segregation coefficient of boron at the Si/SiO₂ interface, defined by

$$m = \frac{\text{concentration of B in Si}}{\text{concentration of B in SiO}_2}$$

was determined from SIMS profiles, as shown in Fig. 8a and 8b. Results of these calculations are given in Fig. 8c. The accuracy of measurement is 5%. m increases from 0.3 to 1 bar to 0.92 at 20 bar, i.e., the surface concentration in silicon at 20 bar is 2.5 times greater than at 1 bar. This result is in good agreement with the findings of Fuoss *et al.* (10), who recently reported a ratio of 2.48 between 1 and 10 bar at $T_{ox} = 850^\circ\text{C}$.

Discussion

Our investigations show that the shape of the bird's beak and, in particular, its lateral extension L_{BB} are independent of oxidation pressure. This corroborates the results of Wu *et al.* (11), who noticed a 30 nm increase in L_{BB} at 10 bar compared to that at 1 bar. This increase is within the accuracy of our SEM measurements.

In this work, we have used the EBIC signal obtained at a single-line scan of the electron beam to determine the 2-D redistribution of boron. To our knowledge, this is the first use of EBIC for such purposes. Crucial to our study were the choice of a test device composed of a repetitive line pattern and the use of SIMS data to correctly cali-

brate the depth axis of the 2-D plots. In Fig. 4 and 5, we have plotted X_{j1} as a function of the electron range R , as the $X_{j1}(R)$ curves correctly fit the X_{jv} values deduced from SIMS. The low energies used, *i.e.*, $E \leq 10$ keV, further justify our choice of R . Indeed, the relationship between the collection efficiency of our junctions and E is nearly linear. This indicates that the generation mechanism of the electron-hole pairs is mainly limited by the surface recombination velocity.

Thus, according to a simple model of charge-collection (12) the depth of maximum collection shifts towards R , *i.e.*, the maximum depth of penetration. At any rate, our 2-D determination of the junction profiles was carried out merely to compare the different boron redistributions after oxidation.

The modification of the curvature of the junction delineation under the bird's beak revealed by both EBIC and preferential chemical etching was a surprising result. This particular shape may be accounted for as follows: the bird's beak is a region in which local stress within the oxide is likely to slow down growth of SiO_2 (13). According to Hu's model (14), the injection of Si interstitials from the Si/SiO₂ interface will also be reduced, making the oxidation enhanced diffusion (OED) of boron less effective in this area (15).

As outlined in Table I, the main advantage of a high pressure process is a reduction of the oxidation time t_{ox} . Our results further indicate that the shallowness of the junction depth x_{jv} under increasing pressure may be directly accounted for by the reduction of t_{ox} . Our SIMS results served as a first check of the $t_{ox}^{1/2}$ relationship of the in-depth diffusion of boron after heat-treatment. This time behavior suggests that, during high pressure oxidation, boron diffusion may be described using a classical model.

So far, apparently little research has been reported on the segregation mechanism of boron during high pressure oxidation. Recently, Charitat (16) developed the thermodynamic aspect of boron segregation on the basis of Fair's model (17). Assuming that the pressure is much lower in Si than in SiO₂, Charitat stated the thermodynamic equilibrium of boron by adding terms proportional to pressure to the chemical potentials. Therefore, in his model, he obtained an exponential relationship of the segregation coefficient, m vs. P_{ox} . Our results, especially between 5 and 20 bar, are in good agreement with Charitat's prediction.

Conclusions

In summary, we have drawn the following conclusions.
1. High pressure oxidation is not only useful for reducing time. It also appears very attractive for reducing

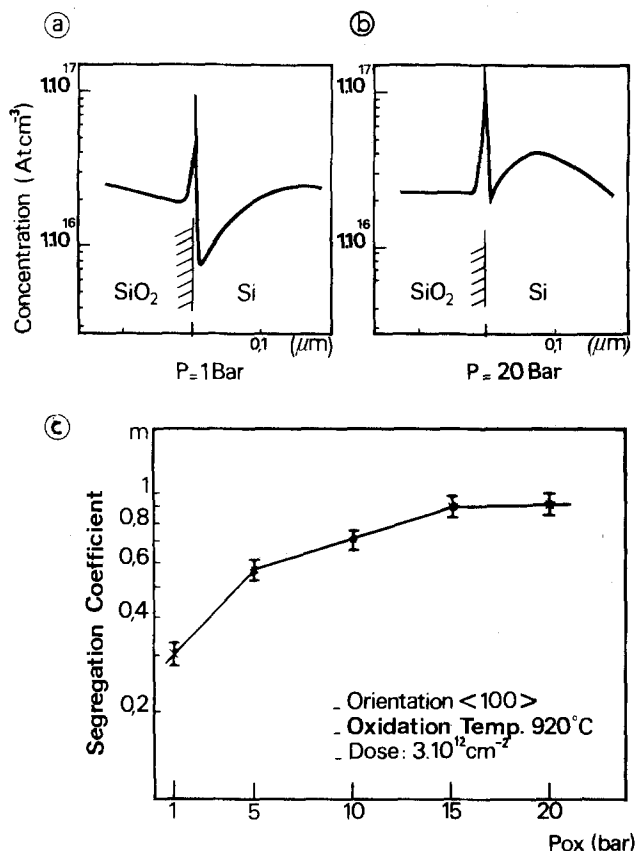

Fig. 8. a and b: SIMS profiles of the boron redistribution in the vicinity of the Si/SiO₂ interface after oxidation at 1 and 20 bar, respectively. c: segregation coefficient m vs. oxidation pressure.

the lateral diffusion of boron in LOCOS structures. For a 3 μm oxide-isolated device, this effect corresponds to a 22% increase in the active regions. With dimensions scaled down to 1 μm , this relative increase will be proportionally greater.

2. Under increasing oxidation pressure, a reduction in the junction depth together with an increase in the surface concentration of boron has been observed. These effects could have interesting implications, e.g., choice of the implant dose for precise adjustment of the threshold voltage of a device would be more straightforward.

3. A modification of the curvature of the p-n junction has been revealed under the bird's beak. This phenomenon is considered to be related to stress effects in the oxide.

4. The pumping of boron within the oxide is reduced in a high pressure process. This effect is correlated with the increase in the surface concentration of boron in silicon.

Acknowledgments

The authors would like to thank Mr. Montier, Dr. Bois, and Dr. Trilhe for their encouragement during this study. Dr. Demoulin, Dr. Mathiot, and Ms. Dargent are also thanked for their critical reading of the manuscript, and Mr. Paillet, Dr. Blanchard and Dr. Payo-Casares for their technical assistance in this work.

An AES Investigation into the Phase Distribution of Ion-Implanted Oxygen in Silicon N-Channel Devices

C. G. Tuppen and G. J. Davies

British Telecom Research Laboratories, Ipswich, IP5 7RE, England

ABSTRACT

The buried oxide layer formed by high dose ion implantation has been shown, by Auger depth profiling, to be stoichiometric SiO_2 . A detailed examination of the Si KLL Auger transition suggested that regions corresponding to the tails of the implant profile contained oxygen randomly distributed in the silicon lattice. A model has been produced which accounts for the observed Auger spectrum associated with such a distribution. Ion beam-induced mixing and broadening effects are assessed, and the minimum detectable size of SiO_2 particles is calculated.

A number of recent communications have described the successful fabrication of LSI circuits on silicon-on-insulator (SOI) substrates prepared using ion-implantation techniques (1-3). The good electrical characteristics of these circuits have established SOI as a viable alternative to the established silicon-on-sapphire (SOS) technology. The insulating layer is prepared by high energy oxygen ion implantation with a sufficiently high dose to form a buried oxide layer. The near-surface silicon retains its crystalline properties (4), and, following a high temperature anneal, can be overgrown with good quality epitaxial silicon (4).

A number of analysis techniques have been used to study the implantation process and subsequent device-fabrication steps. These have included cross section transmission electron microscopy (TEM) (2, 4, 5-7). Rutherford backscattering spectroscopy (RBS) (2, 7-8), secondary ion mass spectrometry (SIMS) (7), x-ray photoelectron spectroscopy (XPS) (6-7), and Auger electron spectroscopy (AES) (2, 4, 6, 7, 9). Previously, AES has been used, qualitatively, to determine the shape of the implanted oxygen profile (6, 7), but not for accurate quantitative analysis.

This paper describes an AES investigation into the distribution, dose, and chemistry of the implanted layers.

Particular attention has been paid to the chemical form of the oxygen/silicon interaction both in the main body of the implant and more particularly in the interface region. The discussion includes a section on two alternative, theoretical models which describe different oxide phase distributions. The effect of sputter-cascade mixing is also considered.

Experimental

Substrates for implantation were 17-23 $\Omega\text{-cm}$, boron-doped, p-type silicon of (100) orientation. The buried oxide structures were prepared using an electrostatically scanned, 400 keV, molecular O_2^+ ion beam¹. All doses have been converted to equivalent 200 keV, atomic O^+ doses. Specimens were implanted through a 2 \times 2 cm silicon mask, and were supported on silicon points to reduce conductive heat loss, thus allowing a higher implantation temperature to be attained. Typical ion beam currents were in the range 40-52 μA , resulting in substrate temperatures in the range 450°-500°C.

Following implantation, the substrates were capped with CVD silica and annealed in nitrogen at 1150°C for 2h. A thin epitaxial Si layer (0.02 μm) was grown by CVD

¹ Courtesy of Dr. P. L. F. Hemment, Surrey University, Guildford, England.

from SiCl_4/H_2 at 1170°C for 75s. Devices were then fabricated using the standard $5\ \mu\text{m}$ n-MOS process.

AES was performed on a VG Scientific MA500 scanning Auger microscope fitted with a 5 keV argon ion gun. The spectrometer was controlled by an HP1000 minicomputer, which stored all the spectra on disk. This allowed detailed postprofiling examination of peak energy shifts and was also used for computer simulations of Auger spectra.

A series of samples was studied with doses ranging from 1.1×10^{18} to $3.3 \times 10^{18}\ \text{O}^+\ \text{cm}^{-2}$. Some were analyzed "as implanted," while others were profiled following various stages of the circuit fabrication process.

Results

Auger depth profiles were recorded by multiplexing the Si KLL, Si LVV, and O KLL transitions. Sputter depth scales were calibrated from a combination of ball-lapped craters and Dektak II surface-profile measurements. Quantification of Auger peak heights was complicated by changes in the relative atomic sensitivity of silicon. In the transition from elemental Si to stoichiometric SiO_2 , the relative sensitivity increased by a factor of 3.4. In view of this large matrix effect, all calculations were based on the oxygen peak heights, which were taken as directly representative of the oxygen concentration. Calibration of oxygen concentrations in the implanted region was based on spectra obtained during the same profile from silica capping layers and, in the case of device structures, silica gate oxides.

The Auger depth profile through a polysilicon capacitor fabricated on a $2.0 \times 10^{18}\ \text{ions cm}^{-2}$ implanted substrate is shown in Fig. 1. In this case, quantification of the silicon concentration was achieved using the relative sensitivity of silicon in silica, and so the profile is only truly valid in areas of stoichiometric SiO_2 . It does, however, show that the implant saturates at stoichiometric SiO_2 and also demonstrates the good depth resolution obtained during this work. Taken from the surface, this profile clearly displays the following layers: $0.8\ \mu\text{m}$ SiO_2 passivation, $0.3\ \mu\text{m}$ polysilicon, $0.05\ \mu\text{m}$ gate oxide, $0.02\ \mu\text{m}$ epitaxial silicon, and, finally, the ion-implanted oxygen.

Figure 2 shows how the shape of the oxygen profile changed as the dose was increased from 1.1×10^{18} to $3.3 \times 10^{18}\ \text{ions cm}^{-2}$. For doses below $1.8 \times 10^{18}\ \text{ions cm}^{-2}$, the implant failed to reach stoichiometric SiO_2 , and the profile shape follows a distorted gaussian curve with the leading edge of the profile displaying a steeper gradient than the trailing edge. The $1.8 \times 10^{18}\ \text{ions cm}^{-2}$ profile shows a well-formed, flat-topped SiO_2 region with very steep sides. As the dose was increased still further, the flat-topped region widened and the leading edge of the implant approached the surface of the substrate. Profiles

Fig. 2. A series of oxygen Auger depth profiles for implants in the range $1.1\text{--}3.3 \times 10^{18}\ \text{ions cm}^{-2}$.

from annealed specimens frequently displayed significant structure in the wings of the implant, e.g., the $2.4 \times 10^{18}\ \text{ions cm}^{-2}$ profile in Fig. 2. These findings are in accord with those of other workers (10, 11) and have been explained in terms of preferential nucleation centers (11).

Depth scales were determined using a series of ball laps on the $1.8 \times 10^{18}\ \text{ions cm}^{-2}$ implant. Penetration of the implanted layer by the ball lap was confirmed using Auger line scans, and accurate depths were then established using a surface profiler. Measurements gave an average implant depth of $4000 \pm 200\ \text{\AA}$ and a layer thickness of $2100 \pm 200\ \text{\AA}$.

An implant dose could then be calculated from the integrated area under the oxygen Auger depth profile, assuming the following.

1. The O atomic density in the stoichiometric SiO_2 layer was $5.33 \times 10^{22}\ \text{atomic cm}^{-3}$ (12). A high silica density value is considered appropriate, as the oxide would have been under severe compression during growth.
2. The sputter rate was constant throughout the implanted material.
3. Interference fringe errors in the ball-lap measurements were minimal.

Using the derived $1.8 \times 10^{18}\ \text{ions cm}^{-2}$ implant data, a plot of calculated dose vs. measured dose for the full range of profiles is shown in Fig. 3. The points all lie on a straight line with a slope of ~ 1 .

The Si KLL peak energy was monitored for all profiles and confirmed the assigned SiO_2 stoichiometry in the

Fig. 3. Plot of implant dose calculated from the integrated area under oxygen Auger depth profiles vs. the dose measured during ion implantation.

Fig. 4. A combination plot of the leading edge of the oxygen Auger depth profile for an unannealed 1.8×10^{18} ions cm^{-2} implant, together with the Si KLL spectrum at various points on the profile. The negative excursion of each spectrum is in line with the appropriate sputter depth. The dashed line represents the maximum sputter broadening contribution at a fractional oxygen concentration of 0.5 when compared to SiO_2 .

flat-topped regions. Concentrating on the near surface tail of the unannealed 1.8×10^{18} ions cm^{-2} implant profile, the Si peak showed a gradual transition from the elemental spectrum to a fully oxidized spectrum (Fig. 4). In line with a recent XPS study (13), the integrity of the silica, both in the implants and capping layers, was found to be unaffected by ion bombardment. Also, electron-beam irradiation was kept to a minimum, and, therefore, subsequent reduction of the oxide was also minimized.

Analysis of Results

The close agreement shown earlier between calculated and measured doses suggests that the Auger profiles are a good representation of the implanted-oxygen distribution. A theoretical model of the implantation process has already been produced and used to simulate these Auger profiles. A preliminary report of this model has been described elsewhere (14); a more complete description will be published shortly.

The shape and energy of the Si KLL peak can be used as an indication of the phase distribution of oxygen in the lattice. Although it has been shown that silicon is present as stoichiometric SiO_2 in the majority of the implant region, the spectra recorded in the near surface tail (Fig. 4) need to be discussed in terms of the oxygen phase distribution.

Two independent models have been proposed for the phase distribution of oxygen in nonstoichiometric silicon oxides; the microscopic-mixture model and the random bonding model (15, 16). In the microscopic-mixture model, the oxide is assumed to be composed of a mixture of discrete regions of SiO_2 in the Si lattice. In the random bonding model, the oxygen is considered to be randomly distributed in the Si lattice, giving a mixture of atomically localized oxides. These take the form of highly distorted tetrahedra with the general formula $\text{Si}(\text{Si}_x\text{O}_{4-x})$ where $0 \leq x \leq 4$.

The microscopic-mixture model.—Spectra can be theoretically simulated using the microscopic-mixture model, by forming a theoretical matrix of Si and SiO_2 peaks (17). This technique was confirmed by Auger analysis of a specially prepared silicon substrate partially covered by a silica layer. The electron beam was kept at a fixed raster size and moved stepwise across the Si/ SiO_2 boundary. Using this method, intermediate spectra were recorded, ranging from elemental silicon to stoichiometric silica. The peak shapes and energies established in this way were found to mirror those derived by computer simulation. These showed a distinct double peak, unlike the Au-

ger spectra recorded from ion-implanted material (Fig. 5), and gave incorrect energy shifts. A summary of experimental and calculated peak energies is given in Fig. 6.

A possible cause of the discrepancy mentioned above could be a loss of resolution in spectra recorded during a depth profile due to sputter broadening. At any given

Fig. 5. KLL Si Auger spectra at a fractional oxygen concentration of 0.65 compared to SiO_2 . Curve a: recorded during depth profile. Curve b: simulated using the microscopic-mixture model. Curve c: simulated using the random bonding model.

Fig. 6. Plot of Si KLL peak energies vs. effective SiO_2 concentration for spectra recorded during depth profiles (O), spectra simulated using the microscopic-mixture model (X), and spectra simulated using the random bonding model (+).

point on the profile curve shown in Fig. 4, spectra will contain components due to Si/SiO₂ ratios distributed about that point and described by a gaussian sputter broadening distribution function. Such a function is included in Fig. 4 and has been calculated on a worst possible case based on the broadening equation derived by Hofmann (18). After taking account of such a distribution in the theoretical microscopic-mixture model, a second set of simulations significantly failed to alter the results already described. The double-peak structure remained intact, and the peak energies showed only minor changes.

The random bonding model.—The random bonding model can be described in terms of a simple statistical distribution of oxygen in the silicon lattice (15). This model assumes that each tetrahedrally coordinated silicon atom can be surrounded by any number of oxygen atoms, up to a maximum of four. Each of the five possible tetrahedral oxide structures are assumed to be equally probable. The actual distribution varies according to the fractional oxygen concentration relative to SiO₂. In addition, the original model has been modified to take account of the change in density between silicon and silica (Fig. 7). This distribution was then used to simulate the Si KLL Auger spectrum for various oxygen concentrations.

A recent communication (19) has shown that chemical shifts of the Si KLL transition in stoichiometric binary compounds is linearly related to the difference in electronegativities between Si and its partner. This is supportive evidence for the assumption made by Johansson *et al.* (17) that the chemical shift for each of the five possible tetrahedral oxide coordinations will follow a linear relationship.

The simulation was based on an elemental silicon Auger peak, and chemical shifts were calculated from a linear scale. Taking account of the change in relative atomic sensitivity in the transition from Si to SiO₂, a spectrum was produced for each of the five possible oxide coordinations. Following the distribution shown in Fig. 7, the peak shape and energy of the Si KLL transition was then calculated for the full range of oxygen concentrations. In line with the implant profiles, the peaks showed a gradual transition from Si to SiO₂ with no evidence of the double peak predicted by the microscopic-mixture model, (Fig. 5). A plot of simulated peak energies *vs.* the fractional oxygen concentration relative to SiO₂ (Fig. 6) shows that the random bonding model comes very close to predicting the experimentally observed results.

Finally, effects due to ion beam mixing have to be considered. During low energy ion etching, some of the energy of the incident ion beam is distributed amongst the near-surface lattice atoms. This causes random scattering

and collision processes, which disrupt the local order of the lattice. The sputter broadening of interfaces is, in part, attributable to this effect and has been modeled by Anderson (20) in terms of a fixed-step diffusion process. Under the sputtering conditions used in this work, Anderson's equation gives a value for the sputter broadening of 100Å. To a first approximation, this value can be taken as the smallest size of discrete SiO₂ particles detectable during the set of depth profiles reported here and places a rider on the comparison between the oxygen-distribution models discussed above. Any silica particles distributed in the silicon lattice that were much less than 100Å in size would have been "randomized" by the cascade mixing process and would thus be indistinguishable from the random bonding model.

Discussion

The exact phase distribution of oxygen in single-crystal silicon has been the subject of much discussion. This has centered mainly on low concentrations of oxygen (< 10¹⁸ at. cm⁻³) dissolved in Czochralski-grown ingots (21-24). After extended high temperature annealing (650°-1000°C) precipitation of the dissolved interstitial oxygen was found. The rate of precipitation and resultant size of the precipitates has been shown to depend on the initial oxygen concentration, the number of lattice defects, the annealing time, and temperature.

The unannealed 1.8 × 10¹⁸ ions cm⁻² sample described in Fig. 4 was implanted with a substrate temperature of 500°C. The mobility of interstitial oxygen at this temperature is likely to be small, and we would, therefore, expect the majority of implanted oxygen to remain in the interstitial form. Interstitial oxygen would be described by the random bonding model and corresponds to the phase measured by Auger analysis. TEM micrographs of this sample have been published elsewhere (4), and preliminary interpretations showed no evidence of SiO₂ precipitates > 200Å.

One final parameter that should be considered is the local lattice temperature at the end of the implant pathway. This could be considerably higher than that of the surrounding bulk material and may give rise to localized precipitation effects. The magnitude and precise physical meaning of an increase in local temperature is very difficult to define, as the exact mechanisms and range of energy loss at termination of the implant process are not clearly understood. However, Shimura (25) has demonstrated redissolution of precipitates during 1230°C anneals of Czochralski silicon. Therefore, if the local temperature exceeded ~ 1200°C precipitate formation would not be expected.

The results presented in this paper represent the first stage of a detailed AES investigation into device-quality oxygen ion-implanted layers. A subsequent report will consider, in detail, the affects of annealing the implants and discuss the formation of structure in the wings of the profile. In addition, lower energy ion beam sputtering will be employed to decrease the minimum detectable particle size in proportion to the square root of the ratioed energies, thus reducing areas of uncertainty.

Conclusions

1. Auger depth profiles have been recorded for oxygen ion implants in the range 1.1-3.3 × 10¹⁸ ions cm⁻². The profile distributions have been used to model the implantation process theoretically.
2. Implant doses calculated from Auger profiles accurately matched values measured during implantation.
3. The oxygen Auger depth profiles for doses > 1.4 × 10¹⁸ ions cm⁻² displayed flat-topped plateaus which corresponded to an implanted stoichiometric SiO₂ layer.
4. An initial study of the Si KLL Auger peak shape has suggested that oxygen in the near-surface tail of the implant profile was present as a mixture of atomically random oxide species. The alternative microscopic-mixture model has been discounted for silica particles > 100Å in

Fig. 7. The statistical distribution of silicon atoms in the nonstoichiometric oxides described by the random bonding model. The silicon atoms are present in the form of highly distorted tetrahedra with the general formula Si-(Si_xO_{4-x}).

size. Future work at lower ion beam energies will reduce the value of this minimum detectable particle size.

ABSTRACT

We have examined the kinetics of low pressure chemical vapor deposition of tungsten by the hydrogen and silicon reduction of WF_6 within a pressure range of 0.1-5 torr and a temperature range of 250°-500°C. The rate-limiting mechanism for the hydrogen reduction system was determined to be the dissociation of H_2 adsorbed on the surface, with an activation energy of 0.71 eV. A self-limiting deposit results from the WF_6 -Si reaction, the thickness and structure of which are dependent upon the initial native oxide characteristics. Deposition occurs selectively on materials that react directly with WF_6 or yield monatomic hydrogen. In the presence of hydrogen, the degree of selectivity is a function of temperature, substrate material, and surface cleanliness.

A number of potential integrated-circuit applications exist for selectively deposited tungsten thin films. Gargini and Beinglass (1, 2) have demonstrated that selectively deposited tungsten (1000-1500Å) on polysilicon and monosilicon surfaces within MOS device structures can serve as an interconnect shunt material and contact diffusion barrier, respectively. By selective deposition it is meant that tungsten is deposited only onto certain materials on the substrate while the surrounding regions remain essentially free of any deposit. Low pressure chemical vapor deposition (LPCVD) processing provides several distinct advantages over atmospheric CVD techniques. These advantages include increased control over the dep-

osition ambient, large load-size throughput, lower reactant gas flows, high purity deposits, and excellent deposit thickness uniformities and conformities.

Tungsten hexafluoride is well suited as a source gas for tungsten deposition on integrated-circuit substrates since it can be reduced by interactions with either hydrogen or directly with silicon. Chemical vapor deposition of tungsten has been reported by the hydrogen reduction of WF_6 (3-8) and by the silicon reduction of WF_6 (9-12) according to the reactions

and

As will be shown, it becomes advantageous to utilize both

reduction reactions to selectively deposit tungsten films of an appreciable thickness onto monocrystalline or polycrystalline silicon surfaces.

A significant amount of work has been devoted to explain the reduction mechanism of WF_6 in the presence of hydrogen. In particular, Bryant (13) performed an exhaustive investigation of all previously available deposition rate data for the hydrogen reduction of WF_6 under experimental conditions in which gas-phase diffusion-controlled limitations were absent. His conclusions agree with the model presented earlier by Cheung (14), which states that the dissociation of H_2 molecules adsorbed on the substrate was the rate-limiting mechanism under surface-controlled reaction conditions. Since surface control of a chemical vapor deposition reaction is favored in relatively low pressure and temperature regimes, it was anticipated that the kinetic evaluation of low temperature LPCVD of tungsten by hydrogen reduction would yield data in agreement with the findings of Cheung and Bryant.

Much less effort has been committed to explain the reduction mechanism of WF_6 by interactions directly with silicon. Morosanu and Soltuz (15) reported a linear dependence between the tungsten deposit thickness and the reaction time for thin tungsten films ($\leq 10,000\text{\AA}$) deposited in an atmospheric CVD flow system. Melliar-Smith *et al.* (11) noted a limiting tungsten thickness of 300-400\text{\AA} was reached when WF_6 was reduced at a surface within an inert atmosphere. Sauermann and Wahl (12) also observed a limiting tungsten deposit thickness which displayed a dependence on the deposition temperature under high flow atmospheric conditions.

The purpose of this study was to examine the reaction mechanisms involved in low temperature (250°-500°C) low pressure (0.1-5 torr) CVD of tungsten. This particular regime is of practical interest for use in the fabrication of integrated circuits where both lower tungsten deposition rates and selective deposition is required. Both the hydrogen and the silicon reduction of WF_6 were evaluated. Experiments were designed to isolate and study each reduction reaction uniquely, without complicating interactions from the other. An explanation of the two-stage tungsten growth sequence that occurs on silicon in the presence of hydrogen was formulated and experimentally verified. A discussion of the two separate reduction systems as well as the mechanism for selective deposition is presented.

Experimental Procedure

The tungsten film depositions were carried out in a low pressure CVD system using a three-zone resistance-heated horizontal furnace 165 cm long. A quartz furnace tube 203 cm long with an inner diameter of 126 mm was centrally positioned within the furnace and served as the reaction chamber. A quartz boat was used to position the substrates vertically within the tube. The chamber interior is evacuated with a series combination of a 164 c.f.m. Roots blower and a 36 c.f.m. (at 1 atm) rotary-vane mechanical pump. Gas injection ports located in a load door assembly allowed for introduction of the processing gases into the chamber. Total chamber pressure was controlled by adjusting the speed of the Roots blower pump together with the gas flow rate into the tube. Gases used in the experiments were tungsten hexafluoride (99.8% WF_6), hydrogen, and argon (99.9998% Ar). The hydrogen was purified using an in-line palladium diffuser element.

All gas flows were controlled using valves and automatic mass flow controllers linked to a microprocessor. The WF_6 exists as a liquid source, and, hence, a resistance heating jacket was placed around the source bottle and adjusted to obtain the desired inlet gas line pressure. The WF_6 gas lines and mass flow controller were heated to avoid condensation of the source gas upon interior flow surfaces. Temperature within the three heated zones of the chamber was monitored with a three-position thermocouple array placed in close proximity to the wafer substrates. The temperature was controlled to within $\pm 2^\circ\text{C}$ of the desired value within the deposition zone. Pressure

was monitored with a capacitance manometer positioned within the chamber. The vacuum integrity of the system was ensured with helium leak detection techniques. Exhaust and by-product gases were handled by an exhaust hood and water scrubber apparatus. A schematic diagram of the system is shown in Fig. 1.

The deposition substrates were 100 mm diam 7-21 $\Omega\text{-cm}$ p-type <111>-oriented single-crystal silicon wafers. Three types of substrates were used: bare silicon, patterned oxide-coated, and patterned aluminum-coated. For the oxide-coated substrates, a 3000\text{\AA} layer of undoped SiO_2 was thermally grown on the Si and patterned into a simple repetitive bar structure by conventional photolithographic techniques. The aluminum-coated samples were prepared by depositing a 1500\text{\AA} evaporated Al layer atop 3000\text{\AA} of thermally grown SiO_2 . Both the bare and oxide-patterned Si substrates received a 2 min dilute hydrofluoric acid preclean prior to deposit, followed by a deionized water rinse and spin dry. The aluminum-coated samples received no pretreatment prior to deposition. Tungsten deposition thickness was determined using β -backscatter and stylus profilometer measurement techniques. The amount of silicon thickness consumed during tungsten deposition was determined by step height measurements and transmission electron microscopy.

The tungsten is deposited according to the following sequence. The substrates are cleaned by a wet chemical pretreatment technique. The loaded reactor tube is evacuated to a base pressure of less than 0.02 torr. The tube is then purged with hydrogen or argon, typically at a flow of 1500 cm^3/min and a system pressure of 0.3 torr. After the substrates reach the desired processing temperature, the chamber is again evacuated and metered flows of the processing gases are introduced into the chamber. Steady flow and pressure conditions are maintained for the deposition time period, after which the tube is evacuated. Dry nitrogen is used to backfill the chamber to atmospheric pressure. The samples are then cooled and removed.

The chemical vapor deposition of tungsten was performed in a low pressure regime of 0.1-5 torr for a temperature range of 250°-500°C. During the course of our experiments, the gas flow rates of WF_6 , hydrogen, and argon ranged between 20-200, 200-2000, and 200-2000 cm^3/min , respectively. The hydrogen reduction of WF_6 was studied using H_2 and WF_6 gases. Aluminum-coated samples served as the deposition substrates. Deposition times for tungsten on aluminum ranged from 1 to 180 min. The silicon reduction of WF_6 was examined using a hydrogen-free mixture of WF_6 and argon gases. The deposition substrates were either bare or oxide-patterned monosilicon wafers. Deposition times for tungsten on silicon ranged from 0.1 to 90 min.

Results and Discussion

Hydrogen reduction of WF_6 .—It was observed early in our studies that an adherent tungsten deposition could be readily initiated and sustained on aluminum surfaces. The use of aluminum-coated substrates with WF_6 and H_2 reactant gases enabled us to study uniquely the hydrogen

Fig. 1. Schematic diagram of the tungsten-deposition apparatus

reduction system without any additional complicating effects from WF_6 -silicon interactions.

The deposition rate of tungsten was examined as a function of the substrate temperature between 250° and 500°C. The growth rate of tungsten was found to be constant with respect to time. Arrhenius plots were assembled from the temperature-rate data for several total reaction pressures (Fig. 2). The H_2/WF_6 mass flow ratio was held constant throughout the course of experiments for each total pressure system. The plots display a constant slope throughout the temperature and pressure ranges evaluated, giving evidence of a consistent rate-limiting reaction mechanism. From the Arrhenius plots an activation energy, E_a , of 0.71 eV/atom (69,000 J/mol) was calculated.

A pressure dependence of the tungsten deposition rate is apparent in Fig. 2. This dependence was displayed more clearly by plotting the growth rate as a function of total pressure (Fig. 3) for the same data comprising the previous figure. As mentioned earlier, the H_2/WF_6 molar ratio remained essentially constant throughout these experiments. The deposition rate is seen to display a square root dependence on the total pressure ($R \propto P^{1/2}$).

Further experiments were performed to examine the reaction order of the WF_6 - H_2 system with respect to each individual reactant. A correlation between the deposition rate and changes in the H_2 partial pressure was first obtained. Shown in Fig. 4 is the rate as a function of the H_2 partial pressure component. During these depositions, the WF_6 partial pressure was maintained constant. Data were obtained for substrate temperatures between 270° and 475°C. The growth rate clearly displays a square root dependence on changes in the H_2 partial pressure ($R \propto P_H^{1/2}$). Similarly, the correlation between deposition rate and the WF_6 partial pressure was obtained while maintaining the H_2 partial component constant (Fig. 5). The tungsten growth rate displays no dependence on changes in the WF_6 partial pressure ($R \propto P_{WF_6}^0$). The reaction order for this system with respect to hydrogen and tungsten hexafluoride was thus determined to be one-half and zero, respectively, under the stated conditions.

Both the temperature and pressure dependence of the reaction rate suggest H_2 dissociation as the rate-limiting surface mechanism. The calculated activation energy (0.71 eV/atom) from the data represented in Fig. 2 is in close agreement with the reported value of 67,000 J/mol (0.69 eV/atom) for H_2 surface diffusion on tungsten (16, 17). According to Cheung (14), H_2 dissociation is con-

trolled by the jumping of one of the H atoms to a neighboring site. The calculated E_a value is also in excellent agreement with the value of 16,000 cal/mol (0.69 eV/atom)

Fig. 5. Deposition rate as a function of WF_6 partial pressure for several temperatures (WF_6 - H_2 system).

obtained by Holman and Huegel (5) for a surface-controlled WF_6 - H_2 reaction.

The assessed reaction order of the WF_6 - H_2 system with respect to total and partial pressures provides further evidence for H_2 dissociation as the rate-controlling mechanism. Cheung (14) noted that either H_2 dissociation or HF desorption could be consistent rate-limiting processes under certain conditions for the surface-controlled reduction of tungsten hexafluoride. He proposed that the effect of total pressure on the reaction rate would provide the most critical test of the controlling mechanism. For a constant feed-gas composition, the deposition rate should vary as the square root of the total pressure if the rate-limiting mechanism were that of H_2 dissociation. This was indeed the case demonstrated in our experiments (Fig. 3). The square root total pressure dependence of the tungsten growth rate was further deciphered by examination of the rate with respect to individual reactant pressure (Fig. 4 and 5). The reaction orders derived for CVD tungsten formation kinetics indicate that only the rate-limiting kinetic step of H_2 dissociation would yield the observed dependences (13).

Silicon reduction of WF_6 .—The deposition rate of tungsten on silicon was examined for several substrate temperatures using WF_6 and Ar gases. The tungsten growth rate on Si is not linear with respect to time. The reduction reaction between WF_6 and Si proceeds rapidly until a limiting deposit thickness is reached. Once this limiting layer is achieved, no further deposition was observed to take place (Fig. 6). It is to be noted that the limiting deposit thickness was observed within the shortest controllable deposit time of 0.1 min (6s), and that this thickness appears relatively independent of the temperatures examined. The consistent results shown in Fig. 6 were obtained by loading all substrates into a reactor tube cooled to room temperature, and then ramping up to tempera-

Fig. 6. Thickness of tungsten deposit on silicon as a function of deposition time (Ar: WF_6 flow = 10, 1250 cm^3/min total flow, 0.5 torr).

ture with an inert ambient prior to performing the deposition.

The deposition of tungsten resulting from WF_6 -Si reactions occurs at a rate of at least 1000 Å/min until the limiting deposit thickness is reached. Our findings with respect to a limiting deposit thickness of 100-150 Å for the temperature range of 270°-450°C are in accord with the results reported by Melliar-Smith *et al.* (11). They observed a limiting tungsten thickness of 300-400 Å when tungsten hexafluoride was reduced by silicon in an inert atmosphere between 420° and 880°C. Under no conditions did we observe a linear dependence of tungsten deposit thickness on reaction time, as reported by Morosanu and Soltuz (15).

The thickness and physical structure of the deposit layer were found to be extremely dependent upon the initial silicon surface preparation, and hence the native oxide characteristics. Evidence of this is seen in Fig. 7, where the limiting deposit thickness is recorded for two different load/preparation techniques. Substrates receiving either no pretreatment or an inadequate wet chemical cleaning treatment often displayed visible "streaking" across the deposit layer. This streaked appearance is a result of nonuniformities existing in the deposit thickness and surface roughness across a substrate. A very smooth surface is typical of tungsten deposit regions where a limiting thickness of less than a few hundred angstroms has been reached (Fig. 8). These regions appear very specular under optical light inspection. Film regions possessing a greater limiting deposit thickness display an increasing surface roughness, appearing cloudy or milky-white under optical inspection.

Fig. 7. Limiting tungsten deposit on Si as a function of temperature for two deposition loading techniques (Ar: WF_6 flow = 10, 1250 cm^3/min total flow, 0.5 torr, 10 min deposit time).

Fig. 8. SEM micrographs showing surface roughness for a limiting tungsten deposit of (a, top) 120 Å and (b, bottom) 800 Å.

The surface roughness of the deposited-tungsten layer was found to correlate with the tungsten-to-silicon interface roughness. Cross-sectional profiles of the W-to-Si interface were obtained using a stylus profilometer after removing the deposited layer in a solution of hydrogen peroxide. Thin deposits display both a very smooth W surface and a very even W-to-Si interface profile. Deposits that possess a greater limiting deposit thickness display an extreme W surface roughness ($\approx 400\text{-}800\text{Å}$) and a very uneven W-to-Si interface (Fig. 9). These observations were also confirmed using transmission electron microscopy (TEM) analysis of several prepared cross-sectional sample specimens (18).

No evidence of continued WF_6 -Si reactions exists after a limiting deposit layer is formed. The data of Fig. 6 do not suggest a diffusion-controlled transport mechanism of WF_6 through the deposit layer to the W-Si interface exists after the initial reaction stage. Scanning transmission

Fig. 9. Profile cross section of the exposed W-to-Si interface for a limiting deposit of (a) 120 Å and (b) 800 Å, after removal of tungsten material.

electron microscopy/energy dispersive x-ray analysis (STEM/EDX) and electron diffraction analysis of deposits obtained at 300° and 425°C show the tungsten films to be comprised of monocrystalline W grains, containing no large (> 1 atom percent [a/o]) amounts of Si. An abrupt interface exists between the tungsten grain structure and the silicon lattice. At higher processing temperatures, the underlying silicon can be expected to react with tungsten in the formation of WSi_2 . WF_6 species will react only with exposed regions of silicon until a continuous tungsten product layer is formed.

It can be argued that a more homogeneous rate of reaction between WF_6 and Si across a surface would result in a continuous limiting layer being formed with a minimal amount of silicon consumption. The presence of an oxide layer on the silicon surface can act as a barrier to the WF_6 -Si reaction. Where nonuniformities in the thickness and structure (e.g., pinhole density) of the oxide occur, the reaction will first initiate at preferred sites where the WF_6 can penetrate the barrier. Lateral tungsten growth from locally adjacent sites contributes to the formation of a continuous layer. As the density and uniformity of reaction sites increases, a continuous product layer is formed earlier, the resultant W-Si interface is more even and less consumption of silicon is required to yield the passivating layer. Where silicon surfaces have been exposed to higher temperatures in the presence of an oxidizing ambient, limiting deposits possessing both a greater thickness (Fig. 7) and a greater W-to-Si interface roughness (Fig. 9b) have resulted. As the thickness of the initial surface oxide layer continues to increase, discontinuous layers of islandlike growths, as well as no tungsten growth at all, were observed.

The thickness of silicon consumed during deposit was measured for the sample group prepared at 300°C using a number of deposit times. The ratio of silicon depth consumed to tungsten thickness deposited was observed to be approximately 2:1. Considering the stoichiometry of the WF_6 -Si reaction, calculations predict that 1.9 Å of silicon would be consumed for each 1 Å of tungsten deposited. This corresponds well to our observed 2:1 ratio.

Growth sequence on Si in presence of hydrogen.—A problem arises in using only the silicon reduction of WF_6 to perform depositions on silicon because only a limiting tungsten layer is achievable. Thus, if controllable deposition thicknesses of greater than several hundred angstroms are desired with minimal Si consumption, it becomes necessary to use both the silicon and hydrogen reduction reactions to result in thicker deposit layers. On the basis of separate examination of the reaction mechanisms of the WF_6 -Si and WF_6 - H_2 systems, a model was proposed and verified for the growth sequence that occurs on silicon in the presence of both WF_6 and hydrogen.

Examination of the growth sequence on silicon substrates suggests the following steps result (Fig. 10). The precleaned substrates are introduced into the reactor, and a deposition cycle is accomplished in which both WF_6 and H_2 gases are present. The exposed regions of silicon rapidly react with and reduce WF_6 , yielding a thin limiting

Fig. 10. Sequence of selective growth on Si in presence of hydrogen

tungsten deposit. As this reaction involves direct Si consumption, the ensuing growth and deposit occurs internal to the original silicon bulk structure. Once continuous, however, the limiting deposit layer passivates the WF_6 -Si reaction and provides an initiatory metal layer now capable of sustaining hydrogen dissociation. As dissociation occurs, the WF_6 - H_2 reaction results in additional amounts of tungsten deposit at a constant growth rate. This phase of growth thus continues until the desired final deposit thickness is achieved. To verify the existence of a two-stage growth sequence, tungsten films were deposited at lower substrate temperatures of 270°, 300°, 325°, and 350°C onto silicon substrates in the presence of WF_6 and H_2 . Thickness measurements performed after various deposit times demonstrate clearly the occurrence of a two-stage growth sequence (Fig. 11).

Selective deposition.—Tungsten was deposited on a number of additional samples prepared by patterning various materials on silicon substrates. These samples provided information as to the selective nature of low pressure CVD of tungsten. In the presence of tungsten hexafluoride and argon, selective limiting deposits of tungsten were observed on both monocrystalline and polycrystalline silicon surfaces within the entire temperature and pressure ranges examined. These areas of exposed silicon were immediately adjacent to areas of both silicon dioxide and silicon nitride on the substrate. Rutherford backscattering (RBS) analysis resolved the amount of residue accrued on such adjacent dielectric surfaces to be much less than one atomic monolayer (10^{15} atom/cm²) of tungsten, while also confirming the absence of tungsten within the bulk material. The surface of the quartz reaction chamber and substrate holder remain visibly free of any tungsten deposit when using WF_6 and Ar gases only, even after many hours of accumulated processing time.

In the presence of tungsten hexafluoride and hydrogen, selective deposition was observed to be dependent upon temperature, the local chemical composition of the surface, and surface cleanliness. As discussed previously, the initiation of a tungsten deposit on a particular material depends on the ability of this material to either (i) re-

duce directly the hexafluoride species, as in the case of silicon, or (ii) yield monatomic hydrogen. Certain materials act as nucleating surfaces throughout the entire 250°-500°C temperature range examined. Other materials, however, such as silicon dioxide, were seen to be both nucleating and non-nucleating, depending on the specific preparation of the oxide layer and conditions of the deposit. In general, increasing temperature leads to a loss of selectivity and deposition results on all materials present. Surface cleanliness also plays a role in the selective nature of the deposition, as contamination can locally retard or enhance the ability of a surface to initiate a deposit.

Cuomo and Laff (19) reported the ability to selectively deposit tungsten onto certain desired nucleating surfaces by chemically ablating the remaining portions of the substrate surface area. Such ablation is a consequence of attack by either the hexafluoride metal compound or hydrogen fluoride by-product, and is facilitated by high vapor concentrations as well as high reactor temperatures. Using low pressure CVD of tungsten, an ablative mechanism is not required in order to achieve selective deposition. Typically, for pressures below 1 torr, less than 20Å of SiO_2 is eroded in depositing 2000Å of tungsten selectively. The specific mechanism for selective deposition using low temperature-low pressure CVD techniques appears directly linked to free silicon and hydrogen surface interactions, and remains the focus of continuing studies.

Conclusions

The lower temperature-pressure conditions examined in the chemical vapor deposition of tungsten yield surface-controlled reactions for both the hydrogen and silicon reduction of WF_6 . The rate-limiting mechanism in the WF_6 - H_2 system was found to be the dissociation of hydrogen on the substrate. An activation energy of 0.71 eV/atom (69,000 J/mol) was found for this reaction. The deposition rate displays a square root dependence on the H_2 partial pressure. Observed deposition rates range from 10 to 3500 Å/min.

For the WF_6 -Si system, limited deposits of a controlled thickness (100-150Å) were formed on monocrystalline Si at all temperatures examined. The resultant surface roughness and film thickness are dependent upon native oxide characteristics, and hence the Si surface preparation. In the presence of hydrogen, a two-stage tungsten growth sequence occurs on silicon. Within a patterned substrate, an ablation mechanism is not necessary for selective deposition, as less than 20Å of SiO_2 is eroded in depositing 2000Å of tungsten.

Acknowledgments

Special acknowledgment is given to E. van de Ven for suggesting this topic and for his support throughout the experimental work. The authors wish to thank C. Vorst, G. de Groot, and S. Turner for sample preparation; and G. Delgado for experimental assistance. Appreciation is expressed to W. Stacy for the TEM, STEM/EDX, and electron diffraction analyses; and Y. Tamminga for the RBS analyses. Helpful discussions with E. Sabin are also acknowledged.

Modeling of Sulfur Incorporation during Low Pressure CVD of GaAs (100) in the Ga-HCl-AsH₃-H₂-H₂S System

J. Korec, D. Grundmann, and M. Heyen

Institute of Semiconductor Electronics, Technical University Aachen, D-5100 Aachen, Germany

ABSTRACT

An extension is presented of an earlier model of the epitaxial growth of GaAs (100) under reduced pressure to include sulfur incorporation. In describing the growth of doped crystals, the dopant is treated in the same manner as the lattice components. Its incorporation flux is obtained from a dynamic balance between diffusion of the gaseous reactants towards the substrate and a sequence of surface processes. In the case of sulfur doping, the process is described as first leading to the formation of GaS which subsequently yields a regular solution GaAs_{1-x}S_x. The molar ratio x is determined by the ratio of the incorporation flux of the dopant and the growth rate of GaAs. Model calculations show quantitative agreement with the experimental data for the Ga-HCl-AsH₃-H₂-H₂S system at various H₂ pressures.

Reduction of the total pressure in the deposition system leads to improved uniformity of the thickness and dopant concentration of epitaxial films. For this reason, the low pressure technique has gained considerable importance in the technology of semiconductor devices.

The growth and doping of GaAs deposited under reduced H₂ pressures have been the subjects of recent investigations in our laboratory (1, 2). The topic of the present study is the analysis of the kinetics of the dopant incorporation for the case of the Ga-HCl-AsH₃-H₂-H₂S system at low H₂ pressures. As in the modeling of the growth process, a description of dopant incorporation requires taking into account the complete series of kinetic steps of diffusion in the gas-phase, adsorption, chemical reaction, and surface diffusion (3). To this end we will extend the model of GaAs growth on (100) surfaces for atmospheric (4) and reduced total pressures (5) to include sulfur incorporation. The model considerations will be focused on the experimental results published by Veuhoff *et al.* (2).

Model of Dopant Incorporation

Following Stringfellow (6), the sulfur incorporation in GaAs will be treated as the formation of GaS and its dissolution into GaAs to give a regular solution GaAs_{1-x}S_x. The diffusion of H₂S through the gas phase towards the growth surface should obey the mass-balance equation for sulfur atoms

$$k_{d,H_2S} (p_{H_2S}^0 - p_{H_2S}) = J_{GaS} \quad [1]$$

with

$$k_{d,H_2S} = \left(\frac{D_{0,H_2S}}{D_{0,HCl}} \right)^{2/3} k_{d,HCl} \sqrt{\frac{V}{P}} \quad [2]$$

where k_{d,H_2S} is the mass-transfer coefficient, $p_{H_2S}^0$ the input

Key words: doping, gas phase epitaxy, growth kinetics.

partial pressure of H₂S, p_{H_2S} the H₂S pressure near the substrate surface, J_{GaS} the formation flux of the GaS in the solid mixture, D_{0,H_2S} and $D_{0,HCl}$ the gas-phase diffusion coefficients for H₂S and HCl in H₂ at 273 K, V the linear gas velocity, and P the total pressure. We will put the latter quantity equal to the H₂ pressure in the reactor. The ratio of D_{0,H_2S} and $D_{0,HCl}$ is estimated to be 1.057; the value of $k_{d,HCl}^0$ is known from our growth calculations to be $7 \cdot 10^4 \mu\text{m h}^{-1} \text{bar}^{-1}$ (5).

The mass transport in the gas phase is followed by adsorption of the species and chemical reaction at the substrate surface

where v denotes a surface site of the arsenic sublattice; these adsorption sites were assumed to be the same in the doping and growth processes (4). Reaction [7] includes a surface diffusion step. However, in the growth model, the effect of surface diffusion was neglected for the (100) substrate orientation, and the same will be done here. The rate-limiting step on the surface is assumed to be reaction [5] leading to formation of GaS. Following the earlier study (3), the rate of this reaction is described in terms of the activated complex theory

$$J_{GaS} = \sigma \cdot \mathcal{H} \cdot \frac{k \cdot T}{h} \cdot z^* (\lambda_{\text{GaCl}(ad)} \cdot \lambda_{\text{H}_2\text{S}(ad)} - \lambda_{\text{GaS}(ad)} \cdot \lambda_{\text{HCl}} \cdot \lambda_{\text{H}} \cdot \lambda_v) \quad [8]$$

where σ is the thickness of the absorbed layer, \mathcal{H} the transmission coefficient, k Boltzmann's constant, T the

substrate temperature, h Planck's constant, z^* the partition function of the activated complex $\text{GaCl}\cdot\text{H}_2\text{S}^*_{(\text{ad})}$, and λ_i the absolute activity of the species i .

Assuming the equilibrium state for the reactions [3], [4], [6], and [7], we obtain (see Appendix)

$$\lambda_{\text{GaCl}(\text{ad})} = \lambda_{\text{GaCl}} \cdot \lambda_v \quad [9]$$

$$\lambda_{\text{H}_2\text{S}(\text{ad})} = \lambda_{\text{H}_2\text{S}} \cdot \lambda_v \quad [10]$$

$$\lambda_{\text{H}} = \lambda_{\text{H}_2}^{1/2} \quad [11]$$

$$\lambda_{\text{GaS}(\text{ad})} = \lambda_{\text{GaS}(\text{s})} \cdot \lambda_v \quad [12]$$

By expressing the absolute activities λ_i in terms of the absolute activities in the standard state λ_i° and activities of the species i , we can rearrange Eq. [8] to the form

$$J_{\text{GaS}} = C \cdot \theta_v^2 (P_{\text{GaCl}} \cdot p_{\text{H}_2\text{S}} - a_{\text{GaS}(\text{s})} P_{\text{HCl}} P_{\text{H}_2}^{1/2}/K) \quad [13]$$

with

$$C = \sigma \cdot \mathcal{K} \frac{k \cdot T}{h} z^* \cdot \lambda_{\text{GaCl}}^\circ \cdot \lambda_{\text{H}_2\text{S}}^\circ (\lambda_v^\circ)^2 \quad [14]$$

Since at typical H_2S pressures, the effect of S containing species on the fraction of free adsorption sites θ_v is negligible, we will use the value of θ_v calculated from the growth model in absence of H_2S (4). The equilibrium constant K in Eq. [13] is the equilibrium constant of the overall reaction, which may be obtained by addition of the reactions [3] through [7]

The activity $a_{\text{GaS}(\text{s})}$ appearing in Eq. [13] can be expressed in the form

$$a_{\text{GaS}(\text{s})} = x_{(\text{s})} \exp \left[\frac{(1 - x_{(\text{s})})^2 E}{k \cdot T} \right] \quad [16]$$

where $x_{(\text{s})}$ is the molar ratio of GaS incorporated in the solid at the semiconductor surface and E the interaction energy between GaAs and GaS. Taking into account that the molar ratio x has values between 10^{-6} and 10^{-3} , we see that the activity of the GaAs phase remains close to unity also in doped samples and simplify Eq. [16] to

$$a_{\text{GaS}(\text{s})} = x_{(\text{s})} \exp \left(\frac{E}{kT} \right) \quad [17]$$

The flux J_{GaS} discussed above (Eq. [13]) describes the incorporation of neutral S atoms into the substrate surface. In a next step, they are ionized, possibly after being covered by the next grown monolayer

As one can expect, different binding energies of dopant atoms near the surface and in the bulk of the crystal, the concentration of ionized S atoms in the volume $[\text{S}^+_{(\text{b})}]$ can differ from that at the surface $[\text{S}^+_{(\text{s})}]$. At given growth conditions, the volume concentration should be adjusted accordingly

$$\text{S}^+_{(\text{s})} \rightleftharpoons \text{S}^+_{(\text{b})} \quad [19]$$

If the total process of S uptake takes place at near equilibrium conditions, one could expect for $[\text{S}^+_{(\text{b})}] < n_i$

$$[\text{S}^+_{(\text{b})}]_{\text{eq}} \sim \frac{p_{\text{H}_2\text{S}}}{n_i} \quad [20]$$

and for $[\text{S}^+_{(\text{b})}] = n < n_i$

$$[\text{S}^+_{(\text{b})}]_{\text{eq}} \sim p^{1/2}_{\text{H}_2\text{S}} \quad [21]$$

where n_i is the intrinsic electron concentration at growth temperature ($5 \times 10^{16} \text{ cm}^{-3}$ at 1000 K). However, it was observed that the carrier concentration depends linearly on the H_2S pressure for sulfur concentrations corresponding to the entire accessible range of electron concentrations, namely, up to $3 \times 10^{18} \text{ cm}^{-3}$ (7). Hurle (8) explained this apparent discrepancy by postulating the existence of a high concentration of donor-type As vacancies fixing the

Fermi level at growth temperature for all sulfur concentrations. However, Veuhoff *et al.* (9) could show that the sulfur uptake continues linearly beyond the saturation level of the electron concentration, namely, up to approximately $5 \times 10^{19} \text{ cm}^{-3}$. It seems unlikely that the vacancies in a CVD-grown material could reach concentrations as great as 10^{20} cm^{-3} .

A second possible explanation was given by Zschauer and Vogel (10) and Casey and Panish (11) for LPE of GaAs. These authors postulate a pinning of the Fermi level at the surface due to a large density of acceptor-like surface states. Following this hypothesis, the linear uptake of the dopant can be explained provided that the growth rate is higher than the rate of exchange of dopant atoms between the surface region and the volume of the film. Assuming that in this case equilibrium exists between the gas phase and the substrate surface one obtains

$$[\text{S}^+_{(\text{b})}] = [\text{S}^+_{(\text{s})}]_{\text{eq}} \sim \frac{P_{\text{H}_2\text{S}}}{n_{(\text{s})}} \quad [22]$$

where the surface electron concentration $n_{(\text{s})}$ does not depend on the doping level. It has been observed in UHV experiments at room temperature that the adsorption of hydrogen atoms on clean n-type (110) GaAs causes acceptor-like defects which lead to a depletion of the surface (12). However, it should be mentioned that there is no direct experimental evidence for the pinning of the Fermi level under growth conditions.

The same qualitative results concerning the doping in CVD systems can be obtained by simply assuming different binding energies for neutral dopant atoms at the interface and in the volume of the semiconductor. Also in this case, for growth rates larger than some critical value, the dopant atoms incorporated in the surface are trapped by the growing layer. At smaller growth rates, the trapped dopant atoms have the possibility of adjusting their concentration in the volume in accordance to the constraints of equilibrium thermodynamics. For all cases mentioned above, the molar ratio of dopant in the volume $x_{(\text{b})}$ will be adjusted to the surface conditions ($x_{(\text{s})}$); the level of adjustment is determined by the ratio of diffusion rate and the rate of motion of the growing surface (13)

$$k_r = \frac{x_{(\text{b})}}{x_{(\text{s})}} = k_{\text{eq}} + (1 - k_{\text{eq}}) \exp(-r_c/r) \quad [23]$$

with

$$k_{\text{eq}} = \left(\frac{x_{(\text{b})}}{x_{(\text{s})}} \right)_{\text{eq}} \quad [24]$$

$$r_c = D_s/d \quad [25]$$

$$r = \Omega_{\text{GaAs}} J_{\text{GaAs}} \quad [26]$$

where k_{eq} is the equilibrium value of the distribution coefficient k_r , r_c is the critical growth rate determined by the ratio of the diffusion coefficient of sulfur D_s in GaAs and the width of the region over which the dopant gradient at the interface extends, and r is the actual growth rate related to J_{GaAs} by the molecular volume of GaAs in the solid Ω_{GaAs} .

Consideration of dopant redistribution in the solid requires an estimation of two parameters, k_{eq} and r_c . The values of these parameters can differ for the various models discussed above, but the formal description on this phenomena by Eq [23]-[26] should remain valid.

An immediate consequence of the mass balance for sulfur atoms, is that the net diffusion flux of sulfur containing species in the gas phase (Eq. [1]) equals the incorporation flux of GaS (Eq. [13]). The molar fraction of GaS incorporated in the bulk of the growing film is given by

$$x_{(\text{b})} = \frac{J_{\text{GaS}}}{J_{\text{GaS}} + J_{\text{GaAs}}} \approx \frac{J_{\text{GaS}}}{J_{\text{GaAs}}} \quad [27]$$

Introducing Eq. [13], [17] and [23] in Eq. [27] yields

$$x_{(\text{b})} = \frac{C \theta_v^2}{J_{\text{GaAs}}} (p_{\text{GaCl}} p_{\text{H}_2\text{S}} - x_{(\text{b})} p_{\text{HCl}} p_{\text{H}_2}^{1/2} K_{\text{eq}}/k_r) \quad [28]$$

with

$$K_{eq} = \exp(E/kT)/K \quad [29]$$

For p_{H_2S} follows from Eq. [1] and [27]

$$p_{H_2S} = p^{\circ}_{H_2S} - x_{(b)}J_{GaAs}/k_{d,H_2S} \quad [30]$$

Substituting p_{H_2S} in Eq. [28] using Eq. [30], we obtain

$$x_{(b)} = \frac{p^{\circ}_{H_2S}}{J_{GaAs} \left(\frac{1}{C\theta_v^2 p_{GaCl}} + \frac{1}{k_{d,H_2S}} \right) + \frac{K_{eq} p_{HCl} p^{1/2}_{H_2}}{k_r p_{GaCl}}} \quad [31]$$

Assuming negligible effect of the doping process on the mass transport balances for GaCl, HCl, and H_2 and on the surface coverage factors for adsorbed species resulting from the growth of GaAs (because $p^{\circ}_{H_2S} \ll p^{\circ}_{HCl}, p^{\circ}_{AsH_3}$), the quantities J_{GaAs} , θ_v , p_{GaCl} , p_{HCl} , and p_{H_2} (Eq. [31]) can be taken from the growth calculations (4, 5). Thus, after estimating the factors C , K_{eq} , r_c and k_{eq} , we can use Eq [31], [2], and [23] to calculate the dependence of the molar ratio $x_{(b)}$ on such technological parameters as $p^{\circ}_{H_2S}$, T , V , P , p°_{HCl} , and $p^{\circ}_{AsH_3}$.

In order to determine the contribution of the different process steps to the overall kinetics of dopant incorporation, we rewrite Eq. [31] as follows

$$x_{(b)} = \frac{p^{\circ}_{H_2S}}{A \cdot r + B \cdot r + E/k_r} \quad [32]$$

where

$$A = 1/(\Omega_{GaAs} i k_{d,H_2S}) \quad [33]$$

$$B = 1/(\Omega_{GaAs} \cdot C\theta_v^2 \cdot p_{GaCl}) \quad [34]$$

$$E = p_{HCl} \cdot p^{1/2}_{H_2} K_{eq}/p_{GaCl} \quad [35]$$

The terms $A \cdot r$, $B \cdot r$, and E/k_r appearing in Eq. [32] represent the contributions of the three limiting factors discussed above: mass transport in the gas phase, kinetics of the surface reactions, and thermodynamics of the incorporation reaction. The largest term is the "bottle neck" factor which dominates and controls the rate of the incorporation process.

Equation [32] implies three possible regimes of control of the dopant-incorporation process. The first one appears when the dopant incorporation is governed by the thermodynamics of the overall reaction [15], so that

$$x_{(b)} = k_r p^{\circ}_{H_2S}/E \quad [36]$$

This situation arises when the kinetic barriers presented by the mass transport in the gas phase and by the surface process have no significant effect on the kinetics of the overall process, e.g., at high deposition temperatures and low total pressures, and/or low growth rates of the host material. It can be seen that only under conditions of thermodynamic control can the process of dopant incorporation be affected by the variable distribution coefficient k_r .

The dependence of the actual distribution coefficient k_r (Eq. [23]) on the growth rate r is shown in the Fig. 1. At low growth rates ($r < 0.1r_c$), the dopant incorporation takes place in equilibrium with the bulk of the solid and the actual distribution coefficient k_r equaling its equilibrium value k_{eq} . This value can be determined from the equilibrium state of the overall reaction

with

$$[GaS^+_{(b)}] = \frac{p_{H_2S} p_{GaCl}}{n_{(b)} p_{HCl} p^{1/2}_{H_2}} \cdot K' \quad [38]$$

From a comparison of Eq. [38] with Eq [35] and [36] follows

$$(k_r)_r < 0.1r_c = k_{eq} = \frac{K_{eq} K'}{n_{(b)} [GaAs]} \quad [39]$$

In the case of extrinsic conditions ($n_i < [GaS^+_{(b)}] = n_{(b)}$) the

Fig. 1. Calculated dependence of distribution coefficient on growth rate of film r . r_c is critical value of the growth rate. $k_{eq} = 0.1$.

equilibrium-distribution coefficient (Eq. [39]) depends on the dopant concentration in the bulk of the film

$$k_{eq} = k^{\circ}_{eq}/x_{(b)} \quad [40]$$

Introducing Eq. [40] in Eq. [36], we obtain the square root dependence expected for the conditions of thermodynamic equilibrium

$$x_{(b)} = \left(\frac{k^{\circ}_{eq} p^{\circ}_{H_2S}}{E} \right)^{1/2} \quad [41]$$

At higher growth rates ($k_r \approx 1$), the equilibrium can only exist between gas phase and surface of the growing film, and the doping kinetics shows a linear dependence on $p^{\circ}_{H_2S}$ (Eq. [36]). Upon further increase of the growth rate, the dopant incorporation will be controlled by one of the kinetic barriers present in the system, that is, mass transport in the gas phase

$$x_{(b)} = p^{\circ}_{H_2S}/A \cdot r \quad [42]$$

or kinetics of reaction [5]

$$x_{(b)} = p^{\circ}_{H_2S}/B \cdot r \quad [43]$$

The diffusive control (Eq. [42]) should be particularly observed at atmospheric pressure, and the kinetic type of the dopant-incorporation control (Eq. [43]) should make itself particularly felt at low pressures and low deposition temperatures.

Comparison with Experiments

The above model was used to describe the experimental data by Veuhoff *et al.* (2). The concentration of the dopant incorporated in the GaAs film was assumed to be equal to the measured electron concentration. Since the data were obtained for a substrate temperature of 1023 K, the values of the model parameters were estimated for this particular substrate temperature only.

The calculated values appear to depend only weakly on the values of r_c and k°_{eq} (Eq. [23] and [40]), but are strongly affected by the values of C and K_{eq} (Eq. [31]). The experimental data could be reasonably reproduced if the values of $5 \mu\text{m/h}$ and 2×10^{-7} were chosen for r_c and k°_{eq} , respectively. Such values would pertain, if pinning of the Fermi level would occur (11). However, as mentioned before, there is no experimental proof that this model is correct. The numerical fitting of the calculated electron concentration to the data presented in Fig. 2 allowed us to determine the values of the factors C and K_{eq} at 1023 K to be $1.5 \times 10^8 \mu\text{m h}^{-1} \text{bar}^{-2}$ and $0.07 \text{bar}^{1/2}$, respectively. These values of the model parameters were used in all subsequent calculations performed in this study.

In Fig. 3, the terms $A \cdot r$, $B \cdot r$, and E/k_r are plotted as functions of the HCl input pressure for the experimental conditions from Fig. 2. It may be seen that the mass transport in the gas phase (term $A \cdot r$) does not present a

Fig. 2. Dependence of electron concentration resulting from sulfur doping on input HCl pressure ($p_{\text{HCl}}^0 = p_{\text{GaCl}}^0$). Curve: fit to Eq. [31]. Experimental points: Ref. (2).

Fig. 3. Dependence of terms in Eq. [32] on input HCl pressure for experimental conditions of Fig. 2.

significant kinetic barrier at low total pressure. Since A does not depend on p_{HCl} , the plot of $A \cdot r$ against p_{HCl}^0 represents the behavior of the deposition rate of GaAs (5), which is roughly constant and amounts $6 \pm 1.5 \mu\text{m/h}$. This growth rate is comparable to the assumed critical growth rate of $5 \mu\text{m/h}$, which implies that $k_r = 0.45 \pm 0.1$. The equilibrium value of $k_r(k_{\text{eq}})$ would be 0.01 for a dopant concentration of 10^{18} cm^{-3} . This means that for thermodynamic control, as obtained for low HCl input pressures (i.e., $<10^{-2}$ bar), under the assumption of this model, the growing film would incorporate about fifty times more dopant atoms than would be obtained if equilibrium with the bulk of the semiconductor would pertain, but about half of the concentration expected for a complete freeze-in of the surface concentration. However, the redistribution effect does not play any role at high input HCl pressures ($>10^{-2}$ bar), where the dopant incorporation process is governed by the kinetics of the surface reactions [3]-[5]. At these conditions, the surface adsorption sites are blocked by the species taking part in the GaAs deposition process, which suppresses the supply of H_2S to the surface.

A comparison of the calculated electron-concentration dependence on the H_2 input pressure with the experimental results is presented in Fig. 4. The corresponding behavior of the terms $A \cdot r$, $B \cdot r$, and E/k_r is plotted in Fig. 5a. For the entire range of the experimental conditions used here, the dopant incorporation process appears to be controlled by the thermodynamics of the incorporation reactions [5]-[7] (term E/k_r). The increase of the H_2 pressure causes an almost linear increase of the GaAs growth rate from $1 \mu\text{m/h}$ at 0.02 bar to $27 \mu\text{m}$ at 0.64 bar. The critical growth rate r_c is reached at about 0.1 bar causing a strong modulation of the thermodynamic term E/k_r by the trapping effect (Fig. 1) in this pressure range. The dependences of the terms A , B , and E on the H_2 pressure are plotted in Fig. 5b. Comparing Fig. 5a and 5b we can see the strong influence of the trapping effect on the behavior of the thermodynamic term E/k_r .

The decrease of the growth rate below the critical value, around a H_2 pressure of 0.1 bar, causes extension of the equilibrium between gas phase and interface into the volume of the solid; the effect of trapping is reduced and the value of k_r decreases with decreasing growth rate. Under these conditions, the dopant uptake does not increase by further lowering $p_{\text{H}_2}^0$. This behavior is indeed observed experimentally. The expected decrease and saturation of the electron concentration at lower H_2 pressures (lower GaAs growth rates) needs further experimental investigation.

The experimentally observed linear dependence of the electron concentration on the input H_2S pressure is obtained also in model calculations, as shown in Fig. 6. The incorporation kinetics appears to be controlled by the equilibrium of reactions [5]-[7]. At the growth rates used in this experiment, $3.5 \mu\text{m/h}$ at total pressure of 0.065 bar and $15.5 \mu\text{m/h}$ at 0.33 bar, the equilibrium state is shifted to the surface conditions and the function k_r has a nearly constant value.

It was experimentally observed that the linear uptake of S atoms from the gas phase continues beyond the saturation value of the electron density appearing in Fig. 6 (9). However, also for the dopant uptake a saturation limit at $5 \times 10^{19} \text{ cm}^{-3}$ was found, which is not considered in our model. For such a high dopant concentration, the regular solution model assumed here loses its validity.

It should be interesting to study this dependence at low GaAs growth rates, where the calculations indicate a sublinear dependence of the dopant concentration in the film on the vapor pressure of H_2S . Thus, at low growth rates (as compared to the critical value) and under equilibrium conditions, the dopant incorporation should take place in equilibrium with the bulk of the semiconductor, and the dependence of $x_{(b)}$ on $p_{\text{H}_2\text{S}}^0$ should approach the square root relationship of Eq. [41].

Conclusions

The method of modeling the CVD processes proposed in an earlier paper (3) can be successfully adopted to describe the incorporation of dopants. Depending on the experimental conditions, the sulfur uptake during the epitaxial growth of GaAs on (100)-oriented substrates in a halide transport system is controlled by the kinetics of the surface reactions [3]-[5] or by the thermodynamics of the dopant incorporation [5]-[7]. The growth rate of the host material is one of the major parameters governing the incorporation process. A reduction of the total pressure in the Tietjen system causes a shift of the deposition conditions from thermodynamics to kinetic control (Fig. 5b) which is well known for the CVD of GaAs. However, the simultaneous decrease of the growth rate of the host material allows the dopant atoms to reach equilibrium concentrations, first at the surface, and next at very low growth rates, within the bulk of the deposited semiconductor film (Fig. 5a). The agreement between model calculations and experimental data may be considered to be an indication of the effect of the redistribution of dopant atoms between the interface and the bulk of the film.

APPENDIX

Description of Adsorption Reaction in Terms of Absolute Activities

Following the discussion published earlier (3), we proposed to describe an adsorption reaction of the type

in terms of activities of participating species, as commonly done in the description of the kinetics of homogeneous chemical reactions (14). The absolute activity λ_i of a species i is defined as

$$\lambda_i = \exp(\mu_i/kT) \quad [A-2]$$

where μ_i is the chemical potential (Gibbs free energy per molecule). Introducing a standard state for species i , one can express the absolute activity λ_i by means of an activity a_i of this species

$$\lambda_i = \lambda_i^\circ \cdot a_i \quad [A-3]$$

The absolute activity of the species i in the standard state λ_i° can be calculated using the method of statistical thermodynamics (3, 14). For an ideal gas, the activity a_i of species i in the gas phase is

$$a_i = \frac{p_i}{P^\circ} \quad [A-4]$$

where P° is the standard pressure (10⁵ Pa). The activity of an adsorbed species i has been proposed to be defined as (3)

$$a_{i(ad)} = \theta_i = C_{i(ad)}/C_s^\circ \quad [A-5]$$

where θ_i is the surface-coverage factor, $C_{i(ad)}$ the concentration of species i adsorbed at the surface, and C_s° the concentration of surface sites available for adsorption.

The condition for equilibrium state of reaction [A-1] can be expressed as follows

$$\lambda_A \cdot \lambda_v = \lambda_{A(ad)} \quad [A-6]$$

Substituting Eq. [A-3] in [A-6] and considering [A-4] and [A-5], we obtain for the equilibrium constant of the reaction [A-1]

$$K_{A(\text{ad})} = \frac{\lambda_v^{\circ} \lambda_A^{\circ}}{\lambda_{A(\text{ad})}^{\circ}} = \frac{\theta_A}{\theta_v(p_A/P^{\circ})} \quad [\text{A-7}]$$

Technical Notes

The Elimination of Devitrification Defects in Antimony Buried-Layer Diffusions

A. R. Alvarez and F. Pintchovski

Motorola Semiconductor, Incorporated, Mesa, Arizona 85202

Doped silicate glasses are widely used as diffusion sources for buried layers in bipolar technology. Thermal oxide is commonly used as a diffusion mask in these processes. More recently, the use of silicon nitride/silicon dioxide as a diffusion barrier for this application has been reported (1).

During the diffusion of boron, phosphorus, arsenic, and antimony from doped glass sources, a common type of glass damage occurs, devitrification, and this damage propagates into the silicon substrate (2). Devitrification can be defined as a phase transformation in which amorphous silica changes to a crystalline form, either cristoballite or trypidite. In this note, a composite $\text{Si}_3\text{N}_4/\text{SiO}_2$ diffusion mask is described. This mask was found to greatly decrease the levels of devitrification damage induced by antimony diffusions from a doped glass source. The reduction in defect density at buried layer led to improved breakdown characteristics in NPN transistors and a concomitant increase in functional circuit yields.

Experimental

Thermal SiO_2 and $\text{SiO}_2/\text{Si}_3\text{N}_4$ composites were evaluated as diffusion masks for antimony. The thermal oxide was grown in steam at 1200°C to a thickness of 1500 nm. A number of $\text{SiO}_2/\text{Si}_3\text{N}_4$ thickness combinations (Table I) were used. For the composite layer, SiO_2 was steam grown at 1000°C , while the Si_3N_4 was deposited by LPCVD at 780°C using ammonia and dichlorosilane as source gases (Fig. 1). An LPCVD antimony-doped SiO_2 glass was used as a diffusion source (3). Diffusions were carried out at 1250°C in an N_2/O_2 atmosphere.

Defect densities were obtained by averaging measurement taken at five points on a wafer. The measurements were performed using a microscope equipped with Nomarski interference contrast. Each measurement involved defect counting over a 0.0085 cm^2 area. A typical devitrification defect produced during the Sb buried-layer diffusion is shown in Fig. 2. Breakdown measure-

200	20	0-90
200	40	0-40
200	100	0
1500	—	150-400

Buried layer: $\rho_s = 15-17 \Omega/\square$, $X_1 = 9 \mu\text{m}$.

ments of the collector-substrate diode formed in standard junction isolated bipolar integrated circuits were used to evaluate the electrical consequences of the defects.

Results and Discussion

Defect characterization of the Sb buried-layer process using SiO_2 as the diffusion mask indicated a very high defect density. The defect density vs. sheet resistance of the buried layer is plotted in Fig. 3. Microprobe analysis (EDAX) confirmed the presence of Sb at the defect sites in the silicon after glass removal. Examination of p-n

Fig. 1. Schematic representation of test structures: (i) thermal oxide diffusion mask, (ii) $\text{SiO}_2/\text{Si}_3\text{N}_4$ composite diffusion mask.

Fig. 2. Devitrification defect on thermal oxide diffusion mask

junction I-V characteristics verified the electrical activity of the defects. The Sb defects degraded collector-substrate breakdowns (BV_{CSO}) on fully processed NPN transistors. The resultant BV_{CSO} distribution was multimodal, since the breakdown voltage was dependent on the location of the defect (Fig. 4a). A simple heuristic argument is proposed to explain the distribution. Depending on the location of the defect, the avalanche breakdown voltage is determined by dopant concentration or is thickness limited by lateral depletion spread (Fig. 5). In the thickness-limited situation, breakdown is probably degraded further by the asperity of the defects'

configuration. When no defect is present, BV_{CSO} is nominally 200V. If the Sb defect overlaps the isolation diffusion, BV_{CSO} is reduced to approximately 35V. When the defect is located between the normal buried-layer pattern and the isolation diffusion, BV_{CSO} is again degraded, 110V being the dominant mode in this experiment.

From the defect density data, a first-order yield analysis was performed in order to estimate the effect of defect density on yield. The area subject to Sb defect-induced failure is from the edge of the buried-layer pattern to the center of the isolation pattern. Using this definition of "active" area, the yield model

$$\text{Yield} = \exp(-DA) \quad [1]$$

where D = effective defect density and A = critical area, was fitted to existing data. Equation [1] does not take into account defect clustering or a nonrandom distribution of defects across a wafer. Even so, it correlated well with observed yields, confirming devitrification as a dominant failure mode in the particular class of circuits studied.

Devitrification of SiO_2 during Sb and As diffusions is well documented (3, 4). It was felt that the suppression of SiO_2 devitrification would greatly reduce the defect density at the buried layer. During the course of experimentation, it was observed that besides being an effective diffusion barrier, an SiO_2/Si_3N_4 composite eliminated the devitrification problem. Defect density data vs. composite mask structure is given in Table I. Devitrification defects were not observed for nitride thicknesses greater than 100 nm. It follows that the devitrification-defect density is independent of the buried-layer sheet rho for nitride thicknesses greater than 100 nm. The composite mask exhibited similar results when a spin-on antimony solution was substituted for the LPCVD predeposition

Fig. 3. Devitrification defect density vs. buried layer sheet resistance.

Fig. 4. Relative frequency vs. breakdown voltage: (A) thermal oxide diffusion mask, (B) SiO_2/Si_3N_4 composite diffusion mask.

Fig. 5. Electric field vs. distance with and without devitrification defect

(5). An additional benefit of the composite is the elimination of the very long oxidation process previously required when an oxide mask alone was used.

Because of the reduction in defect density at the buried-layer step, utilization of the composite mask resulted in higher yields to the BV_{CSO} test. Breakdown data for NPN transistors processed with the composite mask exhibited a single mode centered at 190V (Fig. 4b).

Conclusion

An SiO_2/Si_3N_4 composite was found to essentially eliminate devitrification defects commonly associated with oxide-masked antimony buried-layer diffusions. The reduction in defect density significantly increased the yield of NPN transistors with 200V BV_{CSO} . The composite mask makes it possible to fabricate low sheet rho Sb buried layers with negligible yield loss due to diffusion-mask devitrification.

Improved Techniques for Orientation of (100) InP and GaAs Wafers

E. A. Caridi and T. Y. Chang

AT&T Bell Laboratories, Holmdel, New Jersey 07733

The distinction between $[011]$ and $[0\bar{1}\bar{1}]$ directions on (100) InP and GaAs substrates is often of crucial importance in epitaxial growth and device fabrication. In molecular beam epitaxy (MBE), the interpretation of the reflection high energy electron diffraction (RHEED) pattern depends on along which of these two directions the electron beam is directed (1). For the fabrication of various stripe geometry lasers (2) and etched mirror lasers (3), the identification of these two directions is essential since their etching properties are very different. The properties of FET's fabricated on (100) substrates have also been found to be orientation dependent due to the piezoelectric effect (4). It has been common practice to identify the $[011]$ and $[0\bar{1}\bar{1}]$ directions by patterning and etching mesas or orthogonal grooves on the substrate followed by an inspection of the cleaved cross section (5). This procedure is both tedious and wasteful of material. Recently, a simpler method based on the inspection of natural etch patterns on cleaved $\langle 011 \rangle$ surfaces has been introduced (6). This latter method minimizes the waste of material. However, the contrast between different etch patterns is relatively weak and easily confused. We describe in this paper novel techniques that are simple, unambiguous, and applicable to polished and unpolished substrates. By preparing the substrate in a prescribed manner, the orientations can always be ascertained almost instantly without wasting any material.

We find that the orientations on saw cut (100) surfaces of InP wafers can be most effectively revealed by removing 30 μm or more of the material per surface by

free etching in a 1:1:1 mixture of 96% H_2SO_4 :30% H_2O_2 : H_2O (7). Large wafers may be placed in a rack made of inert material (*e.g.*, Ta) and immersed in the solution for treatment. To obtain the desired result, it is essential that the solution be mixed immediately before use. The effectiveness of the mixture diminishes rapidly within a few minutes. For about 400 ml of solution, the temperature will remain at 85° to 90°C due to the exothermic nature of the solution. The appropriate etch time in such a case is 5 min. For treating small test pieces using less than about 200 ml of solution, it is necessary to preheat the beaker and maintain the solution temperature at about 80°C on a hot plate. In this latter case, the appropriate etch time is 20 min. A photomicrograph of the resulting surface is shown in Fig. 1. Greatly elongated parallel etch pits are clearly evident. In the case of a (100) saw cut GaAs surface, etching in a solution of 1:8:8 H_2SO_4 : H_2O_2 : H_2O (8) at a temperature of 55°C for 3 min produced features as shown in Fig. 2. The amount of material removed per surface is about 50 μm .

Similar preferential etching characteristics can be revealed on a polished surface of InP or GaAs. In this case, it becomes necessary to produce some etch pits on the surface first and then develop them into distinct orientation dependent features by using the 1:1:1 sulfuric etch for InP and the 1:8:8 sulfuric etch for GaAs.

A standard technique used to reveal the crystalline defects on InP single crystal is the Hubers etch (9) which is a solution of H_3PO_4 :HBr in a 2:1 ratio. Figure 3a shows the characteristically symmetric etch pits produced after 2 min in the Hubers etch. These pits can be preferentially etched to produce the elongated features similar to those

Fig. 1. Saw cut (100) surface of InP after etching for 20 min in 1:1:1 $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ at a temperature of 80°C . The area of the figure is about $90\ \mu\text{m}$ by $60\ \mu\text{m}$.

Fig. 2. Saw cut (100) GaAs surface after a 3 min etch in 1:8:8 $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ at a temperature of 55°C . The area of the figure is about $90\ \mu\text{m}$ by $60\ \mu\text{m}$.

on the saw cut surface (Fig. 1 and 2) with the 1:1:1 sulfuric etch. Figure 3b shows the same area as Fig. 3a after being etched in the 1:1:1 sulfuric system at 80°C for 5 min.

A polished (100) GaAs surface can be suitably roughened by etching for 5 to 10 min in a 1:1:1 solution of 38% $\text{HCl}:\text{H}_2\text{O}_2:\text{H}_2\text{O}$. When this is followed by a 3 min etch using a 1:8:8 solution of $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$, one obtains a characteristically elongated etch pattern similar to that shown in Fig. 2, but the scale is an order of magnitude finer.

It has been determined by comparison with known etching characteristics of GaAs (10) and InP (7) that in all the above cases the pits are preferentially etched in the $[01\bar{1}]$ direction. This has been confirmed by the observed RHEED pattern taken in an MBE chamber when the crystal is put through the temperature cycle (1).

In all the above discussions, the designation of $[011]$ and $[01\bar{1}]$ directions are surface specific in that the substrate surface of interest (the front surface) is always defined as the (100) surface. To examine the properties of the back surface, which is the $(\bar{1}00)$ surface in the initial definition, one must redefine the back surface as (100). Simultaneously, in order to preserve the right-handedness of the coordinate system, one must reverse one more coordinate (say the third coordinate). As a result, the orientations of $[011]$ and $[01\bar{1}]$ on the back surface are rotated 90° from those on the front surface. Consistent with such a surface specific definition, we find that all the etch patterns described above are rotated 90° on the back surface of the substrate. This phenomenon of 90° rotation can be understood macroscopically from the 90° rotation of the relative locations of intervening $\{111\}$ facets of type A [Group III surface] and type B [Group V sur-

Fig. 3. (a, top) A polished (100) surface of InP is shown after 2 min in an Hubers etch. (b, bottom) Same area as (a) after etching with 1:1:1 $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ for 5 min. The area of each figure is about $120\ \mu\text{m}$ by $90\ \mu\text{m}$.

face] (11) on opposite substrate surfaces (6). It can also be understood microscopically from the 180° reversal of the surface atomic arrangement as one goes from (011) surface to $(01\bar{1})$ surface, as well as from the 90° rotation of surface bonds on opposite surfaces of the substrate (assuming both Group III stabilized or both Group V stabilized).

We find the most convenient way to keep track of the substrate orientation is to develop the etch patterns on both sides of an unpolished wafer and then polish one side for epitaxial growth and processing. The orientation can always be ascertained simply by inspecting the back surface while keeping in mind the 90° rotation between front and back surfaces. This method is simple, unambiguous, and incurs no waste of material. The removal of saw cut damages by the etching process should also be beneficial to epitaxial growth.

Cadmium Selenide Interface States Studied by Electrochemical Photocapacitance Spectroscopy

Ron Haak* and Dennis Tench*

Rockwell International Science Center, Thousand Oaks, California 91360

With time and the efforts of many workers, it has become increasingly clear that surface oxides play a key role in determining the electrical properties of the II-VI materials. For n-CdSe, recent literature reports indicate that oxygen chemisorbs on the semiconductor surface to produce a negatively charged interface state (1), which dominates the performance of electronic devices based on this material (2). In view of the obviously important implications of such findings, additional work in this area is certainly warranted.

In the present work, the electrochemical photocapacitance spectroscopy (EPS) method (3, 4), which involves measuring the differential capacitance for the reverse-biased semiconductor in an electrolyte as a function of incident subbandgap light, was applied to further elucidate the nature of interface states on n-CdSe. This method has been shown to be an unusually sensitive means for characterization of deep levels in various semiconductor materials (4). In aqueous electrolytes, the interfacial oxide structure might be expected to be similar to that formed in the ambient atmosphere. A key goal in the present work was to establish unequivocally the location of the state associated with oxygen adsorption. Note that an alternate interpretation for previous data was that the observed states actually resided in the bulk and were rendered detectable by the enhanced thickness of the semiconductor space-charge layer resulting from the negative surface charge associated with adsorbed oxygen.

Experimental Details

The electrochemical photocapacitance spectroscopy (EPS) method, apparatus, and procedures have been described in detail previously (4). Electrolytes used in the present studies were 0.5M aqueous KOH and 0.1M tetraethylammonium perchlorate/acetonitrile. The reference electrode was a double-junction Ag/AgCl in the former electrolyte and a Ag/Ag⁺ (0.1M AgNO₃, 0.1M tetraethylammonium perchlorate-acetonitrile) in the latter. All potentials are reported relative to the flatband potential (U_{FB}), which was determined by ac impedance measurements to be -0.9V vs. Ag/AgCl in the aqueous solution and -0.9V vs. Ag/Ag⁺ in the acetonitrile electrolyte. The wavelength scan rate in nanometers per second is given in the figure captions.

The n-CdSe electrodes (0.2 cm² × 0.1 cm thick) were cut perpendicular the Z-axis from rods obtained from Cleveland Crystals, Incorporated (Cleveland, Ohio), and had charge carrier concentrations in the 10¹⁷/cm³ range. Ohmic contacts were made with In-Ga alloy. After attachment of a wire lead via silver epoxy, the electrode was sealed in Torr Seal[®] resin (Varian Associates, Palo Alto, California). Electrodes were polished on aqueous alumina powder slurries, to 1 μm particle size, unless otherwise noted. Chemically etched electrodes were immersed in 50 volume percent (v/o) HNO₃ for about 10s, then dipped in aqueous polysulfide solution (1.0M S + 2.5M Na₂S + 1.0M KOH) to remove excess Se from the surface. Photoetching was performed in an aqueous basic ferricyanide solution.

Results and Discussion

Figure 1 shows an EPS spectrum for a photoetched single crystal of n-CdSe in a basic aqueous electrolyte. Three capacitance increases/plateaus, associated with

*Electrochemical Society Active Member.

Key words: cadmium selenide, surface states, oxygen adsorption.

transitions from donor states at 1.04, 1.21, and 1.34 eV (onset values) to the conduction band, are evident. A capacitance decrease near the bandedge (at 1.60 eV), corresponding to a transition from the valence band to a donor state ~ 0.2 eV below the conduction bandedge, is also resolved. Note that, as might be expected, the onset energies for these phototransitions are found to depend on the solvent, and the observed or apparent values are affected by the concentration of the state in question and by interference from energetically adjacent states as their concentrations vary. Since such shifts in onset energy are sufficiently small so that there is little doubt concerning the identity of the different states, they are referred to below by the onset energies given here, but the spectra are labeled with the actually observed values, which are also given in parentheses in the text.

The probable origin of these levels can be ascertained by comparison of the EPS results with the vacuum surface photovoltage data for single-crystal n-CdSe reported by Brillson (1). Figure 2 shows an EPS spectrum for chemically etched single-crystal n-CdSe (curve 1), and surface photovoltage spectra for oxygen-adsorbed¹ (curve 2) and vacuum-cleaved (curve 3) surfaces. Note that the observed onset for the 1.21 eV state is somewhat higher in energy (1.28 eV) in this case, presumably because of interference from a large concentration of the 1.04 eV state. It is evident that the surface photovoltage spectrum for the oxygen-adsorbed surface and the EPS spectrum are very similar, indicating that the same bandgap states are involved. The 1.04 eV transition, and possibly the transition

¹Such a surface gave results very similar to those for an etched surface and might be expected to be comparable to that in an aqueous solution.

Fig. 1. EPS spectrum (5 kHz, 1.0 nm/s) and associated energy levels/phototransitions for a photoetched n-CdSe single crystal (0.9V vs. U_{FB}) in aqueous 0.5M KOH solution.

Fig. 2. Comparison of an EPS spectrum (5 kHz, 0.1 nm/s) for chemically etched single-crystal CdSe (0.7V vs. U_{FB}) in 0.5M KOH solution (curve 1) with surface photovoltage spectra reported in Ref. (1) for (curve 2) oxygen-adsorbed (70% coverage) and (curve 3) vacuum-cleaned (LEED-ordered) single-crystal n-CdSe.

at 1.21 eV (not resolved by the vacuum technique), must involve interface states associated with oxygen adsorption, since no change in surface photovoltage was observed for the vacuum-cleaved CdSe (curve 3) in this energy range. The densities of these states, calculated from the capacitance changes (4), are $5 \times 10^{12}/\text{cm}^2$ and $4 \times 10^{11}/\text{cm}^2$, respectively. The 1.34 eV transition is apparently intrinsic to CdSe since it was detected by Brillson for both vacuum-cleaved and oxygen-adsorbed CdSe crystals.

Although the capacitance decrease occurring just below the bandedge (at ~ 1.6 eV) is not always clearly resolved in EPS spectra because of interference from band-tailing, the state responsible (~ 0.2 eV below the conduction bandedge) always seems to be present in CdSe, at least in small concentrations, and is noteworthy. Brillson (1) found that argon-bombardment enhances the corresponding feature in surface photovoltage spectra, indicating that the state involved is associated with a lattice defect. EPS studies, which will be the subject of a future publication, have shown that this state is a donor-type interface state which is present in large concentrations in polycrystalline material prepared under some conditions.

EPS data for n-CdSe in aqueous solutions also correlate extremely well with other solid-state literature data for oxygen-adsorbed surfaces (2, 5-10). Another example is given in Fig. 3, which shows the EPS spectrum from Fig. 2 on the same graph with photocapacitance data reported by Ture *et al.* (2) for an aged Au-CdSe Schottky barrier device. Again, the similarities in the two spectra are striking; the apparent differences in the relative concentrations of the various states (as reflected in the relative magnitude of the associated capacitance changes) and the small shifts in onset energies are not surprising, considering the differences in environment at the two interfaces. It is important to note that these solid-state workers showed that the aging process for their devices involved conversion of the CdSe surface from its normal hexagonal structure to a cubic form, which readily chemisorbs oxygen. It was found that the aging process could be greatly accelerated by polishing the crystal, which produces a cubic surface layer.

Figure 4 shows EPS spectra in 0.5M KOH for a single-crystal n-CdSe after polishing on 1 μm grit without subse-

Fig. 3. Comparison of the EPS spectrum (curve 1) from Fig. 2 with a photocapacitance spectrum (curve 2) for an aged Au-CdSe Schottky-barrier device [after Ref. (2)].

quent etching. Although the onset energies are shifted slightly, it is evident that the 1.04 (1.05), 1.21 (1.26), and 1.6 (1.65) eV transitions observed for the etched surfaces also occur for the polished surfaces, although the corresponding states are present in larger concentrations. That all of these states reside at the interface is supported by the insensitivity of the corresponding capacitance changes to the electrode potential (Fig. 4), which is also observed for etched electrodes. Presumably, the 1.34 eV state is not resolved because of interference from a large concentration of the 1.21 eV state.

Figure 5 shows EPS spectra measured in acetonitrile solution for photoetched n-CdSe single crystals from two different batches of material. From spectrum no. 1 (same material as for studies discussed above), it is evident that the same principal interface states, although shifted

Fig. 4. EPS spectra (5 kHz, 0.3 nm/s) for a polished (1 μm) n-CdSe single crystal at various bias voltages in 0.5M KOH.

Fig. 5. EPS spectra (7 kHz, 2.0 nm/s) in acetonitrile (0.1M Et_4NClO_4) for photoetched n-CdSe single crystals from two batches of material (1.1V vs. U_{EB}).

slightly in energy in some cases, are also present in the nonaqueous solvent. This indicates that the CdSe surface structure formed by etching in aqueous solutions, including the chemisorbed oxygen, is reasonably stable in the nonaqueous solvent. In acetonitrile, however, some "peaking" generally occurs in the plateau regions for both the 1.04 (1.03) and 1.21 (1.28) eV states. Transitions from the valence band to bandgap states (which would bring about capacitance decreases) could produce such effects, but would require the introduction of two acceptor states at specific energies, which is highly unlikely. It is much more probable that the surface oxide structure, which is responsible for these states, is somewhat electrically decoupled from the conduction band in the acetonitrile environment so that the associated phototransitions are more localized, *i.e.*, involve an excited-state intermediate and thermal activation of the electron into the conduction band (4).

For material no. 2 (Fig. 5), the 1.40 eV transition is apparently enhanced, and a capacitance decrease, corresponding to a transition from the valence band to a bandgap state, is evident at longer wavelengths; the observed "tail" is superimposed on the normal 1.04 eV transition. This long wavelength tail is also observed for material no. 2 in aqueous solvents and is apparently associated with excess selenium in the crystal, since photoetching in aqueous sodium sulfate solutions, which is known to produce a selenium layer on CdSe surfaces, greatly enhances the magnitude of the long wavelength capacitance decrease.

At less positive potentials, significant CdSe surface reactions do occur in acetonitrile solution. This is illustrated in Fig. 6, which shows EPS spectra for an n-CdSe single crystal as a function of electrode potential. Normal spectra are observed at more positive potentials. As the electrode potential is decreased, however, the 1.21 (1.26) eV transition slowly disappears and the 1.04 eV transition

Fig. 6. EPS spectra (7 kHz, 0.3 nm/s) in acetonitrile (0.1M Et_4NClO_4) for a photoetched n-CdSe single crystal as a function of electrode potential.

becomes more pronounced. Apparently, the oxide structure associated with the 1.21 (1.26) eV state is electrochemically reduced to that corresponding to the 1.04 eV state, a process which to some extent is reversible. As might be expected, although the qualitative features are consistent, the quantitative aspects of EPS spectra for CdSe in acetonitrile are very difficult to reproduce, which, apparently, is a consequence of the instability of the surface oxide in this media.

Solid Solutions and Phase Transformations in the System ZnS-CdS under Hydrothermal Conditions

Shoji Kaneko, Hideo Aoki, Yuji Kawahara, and Fumio Imoto

Zinc sulfide (ZnS) and cadmium sulfide (CdS) have the same two crystal structures, the cubic zinc-blende form transforming to the hexagonal wurtzite form as temperature is increased (1). Solid solubilities and phase transformations in the ZnS-CdS system were investigated using powder compacts heated in He, HCl, or H₂S (2, 3), and in single crystals grown by the chemical transport method (4, 5) or the Bridgman method (6). The ZnS-CdS phase relationships in hydrothermally processed samples have not been investigated except for a brief description of solid solution formation by Kremheller *et al.* (7).

In previous papers, we suggested that hydrothermal reaction was a useful synthesis method for inorganic powder materials (8-11). We further found that solid solution formation and phase transformations in the ZnS-MnS system were promoted by hydrothermal treatments (12). The present investigation was undertaken to elucidate the phase relationships in hydrothermally treated ZnS-CdS mixtures.

Experimental

High purity ZnS and CdS [> 99.99 weight percent (w/o)] for luminescent applications (Dai Nippon Painting Company, Limited) were used as starting materials. After combining the two powders in an agate mortar with ethyl alcohol, the mixture was dried overnight in an oven at 90°C and sealed, together with a 50% water charge, in a test-tube type autoclave (ca. 8 cm³ volume). The autoclave was heated in an electric furnace controlled to $\pm 2^\circ\text{C}$. Samples containing 0-100 mol percent (m/o) CdS at 10 m/o intervals were held in the furnace at 200°-400°C for 24h. After this treatment, the autoclave was rapidly removed from the furnace and submersed in ice water.

The phases present and the extent of solid solution formation were confirmed from x-ray diffraction patterns using a Rigaku Geigerflex Model D-2 with Ni-filtered CuK α radiation, and high purity silicon was used as an internal standard.

Results and Discussion

Crystalline phases.—It is well known that the cubic \rightarrow hexagonal transformation in ZnS takes place at 1020°C in a dry process (13). In the present hydrothermal study, the pressure was varied from 16 atm (1.6 MPa) at 200°C to 200 atm (20 MPa) at 400°C, depending on the treatment temperature, because of the constant 50% water charge (14). The phase transformation to hexagonal ZnS was not observed even at 400°C and 200 atm pressure. The transformation temperature of CdS in a dry process has not been well established, although it is known that the cubic \rightarrow hexagonal transformation is complete at 600°C in well-purified N₂ or Ar atmospheres. The phase transformation of CdS started to occur at 250°C using the present hydrothermal treatment, proceeded gradually above this temperature, and was completed at 300°C (Fig. 1). Increased pressure alone does not depress the transformation temperature this far until it has reached several hundred atmospheres (15, 16). Consequently, it is probable that the phase transformation observed under hydrothermal conditions has been facilitated by interaction with

Key words: inorganic, crystallography, solubility, system ZnS-CdS, hydrothermal treatment.

the included water (17) rather than by the pressure alone (14). Phase boundaries in the ZnS-CdS system under hydrothermal conditions are shown in Fig. 1. A complete ZnS-CdS solid solution was not formed by the hydrothermal treatment over the temperature and pressure ranges investigated. The solubility of ZnS in CdS increases and the solubility of CdS in ZnS decreases with increasing temperature. Adding ZnS to CdS under hydrothermal conditions decreases the cubic \rightarrow hexagonal transformation temperature. The solubility of ZnS in CdS is ca. 50 m/o and that of CdS in ZnS ca. 10 m/o at 400°C, suggesting that the zinc ion, which has a smaller ionic radius (0.74Å), was easily incorporated into the CdS lattice, but that the cadmium ion, which has a larger ionic radius (0.97Å), was not so easily incorporated into the ZnS lattice.

No intermediate compounds such as hydroxides, sulfates, or oxysulfates were identified from the x-ray diffraction patterns. Thus, although the effect of hydrothermal conditions on the phase relationships is important, its precise role is not clear.

Lattice constants of the solid solutions.—Figure 2 shows the lattice constants of solid solutions in the system ZnS-CdS calculated from the x-ray diffraction data by Cohen's least squares method (18). The lattice constant (a) of the cubic ZnS solid solution (ss) increased with increasing CdS content according to Vegard's law. Cubic ZnS ss was identified in the x-ray pattern of the 400°C sample up to 50 m/o CdS, but the lattice constant could not accurately be determined beyond 20 m/o CdS owing to the weakness of the ZnS x-ray peaks. A similar effect in the hexagonal CdS ss limited lattice parameter determination to ≤ 50 m/o ZnS (Fig. 2). The lattice constants a and c of hexagonal CdS decreased with increasing ZnS content.

Hume-Rothery's rules are almost satisfied between the hexagonal forms ZnS and CdS, so that a complete range of solid solution should be formed between the two sul-

Fig. 1. Phase diagram of the system ZnS-CdS under hydrothermal conditions. ■: cubic-ZnS ss, □: cubic-CdS ss, ○: hexagonal-CdS ss.

Fig. 2. Variation of lattice constants with composition in ZnS-CdS solid solutions treated hydrothermally at 400°C.

vides. The fact that two-phase regions existed in the system ZnS-CdS presumably stems from slight differences in the planar stacking of the two phases; cubic ZnS and hexagonal CdS formed under hydrothermal conditions, as previously observed in the system ZnS-MnS (12).

Summary

The cubic→hexagonal transformation of ZnS did not occur under hydrothermal conditions up to 400°C, while that of CdS was shifted to lower temperatures by hydro-

thermal treatments and additions of ZnS in solid solution. The cubic→hexagonal transformation of CdS ss was complete at 300°C. The formation of ZnS-CdS solid solutions was verified by variation of the lattice constants as a function of composition. In the system ZnS-CdS, the plots of the lattice constants of ZnS- and CdS-rich solid solutions vs. composition followed Vegard's law. The solid solubility of ZnS in CdS increased with an increase in temperature, while that of CdS in ZnS decreased with increasing temperature.

Electrodeposition of Nickel and Cobalt Oxides onto Platinum and Graphite Electrodes for Alkaline Water Electrolysis

Yih-Wen D. Chen and Rommel N. Noufi*

Solar Energy Research Institute, Golden, Colorado 80401

ABSTRACT

Smooth, compact, and bright films of nickel and cobalt oxides were prepared from 0.5M acetate aqueous solutions and electrodeposited onto platinum and graphite electrodes. Oxygen evolution potentials in 1M NaOH at room temperature were about 150-170 mV lower on nickel(III) oxide [NiO(OH)] and cobalt(III) oxide (Co₂O₃)-coated anodes than on bare anodes. Scanning electron micrographs of NiO(OH) deposits showed no morphological change after extensive electrolysis, and electrocatalytic activity was stable in long-term controlled-potential coulometric electrolysis. However, the electrocatalytic activity of Co₂O₃ showed initial decay followed by a fairly constant behavior. No visible change in the surface of the Co₂O₃ deposit was observed after extensive electrolysis.

The electrochemical properties of metal oxide electrodes have attracted interest over several decades. Early work was oriented toward understanding thick films relevant to battery development (1). The objective of more recent studies has been to develop a fundamental understanding of the redox processes in these films (2, 3). Since hydrogen has recently been considered one of the clean fuels for energy storage (4-6), its production by various methods (7-9) has been proposed. Splitting water to hydrogen and oxygen by electrolysis remains the simplest and most economical method. One drawback in alkaline water electrolysis is the high overvoltage of the oxygen evolution on anodes.

Although metal anodes have been conventionally used for water electrolysis (10-12), their use is not feasible because these anodes [especially nickel anodes (13)] tend to form a nonconducting oxide film, causing oxygen evolution to deteriorate with time. Metal oxides that can provide a catalytic path for oxygen evolution have been recognized (2). Most of the anodic metal oxides studied were formed by anodization of the bare substrates in alkaline solution (14-17). In this paper, we investigate electrodeposition of thin films of nickel and cobalt oxides on platinum and graphite to study an inexpensive method to prepare and characterize these very thin film electrocatalysts. The objective of the above task is to apply the results to semiconductor photoelectrodes in order to bring about or facilitate the photoelectrolysis of water.

Experimental

Reagents.—Sodium acetate and sodium hydroxide are Baker-analyzed reagents. Nickel(II) sulfate was obtained from Johnson Matthey Chemical, Limited, and cobalt(II) acetate was obtained from Alfa Products. All of the reagents were reagent grade and were used without further treatment.

Electrodes.—Rotating platinum disk and graphite disk electrodes (area = 0.20 cm²) were obtained from Pine Instrument Company. The electrodes were polished with 1, 0.3, and finally with 0.05 μm aluminum oxide.

Cells.—All measurements and electrodeposition were performed in a three-electrode cell and are compared with the saturated calomel electrode (SCE) results. The cell assembly is simply a beaker with 250 ml capacity and a Teflon cap with four holes for the rotating disk electrode, reference electrode, counterelectrode, and gas dispersing tube. To keep the reference electrode from contaminating the electrolyte, a Beckman junction tube (no. 531041) was used to fill the support-

ing electrolyte. All experiments were conducted at room temperature and under argon atmosphere.

Apparatus.—A PAR Model 173 potentiostat with Model 175 Universal programmer and Model 179 Digital coulometer was used to control potential electrodeposition, cyclic voltammetric measurements, and potential coulometric electrolysis of water. A Houston Model 200 X-Y recorder registered the data.

Analysis of the film.—The nickel and cobalt contents in the film were determined by dissolving the metal oxides in 1% HNO₃ and measuring by atomic absorption.

Results and Discussion

Electrodeposition of nickel(III) oxide on platinum and graphite electrodes.—The nickel(III) oxide, NiO(OH), was previously formed when nickel(II) oxide was electrochemically oxidized to the +3 oxidation state (14-16). In this investigation, NiO(OH) was prepared directly from 0.5M sodium acetate aqueous solution with 0.05M NiSO₄. Figure 1 illustrates the cyclic voltammogram for the oxidation of nickel(II) ion onto platinum. On the first anodic scan, no obvious anodic peak was observed; however, on the subsequent cycles, anodic peaks were easily identified. Upon scan reversal, reduction waves of the oxide were observed. The increase in redox peaks with each cycle indicates the

Fig. 2. Controlled potential coulometric electrodeposition of NiO(OH) on rotating (900 rpm) platinum disk electrode (0.20 cm^2) in aqueous solution containing 0.05 M NiSO_4 and 0.5 M sodium acetate at (a) 1.025 V , (b) 1.050 V , (c) 1.075 V , and (d) 1.100 V vs. SCE.

growth of the deposit. At potentials $>1.0 \text{ V}$, anodic currents [the result of electrocatalytic evolution of oxygen at the NiO(OH) film] increase with each cycle. This increase is seen again in Fig. 2, which illustrates controlled potential coulometric electrodeposition at different anodic limits. At each anodic limit, the anodic current decreases initially until $\sim 0.06 \text{ mC}$ had passed, which is the estimated quantity needed for monolayer deposition ($\sim 0.30 \text{ mC/cm}^2$) (18). After monolayer formation, the current density increases during the extensive electrodeposition because of electrocatalytic

Fig. 4. Cyclic voltammograms at 50 mV/s for a rotating (900 rpm) platinum disk electrode (0.20 cm^2) in 1 M NaOH aqueous solution. Curve a: uncoated platinum electrode. Curve b: NiO(OH)-coated platinum electrode electrodeposited at $+1.10 \text{ V}$ with 15 mC passed, on rotating (900 rpm) platinum disk electrode, in an aqueous solution containing 0.05 M NiSO_4 and 0.5 M sodium acetate.

oxidation of water. Through x-ray photoelectron spectroscopy (XPS), the deposition product was identified as predominantly NiO(OH) (see Fig. 3), which is similar to the results obtained from the anodic oxidation of the Ni(OH)₂ film (14-16). Therefore, the NiO(OH) species seems essentially responsible for the catalyzed oxygen evolution. The oxygen evolution occurring with the anodic electrodeposition of NiO(OH) film is also evident from the analysis of the nickel content in the film (measured by atomic absorption, as shown in Table I). The coulometric efficiency of the deposition decreases with increase in applied potential.

The controlled potential coulometric electrodeposition of NiO(OH) on platinum and graphite electrodes yields reproducible, compact, and smooth films. With this method, thick conducting films can be deposited over 1 C/cm^2 . In comparison, passive oxide films were normally grown on nickel electrodes with limited thickness (19-21).

The electrocatalytic evolution of oxygen was also observed in 1 M NaOH aqueous solution, where the

Fig. 3. XPS spectra of NiO(OH) electrodeposited on platinum (0.25 cm^2) at a potential, $E_a = 1.10 \text{ V}$ with $Q = 3.7 \text{ mC}$ in an aqueous solution containing 0.5 M sodium acetate and 0.05 M NiSO_4 . A, left: XPS spectrum of the immediate surface. B, right: XPS spectrum of the bulk.

Fig. 5. Oxygen evolution at NiO(OH)-coated platinum electrode (0.20 cm^2) at $+0.55 \text{ V}$ in 1 M NaOH aqueous solution. Curve a: current-time curve for initial electrolysis. Curve b: current-time curve for continuous electrolysis after 3 days. The NiO(OH)-coated anode was prepared by electrodeposition on rotating (900 rpm) platinum disk electrode (0.20 cm^2) at $+1.0 \text{ V}$ with 10 mC passed in an aqueous solution containing 0.05 M NiSO_4 and 0.5 M sodium acetate.

oxygen evolution potential was about 150 mV lower on the NiO(OH) electrode than on the platinum anode (as shown in Fig. 4). The long-term stability of oxygen evolution on NiO(OH) film was tested in 1 M NaOH , and the film showed good stability. Initially, the catalytic current increased sharply, and then reached steady state after a few minutes (Fig. 5). The electrolysis continued for 3 days with no decay in current. Therefore, no passive oxide film formed, and there was also no morphological change in the NiO(OH) film (Fig. 6).

Electrodeposition of cobalt(III) oxide onto platinum and graphite electrodes.—Cobalt(III) oxide films were prepared by electrodeposition onto platinum and

Fig. 6. Scanning electron micrographs of NiO(OH)-coated platinum electrode (times 2000) for (a, top) before and (b, bottom) after oxygen evolution in 1 M NaOH aqueous solution.

Fig. 7. Cyclic voltammograms at 50 mV/s for a (a, left) rotating (900 rpm) platinum disk electrode (0.20 cm^2) and (b, right) rotating (900 rpm) graphite disk electrode (0.20 cm^2) in aqueous solution containing 0.05 M Co(OAc)_2 and 0.5 M sodium acetate.

graphite electrodes in essentially the same way as the NiO(OH)-coated electrodes. Cyclic voltammograms of the oxidation of cobalt(II) ion onto platinum and graphite electrodes were basically the same for both electrodes (Fig. 7). On the first anodic scan, no obvious anodic peak was observed; however, on the subsequent cycles, anodic peaks were observed. On the scan reversal, broad and relatively small reduction waves were observed. The increase in peak height with each cycle indicates the growth of the film. The oxidation currents at the anodic limit increase while the film is continuously deposited, indicating the electrocatalytic evolution of oxygen. However, the catalytic effect by the cobalt oxide is not as clear as it is with NiO(OH); a more complicated film growth behavior is observed (Fig. 8). At each anodic limit, the oxidation current decreases initially until ~ 0.10 mC had passed, which is the estimated quantity (~ 0.5 mC/cm²) required for

monolayer deposition (21). After the monolayer formation, the current density increases and then decreases during bulk electrodeposition. The increase in the current density might indicate catalytic oxygen evolution, followed by a decrease in current density due to the less conducting character of the film. The electrodeposited film was not stable in air. The orange film gradually changes to green on the surface and becomes soluble in 1M NaOH. However, the underlayer of the green film stays orange and stable in 1M NaOH. XPS measurements were not sensitive enough to distinguish between the binding energies of Co₂O₃, Co₃O₄, and CoO (Fig. 9). However, Co₂O₃ is most likely the cobalt oxide deposited because the stoichiometry fits the analytical results of coulometric efficiency of the electrodeposition at lower applied anodic potential (Table I). At the lower potential, over 90% coulometric efficiency based on Co₂O₃ film formation is observed.

Fig. 8. Controlled potential coulometric electrodeposition of cobalt(III) oxide on rotating (900 rpm) platinum disk electrode (0.20 cm²) in an aqueous solution containing 0.05M Co(OAc)₂ and 0.5M sodium acetate at (a) 0.80V, (b) 0.85V, and (c) 0.90V vs. SCE.

Fig. 10. Cyclic voltammograms at 50 mV/s for a (a, left) rotating (900 rpm) platinum disk electrode (0.20 cm²), and (b, right) rotating (900 rpm) graphite disk electrode (0.20 cm²), in 1M NaOH aqueous solution. Curves 1: uncoated platinum or graphite electrode. Curves 2: cobalt(III) oxide-coated platinum or graphite electrode at +0.80V with 10 mC passed from an aqueous solution containing 0.05M Co(OAc)₂ and 0.50M sodium acetate.

Table I. Coulometric efficiency of electrodeposition of nickel(III) and cobalt(III) oxides^a

Sample number	Metal analyzed	Q _a ^b (mC)	E _a ^c (V)	C ^d (ppm)	Coulometric efficiency (%)
1	Ni	30	1.10	0.47	28
2	Ni	30	1.07	0.55	32
3	Ni	30	1.00	0.62	36
4	Co	30	0.80	1.65	93
5	Co	30	0.90	1.55	88
6	Co	30	1.05	1.32	75
7	Co	30	1.10	1.12	63

^a An aqueous solution of 0.5M sodium acetate and 0.05M NiSO₄ was used to electrodeposit NiO(OH) on a rotating (900 rpm) platinum disk electrode. An aqueous solution of 0.5M sodium acetate and 0.05M Co(OAc)₂ was used to electrodeposit cobalt(III) oxide on a rotating (900 rpm) graphite disk electrode.

^b The number of coulombs applied for electrodeposition.

^c The constant anodic potential applied for electrodeposition.

^d Metal oxides were dissolved in 10 ml 1% HNO₃ and were measured by atomic absorption.

^e Coulometric efficiency is based on NiO(OH) and Co₂O₃ formation.

The electrocatalytic evolution of oxygen was evident in 1M NaOH aqueous solution where the oxygen evolution potential was about 170 mV lower on Co₂O₃ than uncoated anodes (see Fig. 10). The long-term stability of oxygen evolution on Co₂O₃ film was tested in 1M NaOH, and this film also showed good stability (Fig. 11). Contrary to NiO(OH), the catalytic current initially decreases sharply and stays fairly constant during extensive electrolysis. Initially, the catalytic current of Co₂O₃ is larger than that of NiO(OH). However, after extensive electrolysis, the catalytic current of Co₂O₃ becomes less than that of NiO(OH). Essentially, no visible change in the cobalt(III) oxide film was observed after long-term oxygen evolution experiment.

Electroactive Properties of Polyaromatic Molecules

Robert J. Waltman, A. F. Diaz,* and Joachim Bargon¹

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

Electroactive and electrochromic films of electropolymerized polyazulene and polythiophene have been found to be surprisingly insensitive to common solvents and temperature. As electrodes in all-organic batteries these thin polymeric films allow current densities of 2 mA/cm² at open-circuit voltages of 2.3V. The electrochromic properties suggest application in electro-optical displays.

The variety of compounds which have been found to undergo electrochemical polymerization have demonstrated the facility of the electrochemical approach to synthesis of electrically conducting polymeric films. Such films have been prepared from molecules which represent all pertinent classes of aromatic compounds. They include the heterocyclic pyrroles (1, 2), thiophenes (3-5), furan (5), carbazoles (6, 7), the polynuclear aromatic hydrocarbons pyrene or fluorene (8), and even the nonbenzenoid aromatic hydrocarbon azulene (9). When in the oxidized form, all of these polymers are semiconducting (10^{-6} - $10^2 \Omega^{-1} \text{cm}^{-1}$), with polypyrrole exhibiting the highest conductivities of $10^2 \Omega^{-1} \text{cm}^{-1}$. Thin films from polypyrrole, polythiophene, and polyazulene which are supported by a Pt surface are also attractive, because they exhibit electroactive and electrochromic properties. Thus, electrically conducting polymers become suitable for application in electro-optic display devices (10) or as electrode materials (11). Successful application in the latter has been demonstrated by the fabrication of a lightweight, rechargeable battery employing a polyacetylene electrode, whereby large power and energy densities were obtained (12). The fact that electrochemically prepared polymers, such as polythiophene or polyazulene, have similar properties, points to their potential application in energy technology as well. Accordingly, we report herein some properties of these materials relevant to their applications in battery technology.

Experimental

All compounds were obtained from commercial sources. Polythiophene and poly- β -substituted thiophenes were prepared by the electrochemical oxidation of the appropriate thiophene monomers in a three-electrode, single- or two-compartment cell. Platinum, gold, and sodium chloride calomel (SSCE) were used as the working, counter, and reference electrodes, respectively. The solutions were typically 10^{-4} - 10^{-3}M in monomer, in a 0.1M electrolyte/acetonitrile solution. The electrolyte, usually tetraethylammonium tetrafluoroborate (TEAFB), was recrystallized from alcohol-ethyl acetate and dried under vacuum. The acetonitrile (Burdick and Jackson, spectrometric grade) was used directly without further purification. The solutions were bubbled with argon for 5-10 min, and protected by an argon blanket. Cyclic voltammograms of polymer films were measured in electrolyte solutions containing no other electroactive species. All electrochemical measurements were performed with an IBM EC225 Voltammetric Analyzer.

Results and Discussion

Electrochemical data.—Cyclic voltammetric data for some thiophene monomers and their corresponding polymers are given in Table I. All of the monomers show irreversible oxidation peaks and give rise to colored solutions upon electro-oxidation. The value of n for the oxidation reaction was estimated from the

2,5-dimethylthiophene	1.77	1134	0.4	1.2	

Nicholson and Shain treatment for a totally irreversible electron-transfer process which provides $n^{3/2} D^{1/2}$, where D was assumed equal to $10^{-5} \text{cm}^2 \text{s}^{-1}$. In general, the reaction of compounds which produce polymer films occurs on the electrode surface and has n values between 2 and 3, as estimated from cyclic voltammetry. From elemental analysis, n values between 2.07 and 2.17 are obtained for some of these polymers. The reaction of compounds which produce soluble products and, therefore, occur away from the electrode, has n values between 1 and 2, depending upon whether monomeric ($n = 2$) or dimeric ($n = 1$) products are formed (13). Accordingly, the α, α' -blocked 2,5-dimethylthiophene has an n value of 1.2, similar to 2,5-dimethylpyrrole (13).

Whereas low molecular weight products are obtained from α -substituted heterocycles, polymeric films are indeed obtained from certain β -substituted monomers. The cyclic voltammogram of a typical 60 nm thin film of polythiophene on a Pt surface obtained from the electropolymerization of 2,2'-bithiophene is shown in Fig. 1.

Fig. 1. Cyclic voltammogram of [Pt]-polythiophene-BF₄ film in 0.1M TEAFB/CH₃CN solution.

The details of the electroactive properties of these films have been previously considered (4), and no reiteration is necessary here. However, it is important to point out that these films can be cycled repeatedly between the oxidized, conducting state and the neutral, nonconducting state, an event which is accompanied by a reversible color change from green-back to a pale-copper color, respectively. The cycling behavior is observed for polythiophene films derived from either the monomer or the 2,2'-dimer. The anodic peaks obtained from the dimer derived polymer films, however, are noticeably sharper with peak widths at half height (PWHH) of ca. 90 mV for 60 nm films, while monomer derived films of the same thickness have PWHH of ca. 300-350 mV. Since it is known that the oxidation and reduction reaction is controlled by the diffusion of counteranions into and out of the surface-localized film, diffusion of ions through the dimer-derived film is less limiting. This may also reflect the more regularly α,α' -linked monomer units in the dimer-derived film. The sensitivity of the electrical properties of polythiophene to linkages between monomer units other than α,α' -bonds has been pointed out by Sanechika *et al.* (14). In particular, they found that the electrical conductivity of polythiophene decreases with increasing β -linkages introduced between monomer units.

Figure 1 also shows that the peak oxidation potential of polythiophene occurs at +1.0V. This is far anodic of the peak oxidation potential of polypyrrole (-0.15V), with the important consequence that polythiophene films are much more stable, especially to the presence of oxygen. Thus, unlike polypyrrole, neutral or electrochemically oxidized polythiophene films can be exposed to air, or even passed under a stream of oxygen, yet when put back into an electrolyte solution and cycled electrochemically, they retain their switching capabilities. However, ESCA studies of the neutral films reveal the presence of bonded oxygen at the surface of these materials. For neutral polythiophene films exposed to air for 24h, the C:S:O ratio is 4.0:0.55:1.0, respectively, while a 14 day exposure reveals a C:S:O ratio of 4.0:0:5.1, respectively (15). However, the surface properties are not representative of the bulk properties of the film, as is evidenced by its ability to retain electrochemical switching.

The electrochemical behavior of polyazulene films is similar to that of polythiophene films insofar that they too are electroactive and electrochromic (Fig. 2). The peak oxidation potential of the polymer film occurs at +0.650V, *i.e.*, lower than the polythiophene counterpart but still anodic of polypyrrole.

Stability of films.—For successful performance of these materials in various applications, such as in batteries, apart from the desirable electroactivity of the films, their stability under different conditions becomes of paramount importance. Thus, thicker films from polythiophene and polyazulene can be peeled off from the Pt anode. These are flexible, continuous, free standing films which are electrically conducting to the extent of $1 \Omega^{-1} \text{ cm}^{-1}$. The oxidized, conducting forms of these polymer films are also remarkably stable under different conditions. They are insoluble in strong acids, bases, or common organic solvents. For example, when oxidized films are placed in 6M HCl or NaOH, or in a solvent such as dichloromethane for 1h, they retain their electroactive properties when subsequently electrochemically cycled. The thicker films are also thermally stable to heating at 80°C for several hours. When kept for 3h at this temperature, polyazulene and polythiophene show a decrease in conductivity from 0.4 to 0.2 $\Omega^{-1} \text{ cm}^{-1}$, and from 0.1 to 0.04 $\Omega^{-1} \text{ cm}^{-1}$, respectively, while heating for 20h results in a ten-fold decrease in their conductivities. Whereas the thick films show moderate stability to heating, the thin films display a sensitivity of the switching behavior to changes in temperature. Thin films were

Fig. 2. Cyclic voltammogram of [Pt]-polyazulene- BF_4 film in 0.1M TEAFB/ CH_3CN solution.

cycled repeatedly in the temperature range between 0.0° and 80°C, and were found to be stable under these conditions for at least several hours. The electroactive properties are still retained (Fig. 3), and the peak oxidation potential shifts cathodically by 0.88 mV deg^{-1} with increasing temperature (Fig. 4). The 70 mV shift in the oxidation potential is reversible in this range, and a noticeable sharpening of the anodic peak is observed at higher temperatures (Fig. 3).

Apart from the demonstrated temperature stability, these data also allow information concerning the energetics of the switching reaction in this temperature range. The reaction is electrochemically irreversible and thus the relation $dG = -nFE$ cannot be applied. However, the dE/dT dependence is real and can be related to $d(dG)/dT$, which provides $-dS$. Thus, $dS = nF(dE/dT) = -3.4 \text{ cal deg}^{-1}$, whereby $n = 0.17$, *i.e.*, the amount of charge consumed in the partial oxidation of the film, as can be derived from elemental analysis data. This change of state also involves a change in composition where anions are incorporated into the film in order to balance the positive charges along the polymer chain. The sign and magnitude for the entropy term dS is consistent with what is characteristic for molecular complex formation (16). The sign for dS suggests that as the film switches from the neutral to the oxidized state, accommodation of counteranions (which is necessary to balance the positive charge induced in the polymer chain) results in a structure more rigid than in the neutral state of the film.

Substituent effects.—The eventual application of these materials in energy technology or in other fields will demand some chemical modifications in order to meet particular criteria. For example, we have demonstrated previously that the conductivity of polythiophene can be increased 100-fold with the introduction of a single β substituent (4). The fraction of counteranions in the film can also vary depending on which substituent is introduced into the parent polymer. Correspondingly, an investigation of polythiophene films with appropriate β substituents showed that when the peak oxidation potential of some β -substituted monomers are plotted against their respective Hammett substituent constants, a linear correlation is obtained (Fig. 5). The shift in the peak oxidation potentials of the series of β -substituted thiophenes is de-

Fig. 3. Cyclic voltammograms of [Pt]-polythiophene-BF₄ as a function of temperature in 0.1M TEAFB/CH₃CN.

pendent on three parameters: namely, their polar, steric, and mesomeric effects, which are exerted by the substituents (17). This behavior can be described by the usual Hammett-Taft

$$E = \rho_{\pi}\sigma + S$$

equation where $\rho_{\pi}\sigma$ describes the polar-mesomeric

Fig. 4. The shift in the peak oxidation potential of polythiophene as a function of temperature.

Fig. 5. Electrochemical peak oxidation potential of thiophene monomers vs. their respective Hammett substituent constants.

parameters, and S accounts for the steric factor (17). Accordingly, Fig. 5 allows three conclusions to be drawn. First, the straight-line fit indicates that all of the monomers are oxidized by the same mechanism, i.e., electro-oxidation results in the removal of a π electron from the thiophene ring. Second, the positive sign for the substituent constant ρ_{π} reveals that as the substituents take on more electrophilic character, the oxidation of the corresponding thiophenes proceed more difficultly. Finally, the steric term S appears to be minimal since for the substituents chosen here, a straight-line fit is obtained. Thus, the primary effect exerted by the β substituents is electronic and described by the $\rho_{\pi}\sigma$ term. One possible interpretation of these facts (Fig. 5) suggests that there is an optimum potential range, i.e., reactivity of the radical cation intermediate, which favors radical cation coupling in the follow-up reaction to yield polymeric films. Thus, under these conditions, polymerization occurs only for the parent thiophene, and the methyl-, bromo-, and iodo-substituted thiophenes. The latter two monomers yield poorly conducting films, while the other two polymers, polythiophene and poly(3-methylthiophene), have conductivities of ca. 10^{-2} - 10^{-1} , and $1 \Omega^{-1} \text{ cm}^{-1}$, respectively. 3-Thiophene carboxylic acid, 3-cyano-, and 3-nitro-thiophene yield no polymers on electro-oxidation under these conditions. Several reasons may be attributed to the lack of polymers obtained from the latter three monomers. One interpretation postulates that the stability (or reactivity) of these monomers is affected by the β substituents. Thus, as the reactivity of the radical cation intermediates increases, as reflected in their increasing oxidation potentials (Fig. 5), the more reactive these intermediates become with respect to nucleophiles, or they undergo other "escape" reactions, e.g., with the solvent or other nucleophilic species in the vicinity of the Pt surface. Thus, one possible effect of these strongly electron withdrawing groups is to destabilize the radical cation intermediate to the extent that radical cation coupling reactions become unfavorable when compared with other reaction pathways. Another reason for their failure to promote electropolymerization may be due to a breakdown of the solvent, since the anodic potentials applied become rather high for the nitro- and cyano-substituted monomers (Table I).

While steric factors do not seem to play any appreciable role in the primary electro-oxidation of the monomer (Fig. 5), their subsequent follow-up reactions (radical cation polymerization) are more susceptible to steric effects, which, therefore, may well play a role in deciding whether polymerization can compete favor-

ably with other potential follow-up reactions, such as with nucleophiles. This may explain the overall inferior quality of the polymer films derived from the 3-bromo- and 3-iodo-thiophenes, even though their oxidation potentials do not differ greatly from that of the parent thiophene monomer. It is, however, interesting to note that while a bulky substituent, such as iodo, allows polymerization (albeit of poor quality), a sterically smaller cyano group does not.

Another example of a property-structure correlation between thiophene monomers and their corresponding polymers is reflected in Fig. 6, where the peak oxidation potentials of some thiophene monomers are plotted against their respective polymers. The straight-line fit suggests that β -substituted monomers and their respective polymers are made up of a related system of π electrons, i.e., the electronic structures of the monomers and their corresponding polymers must be alike. This is consistent with the fact that polythiophene (and polypyrrole) consists primarily of α,α' -linked monomer units (3, 4).

Battery applications.—The stability of polythiophene and polyazulene films as described above suggests application of these materials as battery electrodes. Of particular importance is the high extent of counteranions which can be incorporated into these polymer films, especially into polyazulene, whereby one counteranion is shared by four azulene monomer units (Table II). Polythiophenes are additionally attractive from the standpoint that their film properties are readily altered via substituent groups. Thus, a simple battery cell (as shown in Fig. 7) was assembled utilizing oxidized and neutral polymer films adhered onto Pt as the two terminals. The films were typically 1×2 cm² with a thickness of ca. 10^{-3} cm, corresponding to a film weight of about 1-2 mg. These were immersed into a 0.1M TEAFB acetonitrile solution containing no other electroactive species. The arrows in Fig. 7 indicate the direction of electron flow. A polyazulene battery yielded a maximal open-circuit voltage of ca. 2.3V and an optimal initial short-circuit current of 4 mA. These data are summarized in Table II for both polyazulene and polythiophene batteries. These preliminary results for polyazulene are taken from five such batteries, while those for polythiophene (monomer derived) are based upon a single battery test. Polythiophene batteries derived from the dimer may conceivably yield higher values since they can store more charge (six monomer units share one charge) than the monomer-derived films. The batteries tested so far could be recharged at constant current, e.g., at 1 mA, to yield similar values in the regenerated cells.

Fig. 6. Peak oxidation potential of thiophene monomers vs. their respective polymers in 0.1M TEAFB/CH₃CN.

Table II. Batteries from polyazulene and polythiophene

	Polyazulene	Polythiophene
Elemental composition	(AZ) ₄ ⁺ · BF ₄ ⁻	(TH) ₁₄ ⁺ · BF ₄ ⁻
Current density	0.4-2.2 mA/cm ²	0.02 mA/cm ²
Voltage	0.5-2.3V	0.5V

Our values are actually quite similar to the "all polymer" polyacetylene batteries of MacDiarmid *et al.* (18). However, unlike polyacetylene, which is known to be air sensitive, polyazulene batteries can be open to the air, at least short-term (days) tests revealed no apparent effect of air on the stability of the batteries. However, the long-term effect of oxygen on the rechargeability of polyazulene batteries has not been investigated thus far. Figure 8 shows the voltage change during a constant current discharge of 0.15 mA for a polyazulene cell in 0.1M TEAFB acetonitrile. More work is in progress.¹

¹ After this work was completed, data characterizing the electrochromic behavior of polythiophenes was reported by Garnier *et al.* (19).

Application of Activated Carbon Fiber Fabrics to Electrodes of Rechargeable Battery and Organic Electrolyte Capacitor

M. Nawa, T. Nogami, and H. Mikawa

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Kami, Suita, Osaka 565, Japan

Since the energy crisis, a new energy storage system which does not waste precious raw materials has been required. Graphite intercalation compounds appear to have good prospects as electrode materials in batteries.¹ One product has already been marketed² and it is likely that its importance will grow in the near future. Carbon black with extremely large specific surface area has recently been used as a electric double layer capacitor³ with extremely large specific capacity. It is expected to find a great demand for back-up power source of computer memory. Most of these batteries and capacitors require some treatments to keep the electrode's stiffness. In a search for other electrode materials useful for the batteries and capacitors, we noticed that a special kind of activated carbon fiber (ACF) made from phenolic resin has the following attractive properties as an electrode material:⁴ (1) It has a quite large specific surface area (1500-2500 m²/g), and thereby it is expected to store a large amount of electricity; (2) it has a high electrical conductivity of 60 S cm⁻¹; (3) various types of ACF, such as felt, fiber, cloth and paper sheet can be obtained commercially. Thus, ACF can be directly used as electrodes without any treatment; (4) It is a quite stable material; (5) it has a small bulk density of 0.01 g/cm³ for a cloth; (6) it is a flexible material.

We have made an organic electrolyte capacitor by use of a p-doped ACF as a cathode and a n-doped ACF as an anode.⁵ We have also made a rechargeable battery by use of a p-doped ACF as a cathode and a lithium metal as an anode.⁵

ORGANIC ELECTROLYTE CAPACITOR

Two cloths of ACF (each 3.0 cm², 29

mg), type CH-25 available from Kuraray Chemical Co. Ltd., were separated with a glass fiber filter of 0.25 mm thickness. They were then placed in a glass vessel containing a 1 mol dm⁻³ solution of LiClO₄ in γ -butyrolactone (γ -BL) in an argon atmosphere. Platinum wires were attached to both of the ACF electrodes. After passing 7.1 C, the cell configuration was (ACF^{a-})Li^{a+} | LiClO₄ in γ -BL | (ACF^{a+})(ClO₄⁻)_a. The molar ratio of the dopant to carbon atom was estimated to be $a = 0.0315$ at this stage.⁶ The Voc and Isc were 3.0 V and 975 mA, respectively. The plot of the quantity of electricity recovered against the cell voltage is shown in Fig. 1. The plot deviates from a linear relation more and more significantly as the increase in the cell voltage. The upward deviation from a straight line is due to the co-existence of a capacitive contribution and a contribution from a galvanic cell. The capacitive contribution arises from an electric double layer formed over extremely large surface area of ACF. In view of the high electrical conductivity

Fig. 1. Relation between the quantity of electricity recovered and the cell voltage.

Keywords: activated carbon fiber, organic electrolyte capacitor, rechargeable battery, supecific surface area.

Fig. 2. The changes of the electrode potential vs. Ag/Ag^+ and cell voltage in charge-discharge cycles (charge current: 1.2 mA , discharge load: $2\text{ k}\Omega$). (1) negative electrode; (2) positive electrode; (3) cell voltage.

Fig. 3. The changes of the electrode potentials vs. Ag/Ag^+ and cell voltage in charge-discharge cycle under constant current of $1\text{ mA}/\text{cm}^2$. (1) Li electrode; (2) ACF electrode; (3) cell voltage.

of ACF, graphite structure is assumed to be contained in ACF. The contribution of the galvanic cell arises from the intercalation of Li^+ and ClO_4^- into the ACF lattice. Fig. 2 shows charge-discharge characteristics of the cell between 3.08 V and 1.65 V ($Q_{\text{in}} = 2.16\text{ C}$, $Q_{\text{out}} = 2.08\text{ C}$; 96 % efficiency), and the changes of the electrode potentials vs. Ag/Ag^+ . The change of the potential of $(\text{ACF}^{\text{a}-})\text{Li}^{\text{a}+}$ was about two times as large as that of $(\text{ACF}^{\text{a}+})\text{ClO}_4^{\text{a}-}$. The cycles were reproducible for more than 130 cycles. Although the contribution from galvanic cell is present in this system, its operation resemble the organic electrolyte capacitor. The maximum power density, energy density, and specific capacity were estimated to be $11.1\text{ kW}/\text{kg}$, $36.2\text{ WH}/\text{kg}$, and $36.5\text{ F}/(1\text{ g of ACF})$, respectively, based on V_{oc} , I_{sc} , quantity of electricity recovered and the weights of ACF and LiClO_4 consumed. If the cell is charged and then allowed to stand for one day, 40 - 50 % of charge initially inserted can no longer be recovered on discharge. However, it may be useful for a back-up power source because of the stability of the charge-discharge cycles and of extremely large specific capacity.

RECHARGEABLE BATTERY

A cloth of ACF (38.4 mg , 3.8 cm^2), and a strip of lithium were separated by a glass fiber filter of 0.25 mm thickness. They were then placed in a glass vessel containing a 1 mol dm^{-3} solution of LiClO_4 in $\gamma\text{-BL}$ in an argon atmosphere. Platinum wires attached to the ACF and lithium were connected to the positive

and negative terminals of D.C. power source, respectively. After passing 14.91 C , the battery at the charged state is expressed as $\text{bLi} | \text{LiClO}_4$ in $\gamma\text{-BL} | (\text{ACF}^{\text{b}+})(\text{ClO}_4^{\text{b}-})_{\text{b}}$. The molar ratio of dopant to a carbon atom was estimated to be $b=0.0503$ at this stage.⁶ The V_{oc} of 4.61 V and the I_{sc} of 696 mA were obtained, which correspond to a maximum power density of $14.8\text{ kW}/\text{kg}$, based on the weights of ACF and LiClO_4 consumed. Fig. 3 shows the changes of the electrode potentials vs. Ag/Ag^+ and the change of the cell voltage under a constant current of $1\text{ mA}/\text{cm}^2$ both in charge and discharge processes. Flat voltage could not be obtained, because of the presence of capacitive contribution of the ACF electrode. The present system is basically similar to the Li-graphite battery reported.⁷ However, the capacitive contribution in the Li-ACF battery is much larger than in Li-graphite battery. The theoretical energy density was estimated to $358\text{ WH}/\text{kg}$ based on V_{oc} , quantity of electricity passed and the weights of ACF and LiClO_4 consumed. The energy density in the present system is about 3.5 times as large as that of Li-graphite battery reported.⁷ The present system can store electricity more than three times as large as the Li-graphite battery. A partial charge-discharge cycle between $4.5\text{--}3.6\text{ V}$ ($Q_{\text{in}}=6.84\text{ C}$, $Q_{\text{out}}=5.7\text{ C}$, 83 % of the stored charge) was reproducible for more than 50 cycles. If the cell is charged and then allowed to stand for four days, 60 % of the charge originally inserted can no longer be recovered on discharge. However, the

self-discharge was very little after four days.

Since ACF is a flexible material, we can make a capacitor and a battery with flexibility.

The Importance of Alkali Metal Cations in Acid Environments in Contact with Corrosion-Protective Organic Coatings

Henry Leidheiser, Jr.,* Hyacinth Vedage, Richard D. Granata,* and Malcolm L. White

Department of Chemistry and Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

It has previously been shown that the rate at which polybutadiene coatings delaminate from a steel surface, radially from a defect, upon cathodic polarization is a function of the cation present in the medium (1). The rate of delamination in the presence of different cations decreases in the order, Cs^+ , K^+ , Na^+ , and Li^+ . This same order of relative activity has been observed with other metallic substrates and with alkyd, epoxy and photoactive polymer systems. Our experience to date is that this alkali metal ion effect is ubiquitous and that it probably results from the relative rates of migration of the ions either through the coating or in the liquid layer at the interface under the potential gradient which exists when a cathodic potential is applied. We have recently observed another alkali metal ion effect which we have not yet explained but which effect may possibly be put to a useful purpose in certain situations. A description of this effect is given below.

All investigations have been conducted on a formulated epoxy/polyamideamine. The coating was applied to steel by a doctor blade technique to a thickness of 500 μm , a thickness for use with aggressive environments which is less than that recommended by the formulator. Exposure of coated steel to 0.1M H_2SO_4 at 60°C resulted in the formation in two days or less of blisters. Application of the coating to the as-received, rolled surface after solvent cleaning resulted in the formation of a single large blister that covered the entire 3.2 cm diameter exposed area after 2 days. Sandblasted steel surfaces treated similarly developed many isolated blisters that did not merge in two days. The results were reproducible.

Alkali metal ions were introduced into the sulfuric acid as the sulfate to a concentration of 0.5M, i.e., in a 5/1 ratio of metal

cation to hydrogen ion. The rate of blister formation was remarkably reduced. Small isolated blisters were detected after an average of 5 days in the case of Li^+ ion additions, after an average of 7 days in the case of Na^+ ion additions, and after an average of 10 days for K^+ ion additions.

The following experiment suggests that the alkali metal ions reduce the rate of collection of H^+ ions at the substrate/coating interface. A strip of pH sensitive paper was placed on a piece of glass and was overcoated with a 500 μm thick layer of the epoxy coating. The coated glass was exposed to 0.1M H_2SO_4 at 60°C for two days. The paper indicated the pH at the interface was very low. A similar sample exposed to 0.1M H_2SO_4 - 0.5M Na_2SO_4 for the same length of time yielded no change in color of the pH paper, suggestive of the fact that no significant concentration of H^+ ions had collected at the interface. The results obtained with the pH sensitive paper were also reflected in the coating itself. This coating changes from a black to tan color upon exposure to H_2SO_4 under the conditions of our experiments. The sample immersed in 0.1M H_2SO_4 exhibited this color change both at the top surface in contact with the electrolyte and the bottom surface as viewed through the glass. The sample immersed in the H_2SO_4 - Na_2SO_4 mixture exhibited the color change at the top surface but the bottom surface as viewed through the glass exhibited no change in color. The observations suggest that the alkali metal ion interferes with the transport of the hydrogen ions through the coating.

We have no completely satisfactory explanation for the effect at the present time. Osmotic behavior offers a possible explanation since the amount of water migration through the coating would be expected to decrease with increase in the ionic concentration of the electrolyte. However, it is hard to explain the big differences observed with the different alkali metal ions. The most appealing explanation is that the alkali

*Electrochemical Society Active Member

Key words: acid, coating, corrosion, protection

metal ions compete with the H^+ ions for simple diffusion or electromigration through the coating. The ions also may form strong bonds with the water molecules present in the coating and may reduce the rate at which an aqueous phase develops at the metal/coating interface. The aqueous phase is essential for the corrosion process to occur and consequently the rate of blistering is reduced. The bonding of water by the cations may also change the rate at which the coating swells during exposure to the acid.

ABSTRACT

The photoelectrochemical (PEC) performance of p-InP single crystal, surface modified by the sequential deposition of cobalt and platinum, has been investigated in 6N KOH. Efficiencies of 14.2% were realized from the photocathode for the electrical power savings obtained compared to a platinum cathode, operating at the same current density. A variety of definitions of efficiency for the conversion of light to hydrogen are discussed.

RESULTS AND DISCUSSION

Several approaches have been discussed previously for improving the performance of photoelectrodes by surface modification procedures. These have been discussed in several PEC review articles (1-4). The role of platinum for improving the performance of iron-oxide photoanodes was discussed by us some time ago to assist the photoelectrochemical oxygen-evolution reaction (5). Improving the performance of p-InP in both acid (6,7,8) and alkaline electrolyte (9) for specific photoelectrochemical reactions has also been observed. We wish to report on the enhanced performance of p-InP photocathodes realized by the sequential deposition of Co and Pt on its surface.

The p-InP single crystals (Zn-doped, carrier density $10^{16}/\text{cm}^3$, $\langle 111 \rangle$ surface, obtained from Crysta Comm Inc.) were used in the course of this work. Ohmic contact to the crystal was made by the sequential deposition of Au-Zn-Au followed by sintering at 475°C for 20 seconds. Current collection was via a nickel wire to the ohmic contact using silver epoxy which was then cured at 150°C for one hour. After encapsulation of this current collector and the semiconductor edges, the photocathode surface was etched with concentrated HCl for 10 seconds, during which time gas evolution was observed. Surface modification of

the p-InP surface was performed by the local electrodeposition of cobalt from a 1M CoCl_2 solution at low current density ($1 \text{ mA}/\text{cm}^2$).

The cobalt if electrodeposited uniformly would correspond to a thickness of 200 \AA . However, it is likely that the cobalt becomes deposited at preferred sites (probably defect) on the p-InP surface. Because of this, estimation of light blockage caused by this coating is difficult. Some surface characterization is however presently underway using Raman spectroscopic techniques and will be reported on later (10).

Curve A of Figure 1 shows the initial performance of the unmodified p-InP electrode in 6N KOH under $100 \text{ mW}/\text{cm}^2$ ELH quartz halogen illumination. Here the open-circuit potential vs SCE changed from -500 mV to -350 mV after illumination. Rather small photocurrents ($4 \text{ mA}/\text{cm}^2$ at -800 mV vs SCE) and poor fill factors ($\text{FF} = 0.23$) were characteristic of this electrode. After cobalt deposition, the initial open-circuit potential under illumination became more positive (-300 mV). The photocurrent density at -0.8 V vs SCE increased to $13 \text{ mA}/\text{cm}^2$ and gave a fill factor of 0.48, as shown in curve B of Figure 1.

The p-InP was further modified by placing 1 drop of a 0.01 M chloroplatinic acid solution onto the cobalt-treated surface, followed immediately by rinsing with distilled water. The initial performance of this electrode is shown in curve C of Figure 1, where the photocurrent density at -800 mV increased nominally to $14 \text{ mA}/\text{cm}^2$ with the initial open-circuit potential becoming -200 mV vs SCE. Here the fill-factor remained at 0.48. The electrode potential is about 900mV positive of the reversible hydrogen potential in alkaline electrolyte.

The series of curves A-C in Figure 1 are shown to indicate the incremental improvement in PEC performance that can be achieved by the sequential deposition of Co and Pt. However, greatest PEC performance enhancements on p-InP in alkaline electrolytes were achieved by completing the above sequential

*Electrochemical Society Active Member.

Key words: p-InP, Hydrogen Production, Photoelectrocatalysis

surface modification procedures prior to taking any current-potential measurements. This is shown using a second p-InP electrode prepared in a similar manner. With all p-InP electrodes fabricated, the initial V_{OC} of -200 mV vs SCE gradually drifted to more negative values (≈ 10 mins) and typically equilibrated between -300 and -400 mV. The current-potential curve for this second photocathode is shown in Figure 2. The enhanced performance observed for hydrogen evolution is probably an electrocatalytic effect. For comparison the current-potential curve scans for platinum during both hydrogen (left-hand side of Figure 2) and oxygen evolution (right-hand side of Figure 2) are shown. At the point of maximum power conversion efficiency, the p-InP photocathode gave a photopotential of -0.65 V vs SCE. The fill factor for this electrode was 0.58. At the same current density, the potential of the platinum electrode during hydrogen evolution was -1.24 V vs SCE. Here the cell voltage saving realized by substitution of a platinum electrode for the illuminated p-InP photocathode was 0.59 V. At 24 mA/cm² this corresponds to a power savings of 0.59 V x 24 mA/cm² = 14.2 mW/cm². With an incident illumination of approximately 100 mW/cm² unfiltered quartz halogen lamp (General Electric ELH bulb), the efficiency of solar to chemical conversion can be realized in terms of power saving (6,7), which is defined as

$$\eta = (i \times \Delta V) / I_{\text{light}}, \text{ or } \eta_1 = 14.2\%$$

It is appropriate at this time to compare the various alternative approaches available which have recently been discussed for calculating the efficiency of photoelectrodes. One other approach (6) for calculating the efficiency of such photoelectrodes is to compare the potential (V), at which hydrogen evolution occurs at the optimum power for the photocathode, with the reversible thermodynamic potential of hydrogen ($V_{H_2, \text{rev}}$) in an ideal fuel cell anode (-1.1 V vs SCE). Here it is assumed that overpotential losses at the hydrogen anode and at the oxygen cathode during operation is neglected. This second definition can be written as

$$\eta_2 = \frac{i \times (V - V_{H_2, \text{rev}})}{I_{\text{light}}}$$

With reference to Figure 2, this will give a value of

$$\eta_2 = \frac{24 \text{ mA/cm}^2 \times (-0.65 + 1.1) \text{ V}}{100 \text{ mW/cm}^2} = 10.8\%$$

This value obtained in 6N KOH by us compare to values of 13.3% for p-InP (Rh-H alloy) and 11.4% for p-InP (Pt-H alloy) in

1M HClO₄ electrolyte obtained by others (6). It should be noted, however that direct comparison of such efficiency values may in fact be a little erroneous since different light sources were used by each group.

It should be noted that if direct photoelectrolysis of water is the eventual goal for this work, there are significant advantages to the use of alkaline electrolytes where not only greater stabilities might be realized from photoanodes (or anodes) used with p-InP but oxygen evolution kinetics are well documented to be more rapid.

The efficiency of a PEC process can also be calculated as the power (P) ratio (11)

$$\eta_3 = \frac{P_{\text{stored}}}{I_{\text{light}} + P_{\text{bias}}}$$

from which we obtain an efficiency of

$$\eta_3 = \frac{1.23 \text{ V} \times 24 \text{ mA/cm}^2}{100 \text{ mW/cm}^2 + 1.25 \text{ V} \times 24 \text{ mA/cm}^2} = 22.7\%$$

1.23 V is the thermodynamic voltage of a hydrogen/oxygen fuel cell. The bias voltage of 1.25 V is the voltage between the p-InP and an oxygen-evolving platinum electrode at 24 mA/cm². It should be noted that this definition of efficiency is somewhat insensitive to the magnitude of the bias voltage applied. Although this definition gives a relatively large efficiency value, one should be aware that for water electrolysis between two platinum electrodes under a bias voltage without light, the corresponding efficiency will be larger:

$$\eta_3 = \frac{1.23 \text{ V} \times 24 \text{ mA/cm}^2}{1.84 \text{ V} \times 24 \text{ mA/cm}^2} = 66.8\%$$

Other ways are also available for calculating practical efficiency, including

$$\eta_4 = \frac{P_{\text{stored}} - P_{\text{bias}}}{I_{\text{light}}}$$

which for biased photoelectrodes can give decidedly pessimistic values. In our case we have $\eta_4 =$

$$\frac{1.23 \text{ V} \times 24 \text{ mA/cm}^2 - 1.25 \text{ V} \times 24 \text{ mA/cm}^2}{100 \text{ mW/cm}^2} = -0.48\%$$

A fifth definition of efficiency is to take the high heating value of hydrogen ($\Delta H = 1.47 \text{ eV}$) instead of using the Gibbs free energy $\Delta C = 1.23 \text{ eV}$. One assumption here is that all electrical current in the p-InP is used to make hydrogen under 100% Faradaic efficiency, i.e. no corrosion or other simultaneous side reaction occurs. Thus we can write:

$$\eta_5 = \frac{P_{\text{stored}} \text{ (using } \Delta H) - P_{\text{bias}}}{I_{\text{light}}}$$

or $\eta_5 =$

$$\frac{1.47\text{V} \times 24\text{mA/cm}^2 - 1.25\text{V} \times 24\text{ mA/cm}^2}{100\text{ mW/cm}^2} = 5.3\%$$

We have shown that a variety of efficiency values can be obtained from one electrode, depending upon the definition used. In short, care must be taken when comparing the "efficiencies" of fuel-producing PEC cells as reported by different laboratories.

The PEC performance discussed here for p-InP in alkaline electrolyte gives us the opportunity to design cells which have a high reversibility towards oxygen evolution at the counter electrode and possess good stability and corrosion resistance for the electrode components.

A Model for the Anodic Dissolution of Zinc in Alkaline Electrolyte

Kinetics of Initial Dissolution

Yu-Chi Chang* and Geoffrey Prentice**

Department of Chemical Engineering, The Johns Hopkins University, Baltimore, Maryland 21218

ABSTRACT

We propose a three-step mechanism to describe the kinetics of the initial dissolution of zinc in alkaline electrolyte. The rate-determining step is postulated to be a reversible reaction where a monovalent zinc hydroxide is converted to a soluble zincate. The surface reactions are assumed to occur on activated sites, where Langmuir adsorption is assumed. The reaction scheme is shown to be consistent with experimental quantities such as Tafel slope and reaction order for data obtained near room temperature in approximately 1N hydroxide electrolyte. The thermodynamic consistency of each elementary step is demonstrated from an analysis of available free energy data.

The zinc electrode in alkaline electrolyte is used in currently available battery systems and is a prime candidate for incorporation in advanced energy storage devices (1, 2). Consequently, many investigations have been conducted to determine the kinetic and thermodynamic characteristics of this electrode system. Extensive bibliographies of this work appear in Ref. (3-5). The overall kinetic characteristics (reaction orders, Tafel slopes, etc.) have been determined in numerous studies; however, fewer investigations regarding the elementary phenomena comprising the dissolution process have been conducted. A notable exception is the quantitative treatment presented by Bockris *et al.* (6).

Slow potentiodynamic sweeps on a rotating-disk electrode reveal four characteristic regions on a typical current-potential curve (Fig. 1): (i) an initial dissolution region where the current increases exponentially with potential, (ii) an active dissolution region where the current density increases rapidly with potential in a linear fashion, (iii) a prepasive region where a high level of current is maintained but is not a strong function of potential, and (iv) a passive region where little current flows, irrespective of potential. In the present investigation, we are concerned primarily with the initial dissolution region. In 1N KOH the proposed model is valid in a range near -1.23V vs. NHE.

Spectroscopic and potentiometric studies (7, 8) have demonstrated that the soluble reaction product is a zincate ion; the overall reaction can be represented by

Ranges of the kinetic parameters for this reaction obtained by various investigators are summarized by Bockris *et al.* (6).

Kato *et al.* (9) observed a decrease in collection efficiency with rotation rate for the anodic dissolution of zinc on a rotating ring-disk electrode. This phenomenon has been confirmed by other investigators (4), and variations in collection efficiency with bulk zincate have also been observed.

In this study, we present a detailed analysis of our model and compare the derived results with corresponding experimental quantities and with the results derived from other proposed mechanisms.

Proposed Model

Reaction mechanism.—We are proposing the following three-step mechanism for the anodic dissolution of zinc in the initial stages

Our postulates are that the rate-determining step controls the overall reaction rate and that dynamic equilibria are rapidly established in the other two elementary steps. Although stable monovalent zinc compounds have not been isolated, evidence exists of their presence as short-lived species (10, 11). Reactions involving zinc and the monovalent hydroxide species are assumed to occur on the electrode surface. The third reaction, which involves only a soluble zincate species, is assumed to be a homogeneous reaction occurring in the electrolyte.

Analysis of rate expressions.—We treat the adsorbed species in accordance with Langmuir's hypotheses and

Fig. 1. Typical potentiodynamic sweep on a zinc RDE. 1.0N KOH, 300 rpm, 4 mV/s sweep rate, 25°C.

express the reaction rates in terms of species concentrations and electrode potential

$$r_1 = i_1/F = k_{a1}c_{OH^-} (1 - \theta) \exp[(1 - \beta_1)FV/RT] - k_{c1}\theta \exp(-\beta_1FV/RT) \quad [4]$$

$$r_2 = i_2/F = k_{a2}c_{OH^-}^2 \exp[(1 - \beta_2)FV/RT] - k_{c2}(1 - \theta) c_{Zn(OH)_3^-} \exp(-\beta_2FV/RT) \quad \text{rds} \quad [5]$$

$$r_3 = k_{a3}c_{Zn(OH)_3^-}c_{OH^-} - k_{c3}c_{Zn(OH)_4^{2-}} \quad [6]$$

where θ represents the fractional surface coverage by the ZnOH species.

At steady state, all the reactions proceed at the same rate; the net current density is given by

$$i = 2i_1 = 2i_2 \quad [7]$$

Since reaction [1] is assumed to be fast and essentially at equilibrium, the fractional surface coverage can be obtained from Eq. [4]

$$\theta = k_{a1}c_{OH^-}/[k_{a1}c_{OH^-} + k_{c1} \exp(-FV/RT)] \quad [8]$$

Substitution of Eq. [8] into Eq. [5] yields

$$i_2/F = i/(2F) = k_{a2}k_{a1}c_{OH^-}^3 \exp[(2 - \beta_2)FV/RT] \frac{[(H + 1)k_{c1}] - k_{c2}k_{c3}c_{Zn(OH)_4^{2-}} \exp(-\beta_2FV/RT)}{[(H + 1)k_{a3}c_{OH^-}]} \quad [9]$$

where

$$H = k_{a1}c_{OH^-}/[k_{c1} \exp(-FV/RT)] \quad [10]$$

The equilibrium potential, determined from Eq. [9], is

$$V^0 = RT/(2F) \ln[k_{c1}k_{c2}k_{c3}c_{Zn(OH)_4^{2-}}/k_{a1}k_{a2}k_{a3}c_{OH^-}^4] \quad [11]$$

and the exchange current density is

$$i_0 = 2Fk_{c2}[k_{a1}k_{a2}/(k_{c1}k_{c2})]^{1/2} (k_{c3}/k_{a3})^{(2-\beta_2)/2} c_{OH^-}^{2\beta_2-1} c_{Zn(OH)_4^{2-}}^{(2-\beta_2)/2} (H^0 + 1) \quad [12]$$

where H^0 is the variable H evaluated at the equilibrium potential V^0 . The overpotential represents the departure from the equilibrium potential and can be expressed as

$$\eta = V - V^0 \quad [13]$$

Equation [9], cast in the standard Butler-Volmer form, becomes

$$i = i_0^* [\exp(\alpha_a F \eta / RT) - \exp(-\alpha_c F \eta / RT)] \quad [14]$$

where $\alpha_a = 2 - \beta_2$, $\alpha_c = \beta_2$, and $i_0^* = i_0/[H^0 + 1]/(H + 1)$.

Results and Discussion

In order to calculate the current density as a function of potential, a value for the symmetry factor, a rate constant for reaction [2], and equilibrium constants for reactions [1] and [3] must be determined. The free energies of formation of the reacting species in reaction [3] are known; however, the free energy of reaction for the first two reactions cannot be determined, as they involve the unstable monovalent species for which thermodynamic data are unavailable. As an estimate for the free energy of formation of ZnOH, we chose a value of -65.8 kcal/mol, which corresponds to an equilibrium constant that is consistent with current density-potential data; moreover, this value is close to the free energy of formation of ZnO (-76.6 kcal/mol), as we expect from group contribution considerations. The forward rate constant for reaction [2] was also chosen to be compatible with current-potential data. A summary of kinetic and thermodynamic parameters appears in Table I.

Quantities such as Tafel slope and variation of the exchange current density with concentration are dependent on the choice of symmetry factor in the rate-determining

Table I. Summary of kinetic and thermodynamic quantities

Species	Standard free energy of formation (kcal/mol)	
ZnOH	-65.8	
OH ⁻	-37.6	
Zn(OH) ₃ ⁻	-166.0 to -167.6	
Zn(OH) ₄ ²⁻	205.2 to -206.2	
Reaction	Standard free energy of reaction (kcal)	Kinetic rate constant cm ⁴ /(s mol)
[1]	-28.2	9.3 × 10 ⁹
[2]	-25.0 to -26.6	
[3]	-2.6 to 0	

Thermodynamic quantities were obtained (or derived) from data found in Ref. (7, 12, 13). The free energy of formation of ZnOH and the rate constant were estimated (see Results and Discussion section).

step. The Tafel slopes are obtained directly from Eq. [14]; the anodic Tafel slope is

$$\partial V / \partial \log i_a = 2.3RT / [(2 - \beta_2)F - HF / (H + 1)] \quad [15]$$

and the cathodic Tafel slope is

$$\partial V / \partial \log i_c = 2.3RT / [\beta_2 F + HF / (H + 1)] \quad [16]$$

The variations in the exchange current density with concentration are obtained from Eq. [12]

$$\partial \ln i_0 / \partial \ln c_{OH^-} = 2\beta_2 - 1 - H^0 / (1 + H^0) \quad [17]$$

$$\partial \ln i_0 / \partial \ln c_{Zn(OH)_4^{2-}} = (2 - \beta_2) / 2 \quad [18]$$

Equation [17] indicates that the variation in the logarithm of the exchange current density with pH is dependent on pH. If we choose $\beta_2 = 0.5$ and $V = -1.240$ vs. NHE, $\partial \ln i_0 / \partial \ln c_{OH^-} = -0.33$ when evaluated at $[OH^-] = 1M$; at $[OH^-] = 2M$, $\partial \ln i_0 / \partial \ln c_{OH^-}$ is equal to -0.5 .

The value of the exchange current density calculated from Eq. [12] is 10 mA/cm², which is in agreement with the experimentally determined value at $1M$ KOH and $10^{-2}M$ Zn(OH)₄²⁻. The experimental value is affected by the surface roughness of the electrode, as the true surface area may be 2 or 3 times larger than the geometric area (14). A far more important consideration is the sensitivity of the calculated value to the choice of the symmetry factor. Data for many electrochemical reactions indicate that the symmetry factor is generally near 0.5 (15), and we have chosen this value in calculating i_0 . Because the symmetry factor appears as an exponent in the exchange current density expression Eq. [12], i_0 is extremely sensitive to the value of β_2 . A difference of 0.2 in β_2 causes a change of several orders of magnitude in i_0 ; by contrast, surface area effects are negligible. The quantities that depend on β_2 and the sensitivity of those quantities to changes in β_2 are summarized in Table II.

Table II. Quantities that depend on the symmetry factor

Quantity	Calculated value		Experimental value
	$\beta = 0.5$	$\beta = 0.7$	
α_a	1.5	1.3	1.0-1.6
α_c	0.5	0.7	0.4-0.7
Anodic Tafel slope (mV/decade)	50	70	30-60
Cathodic Tafel slope (mV/decade)	100	70	85-145
$\partial \log i_0 / \partial \log c_{OH^-}$	-0.33	0.07	0.14-0.45
$\partial \log i_0 / \partial \log c_{Zn(OH)_4^{2-}}$	0.75	0.65	0-0.67
i_0 (mA/cm ²)	10	2 × 10 ⁵	10-100

The experimental values are from the summary provided by Bockris *et al.* (6). Exchange current density is based on a zincate concentration of $0.0065M$ as in Ref. (6).

Fig. 2. Current density vs. potential for RDE. Solid line represents experimental data: 1N KOH, 25°C, 800 rpm, from Ref. (5). Dashed line calculated from Eq. [9].

The relation between current density and potential can be calculated from Eq. [9]. Comparison with the experimental data shows the narrow range, near -1.23V vs. NHE, over which the model is valid (Fig. 2). At more anodic potentials, it is likely that reactions involving species such as $\text{Zn}(\text{OH})_2$ and ZnO become more important and would need to be considered in a model for that region.

The reaction orders and the equilibrium potential are not dependent on the choice of symmetry factor. The anodic reaction orders are

$$\partial \ln i_a / \partial \ln c_{\text{OH}^-} = 3 - H / (H + 1) \quad [19]$$

$$\partial \ln i_a / \partial \ln c_{\text{Zn}(\text{OH})_4^{2-}} = 0 \quad [20]$$

and the cathodic reaction orders are

$$\partial \ln i_c / \partial \ln c_{\text{OH}^-} = -1 - H / (H + 1) \quad [21]$$

$$\partial \ln i_c / \partial \ln c_{\text{Zn}(\text{OH})_4^{2-}} = 1 \quad [22]$$

Since H is proportional to hydroxide concentration, the reaction orders vary with pH. A comparison of calculated and experimental reaction orders appears in Table III. All of the calculated values agree with the experimental determinations within the error of the experiment.

Several additional experimental observations are consistent with the proposed mechanism. Armstrong and Bulman (16) performed anodic dissolution studies on a rotating disk electrode. They obtained a linear plot of $1/i$ vs. $1/\omega^{1/2}$ at constant potential. Their analysis showed that the finite slope of this curve was evidence of the reversibility of the overall reaction. This observation is in agreement with our assumption that the rate-determining step is reversible. Armstrong and Bell (17) carried out impedance experiments, which indicated the presence of a single adsorbed intermediate. Their assumption that this intermediate is a monovalent zinc species is in agreement with our model. These investigators also determined the anodic Tafel slope from steady-state measurements. Their results show that the Tafel slope is 44 mV/decade at $V = -1.34\text{V}$ (Hg/HgO) and 120 mV/decade at $V = -1.31\text{V}$. We can evaluate the anodic Tafel slope from Eq. [15] at potentials corresponding to the values where Armstrong and Bell obtained their data. Since the variable H in that equation is potential dependent, the calculated Tafel slope is potential dependent. The Tafel slopes are 50 and 70 mV/decade, respectively. Both the experimental and calculated results show that the Tafel slope increases at more anodic potentials.

The four-step mechanism proposed by Bockris *et al.* (6) yields results that are generally similar to our results; however, there are several distinguishing features. In the

Table III. Comparison of experimental and calculated thermodynamic and kinetic parameters

Quantity	Calculated value	Experimental value
V^0 (V)	-1.26	-1.26
$\partial \ln i_a / \partial \ln c_{\text{OH}^-}$	~2.7	2.6 to 3.5
$\partial \ln i_c / \partial \ln c_{\text{Zn}(\text{OH})_4^{2-}}$	1	0.75 to 1.05

Calculated values are based on $\beta_2 = 0.5$. Experimental values from Ref. (6, 16).

Bockris model there are two adsorbed species, ZnOH and $\text{Zn}(\text{OH})_2^-$; in our model only the former species is considered as an adsorbed species. The reaction order with respect to hydroxide is somewhat different. Although direct comparisons are theoretically possible, the thermodynamic data on which to base a comparison are not available. For example, in the Bockris model $\partial \ln i_a / \partial \ln c_{\text{OH}^-} = 3 - (H + 2K_2 H c_{\text{OH}^-}) / (1 + H + K_2 H c_{\text{OH}^-})$, where K_2 is the equilibrium constant for the reaction $\text{ZnOH} + \text{OH}^- = \text{Zn}(\text{OH})_2^-$. This expression could be compared directly to Eq. [19] if free energy data were available for ZnOH and $\text{Zn}(\text{OH})_2^-$.

In further work, we plan to extend the model to more anodic regions and study the effects of mass transport on dissolution rates.

A Model of the Structure of the Positive Lead-Acid Battery Active Mass

D. Pavlov* and E. Bashtavelova

Central Laboratory of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia 1040, Bulgaria

ABSTRACT

A general model for the organization of the structure of the positive active mass is proposed based on SEM observations of samples, obtained from PAM and pastes with different phase compositions and crystal morphology. The structure is built up of two levels: a first-level microstructure, which consists of small crystals with the form of grains, prisms, plates, and needles organized in porous agglomerate, and a second-level macrostructure. The individual agglomerates (with a screw-like, spherical, prismatic or rock-like shape) are linked in a macroporous skeleton, which supports mechanically the active material, conducts the electric current, and serves as memory, where the conditions for the preparation of the paste, the curing, and the formation of the active material are coded. For convenience, two limiting structures are designated: (i) the "agglomerate type," when the agglomerate structure determines the properties and the cycle life of the plate; and (ii) the "crystalline type," when the microstructure determines the energy performance and the stability of the plate. The "agglomerate-type" structure is obtained from low sulfatized and dense pastes. During cycling, some irreversible processes occur, whereby the "agglomerate" structure is transformed into the "crystalline-type" structure, which in turn is dispersed to individual crystallites. This leads to softening and shedding of the active material and finally to cell failure. The proposed general model reveals the relationships between the performance of the positive plate and the technology of its production.

There are two groups of problems associated with the structure of the positive active mass. The first one treats of the formation of the structure and the conditions upon which it depends, as well as the structure organization. The second group of problems deals with the disruption of the structure during the battery operation. A great variety of structures has been presented in literature. Nevertheless, there is a general agreement concerning their principal functions: part of the PbO_2 serves as a mechanical support and electric conductor, while the rest takes part in the charge-discharge processes. Usually, these two functions have been associated with different structures of the PbO_2 crystals. Thus, Simon and Jones (1) found out that the active material is composed of needlelike or prismatic crystals and of small polyhedrons of nearly equal size. They ascribe the role of a mechanical support to the former, while the latter determine the plate capacity. The reason for this difference in morphology these authors related to the α - and β -modifications of PbO_2 (1). Very soon, however, this relation was experimentally rejected.

It was established that the structure of the PbO_2 active material depends upon two processes, as mentioned below.

Phase composition and the morphology of the crystals in the paste.—Burbank (2), Pierson (3), and Biagetti and Weeks (4) established that in many cases the morphology of the paste crystals is transformed to the structure of the positive active mass by metasomatic processes during formation.

Processes during plate formation.—Pavlov *et al.* (5) revealed that the formation occurs in two stages. During the first, only a part of the paste is oxidized to PbO_2 , while

* Electrochemical Society Active Member.

Key words: lead-acid battery, PbO_2 active mass structure, PbO_2 active mass shedding, agglomerate-type PbO_2 structure, crystalline-type PbO_2 structure.

the rest is converted to PbSO_4 . During the second stage, PbSO_4 is oxidized to β - PbO_2 . Yarnell and Weeks (6) and Butler *et al.* (7) showed that the 4PbOPbSO_4 crystals are oxidized by a solid phase reaction, as a result of which their morphology is acquired by the PbO_2 crystals. The PbSO_4 crystals, however, are oxidized by a dissolution-precipitation mechanism, whereby the morphology of the paste crystals is lost during the formation process. It was also established that the morphology of the PbO_2 crystals at the surface and in the interior of the positive plates is different (8).

The purpose of the present paper is to reveal the general organization of the positive active mass structure, as well as to establish some of the factors which influence this structure during its formation and destruction.

Experimental

Method

The principles upon which the present investigation is based are: (i) the preparation of a large number of structures of the PAM (positive active mass) and the revelation of their common building elements and organization; (ii) on the basis of this organization, to compose a general model of the structure of the PAM; and (iii) to study the relationship between the capacity and cycle life of the positive plate and the type of structure.

Types of Pastes

The variety of structures of the PAM was achieved by preparation of pastes with various phase compositions, while the formation conditions were kept constant. As established by Pavlov and Papazov (9) and Iliev and Pavlov (10), pastes with definite phase compositions and morphology of the crystals can be prepared by varying the ratio between H_2SO_4 and the oxidized lead powder (lead

oxide) H_2SO_4/PbO and the temperature during paste preparation.

In Table I are presented the pastes which were prepared using commercial leady oxide, oxidized to 63% tet-PbO.

Preparation of the Pastes and Plates

3 kg leady oxide was mixed in succession with calculated quantities of water and H_2SO_4 solution s.g. 1.4 in a laboratory mixer at a constant temperature. The mixing continued for 1h. The paste was applied manually on SLI battery grids of a lead alloy containing 6% Sb, 0.1% As, and 0.1% Sn. The applied amount of the paste was similar for all plates. The calculated capacity of a plate was 11 Ah at a 50% efficiency of the PAM.

The plates were cured in a chamber first for 48h at 30°C and 100% relative humidity (RH) and then for 24h at 40°C and 60-70% (RH). After curing, the content of metallic lead did not exceed 1%.

Formation

Elements were assembled of 3 positive and 4 negative plates. The formation was performed in H_2SO_4 (s.g. 1.05) at c.d. 5 mA/cm² and 30°C for 22h. The elements were then cycled in a H_2SO_4 solution (s.g. 1.28) for 5 cycles: 7h charge at 2A and 5h discharge at 2A.

Analysis

First, the morphology of the crystals and structure of the inner parts of the plates were studied by a JEOL T 200 SEM at two magnifications: small for the structure of the active mass and large for the crystal morphology. Second, the phase composition was determined by a TUR M 62 x-ray diffractometer using a Cu K_α cathode. The samples were collected from five different places on the plate. Finally, the pore volume and pore-site distribution were determined by a Carlo Erba 1500 Hg porosimeter. The samples were collected from five different places on the plate.

Electrochemical Performance

Five cells were assembled from each type of paste with three positive and four negative plates. They were tested for: (i) capacity at 20h rate of discharge and 25°C and (ii) cycle life charging for 5h at 1.32A, discharging for 1h with 5.5A (four cycles per day). The capacity was checked every 25 cycles. Every 50 cycles, samples were taken for structural, porometric, and phase investigations. All micrographs of the crystals and structure were taken after full charge of the plate only.

Results and Discussion

Model of Basic Building Elements and Levels of the Structure of the PAM

Figure 1 presents SEM micrographs of PAM from paste "c" containing 4PbOPbSO₄ and tet-PbO.

From the micrographs, it is seen that the smallest elements in the structure of the PAM are the individual crystals.

Table I. Pastes prepared using commercial leady oxide, oxidized to 63% tet-PbO

Phase composition	H_2SO_4/PbO (%)	Density of paste (g/cm ³)	(°C)
A. tet-PbO with small amounts of 3PbOPbSO ₄ · H ₂ O	1	4.3	30
B. 3PbOPbSO ₄ · H ₂ O with small amounts of tet-PbO and orthoromb. PbO	6	4.2	30
C. 4PbOPbSO ₄ with small amounts of tet-PbO and orthoromb. PbO	6	4.3	80
D. PbOPbSO ₄ , 3PbOPbSO ₄ , H ₂ O with small amounts of tet-PbO	12	4.2	30

They have different morphology. The pictures in Fig. 1a and 1b illustrate two different types of morphology of these crystals.

Needlelike and prismatic.—As seen in Fig. 1a, these have grown mainly along the C axis and have a common basis. A large number of the crystals are connected together in an agglomerate. For the case of Fig. 1a, the agglomerates are round.

Platelike crystals.—As seen in Fig. 1b, these have grown along the A and B axes and are connected by sharing the A-B planes. The crystals of this type are so ordered that they form screw agglomerates.

One can observe micropores between the crystals in each agglomerate. The number and volume of these pores depend on the morphology of the crystals. The combination of the crystals and micropores in the agglomerate will be denoted as microstructure of the active mass, which is the first structure level.

Figure 1c shows the SEM micrograph of the same active material with a low magnification. It is seen that the agglomerates have various forms, size, and microstructure and are linked in a branched skeleton (framework). The agglomerates enclose macropores, which are connected in channels, which in turn pierce the plate. The combination of the skeleton of agglomerates with the macropores forms the macrostructure of PAM and presents the second structure level.

It may be supposed that these two structure levels have different functions. In order that the charge-discharge reaction

should proceed at a spot, located deeply in the plate, the following transport processes must occur: (i) flows of H⁺ ions and H₂SO₄ should reach this spot coming from the bulk of the electrolyte, while H₂O should move in the opposite direction. The lowest resistance for these flows is along the macropores, which play the role of an ionic transport system. The micropores produce a large active surface area, and, consequently, they determine the capacity of the plate. (ii) The electrons taking part in the charge-discharge reactions at the above-mentioned spot have to be transported freely in the macrostructure. The agglomerates have the largest cross section, and therefore, low resistance. Hence, the macrostructure serves as a mechanical framework, which conducts the current, forms the ionic transport system, and holds together the microstructures of the individual agglomerates. The microstructures on their part provide the electric charge, which the active mass can yield without its disintegration.

Effect of the Phase Composition of the Paste on the Structure of the Active Material

PAM from 1% H₂SO₄/PbO paste.—Figure 2 presents the structure of a paste and the active mass formed from it.

From Fig. 2b, one can see that only a few of the crystals from the first structural level have clearly expressed prismatic form, while a large part of them appears as grains, which are so tightly linked that it is very difficult to distinguish them. In this case, the agglomerates have a compact granular microstructure. It can be assumed that this morphology of the crystals is related to the high rate of PbO₂ nucleation on the surface of the paste crystals and low rate of PbO₂ crystal growth during formation. PbO₂ has by 4% larger molar volume, as compared to that of PbO. It can be supposed that the PbO₂ grains cover the surface of the paste crystals and some of its inner parts will remain unchanged. As a result, the PbO₂ agglomerates will have a lower microporosity.

Figure 2c shows that the macrostructure is composed of large, shapeless continuously interconnected agglomerates with a rocklike appearance. It is quite similar to the paste structure shown in Fig. 2a. The compactness of the agglomerates, their low microporosity, and their strong

Fig. 1. SEM micrographs of PAM obtained from a $4\text{PbOPbSO}_4 + \text{tet-PbO} + \text{orthoromb. PbO}$ paste. The white lines correspond to $1 \mu\text{m}$.

Fig. 2. SEM micrographs of: (a) $1\% \text{H}_2\text{SO}_4/\text{PbO}$ paste, (b) and (c) PAM obtained from it. The white lines correspond to $1 \mu\text{m}$.

adhesion make this macrostructure very rigid. The role of the microstructure of the agglomerates is strongly suppressed. Consequently, this type of PAM structure can be conventionally denoted as an "agglomerate type."

PAM from 12% H_2SO_4/PbO paste.—Figure 3a presents the structure of the paste and Fig. 3b and 3c that of the active mass.

Figure 3b shows that PAM consists of well-grown and clearcut prismatic crystals. The paste composition is characterized by a high degree of sulfatization. A comparison of Fig. 3a and 3c shows that the shape of the paste crystals is different from that of PAM. This supports the idea that the high sulfatized paste crystals are oxidized by dissolution-precipitation mechanism (6). The regular shape of the crystals implies that the rate of their growth is significant and they polygonize well.

The agglomerates are highly porous, which makes difficult their identification (Fig. 3b). This type of structure will evidently have a large surface area and pore volume, but also a mechanically weak macrostructure. The properties of the active mass will be determined mainly by the features of the individual PbO_2 crystals and the mode of their linking, *i.e.*, by the microstructure level. Thus we could designate conventionally this type of structure as "crystal type."

PAM from 6% H_2SO_4/PbO , 80°C paste.—The micrographs of the crystal and the agglomerate levels of the PAM were presented on Fig. 1. Here, Fig. 4a presents the SEM picture of the structure of the paste and Fig. 4b that of the agglomerate level of PAM.

The $4PbOPbSO_4$ crystals are 15-20 μm long and 2-4 μm wide (Fig. 4a). During formation, this morphology determined the size and shape of the agglomerates (Fig. 1c and 4b), *i.e.*, the second level of the active material structure. Many authors treated the agglomerates as PbO_2 crystals, and, especially Burbank (2), proposed a model according to which the metasomatic processes transform every $4PbOPbSO_4$ crystal into a PbO_2 crystal. According to the model of two-level structure, proposed here, the $4PbOPbSO_4$ crystal is the basic substance upon which the oxidation reaction proceeds, at a vast number of active sites. At these sites, the PbO_2 nuclei are formed which grow, fed by the oxidation reaction. The conversion of $4PbOPbSO_4$ crystal to PbO_2 decreases the volume of the solid phase by 15.38% per gram atom of Pb. As a result of this, micropores are formed between the PbO_2 crystals, through which the reaction is propagated deeply inside the $4PbOPbSO_4$ crystal. This type of structure has a well-built-up transport system of macropores. Its formation occurs during paste preparation and curing. The micropores are built up in the agglomerate structure during the formation.

PAM from 6% H_2SO_4/PbO , 30°C paste.—Figure 5a shows the structure of the paste, and Fig. 5b and 5c that of the PAM.

The paste contains shapeless $3PbOPbSO_4 \cdot H_2O$ crystals, which are well connected to each other (Fig. 5a). When they are oxidized to PbO_2 , the volume of the solid phase decreases by 34% per gram atom of Pb in the compound. Figures 5c and 5b show that both levels—macro- and microstructures—are well developed. The agglomerates have a round shape and are built up of individual crystals with a highly developed system of micropores.

Effect of the Paste Density on the Structure of PAM

This dependence was studied with active materials prepared from pastes obtained at 30°C and a 6% H_2SO_4/PbO ratio, using the following densities, obtained by varying the ratio liquid/oxide (9): (i) $d = 3.70 \text{ g/cm}^3$, with a structure shown in Fig. 6a and 6b, (ii) $d = 4.75$, with a structure shown in Fig. 7a and 7b, and (iii) $d = 4.2$, with a structure shown in Fig. 5b and 5c.

These figures demonstrate that the density of the paste exerts an exceptionally strong influence on both levels (the microstructure and the macrostructure of the active mass).

Fig. 3. SEM micrographs of: (a) 12% H_2SO_4/PbO paste, (b) and (c) PAM obtained from it. The white lines correspond to 1 μm .

Fig. 4. SEM micrographs of: (a) 6% $\text{H}_2\text{SO}_4/\text{PbO}$ 80°C paste, and (b) PAM obtained from it. The white lines correspond to 1 μm .

At a low density of the paste (Fig. 6a and 6b), the agglomerates are built up of individual needlelike and prismatic crystals with a highly developed system of micropores, *i.e.*, we have a "crystal-type" structure. Evidently, this type of structure is produced during the formation of the plates. At lower densities of the paste, the rate of sulfatization processes is very high, and a considerable part of the active material is produced by oxidation of PbSO_4 , obtained during formation.

The active material obtained from dense pastes (Fig. 7a and 7b) has an "agglomerate-type" structure composed of screwlike ordered crystals.

Agglomerates with shapeless grains were observed on some isolated sites. The cured paste was probably not macrohomogenous enough. On the other places, where the active material contained a system of large macropores, the agglomerates consisted of numerous small prismatic crystals. This implies that both the micro- and macrostructure depend on the access of the H_2SO_4 and H^+ fluxes to the layer where the reactions of the plate formation occur. It can be expected that during formation of low density pastes the pH in the reaction layer will be low, in contrast to the case when high density pastes are

Fig. 5. SEM micrographs of: (a) 6% $\text{H}_2\text{SO}_4/\text{PbO}$ 30°C paste, (b), and (c) PAM obtained from it. The white lines correspond to 1 μm .

Fig. 6. SEM micrographs of PAM obtained from 6% $\text{H}_2\text{SO}_4/\text{PbO}$ paste with $d = 3.70 \text{ g/cm}^3$. The white lines correspond to $1 \mu\text{m}$.

formed. This will lead naturally to different oxidation mechanisms and, consequently, to different macro- and microstructures.

Porosity, Pore-Size Distribution and Specific Surface Area

Figure 8 displays the pore distribution graphs of the types of PAM mentioned above.

It is seen that the structures of PAM obtained from a low density paste ($d = 3.70 \text{ g} \cdot \text{cm}^{-3}$) or a higher degree of sulfatization (12% $\text{H}_2\text{SO}_4/\text{PbO}$) have a larger pore volume than those obtained from dense ($d = 4.75 \text{ g} \cdot \text{cm}^{-3}$) or low sulfatized pastes (1% $\text{H}_2\text{SO}_4/\text{PbO}$ ratio).

PAM structure obtained from the paste with $3\text{PbOPbSO}_4 \cdot \text{H}_2\text{O}$ has a larger pore volume than that obtained from 4PbOPbSO_4 paste.

In Table II, the specific surface areas of the above investigated PAM are presented.

Table II shows that the PAM structures obtained from the pastes with low density of high degree of sulfatization have larger active surface areas than those obtained from dense or low sulfatized pastes. The PAM structure obtained from the paste with $3\text{PbOPbSO}_4 \cdot \text{H}_2\text{O}$ has larger active surface than that obtained from 4PbOPbSO_4 paste. The results are in good agreement with the SEM structure observations (Fig. 1-7) and with

the results obtained from the porosity measurements (Fig. 8).

Phase Composition of the Active Material

The ratio of $\alpha/\beta\text{-PbO}_2$ revealed the following trends in the above PAM's: (i) the active mass prepared from the paste with a 1% $\text{H}_2\text{SO}_4/\text{PbO}$ ratio contains significant amounts of $\alpha\text{-PbO}_2$, whereas that obtained from the paste with a 12% $\text{H}_2\text{SO}_4/\text{PbO}$ ratio has practically no $\alpha\text{-PbO}_2$. (ii) PAM prepared from pastes containing $3\text{PbOPbSO}_4 \cdot \text{H}_2\text{O}$ or $4\text{PbOPbSO}_4 \cdot \text{H}_2\text{O}$ at an equal density have a very similar $\alpha/\beta\text{-PbO}_2$ ratio, despite the fact that their micro- and macrostructures are quite different.

These trends reveal the parallelism in the relationships of the $\alpha/\beta\text{-PbO}_2$ ratio and the type of the crystal structure of the active material on the oxidation mechanism of the crystals in the paste. The high sulfatized pastes maintain a low pH value on the reaction layer during the plate formation (5, 11), which leads to the dissolution-precipitation mechanism and formation of a large amount of $\beta\text{-PbO}_2$, as well as to a predominantly "crystal-type" structure. For the low sulfatized pastes, it is just the reverse case.

Fig. 7. SEM micrographs of PAM obtained from 6% $\text{H}_2\text{SO}_4/\text{PbO}$, $d = 4.75 \text{ g/cm}^3$. The white lines correspond to: (a) $1 \mu\text{m}$ and (b) $10 \mu\text{m}$.

Fig. 8. Pore size distribution curves of six different PAM's obtained from the marked pastes.

Evolution of the Capacity and Structure of the Active Mass during Cycling of the Battery

Capacity and cycle life of the cells.—The initial capacity and the number of the charge-discharge cycles to 80% C_{20} at a 50% depth of discharge and 20% overcharge are shown in Table III.

Figure 9 reflects the evolution of the capacity during cycling. The reason for failure of the cells is shown on the respective curves.

From the results in Table III and Fig. 9, the following conclusions can be drawn. The "agglomerate-type" structure has generally low initial capacity and long life, which depends on the type of the agglomerates. Thus the agglomerates of the PAM prepared from $4\text{PbO}\cdot\text{PbSO}_4$ is more resistant to cycling than that of the active mass prepared from $3\text{PbO}\cdot\text{PbSO}_4 \cdot \text{H}_2\text{O}$ paste. The most resistant, probably, is the structure of the active mass obtained from tet-PbO (1% $\text{H}_2\text{SO}_4/\text{PbO}$) paste, but the capacity is below 80%—the lowest permissible limit. The low capacity of some of the "agglomerate-type" structures is probably due to the incomplete formation of the paste crystals, as well as to the low microstructure porosity and the active

Table II. PAM specific surface areas

1% $\text{H}_2\text{SO}_4/\text{PbO}$, 30°C	71	—
6% $\text{H}_2\text{SO}_4/\text{PbO}$, 30°C	101	140
6% $\text{H}_2\text{SO}_4/\text{PbO}$, 80°C	83	215
12% $\text{H}_2\text{SO}_4/\text{PbO}$, 30°C	110	90

Fig. 9. Evolution of cell capacity during cycling of four types of PAM

surface area. During cycling, the residual PbO is oxidized, the porosity and active surface area grow, and the capacity increases.

The active mass with a "crystal-type" structure obtained from a 12% $\text{H}_2\text{SO}_4/\text{PbO}$ paste has a very high initial capacity, which continuously drops during cycling, due to shedding of the active mass.

Evolution of the structure of the active material during cycling.—The structure of the charged active mass obtained from a 1% $\text{H}_2\text{SO}_4/\text{PbO}$ paste after 150 cycles is displayed in Fig. 10.

Fig. 10. SEM picture of PAM obtained from 1% $\text{H}_2\text{SO}_4/\text{PbO}$ paste after 150 cycles.

One can clearly see the tightly linked large agglomerates (Fig. 10) covered by well-shaped prismatic crystals. The juxtaposition of Fig. 2 and 10 reveals that the morphology of the crystals is strongly improved during cycling.

Figure 11 presents the structure of the charged active mass obtained from the 12% H_2SO_4/PbO paste after 100 cycles.

During cycling, the macrostructure is dispersed in well-shaped, not very tightly linked, needlelike, and prismatic crystals.

Figure 12 presents the pictures of the structure of the charged active mass, obtained from a $3PbOPbSO_4 \cdot H_2O$ paste after 100 and 150 charge-discharge cycles.

At 100 cycles (Fig. 12a), the microporosity of the agglomerates has increased during the cycling. At 150 cycles, the agglomerate level of the structure is completely dispersed and transformed into a crystalline structure.

Figure 13 presents the structure of the charged active mass obtained from a $4PbOPbSO_4$ paste.

At 150 cycles, it is still possible to distinguish the agglomerates which have retained the morphology of the $4PbOPbSO_4$ crystals. Besides this, the microstructural level has developed considerably. At 250 cycles, the agglomerate level of the structure is completely dispersed to a highly branched, weakly linked "crystal-type" structure.

Change of porosity during cycling.—Porosity evolution of the above PAM's during cycling is presented in Fig. 14.

Let us accept, conventionally, that the edge of the macro- and micropores is about $0.13 \mu m$ radii of the pores. From the change of porosity with the number of the cycles, the following trends of the structure evolution can be established.

PAM, 1% H_2SO_4/PbO paste.—At the above PAM (Fig. 14), the macro- and micropore systems are not well developed. During cycling, the plate works toward eliminating this deficiency. The PAM first develops the ionic transport system of macropores. As a result, the capacity of the cell rises slightly (Fig. 9a). The corrosion of the grid makes it impossible to follow the further evolution of the structure.

PAM, 12% H_2SO_4/PbO .—During cycling at this type of structure, first the number and volume of the micropores increase. The weakly expressed skeleton of agglomerates (Fig. 3) is dispersed to crystals and branches of crystals of the first structure level. During discharge, part of these

Fig. 11. SEM picture of the structure of PAM obtained from 12% H_2SO_4/PbO paste after 100 cycles.

Fig. 12. SEM pictures of the structure of PAM obtained from 6% H_2SO_4/PbO at $30^\circ C$ paste after: (a) 100 cycles and (b) 150 cycles.

crystals is transformed into $PbSO_4$. It can be supposed that during charge the PbO_2 crystals or branches are formed in new places in the volume of the plate and the volume of macropores increases. Thus, a very weak structure is formed and the PAM softens and sheds. This process is described by Rand *et al.* (12).

PAM, 6% H_2SO_4/PbO , 30° and $80^\circ C$.—During the first 50 cycles, both structural levels of the PAM formed from $4PbOPbSO_4$ paste are reproduced completely. A similar process takes place with PAM formed from $3PbOPbSO_4 \cdot H_2O$ paste. After this period, the number of the micropores begins to increase slowly, which leads to dispersion of the agglomerate level of the structure, which accelerates the shedding of the active mass, which limits the cycle life of the battery.

Summary

In general, it can be stated that during cycling the agglomerate level of the structure evolves through the growth of the individual crystals and their chains, whereby the volume of micropores increases. Part of the crystals and their chains are disrupted due to the mechanical effect of O_2 bubbles, electrolyte convection, or mechanical vibrations.

Fig. 13 SEM pictures of the structure of PAM obtained from a 6% $\text{H}_2\text{SO}_4/\text{PbO}$ paste at 80°C after: (a) 150 cycles and (b) 250 cycles.

Initially, the structure is composed of thick agglomerates, and at the end of cycling of thin crystal branches. The electric network of the active mass raises its ohmic resistance due to deteriorated contacts between the crystals, and the polarization of the plate increases. This evolution of the structure is not uniform over the plate cross section. Hollows can be formed in separate regions, and can grow to large dimensions. Simon and Caulder (13) have investigated these processes. This brings about a deterioration in the ionic transport system of the plate, which also increases its polarization.

The dispersion of the macrostructure depends on the type of the agglomerate skeleton. And as emphasized earlier, the shape of the skeleton level is determined by the phase composition, the structure and density of the paste, and the conditions during plate formation. Conse-

Fig. 14. Evolution of pore size distribution during cycling.

quently, the second structural level, the agglomerate skeleton, is the memory substrate, where the conditions of the technological processes during the plate production are coded.

Electrochemical Calorimetry of the Zinc and Bromine Electrodes in Zinc-Bromine and Zinc-Air Batteries

V. Subrahmanyam Donepudi and B. E. Conway*

Department of Chemistry, University of Ottawa, Ottawa K1N 9B4, Ontario, Canada

ABSTRACT

Direct calorimetric measurements are reported on three half-cell reactions of interest in zinc battery thermodynamics: the Zn/Zn²⁺ reaction in aqueous Br⁻ solution; the Br₂/Br⁻ reaction at Pt and the Zn/ZnO-ZnO₂²⁻ reaction in alkali. An experimental procedure is described for determining the single reaction heats, observable as $T\Delta S$ quantities, in both directions of the above reactions, thus providing a method for eliminating, by difference, the Joule heating effects which are unavoidable in the course of measurements at finite currents. Corrections for entropies of transport are made and discussed. Under certain conditions, where Zn corrosion can occur with evolution of H₂, the $T\Delta S$ heat change for that process is also determinable. Some heat changes for overall cell reactions are also determined.

While enthalpy changes for reversible electrochemical reactions can be obtained from EMF measurements and their temperature coefficients by means of the Nernst equation through the Gibbs-Helmholtz relation, such values are necessarily for the overall, two-electrode reaction. Direct calorimetric measurements, subject to some corrections for ionic entropies of transport, can be applied to evaluation of the heat changes that are associated with the electrochemical reactions at the electrodes of a cell. Such directly measurable heats are, however, associated with the " $T\Delta S$ " quantity for the cell reaction, rather than the ΔH .

It is of interest to recall that the actual enthalpy change, ΔH , for an electrode reaction is not measurable calorimetrically like it would be for a corresponding overall chemical reaction. This is because the ΔH normally constitutes the main component of the ΔG value determining the EMF of the cell. From measurements of the latter at various temperatures, ΔH can, of course, be determined using a form of the Gibbs-Helmholtz equation.

Direct calorimetric measurements made at a suitably designed electrode configuration with an appropriately arranged thermal detection probe, and separated anode and cathode compartments, can also give information on the $T\Delta S$ quantity for single electrode processes which are of interest in a general way in electrochemical thermodynamics and ionic solution electrochemistry. In some papers (1-3), these $T\Delta S$ quantities have been referred to as electrolytic Peltier heats, and values for several redox reactions at electrodes have been reported (4-5). The first reliable work of this kind was done by Lange and Hesse (6) and Lange and Monheim (7) some years ago, but, for many years since that time up until several years ago, few other papers have appeared on this topic.

Renewed interest in electrochemical calorimetry has arisen on account of the importance of measurements of overall and component heat changes in battery processes. Such measurements are essential for understanding the thermochemistry of battery reactions and in assessing practical energy efficiencies as well as evaluating heat changes associated with various contributions to irreversibility in battery charge and discharge cycles.

Significant improvements have been made in experimental technique over that employed in older measurements, e.g., by arranging suitable thermal detection configurations at the electrodes together with modern temperature-sensitive devices of low thermal capacity such as thermistors (8-11b) and Pt/Pt-13% Rh hemisphere probes (11c) used in conjunction with a thermistor bridge and an adiabatic calorimeter vessel. By means of calorimetry, the following types of electrochemical phenomena have been previously studied: (i) electrochemical processes involving adsorbed enzymes at a Hg electrode

(8), (ii) photo-assisted electrochemical reactions (9), (iii) processes in electrodeposition and corrosion (10-11), and (iv) behavior of alkaline cells under load (12) and thermal characterization of internal power losses in Pace Maker batteries (13).

Among various systems employing Zn as the anode material, the Zn/Br₂ (14-19), the alkaline Zn/air (O₂), and the alkaline Zn/NiOOH or Zn/AgO batteries (21) have received much attention in both basic research and in the direction of modern battery technology with the aim of developing mechanically rechargeable batteries, especially for automotive transportation. Various problems that arise with Zn battery systems are well known and have been extensively discussed in the literature (e.g., 16, 20).

In comparison with Zn/halogen batteries, alkaline Zn batteries with air or another oxidizing agent as cathode material have been developed and used over many years (e.g., the Drumm battery, using a combination of Zn with nickel oxide in alkaline medium, was used on the Irish railways in the '30's).

The present paper describes the results of calorimetric measurements carried out on Zn/Zn²⁺ and Br⁻/Br₂ (at Pt) couples in a variety of electrolytes that can be used in the Zn/Br₂ battery. From the results, the $-T\Delta S$ quantities for the electrode reactions have been evaluated, taking into account entropies and heats of ionic transport, and the unavoidable Joule heating effects that are associated with " iR " drop in operating cells.

Comparative experiments were also carried out on the Zn/ZnO-ZnO₂²⁻ reactions in alkaline solutions.

The experimental objective of this study, as mentioned earlier, was to investigate a method for practical evaluation of heat changes in electrode processes and energy efficiencies, as well to establish some individual electrode reaction thermodynamic quantities by means of direct calorimetry.

Experimental

General.—The heat changes accompanying the Zn/Zn²⁺ reaction in bromide solutions or of Zn/ZnO-ZnO₂²⁻ in alkaline solutions were measured under galvanostatic polarization conditions at pure Zn rod electrodes 3.0 mm in diameter. For study of the Br⁻/Br₂ reaction, a black platinumized platinum mesh electrode was used.

The experiments were conducted in an all-glass adiabatic calorimeter mounted in a thermostat, which maintained the temperature around the calorimeter constant to ± 0.01 K. A description of the calorimeter and the associated thermistor bridge is given below, together with the experimental procedure and conditions. Calorimetric measurements were made both in the anodic and cathodic current directions at the same current densities to enable " i^2R " Joule heating effects to be canceled out in the measurements (see below), a procedure that, surprisingly, was not employed previously by most investiga-

* Electrochemical Society Active Member.

Key words: Peltier heats; zinc/bromine, zinc/air batteries, entropy of electrode reactions.

tors, with the significant exception (11d, 11e) of the use of both anodic and cathodic voltammetry scans to provide an approach to isothermal conditions while effecting a calorimetric calibration by means of anodic or cathodic currents passed through an embedded Peltier thermocouple junction.

Calorimeter.—The design of the calorimeter is shown schematically in Fig. 1a. The calorimeter vessel is made from two interconnecting tubular compartments completely sealed within a silvered evacuated jacket in the form of a special Dewar flask. The cathode and anode, and corresponding catholyte and anolyte, were thus separated with a common electrolytic bridge at the top of the two tubes. The maximum distance of separation between the two compartments was ca. 9 cm along the tubes, each of which was 2 cm in diameter. A more constricted bridge region at the top of the cell was avoided in order to minimize electrolytic Joule heating.

Three inlets to the cell were provided: a central one for a N_2 purging tube; a second one for the working elec-

trode, the reference electrode with its Luggin probe, and the thermistor probe; and a third for the counterelectrode. The electrode mounting tubes of glass, were held in the calorimeter inlet ports (Fig. 1a) by means of Teflon tape wound around the boundary region. This provided the opportunity for successive mounting and demounting of various electrode materials, as well as for positional adjustment.

Thermistor bridge.—The thermistor bridge circuit is shown in Fig. 1b. The circuit consists of a 2.5 k Ω type YSI-641 thermistor probe for making the temperature change measurements, together with matching resistances and a 5 k Ω variable resistance. A 0.356V, 1 kHz sinusoidal signal derived from a Servomex signal generator was applied to the bridge as well as to the reference input of a lock-in analyzer (PAR Model 5204). The output signal from the bridge is processed by the lock-in analyzer and becomes amplified when an appropriate sensitivity range is chosen on the analyzer. Prior to the commencement of an experiment, the bridge was balanced and the subsequent off-balance signals due to the exo- or endothermal energy changes, caused by passage of controlled current at a density of $\pm i$ A cm $^{-2}$, were measured and recorded on a Y-time recorder.

The bridge was calibrated by passing known currents, 0.1, 0.2, and 0.3 mA, successively through a 102 k Ω calibration resistor (R_{cal}) mounted adjacent to the thermistor in a similar geometry to that corresponding to the position of the electrode *vis-a-vis* the thermistor. Between each passage of current, time for cooling to the initial temperature was allowed. The calibration sequence was repeated several times for each calorimetric run. Calibration heats were therefore measured with similar sensitivity to that for the electrochemically generated heats at the working electrode. This was achieved by packing the calibration resistor (dimensions approximately 1.5 \times 5 mm) and the thermistor together in a reproducible geometry such that the distance or clearance between the resistance and the thermistor was maintained almost identical with the distance between the working electrode and the thermistor. During actual electrochemical runs, the calibration resistor was removed from the calorimeter to minimize possibility of corrosion.

A calibration line was plotted by relating a series of Joule heating rates, $i^2 R_{cal}$, expressed in mW *vs.* the out-of-balance thermistor signal. Figure 2 shows such a calibration plot; it is satisfactorily linear as anticipated.

Electrodes.—For studies of reactions at Zn, rods of this metal 3 mm in diameter were shaped into small coils having about four turns and apparent geometric areas in the range 17-20 cm 2 . The other ends of each of the rods were abraded to reduce the diameter and soldered to a 0.63 mm copper wire. The electrode was finally sealed to a glass tube holder with Araldite, which was cured overnight at room temperature. As shown in Fig. 1c, the thermistor probe was positioned inside the electrode coil, making close contact with the surface of that electrode. A Ag/AgBr reference electrode was inserted through the side opening tube of the T29/42 female joint (Fig. 1c) and positioned close to the working electrode. The working and reference electrodes, together with the thermistor probe, were held in position by wrapping them with Teflon tape at some distance from their active surfaces.

Solutions.—The heat changes due to the Zn/Zn $^{2+}$ reaction at a zinc electrode in Br $^-$ salt solutions were measured in the following bromide-containing solutions: (i) 0.1, 0.5, 1.0, 2.0, 3.0, and 4.0M ZnBr $_2$; (ii) 1.0M KBr, 1.0M KBr + 0.14M Br $_2$; and (iii) 1.0M ZnBr $_2$ containing 1.0M and 2.0M KBr.

A 1.0M KBr solution containing dissolved bromine at 0.18M was used for studying the Br $^-$ /Br $_2$ reaction at the platinum electrode.

ZnO dissolved in 8.0M KOH solution to a concentration of 1.0M was used for studying the alkaline Zn/ZnO system under simulated battery conditions.

Fig. 2. Calibration line showing Joule heating rates generated by passage of controlled currents through a standard resistor vs. the off-balance thermistor bridge signal. Currents were applied to a 102 k Ω resistor.

The zinc content in the solutions was analyzed by the EDTA titration procedure and the dissolved bromine by the usual iodometric procedure.

Procedure.—In a typical experiment, the calorimeter containing the electrodes and thermistor probe, together with 100 cm³ of the required electrolyte solution, was completely immersed in the water thermostat at 299.4 \pm 0.01 K and allowed to attain thermal equilibrium overnight.

The solution resistance, pH, and the electrode potentials were then measured. Prior to the commencement of polarization experiments, the thermistor bridge was balanced. A Wenking potentiostat was used in the galvanostatic mode, and a series of constant currents between 10 and 40 mA were applied to the cell in 5 mA steps; the resulting thermal transients were recorded over a period of 100s. Prior to current reversal or a change in current, the thermal transient was allowed to reach a reasonably steady state. Usually, this was assisted by passing a few bubbles of nitrogen through the solution while making sure that the solution was not undercooled by evaporation of water from the solution. This procedure avoided prolonged waiting periods for thermal equilibrium to be attained between successive polarizations at different currents. Passage of the controlled currents for the controlled 100s polarization time gave the charges in coulombs, C, passed in the experiments and, hence, with the measured heat change, the electrochemical rate of heating or cooling in J s⁻¹ C⁻¹.

Results

Heat changes.—The Zn/Zn²⁺ reaction in bromide electrolyte solutions.—Polarization of the zinc electrodes in zinc bromide solutions at applied currents between 10 and 40 mA caused the initially balanced thermistor bridge to go out of balance with signals in the positive (exothermic) direction for the anodic and in the negative (endothermic) direction for the cathodic currents. The signal (mV) vs. time traces shown in Fig. 3 were obtained for polarization in 4M aqueous zinc bromide solutions; the responses exemplified in this figure are typical of the heat change behavior of the zinc electrode in all the ZnBr₂ solutions, the ZnBr₂ + KBr solutions and the KBr + Br₂ solutions.

The rate of heat release, $d(-Q)/dt$, expressed in mJ s⁻¹ at each applied current I , was obtained: (i) by correcting the bridge signals for the joule (I^2R) heating by obtaining the difference between the anodic and cathodic signals (e.g., see Fig. 4) and averaging, (ii) knowing the corresponding heat change from a calibration curve such as that in Fig. 2, and (iii) dividing Q by the time period for which the signal was measured. The slope of the straight line shown in Fig. 4, i.e., $d(-Q)/dt \times (1/I)$ was 0.23 J C⁻¹ or, when multiplied by 2F, is -44.4 kJ mol⁻¹, thus corresponding to the $T\Delta S$ term within which is included any heat of ionic transport associated with the Zn/Zn²⁺ reaction at the particular concentration involved. The $T\Delta S$ values for other concentrations of ZnBr₂ from 0.1M up-

Fig. 4. Variation of bridge voltage and rate of heat release with applied current. Conditions as in Fig. 3. Typical thermistor bridge voltage (Y-axis; 25 mV cm⁻¹) vs. time (X-axis; 25 s cm⁻¹) is shown in the inset to illustrate the polarization effect. Differences of the anodic and cathodic extents of heat evolution in Fig. 3 and 4 give the basis for evaluation of the Joule heat contributions to the measured overall reaction heat charges at finite currents.

wards were calculated and are listed in Table I. Also included in this table are data for the effects of KBr additions, *i.e.*, for increase in the Br⁻/Zn²⁺ ratio, and for polarization effects in aq. KBr with and without dissolved Br₂ present.

The 0.1M ZnBr₂ solutions were somewhat unstable, owing to a small but significant degree of hydrolysis. However, addition of a trace of HBr prevented this problem, and a stable solution having an apparent solution resistance of 77.0Ω and a pH of 1.65 resulted. The $T\Delta S$ value was the same as that for a 4M solution, but there was an increase (see Table 1) upon addition of NaClO₄, to give a 1M concentration; this was added to improve the conductivity (apparent solution resistance then = 11.0Ω). There was a slight change in the $T\Delta S$ value when the electrode was polarized in ZnBr₂ solutions containing 1 and 2M KBr, *i.e.*, for an increase in the Br⁻ to Zn²⁺ ratio. However, cathodic polarization in 1M KBr solution was associated with an exothermic reaction (a shift in the bridge signal to the positive direction, see Fig. 5), corresponding to H₂ evolution at Zn. In this case, the cathodic and anodic bridge voltage signals were corrected for the Joule heat component by subtracting the I^2R values that were obtained while polarizing the zinc electrode in bromide solutions of the same ohmic resistance. The heat of the

anodic reaction was the same as for the ZnBr₂ case, while the cathodic reaction heat was around -132 kJ mol⁻¹ (Fig. 5). However, a normal trend was observed when the above solution contained 0.14M dissolved Br₂. This behavior corresponds to the reaction $Zn + Br_2 \rightleftharpoons ZnBr_2$ having the anodic Zn/Zn²⁺ and cathodic Br₂/Br⁻ components, respectively. Visual observations and chemical analyses showed the presence of brownish film adhering to the electrode surface and brown material in solution, with a depletion of the bromine concentration. The calorimetric observations showed evidence that this reaction was assisted by light (observation of discoloration of the solution when a zinc electrode was exposed to aerated as well as deaerated solutions).

The Zn/ZnO-ZnO₂²⁻ reaction in aq. KOH-ZnO solutions.—The results for this system were obtained in a similar way to those for the Zn/Zn²⁺ reaction in Br⁻ solutions described above. The reaction heats were -0.4~-0.5 kJ mol⁻¹ for the Zn/ZnO reaction in 1M Zn(II) solutions in 8M KOH solution, *i.e.*, potassium zincate solutions. These heats are much smaller than those for the Zn/Zn²⁺ reaction in Br⁻ solution.

The Br⁻/Br₂ reaction.—As mentioned previously, the Br⁻/Br₂ reaction was studied at black-platinized platinum mesh electrodes polarized in 1M KBr solution containing

0.18M Br₂ over the range of currents defined above. The $T\Delta S$ value for this reaction, as calculated from the line in Fig. 6, is -81.1 kJ mol⁻¹.

Polarization behavior.—When electrochemical reactions are driven to a condition of irreversibility, corresponding to a total overpotential η at a current density i , the irreversible heat production associated with kinetic effects is $i\eta$ J s⁻¹ cm⁻²; this is always an exothermic heat like the i^2R Joule heat. In order to make corrections when necessary for the $i\eta$ heating effect, polarization measurements were made on the electrode reactions under the same conditions as those employed in the calorimetry experiments. Here only the trends of the polarization behavior will be referred to. In several cases, the anodic and cathodic overpotentials at a given I were approximately equal, so the $i\eta$ heating almost canceled when the heat changes for the cathodic and anodic directions of the electrode reaction, conducted at the same current density, were compared. Here the same principle is used as that referred to earlier for compensating out the I^2R ohmic heating effects. It might be mentioned that compensating out the I^2R and $I\eta$ or $i\eta$ heating effects has not been referred to in most of the previous papers on electrochemical calorimetry except in Scherfey and Brenner's (4, 5) and in Graves's work (11d, 11e); in that of Lange (6, 7), extrapolations to zero I were made to eliminate these effects.

The potentials of unpolarized and polarized zinc electrodes were measured in various bromide solutions and in potassium zincate solution. Similarly, the potentials of platinized platinum-black electrodes in the solutions containing 1M KBr and 0.18M Br₂ were recorded. These values are listed in Table II. The cathodic and anodic polarization was high during polarization in 0.1M ZnBr₂ solution and diminished with increase in the ZnBr₂ concentration. The high cathodic polarization values of -1.19 V vs. Ag/AgBr are typical of the hydrogen evolution or oxygen reduction reactions. The open-circuit potentials of the zinc electrode in the bromide solutions corresponded nearly to the reversible half-cell potential of the zinc electrode, i.e., -0.76 V vs. H₂. However, in alkaline solutions, the measured potential of -1.6 V vs. the Ag/AgBr electrode roughly corresponds to a -0.059×16 mV decrement in the potential due to the pH effect. The potential of the platinum electrode in Br⁻/Br₂ solutions corresponded to the reversible potential of the Br₂/Br⁻ couple. The extents of polarization for anodic and cathodic currents at 40 mA cm⁻² were similar (± 120 mV) in this case but for the Zn electrode in aq. KBr solution, the cathodic polarization was much higher, corresponding to the known H₂ overvoltage behavior at Zn. The significance of the open-circuit potentials will be discussed later.

Fig. 5. Current vs. thermistor bridge voltage and rate of heat release plots for a polarized zinc electrode in 1M aq. KBr solution. Time (X-axis; 25 s cm⁻¹) vs. the thermistor bridge voltage (Y-axis; 10 mV cm⁻¹) traces are shown in the inset of this figure. The cathodic trace illustrates the exothermic response for cathodic current.

Fig. 6. Current vs. bridge voltage and rate of heat release lines for the Br⁻/Br₂ reaction at a black-platinized platinum electrode in 1.0M KBr + 0.18M Br₂ solution. ●: Duplicate data.

Table II. Potentials of zinc in bromide and zincate, and of platinum electrode in bromide + bromine solutions

No.	Solution	Current (mA)					Remarks
		0	10	20	30	40

6.	≈8.0M KOH + ≈1.0M ZnO	1.60	1.58 1.63	1.55 1.61	1.55 1.66	1.53 1.67	R _{app} = 16.4Ω beyond pH range > 14.0
Platinum							
7.	1.0M KBr + 0.18M Br ₂	0.94	0.97 0.90	1.00 —	1.02 0.84	1.06 0.82	R _{app} = 24.0Ω

All the potentials are referred to Ag/AgBr reference electrode. The potentials are negative for zinc and positive for platinum electrodes. At each concentration, the values in first and second rows are for anodic and cathodic polarization, respectively.

Discussion

Interpretation of the experimental TΔS values.—The measured TΔS values, otherwise known as electrolytic Peltier heats, are defined as the heats that must be transferred at any junction in order to keep its temperature constant when F coulombs flow from one side of the junction to another, or when a flow of 1 mol of electrons takes place. Originally, the Peltier heat-change phenomenon referred to the transfer of electrons from one metal to another at a bimetallic junction. Electrochemical Peltier heats obviously involve more complex phenomena, including changes of solvation state of an ion or molecule and change of its charge, as well as the exit or entry of an electron from/to the Fermi level of the metal across the double layer.

When the electrochemical Peltier heat is divided by the temperature T, the value of the entropy \bar{S} transported across the electrode/solution boundary can be obtained. This value is the sum of the entropy changes due to the ionic entropy, the metal entropy, and the metal electron entropy contributions to the entropy change, ΔS, of the reversible electrode reaction and also the entropy changes arising as a consequence of ion transport as the cell reaction proceeds, i.e., the so-called Eastman ionic entropies of transport (22-23), S*. Using known electrochemical and thermodynamic quantities from the literature, Ozeiki *et al.* (2), Tamamushi (3), and Holmes and Joncich (10) have calculated the Peltier heats for the Cu/Cu²⁺ and Ag/Ag⁺ single-electrode reactions and compared them with the observed values. Problems associated with evaluation of Eastman entropies of transport and related quantities have been discussed in the previously published review article by Conway and Bockris (24), and in papers by Agar (1) and Tyrell and Hollis (25). However, for most ions in aqueous medium, except H⁺, the S* quantities are relatively small.

Calculation of the molar Peltier heat for the Zn \rightleftharpoons Zn²⁺ reaction, e.g., for 0.1M ZnBr₂ solution.—We recall that the electrochemical Peltier heat is defined in terms of the component entropy quantities, as follows

$$T \cdot \bar{S} = \text{II, (Molar Peltier heat)} = \left\{ \begin{array}{l} \text{(Net Entropy change } (\Delta S) \text{ due to the reaction)} \\ + \\ \text{(Entropy change due to ionic transport East-} \\ \text{man entropy } (\bar{S}^e)) \end{array} \right\} \times T \quad [1]$$

where T is the temperature (298 K) and \bar{S} is the entropy transported across the interface.

Net entropy change, ΔS, due to the reaction.—ΔS is given by

$$\Delta S = S_i + zS_e - S_M \quad [2]$$

for a reaction of metal M going to ions i and z electrons.

Normally S_e, the entropy of metal electrons, can be neglected relative to the other entropy terms in Eq. [2]. This question has been discussed in Ref. (11d). The basis of the assumption regarding the neglect of S_e is the known small electronic specific heat of metals relative to the Dulong and Petit value for the solid metal lattice at room temperature. C_{p,e} is the ca. 1% of the latter specific heat. The S_e is then correspondingly small. In the case of reaction of zinc, S^o_{Zn} = 41.6 J K⁻¹ mol⁻¹.

The partial g_i ionic entropy is

$$\bar{S}_i = \bar{S}_i^o - R \ln a_i - RT d \ln a_i/dT \quad [3]$$

for an ionic activity a_i. Introducing the molal activity coefficient γ and the molal concentration m_i,

$$\bar{S}_i = \bar{S}_i^o - R \ln m_i - R \ln \gamma - RT d \ln \gamma/dT \quad [4]$$

$$= \bar{S}_i^o - R \ln m_i + S_i^E \quad [5]$$

where S^E_i is the excess entropy of ion i at its concentration m_i.

In dealing with the problem of individual electrode heat changes, it is seen that the individual ionic excess entropies are required in addition to the individual \bar{S}_i^o quantities. The latter are quite reliably known for most simple ions from extra-thermodynamic procedures (1, 22, 23) but the S^E_i values, which are not negligible at appreciable concentrations, are not so easily evaluated in a reliable way. Recourse may be had to data calculated from the Debye-Hückel theory, based on Kielland's work (26), for dilute solutions, but for elevated concentrations where ion size and hydration effects become important (27) in determining γ_i, the required derivative d ln γ_i/dT is difficult to evaluate.

Activity coefficient data for aq. ZnBr₂ have been determined by Gibbard (18) over the temperature range 273-309 K for the concentration range 0.1-4.0M and provide, in principle, the required quantities but in terms of the mean ionic activity coefficient. However, anomalous activity behavior is indicated for this system as a function of concentration as shown in Fig. 7a (18). This is due to the well-known autocomplexation that occurs in zinc halide solutions as indicated by EMF, thermal and Raman spectroscopic experiments (18, 23, 28). Thus, Shchukarev *et al.* (29) reported widely different TΔS values for the formation of ZnBr⁺, ZnBr₂, ZnBr₃⁻, and ZnBr₄²⁻ complex ions.

Using the data of Gibbard, referred to above, and from Kielland (26), we have calculated the S^E_i for Zn²⁺ ion in 0.1M aq. ZnBr₂ assuming that at this concentration it is mainly uncomplexed as follows from the known (21) association constant. K₁ = 10^{-0.6}; S^E_i is found to be 11.4 J K⁻¹ mol⁻¹, so that $\bar{S}_i = -127.7 \text{ J K}^{-1} \text{ mol}^{-1}$ taking the conven-

Fig. 7. Dependence of mean activity coefficients (a) and transport numbers (b) of zinc bromide solution at different concentrations and temperatures.

tional \bar{S}_i° for Zn²⁺ as $-106.5\ J\ K^{-1}\ mol^{-1}$ (23), noting that the corresponding absolute value of \bar{S}_i for Zn²⁺ will be $-152.6\ J\ K^{-1}\ mol^{-1}$, taking $2\bar{S}_{H^+}^\circ = -45.6\ J\ K^{-1}\ mol^{-1}$ (1, 23). It is not possible to evaluate \bar{S}_i for Zn²⁺ at higher concentrations owing to the autocomplexation and lack of corresponding activity coefficient data.

Calculation of the Eastman entropy change due to ion transport— \bar{S} is defined as

$$\bar{S} = (t_{Zn^{2+}} \cdot S^*_{Zn^{2+}} - 2 t_{Br^-} \cdot S^*_{Br^-}) \quad [6]$$

where S^* quantities are the entropies of transport for the species indicated and t the corresponding transport numbers.

The Eastman entropies of Zn²⁺ and Br⁻ ions are 18.8 and $2.5\ J\ K^{-1}\ mol^{-1}$, respectively. The value for the Zn²⁺ ion was obtained from the difference between the transported entropy of hydration and the entropy of hydration itself, $\bar{S}_h - S_h$ (23). The value for the Br⁻ ion is available from Agar (1). The transport numbers for Zn²⁺ and Br⁻ in 0.1M solution where autocomplexation is not appreciable are 0.37 and 0.63, respectively, from the work of Parton and Mitchell (30). At higher ZnBr₂ concentrations, $> 1.0M$, the cation transference number becomes negative, confirming autocomplexation (see Fig. 7b).

Substituting these t values into Eq. [6] gives a value of $\bar{S} = 3.8\ J\ K^{-1}\ mol^{-1}$.

Calculation of the resulting Peltier heat.—From the definition of the Peltier heat, Π , we can now calculate this quantity for the 0.1M ZnBr₂ solution as

$$T \cdot \bar{S} = (-127.7 - 41.6 + 3.8) \times 300 \quad [7]$$

$$= -49.7\ kJ\ mol^{-1}$$

The experimentally observed value from the calorimetric measurements with which the calculated value may be compared is $-44.4\ kJ\ mol^{-1}$ at a concentration 0.1M in ZnBr₂. Other observed data are as follows at the concentrations indicated

$$1.0M\ ZnBr_2 \quad -49.5\ kJ\ mol^{-1}$$

$$4.0M\ ZnBr_2 \quad -44.5\ kJ\ mol^{-1}$$

These differences are outside the experimental errors and are therefore likely to be due to irreversibility effects in the kinetic behavior of the zinc electrode.

The thermoelectrochemical results obtained here for the anodic and cathodic directions of the Zn $\xrightleftharpoons{\pm 2e} Zn^{2+}$

reaction gave rather concentration-independent values of $T\Delta S$ (Table I), except for the 0.5M ZnBr₂ solution. This result is a little surprising in relation to the sequence of $T\Delta S$ values for complexation of Zn²⁺ by Br⁻ to give ZnBr⁺, ZnBr₂, ZnBr₃⁻, and ZnBr₄²⁻ species where formation of the ZnBr₃⁻ complex has an unusually high $T\Delta S$ value of $+101\ kJ\ mol^{-1}$, while $T\Delta S$ for formation of the other ions is small and negative (29). Possible structures of "ZnBr₃⁻" in terms of an aquo-bromo complex have been discussed in Ref. (31). The results (Table I) found in the present work, which were checked in several separate runs, may be rationalized in terms of the situation which actually obtains in a solution of given ZnBr₂ at an appreciable concentration. It is known (28) that all complexes except ZnBr⁺ and the free aquo-ion are present together at appreciable and comparable concentrations, when total [ZnBr₂] is appreciable, so the $T\Delta S$ measured in the discharge of Zn is an overall value, which may not be very sensitive to the component of discharge current from ZnBr₃⁻ and hence to its anomalous entropy of formation from free ions (29).

Peltier heats in other bromide-ion containing and alkaline zincate solutions.—In 1M potassium bromide solutions, polarization is expected to cause zinc dissolution in the anodic and possible hydrogen evolution in the cathodic directions. In these solutions, there can, however, be a certain concentration of zinc ions owing to dissolution of the zinc electrode on open circuit. The approximate concentration can be estimated from the polarization curves where the anodic and cathodic branches can be extrapolated to open circuit. Of course, there can be a slight buildup of zinc ions also during the constant current polarization experiments. Separate polarization measurements made outside the calorimeter show that the zinc concentration in solution due to free corrosion of the zinc electrode can become around 5 mM, corresponding to a corrosion current of 0.9 mA passing during an overnight period (14h). At this concentration, the value of $R\ ln\ c$ is $-52.5\ J\ K^{-1}\ mol^{-1}$.

Using the transport number and Eastman entropy values for K⁺ and Br⁻ ions ($t_{K^+} = 0.51$; $S^*_{K^+} = 7.1\ J\ K^{-1}\ mol^{-1}$; $t_{Br^-} = 0.49$; $S^*_{Br^-} = 2.5\ J\ K^{-1}\ mol^{-1}$), one can obtain the entropy of transport for KBr = $2.4\ J\ K^{-1}\ mol^{-1}$. The molar Peltier heat, upon substitution of S_{Zn} , $S_{Zn^{2+}}$, and S_{KBr} into Eq. [1] and [2], is $-43.2\ kJ\ mol^{-1}$, which can be compared with the experimental value of $-49.2\ kJ\ mol^{-1}$. A polarization in the cathodic direction should cause H₂ ev-

olution to take place when the current exceeds that for the diffusion-controlled reductive deposition of any residual Zn^{2+} ions in solution, depending on their concentration. For a solution at pH 6, the estimated Peltier heat is $-69.4 \text{ kJ mol}^{-1}$. The appropriate values of quantities used in this calculation are given below

$$S_{H_2} = 130.5 \text{ kJ mol}^{-1}; 2\bar{S}_{H^+} = -45.6 \text{ J K}^{-1} \text{ mol}^{-1}$$

$$S_{H^+}^* = 43.1 \text{ J K}^{-1} \text{ mol}^{-1}; S_{OH^-}^* = 58.1 \text{ J K}^{-1} \text{ mol}^{-1}$$

together with

$$t_{H^+} = 0.64 \text{ and } t_{OH^-} = 0.36$$

for the aqueous solutions.

The experimental value is $-132.0 \text{ kJ mol}^{-1}$, so that the excess of $-63.0 \text{ kJ mol}^{-1}$ is due to the ηI term corresponding to the overvoltage of ca. 700 mV that is observed during the polarization (see Table II).

In alkaline solutions, the predicted molar Peltier heat for the Zn/ZnO reaction is 0.6 kJ mol^{-1} ($S_{Zn}^0 = 41.5 \text{ J K}^{-1} \text{ mol}^{-1}$; $S_{ZnO}^0 = 43.5 \text{ J K}^{-1} \text{ mol}^{-1}$). The difference between this and the experimental value is about 1 kJ mol^{-1} ; any explanation to account for this difference will be rather speculative, since the parallel reaction of Zn to form $Zn(OH)_2$ through the pores of the oxide film is well known, and the overall heat change is very small.

Peltier heat of the Br^-/Br_2 reaction at a platinum black surface.—The partial molar entropy of Br^- ion on the absolute scale is $103.7 \text{ J K}^{-1} \text{ mol}^{-1}$ (23). The ionic activity coefficient for Br^- ion at 1.0M concentration, 0.65, was obtained by extrapolating the straight line plot between $\log c_{Br^-}$ and activity coefficient to 1.0M [Kielland, Ref. (26)]. Further, the entropy of aqueous bromine solution (0.18M) was calculated from the known ΔG_f° (3.93 kJ mol^{-1}) and ΔH_f° ($-2.59 \text{ kJ mol}^{-1}$) values (32). The value of $S_{Br_2}^0$ obtained by this procedure is $-21.7 \text{ J K}^{-1} \text{ mol}^{-1}$. The total entropy of ionic procedure, \bar{S}_{KBr} , is already known ($2.4 \text{ J K}^{-1} \text{ mol}^{-1}$) for 1M KBr. As illustrated by the calculation given below, a value of $-74.8 \text{ kJ mol}^{-1}$ is obtained for the molar Peltier heat for this reaction, thus comparing reasonably well with the experimental value of $-81.0 \text{ kJ mol}^{-1}$.

Reaction term

$$\Pi = T\Delta\bar{S} = 300 \left[\frac{(S_{Br_2}^0 - 2\bar{S}_{Br^-} - 2R \ln C_{Br^-} - 2R \ln \gamma_{Br^-} + R \ln C_{Br_2}) - (S_{KBr})}{R} \right] \quad [8]$$

↑
Ionic transport term

where

$$R \ln C_{Br^-} = 0 \text{ when } C_{Br^-} = 1.0M; R \ln C_{Br_2} = -14.2 \text{ J K}^{-1} \text{ mol}^{-1}$$

when

$$C_{Br_2} = 0.18M.$$

Heat changes in the overall Zn/Br₂ cell reaction and energy efficiency evaluation.—While individual electrode heat changes, as $T\Delta S$ quantities, can be measured with reasonable reliability, as we have shown earlier in this paper, it is not possible to obtain from the calorimetric measurements the corresponding enthalpy change, ΔH , for individual electrode reactions, as this would require knowledge of the free energy change for a half-cell reaction or the corresponding absolute half-cell interfacial potential. While such quantities have been discussed frequently, and at length in a recent paper (33), no estimate of a half-cell free energy change can be made with a reliability better than $\pm \text{ca. } 30 \text{ kJ mol}^{-1}$. Thus, energy efficiencies for half-cell processes have little quantitative meaning. However, overall cell efficiency quantities [cf. Ref. (34)] can be determined.

For calorimetric measurement of the overall heat effect associated with the Zn/Br₂ cell reaction, the cell

was set up in the calorimeter and the system allowed to reach thermal equilibrium overnight. The cell potential

was measured, and then the cell was discharged via the measuring resistance, 1.27Ω of the ammeter, where the net current due to zinc oxidation coupled with Br_2 reduction was measured. The thermistor bridge voltage vs. time (trace I) and current vs. time curves (trace II) are shown in Fig. 8. The inflection in the bridge-voltage trace corresponded to the fast current decay which takes place initially and the subsequent attainment of a steady state after 25s. From the bridge signal in the steady state, and based on a previous calibration, the ratio of rate heat release to i yielded a value of 73.4 kJ mol^{-1} , for the total heat quantity $-T\Delta S - I^2R - I\eta$, all exothermic heat changes being taken as nominally negative in the usual way.

For prolonged equilibration times prior to the cell discharges, i.e., 48 and 72h, the $-T\Delta S - I^2R - I\eta$ decreased, possibly because of intermixing and/or consumption of the Br_2 reactant. The values were 50 and 42 kJ mol^{-1} for 48 and 72h equilibration periods, respectively.

As with the individual electrode experiments, calorimetric measurements were made in both directions of the overall cell reaction, i.e., on discharge and charge. This allowed the I^2R component of the heat change to be estimated. At the current of 34 mA (see Fig. 8, curve III), its value was 10.4 mJ s^{-1} or $0.5 \text{ mJ s}^{-1} \text{ cm}^{-2}$, i.e., about 16% of the measured $T\Delta S$ heat or a substantially smaller fraction of the total enthalpy change. The I^2R component is, however, retained in the overall estimate of free energy efficiency given below.

The observed cell EMF was $1.775 \pm 0.015V$, so that the free energy change for the overall reaction is -343 kJ mol^{-1} . From the above value of the observed heat change, ΔH is obtained as -416 kJ mol^{-1} . This gives a "free energy efficiency" of 82% for the overall cell reaction as conducted in the experiment (obviously I^2R depends on solution concentration and cell geometry, and $I\eta$ on current density at a steady current of 34 mA, ca. 1.7 mA cm^{-2}). This value is to be compared with the "thermodynamic" efficiency value, $\Delta G/\Delta H$, of 91% predicted by Gibbard (19). Of course, in practical battery designs, I^2R energy losses can be relatively larger depending on choice of separators and geometries, while η is minimized by maximizing electrode real area, especially at the C cathode.

Conclusions

1. By means of direct calorimetric measurements carried out during the passage of net anodic or cathodic currents under galvanostatic conditions, it was possible to measure the electrolytic Peltier heats, i.e., the $T\Delta S$ values for the following individual, i.e., half-cell, electrode

Fig. 8. Discharge characteristics of the cell Zn/2M ZnBr₂/2M ZnBr₂, 0.38M Br₂/C. Curve I: uncontrolled discharge, i.e., discharge via the resistance of the current measuring resistor. Curve II: current decay with time. Curve III: charge and discharge behavior of the above cell when polarized. X-axis: time = 10 s cm^{-1} for all curves. Y-axis: for curves I and III, bridge voltage = 10 mV cm^{-1} , for curve II, current = 10 mA cm^{-1} .

couples: Zn/Zn^{2+} (in aqueous Br^- solutions) and $Zn/ZnO-ZnO_2^{2-}$ processes at Zn electrodes and the Br^-/Br_2 process at black-platinized platinum electrodes.

2. The experimentally determined Peltier heat ($T\Delta S$) quantities for the above processes, corrected for i^2R Joule heating effects by a compensation measurement involving differences of anodic and cathodic heat effects, and for ionic entropies of transport, compare quite well with values that can be calculated from the relevant thermodynamic and extra-thermodynamic data for the species involved in the above half-cell reaction processes.

3. Polarization measurements gave useful complementary information on deviations from reversibility in the reaction processes studied, in relation to the components of heat change associated with overvoltages at net currents.

4. Calorimetric measurements in the overall reaction in the cell $Zn/2M ZnBr_2, aq./2M ZnBr_2 + 0.38M Br_2/C$ under conditions of free discharge at a steady-state current yielded information on the practical "free-energy efficiency" of the overall cell reaction under conditions where $i\eta + i^2R$ (or $i\eta$ alone) components of irreversible heat production were included. The efficiency thus determined under the experimental condition employed was 82%, which is to be compared with the thermodynamically derivable value of 91% for a Zn/Br_2 battery system behaving reversibly.

Structural Parameters of β -PbO₂ and Their Relationship to the Hydrogen-Loss Concept of Lead-Acid Battery Failure

R. J. Hill and I. C. Madsen

CSIRO Division of Mineral Chemistry, Port Melbourne, Victoria, Australia 3207

ABSTRACT

Full-profile, Rietveld-type, x-ray powder diffraction studies have been performed on β -PbO₂ samples either prepared chemically or obtained from batteries operated under simulated electric vehicle service at 25° and 50°C. After a sharp initial decrease, the unit cell volume and cell edge ratio of battery β -PbO₂ assume relatively stable values which are both independent of the battery capacity and indistinguishable from those of chemically prepared material. A comparison of the observed unit cell volumes with values calculated for given levels of O²⁻/(OH)⁻, Pb⁴⁺/Pb²⁺ coupled substitution in the β -PbO₂ structure indicates that the maximum amount of this substitution is about 0.01 atoms of hydrogen per formula unit. These results suggest that the decline in battery capacity is not a function of the loss of a hydrogen species from the crystal structure of electrochemically active β -PbO₂. Estimates of the changes in PbO₂ crystallite size as a function of battery cycling history show that batteries began service with β -PbO₂ crystallite sizes of around 250Å, irrespective of the temperature of operation, but increased to values of about 700 and 900Å at 25° and 50°C, respectively. Since this increase in crystallite size occurred well before battery failure, the loss in battery capacity with cycling cannot be correlated with the changes in crystallite size and, therefore, with changes in the degree of structural order of the active material.

The decline in performance and eventual failure of lead-acid batteries applied in electric vehicle service is usually associated with a decline in the efficiency of utilization of the lead dioxide in the charged positive plate. This dioxide is primarily present as the tetragonal, or β -PbO₂, modification, although variable amounts of the orthorhombic, or α -PbO₂, form can also occur (1, 2). In addition, significant quantities of amorphous and/or very poorly crystallized and disordered PbO₂ in battery plates have been documented by x-ray diffraction (3-8), thermal decomposition (9, 10), and transmission electron microscopy (11, 12).

Among the more important reasons for the loss of battery capacity may be included: (i) a decrease in the degree of electrical contact between the PbO₂ particles themselves in the plate and between the particles and the current collector (grid), (ii) a decrease in the effective surface area of the particles, and (iii) softening and eventual shedding of material from the plate. However, a further recent suggestion (9, 10, 13-16) is that an electrochemically inactive form of β -PbO₂ develops in increasing amounts during charge/discharge cycling and that the loss of activity, and perhaps tendency toward active material shedding, is related (i) to the loss of a hydrogen species from the crystal structure of the active dioxide material and/or (ii) to an increase in the degree of structural order in the crystals.

In the latter proposed mode of battery failure, the electrochemically active PbO₂ containing the hydrogen species and/or a significant degree of structural disorder is said to progressively change to a more stoichiometric, defect-free variety resembling the chemically prepared product, which has traditionally been considered to be inactive and to contain fewer hydrogen ions. This mechanism has, however, been disputed in regard to the proposed loss of intrinsic PbO₂ activity (17, 18), and also in the claim that chemically prepared PbO₂ is electrochemically inactive (19).

Chemical analyses of bulk samples of electrochemically prepared α -PbO₂ and β -PbO₂ (1, 20, 21) are usually consistent with the general formula PbO_{1.80-1.98}(OH)_{0.04-0.26}, which suggests the presence of a significant amount of hydrogen in the PbO₂ structure. These observations are supported by nuclear magnetic resonance (13), thermogravimetric analysis (9, 10), x-ray photoelectron spectroscopy (22), and inelastic neutron diffraction (11, 12). However, coherent (elastic) neutron diffraction studies of crystalline PbO₂ have been unable to locate ordered sites for the proposed hydrogen atoms and, in addition, have demonstrated that the traditional view of PbO₂ as substantially oxygen deficient is probably incorrect (23-26). Indeed,

Key words: x-rays, protons, crystallography, stoichiometry.

rather than indicating the presence of oxygen vacancies, the neutron diffraction results consistently show a slight deficiency of lead atoms relative to oxygen. The number of lead vacancies has been observed to be in the range 1%-5%, with the balance of positive charges presumed (23) to be achieved by the incorporation of hydrogen ions into the β -PbO₂ lattice, according to the formula

Note that with this model the range of lead vacancies is sufficient to account for the observed range of hydrogen atom contents. However, the validity of these departures from stoichiometry remains in some doubt, since they are, at most, only a few times the estimated standard deviations of the measurements. Furthermore, the amount of hydrogen present in β -PbO₂ samples has been found (11) to correlate with the difference between the total Pb and Pb⁴⁺ content of the material measured by chemical analysis. It has, therefore, been suggested (11, 26) that a more likely mechanism for the incorporation of large amounts of hydrogen atoms may involve the substitution of Pb²⁺ ions for Pb⁴⁺, leading to a formula of the kind

In this model, the presence of hydrogen atoms is not dependent on the presence of either lead or oxygen vacancies in the β -PbO₂ structure.

Since the unit cell volume of rutile-type oxides is a sensitive and predictable function of the ionic radii of the cations present (27), precise measurements of the unit cell dimensions of β -PbO₂ should show a systematic decrease in unit cell volume as the hydrogen atoms (and accompanying Pb²⁺ ions) are lost during cycling of a battery. Furthermore, if chemically prepared PbO₂ contains less hydrogen (and by implication is therefore electrochemically inactive), then the unit cell volume of β -PbO₂ from a failed battery should approach the value for chemically prepared material.

In the present study, we have tested the proposal of the presence of hydrogen species in β -PbO₂ and its relationship with battery capacity by undertaking full-profile Rietveld-type x-ray powder diffraction structure refinements (28) of β -PbO₂ samples prepared chemically and ones taken from batteries operated at 25° and 50°C. The use of a profile-refinement method incorporating the simultaneous analysis of two phases (29) is necessary for this application because of the presence of both α -PbO₂ and β -PbO₂ components in the battery material and the resultant high level of diffraction peak overlap. Moreover, the refinement method has the capability of producing unusually precise lattice parameters because of the

Table I. Proportion of operational life, relative capacity, and quantitative phase composition of the battery samples used for Rietveld structure refinement

* Defined as the ratio of the number of charge/discharge cycles completed at the time of sampling to the total number at the time of failure (75% of the initial battery capacity).

** Battery operated at 25°C: failed after 116 charge/discharge cycles (2621 km).

† Battery operated at 50°C: failed after 246 charge/discharge cycles (7690 km).

requirement that the calculated and observed peak profiles match all along their steep sides as well as at the peak center. As a by-product of the refinement, accurate estimates were also obtained for the changes in crystallite size with battery cycling, which could then be related to changes in crystal structure order/disorder.

Experimental

Origin of β -PbO₂ samples.—After preliminary x-ray screening for phase purity, Univar PbO₂ (batch no. 11409) manufactured by Ajax Chemicals, and Analar PbO₂ (batch no. 81037 B210556) made by Hopkins and Williams, were chosen to represent chemically prepared β -PbO₂.

The battery samples were obtained at regular intervals from the charged positive plates of two 12V, 60 Ah lead-acid batteries operated at 25° and 50°C, respectively, and subjected to charge/discharge cycles that simulated electric vehicle service in an urban environment. Details of the test station design, cell construction, charge/discharge characteristics, sampling procedure, and operational results have been reported in detail elsewhere (8, 30, 31, and references therein). The end of useful battery life was taken as the point at which the discharge capacity, converted to the 20h rate, had fallen to 75% of the nominal rate at 25°C. At failure, the battery cycled at 25°C (B25) completed 116 charge/discharge cycles (2621 km of equivalent distance traveled) and was sampled a total of five times, whereas the battery cycled at 50°C (B50) completed 245 cycles (7690 km) and was sampled seven times (Table I). Both batteries were also sampled at least once in their postfailure period.

X-ray diffraction data collection.—All samples were back-pressed into standard aluminum holders and mounted in a Philips PW1050 diffractometer equipped with a PW1710 automatic step scanning system and a diffracted-beam curved graphite monochromator. Intensity measurements were made at intervals of 0.04° over the 2θ range 22°–117° using CuK α radiation and a step counting time of 5s. The x-ray tube was operated at 45 kV and 26 mA, with 1° divergence and receiving slits. These conditions allowed the collection of profile data for a total of 43 and 121 unique Bragg reflections for β -PbO₂ and (when present) α -PbO₂, respectively.¹ Dead-time corrections were applied automatically during data collection.

Structure Refinement Method

The least squares structure refinements were undertaken with the full-profile Rietveld-type program DBW 3.2 (28, 29), modified to include the application of a Pearson VII diffraction peak profile shape function (32). This

¹A complete listing of the step scan diffraction data for all of the samples is available from the authors upon request.

program can simultaneously refine the structures of two phases using x-ray data obtained from a conventional diffractometer, since it allows for the presence of two wavelengths (*i.e.*, CuK α_1 and α_2). Details of the refinement procedure have been described elsewhere (24, 29, 33). Starting values for the profile parameters were obtained by inspection of the observed diffraction pattern, and those for the atomic structure were taken from the literature (24).

Silicon calibration.—Before applying the Rietveld method to the β -PbO₂ samples, a coarsely crystalline sample of silicon was studied as a calibration standard. This step was required (*i*) to ascertain the potential accuracy, as well as precision, of the unit cell dimension determination, (*ii*) for the experimental determination of the graphite monochromator polarization ratio correction and of the intensity ratio of the CuK α_1 and α_2 reflection pair, and (*iii*) to define the instrumental contribution to diffraction peak broadening during the determination of crystallite size.

The results of the refinement of the Si data using the empirically determined polarization and CuK α_2/α_1 radiation intensity ratios, 0.91 and 0.5, respectively, are given in Table II. The unit cell parameter $a = 5.43113(9)\text{\AA}$ is less than three combined standard deviations larger than the value 5.43083(1) \AA generally accepted as the best absolute estimate of the cell dimension of crystalline Si (34). The application of the Rietveld method to the present problem is, therefore, capable of producing unit cell measurements of acceptable accuracy and precision. Furthermore, the unit cell parameter (and radiation intensity ratio) was found to be statistically invariant for refinements of Si data collected at regular intervals during the course of the study.

The mean dimension of the crystallites in the β -PbO₂ samples was determined from the Scherrer (35) and Warren (36) equations by comparing the values of peak width calculated at a constant 2θ value of 60° (37).

Battery samples.—Depending upon the stage of battery operational life at which sampling took place, the battery samples contained between 6 and 35 weight percent (w/o) of α -PbO₂ (Table I). Rather than exclude these α -PbO₂ "contaminating" peaks from the diffraction profile refinement, they were treated similarly to those of β -PbO₂ by incorporating the α -PbO₂ as a second phase (29). However, details of the α -PbO₂ pattern could only be refined for those samples in which the amount of α -PbO₂ was greater than 15 w/o (Table I), and even then, only the scale factor and a single peak width parameter (for crystallite-size measurements) could be released. No such complication arose for the samples of chemically prepared β -PbO₂, since these were single phase.

^{*} Defined as in Table I.

[†] Conventional Rietveld refinement agreement index (28).

^{**} Obtained from a peak full-width at half maximum (FWHM) relationship fitted to the entire pattern (28, 29).

^{††} Obtained from the Scherrer equation (35) using silicon as the calibration standard.

Final values of all refined structural and profile parameters relevant to the present study are summarized in Table II: the full list of parameters may be obtained from the authors on request.

Results and Discussion

Unit cell volume.—Values for the unit cell volume of the β -PbO₂ crystal structure were calculated from the refined values of the unit cell dimensions (Table II) and are plotted in Fig. 1 against the proportion of battery operational life at the time of sampling (Table I). The unit cell volumes of the two chemically prepared samples are plotted, for convenience, at the 100% position on the battery life scale, along with published values (38-42) of the cell volumes obtained from eight very precise x-ray studies of chemical and natural β -PbO₂. Literature values for β -PbO₂ unit cell volumes determined by neutron diffraction were not considered because of a degree of uncertainty about the exact value of the neutron wavelength used (26).

The most obvious feature of the data plotted for batteries B25 and B50 is that the unit cell volume of the β -PbO₂ component starts service with a high value (about 83.36 Å³), which declines sharply during the first stage of battery operational life. The reason for this sudden drop in cell volume at a time when the capacity of the batteries (and therefore the electrochemical activity of their β -PbO₂) is equal to, or indeed, higher than the initial value at the commencement of service (Table I) is unclear. However, as discussed below, the early stages of the operational life of the batteries are marked by a dramatic increase in the size of the β -PbO₂ crystallites. Moreover, the initial values for the ratio of the unit cell dimensions (see below) are also atypical of the values encountered throughout the remainder of battery service. Both of these observations suggest that the physical properties of the very small crystals present in the very early stages of battery operation are not representative of the better crystallized material which results from charge/discharge treatment. The sharper decline in the unit cell volume of B50 relative to B25 is probably related to the fact that electrolyte diffusion, and charge/discharge reaction rates in general, are more rapid and more uniform at the higher operating temperature of this battery (8, 31).

After the initial "settling in" period, the unit cell volume of the β -PbO₂ in B50 remains fairly constant, while that of B25 tends to increase back towards its starting value. These variations are statistically significant when

compared to the error bars on the data points Fig. 1, but, since each sample taken from the operating battery is of necessity small (in order not to disrupt battery performance), the variations probably reflect small differences in the relative proportions of used and unused β -PbO₂ in the samples between and within individual plates. For B50, the fluctuations in cell volume are less severe than for B25, since the plate material is more uniform in composition and utilization at higher temperature.

In addition, the B50 β -PbO₂ unit cell volume is consistently smaller than that of B25. This observation is also likely to be a function of operating temperature, since a significantly higher proportion (about 45%) of the available β -PbO₂ present in the battery plates takes part in the charge/discharge reaction at higher temperature (9, 31).

Fig. 1. Unit cell volume of the β -PbO₂ crystals in the two batteries B25 (●) and B50 (x) and two chemical preparations (Δ) plotted against the proportion of battery operational life at which sampling took place. The values were calculated from the least squares derived unit cell dimensions and are included along with their associated estimated standard deviations. Also plotted are the unit cell volumes of eight chemical β -PbO₂ samples (○) identified by their literature reference numbers.

Therefore, less of the unreacted, large cell volume β -PbO₂ remains to contribute to the bulk measurement.

The rise in the B25 β -PbO₂ unit cell volume in the post battery failure period (Fig. 1) probably arises from a similar effect, since the rate of "shedding" of the positive plate material is some 50% higher for this battery than for B50, and it is the heavily used material in the outer portions of the plate which is preferentially shed during battery operation (8, 43).

When allowance is made for the atypical nature of the β -PbO₂ present in the very early stages of battery operation, the unit cell volume of the dioxide is either constant (B50) or increases slightly (B25) for the period during which 50% of the capacity of the battery is lost. Even when the unit cell volumes at the beginning of battery operation are included, the total range of volumes exhibited by the battery material, whether healthy (active) or failed (inactive), is not much greater than the range of unit cell volumes observed for chemically prepared varieties of β -PbO₂ (Fig. 1). Behavior of this kind is not consistent with the suggestion that battery capacity declines as a result of the loss of a hydrogen species (and Pb²⁺ ions) from the β -PbO₂ structure, nor with the suggestion that chemically prepared β -PbO₂ is somehow more akin to inactive β -PbO₂ than to active β -PbO₂ (9, 10, 13-16). However, it is clear that comparisons between one or two isolated samples of battery and chemical β -PbO₂ (23, 26) could lead to conclusions in contradiction with the trends displayed by the larger number of samples used in the present study.

In Fig. 2, the unit cell volumes of 12 well-characterized rutile-type oxides (44-53) have been plotted against the cube of the corresponding cation radii. The data all fall close (correlation coefficient = 0.993) to the line

$$\text{Volume} = 41.8987 + 88.2806 (\text{radius})^3 \quad [3]$$

Using the accepted (54) value of 0.775Å for the radius of Pb⁴⁺, the unit cell volume predicted for stoichiometric PbO₂ with regression Eq. [3] is 82.949 Å³. This value has been plotted as the "x = 0.0" point in Fig. 1 and 2, and lies at the lower end of the range of determinations on both electrolytic and chemical β -PbO₂ given in Table II and Fig. 1 (82.926-83.397 Å³). All of the β -PbO₂ samples have unit cell volumes which are, therefore, either equal to, or only slightly larger than, the predicted value for stoichiometric β -PbO₂.

Fig. 2. Variation of the unit cell volume of 12 rutile-type oxides MO₂ with the cube of the radius of the cation M. The line is the least squares regression relation between the two quantities plotted. The two points labeled x = 0.0 and 0.1 represent the predicted volume of lead dioxide with the formulas PbO₂ and Pb⁴⁺_{0.95}Pb²⁺_{0.05}O_{1.9}(OH)⁻_{0.1} respectively.

The Pb²⁺ ion has a radius of 1.19Å in six-fold coordination, significantly different from the Pb⁴⁺ radius of 0.775Å, whereas the O²⁻ and (OH)⁻ radii are very similar with values of 1.36 and 1.34Å, respectively (54). Changes in unit cell volume as a result of the coupled substitution of O²⁻/(OH)⁻ and Pb⁴⁺/Pb²⁺ according to the formula [2] may, therefore, be reduced merely to the effect of the Pb⁴⁺/Pb²⁺ pair on the radius of the octahedral site. The predicted unit cell volume for a given degree of substitution, x, can then be determined by calculating a weighted mean cation radius for the octahedral site and inserting this in the regression Eq. [3].

A comparison (Fig. 1) of the range of observed unit cell volumes (82.926-83.397Å³) with the values calculated from the regression equation suggests that the maximum amount of (OH)⁻ substitution is likely to be of the order of x = 0.01. Hydroxyl contents of up to 25% quoted in the literature (1, 20, 21, 41) for chemical analysis of bulk battery positive plate material cannot relate entirely to substitution in the β -PbO₂ structure, since this would produce unit cell volumes vastly in excess of observed values (Fig. 2). A large proportion of the hydroxyl must, therefore, be present in surface layers and/or noncrystalline fractions of the samples. X-ray photoelectron (22) and infrared (55) spectroscopic studies of chemically and electrochemically prepared lead dioxide, and the related (rutile) oxide TiO₂, respectively, are in support of this conclusion.

c/a ratio.—By taking the ratio of the unit cell dimensions, c/a, rather than their individual values or the product, a²c (the unit cell volume), the effects of some possible systematic experimental errors in the determinations (e.g., 2θ zero error, sample eccentricity, wavelength uncertainty, etc.) are eliminated or reduced. Moreover, information is obtained about the relative changes (distortions) in unit cell dimensions which may otherwise cancel out in a volume calculation.

The c/a ratios for the B25, B50, and chemical preparations of β -PbO₂ have been plotted against the appropriate proportion of battery operational life in Fig. 3. The most notable feature of the data is the rapid decrease in c/a ratio during the first 15% of battery life. As in the case of the variation in β -PbO₂ unit cell volume discussed above, the very early stage of battery operation is atypical of the

Fig. 3. Variation of the β -PbO₂ unit cell edge ratio c/a with the proportion of battery operational life at which the samples were collected. The data are plotted for the same samples and presented in the same manner as in Fig. 1.

remainder of the life of the battery for which the c/a ratio remains very uniform and equal for each battery. This suggests that the β - PbO_2 crystal structure suffers no observable distortion during the period for which more than 50% of the battery capacity is lost.

The c/a ratios determined for the two chemically prepared samples of β - PbO_2 in the present study are significantly higher than the middle- and late-stage battery sample values, but lie well within the range of values obtained from the literature for chemical β - PbO_2 . Indeed, some of the chemical preparations have c/a ratios close to those of the uncycled β - PbO_2 , whereas others have ratios more akin to those of heavily cycled material. As deduced from unit cell volume measurements, therefore, there appears to be no systematic distinction between β - PbO_2 from a failed and a healthy battery, or between electrolytic β - PbO_2 and at least some of the chemical preparations. This is only the case, however, when the trends exhibited by a number of samples are collected together.

As expected, similar conclusions apply when the variations of the two individual unit cell dimensions are analyzed as a function of battery capacity (Table II): like the cell volume and c/a ratio, the a and c values are again high during the early stages of charge/discharge cycling, but they quickly settle down to relatively constant values for the remainder of battery operational life. Moreover, the total range of unit cell sizes for the battery β - PbO_2 is approximately equal to that observed for chemically prepared material. There is no evidence that the a parameter in battery β - PbO_2 is significantly greater than that of chemical samples, as reported by Antonio *et al.* (26) for a more limited number of samples.

Crystallite size.—The mean dimension of the crystallites in the samples analyzed in the present study are plotted against proportion of battery operational life in Fig. 4. Both the 25° and 50°C batteries begin service with β - PbO_2 crystallite sizes of around 250Å, and both experience a substantial increase in size as the batteries are cycled, in agreement with earlier work (3, 5, 10, 41, 56).

For B50, a crystallite size of around 900Å is reached after only 10% of its operational life has been completed, whereas for B25, the rise to its stable value of around 700Å is only reached after 60% of its life. In the postfailure pe-

riod, the size of the β - PbO_2 crystallites in both batteries is around 800Å, approximately halfway between the values obtained for the two chemically prepared β - PbO_2 samples. Once again, therefore, it is clear that chemical preparations are not immediately distinguishable from the electrolytic samples.

The broadening of diffraction peaks can, however, be a result of nonuniform lattice strain brought about by the presence of nonstoichiometry and/or defects in the crystal structure of the material examined, rather than of a real decrease in crystallite size (41). With this possibility in mind, it has been suggested that the decrease in peak width as β - PbO_2 is cycled in a battery represents a change in the β - PbO_2 crystal structure towards a more stoichiometric, defect-free variety which is less reactive electrochemically (9, 10, 13-16).

The results presented for the B25 samples in Fig. 4 are consistent with this idea in that the effective crystallite size increases more or less steadily as the battery capacity declines towards failure. However, for B50 the crystallite size of the β - PbO_2 increased to its battery failure value after only 10% of the operational life passed. Therefore, while the increase in crystallite size for both batteries may well represent an increase in structural order, especially during the first few cycles, it is difficult to attach a consistent relationship between particle size/structural order and the capacity changes observed for both batteries. Moreover, one of the chemically prepared β - PbO_2 samples has a crystallite size which is not much greater than fresh battery material, yet this material is claimed to be defect-free and inactive (2).

During the limited period over which α - PbO_2 was present in sufficient quantities for its crystallite size to be determined, its size was found to remain constant at around 150Å. This very small crystallite dimension is consistent with the results of neutron powder diffraction (24, 26) and transmission electron microscope (12) studies of α - PbO_2 , which suggest that the crystal structure of this phase is highly disordered. In fact, the α - PbO_2 content of the battery samples decreases with charge/discharge cycling (Table I) because it does not reform from the PbSO_4 discharge product (8, 31). The α - PbO_2 measured in the present study is, therefore, material which has not discharged, and its crystallite size is unaltered from that present in fresh battery plates.

Summary and Conclusions

After an initial short period of charge/discharge cycling, the unit cell volume and c/a cell edge ratio of β - PbO_2 reach fairly stable values which are independent of the battery capacity and are indistinguishable from the values obtained from chemically prepared material. The suggestion that battery capacity declines as a result of gradual loss of a hydrogen species from the β - PbO_2 crystal structure, therefore, seems unlikely.

A comparison of the observed unit cell volumes with values calculated for a given level of $\text{O}^{2-}/(\text{OH}^-)$, $\text{Pb}^{4+}/\text{Pb}^{2+}$ coupled substitution in the β - $\text{PbO}_2 \cdot x\text{H}$ formula suggests that the maximum value of x is about 0.01, *i.e.*, little different from stoichiometric β - PbO_2 . Under the constraints of this model of hydrogen atom incorporation, measured (OH^-) contents of up to 25% quoted in the literature for analyses of bulk (crystalline plus noncrystalline) active material must, therefore, relate to the (OH^-) content of surface layers and/or the noncrystalline fractions of the samples, rather than to the β - PbO_2 crystal structure itself. Whether or not hydrogen atoms located in the β - PbO_2 surface layers and/or amorphous material play a role in the electrochemical activity of the positive plate remains to be determined. Furthermore, an alternative model in which hydrogen atoms substitute into the β - PbO_2 structure to compensate for lead atom vacancies may also yet prove to be relevant to the decline in battery capacity.

Batteries operated at both 25° and 50°C begin service with β - PbO_2 crystallite sizes of around 250Å; and experience an increase in size with cycling. However, in the case of the 50°C battery a crystallite size of around 900Å is

Fig. 4. Mean crystallite dimension of battery β - PbO_2 and α - PbO_2 plotted against the proportion of battery operational life at which samples were collected. The data are plotted for the same samples (minus the literature chemical preparations) and presented in the same manner (minus the error bars) as in Fig. 1.

reached after only 10% of its operational life has been completed. The gradual loss of battery capacity with cycle life cannot, therefore, be correlated with the observed relatively sudden increase in crystallite size and/or structural order during the early stages of operation.

Acknowledgments

We are indebted to Dunlop Batteries Australia for supplying battery materials and to the International Lead Zinc Research Organization for their joint support and for permission to publish this work. We also thank K. Harris and D. C. Constable for assistance with sample preparation and battery test rig operation. An early version of the manuscript benefited greatly from constructive reviews by Dr. S. Fletcher, Dr. I. E. Grey, and Dr. D. A. J. Rand.

Determination of the Reliability of Aerospace Ni-Cd Batteries from Survival Data on Cells Fabricated Between 1964 and 1977

A. S. Jordan * and T. D. O'Sullivan

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We have performed a reliability analysis on Ni-Cd cells manufactured between 1964 and 1977 and aged by NASA ("CRANE") in simulated low earth and geosynchronous orbits. Similar cells are used in the construction of Ni-Cd batteries that serve as the energy storage medium in communications satellites. The statistical treatment of cell aging data conforms to techniques applied to semiconductor devices. In low earth orbit, the failure distribution by shorts is lognormal with standard deviation (s) of 1.06, median life (t_m) of 128,000h and activation energy of 0.29 eV. In geosynchronous orbit, the additional failure mode of capacity degradation leads to a bimodal lognormal distribution characterized by t_m of 283,000 and 122,000h and s of 1.14 and 0.27 for short and degradation, respectively. We have also deduced the probability of battery-survival and battery-failure rate, respectively. The inclusion of cell redundancy is a key feature of the analysis. It is shown that enhanced redundancy is a major factor in assuring long-term battery performance.

In view of the high initial cost and impossibility of repair at the present state of the art, no communication system requires a higher degree of long-term reliability than satellite communications. In geosynchronous orbit, the electronic system of transponders is powered by reliable solar cells at all times except during solar eclipses, when the energy storage system that frequently employs two rechargeable Ni-Cd batteries takes over. Each year, the satellite is exposed to two eclipse seasons, each lasting 44 days. During these seasons, the eclipse time varies from 4 to 70 min in a predictable manner. Then, unless the spacecraft's batteries deliver sufficient power above a specified voltage to the transponders, the operating loads must be reduced and the mission's objectives can only be partially met.

In general, solid-state devices, such as solar cells and transponders comprising semiconductor components (1), enjoy a greater reputation for reliability than batteries. Indeed, conventional Ni-Cd batteries exhibit a time-dependent decrease in voltage due to cell degradation as well as cell shorting (2). Since at present the batteries on geosynchronous satellites may well be the life limiting component (2), a study of their reliability is a vital prerequisite in guaranteeing a successful mission of, say, 10 yr duration. The most exhaustive source for life-test data on aerospace Ni-Cd batteries originates from the Naval Weapons Support Center, Weapons Quality Engineering Center at Crane, Indiana (CRANE) (3). The major objective of the current investigation is to determine by means of a large-scale statistical study the reliability of Ni-Cd cells and batteries tested by CRANE. Although these conventional cells are of an early vintage with respect to the date of design and manufacturing, it is considered that their statistical treatment would provide a "benchmark" to compare with more modern cell designs. Moreover, since the battery is but one component of the satellite's communication system, it is thought to be necessary to develop a technique of reliability analysis for batteries consistent with that for solid-state components on board.

Bearing in mind these objectives, in the first part of the paper we briefly describe the structure of conventional Ni-Cd cells and the aging experiments performed at CRANE to assess their reliability. Second, we present an outline of the statistical methodology employed to obtain the cumulative failure function for a large sample when the life testing of the survivors is occasionally terminated. Then, we determine the failure distribution for shorts in Ni-Cd cells aged at three temperatures and deduce the activation energy for the shorting process. In addition, for cells exercised in a simulated geosynchronous orbit, the data, which include both degradation failures and shorts, are analyzed.

At any time of service, the behavior of Ni-Cd cells is directly predictable from the parameters of the failure dis-

tribution. Subsequent, probabilistic reasoning combined with cell parameters leads to equations that forecast the long-term performance of the battery subsystem of any redundant configuration. The two measures of successful mission employed in the calculations are probability of battery survival and battery failure rate, the latter being a quantity preferred by designers of electronic systems. Finally, two alternatives are suggested to assure 10 yr of failure-free battery operation. These are (i) enhanced redundancy using conventional cells and/or (ii) longer median life, potentially achievable in improved designs.

Experimental Data

Ni-Cd cell and battery structure.—This investigation is restricted to the evaluation of reliability data on prismatic Ni-Cd cells (2, 3) manufactured by General Electric between 1964 and 1977. Though some of these cells on test are over a decade old, they are by and large similar to those in use today. The electrodes in these Ni-Cd cells are chemically deposited and have nylon separators; the electrolyte is KOH. The battery under consideration comprises a string of 32 cells, of which at least 29 or 30 must operate to deliver 29V, the minimum required in this realistic example for full power transponder operation. There are two identical batteries on board.

Aging program at CRANE.—The prismatic Ni-Cd cells made by General Electric (GE) were tested at CRANE (3). This facility has been running real-time tests for over 17 yr under NASA supervision. The data base to be treated here is extracted from the annual reports of CRANE. It should be emphasized at the outset that the CRANE testing program includes, besides prismatic cells, cylindrical cells, as well as products of manufacturers other than General Electric. In addition to real-time tests in both low earth and geosynchronous orbits, aging experiments were also performed under accelerated conditions such as different temperatures and charge/discharge rates. This paper focuses on the treatment of real-time data, modified only by moderate temperature acceleration, on prismatic GE cells.

Table I summarizes the total number of suitable cells tested at CRANE and the actual numbers acceptable in our statistical analysis, separated with respect to nominal capacity. The cells excluded were either exercised in a nonstandard orbit or tested only for a few hundred hours before termination. Moreover, some cells were disqualified because at several aging temperatures the sample size was too small to establish the failure distribution with a reasonable degree of confidence.

The cells were tested in groups of five held at the nominal aging temperatures 0°, 22.5°, and 40°C within less than ±2°C. Each pack of five had its own dc power supply for charging and discharging. In low earth orbit, cells at 0°, 22.5°, and 40°C were cycled every 1.5h at 15%, 25%, and

*Electrochemical Society Active Member.

Table I. Cells tested by CRANE and number used in analysis, by nominal capacity

Nominal capacity (Ah)	Total no. of cells	No. of cells used
6	220	128
8	20	20
12	229	148
20	61	48
26.5	10	0
40	10	0
50	12	0

40% depths of discharge. There was essentially continuous monitoring for shorts, detected by a precipitous drop in voltage.

The second mode of orbit simulation is the geosynchronous one, which virtually imitates the operation of a communication satellite. During the two eclipse seasons, each lasting 44 days, the cells were repeatedly charged and discharged for the appropriate length of time, which was controlled by a computer. Aging tests were conducted at 40%, 60%, and 80% depths of discharge, and at 0° and 22.5°C. As was the case in low earth simulations, the shorts were automatically recorded. In addition, the cells exercised in geosynchronous orbit were completely discharged to reveal their remaining capacity. In this manner, the time dependence of the degradation in actual average capacity for a pack of five cells could be determined. It should be emphasized that with the small degree of cell redundancy in series (29 or 30 from 32 must function) feasible on some spacecraft, each cell must retain at least 60% (7.2 Ah) of its nominal capacity (12 Ah) to a 1V cutoff per cell, because otherwise the voltage delivered to the transponders is insufficient for full-power operations. The fraction 7.2 Ah/12 Ah is the nominal depth of discharge. If actual capacities were used, it becomes 7.2 Ah/16.7 Ah = 43%, where 16.7 Ah is the average initial capacity taken from the CRANE data. Any cell can be treated by this method as long as the actual capacity is known.

Statistical Methodology

Previous reliability assessments based on the CRANE data base concentrated exclusively on accelerated tests, especially with regard to charge/discharge rates and depth of discharge. For example, Fedors *et al.* (5) applied the Griffith theory of crack formation in solids to construct a fractional order reaction-rate model of "flaw" propagation in cells to describe failure due to degradation. In contrast, when dealing with real-time aging of cells, one has to consider shorts and degradation. By invoking the well-known lognormal probability distribution to account for both modes, we intend to treat the experimental results in a unified manner. Furthermore, a key feature of our technique is the consistent analysis of failed and terminated cells. Clearly, on the relatively short time-scale of accelerated testing the need to discontinue is reduced.

Life testing of components, such as cells and semiconductor devices, serves two important interrelated functions. One purpose is to unravel, if possible, the major failure mechanisms. The other objective is to lay the experimental foundation for predicting and assuring reliability in operating systems. It has been previously shown that without a large sample size the forecasting of future behavior with a high degree of confidence is impossible (6). Therefore, in analyzing the aging data on shorts from CRANE, an extended sample had to be constructed. In doing so, though, we paid particular attention to unique features of the testing procedure.

Cells were put on test in packs of five at different times. When rack space was needed, experiments were discontinued before all cells in the pack failed. Since shorts represent catastrophic events without a forewarning or precursor, no information can be derived about the time to failure of the terminated survivors. Hence, the statistical treatment employed in describing

the failure distribution must be such that it allows (i) the combination of the testing results on many packs with cells of common characteristics regardless of chronology and (ii) taking into account the removal of operating survivors. Similar conditions have been encountered in the acquisition and analysis of burn-out failure of GaAs power FET's (4). Moreover, appropriate precedents for the necessary statistical reasoning are available, for instance, from medically oriented investigations. Therefore, a brief outline of the technique used to construct the failure distribution for shorts will be sufficient.

In the absence of terminations the cumulative failure function (CFF) corresponding to a given time to failure is usually obtained by evaluating the so-called plotting points (6). If the initial number of cells in the sample is N , and at any time between t_{j-1} and t_j , the number of failed cells is d_j , then at $t_p \geq t_j$ the simplest choice of plotting positions for the CFF is

$$\text{CFF}(t_p) = \sum_{j=1}^p \frac{d_j}{N+1} \quad [1a]$$

The reliability function (7) $R(t_p)$, is then given by

$$R(t_p) = \frac{N - \sum_{j=1}^p d_j + 1}{N+1} \quad [1b]$$

where putting $N+1$ instead of N in the denominator prevents the CFF ever reaching unity, a value that cannot be accommodated in probability plotting.

If, however, at time t_j , r_j cells are removed prior to failure, the above procedure must be altered. Kaplan and Meier were among the first to formulate and solve the problem of the distribution of survival times when completing the measurements is either inconvenient or impossible (8). A maximum likelihood estimate of the survival probability was derived, which can be interpreted by the following appeal to intuition: suppose after 2 yr of testing a group of ten cells, two of them short, and after an additional year one more of the eight survivors fails. Then, imagine another group of five cells, of which one shorts after 2 yr and the remaining four are immediately terminated. The probability of survival or reliability at two years for the joint sample, R_j , is

$$R_j(2) = \frac{12}{15} = 0.80$$

To obtain the reliability of 3 yr $R_j(3)$, one first estimates the conditional probability for 3 yr given survival for 2 yr. Based on the first sample, we find

$$\frac{R(3)}{R(2)} = \frac{8-1}{8} = 0.875$$

Hence, we can write

$$R_j(3) = \frac{R(3)}{R(2)} R_j(2) = 0.70$$

The generalized result of Kaplan and Meier (8) is in the form of the following chain rule

$$R(t_p) = \frac{N_1 - d_1}{N_1} \times \frac{N_2 - d_2}{N_2} \times \frac{N_3 - d_3}{N_3} \times \dots \times \frac{N_p - d_p}{N_p} \quad [2]$$

However, in order to be consistent with Eq. [1b], Herd's version of Eq. [2], where unity is added to both numerator and denominator, was chosen (9, 10). Accordingly, the reliability function and CFF which take into account failures as well as removals are of the form

$$R(t_p) = \prod_{j=1}^p \frac{N_j - d_j + 1}{N_j + 1} \quad [3a]$$

$$\text{CFF} = 1 - R(t_p) \quad [3b]$$

where

$$N_j = N - \sum_{i=0}^{j-1} (d_i + r_i)$$

In general, initially $d_0 = 0$; thus after some algebra it can be shown that if there are no terminations Eq. [3] reduce to Eq. [1].

Results

Failure distribution in low earth orbit.—The CRANE data for shorts on conventional Ni-Cd cells aged in a simulated low earth orbit at 0°, 22.5°, and 40°C were analyzed by means of Eq. [3]. In order to avoid statistical uncertainties due to a reduced sample size, no subdivision with respect to nominal capacity was introduced. In Fig. 1, 2, and 3, we have plotted on lognormal graph paper the time to induce a short at 0°, 22.5°, 40°C, respectively. At each of these temperatures, the course of the data points suggests that the failure distribution for shorts is approximately lognormal (7). By least squares treatment (7), we obtained the best values for the median lives, t_m , and standard deviations, s , which are listed in Table II. The fact that the correlation coefficients (see Table II) are above 0.97 at all temperatures is an indication of the reasonableness of the lognormal failure model for shorts. However, some scatter can be discerned among the standard deviations. But, when their upper and lower limits for the population at the 90% confidence level (7) are compared, a considerable overlap is observed, implying that a common, nearly temperature-independent standard deviation characterizes the distribution.

In order to improve the precision of the calculations by using a larger data base and to determine the activation energy for shorts, we have reduced the results at 40° and 22.5° to 0°C and combined them with the actual data at 0°C. In this fashion, the scatter due to sample size seen at the separate temperatures is minimized. The higher temperature times to failure were adjusted by an acceleration factor based on the Arrhenius law but with a variable activation energy, E_a . Then, the joint sample was repeatedly treated by means of Eq. [3] and that E_a was finally accepted, which led to the smallest root-mean-square difference between the median lives at given aging temperatures (see Table II) and the ones

Fig. 2. The lognormal projection of time to failure by shorts as a function of cumulative failure percentage for Ni-Cd cells aged in low earth orbit at 22.5°C. The solid line was computed from the appropriate least squares estimates listed in Table II. The dashed line is based on a single parameter linear regression, taking $s = 1.06$ from that of the combined sample.

projected to the same temperatures from the median life determined for the total combination at 0°C. In this manner, an E_a of 0.29 eV was evaluated, which corresponds to a root-mean-square difference of 5323h.

Fig. 1. The lognormal projection of time to failure by shorts as a function of cumulative failure percentage for Ni-Cd cells aged in low earth orbit at 0°C. The solid line was computed from the appropriate least squares estimates listed in Table II. The dashed line is based on a single parameter linear regression, taking $s = 1.06$ from that of the combined sample.

Fig. 3. The lognormal projection of time to failure by shorts as a function of cumulative failure percentage for Ni-Cd cells aged in low earth orbit at 40°C. The solid line was computed from the appropriate least squares estimates listed in Table II. The dashed line is based on a single parameter linear regression, taking $s = 1.06$ from that of the combined sample.

Table II. Lognormal parameters for Ni-Cd cells in low earth orbit

Temp (°C)	Shorted cells							Correlation coefficient
	Total no. of cells	t_{mpu} (h)	t_m	t_{mpi}	σ_u	s	σ_l	
40	25/50	22,960	17,770	13,740	1.06	0.86	0.72	0.9701
22.5	29/171	77,420	63,740	52,500	1.16	0.98	0.85	0.9799
0	20/83	181,570	123,660	83,700	1.74	1.42	1.20	0.9722
0 [combined sample]	74/304	148,020	127,640	110,120	1.16	1.06	0.98	0.9833

Confidence level = 90%.

In Fig. 4, we present the time to failure by shorts *vs.* CFF for the joint sample at 0°C. The improved description of the failure data by means of the lognormal distribution is immediately obvious when the total sample is used. Further support for this qualitative viewpoint is found in comparing the increase in the correlation coefficient (0.983) with the average value of the coefficients at the different aging temperatures (0.974). In addition, by blending the data using 0.29 eV, temperature-dependent clustering could be avoided. We have observed such clustering at large assigned activation energies.

In Table II, we have also listed the lognormal parameters and confidence limits of the joint sample. Concentrating on the standard deviation, we find that there is a good overlap between the bounds for the combined sample and those observed at the different aging temperatures. A marginal discrepancy of 0.04 standard deviation units exists between the lower limit of the 0°C sample and the upper limit of the combined one. To be sure, one may attach significance to the apparent temperature-dependent variation in s values in Table II. Without more aging data, this is not statistically warranted for the error bounds were taken at the 90% confidence level. At the 95% level, the overlap becomes acceptable. That the standard deviation of 1.06 obtained for the total sample is satisfactory to describe the data at all three temperatures is demonstrated in Fig. 1, 2, and 3, where the dashed lines represent least squares lines with a fixed slope ($s = 1.06$) and variable intercepts.

Fig. 4. The lognormal projection of time to failure by shorts as a function of cumulative failure percentage for Ni-Cd cells aged in low earth orbit at 0°, 22.5°, and 40°C. Before combination of the total data, the high temperature values were reduced to 0°C using an activation energy of 0.29 eV (see text). The solid line was computed from the appropriate least squares estimates in Table II.

Taking into account the confidence limits, in Fig. 5 we show on an Arrhenius plot that the combined data base in conjunction with the 0.29 eV activation energy provides temperature-dependent median lives consistent with the median lives determined at separate aging temperatures.¹ Therefore, to predict the behavior of conventional Ni-Cd cells operating in low earth orbit which fail predominantly by shorts, we recommend the use of lognormal parameters obtained by treating the total sample reduced to 0°C.

Failure distribution in geosynchronous orbit.—As we have already established, employing the extended data base, that the failure distribution for shorts of conventional Ni-Cd cells exercised in low earth orbit is lognormal, the proposition that cells aged in simulated geosynchronous orbit behave similarly is eminently plausible. Following the previously used computational techniques, we have analyzed the meager CRANE data for shorts arising in geosynchronous orbit (3) and plotted the results in the usual lognormal projection in Fig. 6. The results of the least squares regression for the parameters (7) are listed in Table III. Due to the limited sample size, the evidence for lognormality is not as strong here as in low earth orbit. This is indicated by inspection of the data in Fig. 6, and corroborated by the magnitude of the correlation coefficient. The noteworthy features of the derived parameters are the significant enhancement of t_m in geosynchronous orbit and the gratifying insensitivity of s to the test conditions (1.14 *vs.* 1.06).

In addition to shorts, cells in geosynchronous orbit also exhibited time-dependent degradation in their capacity. Since the degradation process is not catastrophic, the time to failure could be estimated, and thus there is no need in this case to invoke the analysis developed for sudden failure with terminations. Hence, Eq. [1a] and [1b] can be directly used in treating degradation data.

¹Treating the discrete median lives by a conventional least squares technique would give equal weight to each of the three temperatures and not to each failure. The corresponding E_a is 0.34 ± 0.05 eV, which is in reasonable accord with the preferred value of 0.29 eV.

Fig. 5. Logarithm of median life *vs.* reciprocal aging temperature for shorts of Ni-Cd cells aged in low earth orbit (Arrhenius plot). The solid line is based on the t_m of the total sample and $E_a = 0.29$ eV. The discrete points are the median lives obtained at the different aging temperatures and listed in Table II. The error bars and the dashed lines represent the confidence limits on t_m at the 90% confidence level.

Table III. Lognormal parameters for Ni-Cd cells in geosynchronous orbit

Failure mode	Failed cells		t_{mpu} (h)	t_m	t_{mpi}	σ_u	s	σ_1	Correlation coefficient
	Total no. of cells								
Shorts	9/40		439,810	283,400	182,530	1.57	1.14	0.91	0.9184
Capacity degradation	29/29		132,640	122,280	112,690	0.35	0.27	0.22	0.9694

Avg. temp: 11°C.
Confidence level = 90%.

From the CRANE data collection, the variation of the average capacity with time could be extracted for packs of five cells. Due to the meager data base, no temperature-dependent trends were observed between capacity degradation tests conducted at 0° and 22.5°C. In full operation, the design of the transponders on the spacecraft demand at least 60% of the rated capacity (12 Ah) of any cell or 7.2 Ah. As mentioned earlier, in view of the fact that the actual initial capacity of the cells was well above the rated one, namely, averaging 16.7 Ah, the time to failure by degradation was defined as the time at which the capacity is depleted to 43% of its original value. In cases when the time to failure had not yet been reached, a linear extrapolation of the degradation data was employed. This can be generalized for any spacecraft, since the power required is known and the actual capacity of the cells can be measured.

In Fig. 6, we present the time to failure by degradation as a function of CFF in lognormal projection. The number of cells plotted at a given time indicates the cells surviving in a pack of five, i.e., not removed on account of shorts or other defects. The least squares line through the data, together with the relatively high correlation coefficient, suggests that the lognormal distribution provides a good description of capacity degradation failure in Ni-Cd cells. Compared to the failure by shorts, there is a significant reduction in t_m and s in the case of the degradation process. Nevertheless, as is shown later, when redundancy on the spacecraft is taken into account, shorting is much more likely to cause battery failure than degradation. Summing up, Ni-Cd cells aged in

simulated geosynchronous orbits demonstrate a bimodal lognormal distribution, initially by shorts, and then by capacity degradation.

Discussion

Comparison with field experience.—Telemetric information received from Intelsat IV, a communication satellite managed by Comsat, indicates shorts in three cells from a total of 150, the last failure occurring at 6.7 years (2). Evidently, one cannot perform credible statistical analysis on three data points, especially when the largest CFF is only 2%. Nonetheless, linear extrapolation of $\log t$ vs. CFF at $s = 1.1$ yields $t \approx 600,000$ h with at least $\pm 300,000$ h uncertainty. This estimated median life in the field shows a considerable overlap with the one obtained from the CRANE results for shorts aged under geosynchronous conditions (see Table III). Therefore, we conclude that with regard to shorts the long-term behavior in a simulated geosynchronous orbit is in no apparent conflict with actual operating experience on board a spacecraft.

Probability of survival and failure rate of a battery.—For a systems designer, perhaps the most important information involving component reliability is its failure rate (4, 7, 10). At any service life, t , the instantaneous failure rate, $f(t)$, can be calculated from the defining equation

$$f(t) = -\frac{d \ln R}{dt} \quad [4]$$

which in the case of the lognormal distribution is of the form (7)

$$f(t) = \frac{\sqrt{2} \exp\left[-\frac{1}{2s^2} (\ln t/t_m)^2\right]}{\sqrt{\pi}ts \operatorname{erfc} \frac{1}{\sqrt{2}s} \ln t/t_m} \quad [5]$$

In Fig. 7, we have plotted $f(t)$ as a function of service life for cells using $s = 1.1$ and parametrizing t_m between 300,000 and 800,000h. It can be seen that beyond 7 yr of service t_m must be at least 500,000h if it is desired to keep f below 1000 FIT's (1 FIT is defined as one failure in 10^6 h), a value easily surpassed by semiconductor components (1) which may be parts of a transponder.

Fig. 6. The lognormal projection of time to failure by shorts and capacity degradation as a function of cumulative failure percentage for Ni-Cd cells aged in geosynchronous orbit. The solid lines were computed from the appropriate least squares parameters listed in Table III.

Fig. 7. The failure rate for shorts in Ni-Cd cells as a function of service life. The lines were computed from Eq. [5] using a standard deviation of 1.1.

As mentioned earlier, the Ni-Cd battery in reality is a subsystem comprising a fixed number of cells, most of which must be functional at the end of mission to achieve completely successful transponder operations. If the total number of identical cells in a battery is n and at least m cells provide failure-free performance at time, t , with reliability, R , then the probability of subsystem survival, R_s , can be directly obtained from the binomial distribution in the form (10)

$$R_s(x \geq m, n, t) = \sum_{x=m}^n \frac{n!}{x!(n-x)!} [R(t)]^x [1 - R(t)]^{n-x} \quad [6]$$

A typical Ni-Cd battery in a satellite is designed as a string containing, for example, $n = 32$ cells; $m = 30$ or perhaps 29 of these must deliver voltage to the transponders at 10 yr of service. We can conceive $\delta = (n - m)/(n - 1)$ as the degree of redundancy. On the one hand, if $n = m$, then $\delta = 0$ and the design is nonredundant; on the other hand, if $m = 1$, then $\delta = 1$, which is the ultimate in safety. An increase in δ is accompanied by an increase in R_s .

To evaluate the battery failure rate, f_s , from the cell failure rate, we apply the chain rule of differentiation to the general expression equivalent to Eq. [4]. Accordingly

$$f_s(t) = \frac{-d \ln R_s}{dt} = - \frac{d \ln R_s}{dR_s} \frac{dR_s}{dR} \frac{dR}{dt} \quad [7]$$

Substituting the cell failure rate f into Eq. [7], we have

$$f_s(t) = \frac{R}{R_s} \frac{dR_s}{dR} f(t) \quad [8]$$

Performing the differentiation required by Eq. [8] on Eq. [6] provides the battery failure rate in terms of $f(t)$ as

$$f_s(t) = \frac{f(t)}{R_s} \sum_{x=m}^n \frac{n!}{x!(n-x)!} \{x[R(t)]^x [1 - R(t)]^{n-x} - (n-x)[R(t)]^{x+1} [1 - R(t)]^{n-x-1}\} \quad [9]$$

where $f(t)$ and R_s are given by Eq. [5] and [6], respectively.

Clearly, if the lognormal distribution holds and the Arrhenius law is obeyed the method developed herein should be useful in the extrapolation of temperature-accelerated data. However, it provides no guide in relating tests with accelerated charge/discharge rates to real-time results.

Long-term performance of Ni-Cd batteries.—In Fig. 8 and 9, we present the survival probability (Eq. [6]) and failure rate (Eq. [9]) of a Ni-Cd battery as a function of service life. Since in geosynchronous orbit the failure distribution for cells is bimodal, reflecting shorts as well as degradation, the calculations for a battery take into account both mechanisms. The respective standard deviations for shorts and degradation are rounded to 1.1 and 0.3, in accord with the values listed in Table III. For shorts, t_m is a parameter incremented in 100,000h steps between 300,000 and 800,000h, while it is postulated that t_m for degradation is an invariant fraction of that for shorts. Based on Table III, the ratio of t_m 's between shorts and degradation is ~ 2.4 . The assumption invoked implies that any improvement in eliminating shorts as a cause of failure will also lead to a proportionate reduction in degradation. One can observe in Fig. 8 and 9 that capacity degradation is of no concern above a median life of 400,000h.

If one wants to assure the probability of battery survival at no less than 90%, then from Fig. 8, employing the CRANE geosynchronous results ($t_m \approx 300,000$ h), we find the longest allowable service lives of 4.7 and 7.2 yr, respectively, for $m = 30/n = 32$ and 28/32 configurations. To be on the safe side, at 10 yr the 30/32 and 28/32 configurations require median lives of 650,000 and 425,000h, respectively. Clearly, a small increase in the degree of redundancy, δ , extends assured service life more effectively than a minor design-related improvement in t_m . Indeed,

Fig. 8. Probability of Ni-Cd battery survival as a function of service life and cell redundancy. The curves were calculated from Eq. [6]. Probability for both shorts and degradation are shown. Each one of the lines is labeled by the cell median life for shorts and degradation, where applicable; the cell standard deviation is 1.1 and 0.3 for shorts and degradation failures, respectively.

Fig. 9. Failure rate for Ni-Cd battery as a function of service life and cell redundancy. The curves were calculated from Eq. [9]. Failure rates for both shorts and degradation are shown. Each one of the lines is labeled by the cell median life for shorts and degradation, where applicable; the cell standard deviation is 1.1 and 0.3 for shorts and degradation failures, respectively.

the conventional cells tested at CRANE would be acceptable if a δ corresponding to 30/36 were permissible. To be sure, overall weight limitations on a spacecraft make this an unrealistic option for the present generation.

An examination of the battery failure rate reinforces the previous conclusions. Conservatively, we selected 5000 FIT's as the largest permissible failure rate.² This is not quite arbitrary for $f_s = 5000$ FIT's implies one battery failure per 20 yr of service, which seems safe, as it is at least twice the life expectancy of current communications satellites. The cells in the CRANE compilation guarantee battery failure rates in geosynchronous orbit below 5000

²This translates into a survival probability of slightly over 90%.

FIT's at service lives less than 3.6 and 6.2 hr for 30/32 and 28/32 configurations, respectively. Again, without excess redundancy (30/32), t_m of ~650,000h is necessary, while for a more redundant design (28/32), t_m ~450,000 would be sufficient at 10 yr of service. Of course, perhaps we have a low estimate for t_m , and its true population value may be near the upper limit given in Table III (~440,000h). Consequently, a battery service life over 6 yr could be assured in the standard (30/32) configuration. Nonetheless, one should not infer that Ni-Cd cells in the 30/32 mode do not perform satisfactorily at 10 yr of service because the state of the art in cell fabrication has advanced beyond the technology of the 1964-1977 period.

ABSTRACT

The characteristics of copper sulfide cathodes have been evaluated in typical organic electrolyte lithium batteries. The behavior of α -Cu₂S (chalcocite), Cu_{1.76}S (digenite), and CuS (covellite) is discussed in terms of mechanism of reaction, discharge properties, and energy content. In view of possible use in primary, voltage-compatible lithium batteries, Cu₂S shows the most interesting performance, both in terms of constancy of the operational voltage and in terms of discharge rates.

Within a research program on the relationship between electrochemical behavior and structure of solid materials which can be used as cathodes in primary and secondary lithium organic electrolyte batteries (1-5), the following copper sulfides have been studied in this work: α -Cu₂S (chalcocite), Cu_{1.76}S (digenite), and CuS (covellite).

The behavior of these materials has been examined by determining the mechanism of the electrochemical reaction, the discharge properties, and the energy content.

Experimental

The copper sulfides have been synthesized from the elements using powdered Cu and S (reagent grade chemicals, dried under vacuum prior to use).

Chalcocite, α -Cu₂S, has been prepared in a two-compartment glass envelope. The two starting elements, *e.g.*, Cu and S, were separately placed in each compartment. After sealing under vacuum, the envelope was heated,

*Electrochemical Society Active Member.

maintaining the Cu compartment at 475°C and the S compartment at 350°C, respectively. After annealing for two days, the envelope was cooled still keeping a temperature gradient between the two compartments.

Digenite, Cu_{1.76}S, has been prepared by heating in air a compressed pellet of a Cu-S mixture (with a slight excess of S). Covellite, CuS, has been obtained by annealing a stoichiometric amount of Cu and S in an evacuated glass ampul for six days at 480°C.

The structure of the final compound was in all cases controlled and characterized by x-ray analysis.

The solvents used, *e.g.*, propylene carbonate (PC) and γ -butyrolactone (BL), pure commercial products, were further purified by fractional distillation. All the lithium salts, *e.g.*, LiClO₄, LiAsF₆, and LiCF₃SO₃ were reagent grade chemicals.

Typical two electrode, button-type laboratory cells were used for the discharge tests. The structure of these cells has been described previously (2, 4, 5).

Fig. 2. X-ray spectra of the Cu₂S cathodic material before (a) and after (b) discharge in a lithium organic electrolyte cell (CuKα).

Fig. 3. X-ray spectra of the Cu_{1.76}S cathodic material before discharge (a), after 0.25 F/mol discharge (b), and at the end of the discharge (c) in a lithium organic electrolyte cell (CuKα).

The discharge curves and cell characteristics were controlled and analyzed by a computer system on line with the potentiostat.

Results and Discussion

Typical 0.5 mA/cm² constant current discharge curves of lithium organic electrolyte cells using the three copper sulfide cathodes are shown in Fig. 1.

The reduction of Cu₂S is a single process consuming 2F/mol of sulfide. After the complete discharge, the cathodic mass was analyzed by x-rays.

The spectrum, reported in Fig. 2b, revealed only the presence of metallic copper and of lithium sulfide. Comparison with the spectrum of the starting Cu₂S, shown in Fig. 2a, indicates that the electrochemical reaction had proceeded to completion.

The discharge reaction of the Li/Cu₂S cell may then be safely identified as

The formation of copper during discharge is a favorable event. The metal gives the cathodic mass sufficient elec-

CuS

Fig. 4. X-ray spectra of the CuS cathodic material before discharge (a), after 0.4 F/mol discharge (b), and at the end of the discharge (c), in a lithium organic electrolyte cell (CuK α).

Fig. 5. Typical discharge curves at 0.5 mA/cm² of the Li/Cu_{1.76}S couple in various electrolytes.

tronic conductivity to be used without additives (such as graphite), and this is beneficial in terms of overall energy density. Furthermore, the exceptionally flat discharge curve shown in Fig. 1 is a direct result of the production

of finely dispersed copper which keeps the resistance of the cathodic mass low throughout cell life.

Digenite, Cu_{1.76}S, shows a more complex, two-stage discharge process. The first starting at 2.1V (vs. Li) and

Fig. 6. Typical discharge curves at 0.5 mA/cm² of the Li/Cu₂S couple in various electrolytes.

about 0.25 F/mol deep, and the second starting at 1.6V (*vs.* Li) and up to about 1.8 F/mol (see Fig. 1). In an attempt to clarify the discharge mechanism, x-ray analyses were done on cathodic masses after a discharge of 0.25 F/mol and at the end of the discharge (Fig. 3). In the first case, a very complex spectrum was found in which all the reflections of the starting material ($\text{Cu}_{1.76}\text{S}$) had disappeared, indicating that radical structure modifications had followed the first reduction step. In contrast, at the end of the discharge, the spectrum was well defined and showed only the reflections of Cu and of Li_2S . Since digenite may be considered a solid solution of 20% CuS and 80% Cu_2S , the discharge data shown in Fig. 1 and the x-ray analysis suggest that the first stage of discharge was due to the reduction of the CuS fraction via the reaction

and the second was due to the reduction of the residual Cu_2S fraction via the reaction

Several experimental results confirm this hypothesis. They are: (i) Some reflections of Cu_2S could be identified in the complex x-ray spectrum after the first plateau (see Fig. 2). (ii) The coulombic ratio between the first plateau (0.25 F/mol) and the second plateau (1.55 F/mol) approaches the ratio between CuS (20%) and Cu_2S (80%) in the $\text{Cu}_{1.76}\text{S}$ compound (see Fig. 1). (iii) The second discharge plateau of the Li/ $\text{Cu}_{1.76}\text{S}$ cell approaches that of the Li/ Cu_2S cell (see Fig. 1).

As in the case of digenite, the discharge of covellite, CuS, also seems to follow a two-step route, with a first plateau around 2V (*vs.* Li) extending for 0.4 F/mol and a second at about 1.1V (*vs.* Li) extending for 0.9 F/mol. X-ray analyses at various discharge depths are shown in Fig. 4. At 0.4 F/mol, reflections of CuS, Cu_2S , and Li_2S are present while no reflections of Cu are observed (Fig. 4b). After complete discharge (0.9 F/mol), reflections of Cu, Li_2S , residual CuS, and several others including $\text{Cu}_{1.96}\text{S}$ and Cu_2S , could be identified (Fig. 4c). The mechanism of reduction is then very complex, as has been pointed out by Dampier (6) and by Gabano *et al.* (7), who originally investigated the characteristics of the Li/CuS couple in organic electrolyte cells.

The complexity of the discharge mechanism and the poor coulombic efficiency (see Fig. 1) suggest that CuS is not a very promising cathode material for lithium batteries. From this point of view, $\text{Cu}_{1.76}\text{S}$ and particularly

Table I. Characteristics of Li/ $\text{Cu}_{1.76}\text{S}$ and of Li/ Cu_2S , organic electrolyte batteries at room temperature

Current density (mA/cm ²)	Average voltage (V)	Depth of discharge (F/mol)	Specific capacity (Ah/kg)	Specific energy (Wh/kg)
$\text{Li}/\text{Cu}_{1.76}\text{S}$				
0.1	1.64	1.8	333	548
0.3	1.62	1.75	315	510
0.5	1.58	1.75	311	494
1.0	1.52	1.3	229	349
$\text{Li}/\text{Cu}_2\text{S}$				
0.1	1.62	1.9	313	508
0.3	1.61	1.9	309	497
0.5	1.57	1.8	295	462
1.0	1.54	1.7	280	431
2.0	1.49	1.4	220	327
4.0	1.42	1.1	189	268

Cu_2S show much more interesting performance. Therefore, this study has been concentrated on these two sulfides.

The influence of the electrolyte on the discharge characteristics of Li/ $\text{Cu}_{1.76}\text{S}$ and of Li/ Cu_2S cells is shown in Fig. 5 and 6, respectively, where discharge curves at 0.5 mA/cm² are compared in various electrolytes. For the Li/ $\text{Cu}_{1.76}\text{S}$ system, there are some differences between electrolytes with the LiAsF₆-BL electrolyte appearing to be the most efficient (Fig. 5). For the Li/ Cu_2S cell, all the electrolytes tested behaved satisfactorily (Fig. 6). Note the exceptional flatness of the discharge curves for the Li/ Cu_2S system at an operational voltage of about 1.5V.

The superior behavior of the Li/ Cu_2S cell is also confirmed by the results of Fig. 7 which illustrates the discharge behavior at various rates: the discharge curves remain flat even at very high current densities.

The discharge characteristics of the two copper sulfide cathodes examined in this study are summarized in Table I.

The values of the operational voltages and of the energy densities make these sulfides, and Cu_2S in particular, very promising cathodic materials for voltage compatible ambient temperature lithium batteries.

Finally, the reversibility of the electrochemical reaction in the Li/ Cu_2S system has been investigated in view of possible applications as a rechargeable system. Cu_2S discharged down to 1.5 F/mol at 0.5 mA/cm², can indeed recover more than 90% of the capacity during the first recharge at the same current density. However, the x-ray

Fig. 7. Typical discharge curves of the Li/LiClO₄-PC/ Cu_2S battery at various rates and at room temperature.

analysis, run at various stages of the recharge process, showed a progressive attenuation of the Cu and Li_2S reflections, followed by the formation of a complex mixture of sulfides (e.g., $\text{Cu}_{1.96}\text{S}$, Cu_2S , $\text{Cu}_{1.8}\text{S}$, CuS).

The rather complicated oxidation mechanism for the $\text{Li}/\text{Cu}_2\text{S}$ system excludes any immediate application of this system in secondary lithium batteries.

Electron Microscopy Study of Formation of Thick Oxide Films on Ir and Ru Electrodes

V. Birss,^{*,1} R. Myers, H. Angerstein-Kozłowska, and B. E. Conway*

Department of Chemistry, University of Ottawa, Ottawa K1N 9B4, Ontario, Canada

ABSTRACT

The thick (5-60 μm) oxide films that can be formed electrochemically at Ir and Ru electrodes are examined by scanning and transmission electron microscopy. Their morphologies are discussed in relation to the remarkable reversibility of redox processes associated with the thick films and the enhancement of apparent electrocatalytic effectiveness of the oxide films, which is found for anodic Cl_2 and O_2 evolution processes to increasing extents with growth of the oxide film. The latter effects are much larger at Ir than at Ru. This difference is likely to be associated with the different morphologies of electrochemically grown oxide films that are observable on these two metals. In the case of Ir, the apparent enhancement of electrocatalysis for anodic Cl_2 or O_2 evolution seems to be associated with development of a hyperextended, microporous, hydrous oxide film that is accessible to H_2O and Cl^- ions. Comparisons are made with thermally formed oxide films generated by decomposition of RuCl_3 coatings.

The formation of oxide films on noble metals has been the subject of a large number of papers on account of the interest of this topic for (i) electrocatalysis of organic molecule oxidations (1-3), anodic Cl_2 evolution (4-6), and O_2 reduction (7), and (ii) as a model-type system for studying the transition from monolayer oxide film formation to development of multilayer oxide phases (8-10) on metals. The states of thick oxide films on Ir and Ru, where the oxides are principally IrO_2 and RuO_2 , respectively, are of particular interest in relation to electrocatalysis for Cl_2 evolution as treated in previous papers from this and other laboratories.

Much of the earlier work was concerned with the mechanisms and characteristics of formation of monolayer films of OH and O species on Pt and Au, and the resolution of the reversible from the irreversible stages of the oxide film formation processes at the submonolayer level of coverage. [For review, see Ref. (3).]

The growth law for potentiostatic oxide film extension at Pt was established by Gilroy and Conway (11) as the direct logarithmic one in time, even at submonolayer levels of surface oxide formation, and a possible mechanism for this behavior was treated by Gilroy (12). Applications of the Mott-Cabrera "high field" growth mechanism (13), which applies to development of thicker insulating dielectric films, were made by Ord and Ho (8), by Damjanović *et al.* (9, 10), and in related ways by Vetter and Schultze (14).

The first indication that the oxide film formation and growth process at Ir is different from that at Pt or Au was

given in the work of Stonehart *et al.* (15), who showed that surface oxide formation and reduction at Ir behaves as a reversible process which can also be observed as optically (16) reversible. Subsequently, a number of papers appeared characterizing this "reversible" type of oxide film behavior; in particular, Gottesfeld *et al.* (17) showed that the reversible behavior is not associated with metal oxidation and reduction of oxide back to the metal, but rather the oxide remains on the surface throughout a cyclic variation of potential between 0.0 and 1.4 E_{H} , but a redox process takes place within the film. The transition between true OH/O monolayer formation and reduction at Ir and development of thicker films was recently studied by Mozota and Conway (18).

Following the work on Ir (15, 18, 19, 20), similar behavior was found at Ru by Hadži-Jordanov *et al.* (21) in this laboratory and by Rand *et al.* (22), and the transition from monolayer oxide formation and reduction to reversible redox behavior at oxide films formed at Ru either thermally or by potential cycling was demonstrated in the work of Hadži-Jordanov *et al.* (21). Since that time, Burke (23) has shown that similar behavior can be generated at several other metals, even Rh and Pt, by a potential cycling regime.

By extensive cycling at Ir and Ru, optically and electron optically visible oxide films can be generated and their morphologies examined and related to their electrochemical behavior, e.g., electrocatalysis for Cl_2 (24) or O_2 (25, 26) evolution reactions. This paper reports scanning electron microscopy studies on such oxide films. Elsewhere (30), we report XPS results on the electronic states of Ir and O in electrochemically formed oxide films at Ir.

^{*}Electrochemical Society Active Member.

¹Present address: Department of Chemistry, University of Calgary, Calgary, Alberta, Canada.

Experimental

Electrodes.—High purity-grade (Materials Research and Engelhard) Ir rod or wires were employed as the Ir electrode materials. The 4 mm diam rod was cut into 0.5 mm thick circular sections and spot-welded to an Ir wire that was presealed into a soft-glass tube as electrode holder. Ir wire electrodes were spot-welded to a very short length of fine Pt wires presealed into glass tubes. The purpose of this procedure is to avoid preoxidation of Ir, which can occur under flame treatment. Zone-refined Ru rods were also obtained from Materials Research Company, cut, and similarly mounted or directly sealed into glass tubes. Ru wire was not obtainable.

Solutions.—1.0 or 0.5M aqueous H_2SO_4 solutions used in the work were prepared from Cl⁻-free BDH Aristar grade sulfuric acid; in our experience, this is the best grade of this acid available from the point of view of purity. Pyrodistilled water (27) was used for preparation of all solutions, and high purity techniques were employed in all the electrochemical experiments, as reported elsewhere (18, 24, 27).

Types of experiments.—Oxide films were generated on Ru and Ir electrodes by a potential-cycling regime [cf. Ref. (18-21)] using an anodic potential limit of at least +1.4V and a cathodic limit of +0.05V E_H . Potentials were referred to that of an H_2 reversible electrode in the same solution (scale designated " E_H , V"), but in a separate compartment of a three-compartment cell. The potential cycling regime was established by means of a cyclic voltammetry setup employing a Wenking potentiostat and a function generator in the usual way. The counterelectrodes were always made of the same metal, Ru or Ir, as that used as the respective test electrode in order to avoid contamination by a foreign metal, e.g., from a Pt counter-electrode by dissolution [cf. Ref. (28)].

In some experiments, potentiostatic oxide film formation was investigated. As found previously (15), the oxide film on Ir cannot be grown in time by holding the potential constant at an appropriate value, 1.4 ~ 1.6V E_H ; only under a cyclic-potential program does it grow. However, the oxide film at Ru can be grown either by the cycling regime or under constant potential conditions, viz., at > 1.45V, E_H , with the growth rate increasing with higher anodic potentials.

During the course of the growth of the film on Ir, the now well-known electrochromic effect (29) is observed, provided the extent of oxide film thickening is not too great (18), when the film becomes black at all potentials. Ru also showed some electrochromic effect in alkaline solution, but this is less marked than that at Ir.

During the oxide film-formation process, either at Ir or Ru, some dissolution of the metals occurs giving brownish solutions after prolonged cycling. The dissolution (at Ru) is greater under cycling conditions [cf. Ref. (28)] than under steady anodic polarization.

In another set of experiments, growth of the oxide was carried out at Ru under constant current conditions or under the influence of a program in which the current was increased from 0.1 to 5 mA cm^{-2} over 4h. The extent of growth of the oxide film under constant current conditions for 4 ~ 5h was found to be equivalent to that under potential cycling (0.05 to 1.45V, E_H) over a period of 3 ~ 4 days. Of course, in a potential cycling regime, the fraction of time spent in each half-cycle over the potential range where oxide growth rate is significant, will only be ca. 20%. Under controlled current conditions, however, O_2 gas is evolved so that the film growth partial current is a small fraction of the overall current passing. If O_2 , rather than Cl_2 [cf. Ref. (24)], is evolved at oxidized Ir electrodes, the oxide film suffers mechanical degradation. This does not occur when Cl_2 is evolved.

Scanning electron and optical microscopy.—A "Semco" Nanolab 7 scanning electron microscope was employed to study the morphology of the oxide films up to high magnifications using a LaB₆ filament. Photomicrographs

were taken at various tilt angles which illustrated three-dimensional aspects of morphologies. The oxides of Ir or Ru generated in these experiments did not require coating by C or Au as they were already quite conducting.

Optical microscopy observations were also made using a Nomarski interference microscope.

X-ray emission analyses.—The SEM was fitted with Microspec wavelength and KeveX energy dispersive x-ray analyzer systems, which enabled elemental compositions of materials to be monitored during SEM.

O:Ru and O:Ir ratios were evaluated using the x-ray spectrometers attached to the SEM. The oxygen:metal ratios were determined on various samples of oxidized Ru or Ir by reference to thermally formed bulk standard materials (RuO_2 and IrO_2). The Ru count rate was determined on the electrochemically formed oxide film at Ru and compared with that from the RuO_2 standard. Similar measurements were made on oxidized Ir electrodes.

Morphology and electrochemical history.—Photomicrographs were taken on oxide films grown to various thicknesses. Each sample was characterized by a cyclic voltammogram taken just before the electrode was transferred, after a brief wash in pyrodistilled water, to the SEM chamber. With some electrodes, a cyclic voltammogram was taken also immediately after the electron microscopy to check if any irreversible changes had occurred on account of the electron microscopy observations, e.g., due to vacuum drying or electron-beam reduction. The cyclic voltammograms for Ru were hardly changed after exposure of the oxide films in the SEM.

The optical microscopy was done on electrodes transferred in the wet state to the microscope stage so that artifact structures that could result from drying at an elevated temperature were avoided.

Several micrographs were made by transmission electron microscopy (TEM) after making replicas by means of collodion treatment. This procedure gave highest levels of magnification up to 25 nm per cm of the printed photographs. In the TEM instrument, electron diffraction characterization of the actual object material could also be made.

"Electrochemical" film thickness.—By means of the cyclic voltammetry measurements, the electrochemically determined apparent film thickness of the oxide films was determined in terms of the ratio, CEF, of the charge under the cyclic voltammogram, $i dt = i/s \cdot dV$, for a sweep-rate $s = dV/dt$, for a given oxide film to that for initial true monolayer² formation or reduction (18). This ratio was termed the "charge enhancement factor" (CEF) in previous publications (18, 24).

Results and Discussion

Electrochemical characterization of oxide films at Ir and Ru.—Typical cyclic voltammograms showing the transition from monolayer to multilayer oxide film formation at Ir and Ru are shown in Fig. 1 and 2, and illustrate the major difference between the behavior of the two-dimensional surface monolayer processes, which are irreversible, and the reversible behavior of the multilayer films having CEF values up to several hundred (18). The variation in the shapes of the cyclic voltammograms with potential for oxide films formed at Ir (Fig. 1) is principally due to the change of conductivity (31) of the oxide film at Ir as it is reduced from IrO_2 to Ir_2O_3 (29) at potentials < ca. 0.65V E_H . In the case of the ruthenium oxide film (Fig. 2), good conductivity is retained throughout the potential range 0.05-1.4V E_H , i.e., down to the H_2 re-

²Care must be exercised at Ir or Ru in the evaluation of the true oxide monolayer formation and reduction cyclic voltammogram (18); thus, it is easy for multilayer oxide formation to begin unless the potential limits of the cyclic voltammogram are carefully controlled and appropriately limited (18). Such effects are seen in some previously published work (30) where monolayer behavior was referred to, but, in fact, the currents correspond to some multilayer redox component processes.

Fig. 1. Cyclic voltammograms for Ir electrode at 295 K showing transition from monolayer oxide film formation and reduction to development of multilayer oxide films with reversible oxidation-reduction region after cycling.

Fig. 2. Cyclic voltammograms for Ru electrode showing monolayer to multilayer oxide film transition, as with Ir shown in Fig. 1

versible potential in the "reduced" state as well as in the oxidized state.

The thicknesses of oxide films estimated from CEF values (based on 0.3 nm per layer, corresponding to passage of charge of $220 \mu\text{C cm}^{-2}$) are substantially smaller than are indicated from the dimensions of edges of cracked films that are observed in SEM pictures (see below). A comparison of normalized currents at a given potential ($0.8V E_H$) in the cyclic voltammograms for Ru and Ir during the growth under cycling conditions, with the film thicknesses observed in the SEM, is shown in Fig. 3. These lines give an approximate idea of the relationship between the effective "electrochemical" thickness of the films and the apparent (*i.e.*, allowing for porosity in the structures) geometrical thickness. The discrepancy is by a factor of *ca.* 10 or more for Ir oxide films and 50-100 for Ru oxide films grown electrochemically. These discrepancy factors may be due to (i) microporosity in the hydrous oxide films, and/or (ii) limited electrochemical accessibility of the material inside the films, or (iii) to electrochemical redox activity being restricted only to the surfaces of pores; that is, the charging/discharging processes observed in cyclic-voltammetry experiments may arise quasi-two-dimensionally at the surface of a hyperextended microporous structure.

Optical interference microscopy observations.—The first microscopic observations of the oxide film on cycled Ru electrodes were made by means of a Nomarski optical interference microscope, with the electrodes still in a wet or damp state. Two photographs of the oxide film developed after *ca.* 200 cycles of potential change from 0.05 to 1.4V E_H are shown in Fig. 4a. This photo

Fig. 3. Relation of normalized currents at 0.8V E_H for Ru and 1.0V for Ir in cyclic voltammograms taken during the oxide film growth during cycling, to film thickness determined by SEM observations. (Normalized currents are approximately proportional to CEF's.) Conditions: 0.5M H_2SO_4 , 298 K, cycling between 0.0 and 1.5V E_H , at 0.1 V s^{-1} .

Fig. 4. Nomarski optical microscope photos of the hard shell layer that develops on Ru electrodes as they are oxidized in a potential cycling program. Original photos are Kodachrome showing interference contrast colors of various regions of the surface. a (top left): initial stage of film formation, *ca.* 50 nm. b (top right), c (bottom left), and d (bottom right): thicker films peeling off electrode, *ca.* 5 μm .

shows that the oxidized Ru electrode has a smooth shiny outer surface layer, but the underlying thick film formation cannot be observed in the SEM (see below). After thick film formation has occurred, this smooth outer layer seems to overlay some looser oxide material underneath it (Fig. 4b). The smooth outer layer is extremely hard, as was indicated by its resistance to attempts to probe into it with a steel needle. However, by means of the needle or a scalpel, flakes of this hard oxide layer can be separated off from the underlying bulk Ru oxide or the metal, revealing a looser material beneath. At Ir, such a layer is not observed.

An interesting aspect of the development of the oxide films on Ru is that if the original metal surface is scratched, or otherwise retains some polishing lines, the scratch marks are retained on the outside of the electrochemically grown oxide film. The outer surface of the oxide film, referred to above, has an appearance shown in Fig. 4a and 4b. The retention of the scratch marks indicates that the oxide film grows by migration of OH or O ions into the film rather than the reverse process of metal ion formation and migration outwards (*cf.*, the radioisotope marking procedure of Davies (32) for studying O or metal ion migration processes in oxide-film formation at base metals) coupled with provision of OH⁻ or O²⁻ species from H₂O at the oxide/solution interface.

More detailed indications of the structure of the oxide films at Ru and Ir are given by the electron microscopic observations to be described next.

Scanning electron microscopy observations.—In this section, we shall describe, first, the general morphology of the oxide films at Ru and Ir as seen with the SEM and then refer more specifically to certain aspects of the morphology of the oxide films, *e.g.*, the presence of columnar structures and the identification of rather small scale porosity.

General morphological features.—The appearance in the SEM of the hard outer layer material, referred to above, is shown in Fig. 5. The persistence of the original scratch marks on the metal, now on the outer surface of

Fig. 5. SEM photos of the hard outer shell layer at an electrochemically oxidized Ru electrode (cf. Fig. 4a and 4b). Note retention of scratch marks.

the oxide film, is seen again. At higher magnification, the general appearance of the film is shown in Fig. 6, where the scratch marks are again clearly seen on the outside of the film. Figure 6 shows the structure of the film at a still higher magnification ("4.0 μm " scale) looking into its edge.

Figure 8 shows a region where some oxide has broken away, exposing an underlying oxide or the substrate Ru metal itself. (Compare the optical photomicrographs in section 2, Fig. 4a and 4b). The CEF values for the oxide films shown in the above figures are ca. 400. The depth of the depression in Fig. 8 is ca. 6 μm , indicating an oxide thickness of at least this magnitude. The CEF was 400 which would correspond only to an "electrochemical thickness" of ca. 0.12 μm . This verifies the deduction that the electrochemical charge associated with a change of oxidation state of the film in cyclic voltammetry experiments corresponds to only a small fraction of the oxide film material actually generated by the potential cycling procedure. Alternatively, the film is highly porous or the reversible electrochemical activity originates only at the outer regions of a porous structure.

The oxidation behavior of Ir appears to be significantly different from that of Ru in the following ways. Although a thick oxide film can also be formed, as at Ru, it is only generated by potential cycling, not under constant potential or constant current conditions where

Fig. 6. General appearance of the oxide film at a Ru electrode at higher magnification than that of Fig. 5. Note retention of scratch marks.

Fig. 7. SEM photo of the oxide film at Ru at high magnification showing edge of a fractured region.

Fig. 8. SEM photo of the oxide layer at Ru showing a region where the film has broken away exposing underlying material.

Ru will form a thick oxide film. Also, very little dissolution of Ir is detectable, even after several hundred growth cycles; hence Ir oxide film growth is not connected with a dissolution redeposition cycle. This is demonstrated by the independence of growth rate upon electrode rotation (Fig. 9) (0 or 4000 rpm) using an Ir rotating disk electrode. At Ru, by contrast, appreciable metal dissolution takes place during the oxide forming process, as can be seen visually from the gradual coloration of the solutions which became brown.

Figures 10a, 10b, and 10c show the structure of an electrochemically formed oxide film at Ir with a CEF of 180. Again, the thicknesses of the films are substantially greater than corresponds to the CEF value. A cracked structure, similar to dried-out mud, is seen, and, although the oxide film appears to be peeling off in some photos, it was found that electrochemically oxidized Ir electrodes are mechanically stable to Cl_2 evolution for extended periods of time at 100 mA cm^{-2} . Thus, a given electrode does not suffer diminution of CEF by this treatment, though the stability to O_2 evolution is not as good as to Cl_2 evolution.

The "tubular" pore structures found at oxidized Ru (Fig. 11 below) are not observed at Ir although the apparent electrocatalytic behavior (24) for Cl_2 evolution does suggest the presence of a microporous, hyperextended large area structure.

Specific morphological features.—Under certain conditions and/or at high magnifications, several special fea-

Fig. 9. Independence of anodic currents in cyclic voltammograms for oxidation processes at Ir electrode on electrode rotation rate. CEF's are independent of rotation rate. (Outer lines show breadth of errors; differences at various rotation rates are less than these errors.)

tures of the structure of the oxide films formed on Ru can be observed.

First, Fig. 11 shows the remarkable columnar structure that is seen in a fracture section across the oxide film grown at a fast cycling rate (1 V s^{-1}) to a CEF of ca. 200. The photo in Fig. 12 shows this columnar structure at a higher magnification together with top ends of the parallel columns. The orientations of the columnar structures seem to depend on the grain orientation of the original metal or else specific orientations of grains of oxide are developed during the oxide growth, as shown in Fig. 13. As will be discussed later, these columnar structures may result from anodic etching with concurrent oxide film formation at the etched regions, *i.e.*, involving a nonpassivating oxide layer.

An oxide film that has been formed at a Ru electrode by constant-current oxidation or by a programmed change of current (Fig. 14), in both cases with concomitant O_2 evolution, does not show the columnar structures illustrated above. The structure is more amorphous and is associated with a higher O:Ru ratio, determined in the x-ray spectrometry experiments, than is found at the cycled material. However, these experiments always gave substantially lower O:Ru ratios than correspond to the nominal stoichiometric composition " RuO_2 " taken for a thermally prepared RuO_2 specimen as standard. At electrochemically oxidized Ir, the corresponding O:Ir ratios were larger and closer to the expected " IrO_2 " stoichiometry for an IrO_2 standard.

Pore structures.—Attempts were made at high SEM magnifications to detect a pore structure that might account for the large oxidation/reduction charge associated with the electrochemical behavior of oxide films developed on Ir and Ru to appreciable thicknesses (CEF values of 200-500). The columnar structures developed at Ru under certain conditions (*cf.*, Fig. 11, 12, and 13) indicate the possibility of extended pores down or between the columns. However, direct high magnification observations in the SEM were unable to distinguish fine-scale roughness from possible entrances to pores in the surface, *e.g.*, in Fig. 6. Because of this problem, several observations were made at very high magnifications by means of TEM which are described below.

Fig. 10. SEM photos of the structure of electrochemically formed thick oxide films at an Ir electrode. (Note cracked structures not seen at Ru, and absence of outer shell layer.)

Morphologies of other deposits.—Comparison with oxide films formed in other ways is of some interest. Figure 15a shows the morphology of an RuO_2 oxide film formed thermally from a RuCl_3 -coated electrode (Ti substrate, as with a DSA-type electrode). Figure 15b shows an oxide film developed by the cycling procedure from Ru electroplated on Au. Compared with features developed in the oxidation of bulk Ru, the oxide structure seems to be influenced mainly by the morphology of the electroplated Ru metal substrate.

Transmission electron microscopy.—During the SEM studies of the oxide films formed at Ru by potential cy-

cling, it had been noticed that columnar structures develop in the latter material (see Fig. 5 and 11-13). It was possible to replicate the oxide surface with Formvar and, in so doing, to include some fragments of the oxide layer formed at Ru by the cycling procedure in the Formvar replica. These replicas were then examined by transmission electron microscopy. (Fig. 16a and 16b).

Figure 16a shows a TEM photograph of such a replica of the surface of the columnar film on Ru. At these high magnifications (scale of original photo 60 nm per cm), the oxide material is seen to be made up of remarkable parallel cylindrical bodies ca. 30 nm in diameter. Some are seen to have become separated and apparently bent around on top of other material. Details at a level of res-

olution of < 5 nm can be detected in this photo. An SEM picture of the actual replica of the columnar material is shown in Fig. 16c.

Since the TEM photo shows the image of a replica, it is to be noted that the apparent topology is a negative of that of the actual sample fragment.³

The small pieces of oxide which were extracted into the replica from this region appear as the very dark areas of the TEM photograph in Fig. 16a at the lower right. The fact that the tiny oxide fragments exhibit the same columnar structure as in the replica material (*cf.* Fig. 16a) confirms the interpretation of the photomicrographs that highly oriented pores are an intrinsic part of the oxide structure. It should also be noted that the outer walls of the pores in the oxide pieces align well with the observed column edges on the remainder of the replica, demonstrating the accuracy of the replication procedure and the homogeneity of the structure. Figure 16a shows also that the channels or pores of this oxide region are of approximately 10-15 nm diam. Figure 16b is another TEM photo of a different replica of the oxidized Ru surface taken from an area where the outer layer of the oxide was still completely intact (*cf.* Fig. 4a, 4b, and 5), so that this photo shows the actual outer surface of the oxide. This photo shows many circular features having a diameter of *ca.* 10 nm. It is possible that these features are the exposed ends of some of the pores in the oxide film. The background has a fine structure on the order of 1 nm in dimensions, probably due to carbon coating the replicas.

³It is also to be noted that Formvar replicas of a smooth substrate surface are themselves entirely structureless, so the columnar features in Fig. 16a are not artifacts of the replication procedure. In any case, the columnar structures are seen directly under the SEM (Fig. 11-13).

An SEM photo of the oxide fragment shown in Fig. 16a is reproduced in Fig. 16c. Once again, the columnar structure is clearly seen.

In the case of Ir oxide films, these columnar structures could not be detected, and the fine structure at high magnifications seems generally like that of an amorphous material. Presumably, the apparent high area indicated by the proportionality of electrocatalytic activity for anodic Cl_2 evolution (24) to film thickness (CEF) is associated with a highly microporous structure with dimensions below those resolvable in the SEM. We refer to this as a hyperextended material.

Comparison of oxide films at Ir and Ru.—These results lend credence to the view that the high capacity for acceptance of electrochemical charge exhibited by the hydrous oxide type of materials that can be generated on Ir, Ru, and other metals [*cf.* Burke (23)] is connected with a high area pore structure which provides access for electrolyte ions and passages or chemical water channels for migration of the protons required in the oxide redox processes; these are of a remarkably reversible kind.

From an electrochemical point of view, the striking feature (18, 19, 21) of these anodically formed thick oxide films is that they exhibit a charge *vs.* potential relationship of the same kind as that of an electrochemical two-dimensional surface process, *e.g.*, submonolayer surface oxidation of Pt or underpotential deposition of metal monolayers on Au, and yet the material is demonstrably present in bulk form. In particular, for any given fractional degree of oxidation or reduction of the material, there is a corresponding reversible potential, as with an electrosorption isotherm (33) or with a three-dimensional redox system, as in the case of a redox titra-

tion. For a normal bulk phase oxide, on the contrary, there is: (i) an almost unique (theoretically, actually unique) single-valued potential for the formation or reduction of the oxide, and (ii) in a cyclic voltammetry experiment, the current *vs.* potential profiles in anodic and cathodic directions are never mirror images of each other, but correspond to processes requiring an overpotential in either direction for significant currents to pass; hence, the anodic and cathodic *i vs. V* profiles are completely asymmetric with respect to one another for other solid bulk phase materials.

While the electrochemical behavior of Ir and Ru is in some ways similar with respect to the development of thick oxide films upon potential cycling which exhibit reversible redox behavior over a wide range of potentials (wider at Ru than at Ir due to loss of conductivity (18, 31) in Ir oxide films below ca. 0.65V E_H , associated with reduction to a lower valence state of the Ir ions), the present work demonstrates important structural and some significant chemical differences in the films.

The principal structure difference is the development of the columnar features in the case of oxidized Ru and the retention of a hard surface on the exterior of the electrochemically generated oxide films at Ru. At Ir, neither of these features is observed and the oxide appears structurally more homogeneous (amorphous) apart from "mud cracks." Also, with Ir, no hard outer surface is retained. It may be suggested that the structures developed at Ru are the result of anodic etching accompanied by formation of a thin layer of oxide on the structures resulting from etching. This would be consistent with the appearance of substantial quantities of dissolved Ru species in solution during the film formation process under cycling or dc polarization conditions. An oxidized etched structure would also be consistent with the low O:Ru ratios found in comparison with the higher O:Ir ratios found at Ir, where the oxide film structure is visibly different. Thus, at Ru, the x-ray signals may originate relatively more from unoxidized metal contained in the film than is the case at Ir. However, the electrochemically accessible surface at the Ru material is certainly in an oxidized state, as indicated by the "reversible" cyclic voltammogram and the associated increase of CEF with cycling (Fig. 2), as well as by the difference of the features of the cyclic voltammogram compared with that for monolayer oxide formation and reduction [see Ref. (21)]

Other electrochemical differences in the properties of the films at Ru and Ir can be summarized as follows: (i) failure of oxide films to grow at Ir under dc potentiostatic conditions while they do grow at Ru under constant current or constant potential polarization, as well as by cycling; (ii) progressive increase of anodic Cl_2 or O_2 currents with oxide film thickness (CEF) at Ir but noticeably less at Ru electrodes, and (iii) dissolution of soluble species during oxide film formation at Ru but not significantly at Ir. Also, the change of conductivity of oxide films at Ir with potential (18, 31), referred to earlier, is to be noted.

The thick oxide film at Ir seems to be developed as a hyperextended hydrous oxide layer in which redox processes involving the Ir itself can proceed reversibly⁴ and in which, through a microporous structure, other faradaic reactions, such as oxidation of Cl^- , can also occur at currents proportional to CEF (24) and hence probably to real electrochemically accessible area. However, at Ru, while similar redox processes involving some ionic states (Ru II, Ru III, Ru IV) of Ru itself can evidently take place reversibly, the body of the film structure remains inaccessible for other faradaic reactions, such as Cl_2 evolution. This, we suggest, may be due to the presence of the impervious outer layer of oxide which is seen to exist at Ru but not at Ir electrodes.

⁴Very recently, photos of thick films that can also be formed on Pt (34) have been published (35). However, the films do not show reversible redox behavior like that at Ru or Ir.

Acknowledgments

We are grateful to Mr. Dwight Craig for perceptive discussions throughout the conduct of this work. Grateful acknowledgment is also made to Continental Group, Incorporated for support of this work and for provision of an electron microscope and associated x-ray spectrometry facilities at the University of Ottawa. We are also indebted to Mr. M. Shevalier for the SEM measurements of film thicknesses on Ir at various CEF's.

Carbon Dioxide Reduction at a Metal Phthalocyanine Catalyzed Carbon Electrode

S. Kapusta* and N. Hackerman**

Department of Chemistry, Rice University, Houston, Texas 77251

ABSTRACT

Metal phthalocyanines (metal = Co, Ni) deposited on carbon electrodes have been found to catalyze the electroreduction of carbon dioxide to formic acid in acid solutions ($pH = 3-7$). The overpotential for CO_2 reduction on cobalt phthalocyanine is approximately 200 mV lower than on the best metal cathodes at currents up to 10 mA/cm^2 . The main reaction product in long-term electrolysis is the formate ion at $pH > 5$. Methanol is also produced at lower pH values. The phthalocyanine becomes inactive in the less acid solutions once a fairly negative potential is imposed, probably due to an irreversible reduction of the catalyst.

Even though the activity of metal phthalocyanines towards the reduction of oxygen in aqueous solutions has been extensively studied [(1-3) and references therein], their use as electrocatalysts for the reduction of carbon dioxide has attracted much less attention. The only results available (4, 5), corresponding to cobalt and nickel phthalocyanines adsorbed on amalgamated platinum electrodes, show a single reduction step preceded by the formation of a CO_2 complex. The activity of the electrode decreases sharply once a fairly negative potential is reached. These results prompted us to repeat these experiments in order to obtain a better understanding of the kinetics and mechanism of the reaction. In particular, we concentrated on the effect of the central metal ion and the supporting electrode material on the activity of the metal phthalocyanines. The results of long-term electrolysis have also been analyzed.

Experimental

All measurements were performed in a standard three-compartment cell at $23^\circ \pm 0.2^\circ C$. The working electrode was a glassy carbon rod (Atomergic Corporation, Plainview, New York) having a 0.07 cm^2 cross section and mounted on either a Teflon or a Pyrex glass support. The electrode was polished using $0.05 \mu\text{m}$ alumina and ultrasonically cleaned prior to depositing the catalyst. The metal phthalocyanines were prepared as described in (6). They were deposited on the polished carbon surface from a concentrated sulfuric acid solution by diluting the solution with water. By this method, approximately $10 \mu\text{g/cm}^2$ of metal phthalocyanine was deposited on the carbon surface (1). The catalyst is probably not deposited uniformly but rather forms islands of different thicknesses.

Solutions were prepared from analytical-grade reagents and conductivity water. Both N_2 and CO_2 gases were purified by passing them through hot copper turnings and then through a wash bottle containing an acid solution of chromium (III) sulfate and amalgamated zinc granules. The analysis of the solution after long-term electrolysis was performed using a GC fitted with a flame ionization detector. The actual conditions are described in Ref. (7).

Standard potentiostatic and potentiodynamic techniques were used for the electrochemical experiments. Current densities have been calculated on the basis of the apparent area of the electrode. All potentials are referred to the saturated calomel electrode (SCE).

Results and Discussion

Figure 1 shows current vs. potential curves obtained under potentiodynamic conditions on phthalocyanine-modified carbon electrodes. Regardless of the pH value of the solution, CO_2 is not reduced on bare carbon electrodes. The current due to hydrogen evolution under these conditions is practically zero up to about -1.6V .

**Electrochemical Society Honorary Member.

The activity of the catalyst towards the reduction of CO_2 is judged from both the potential at which an increase in current with respect to background (*i.e.*, bare carbon) is noted and from the shape of the reduction curve (*i.e.*, whether or not a diffusion-limited current is observed). The overall effectiveness of the phthalocyanines for catalyzing the CO_2 reduction reaction depends markedly on the central metal ion. The relative order of activity was found to be $Co^{2+} > Ni^{2+} \gg Fe^{2+} = Cu^{2+} > Cr^{3+}, Sn^{2+}$, etc. This order is quite different from that usually reported for the oxygen-reduction reactions (7), especially regarding the relative activity of the iron phthalocyanine. In all following experiments, only cobalt (CoPc) and nickel (NiPc) phthalocyanines were used.

Two current peaks can be observed in the potentiodynamic traces of curve 1 in Fig. 1. Similar but smaller peaks were also observed in CO_2 -free solutions and attributed to the reduction of the CoPc with formation of mono- and dianions, respectively (4). The ability of the catalyst to reduce CO_2 is therefore closely associated with

Fig. 1. Potentiodynamic i vs. E curves measured on glassy carbon electrodes covered with metal phthalocyanines. Curve 1: (—) cobalt. Curve 2: (---) nickel. Curve 3: (- · -) iron or copper. Curve 4: (· · ·) bare carbon electrode. $0.5M Na_2SO_4 + 0.1M NaHCO_3$ solution, saturated with CO_2 at normal pressure. Sweep rate: 0.05 V/s .

Fig. 2. Potentiodynamic i - E curves measured on glassy carbon electrodes covered with CoPc. Curve 1: (—) first sweep. Curve 2: (---) second sweep. Curve 3: (· · ·) third sweep following activation at 1.0V for 1 min. Similar conditions as in Fig. 1.

its oxidation state, as is also the case for oxygen (8). The i - E curve can be cycled several times with very little hysteresis and good reproducibility as long as the cathodic switching potential is kept positive to the first current peak (about -1.55 V). In neutral and slightly acid solutions (pH 5-7), the loss of activity of the phthalocyanines for CO_2 reduction is noted once this limit is exceeded. The current is then much lower for the second i - E curve than for the initial sweep. In fact, the activity of the modified electrode is reduced to that of a bare carbon electrode after a few cycles to -1.6 V or an extended voltage excursion

to -1.9 V. This effect can be observed by comparing the results shown in Fig. 2 with curve 4 in Fig. 1. Polarizing the electrode at about 1.0V for a few minutes partially restores the activity of the catalyst. The highest reduction currents obtained on these "restored" electrodes is about 40% of those measured initially. The mechanism of deactivation is not yet understood, although it probably involves either poisoning of the electrode by a reaction intermediate or the irreversible reduction of the catalyst.

The magnitude of the cathodic current peaks increases linearly with the concentration of CO_2 . The sweep-rate dependence of the peak current and peak potential, shown in Fig. 3, are consistent with a diffusion-limited irreversible electron transfer having a Tafel slope of -110 ± 10 mV (9). The diffusion coefficient of CO_2 can be estimated from the slope of the i_p vs. $v^{1/2}$ plot to be about 1×10^{-5} cm^2/s . Diffusion-limited currents have been observed on metal electrodes only at potentials 200 mV more negative than on CoPc modified electrodes. Figure 4 shows cathodic Tafel plots measured on both CoPc and NiPc under potentiostatic conditions. The results obtained on tin cathodes (10) are shown for comparison. The slopes of the linear portions (*i.e.*, -120 mV/decade), are consistent with the results of the potentiodynamic experiments and indicate that transfer of the first electron to a CO_2 molecule is the rate-determining step of the reaction.

Limiting currents are reached on both CoPc and NiPc at about the same potential, although the magnitude of these currents is quite different. Of course, no difference should be expected if these were diffusion-limited currents. We believe that deactivation of the NiPc occurs before the diffusion limit is reached, although kinetic complications (*i.e.*, a difference in reaction mechanism) could also explain the lower currents. The total cathodic charge measured on PcCo during a single sweep between -0.6 and -1.4 V is about 30 mC/cm^2 . This large value, compared with about 0.2 mC/cm^2 expected for a unit turnover ratio, confirms the catalytic nature of the process.

At $pH < 6$, the i - E profile shows a new reduction peak at a potential of about -1.2 V, in addition to the main peak at -1.55 V (Fig. 5). The ratio of the peak currents is about 2.5 to 1, and depends very slightly on pH . We have not yet been able to identify the processes associated with each peak, although we expect to gain a better understanding from ring-disk electrode experiments currently under way. We suspect, however, that the presence of two re-

Fig. 3. Sweep rate dependence of the cathodic peak current, i_p , and peak potential, E_p , measured on a CoPc covered carbon electrode. Same solution as in Fig. 1, CO_2 saturated.

Fig. 4. Potentiostatic Tafel plots measured on CoPc-(1) and NiPc-(2) covered carbon electrodes. Results for tin (3) taken from Ref. (11). Similar conditions as in Fig. 1.

duction peaks is related to the reduction of CO_2 beyond the formate stage. In fact, the amount of methanol produced in long-term electrolysis of CO_2 solutions increases on lowering the pH in the range 7-3, although it never reaches a current efficiency larger than 5%. The main reaction product is in all cases the formate ion.

Previous reports (5) indicated that the shape of the i - E plot depended on the time the electrode was held at potentials more positive than about -1.0V , due to the formation of a CO_2 -phthalocyanine complex. We found no evi-

dence for this process. It seems likely that the reported effect was caused by a time-dependent coverage of the electrode with water-soluble phthalocyanines, and not by a slow complex formation reaction.

The substrate has a strong influence on the activity of the metal phthalocyanines towards the reduction of CO_2 . Graphite and glassy carbon seem to be specific in their ability to utilize phthalocyanines as catalysts. As mentioned earlier, the overpotential for this reaction on CoPc deposited on glassy carbon is about 200 mV lower than on the best metal cathodes. Some activity was also observed using high overpotential metals (Hg, Pb) as supports. On other electrodes, *e.g.*, Pt and Au, the phthalocyanines have essentially no catalytic activity towards CO_2 reduction. These results agree with those obtained for the reduction of oxygen (11), and suggest that the bonding between the substrate and the catalyst determines the electrode activity.

The limiting potential at which the catalyst retains its activity becomes more negative on lowering the pH of the solution. To test the short-term stability of the phthalocyanines, a CoPc electrode was operated continuously for 72h at potentials between -1.4 and -1.2V and current densities of about 1 mA/cm^2 in a 0.1M NaHCO_3 solution saturated with CO_2 . The cathodic charge was equivalent to 260 C/cm^2 . No significant loss of activity was observed. The solution was analyzed after this electrolysis using the GC technique described earlier. The main reaction product was the formate ion formed with a current efficiency of about 60%. Methanol was produced only in those solutions having a pH value lower than 4, indicating that formic acid (rather than the formate ion) is the reacting species for the second reduction process. The maximum current efficiency for methanol formation was about 5% at pH = 3.

Further information about the system can be obtained from measuring the electrode impedance. Figure 6 shows the potential dependence of the differential capacitance of a CoPc-covered carbon electrode in solutions saturated with N_2 and CO_2 . The capacitance measured at 1 kHz is in good agreement with the double layer capacitance determined from complex plane analysis ("Cole-Cole" plots). The difference between both curves in Fig. 6 can be attributed to a difference in the pH value of the solutions. Therefore, the capacitance maximum is not associated with the formation of a CO_2 complex, as previously sug-

Fig. 5. Potentiodynamic i - E profiles measured on CoPc-covered carbon electrodes in solutions saturated with CO_2 . Curve 1 (---) $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$ buffer at pH = 5.8. Curve 2: (—) acetate buffer or phosphate buffer at pH = 4. Sweep rate = 50 mV/s .

Curve 3: (- · -) bare carbon electrode in CO₂-saturated solution. Frequency = 1 kHz. Sweep rate = 0.01 V/s.

gested (5). It is more likely due to a change in the oxidation state of the central ion. The potential at the maximum (-1.1V in CO₂-saturated solutions) corresponds either to the foot of the first current peak in the *i*-*E* plots (Fig. 1), or to the first current peak at pH < 6. In any case, we think that there is a close relationship between the oxidation state of the central ion, the catalytic activity of the electrode, and its differential capacity.

In conclusion, metal phthalocyanines are promising electrocatalysts for the electroreduction of CO₂ in aqueous solutions. The reaction product in nearly neutral solutions is the formate ion, although methanol is also obtained in more acid solutions. Future work will be directed towards an understanding of the mechanism of the reaction and the deactivation of the catalyst in order to increase its long-term stability.

Kinetics of Repassivation of Nickel/Copper Alloys in Alkaline Solution

R. D. K. Misra* and G. T. Burstein

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge CB2 3QZ, England

ABSTRACT

Data have been obtained for the rate of repassivation of nickel and binary nickel/copper alloys at pH 14. The fresh metal surfaces, which are created *in situ*, react initially to produce a monolayer of oxide. This monolayer is formed by random oxidation of exposed metal atoms at a rate which is unaffected by the copper content of the material. Subsequent film thickening occurs by ion migration through the film under high electric field. The copper content of the alloy affects this process only to a small extent, the reaction being largely controlled by the nickel component. The rate constants are given.

Growth of anodic oxide films on nickel in alkaline solutions has been investigated in some detail owing to the use of the metal as an electrode material in nickel/iron and nickel/cadmium batteries (1-11). Film growth is also of importance in the maintenance of passivity of nickel and alloys containing nickel.

It is now commonly accepted that anodic oxidation of nickel in alkaline solutions leads initially to the formation of a film of $\text{Ni}(\text{OH})_2$ (1-11). Ellipsometry has shown that this film is $\beta\text{-Ni}(\text{OH})_2$ (4) although it may be formed from $\alpha\text{-Ni}(\text{OH})_2$ (7, 8, 10). Recent experiments have shown that when $\beta\text{-Ni}(\text{OH})_2$ is formed, it cannot readily be reduced electrochemically (10). At higher potentials this film is converted to $\beta\text{-NiOOH}$ (2, 6, 7, 10) although little is known about the kinetics and mechanisms of growth of, and transformations between these oxide phases. For the $\text{Ni}(\text{OH})_2$ layer, formed anodically from the metal both dissolution followed by precipitation (9, 12) and direct solid-state surface oxidation (6, 9) have been proposed. Thickening of the $\beta\text{-Ni}(\text{OH})_2$ film has been shown to follow the Cabrera-Mott (13) formalism of high field-assisted ion transport (10, 11).

Pourbaix' thermodynamic calculations for equilibrium of nickel with aqueous solutions of pH 14 (14) provide data for additional oxides of nickel, including Ni_3O_4 and NiO_2 , but no consideration of the NiOOH phase was made.

Anodic oxide films on Ni-Cu alloys have received less attention although oxidation in dry oxygen and steam environments has been characterized (15-17). The anodic oxidation of Monel 400 (70% Ni, 30% Cu) in LiOH solution is found to approximate most closely to the oxidation of the major component of the alloy (12). In an earlier paper (18) we established that passivity of a range of Ni-Cu alloys in 1M H_2SO_4 solution was due to oxide film growth by ion migration under high electric field. The rate-controlling parameters are a function of the copper content of the alloy, but the alloys largely follow the kinetics of film growth associated with pure nickel. It was concluded that the film was fundamentally a nickel oxide, containing varying amounts of copper ions depending upon the alloy composition.

In this paper we establish the oxide growth parameters for Ni, Ni-30%Cu, Ni-50%Cu, and Ni-70%Cu in 1.0M KOH, pH 14, using the scratched electrode in order that film growth could be studied starting from the bare metal surface. The technique is useful in this case owing to the apparent irreducibility of the nickel oxide film (10). Alloys of the above compositions are all single phase homogeneous solid solutions, and the data obtained are not complicated by varying metallurgical microstructures.

Experimental

The scratched rotating disk electrode technique was used to investigate the repassivation of nickel and binary

alloys of nickel and copper in 1.0M KOH. The technique has been described extensively in previous papers (19-26).

The electrodes were made from 99.999% pure metals. Alloys were synthesized by arc melting followed by homogenization. The electrolyte was AR grade KOH made to 1.0M with doubly distilled water; it was purged with pure nitrogen before and during use.

Scratches are generated on the electrode disk (~0.5 cm diam) rotating at 100 Hz. A stylus contact time of ~1.5 ms produced a scratch ~0.15 cm long by ~40 μm wide by ~3 μm deep. The electrode was held at constant potential with respect to a saturated calomel reference electrode. The current transient consequent upon generation of the scratch was recorded superimposed onto the steady-state background current flowing from the whole electrode surface. A typical anodic current transient is shown in Fig. 1. Parameters taken from each transient are given by the maximum observed bare surface current density i_s , the current density flowing from the scratch at time t after scratching, $i(t)$, and the charge density that has flowed from the scratch at time t , $q(t)$. These are quantified by

$$i_s = \frac{1}{2\pi r \omega y} \frac{dI}{dt} \quad [1]$$

$$i(t) = \frac{1}{2\pi r \omega y t_c} [I(t) - I_b] \quad [2]$$

$$q(t) = \frac{1}{2\pi r \omega y t_c} \int_0^t [I(t) - I_b] dt \quad [3]$$

where dI is the increase in current on the scratch in time dt during scratching, $I(t)$ is the total current flowing from the whole electrode at time t after scratching, I_b is the base current flowing from the whole electrode before scratching, t_c is the contact time of the stylus, y is the scratch width, r is its distance from the center of rotation and ω is the electrode rotation rate.

Current transients were quantified as a function of electrode potential E (presented on the normal hydrogen electrode scale). The metals used were pure Ni, Ni-30Cu, Ni-50Cu, and Ni-70Cu where the amount of copper is expressed in weight percent. All experiments were performed at ambient temperature of $(19^\circ \pm 2^\circ)\text{C}$.

Results

The magnitude of the rate of reaction of the freshly bared metal surface is given by i_s . Although i_s is a differential quantity (see Eq. [1]), when its value is high it probably does not give a measure of the true bare surface reaction rate. Nevertheless, it provides a guideline for the bare surface reactivity of the material when plotted as a function of electrode potential.

The "bare surface polarization curve" for pure nickel in 1.0M KOH is shown in Fig. 2. It shows a unique potential, E_{ms} , at which zero net current flows from the scratch. For

* Electrochemical Society Student Member.

potentials negative with respect to this bare surface mixed potential the net current flowing from the scratch is negative. At all potentials positive with respect to E_{ms} the current flowing from the scratch is positive. The first

Fig. 2. Bare surface current density, i_s (\circ , \bullet) and steady-state current density, i_b (broken line) as a function of potential for nickel in 1.0M KOH. White points cathodic, black points anodic.

250 mV of the anodic branch shows linear behavior ($\log i_s \propto E$) and therefore obeys Tafel's law. For potentials higher than this the current continues to increase with E , but at a slower rate, until a peak bare surface current density of ~ 15 A cm^{-2} , and this is followed by a steady decrease in i_s for continuing increase in E . For comparison, the steady-state current density (i_b) flowing from an unscratched nickel electrode is also shown. The values of i_s lie up to 5 orders of magnitude higher than i_b . Bare surface polarization curves for the three Ni-Cu alloys were similar to that of nickel, each showing a small linear anodic Tafel region over 1-2 decades in i_s . Values of the bare surface mixed potential and the anodic Tafel slope (in i_s) are given in Table I. The anodic Tafel slope, $\partial E / \partial \log i_s$, is 149 ± 4 mV and is invariant with the alloy composition, at least when the mole fraction of nickel, $X_{Ni} > 0.3$. The value of E_{ms} is a function of X_{Ni} (also given in Table I) although the dependence is small. Such data can be fitted to a logarithmic plot in X_{Ni} which gives the empirical relationship

$$E_{ms} \text{ (mV, NHE)} = -639 - 92 \log X_{Ni} \quad [4]$$

The rate of decay of current density on the scratch can be analyzed in a number of ways. The simplest of these is a plot of $\log i(t)$ against $\log t$. Such a plot is shown for current decay on scratched nickel in Fig. 3 for a range of potentials. At low potentials these plots are curved and show a progressively increasing rate of current decay as the decay proceeds. At higher potentials, however, the plots are linear except for data taken at very short times after scratching. In this connection it is important to bear in mind that because the scratch is not created instantaneously, but requires a finite time to be formed ($t_c \approx 1.5$ ms) the position $t = 0$ is rather arbitrarily defined as that point at which the scratch is half of its final length. This creates an error in the time scale for short times after scratching and contributes to the curvature of the lines in Fig. 3 in that region. The high potential transients show linearity however, for $t \geq 4$ ms, and this linearity covers almost three decades in $i(t)$ and t . The slopes, $\partial \log i(t) / \partial \log t$ of these graphs were found to be independent of potential and alloy composition for all four materials. They give a mean, $\partial \log i(t) / \partial \log t = -0.97 \pm 0.01$, independent of potential and alloy composition. Plots of the type shown in Fig. 3 are by nature empirical and do not directly provide the mechanism of film growth as has been described earlier (18, 23, 26). Detailed information on the kinetics and mechanism of the process can, however, be obtained by describing $i(t)$ as a function of $q(t)$, the total charge density passed on the scratch at time t .

Two kinetically distinct processes can be defined from the data, depending upon potential. At low potentials (but still positive with respect to E_{ms}) a range exists where $i(t)$ is linearly related to $q(t)$. This region corresponds to the data which show curvature in Fig. 3 ($\log i(t) / \log t$ plots). The data are presented in Fig. 4 for a number of electrode potentials for all four materials. The current density $i(t)$ decays linearly with the charge density passed, $q(t)$, up to a maximum of $q(t) \approx 530 \mu\text{C cm}^{-2}$. The current decay plots are representative of those occurring at low anodic charge densities.

At higher potentials Fig. 3 shows that the decay of $i(t)$ with respect to $q(t)$ should be different from that described by Fig. 4, and this is indeed the case. Data for the Ni-30Cu alloy are presented in Fig. 5 as a function of E . The graphs show that $\log i(t)$ decreases linearly as $q(t)^{-1}$ decreases for at least two decades in $i(t)$, although for high values of $q(t)^{-1}$ the graphs are curved. The same be-

havior was shown for all four metals at potentials above those described by Fig. 4. The kinetics and mechanism are described quantitatively below.

Discussion

The enormous acceleration in electrochemical reaction rate produced by scratching the electrodes is a direct consequence of removal of the existing surface oxide films. The depth of the scratch (ca. $3 \mu\text{m}$) is far greater than the thickness of the pre-existing film and its creation thus involves exposure of bare metal surface to the electrolyte. The work that is put into the metal surface by the machining action has itself been shown to be of relatively little consequence on the rate of reaction for similar experiments on silver (21) and bismuth (25) electrodes, and it is reasonable to assume the same to be true for the data presented here.

The cathodic branch of the bare surface polarization curve observed at low potentials (see Fig. 2) is undoubtedly a consequence of accelerated hydrogen evolution on the scratch surface, since water is the only reducible species of any significant concentration. It should be noted that E_{ms} is positive with respect to both the observed steady-state mixed potential as well as the equilibrium hydrogen potential ($E_o = -827$ mV (NHE) at pH 14 and 1 atm H_2). It is therefore evident that water is reduced on the scratch surface at an underpotential with respect to E_o . This cathodic current represents the nonsteady-state reaction $\text{H}_2\text{O} + e^- \rightarrow \text{H}_{ads} + \text{OH}^-$ on the bare metal surface. Interpretation of the kinetics of this reaction are, however, hampered by the presence of even trace amounts of oxygen or dissolved metal ions in the electrolyte. Because of the very high electrode rotation speed used for these experiments ($\omega = 100$ Hz) trace amounts of reducible species provide detectable cathodic base currents which may then be perturbed by the scratching process. It is not yet known whether this would provide a significant error in E_{ms} although the fact that E_{ms} is a systematic function of X_{Ni} (see Eq. [4]) implies that the error is small.

Polarization Curves

In a previous paper (18) describing the behavior of nickel and nickel/copper alloys in acid solutions it was found that the bare metal surfaces reacted anodically at potentials below those expected from the thermodynamic potentials for nickel and for copper, equilibrating with their oxides. Although anodic dissolution was still thermodynamically possible the fact that a transient was observed at all means that a film had been scraped away

Fig. 4. Decay of current density as a function of charge density passed in 1.0M KOH at potentials of \blacksquare : -605 mV (NHE), ∇ : -580 mV (NHE), \blacklozenge : -555 mV (NHE), \bullet : -530 mV (NHE). (a) Ni, (b) Ni-30 Cu, (c) Ni-50 Cu, (d) Ni-70 Cu.

[13] for scratched Ni-30Cu in 1.0M KOH. \circ : -380 mV (NHE), \triangle : -255 mV (NHE), \diamond : -105 mV (NHE), \blacklozenge : -5 mV (NHE), \blacktriangledown : 45 mV (NHE), $+$: $+95$ mV (NHE), \blacksquare : $+145$ mV (NHE), \bullet : $+195$ mV (NHE).

and analysis of the anodic charge densities involved showed that the film existing at potentials below the Ni/NiO equilibrium potential is of the order of a monolayer in thickness.

Formation of an oxide monolayer at a thermodynamic underpotential with respect to that required for a bulk oxide was not observed in the present results taken at pH 14. The value of E_{ms} for pure nickel, which is the potential below which anodic activity on the scratch is not observed, (see Table I) is in fact 74 mV more positive than the Ni/NiO equilibrium potential [-717 mV (NHE)] (27), and the data provide no evidence of underpotential anodic activity. The same is true of the nickel/copper alloys (Eq. [4], Table I), although these materials all display an E_{ms} value well below the equilibrium potential for the Cu/Cu₂O reaction [-356 mV (NHE)] (27), even where the mole fraction of Ni, $X_{Ni} = 0.3$. It is, of course, possible that nickel does possess such underpotential anodic activity as shown at pH 0 (18), but its observation is masked by the accelerated cathodic reaction on the scratch (see Fig. 2). Indeed, copper itself has been shown to be anodically active at potentials well below -356 mV (NHE) at pH 14 (22). The fact that the cathodic reaction is more strongly accelerated on scratched nickel than on scratched copper surfaces is seen clearly by inspection of the cathodic branches of the bare surface polarization curves for either metal. Thus, for example, at $E = -1000$ mV (NHE), pure Ni gives $i_s \approx 2$ A cm⁻² (Fig. 2) while pure Cu at the same potential and pH gives $i_s \approx 0.1$ A cm⁻² (22), both being cathodic values.

It is a curious consequence of this, that although copper is thermodynamically more noble than nickel when equilibrated with water (27) the E_{ms} values imply that the freshly generated nickel surface is apparently more noble than that of copper, and this can be seen to hold true for the alloys as well (Eq. [4]). It is not yet known whether this order of bare surface reactivity would be observed in the absence of the bare surface cathodic curve or not. All the anodic values of i_s for the 4 metals (see Fig. 2 and Eq. [4]) are, however, measured at a thermodynamic overpotential for Ni in equilibrium with NiO [or Ni(OH)₂].

The anodic Tafel slope, $\partial E/\partial \log i_s$ (see Table I) is 149 ± 4 mV and is indicative of the first electron transfer step being rate determining. We can write this for pure Ni as a pH dependent or independent reaction as

The solubility of Ni(II) is negligible at this pH and thus reaction [5] or [6] must be followed by rapid formation of the first monolayer of Ni(II) oxide (either NiO or Ni(OH)₂). Using reaction 6 we can write

$$i_s = k_6 \exp\left(\frac{\beta FE}{RT}\right) \quad [7]$$

where k_6 is the potential independent rate constant for reaction [6] and $\beta = 0.4$, and this equation will hold only for the initial reaction rate at which no charge has yet flowed. This can only be true where the actual value of i_s is relatively low. For higher values of i_s , significant quantities of charge flow in the period required to measure i_s ; thus i_s is itself underestimated by virtue of the growing film (see below).

It is also possible to investigate the current density flowing from the scratch at zero charge density (and therefore, by definition, zero time) by extrapolation of plots of $i(t)$, and this is considered below.

Film Growth at Low Overpotentials

At low anodic overpotentials, within the Tafel regions of the bare surface polarization curves (see Fig. 2) the $\log i(t)/\log t$ plots for nickel and the three alloys are all curved. The decay of current density obeys the linear relationship between $i(t)$ and $q(t)$ demonstrated in Fig. 4. In the absence of dissolution these kinetics are best seen as

the lateral growth of film over the scratch surface with negligible film thickening. One would expect this to occur during the growth of the first monolayer of oxide. For the process to follow the kinetics indicated by Fig. 4 the oxidation process must be totally random involving no nucleation and growth stages. Thus the observed rate of reaction at time t after scratching is simply the current flowing from that portion of the surface not yet covered by film at that instant. We can thus write for constant potential

$$i(t) = i(0) \left[1 - \frac{q(t)}{q_m} \right] \quad [8]$$

where $i(0)$ is the potential dependent rate constant defined by $i(t)$ at $q(t) = 0$ and therefore at $t = 0$, and q_m is the charge density associated with generation of the completed monolayer. Assuming reaction [6] to be rate controlling, we can replace Eq. [7] by

$$i(0) = k_6 \exp\left(\frac{\beta FE}{RT}\right) \quad [9]$$

Equation [8] is obeyed by the data in Fig. 4 for all four metals. The real bare surface current density in the absence of any film is $i(0)$ and this was obtained by extrapolation of plots of the type shown in Fig. 4. Such a plot is shown in Fig. 6. The graph is short in its range of potentials owing to the relatively short range over which linear $i(t)$ vs. $q(t)$ behavior is observed. The Tafel slopes are listed in Table I alongside those taken from the i_s data. They are independent of the metal composition and have a mean value $\partial E/\partial \log i(0) = 93 + 1$ mV. From these data it is not quite so obvious that reaction [5] or [6] is rate controlling although Eq. [9] may still be applicable, with $\beta = 0.64$. Nevertheless, the rate constant is provided as a function of potential and its value is high. Furthermore, there is no significant dependence of $i(0)$ on the Cu content of the material, demonstrating that it is the oxidation of Ni which controls the rate of oxidation of the alloys, even where $X_{Ni} = 0.3$. Presumably, the oxide monolayer actually contains oxidized Cu since Cu is capable of oxidizing to the extent of a monolayer at these potentials, (22). As such reaction [6] is more accurately written for the alloys as

Fig. 6. Maximum bare surface current density, $i(0)$ (Eq. [9]) as a function of potential for scratched nickel and nickel-copper alloys. ∇ : Ni, \bullet : Ni-30 Cu, \bullet : Ni-50 Cu, \square : Ni-70 Cu.

the product of which is then oxidized to a monolayer containing a mixed NiO/Cu₂O lattice.

Although one cannot define the equilibrium potential for monolayer formation, it is possible to extrapolate the lines in Fig. 6 to the potential for Ni equilibrating with bulk NiO and produce the exchange current density $i_0(0)$ for $q(t) = 0$. The value is independent of the metal composition and provides for the four metals $i_0(0) = 0.013 \pm 0.002 \text{ A cm}^{-2}$.

The values of q_m , the anodic charge density passed in order to complete the monolayer (but in the absence of film thickening), can also be obtained from Fig. 4. It is the value of $q(t)$ when $i(t) = 0$, (Eq. [8]) and is seen to be independent of the metal composition but shows a small increase with increasing potential. The data are shown in Fig. 7. Measured values of q_m range between ~ 0.3 and 0.53 mC cm^{-2} and there is linear dependence upon potential. The lowest of these values is what might be expected from oxidation of surface Ni atoms, each by two electrons, to produce a monolayer of oxide film, in line with similar measurements made on other materials (20, 22, 24, 25, 28-30). It is also in line with the Ni(I) monolayer proposed for underpotential oxidation of Ni in acid solutions, where the mean charge density involved is $\sim 0.16 \text{ mC cm}^{-2}$ (18). The monolayer in the present case can be envisaged as a simple lattice of alternate Ni²⁺ and O²⁻ ions of 1 atom thickness produced by oxidation of about half the original surface Ni atoms, in line with previous work (24). Oxidation of the complete surface layer of metal atoms would then produce a monolayer of oxide of 2 atoms thickness with the same structure. Formation of such a monolayer would involve evolution of $\sim 0.6 \text{ mC cm}^{-2}$ of anodic charge density and this is close to the observed values at the highest potential of Fig. 7. Such behavior is not inconsistent with the fact that these reaction rates are all measured at an overpotential for NiO [or Ni(OH)₂] formation.

The line presented in Fig. 7 is that produced by linear regression of all the data for the four metals and it is interesting to note that extrapolation of the line to $q_m = 0$ pro-

Fig. 7. Maximum bare surface charge density, q_m , as a function of potential for scratched nickel and nickel-copper alloys, ▽: Ni, ◇: Ni-30 Cu, ●: Ni-50 Cu, ■: Ni-70 Cu.

duces an intercept of $E = -710 \text{ mV (NHE)}$. This is extremely close to the equilibrium potentials (E_0) between Ni and NiO or Ni(OH)₂ [-717 and -711 mV (NHE) , respectively] (27) at pH 14, with the implication that below E_0 the metal carries no Ni(II) oxide at all. It is also indicative of the fact that it is the oxidation of Ni itself which controls oxidation of the alloys at these potentials. However, extrapolation of Fig. 7 is open to question since the reasons for potential dependence of q_m are not yet known.

It should be noted that if film thickening were to occur at a significant rate at these potentials then the data shown in Fig. 4 would be expected to show deviation from linearity, particularly at the lower values of $i(t)$.

Film Growth at High Overpotentials

At higher anodic overpotentials the $\log i(t)/\log t$ plots are linear (Fig. 3) for Ni and the Ni/Cu alloys. The charge densities involved in the decay of $i(t)$ are now significantly higher and certainly well in excess of that required for formation of a monolayer of film (see Fig. 5). This means that the equivalent monolayer charge density has been exceeded in a short time compared with the stylus contact time, and the decay in scratch current density is due to film thickening. By assuming that the rate of reaction at time t is controlled by ion migration under high electric field through that thickness of film already reformed, $x(t)$, we can write the classical film growth equation

$$i(t) = A \exp \left[\frac{BV}{x(t)} \right] \quad [11]$$

where V is the constant applied voltage. If all the anodic charge density passed on the scratch goes towards film growth then $x(t)$ is related to $q(t)$ by

$$x(t) = \frac{Mq(t)}{zF\rho} \quad [12]$$

where M is the molecular weight of the film, ρ is its density, and z is the charge number of the metal cation. When all the applied potential difference lies across the film then $V = E - E_g$ where E_g is the potential at which the field is zero. Thus

$$i(t) = A \exp \left[\frac{BzF\rho (E - E_g)}{Mq(t)} \right] \quad [13]$$

Equation [13] in logarithmic form is seen to be obeyed in Fig. 5 for repassivation of Ni-30Cu and is also obeyed for the remaining materials where $i(t) < 3$ to 4 A cm^{-2} ; the equation is followed for at least 2 decades in $i(t)$ for all 4 materials.

The rate constant, A , from Eq. [13] was calculated from the intercept of the $\log i(t)/q(t)^{-1}$ curves at $q(t) = \infty$, and values are listed in Table II. There is no variation of A with electrode potential and no significant variation with alloy composition. The mean value is $\log (A/\text{A cm}^{-2}) = -5.4 \pm 0.5$. Differentiation of Eq. [13] gives

$$\frac{\partial \log i(t)}{\partial q(t)^{-1}} = \frac{BzF\rho (E - E_g)}{2.3M} \quad [14]$$

and the high field gradient should therefore be linearly related to the applied potential. This graph is shown for the four materials in Fig. 8. The data for each metal describe two regions of film growth, depending upon potential and both regions can be fitted to Eq. [14]. Transition from the low potential region of Fig. 8 to the high potential region is observed at $\sim +40 \text{ mV (NHE)}$. The data are described by the gradient of Eq. [14] as

$$\frac{\partial}{\partial E} \left[\frac{\partial \log i(t)}{\partial q(t)^{-1}} \right] = \frac{BzF\rho}{2.3M} \quad [15]$$

and the intercept, E_g , where $\partial \log i(t)/\partial q(t)^{-1} = 0$. These parameters are listed in Table II for the two regions of $E < 40 \text{ mV (NHE)}$ and $E > 40 \text{ mV (NHE)}$.

Fig. 8. Gradient of high field current decay on scratched nickel and nickel-copper alloys in 1.0M KOH as a function of potential ●: Ni, ▼: Ni-30 Cu, ■: Ni-50 Cu, ▲: Ni-70 Cu.

Values of E_g are independent of the alloy composition. The mean values are $E_g = -694$ mV (NHE) for $E < 40$ mV (NHE) and $E_g = +18$ mV (NHE) for $E > 40$ mV (NHE). The lower value is very close to the equilibrium potential (E_0) between Ni and NiO [or Ni(OH)₂] (*loc. cit.*) and to the intercept of Fig. 7; it is clear that the growing film is one of the Ni(II) oxides from the moment of inception of the oxide on the newly generated metal surface and that its occurrence is in complete accord with equilibrium thermodynamics. This means that for the alloys copper plays no significant thermodynamic part in the reaction. Since equilibrium between Cu and its oxides occurs at a significantly more noble potential its electrochemical ac-

tivity in the alloys must be enhanced to that of nickel simply by virtue of the presence of Ni.

The measured value of E_g for the higher potential region [+ 18 mV (NHE)] can be interpreted in terms of oxidation of the nickel to one of its higher oxides. According to Pourbaix (27) this could be

with

$$E_0 [\text{mV (NHE)}] = 897 - 59.1 \text{ pH} \quad [17]$$

or

$$E_0 [\text{mV (NHE)}] = 876 - 59.1 \text{ pH} \quad [18]$$

Table II. Measured parameters for film growth under high electric field (Eq. [11], [13]-[15], [19], [20]) for Ni/Cu alloys in 1.0M KOH

This observation is consistent with previous work by more conventional electrochemical experiments as well as ellipsometric measurements (4), although the phase formed at higher potentials may be β -NiOOH (2, 6, 7, 10), not considered by Pourbaix.

The gradient given by Eq. [15] (see Table II) is, now, a function of the alloy composition. For each material, its value at higher potentials [$E > 18$ mV (NHE)] is some 15 times that at lower potentials [$E < 18$ mV (NHE)]. The data are plotted in Fig. 9 as a function of the alloy composition. The relationship is approximately linear in mol fraction of Cu and gives empirically

$$\frac{\partial^2 \log i(t)}{\partial q(t)^{-1} \partial E} (\text{C cm}^{-2} \text{V}^{-1}) = 0.021 - 0.015X_{\text{Cu}} \quad [19]$$

for $E < 18$ mV (NHE), and

$$\frac{\partial^2 \log i(t)}{\partial q(t)^{-1} \partial E} (\text{C cm}^{-2} \text{V}^{-1}) = 0.325 - 0.220X_{\text{Cu}} \quad [20]$$

for $E > 18$ mV (NHE). Equation [19] is quantitatively comparable with that for film growth at low current densities on the same materials in acid solutions (18), where

$$\frac{\partial^2 \log i(t)}{\partial q(t)^{-1} \partial E} (\text{C cm}^{-2} \text{V}^{-1}) = 0.023 - 0.014X_{\text{Cu}} \quad [21]$$

The quantity described by Eq. [15] and [19]-[21] is a property of the film only, and by Eq. [15] can be used to define B , provided values for z , ρ , and M are assumed. For NiO growing on pure Ni we have $z = 2$, $\rho = 6.7 \text{ g cm}^{-3}$ and $M = 74.6 \text{ g mol}^{-1}$. From Eq. [19] $B = 2.8 \times 10^{-6} \text{ cm V}^{-1}$. If the oxide is $\text{Ni}(\text{OH})_2$, as described by others (1-11) then $\rho \approx 3.9 \text{ g cm}^{-3}$ (31) and $M = 92.7 \text{ g mol}^{-1}$, whence $B = 6.1 \times 10^{-6} \text{ cm V}^{-1}$. The value of B can be interpreted, as previously (18), in terms of the half-width (b) of the energy barrier towards migration of the cations through the oxide. Thus

$$b = \frac{BkT}{ez} \quad [22]$$

where k is the Boltzmann constant, T the temperature, e the electronic charge, and z the charge number. For pure NiO or $\text{Ni}(\text{OH})_2$ growing on pure Ni we obtain $b = 0.35 \text{ nm}$

or 0.76 nm , respectively, and the values are reasonable in terms of approximate lattice spacings. Variation of B with copper content of the alloy can then be interpreted in terms of changes in the parameters associated with ion migration in the film. Inspection of Eq. [15] and [22] shows that such variation (shown in Fig. 9) occurs in the parameter $bz^2\rho/M$ as the film composition, and perhaps structure, change with the incorporation of Cu cations, either as Cu^+ or as Cu^{2+} . While it is not possible to determine which of the film constants individually are changing, it is clear that the growing film is based on the nickel oxide lattice, and not copper oxide, both in terms of the thermodynamic as well as the kinetic parameters. It is also clear that there are no abrupt changes in these properties with copper content, at least up to 70% Cu in the alloy (and therefore in the film as well); the oxidized copper must thus form a uniform homogeneous solid solution in the nickel oxide lattice. The same deduction can be made for passive films grown on these materials in acid solutions (18).

The film growth parameters under conditions of high applied potential [$E > 18$ mV (NHE)] are more difficult to explain. The value of A is the same as that for lower potentials but the value of B for pure Ni as determined from Eq. [15] and [20] (see Fig. 9) are considerably larger, no matter which stoichiometry one assigns the oxide. Thus, for Ni_3O_4 , which we now write as $\text{NiO}_{1.3}$, $\rho = 3.6 \text{ g cm}^{-3}$, $M = 79.5 \text{ g mol}^{-1}$ (of $\text{NiO}_{1.3}$) and z has a mean value of 2.7. This gives $B = 6.5 \times 10^{-5} \text{ cm V}^{-1}$ and $b = 6.2 \text{ nm}$. The latter value is too large to be associated with a simple energy barrier in the oxide. It is possible that this film is duplex or even multiplex in nature with a more complex field distribution through its thickness. Nevertheless, the effects of copper on the process are exactly analogous to those effects observed with the lower potential film, as is seen in Fig. 9. In both regions of potential the nucleation and growth of the passivating film is controlled by nickel oxide; only the field strength across the films is modified by the presence of copper, and this is true for alloys of composition $0.3 \leq X_{\text{Ni}} \leq 1$.

The parameters described above for film growth under high electric field (A , B , and E_0) for $E < 18$ mV (NHE) are fully consistent with those describing repassivation of these materials in acid solution (18). The early kinetic region in acid solutions, which is described by a high value of A (18), was not, however, observed at pH 14.

Conclusions

1. The initial step in the repassivation of a freshly generated nickel surface in alkaline solution is the formation of a monolayer of NiO or $\text{Ni}(\text{OH})_2$. The reaction occurs with an apparent bare surface exchange current density of 13 mA cm^{-2} and an anodic Tafel slope of 93 mV . The mechanism of formation of this monolayer does not involve separate nucleation and lateral growth steps but consists of random oxidation of exposed metal atoms. No evidence has been found for nickel reacting anodically at potentials below the Ni/Ni (II) equilibrium potential although this has been observed for repassivation in acid solutions. The measured anodic charge required to complete the monolayer is a function of the applied potential.

2. The initial step in the repassivation of freshly generated surfaces of nickel/copper alloys containing up to 70% Cu is quantitatively similar to that described above for pure nickel. No effects of copper, either thermodynamic or kinetic, can be observed on the growth of the first monolayer of oxide.

3. Thickening of the Ni(II) oxide passive film on nickel in alkaline solution (pH 14) beyond the first monolayer coverage obeys the equation relating the rate of reaction to the high electric field across the film (Eq. [13]). For potentials below +18 mV (NHE) this occurs with $A = 4 \times 10^{-6} \text{ A cm}^{-2}$, $B = 6 \times 10^{-6} \text{ cm V}^{-1}$, and $E_0 = -694 \text{ mV}$ (NHE). For potentials above +18 mV (NHE) the film is oxidized to a higher oxide and growth of the film occurs with the same value of A , but with $B = 6.5 \times 10^{-5} \text{ cm V}^{-1}$ and $E_0 = +18 \text{ mV}$ (NHE).

Fig. 9. $\partial/\partial E [\partial \log i(t)/\partial q(t)^{-1}]$ as a function of the mol-fraction of copper. ■: $E < 18$ mV (NHE), left-hand ordinate. ●: $E > 18$ mV (NHE), right-hand ordinate.

4. Oxide film thickening during repassivation of nickel/copper alloys containing up to 70% Cu obeys Eq. [13] with A and E_0 values similar to those described for Ni. The high field gradient (and therefore the B value) however, decreases with increase in the copper content of the alloy for both film growth regions ($E < \text{and} > +18$ mV (NHE)).

ABSTRACT

Nickel was electrodeposited on copper substrates from sulfamate-sulfite, sulfamate, chloride, and chloride-sulfate electrolytes. The crystalline orientation was determined by x-ray diffraction, the magnetic orientation by Mössbauer spectroscopy of Co-57-doped deposits, and the stress by electrode deflection. The stress level was correlated with the relative intensity of the lines in the Mössbauer emission pattern in the case of deposits with a (100) preferred orientation.

The stress developed in nickel electrodeposits has been of interest for many years because of concern that internal stress may reduce corrosion resistance and also may lead to deformation of the substrate when the substrate is thin. The goal of the studies reported herein was an exploration of techniques based on Mössbauer spectroscopy that might be utilized for qualitative or quantitative measurements of the stress level in nickel electrodeposits. This goal has not yet been totally achieved but partial success has been obtained in the case of deposits with a (100) preferred orientation.

We report in this and the following paper the results of studies of nickel electrodeposits utilizing x-ray diffraction, Mössbauer emission spectroscopy of deposits doped

* Electrochemical Society Active Member.

with Co-57, and positron annihilation spectroscopy. For convenience in presenting the results, the first paper deals with the measurements related to stress in the deposits and the second paper deals with measurements related to structural imperfections.

Experimental

The test samples were prepared by electrodeposition of nickel on copper substrates from four different plating solutions: sulfamate-sulfite, sulfamate, chloride-sulfate, and chloride. The copper substrates were 0.2 mm thick and were surfaced prior to electroplating by abrasion with pumice, etching in dilute HNO_3 , and washing in distilled water. The experimental conditions for the forma-

tion of the deposits are summarized in Table I. Deposits from the chloride-sulfate bath were prepared over a temperature range of 20°-60°C. The surface active agent, sodium lauryl sulfate, was added in three cases to minimize pitting. The deposit thickness was 250 μm in the case of the panels utilized for the x-ray diffraction studies and was 30 μm in the case of the panels utilized in the Mössbauer studies. In the latter case, a small amount of Co-57 in the form of the chloride was added to the plating bath in order to yield an electrodeposit that was doped with Co-57. The stress in the deposit was measured in four cases using the deflection of the cathode as developed by Hoar and Arrowsmith (1). One side of the cathode was coated with a commercial epoxy-polyamide coating known as "Abdeck" so as to limit the electrodeposit to one side of the cathode. It is not felt that stresses due to water uptake by the coating were significant since the stress measurement was made within 10 min of immersion in the plating bath.

X-ray diffraction data were accumulated using a DRON-3 diffractometer and the K_α radiation of molybdenum. The emission Mössbauer spectra were obtained using a spectrometer manufactured by Ranger Electronics. The absorber was K₄Fe(CN)₆·3H₂O, and all chemical shifts are given relative to this standard. The spectra were fitted by Lorentzian functions.

Results

Stress measurements.—The measured values of the stress are tabulated for four electrodeposits and literature

Table II. Residual stresses in nickel electrodeposits

Sample	Residual stress (N/mm ²)		Reference
	Our results	Results taken from the literature	
1		-130	(2)
2	15	17.5	(2)
3	170	260	(3)
4		410	(4)
5		410	(4)
6	260	490	(4)
7	280	490	(4)
8		580	(4)

values are cited for deposits prepared under all eight conditions in Table II. It will be noted that our measured values are lower than those taken from the literature.

X-ray diffraction measurements.—The results of the x-ray diffraction measurements are given in Table III. Data are also given for rolled nickel and the values for powdered nickel from the ASTM standard card file are given at the end of the table.

The deposit from the sulfate-chloride bath exhibited very strong (100) preferred orientation as has been reported previously (5, 6). Samples 1 and 2 exhibited a weak (100) preferred orientation and samples 4-8 exhibited a weak (110) preferred orientation.

The x-ray diffraction characteristics of plating bath 3 were also studied as a function of temperature over the range of 20°-60°C. The strong (100) preferred orientation was maintained over the temperature range, 30°-55°C.

Thermal treatment of sample 3 at 500° for 1h in an argon atmosphere did not change the crystalline orientation, and the sample maintained the strong (100) preferred orientation.

Mössbauer spectroscopic measurements.—Mössbauer data for 13 nickel deposits doped with ⁵⁷Co are summarized in Table IV. The isomer shift, the quadrupole splitting, and the effective magnetic field values are those characteristic for ⁵⁷Co atomically dispersed in nickel. The only parameter that exhibited significant differences for deposits formed under different experimental conditions was the relative line intensities, given as *R* in the table. This parameter is determined by the magnetic orientation

of the domains in the nickel electrodeposit, and it is affected by the crystalline orientation and by the internal stress (7, 8). Representative spectra are shown in Fig. 1. The ratio of lines 3 to 1 should be unaffected by changes in orientation, and the spectra shown in Fig. 1 do indeed indicate that this ratio is a constant.

Discussion

Previously, it has been predicted (9) that the stress level in nickel electrodeposits can be determined from Mössbauer emission spectra provided that the orientation of the deposit is (100). The reasoning behind this conclusion will be briefly stated, but the original publication should be consulted for a more detailed summary.

The easy directions of magnetization in a magnetic material are determined by the magnetocrystalline anisotropy and the mechanical stress brought about by magnetostriction. These easy directions are the possible directions for domain magnetization. The relative abundance of the various easy directions is determined by the requirement that the magnetostatic energy should be a minimum. The domain structure, and especially the domain sizes, are related to the necessity for the presence of domain walls where spins out of the easy direction exist. In a magnetic metal, all these effects are coupled and the domain pattern is determined by a local minimum of the sum of the magnetocrystalline, magnetoelastic, elastic, magnetostatic, and domain wall energies.

The magnetic orientation of the sample relative to the spatial orientation of the sample can be determined by measurement of the relative areas of the first and sixth lines in the Mössbauer emission pattern to the second and fifth lines

$$R = \frac{A_1 + A_6}{A_2 + A_5} = \frac{3/4 (1 + \cos^2 \theta)}{\sin^2 \theta} \quad [1]$$

where A_i is the area of the i th line of the Mössbauer spectrum and θ is the angle between the directions of the propagation of the gamma rays and the magnetization (10).

It was suggested that stress in the electrodeposit changes the easy direction of magnetization from the normal (111) direction to the (110) direction in those cases where the (100) plane lies parallel to the metal surface. The magnitude of the stress is assumed to determine the fraction of the domains which have a (110) direction of magnetization. The fraction shows up in the ratio of the line intensities as given in the above equation.

The predicted relationship (9) between the value of 3/R and the stress level in nickel electrodeposits with a (100) preferred orientation is given in Fig. 2. Experimental points determined in this study for samples 1-3, the only ones of the set with a (100) preferred orientation, are also included in the figure. The point for sample 2, in which the stress level was low, falls on the theoretical curve, whereas the points for samples 1 and 3 are seriously off the curve. The zero stress level value is an assumed value taken from the sample heated at 500°C in argon.

A strong (100) orientation is maintained over the temperature range of 30°-50°C in the case of the panels plated from the sulfate-chloride bath. Mössbauer measurements on similar samples indicated that the 3/R values increased approximately 20% for each 10°C increase in bath temperature. Data given by Brugger (11) and Croly (12), as summarized by Safranek (4), indicate that the stress level in deposits from the sulfate-chloride

Fig. 1. Representative Mössbauer emission spectra from nickel electrodeposits doped with Co-57.

Fig. 2. Comparison between the theoretical curve developed in Ref. (9) and the experimental values for electrodeposits with a (100) preferred orientation. The point at 130 N/mm² represents the literature value for a sample with compressive stress.

bath decreases over the temperature range of interest, namely, 30°-50°C. Thus, these data also support the prediction that deposits with a (100) preferred orientation exhibit a Mössbauer hyperfine split pattern whose character is related to the stress level in the deposit.

One other piece of information supports in a qualitative way the relationship between $3/R$ and the stress level in (100) oriented nickel electrodeposits. Sample 3 was heated at 500°C in an argon atmosphere for 6h and the $3/R$ value was determined after slowly cooling the sample to room temperature. The $3/R$ value increased from its original value of 0.4 to approximately 2, a value characteristic of a very low stress level in the deposit. Concurrently with the change in relative intensity of the lines in the hyperfine split spectrum, the measured effective magnetic field increased to 29.2T from its original value of 26.8. The probable explanation for this increase in the effective magnetic field is the aggregation of cobalt atoms within the nickel matrix.

The measurement of stress, or changes in stress level on thermal treatment by the emission Mössbauer technique, is not practical for routine commercial applications because of the necessity to use the radioactive isotope ⁵⁷Co. However, the method may have application in laboratory studies or in the development of a process. Also, presently the method appears applicable only to deposits with a (100) preferred orientation. This limitation does not seem to be unduly restrictive since deposits made from the sulfate-chloride bath under common conditions of current density and temperature in the absence of organic addition agents ordinarily exhibit a strong (100) preferred orientation.

It does appear that there is a relationship between the ratio of lines 1 and 2 in the Mössbauer spectra and the stress for nickel deposits with a (100) preferred orientation. The chief difficulty is that the line ratio is much less sensitive to stress than the theoretical conclusions in Ref. (9) suggest. Refinements in the theoretical treatment are warranted.

ABSTRACT

Positron lifetime measurements were made on nickel electrodeposits. The shapes of the lifetime spectra depended on the conditions of the electrodeposition. The defect structure of the crystal lattice of the electrodeposits was analyzed on the basis of the parameters of the positron annihilation measurements. The effect of heat-treatment on the lifetime spectra was studied and the hydrogen concentration in the electrodeposited nickel was estimated.

Positron annihilation measurements have proven very useful in studies of the defect structure in metals. Such measurements are made by injecting positrons generated during the radioactive transition in ^{22}Na . The positrons are thermalized on a time scale which is short compared to their lifetimes. The annihilation rate of a positron-electron pair is a function of the electron density sampled by the positrons at the time of annihilation. In condensed media, most of the positrons annihilate with an electron into two gamma quanta, each with an energy of 511 keV, in the center of the mass frame of the annihilating positron-electron pair. The momentum of the positron after thermalization can be neglected in first order and the electron momentum is assumed by the gamma quanta. This fact results in deviations from the 180° angular difference between the two gamma quanta as well as in a Doppler broadening of the 511 keV annihilation radiation in the laboratory framework. The three major parameters that arise from positron annihilation experiments in metals are: positron lifetime, angle between the two gamma quanta formed, and the Doppler broadening of the gamma quanta. Measurements in this report are limited to positron lifetimes.

Positrons may be trapped in vacancies, dislocations, vacancy clusters, voids, and in almost any type of structural disorder. The annihilation of positrons in a trapping site results in a longer lifetime and in a narrower angular or energy distribution of annihilation gamma quanta than values measured for untrapped positrons. Annihilation of positrons in a specific type of trapping site results in specific parameters for the annihilation process. Consequently, the positron lifetime spectra contain information about the shape and concentration of the defects in crystalline materials (1).

The data generated in the positron lifetime measurements yield a plot of positron lifetime *vs.* number of events associated with that lifetime. The spectrum was analyzed to obtain the following information: average lifetime ($\bar{\tau}$), lifetime of major components of spectrum (τ_1 and τ_2), and their intensity (I_i).

The measurements reported herein represent positron lifetime measurements on the nickel electrodeposits studied by x-ray diffraction and Mössbauer spectroscopy in the preceding paper (2).

Experimental

The samples were prepared by electrodeposition of nickel on copper substrates. The experimental conditions for deposition are given in the preceding paper (2).

*Electrochemical Society Active Member.

Positron lifetime measurements were performed using a lifetime spectrometer based on NE 111 plastic scintillators, XP 1021 photomultipliers, and ORTEC electronics with double-energy gating (3) with a self-resolution of ~ 320 ps as determined by ^{60}Co . A sandwich-type sample-source arrangement was applied with the ^{22}Na positron source in the $(4-6)\times 10^5$ Bq activity range; the source holder was a ~ 1 mg/cm² thick Mylar foil.

The lifetime spectra were deconvoluted with the POSITRONFIT EXTENDED (4) program, taking into account the source correction given by Bisi *et al.* (5), the intensity of which was around 7%. The results of the two-component unconstrained evaluations were the most reliable and resulted in a variance in the 1.0-1.3 range for all the spectra. The error bars in the figures are all one standard deviation of the values given by the computer. Selected spectra were accumulated repeatedly. The extracted parameters of the independent measurements fell within one standard deviation. The average lifetime $\bar{\tau} = \sum I_i \tau_i$ was calculated for all spectra (where τ_i is the lifetime of positrons annihilating in the *i*th state, and I_i is the intensity of the *i*th component). This value was rather insensitive to the type of evaluation and was within ± 2 ps the same value independent of the number of terms in the evaluation.

Isothermal heat-treatments were performed *in vacuo*. The samples were maintained at the given temperature for 1h. They were then allowed to cool slowly to room temperature. All measurements were taken at room temperature.

Results

The average lifetime values for all the as-deposited samples are shown in Fig. 1 as a function of the literature values for the stress in such deposits. It is likely that the longer positron lifetimes are associated with higher stress levels and that shorter positron lifetimes are associated with lower stress levels, but the chemical effect cannot adequately be evaluated because all the high stress deposits were formed in baths containing chloride.

The effect of current density on the average positron lifetime is shown in Fig. 2 where it will be noted that the short lifetimes are associated with deposits formed at low current densities and the longer lifetimes are associated with deposits formed at higher current densities.

Figure 3 gives data on samples deposited from the sulfate-chloride bath over a temperature range of 20° - 60°C . The solid points in the figure represent measurements made on the same samples after aging at room temperature for 6 months. The arrows indicate the direction in

Fig. 1. The average positron lifetime for all unannealed samples plotted as a function of stress in the deposit. Literature stress values are used in this representation.

which the data changed. The summation of the effects indicated that the concentration of the long lifetime component increased during the aging.

Figures 4 and 5 summarize data for samples 1, 2, 3, and 8 as a function of the temperature to which the deposit was heated. It will be noted that the average lifetime of the positrons in samples 1 and 2 was approximately 160 ps for annealing temperatures below 300°C and was in the range of 250-290 ps for samples 3 and 8 for annealing temperatures of 200°C and below. The value of $\bar{\tau} = 160$ ps indicates the presence of a substantial concentration of structural imperfections such as vacancies, dislocations, and other defects in the as-deposited state in samples 1 and 2. The average lifetime of the as-deposited samples 3 and 8 is significantly above the lifetime value of 180 ps characteristic of the saturation lifetime for single vacancies in nickel (6). The presence of more extended defects in the as-deposited state of samples 3 and 8 is indicated.

Discussion

The average lifetime of the positron in electrodeposited nickel is related to the internal stress as shown in Fig. 1 and to the current density utilized in the deposition process as shown in Fig. 2. Samples prepared at low current density and with low internal stress had positron average

Fig. 2. The average positron lifetime for all samples plotted as a function of the current density utilized in the deposition process.

Fig. 3. Positron lifetime data for deposits formed in the sulfate-chloride bath over a temperature range of 20°-60°C. The solid points are measurements made after aging at room temperature for 6 months. The arrows indicate the direction of change.

lifetimes of the order of 160 ps, whereas the samples formed at higher current density and with high internal stress had positron average lifetimes of the order of 260 ps. These early results led us to believe that the positron average lifetime might be used to determine quantitatively the stress level in the deposit nondestructively. However, the measurements shown in Fig. 3 lead us to believe that a simple relationship between stress level and positron average lifetime does not exist. It is well known that an increase in the temperature of deposition in the case of the sulfate-chloride bath results in a decrease in the internal stress (7), yet the positron average lifetime of sample 3 increased slightly with an increase in deposition temperature in the range of 20°-60°C. In fact, the value of τ_1 exhibited a minimum at a plating temperature of 40°C while the value of I_2 was a maximum at the same plating temperature. It is apparent that the magnitude of I_2 , which is related to the three-dimensional defect concentration, determines, to a major extent, the value of the positron average lifetime. The value of τ_2 was not a function of the temperature of deposition and was in the range of 320-350 ps.

Aging of the samples for 6 months resulted in a slight decrease in the value of τ_1 and a slight increase in the value of τ_2 . The large increase in I_2 suggests that the defect pattern within the deposit changes over time with a trend towards larger volume defects and a corresponding diminution in the number of dislocations and vacancies. These changes in the positron lifetime parameters are consistent with the vacancy clustering model which will be discussed later.

Isochronal annealing studies.—In earlier publications dealing with positron annihilation in electrodeposited nickel, it was conjectured that the trapping centers could

Fig. 4. Positron lifetime data for samples 1 and 2 after annealing at elevated temperatures.

be interpreted in terms of single vacancies and vacancy clusters (8, 9). Data obtained following heat-treatment have yielded evidence that the defect structure of electro-deposited nickel is more complex than originally supposed.

Let us consider first the behavior of the positron lifetime parameters during isochronal annealing of samples containing a relatively small number of lattice defects in the as-deposited state, such as those found in samples 1 and 2. The values of $\bar{\tau}$, τ_1 , τ_2 , and I_2 as a function of annealing temperature are summarized in Fig. 4. It is clear that at least two types of defects are created during deposition. One of them, with $\tau_2 = 250$ - 280 ps and $I_2 = 0.22$, is associated with divacancies by analogy with the known value for τ_{2v} for divacancies in bulk nickel, namely, 250 ps (6). We thus attribute this component to small three-dimensional microvoids having, on average, the volume of a divacancy. The value of the shorter lifetime component, $\tau_1 = 125$ ps, is slightly greater than the characteristic lifetime for annihilation in bulk nickel, namely, 110 ps (6). Thus, it appears that the shorter lifetime is an average value for annihilation of positrons in the untrapped state and a lifetime characterizing annihilation in weak traps such as vacancies and dislocations. The fact that the τ_1 and I_2 parameters are not significantly changed by annealing at 200°C suggests that the weaker traps are dislocations since vacancies are mobile at 80°C in nickel. Dislocations, on the other hand, start to decrease in number when annealing is carried out above 200°C , as inferred from previous positron annihilation experiments (6).

The high value of τ_2 at the highest annealing temperature of 500°C suggests that the deeper traps are micro-

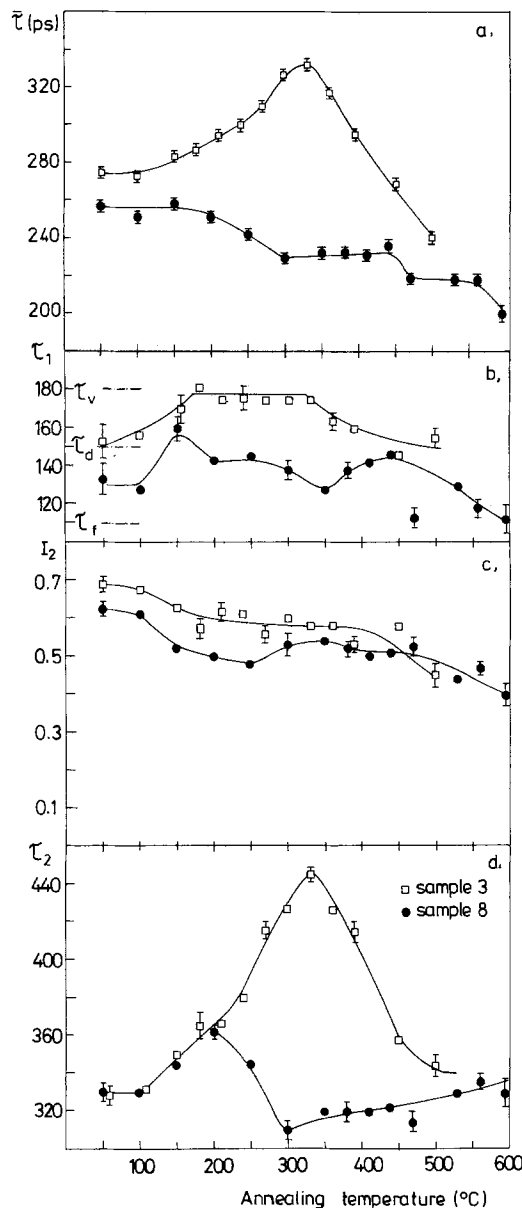

Fig. 5. Positron lifetime data for samples 3 and 8 after annealing at elevated temperatures.

voids of size equivalent to trivacancies or greater. It is tentatively suggested that these traps represent trivacancies formed on (111) planes, perhaps during growth or perhaps during the annealing treatment.

The annihilation parameters changed dramatically when the annealing temperature exceeded 200°C . A decrease in the values of τ_1 and τ_2 was accompanied by a large increase in I_2 as a consequence of an increase in the number of small three-dimensional defects. The value of τ_2 is much less for the samples annealed at 250 - 500°C than for the sample annealed at 200°C . It is conjectured that these values are representative of a defect volume less than that characteristic of a trivacancy, possibly single vacancies.

The decrease of τ_1 is simply a consequence of the increase in trap density since the increase means a higher escape rate from the "free" state of positrons, *i.e.*, a higher trapping rate in defects.

The increase in the value of I_2 for samples annealed above 200°C is attributed to the increase in the trap density because of vacancy generation by dislocation climb (10). Once vacancies are generated, they migrate to sinks such as dislocations and grain boundaries and condense to small vacancy clusters both at grain boundaries and within the interior of the grains. The decrease in I_2 and the increase in τ_2 in samples annealed above 350°C sug-

gests such an intragrain vacancy clustering mechanism. As the vacancies aggregate to divacancies, trivacancies, and higher order vacancy agglomerates, the number of small trapping centers decreases while their average size increases. Such a process has been detected previously in deformed nickel containing a small amount of antimony impurity which served as a nucleation center for vacancy clusters (6).

Samples annealed at 550°C yield positron parameters that approximate the unannealed deposit. This fact suggests that there is a highly stable configuration of small three-dimensional defects which are resistant to heat-treatment. As vacancy clusters and dislocations are known to anneal out of nickel totally at 450°C by recrystallization, it is proposed that these open volume defects are associated with grain boundaries.

Let us consider next the heat-treatment of samples 3 and 8 with the high values of internal stress. These data are summarized in Fig. 5. In the case of sample 3, the values of τ_1 and τ_2 increase at annealing temperatures of 200°C and below. In the 200°-330°C range, τ_2 increases further while τ_1 remains constant and is practically equal to the saturation lifetime of positrons trapped at single vacancies, namely, 180 ps (6). Annealing above 300°C caused both lifetimes to decrease with an increase in temperature until they reached values at 500°C approximately the same as those of the as-deposited samples. The value of I_2 decreases from 0.7 to 0.45 as the annealing temperature is increased from the as-deposited temperature to 500°C.

The values for τ_1 in the as-deposited state were sufficiently high that it appears that there is very little annihilation from the "free" state. The positrons presumably are rapidly localized after thermalization and the subsequent annihilation takes place in dislocations or microvoids. In the annealing range of 170°-330°C, the value of τ_1 is approximately 180 ps, a value characteristic of single vacancies.

The nature of positron traps in nickel electrodeposits.—We will now offer suggestions concerning the nature of the positron traps in nickel electrodeposits. Ample evidence exists for the presence of hydrogen in metals and the association of this hydrogen with a defect structure in the metal. For example, hydrogen embrittlement of metals is attributed to the segregation of hydrogen at dislocations and grain boundaries and the subsequent development of voids and microcracks along such imperfections (11). The clustering of hydrogen atoms in dislocations is presumed to be responsible for the increase in hydrogen absorption by steel during cold working (12). The high activation energy of hydrogen diffusion in iron near room temperature was explained by the excess energy required to free hydrogen from dislocations (13). Observations have been made of the precipitation of hydrogen into bubbles and the nucleation of bubbles preferentially at dislocations and grain boundaries in the case of hydrogen-loaded copper (14). Hydrogen embrittlement occurs in nickel at temperatures and strain rates at which hydrogen atoms can segregate to moving dislocations. Grain boundary cracks have been detected by TEM in hydrogen-charged nickel, which exhibited intercrystalline brittle fracture (15).

The migration energy of hydrogen in nickel is $E_m = 0.38$ eV (15), which is low in comparison with the migration energy of monovacancies $E_{1v} = 1.2$ eV (6) and the activation energy of self-diffusion $Q_{1v} = 2.88$ eV (16). These values indicate that the diffusion of hydrogen atoms in nickel takes place via interstitial sites. It is also clear from the value of the migration energy that the hydrogen is mobile below room temperature in nickel and that the hydrogen rapidly precipitates at dislocations and grain boundaries. The typical values of the hydrogen content of electrodeposited nickel of 10-200 ppm indicates that considerable hydrogen is to be expected in the nickel deposits used in this study (17). The precipitation of hydrogen at dislocations and grain boundaries and the subsequent formation of molecular hydrogen in dislocation cores pro-

duce local distortion of the lattice. The net effect of this distortion is a diminution in the nickel ion core electrons and a local decrease of electron density within this region. Such imperfections are possible traps for positrons.

The long lifetime component in the unannealed samples is attributed to the annihilation of positrons in hydrogen bubbles formed along grain boundaries. These hydrogen bubbles remain as free volume after heat-treatment and the diffusion of hydrogen out of the sample. The effect of dissolved oxygen in the electrodeposited nickel is probably less than that of dissolved hydrogen because the oxygen is probably present as nickel oxide or as an occluded salt containing oxygen. Migration of oxygen is hindered by the compound formation.

A second consideration in appraising the positron traps is the character of the trapped hydrogen. When hydrogen enters a metal such as nickel, it yields its electron to the conduction bands of the metal and exists in the lattice as a proton (18). Vacancies, microvoids, and dislocations have effective attractive potentials for positively charged particles such as hydrogen ions and positrons, and these particles are thus attracted to such sites. It has been suggested by Alex *et al.* (19) that proton trapping at these defects could reduce the attractive potential between the defects and the positrons. This reduction is probably more effective than in the case of hydrogen bubbles. In the case of vacancies, total trapping inhibition is possible.

The release of protons from vacancies and protons or hydrogen molecules from hydrogen precipitates at grain boundaries increases both the trapping probability and consequently, the positron lifetimes.

The increase of τ_1 upon annealing at moderate temperatures, as shown in sample 3 of Fig. 5, may be explained in terms of irreversible thermally activated proton detrapping from initially screened vacancies which then become effective positron traps. The initial increase in the value of τ_2 with an increase in annealing temperature in the case of sample 3 shown in Fig. 5 is illustrative of the reduction of electron density in more extended imperfections which, in turn, is explained by the release of protons or hydrogen. A similar increase in τ_2 was observed in the case of samples 1 and 2 shown in Fig. 4. The release of hydrogen molecules from grain boundary segregates may proceed by short cut diffusion along dislocations which are known to form dense tangles around such imperfections (14). Another possible explanation for the initial increase in τ_2 at low annealing temperatures is the migration of vacancies to grain boundary hydrogen precipitates with resultant increase in defect size.

The available data permit an estimate of the amount of hydrogen released from vacancies during thermal treatment under certain assumptions. The assumptions are the following: (i) only a single proton or hydrogen atom is trapped in every vacancy, (ii) saturation trapping occurs in dislocations in the as-deposited state, (iii) a simple three-state trapping model reasonably approximates the real condition. The annihilation channels in the trapping model are: "free," dislocation-, and vacancy-bound state annihilation. The lifetime spectrum is then

$$S(t) = \lambda_1 I_1 \exp(-\lambda_1 t) + \lambda_d I_2 \exp(-\lambda_d t) + \lambda_{1v} I_3 \exp(-\lambda_{1v} t) \quad [1]$$

where $\lambda_i = \lambda_f + K_d + K_{1v}$, K_d , and K_{1v} are trapping rates to dislocations and vacancies; $I_i = K_i/\lambda_i - \lambda_i$, as $i = 2$ or 3 on the left side, i must be replaced by d or $1v$ on the right; $I_1 = 1 - I_2 - I_3$; λ_f , λ_d , and λ_{1v} are the annihilation rates of different positron states; and $\lambda_i = \tau_i^{-1}$, if $i = f, d$, or $1v$.

The average lifetime is then

$$\bar{\tau} = I_1 \tau_1 + I_2 \tau_2 + I_3 \tau_3 \quad [2]$$

$$= (1 + \tau_d K_d + \tau_{1v} K_{1v}) / (\lambda_f + K_d + K_{1v})$$

This gives a linear relation between K_{1v} and K_d

$$K_{1v} = [K_d(\bar{\tau} - \tau_d) + \bar{\tau}\lambda_f - 1] / (\tau_{1v} - \bar{\tau}) \quad [3]$$

The trapping rates are proportional to defect concentra-

tions $K_i = \mu_i \times C_i \cdot C_i$ is the trap concentration and μ_i is the specific trapping rate to the i th type defect.

Utilizing a simple two-state trapping model (20), we give an estimate for the dislocation density in sample 3. For this purpose, we set $K_{1v} = 0$ in the above formulas, and from Eq. [2] we find that the dislocation density is given by

$$\rho_d = \frac{1}{\mu_d \cdot \tau_f} \cdot \frac{\bar{\tau} - \tau_f}{\tau_d - \bar{\tau}} \quad [4]$$

where $\bar{\tau}$ is the mean lifetime, $\tau_f = 110$ ps, $\tau_d = 150$ ps, and $\mu_d = 1.2 \text{ cm}^2 \text{ s}^{-1}$ is the trapping rate per unit dislocation concentration (21). Taking the statistical uncertainties of our data into account and presuming that only dislocations contribute to τ_1 , insertion of $\bar{\tau} = \tau_1$ into Eq. [4] gives $\rho_d = 5 \times 10^{10} \text{ cm}^{-3}$ as an estimate for the dislocation density in sample 3.

Let us use this estimate, which is equivalent to $K_d = 6 \times 10^{10} \text{ s}^{-1}$, and apply Eq. [3] for $\tau_1 = \bar{\tau}$ [$\tau_{1v} = 180$ ps (9)]. The trapping rate to single vacancies, which causes saturation trapping in such defects, is then $K_{1v} = 4.2 \times 10^{11} \text{ s}^{-1}$. This value corresponds to $C_{1v} \cong 190$ ppm vacancy concentration and, under our assumption, to the same hydrogen concentration as well. This value is a lower limit for the hydrogen content of sample 3 as it does not count the precipitated hydrogen at grain boundaries.

The slight decrease of I_2 below 200°C (Fig. 5c) is simply the consequence of the increase in the trapping rate to weaker traps (dislocations and vacancies in this case), $K_w = \mu_w \times C_w$; that is, to the increase of weaker trap concentration. (K_w = trapping rate, μ_w = specific trapping rate, and C_w = the concentration of weaker traps.) In the case of saturation trapping at two types of defects, the intensity ratio of the two lifetime components in the lifetime spectra is equal to the trapping rate ratio

$$\frac{I_2}{I_1} = \frac{K_b}{K_w} \quad [5]$$

Since we believe that annihilation of positrons localized at hydrogen bubbles gives rise to the long lifetime component, K_b is the trapping rate to hydrogen bubbles. As K_w changes strongly compared with K_b , the intensity ratio changes accordingly.

Using Eq. [5], we obtain an estimate for the lower limit of the concentration of precipitated hydrogen. We replace K_w by $K_{1v} = 4.2 \times 10^{11} \text{ s}^{-1}$ and take $I_1 = 0.4$ and $I_2 = 0.6$ from Fig. 5c. The trapping rate to bubbles is then $K_b = 6.3 \times 10^{11} \text{ s}^{-1}$. The trapping rate is proportional to the bubble concentration $K_b = \mu_b \times C_b$, where μ_b is the specific trapping rate or trapping rate per unit trap concentration. Calculations show that the specific trapping rate for small spherical microvoids is proportional to the number of vacancies building up the microvoid $\mu = nX\mu_{1v}$ (22). μ_{1v} is the specific trapping rate to single vacancies and n is the number of vacancies which have the same total volume as the void. It has been calculated (23) that the positron lifetime is a slowly varying function of the void volume if $n > 5$ and $\tau_{\text{void}} = f(nXV_0)$, where V_0 is the volume of a vacancy in nickel. Utilizing this relationship, one could, in principle, estimate n and μ . In our case, we must replace n by $n_{\text{eff}} = \eta X n$, where η accounts for the screening effect of hydrogen inside the void. At $\tau_2 \cong 360$ ps, $n_{\text{eff}} \cong 6-7$ (6), and employing $\mu_{1v} = 2.2 \times 10^{15} \text{ s}^{-1}$ (21), we get $C_b \cong 40$ ppm for the lower limit of bubble concentration. From the estimated hydrogen density in such bubbles, $\sim 0.1 \text{ g/cm}^3$ (14), and from the estimated volume of the bubbles $V_b = n_{\text{eff}}XV_0$, it follows that, on average, every defect could accommodate two hydrogen molecules. We reach an estimate of the precipitated hydrogen concentration: $C_{\text{H}_2} \cong 80$ ppm. The total H_2 content of our sample is then at least $C_{\text{H}_2} = 175$ ppm.

Vacancy clustering is observable in sample 3 as a steep increase of τ_2 above 200°C, despite the near-saturation behavior of I_2 and the absence of a peak in this parameter around 350°C. It is noteworthy, however, that the minimum in τ_2 coincides with the peak in I_2 for samples 1 and

2, a fact which also supports the vacancy clustering picture. The decrease of τ_2 observed between 200° and 300°C in the case of samples 1 and 2 was not observed for sample 3, because the high concentration of single vacancies in sample 3 leads to the appearance of a separate vacancy component in the deconvoluted lifetime spectrum as $\tau_1 \cong \tau_{1v} = 180$ ps. The interpretation is that only higher vacancy agglomerates contribute to τ_2 .

Above 330°C, all the positron parameters decrease, indicating the disappearance of defects.

The behavior of positron parameters of sample 8 is the most complicated. The behavior of I_2 (Fig. 5c) is similar to that of sample 3. τ_2 increases in the same way as for sample 3 up to 200°C, whereas the subsequent behavior is similar to that of samples 1 and 2 (Fig. 5d). The evolution of τ_1 in Fig. 5 resembles that in Fig. 4b.

Conclusions

During the course of deposition, at least three different types of structural defects which are effective trapping centers for positrons are created in nickel. These are dislocations, lattice vacancies, and more extended three-dimensional imperfections having at least the volume of three vacancies. The latter defects are probably hydrogen segregations at grain boundaries.

The concentration of defects is highly dependent on the plating conditions (2).

Some of the defects are filled with hydrogen ions. The release of protons takes place at ambient temperatures.

The stability of some more-extended defects against high temperature heat-treatments indicates that these lattice distortions are associated with grain boundaries.

The annealing of deposits takes place as a result of vacancy-migration above 200°C and intracrystalline agglomeration to vacancy clusters.

Diffusion-Controlled Multisweep Cyclic Voltammetry

III. Deposition of Silver on Stationary and Rotating-Disk Electrodes

P. C. Andricacos* and P. N. Ross, Jr.*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

ABSTRACT

An experimental study of diffusion-controlled silver electrodeposition has been carried out in order to investigate the applicability of the model for reversible metal deposition during multisweep cyclic voltammetry. For a stationary planar electrode, excellent agreement between theory and experiment has been obtained for the position of the cathodic current maxima on the potential axis, as well as for the dependence of their magnitude on parameters such as sweep rate, cathodic reversal potential, and number of applied sweeps. Anodic currents measured at the foot of the wave deviated from theoretical predictions as a consequence of the small but uncompensated resistance of the electrolyte. In an effort to predict and therefore control the amount of deposit, integral charges associated with each sweep have been measured and successfully correlated with the parameters of the experiment. It has been found that at millimolar concentrations, deposit thicknesses of the order of up to 20 monolayers can be formed with quantitative control. Experiments with a rotating-disk electrode have demonstrated that a periodic current response is obtained upon multiple sweeping, as predicted by theory. First sweep and periodic currents normalized with respect to the limiting current could be correlated with the dimensionless sweep rate in accordance with the theoretical predictions. Contrary to previous investigations, the diffusion coefficient of the silver ion was determined by limiting current measurements, and the value thus obtained was subsequently used to successfully correlate stationary electrode cyclic voltammetry data. During limiting current measurements with very slow sweeps, the development of surface roughness was observed as a significant increase of the current from the constant value obtained at faster sweeps. Based on the dimensionless sweep rate, a semiempirical criterion was developed for the optimal conditions for the potentiodynamic determination of steady-state limiting currents, the use of which may eliminate errors arising from both transient effects and surface area increase due to roughness.

In previous communications (1, 2), we presented calculations for diffusion-controlled cyclic voltammetry (CV) for both a stationary planar and a rotating-disk electrode (RDE) for reversible depositions at unit deposit activity. These represented extensions to previous linear sweep voltammetry (LSV) analysis for the stationary electrode (3) and the RDE (4), and were carried out in order to predict the effects of multiple sweeping on the deposition current and charge. For an experimental investigation of the theoretical predictions, we chose the electrodeposition of Ag. This was for several reasons. The kinetics of this reaction are very fast, so the reaction can be considered reversible and controlled by diffusion, as required by the theory. The equilibrium potential is sufficiently anodic to allow for a wide selection of values for the potential at which the sweep is reversed (other reversible systems such as Sn^{2+}/Sn do not allow for this possibility due to the onset of H_2 evolution). Since Ag deposits are usually rough and the amount of deposit is quantitatively related to sweep rate, manipulation of sweep rate values can be used to induce electrochemically noticeable roughness, thereby contributing to a quantification and possibly an elucidation of this phenomenon. Previous investigation (5, 6) of the Ag system by LSV have shown agreement between theory and experiment for stationary electrodes, but the value of the diffusion coefficient of the Ag^+ ion used by Mamantov *et al.* (5) originated from a non-electrochemical measurement by Stackelberg *et al.* (7). However, Bachmann and Dohrmann (6) obtained their diffusivity value by essentially fitting the Delahay LSV model (3). In the present investigation, consistency is sought by measuring diffusivity from limiting currents and using the value thus obtained to correlate stationary

electrode and RDE single-sweep and multisweep voltammetry data. Also, in limiting current measurements by Kraichman and Hogge (8), as well as in a previous LSV-RDE study by Andricacos and Cheh (4), gelatin was used in the electrolyte as a leveling agent, but as we are interested in this study in the effects of roughness on multisweep voltammetry, no leveling agents were employed.

Experimental

Experiments were performed in a glass three-compartment cell. Silver wires were used for both reference and counterelectrodes. The working electrode was a Pine Instruments Au RDE with a geometrical area 0.46 cm^2 polished to a mirror finish. When rotating, it was driven by a Pine Instruments Analytical Rotator assembly. The electrolyte composition was $1.1(2) \times 10^{-3} \text{ AgNO}_3$ in 1M HClO_4 ; it was prepared from reagent-grade AgNO_3 (Allied Chemical), electronic-grade HClO_4 (Apache Chemicals), and pure H_2O (Harleco). No further purification was attempted. The electrode potential was controlled with a PAR potentiostat (Model 173D) connected to a PAR Universal Programmer (Model 175). The potentiostat was equipped with a digital coulometer (PAR Model 379), and both current and integral charge were recorded either with an X-Y recorder or an oscilloscope depending on the sweep rate.

The Au RDE at zero rotation speed served as a stationary planar electrode. It was preferred relative to other possibilities because its configuration minimized possible natural convection complications, *i.e.*, downward facing with the density increasing from top to bottom (9). An inert substrate was chosen instead of Ag to avoid repeated polishing and subsequent irreproducibilities in the initial condition of the surface.

The Au RDE was initially immersed in the O_2 free electrolyte at a potential of 0.200V anodic to that of the refer-

Fig. 1. Cyclic voltammogram of a stationary Au disk electrode immersed in $1.1 \times 10^{-3} \text{ M AgNO}_3 + 1 \text{ M HClO}_4$. Sweep rate: $0.050 \text{ V} \cdot \text{s}^{-1}$. The potential region is anodic to a Ag wire reference electrode in the same electrolyte.

ence Ag wire and was subsequently cycled in the UPD region. Figure 1 shows a typical voltammogram obtained at 0.050 Vs^{-1} . Peaks I, I' represent underpotential deposition and stripping, whereas peaks II, II' probably originate from an alloying state (10). These peaks were invariant with rotation speed, whereas peaks III, III' were rotation dependent and were taken as bulk deposition. Bulk deposition occurred at potentials slightly anodic to zero *vs.* Ag wire, since the Nernstian potential is apparently not established at monolayer coverages. If the cathodic sweep is extended well into the bulk-deposition region, the resulting diffusion-controlled peak is of lower magnitude

and appears at more cathodic potentials compared to an electrode initially covered with Ag. A simple excursion into the UPD region is thus not sufficient to establish the Nernstian equilibrium potential of Ag corresponding to unit activity at the surface. Unit activity was achieved by preplating the RDE surface at -0.025 V and 1600 rpm until a deposit equivalent to a charge of $\text{ca. } 10^{-2} \text{ C cm}^{-2}$ had accumulated on the surface. The potential of the preplating was chosen sufficiently away from the limiting current to avoid powder formation (9). Upon open circuiting, the RDE potential was within 0.001 V relative to the Ag wire and remained constant for at least 15 min . The potentiostat was reconnected and the electrode potential adjusted so that exactly zero current passed as judged by the digital coulometer registering less than 10^{-7} C for at least 1 min . This procedure guaranteed that the anodic reversal potential was exactly the equilibrium at unit surface activity. After this initial preparation, the cathodic reversal potential was chosen, and multisweep measurements were taken. Upon completion of the measurements, the electrode potential was swept into the anodic region again, and the deposited Ag was stripped at $+0.020 \text{ V}$. After some time, the anodic current dropped to $\text{ca. } 0$, leaving residual Ag at a surface activity consistent with an equilibrium potential of 0.020 V . Slow sweeping at 0.001 Vs^{-1} in the anodic direction resulted in stripping of all deposited Ag both during preplating and CV measurement. For each sweep rate, the procedure was repeated and yielded results reproducible to better than 1%. For the limiting current measurements the preplating step was omitted.

Results and Discussion

Cyclic voltammetry on a stationary planar electrode.—Figure 2a shows a typical multisweep voltammogram for Ag deposition on the Ag-preplated Au horizontal disk electrode. The same voltammogram unfolded in time appears in Fig. 2b. The second representation is better if the emphasis is on the measurement of current peak heights. Figure 2c is the corresponding charge/potential diagram. Since such diagrams have not appeared in the literature before, a brief qualitative description will be given here. The curve 0-a-b-c in Fig. 2c corresponds to the charge in the first complete sweep, including both cathodic and anodic portions. Point a is the value of the charge at the end of the first cathodic sweep, *i.e.*, at the cathodic reversal potential. During the reverse sweep, the charge continues to increase in the cathodic direction until it reaches an extremum at point b; this corresponds to the potential at which the current changes from cathodic to anodic. Since the current remains anodic until the end of the reverse sweep, the cathodic

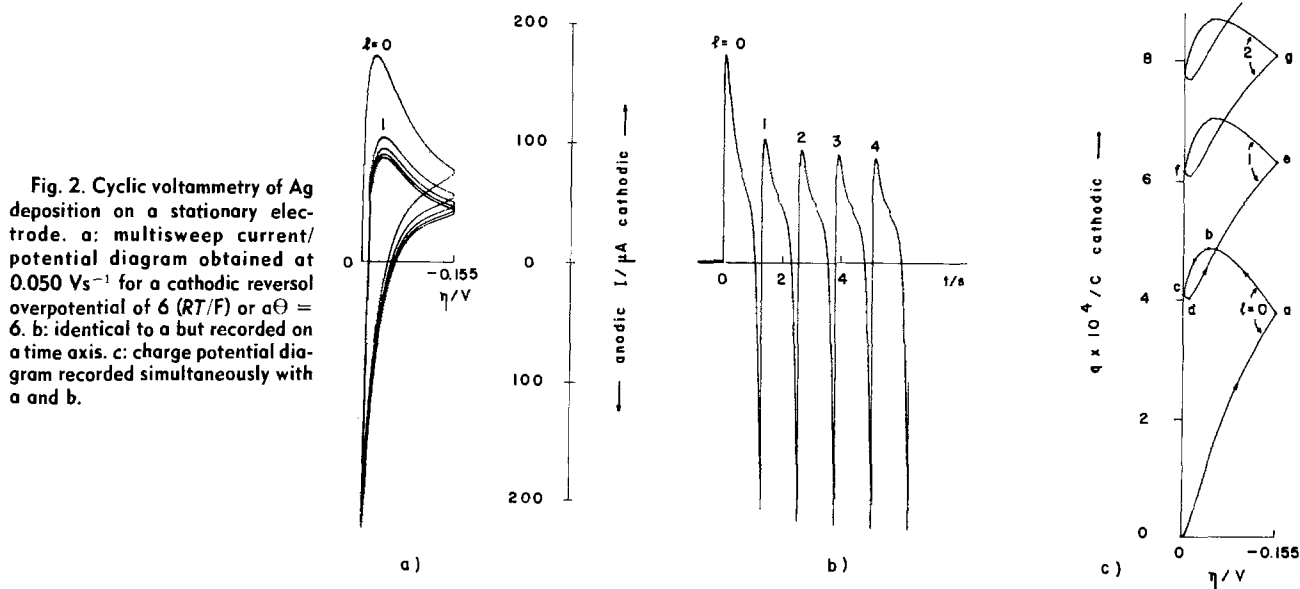

Fig. 2. Cyclic voltammetry of Ag deposition on a stationary electrode. a: multisweep current/potential diagram obtained at 0.050 Vs^{-1} for a cathodic reversal overpotential of $6 (RT/F)$ or $\alpha\Theta = 6$. b: identical to a but recorded on a time axis. c: charge potential diagram recorded simultaneously with a and b.

charge decreases from point b to c. For a very short time after c, the decrease continues corresponding to that interval during the second sweep that the current is anodic. At point d, the current becomes cathodic, and the cathodic charge starts increasing again. The general features of the charge-potential diagram are retained as the number of applied sweeps is increased. However, relative magnitudes change, and the quantitative aspects of this change will be discussed below.

Peak potentials.—The overpotential at which the cathodic current maximum is observed is predicted (3) to be equal to $0.854 (RT/nF) = 0.022V$ for $l = 0$ ($T = 25^\circ C$, $n = 1$) and increases (2) to at most $1.3 (RT/nF) = 0.033V$ upon multiple sweeping; it is independent of the sweep rate, diffusivity, and bulk concentration for reversible depositions at unit deposit activity. These predictions were verified to within 0.003V.

Cathodic current maxima.—The theoretical analysis predicts cathodic current maxima given by the relations (2)

$$i_{c,max}^l [(at_c)_{max}^l; a\theta] = A c^b v^{1/2} I_{c,max}^l [(at_c)_{max}^l; a\theta] \quad [1]$$

$$\text{and } A = (nF)^{3/2} (RT)^{-1/2} D^{1/2}$$

where l is the number of already applied complete sweeps, v the dimensional sweep rate, c^b the bulk concentration of Ag^+ , $a = (nF/RT)v$, $(at_c)_{max}^l$ is the dimensionless peak overpotential in multiples of RT/nF , θ the time duration of each anodic or cathodic part of the sweep, and $a\theta$ is the dimensionless reversal overpotential in multiples of RT/nF . $I_{c,max}^l$ is the maximum value within a sweep of the cathodic current-density function, the values of which can be computed from the equations given in Ref. (2).

Experiments were performed at three cathodic reversal overpotentials: 0.104, 0.155, and 0.411V, corresponding to $a\theta = 4, 6$, and 16, respectively. The anodic reversal potential was always at the equilibrium value. Values of the current function necessary for the calculations are given in Table I. Plots of $i_{c,max}^l$ vs. $v^{1/2}$ are shown in Fig. 3. The solid lines in these figures correspond to the theoretical predictions of Eq. [1] and agree very well with the experimental data. Since this is the case, a value for D_{Ag^+} can be extracted from the multisweep CV data and Eq. [1], as was done by Bachmann and Dohrmann (6) using the Delahay model (3) predictions for LSV ($l = 0$). The value extracted from the CV data was $1.4 (2) \times 10^{-5} \text{ cm}^2\text{s}^{-1}$, which is also consistent with the value calculated from the RDE limiting current measurements to be described.

The value of the potential at which the sweep is reversed is immaterial for the current maximum during the first sweep ($l = 0$). However, it significantly affects its magnitude during subsequent sweeps. As $a\theta$ increases, the height of the second ($l = 1$) maximum decreases. Furthermore, the differences between sweeps for $l > 1$ decrease with increasing $a\theta$. This is in agreement with the computational observation (2) that in the limit $a\theta \rightarrow \infty$, the

* Independent of $a\theta$; computed in Ref. (3).

current becomes periodic. It is interesting to note that even after ten sweeps the cathodic current density maxima computed on the basis of the geometrical area of the electrode are still described by Eq. [1].

Anodic current maxima.—Anodic current maxima are the anodic currents measured at the end of the l th anodic or the beginning of the $l + 1$ cathodic sweep, i.e., they are the currents measured at the equilibrium potential for $l > 0$. They are described by an equation identical to Eq. [1], the only difference being in the values of the current function

$$i_{a,max}^l = A c^b v^{1/2} I_{a,max}^l \quad [2]$$

$I_{a,max}^l$ values relevant to the experimental conditions of the present study are given in Table I. Figure 4 shows a comparison between the predictions of Eq. [2] (solid lines) and the experimental points.

It is observed that the measured currents are lower than those predicted by Eq. [2]; the deviations are more pronounced at the higher sweep rates and the lower values of $a\theta$. Such deviations would be expected from a small iR effect since the current variation near the equilibrium potential is very steep and it becomes steeper the faster the sweep rate and the smaller the $a\theta$ value. An alternative effect with a similar pattern of deviation with sweep rate, and $a\theta$ can be thought of as arising from finite kinetics of the dissolution reaction. However, no additional evidence of kinetic limitations was observed. It should be noted that anodic current deviations are not expected to propagate with l since they occur over very short time intervals. Maximum anodic currents do not exhibit a strong dependence on either the number of cycles or the reversal potential. Generally, they increase with l and $a\theta$, and this behavior is not difficult to rationalize in terms of the computed concentration profiles (1).

¹Equivalently, $I_e^{l+1}(0; a\theta)$.

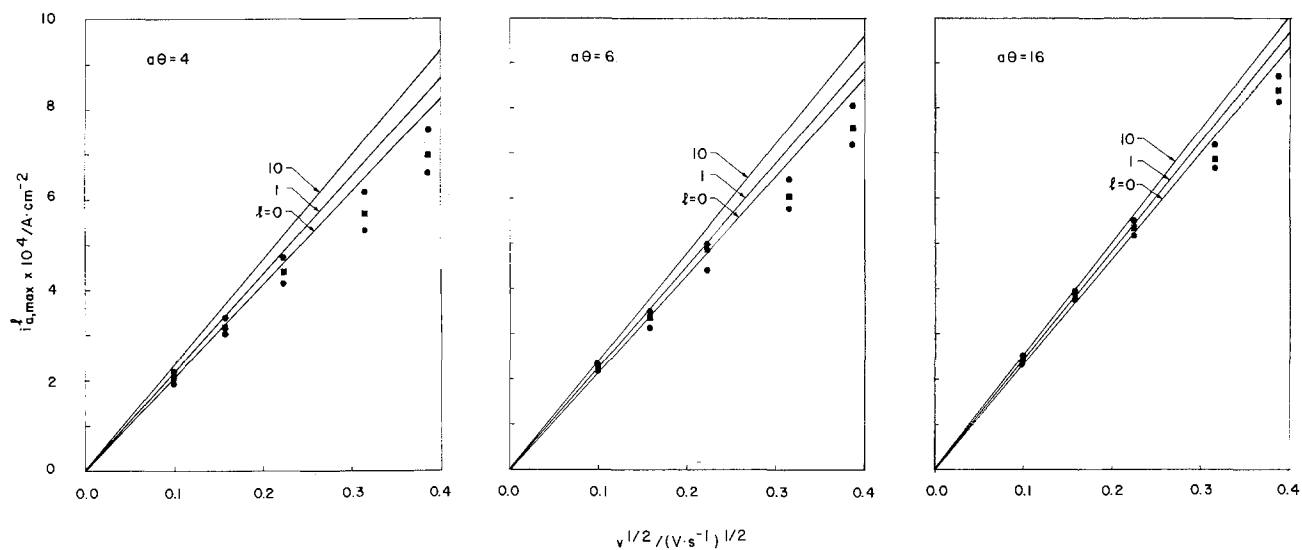

Fig. 4. Dependence of the maximum anodic current on the square root of sweep rate, the number of applied sweeps, and reversal overpotential. Solid lines are predictions of Eq. [2] (stationary electrode cyclic voltammetry).

Cathodic charges.—Integral cathodic charges as functions of l and $\alpha\theta$ are shown in Fig. 5 and 6. In Fig. 5, the quantity q_c is the amount of charge accumulated during the $l + 1$ cathodic sweep; its value can be read off easily from a charge/potential diagram such as the one appearing in Fig. 2c. For instance, for $l = 0$, q_c^0 is the value at point a; for $l = 1$, q_c^1 , i.e., the charge during the second cathodic sweep, is the difference between points e and c; for $l = 2$, q_c^2 is the difference between points g and f, and so on.

Charge has a linear dependence on the inverse of the square root of the sweep rate (2) as shown by

$$q_c^l(\alpha\theta) = Bc^b v^{-1/2} Q_c^l(\alpha\theta) \quad [3]$$

and $B = (nFRTD)^{1/2}$

where Q_c^l is the charge density function, values of which are given in Table I, computed from the equations of Ref. (2). Good agreement between Eq. [3] and experiment can be seen in Fig. 5, except in the case for $\alpha\theta = 16$ and $l > 0$ in the low sweep-rate range. The charge deviations under these conditions are not accounted for by the anodic current deviations in Fig. 4. Although one would expect that lower measured anodic currents would yield higher cathodic charges, the time duration over which these lower anodic currents are measured is too small to account for the deviations appearing in Fig. 5. We attribute these deviations to a roughness effect. Although it may not affect the value of the current density at any given potential, its effect is enhanced when one integrates over the entire current curve. This explanation is consistent with deviations appearing at conditions that produce high total change, e.g., low sweep rates, high reversal potentials, and values of l greater than 0.

As can be seen from Fig. 5, the amount of deposit accumulated even after multiple potential sweeps is very small. Assuming that the formation of a Ag monolayer requires $2 \times 10^{-4} \text{ C cm}^{-2}$, it is seen that the largest value ($\alpha\theta = 16$, $v = 0.010 \text{ Vs}^{-1}$) measured on the first sweep corresponds to about 15 monolayers. During the reverse sweep, the charge remains almost constant (e.g., points a and d on Fig. 2c) and increases by about ten more monolayers during the second cathodic sweep ($l = 1$). Although the net amount is only of the order of the order of 20 monolayers, a roughness effect is detectable from the deviations of the charge from that predicted by the theory. It should be noted that if the roughness originated from preplating, it should manifest itself during the $l = 0$ sweep; however, the $l = 0$ results agree with Eq. [3], in which the geometrical area of the electrode has been used.

A plot of the dimensionless net charge density function, Q_n^l , is shown in Fig. 6. Theoretical predictions (2) are given in Table I, whereas experimental values are obtained from

$$Q_n^l(\alpha\theta) = q_n^l(\alpha\theta)/Bc^b v^{-1/2} \quad [4]$$

where q_n^l is the value of the charge at the equilibrium potential. For instance, with reference to Fig. 2c, q_n^0 corresponds to point c, q_n^1 to the difference between points f and c, and so on. Q_n^l depends only on l and $\alpha\theta$, and not on the sweep rate. Therefore, for fixed l and $\alpha\theta$, q_n^l should be the same, irrespective of which pair of q_n^l and v values is used. Results in Fig. 6 have been computed for $v = 0.150 \text{ Vs}^{-1}$ and the corresponding q_n^l values; however, if data for 0.010 Vs^{-1} were used, the deviations observed for $\alpha\theta = 16$ and $l = 1, 2$ appear in Q_n^l as values higher than the ones obtained for $v = 0.150 \text{ Vs}^{-1}$.

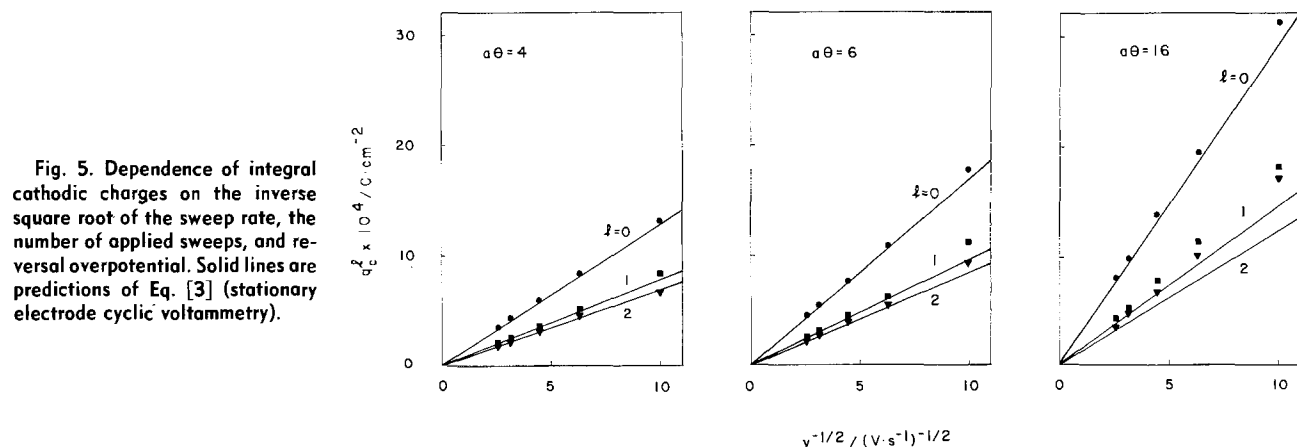

Fig. 5. Dependence of integral cathodic charges on the inverse square root of the sweep rate, the number of applied sweeps, and reversal overpotential. Solid lines are predictions of Eq. [3] (stationary electrode cyclic voltammetry).

Fig. 6. Dependence of the net charge density function on reversal overpotential. Solid lines are theoretical predictions and points are experimental results correlated by Eq. [4] (stationary electrode cyclic voltammetry).

Figure 6 indicates that potential sweeping from the equilibrium to some reversal value and back always results in the formation of a net deposit on the surface. The amount is maximum for the first sweep, but decreases considerably upon multiple sweeping. In the limit $l \rightarrow \infty$, the hypothetical charge density during the complete sweep is predicted (2) to be 0, and this trend appears in Fig. 6.

Cyclic voltammetry on a rotating-disk electrode.—Experiments were performed at two rotation speeds, 80 and 400 rpm, and at sweep rates varying from 0.050 to 10 Vs^{-1} , corresponding to a variation in the dimensionless sweep rate, σ ; between 5 and 215. Double layer currents were corrected for with a constant value of $50 \mu\text{f cm}^{-2}$ measured by the method of Bachmann and Dohrmann (6). Since the double layer capacitance is a potential-dependent quantity, errors are introduced especially at sweep rates higher than 2Vs^{-1} , at which double layer currents are a significant portion of the measured total.

A representative RDE voltammogram appears in Fig. 7a, obtained at 0.1Vs^{-1} and a rotation speed of 80 rpm. The value of the dimensionless sweep rate

$$\sigma = \frac{nF}{RT} v \frac{\delta^2}{D} \quad [5]$$

(where δ is the thickness of the Nernst diffusion layer computed from the Levich theory) is ca. 11 at this sweep rate and rotation speed. Since $\sigma > 3$, a peak of magnitude $i_{c,\text{max}}^0$ should appear on the first sweep (1, 4), as was observed. For $\sigma > 4$, this peak is the same as if the electrode were stationary. If ω is increased to 400 rpm, the $\sigma > 3$ condition is not satisfied and no current peak should appear; such a peak was not observed when ω was increased to 400 rpm. The sweep in Fig. 7a was reversed at an overpotential of 0.300V , where a limiting current was observed. Since the characteristic time of the RDE, δ^2/D , was approximately 2.8s and the duration, Θ , of each sweep 3s, the periodicity criterion (1) requiring $\Theta > \delta^2/D$ was strictly satisfied. It is then expected (1) that the current response during the second cathodic sweep be periodic, i.e., not change during multiple sweeping. This behavior is confirmed in Fig. 7a; the height of the periodic cathodic current maximum, $i_{c,\text{max}}$, is lower than $i_{c,\text{max}}^0$ and does not change upon multiple sweeping.² Similarly, the magnitude of the anodic current, i_a , at the foot of the wave is always constant, provided that the periodicity criterion is satisfied. It should be noted here that it is not always possible to meet the periodicity requirement exactly. For

²Errors arising from double layer capacitance corrections are more significant in the value of the periodic current maximum, since $i_{c,\text{max}} < i_{c,\text{max}}^0$, and their difference increases with increasing σ .

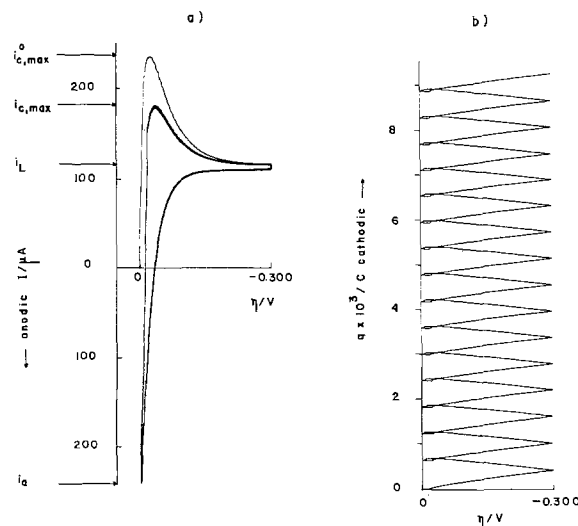

Fig. 7. Cyclic voltammetry of Ag deposition on a rotating disk electrode. a: multisweep current/potential diagram obtained at 0.100Vs^{-1} and $\omega = 80 \text{rpm}$ showing the first sweep and periodic current responses. b: charge/potential diagram recorded simultaneously with a.

instance, with a characteristic time of 2.8s (80 rpm) and a sweep rate of 1Vs^{-1} , 2.8V of potential range are required. However, even for $\Theta > 0.1 (\delta^2/D)$ the deviation of the current from that for the exact periodic state is not experimentally significant, as was confirmed by the observed voltammetry.

Figure 7b is the charge/potential diagram corresponding to the RDE voltammogram of Fig. 7a. Due to the electrode rotation, more deposit is accumulated on the RDE than on the stationary electrode at the same conditions. The amount of deposit, and equivalent charge, is mostly defined by Θ and the limiting current, i_L . Since the electrode current is near i_L for most of the time, and since the excess cathodic charge in the cathodic current peak is partially counterbalanced by the anodic charge near the equilibrium potential, the charge/potential diagrams have a much simpler (nearly linear) appearance than the stationary electrode diagrams (Fig. 2c).

LSV current functions are related to σ by (1, 4)

$$J_{c,\text{max}} = \frac{i_{c,\text{max}}^0}{i_L} = 0.61 \sigma^{1/2}, \sigma > 4 \quad [6]$$

It should be noted that an experimental investigation of Eq. [6] does not require knowledge of the bulk concentration of the reactant or the electrode area as long as it remains constant during the performance of the experiment. Due to the dimensionless nature of Eq. [5], it is possible that different combinations of rotation speed and sweep rate yield the same value of σ . However, the measured peak currents when normalized with respect to the appropriate i_L , should yield the same J . This was, in fact, observed, as shown by the results of Fig. 8.

The periodic current maxima correlation (1)

$$J_{c,\text{max}} = \frac{i_{c,\text{max}}}{i_L} = 0.88 \sigma^{0.251}, \sigma > 9 \quad [7]$$

is seen (Fig. 9) to agree well with the experimental data. Again $J_{c,\text{max}}$ is independent of electrode area and reactant bulk concentration. In addition, its value for a particular δ does not depend on the particular combination of ω and v that gives rise to this value of σ . The dependence of $J_{c,\text{max}}$ on σ is weak and requires a large range of sweep rates for its experimental determination. However, if low rotation speeds are used, this is not a significant disadvantage. At low rotation speeds, a periodic state is established, unlike the l dependence of a stationary electrode response, and can be retained for longer times since deposit accumulation is also lower.

Figure 10 shows the dependence of the periodic dimensionless anodic current function maximum on σ , which is

Fig. 8. Dependence of the first sweep cathodic current maximum on the dimensionless sweep rate. Solid line is the prediction of Eq. [6] (RDE cyclic voltammetry).

Fig. 9. Dependence of the periodic cathodic current maximum on the dimensionless sweep rate. Solid line is the prediction of Eq. [7] (RDE cyclic voltammetry).

predicted (1) to be

$$J_a = \frac{i_a}{i_L} = 1 - \sigma^{1/2}, \sigma > 9 \quad [8]$$

The experimental observations deviate from the predictions of Eq. [8] in a manner analogous to the i_a for the stationary electrode. The deviation is higher at the higher rotation speed, and this is consistent with an iR effect, since at higher rotation speeds anodic current variations are steeper near the equilibrium potential.

Limiting current measurements.—Limiting currents were measured potentiodynamically in the rotation speed range 100–6400 rpm and were found to depend linearly on $\omega^{1/2}$ with zero intercept. Based on the geometrical area of the electrode, the extracted value for D_{Ag^+} was $1.4 (2) \times 10^{-5} \text{ cm}^2\text{s}^{-1}$, in excellent agreement with the one reported by Bachmann and Dohrmann (6), and consistent with the value obtained from the CV data analysis above.

The possible errors associated with the determination of limiting currents by potential sweeping have been the subject of some discussion in the literature (11). It is believed that if the sweep rate is very high the resulting mass-transfer situation is transient and does not yield an accurate measurement of mass-transfer coefficients in

Fig. 10. Dependence of the periodic anodic current maximum on the dimensionless sweep rate. Solid line is the prediction of Eq. [8] (RDE cyclic voltammetry).

the steady state. However, if the sweep rate is very low, and the reaction under study is electrodeposition, the onset of surface roughness with characteristic size similar to the diffusion layer thickness may also yield an erroneous limiting current measurement.

The fact that the potentiodynamically measured limiting currents yielded a value of D_{Ag^+} that is consistent with other literature indicates these objections to the potentiodynamic method require qualification. The more serious limitation is related to the control of the total amount of deposit during the time period required for limiting current measurements. Potentiodynamically, the amount of deposit is not controlled directly, but indirectly by choice of rotation speed and sweep rate. The choice of these two parameters must be made judiciously to obtain true limiting current measurements that are relatively unaffected by surface roughness. For the combination of rotation speed and sweep rate such that $\sigma > 3$, as in Fig. 7, the limiting current can be measured with the deposition of less than $1 \text{ mC} \cdot \text{cm}^{-2}$. There may be circumstances where i_L measurement using $\sigma > 3$ is not possible, due to very high sweep rates or to insufficient potential range (competing reactions). However, when $\sigma > 3$, and for reactions which are not kinetically limited, the current increases more sharply to i_L (1), so that the measurement can be made in a narrower potential region, but the quantity of deposit will be much larger, and the possibility of roughness effects much greater. Roughness effects were clearly evident for some combinations of rotation rate and sweep rate, as shown in Fig. 11.

For very low values of the sweep rate (0.002 and 0.005 Vs^{-1} , Fig. 11) there appear to be well-defined conditions at which the current increases beyond the i_L value. Since the electrode potential is such that no other reactions besides Ag deposition can occur, this increase must be attributed to an increase of the effective surface area of the electrode through the formation of irregularities of characteristic dimension comparable to the thickness of the diffusion layer. It is also possible that these irregularities once formed may further enhance mass transfer through their effect on the hydrodynamics of the system. Table II shows results obtained at different sweep rates and rotation speeds for the potential and the integral charge at which the measured current becomes greater than the limiting current. Several features of these results should be noted: at the same rotation speed, less deposit and more overpotential is required at increasing sweep rates; at the same sweep rate, the critical over-potential in-

Fig. 11. Potentiodynamic limiting current determination at 1600 rpm and 0.025 Vs⁻¹ (curve 1), 0.005 Vs⁻¹ (curve 2), and 0.002 Vs⁻¹ (curve 3).

creases with increasing rotation speed; assuming uniform deposition, the height of the deposit at the onset is at least 100 times smaller than the boundary layer thickness.

It should be noted also that the characteristic amounts of Ag deposited in Table II are approximately 10-100 times greater than in the other CV curves which were used to test the RDE theory. Collectively, these observations indicate that the irregularities are confined to a very small (e.g., 1%) fraction of the total surface, possibly at the very edge of the disk. We do not, however, offer a definitive physical interpretation of the surface roughness.

Conclusions

An experimental investigation of Ag deposition by multisweep cyclic voltammetry has shown excellent agreement between experiment and a model assuming reversible kinetics at unit activity of the deposit. The anodic reversal potential was set to equal the equilibrium potential of the electrode, while sweep rate, number of applied sweeps, and cathodic reversal potential were treated as parameters.

For the stationary electrode, cathodic current maxima (peaks) were observed that continuously decreased in magnitude with increasing number of applied sweeps, while the peak potential shifted in the cathodic direction. Peak heights were a linear function of the square root of the sweep rate with slopes which depend on the value of the current function at a given cathodic reversal potential as well as on the diffusion coefficient of the ion, its bulk concentration, and the area of the electrode. Although each complete sweep results in the formation of a net deposit, the electrode geometrical or projected area could be

used to compute current densities at millimolar concentrations even after the application of ten complete sweeps at 0.010 Vs⁻¹ extending for 0.411V in the cathodic potential region. The integral charges associated with each potential sweep on the stationary electrode followed a linear dependence on the inverse of the square root of the sweep rate. As the number of applied sweeps increases, less deposit is formed during a cathodic sweep. However, even at deposit thicknesses of the order of 20 monolayers, a surface roughness effect was observed as a deviation of the measured charge density from the value computed on the basis of the geometrical area of the electrode.

Cyclic voltammetry experiments performed on the RDE verified the prediction that a periodic current response is obtained during the second and subsequent potential sweeps. In addition, current maxima were obtained when the dimensionless sweep rate exceeded 3, in agreement with theoretical predictions.

When the magnitudes of the cathodic current maxima were normalized with respect to the limiting current at a particular rotation speed, the resulting dimensionless quantity was correlated to the dimensionless sweep rate. For $\sigma > 9$, the periodic dimensionless current was shown to vary linearly with $\sigma^{1/4}$. It was concluded that cyclic voltammetry on the RDE should be performed at low rotation speeds to avoid excessive deposit accumulation and the need for high sweep rates. At these rotation speeds, the limiting current as well as the first and periodic current maxima are well defined, and the RDE correlations can be subsequently used for diagnostic purposes without accurate knowledge of the value of the electrode surface area or the bulk concentration of the reacting species.

In correlating cyclic voltammetry data for both stationary and rotating-disk electrodes, knowledge of the diffusion coefficient of the reacting ion is required. In this investigation a diffusivity value for D_{Ag^+} was obtained by RDE potentiodynamic limiting current measurements. At moderate sweep rates, a limiting current plateau was obtained which was accurately described by the Levich equation. However, at much lower sweep rates, nonuniform deposit accumulation caused the limiting current to increase above its previously determined value. In order to avoid surface roughness and transient effects and also in order to maximize the potential range over which the limiting current is observed, it is concluded that the optimal value of the sweep rate is the one just before the appearance of the cyclic voltammetry current peak. For reversible deposition reactions, this value can be found from the requirement that the dimensionless sweep rate be equal to 3.

Sulfur Chemistry in Equimolar NaOH-H₂O Melt

I. Electrochemical Oxidation of Sodium Sulfide

M. N. Moscardo-Levelut and V. Plichon

Laboratoire de Chimie Analytique des Milieux Réactionnels, ESPCI, 75231 Paris Cedex 05, France

ABSTRACT

Both anodic steps of sulfide oxidation at a gold electrode have been studied in the equimolar NaOH-H₂O melt at 100° and 140°C by voltammetric techniques and electrolysis associated with UV spectrophotometry. The first step leads to S₂²⁻, S₃²⁻, and molecular sulfur following the time scale of the techniques, and the second one to sulfite anion. The influence of temperature is discussed. Application to analytical characteristics of polysulfides is given. The most interesting feature is the distinction between di- and tri-sulfide with the help of their anodic waves and UV spectrum.

This and the following paper are devoted to the study of the sulfur compounds from sulfur disproportionation in strongly basic media. This reaction plays an important role in the utilization of this abundant raw material because it leads to polysulfides, which are used as intermediates in organic or inorganic synthesis (1). This disproportionation reaction is quite complex and is not rigorously controlled, partly because of a lack of convenient analytical tools. Better control could be expected via the spectrophotometric or the electrochemical properties of the relevant species, but a survey of the literature (2) reveals a lack of knowledge about the nature and the properties of the ions, which must be considered in the strongly alkaline and high temperature conditions in which the reaction generally starts (liquid sulfur with sodium hydroxide at temperatures above 120°C).

In view of these arguments, we investigated the electrochemical and UV behavior of the various species from the sulfur disproportionation, *i.e.*, sulfide, polysulfides, and sulfur oxyanions in the equimolar melt NaOH-H₂O at temperatures between 100° and 140°C. Relevant properties of water-NaOH mixtures have been studied and reviewed largely by Tremillion *et al.* (3). These melts are ionic liquids and transparent in the near-UV down to 310 nm. Their acidity is characterized by the pH₂O or by the related pHO⁻ or pO²⁻ function. But except around the pure components composition, the pH₂O is quite buffered in a given melt, depending on the H₂O/HO⁻ ratio, so that the pH₂O need not be regarded as an important parameter in the equimolar melt, contrary to the analogue pH in water. On the other hand, the potential can be varied over a wide range, allowing use of electrochemical techniques. The melting temperature of the equimolar melt is 64.5°C (4, 5).

This first paper deals with the electrochemical oxidation of sodium sulfide. Only a few works in the literature are concerned with strongly basic solutions. The first electrochemical studies date from the beginning of this century. Among them, we can mention Fetzner's (6) works in 4M sodium hydroxide. This author has shown by controlled current electrolysis that oxidation of concentrated sulfide solutions leads at low current density to polysulfides, and at high density to sulfate and dithionate.

By controlled potential electrolysis, Bohnholtzer and Heinrich (7) distinguished sulfur formation and its dissolution into polysulfides, then, at a more oxidizing potential, the formation of sulfate and dithionate. For his part, Gerischer (8) showed that the predominant species are in

turn polysulfide, thiosulfate, and sulfate. Allen and Hickling (9), studying the mechanism and the kinetics of the oxidation, concluded that the first oxidation step of sulfide ion in 1M NaOH solution on platinum or gold electrode leads to polysulfides.

Redox potentials of polysulfides have been calculated (10) or measured (9, 11, 12) in weakly alkaline conditions. Though severe discrepancies exist in the values, the redox potentials of polysulfides fall within very narrow limits in water; thus when they exist, they will be necessarily present simultaneously.

As all these results were obtained in solutions not concentrated enough in NaOH to be extrapolated to the equimolar melt, we undertook investigations on the electrochemical oxidation of sulfide by means of steady-state voltammetry, cyclic voltammetry, chronoamperometry, and controlled potential coulometry.

Experimental

Cells.—Two kinds of materials were used, Pyrex for experiments at 100°C, and Teflon at 140°C. Unexpected absence of corrosion of Pyrex and quartz at 100°C allowed us to use a conventional Pyrex cell with five exits and a thermostated jacket. The cell remains unattacked during more than one year. At 140°C, attack was fast, and a Teflon cell, similar to the conventional Pyrex one, was used. Silicone oil was circulated inside the jacket in order to control the temperature at ±1°C.

Spectrophotometric measurements could be performed only at 100°C because of the attack of silica at higher temperatures. The Pyrex electrochemical cell was for this purpose supplied with two horizontal grindings, through which ran two silica optic fibers with polished faces. Both fibers were directly dipped into the melt, with no protection, and no attack occurred. The optical path was the distance between both polished plane ends of the lined-up fibers (generally 0.315 cm measured by a calibrated wedge clock).

Electrodes.—The working electrode was either a gold disk electrode ($\phi = 0.5$ or 1.0 mm) sealed into Pyrex glass or Teflon according to the temperature, or a cylindrical gold gauze for electrolysis.

All potentials are referred to the system Ag/Ag(I) saturated with Ag₂O (13). We checked its reversibility and its stability in our melt. The reference electrode was a silver wire dipped into the melt saturated with Ag₂O contained in a compartment made either of a Pyrex tube thinned at one end or of porous Teflon to ensure sufficient electrical junction. For cyclic voltammetry and step chronoamperometry, a Pt wire was used as quasireference electrode because the impedance of the thinned tube was

much too high for fast experiments (14). The auxiliary electrode was a platinum wire separated from the bulk of the melt by a glass frit or a Nafion membrane (du Pont) mounted in a Teflon cylindrical holder. The glass frit, of medium porosity, was slightly attacked by the melt and had to be changed often.

Instrumentation.—Electrochemical instrumentation was standard and entirely commercial (Tacussel). The spectrophotometer was an apparatus running in single-beam mode. The light beam issued from a xenon arc (XBO 75W Osram) associated to a monochromator (H 20 Jobin-Yvon) and was focused on the first quartz fiber (Quartex) which dipped into the solution. The light beam went through the solution and was sent with another quartz fiber exactly aligned on the first one to a photomultiplier (R 212 Hamamatsu), which detected the transmitted light. Normalization of the signal, *i.e.*, correction of the signal for variation of the incident flux of the PM response with wavelength was achieved by point-to-point division of the signal by a reference one. Stability with time of the light flux was frequently checked during experiments by measuring the signal at a wavelength where sulfur compounds do not absorb.

Reagents.—All reagents were Prolabo quality RP Normapur used without further purification. Hygroscopic Na₂S 9H₂O was periodically titrated by standard procedures. Nitrogen employed to maintain an inert atmosphere above the melt was saturated with H₂O by a bubbler which contained water at the same vapor pressure as the 1.1 melt.

Results and Discussion

Current-voltage curves of sulfide oxidation at a gold electrode are shown in Fig. 1 for voltammetry at a rotating electrode, in Fig. 2 for potential step chronoamperometry, and in Fig. 3 for cyclic voltammetry. They show that oxidation of Na₂S occurs in two main steps for

$2e^-/S^{2-}$ would result in the unrealistic value of more than $6e^-/S^{2-}$ for the second wave, according to their relative height. Confirmation was carried on by controlled-potential electrolysis on the first plateau (less than $2e^-/S^{2-}$, see below). But, polysulfides or sulfur could not be ruled out, since their occurrence is now well established in molten salts. Before we investigate this problem in more detail, we shall first comment on the nature of the polysulfides which exist in the 1-1 melt, the di- and tri-sulfide S_2^{2-} and S_3^{2-} . The two classic ways of polysulfide preparation in a basic medium are addition of S_8 to a sulfide solution and S_8 disproportionation. Very simple experiments show that, depending on the method, two different polysulfides, both yellow colored, are obtained in this melt: (i) for case a, by addition of sulfur to sulfide in excess, a UV peak appears at $\lambda_{max} = 365 nm$, i.e., with higher absorption at 365 nm than at any other wavelength, for instance, the arbitrarily chosen value $\lambda = 330 nm$ ($A_{365} > A_{330}$). The first oxidation wave of S^{2-} does not decrease with S addition, which means that the obtained S_x^{2-} is electro-oxidizable at the same potential as S^{2-} . (ii) For case b, by disproportionation of S_8 in a sulfide-free melt, a UV band appears, but with $A_{365} < A_{330}$. No oxidation wave corresponding to the first wave of S^{2-} is observed, which indicates that this polysulfide is not electro-oxidizable in that potential range.

In both cases, a reduction wave of polysulfides appears roughly at the same potential. Since the well-known stability order of polysulfides is (15, 16) in basic media $S_2^{2-} > S_3^{2-} > S_4^{2-}$, etc., the simplest and most logical assignment is the following. In presence of S^{2-} in excess (case a), the less sulfur containing species is obtained, i.e., S_2^{2-} . The wavelength of its maximum absorption agrees with the published value for S_2^{2-} (16). In the disproportionation case b, the polysulfide which follows in the stability order, that is, S_3^{2-} , can be assumed. This assignment has been proved by electrolysis experiments, described in the next paragraph. In these experiments, a polysulfide with the same characteristics ($A_{365} < A_{330}$, no oxidation wave at the potential of the first S^{2-} wave) is obtained for $1.23e^-/S^{2-}$ to be compared to 1.0 for S_2^{2-} , 1.33 for S_3^{2-} , and 1.5 for S_4^{2-} .

Details of the electrochemical and spectrophotometric properties of these polysulfides are reported in the last paragraph. No other polysulfide has been detected, and the distinction between S_2^{2-} and S_3^{2-} can be clearly achieved via criteria a and b mentioned above.

First Oxidation Step

Main features of the wave.—Wave and peak were analyzed according to the usual procedure. Linear plots of the wave height or of the peak current vs. the square root of the electrode rotation speed or of the potential sweep rate indicate a process limited by the sulfide diffusion. The diffusion coefficient D of the sulfide ion has been deduced from chronoamperometry measurements on the plateau of the wave. On the time scale of experiments (1s-10 ms), linear decrease of current vs. $t^{-1/2}$ is observed according to Cottrell's equation valid on the diffusion plateau whatever the reversibility of the process (17)

$$D = \frac{i^2 \pi t}{(n FAC)^2}$$

where n , F , A , and C are the number of electrons, the Faraday constant, the electrode area, and the sulfide concentration, respectively. At $100^\circ C$, we obtain a value of D equal to $4.3 \cdot 10^{-6} cm^2 s^{-1}$, assuming a value of $n = 4/3$ (see below). This low value can be explained by the high viscosity (18) of the medium ($\eta = 8 cP$).

Wave analysis gives straight lines of E vs. $\log i/(i_1 - i)$ plot with a slope of 90 mV. Compared to a slope of 74 mV for a one-electron reversible system at $100^\circ C$, the electrode reaction appears to be irreversible, in agreement with the large anodic and cathodic peak separation observed in cyclic voltammetry (Fig. 3).

Controlled potential electrolysis.—Controlled potential electrolysis of Na_2S at a cylindrical gauze electrode has been performed on the plateau of the first oxidation step of sulfide [$-0.5V$ vs. $Ag/Ag(I)$]. The yellow color developed meanwhile provides obvious evidence of the formation of polysulfides during the electrolysis, and their appearance has been followed by simultaneous recording at regular periods of their UV spectrum (Fig. 4) and their voltammetric waves at a rotating gold electrode (Fig. 5).

If the oxidation process was a simple one: $Red \rightarrow Ox$, the electrolysis current I should vary as the concentration of Red, i.e., in inverse proportion to the number F/S^{2-} of Faraday exchanged per mole of sulfide (linear plot of I vs. F/S^{2-}), and the absorbance should increase in direct proportion to F/S^{2-} whatever the wavelength in the absorption band of Ox. The break observed for 1.3 F/S^{2-} and the discrepancies between the curve A_{365} and A_{330} vs. the number of Faraday per mol of sulfide (Fig. 6) show that the oxidation of sulfide cannot be assigned to a simple reaction. Three main parts must be considered in the course of the electrolysis.

First part: $F/S^{2-} < 0.5$.—During this first part, A_{365} increases at a higher rate than A_{330} , which indicates the prevailing formation of S_2^{2-}

Fig. 4. UV spectra recorded during the electrolysis at $E = -0.5V$ of a $9.1 \cdot 10^{-3} M S^{2-}$ solution in $NaOH-H_2O$ (1-1) melt at $100^\circ C$. Number of Faradays per sulfide mole are indicated on each curve. Optic path: 0.315 cm.

Fig. 5. Voltammetric curves at a rotating gold electrode ($S = 0.20 \text{ mm}^2$) recorded during the electrolysis at $E = -0.5 \text{ V}$ of a $9.2 \cdot 10^{-3} \text{ M S}^{2-}$ solution in NaOH-H₂O (1-1) melt at 100°C . Number of Faradays per sulfide mole is indicated on each curve.

This reaction is not quantitative as shown by the non-linear increase above 0.2 F/S^{2-} of the absorption at 365 nm and by the maximum value of 0.8 F/S^{2-} instead of 1 required for complete oxidation. Above 0.2 F/S^{2-} , the less absorbing trisulfide S_3^{2-} must begin to appear, though there is no clear proof. This short range does not allow any significant extrapolation to zero of the electrolysis current to get the number of exchanged electrons and make a distinction between S_2^{2-} and S_3^{2-} .

Though S_2^{2-} has the same first anodic wave as S^{2-} , the limiting current of the first wave decreases (Fig. 5) because two sulfides lead to only one S_2^{2-} , which involves a 50% decrease in concentration of electroactive species.

Second part: $0.5 < \text{F/S}^{2-} < 1.3$.—If electrolysis is carried out beyond 0.5 F/S^{2-} , the remaining sulfide and the disulfide which is electro-oxidizable at the same potential as sulfide are oxidized into trisulfide, as shown by the lower increase rate, or even decrease above 0.8 F/S^{2-} , of A_{365} compared to A_{330}

Both sulfides clearly coexist during a certain time, but the presence of S_3^{2-} becomes obvious at $\text{F/S}^{2-} > 1$, since $A_{330} > A_{365}$ and the current of the anodic first wave falls to a small value. Extrapolation of the electrolysis current indicates that it would be zero for consumption of $1.23 \pm 0.05 \text{ F/S}^{2-}$ at 100° and 140°C . Compared to the theoretical values of 1 needed for oxidation of S^{2-} into S_2^{2-} , 1.33 into S_3^{2-} , and 1.5 into S_4^{2-} , this experimental value attests the formation of the trisulfide and not the tetrasulfide S_4^{2-} . This result shows also that S_3^{2-} cannot be produced by disproportionation of sulfur obtained as a transitory species in the mechanism described below because, in that case, extrapolation to zero current would lead to a value of 2 F/S^{2-} .

Third part: $\text{F/S}^{2-} > 1.3$.—It is fundamental to realize that the time scale of the last part of the electrolysis is widely different: hours instead of 40 min (see time axis of Fig. 6). During this period, one observes the simultaneous disappearance of the yellow color, of the UV band, and of the anodic and cathodic voltammetric curves. These concordant observations mean that the trisulfide ion disappears via a process which is too slow to be mass-transport limited. We supposed that S_3^{2-} is unstable and slowly disproportionates into an oxyanion $\text{S}_x\text{O}_y^{2-}$ and an electroactive species S^{2-} or S_2^{2-} , which is again oxidized in S_3^{2-} . The hypothesis explains the slow decrease of the electrolysis current (Fig. 6). Because of the low value of the current and of the long time required for the electrolysis, no significant extrapolation of the I - F plot of Fig. 6 could be performed to gain information on the disproportionation reaction. Electrolysis must end when sulfide and polysulfide are completely changed into a more stable oxyanion.

Evolution of the anodic and cathodic limiting current at the rotating gold electrode recorded during the elec-

Fig. 6. Variations of A_{330} , A_{365} , and I (electrolysis current) during the electrolysis of sulfide on the first plateau. Experimental conditions same as Fig. 4 and 5.

trolysis (Fig. 5) agrees qualitatively with the appearance of polysulfides. Nevertheless, quantitative analysis did not allow a clear distinction between the di- and trisulfide formation (19).

We can sum up the first step of Na_2S electrolysis with the following scheme

$n > 4/3 \text{ F/mol Na}_2\text{S}$: slow disproportionation of S_3^{2-}

Number of electrons involved at voltammetric time scale.— In the classic scheme of formation of polysulfides via an EC mechanism, molecular sulfur is supposed to be first obtained

We shall now consider which compound among the possible S_2^{2-} , S_3^{2-} , or S and species is obtained at the time scale of voltammetric experiments, widely different from the time scale of controlled-potential electrolysis.

A distinction between insoluble molecular sulfur and soluble polysulfides was achieved via cyclic voltammetry experiments. At medium sweep rate ($v < 2 \text{ V s}^{-1}$), Fig. 3 shows the reduction peak associated with the first oxidation peak. Both its diffusive shape [linear i_p vs. $v^{1/2}$ plot, slow decrease to zero instead of the sharp fall observed when reduction of sulfur deposit occurs as, for example, in $\text{PbCl}_2\text{-KCl}$ melt (20)] and its potential (the same as the reduction potential of a polysulfide solution prepared by disproportionation of sulfur into the melt) ruled out molecular sulfur deposit. Reaction [2] prevails at low sweep rate. The polysulfide must be S_3^{2-} and not S_2^{2-} , since S_2^{2-} is anodically oxidized at the potential of the first wave. S_3^{2-} can be seen only at the beginning of large-scale electrolysis when a chemical reaction between the anodically produced trisulfide and the remaining sulfide in large excess can occur in the bulk of the cell.

When scanning the potential at a sweep rate higher than 2 V s^{-1} , in addition to the oxidation and reduction peaks observed at slower sweep rate, a new reduction peak appears at less negative potential than the former (Fig. 7). This peak was attributed to the intermediate formation of sulfur via reaction [1].

As this reduction peak is ill-shaped and merges into the main one with increasing potential sweep rate, a quantitative diagnostic was tried only on the anodic peak i_A . In diffusive conditions, $i_A v^{-1/2}$ is proportional to the number of exchanged electrons and should increase from less than $2e^-/\text{S}^{2-}$ at low sweep rate (minimum $1e^-/\text{S}^{2-}$ for S_2^{2-} , $4/3$ for S_3^{2-} , 1.5 for S_4^{2-} , etc.) to $2e^-/\text{S}^{2-}$ at higher sweep rate, that is a twofold maximum increase.

A plot of $i_A v^{-1/2}$ vs. $\log v$ is shown on Fig. 8. The constant value of $i_A v^{-1/2}$ when $v < 2 \text{ V s}^{-1}$ agrees with a single diffusive step (oxidation in S_3^{2-}), but at a higher sweep rate, much more than a twofold increase was observed without apparent limit. For want of something better, we supposed that sulfur forms a deposit on the electrode which artificially increases its area. Since an $i_A v^{-1/2}$ plot has no simple meaning in those conditions, no kinetic study could be performed.

In cyclic voltammetry experiments, we have shown that a polysulfide is obtained with probably $n = 4/3$ except at high sweep rate ($v > 2 \text{ V s}^{-1}$) where sulfur was detected ($n = 2$). Only polysulfide was observed in double-step chronoamperometry at the time scale of our apparatus ($1\text{s} < t < 0.01\text{s}$): the backward cathodic reaction is diffusion controlled (linear i_c vs. $t^{-1/2}$ plot) which excluded a deposit of insoluble sulfur during the forward anodic step (Fig. 2). As in cyclic voltammetry at low sweep rates and for the same reason, S_3^{2-} must be considered as the most probable final species ($n = 4/3$).

Fig. 7. Cyclic voltammetry of a $1.6 \cdot 10^{-2} \text{ M}$ solution of sulfide in $\text{NaOH-H}_2\text{O}$ (1-1) melt at 100°C at a gold electrode (area: 0.20 mm^2). Scanning rate: 20 V s^{-1} . Quosireference electrode: Pt wire.

On the contrary, at a rotating gold electrode, several arguments are in favor of a sulfur deposit when current potential curves are slowly recorded (2 mV s^{-1}). The first one is explained in the second paper (21), where it is shown that disulfide and sulfide are oxidized with the same number of electrons which is necessarily two, and which agrees with reaction [1]. The second reason is that polysulfides react with sulfite (21). Since anodic curves of sulfide recorded at a rotating electrode are not influenced by the presence of sulfite in solution, it may be supposed that sulfur is obtained instead of polysulfide. The third reason is the curious influence of temperature on the anodic wave detailed below and easily explained by a sulfur deposit. The last proof comes from the value of the ratio of limiting currents of the two anodic steps, which does not agree with chronoamperometry and cyclic voltammetry results (Table I) and can be still explained by a sulfur deposit.

From all these reasons, we believe that molecular sulfur and not polysulfide is obtained at a rotating gold electrode. As this deposit modifies the electrode sur-

Fig. 8. $i_A v^{-1/2}$ vs. $\log v$ plot for the first oxidation peak of a $2.25 \cdot 10^{-2} \text{ M}$ sulfide solution.

face, quantitative measurements required for the determination of the diffusion coefficient or the number of electrons involved in the second step have only been performed via chronoamperometry experiments, since sulfide is oxidized to the S(IV) state without going through the intermediate S(0) state.

Second Oxidation Step

The second oxidation wave, proportional to sulfide concentration, was found to be controlled by diffusion of the sulfide ion as proved by the straight lines of limiting or peak current plot *vs.* the square root of electrode rotation speed or potential sweep rate. The electrochemical process involved is irreversible, as indicated by the absence of a reduction peak in cyclic voltammetry, even at high potential-sweep rate (Fig. 7). The number of electrons exchanged during this second step has been calculated by two different means: comparison of heights of the two anodic waves and electrolysis on the second plateau. The ratio of the limiting current deduced from chronoamperometry measurements or cyclic voltammetry (Table I) leads to $n = 4$ (4.0 and 3.9, respectively), that is, for the total electron number of the two waves a value of 5.3. This result is not far from the value of 5.8 obtained by electrolysis of a S²⁻ solution directly on the second plateau. No polysulfides are formed during the course of electrolysis since no UV band has been transitively detected.

It may be concluded that the oxidation of sulfide leads to S(IV). Since the only known sulfur compounds in high alkaline hydroxide solution are oxyanions, the second oxidation step of sulfide would lead to sulfite ion, according to the reaction

Influence of Temperature

Stationary voltammetric curves at a rotating gold electrode have been recorded for temperatures between 74° and 146°C (Fig. 1). Both waves increase in the same way, but the limiting current *vs.* temperature plot presents two discontinuities around 90°/100° and 140°C (Fig. 9). If variations of current are due to a change of physical properties of solvent, the current should be consistent with the Levich equation (17) and proportional to $\eta^{-5/6} \rho^{7/6}$ (η = kinematic viscosity, ρ = density), which is not verified experimentally. No discontinuity is observed in any physical properties of the solvent in that temperature range (18, 22). It is more credible to attribute such current discontinuities to changes of physical properties of sulfur (23). The first discontinuity between 90° and 100°C might be due to the transition between the two solid phases αS_8

Fig. 9. Variation of limiting currents i_1 and i_2 *vs.* temperature (data from Fig. 1).

$\approx \beta\text{S}_8$ and the second one around 140°C to the polymerization of liquid sulfur. The variations of the electrical conductivity, resistivity, and viscosity of sulfur *vs.* temperature are similar to the one that we observed for wave heights beyond 120°C. This conductivity increases beyond the sulfur melting point to reach a maximum around 160°C before decreasing. Considering the electrical resistivity, it varies from $10^{12} \Omega\text{cm}^{-1}$ at 115°C to $2 \cdot 10^{10} \Omega\text{cm}^{-1}$ at 130°C. A sudden change is noticed for the viscosity which decreases to 6 cP at 150°C, then increases quickly to reach 43 cP at 170°C.

Although unproved, this explanation would support the sulfur deposit hypothesis put forward to explain the curious value of the limiting currents at a rotating gold electrode, or the unexpected increase of the $i_{A0}^{-1/2}$ function in cyclic voltammetry.

Controlled potential electrolyses at 140°C on the first or the second plateau do not display any change relative to 100°C results except for the rate of reactions. At 100° and 140°C, the oxidation mechanisms must be the same, only the kinetics are different, as the time scale recorded on Fig. 10 shows. Reactions become faster when temperature is increased. That is true not only for the formation of trisulfide, but also for its disproportionation.

Properties of S₂²⁻ and S₃²⁻

The disulfide is quite stable over 2h at 100° and 140°C in oxygen-free atmosphere. On the contrary, the trisulfide slowly decomposes at 100°, and more rapidly at 140°C. These results agree with previous observations in less basic media: the stability of polysulfide ions decreases when temperature, length of the chain, and alkalinity increase (15, 24-26).

We have not studied the decomposition reaction of S₃²⁻ because of a lack of analytical tools for oxyanions and because of the crossed reactions between the possible products of the reaction (21). We can only state that a mixture of disulfide (very slight increase of A_{365}) and monosulfide (increase of the first anodic wave, decrease of the reduction wave) appears without any other information about the presence of oxyanion. A steady state seems slowly reached at 100°C, and more quickly at 140°C, which could correspond to the equilibrium between S²⁻, S₂²⁻, S₂O₃²⁻, and SO₃²⁻ studied in the second paper (21).

The disulfide has a band located at 365 nm, in agreement with published values (16, 27, 28). For the trisulfide,

Fig. 10. Electrolysis current on the first anodic step ($E = -0.5\text{V}$) of a $1.1 \cdot 10^{-2}\text{M}$ solution of S²⁻ in NaOH-H₂O (1-1) melt at 100° and 140°C.

Fig. 11. Determination of the molar absorptivity at 330 and 365 nm of S_2^{2-} in NaOH- H_2O (1-1) melt at $100^\circ C$. Initial concentration of S_2^{2-} : $0.91 \cdot 10^{-2} M$ (\blacktriangle); $1.35 \cdot 10^{-2} M$ (\square); $1.70 \cdot 10^{-2} M$ (\bullet); and $2.09 \cdot 10^{-2} M$ (∇ and \blacksquare).

the maximum at 303 nm could not be observed because of the melt absorption below 310 nm, and the visible band at 416 nm noticed by Giggenbach (16) was not detected.

Molar absorptivities, ϵ , were measured by application of the Beer-Lambert law to solutions of sulfide electrolyzed at less than $0.2 F/S_2^{2-}$ and $1.2 F/S_2^{2-}$ assuming a 100% yield for the oxidation into S_2^{2-} in the first case and into S_3^{2-} in the second case. Due to experimental difficulties of spectrophotometry in molten salts, a 5% reproducibility was obtained (Fig. 11). Results are detailed in Table II.

Good agreement with published values is obtained for S_2^{2-} , but some discrepancies arise for S_3^{2-} . Because of the slow degradation of S_3^{2-} into S_2^{2-} , our value at 330 nm could be slightly low and the one at 365 nm slightly high, which is not in opposition with the work of Giggenbach. However, we do not believe that it could explain a variation of a factor of almost two. Besides differences in temperature and solvent, we would like to point out that results of Ref. (16) should be treated with caution because each individual spectrum of polysulfides was calculated using for HS^- a pK_A value of 17.1 (29) which has been criticized (30) instead of 13, the value generally accepted (30-32), except recently (33).

Both polysulfides can be oxidized or reduced at a rotating gold electrode, as has been shown in Fig. 5. Figure 12 shows typical cyclic voltammometric experiments at a stationary gold electrode recorded for disulfide in presence of sulfide and for trisulfide. Both polysulfide ions are reducible at the same potential. This peak is diffusive (linear plot of i_p vs. $v^{1/2}$ when $v < 1 V s^{-1}$) and irreversible. It leads to sulfide: electrolysis at $-1.15V$ allows the recovery of S^{2-} characteristic voltammometric curves and ends up after $1.9 \pm 0.2 F/S_2^{2-}$ and $4.2 \pm 0.2 F/S_3^{2-}$ according to the following reactions

This reduction step characterizes the presence of polysulfides in solution, but does not allow a distinction between them. This distinction is achieved via the anodic waves: the disulfide is oxidized in two steps, the trisulfide in only one. These waves have not been studied in more detail but by analogy with sulfide, since half-

Table II. Molar absorptivity of S_2^{2-} and S_3^{2-} (ϵ in $M^{-1} cm^{-1}$)

	This work	After Ref. (16)
S_2^{2-}	$\epsilon_{330} = 405 \pm 25$	260
S_2^{2-}	$\epsilon_{365} = 870 \pm 50$ (max)	850
S_3^{2-}	$\epsilon_{330} \approx 580$	1020
S_3^{2-}	$\epsilon_{365} \approx 380$	130

wave potentials are similar, one can suppose that the same reactions occur.

The voltammetric curves and the UV spectra of the sulfur compounds can be used as an analytical tool to characterize their presence in the NaOH- H_2O melt and to measure their concentration. It will be applied in the second paper (21) to study the crossed reactions between sulfur compounds.

Sulfur Chemistry in Equimolar NaOH-H₂O Melt

II. Chemical Reactions Between Sulfur, Sulfide, Polysulfides, and Oxyanions

N. M. Moscardo-Levelut and V. Plichon

Laboratoire de Chimie Analytique des Milieux Réactionnels (ERA 953), ESPCI, 75231 Paris Cedex 05, France

ABSTRACT

Chemical reactions of sulfur compounds have been studied in equimolar NaOH-H₂O melt at 100°C by voltammetry and UV spectrophotometry. Disproportionation of sulfur is fast and quantitative according to

On the contrary, addition of sulfur to sulfide is not quantitative and gives S₂²⁻ besides prevailing sulfur disproportionation. SO₃²⁻ reacts with S₂²⁻ and S₃²⁻, while S₂O₃²⁻ decomposes S²⁻. A pseudo-equilibrium is observed: S²⁻ + S₂O₃²⁻ ⇌ S₂²⁻ + SO₃²⁻ with concentration quotient Q = 10^{-0.8}.

This paper is devoted to the chemical reactions which occur in the equimolar NaOH-H₂O melt at 100°C and 140°C between the following sulfur compounds: molecular sulfur, sulfide, polysulfides S_x²⁻, and oxyanions S_xO_y²⁻. Though most of these reactions are qualitatively known or simply widely accepted sometimes without definite publication to support them, some discrepancies still arise in the literature.

We shall focus first on the disproportionation reaction of molecular sulfur. Dissolution of sulfur in basic aqueous solution is industrially used to prepare polysulfide solutions. It has been shown since the beginning of the century that sulfur dissolution leads to polysulfides and oxyanions, according to a disproportionation reaction. Resulting compounds are not clearly known: sulfite or thiosulfate on the one hand, or mono-, di-, tri-, or tetrasulfide on the other.

Polysulfides S_x²⁻ have been recognized in numerous reports (1-3), with mean rank, *x*, from 2.5 to 4 according to the conditions of NaOH concentration and temperature (3). A complex mixture is generally assumed. However, both sulfite and thiosulfate have been claimed by Calcagni (1) in 66 weight percent (w/o) NaOH. Thiosulfate has been suggested by Schulek *et al.* (2) at 100°C and Ugorets *et al.* (3) up to 200°C. However, it is known that a precipitate of sulfite is obtained in industrial conditions.

The rate of the disproportionation reaction strongly depends on the conditions of temperature and NaOH concentration. It increases with both parameters (1, 4). For instance, at room temperature, no reaction occurs in 0.1M NaOH, while 1 month is required in 1M and only 24h in 5M. At 100°C, reaction is not yet observed in 0.1M, while a few hours in 1M, and, as we shall see, a few minutes in the equimolar melt, are quite enough to achieve sulfur dissolution.

When sulfur is dissolved in sulfide containing solutions, addition reactions may compete with the disproportionation

Keywords: sulfur, polysulfides, sulfur oxyanions, hydroxide-water melt.

There has been research directed at determining what polysulfides can be produced. In reviewing the literature, one finds conflicting reports as to the nature of the polysulfide species because of the difficulty of distinguishing between mixtures and pure compounds.

In aqueous alkaline solutions, Schwarzenbach and Fischer (5) concluded that disulfide and trisulfide were not present. They showed that only the polysulfides of highest rank, such as S₄²⁻ and most likely S₅²⁻, are obtained, contrary to the old study of Peschanski and Valensi (6), who suggested that S₂²⁻, S₃²⁻, S₄²⁻, and S₅²⁻ are present and depend upon the pH and the amount of sulfur added to sulfide solution.

For high pH ranges (OH⁻ concentration up to 18M), Giggenbach (7) has calculated the equilibrium distribution of the various species at 25°C as a function of OH⁻ concentration. An increase of sodium hydroxide concentration displaces equilibria towards smaller polysulfide ions.

All these complex equilibria are disturbed by the presence of oxyanions. Ahlgren and Lemon (8) and then Giggenbach (9, 10) have shown that in neutral medium, SO₃²⁻ reacts with polysulfides according to

This reaction is used for the titration of polysulfides (11, 12) though it is slow and quantitative only above 50°C and in presence of sulfite in excess. At higher temperatures, the compounds obtained react to form new polysulfides: Giggenbach (9, 10) observes that at high temperatures addition of sulfite to polysulfides leads first to an increase of the polysulfide concentration before the usual decrease. Values of *x* are unknown because various mixtures probably result.

Disproportionation of oxyanions must also be taken into account; however, disproportionation constants of

sulfite and thiosulfate have been published only for a weakly basic medium, assuming S^{2-} and SO_4^{2-} as final products (13, 15).

Two reasons, among others, may explain discrepancies about the nature of the compounds formed in these reactions, and particularly from the sulfur disproportionation. The first one supposes a change in the nature of the prevailing reaction (e.g., the disproportionation reaction) with the solvent composition, since published information has been obtained in a wide range of solvent composition and temperature. The second one assumes a permanency of the initial step (e.g., disproportionation) and explains changes in final products by variations in stability of the initial ones with experimental conditions. For instance, it has not been proved if the industrially obtained sulfite is directly formed by disproportionation of molecular sulfur or results from a further disproportionation of, for example, trisulfide or thiosulfate in the very high concentration conditions generally used.

We did not attempt to observe the influence of the solvent. All the reactions we speak about were studied in the same experimental conditions. In this paper, we shall try to give an answer, valid for the equimolar NaOH-H₂O melt at 100°C or 140°C, to the following questions: what is the nature of the disproportionation reaction of sulfur? Is there any competition between disproportionation, fast in this melt, and addition reaction when molecular sulfur is added to a sulfide containing solution? What is the influence of the oxyanions? We were helped by the fact that only two polysulfides exist in the melt, S_2^{2-} and S_3^{2-} , which have different voltammetric and UV characteristics (16).

Experimental

Methods of preparation of polysulfide solution.—Several methods of preparation exist, but none gives pure solutions of polysulfides. Generally, a mixture of polysulfides and/or oxyanions is obtained, the proportion depending on the ratio of reagents, on the temperature, and on the reaction time. Three methods will be specially discussed: disproportionation of sulfur, addition of sulfur to sulfide, and electrochemical oxidation of sulfide.

Disproportionation of sulfur.—The dissolution of sulfur directly into the melt, an industrial method, is perhaps the simplest. As we shall see, it leads to S_3^{2-} initially free of S_2^{2-} , but thiosulfate is present. This method offers two advantages: it is a very simple one, and the concentration of S_3^{2-} can be easily calculated, though it is valid only just after the dissolution of sulfur, since S_3^{2-} is unstable. Its disadvantages come from the presence of thiosulfate and later of the degradation products of both S_3^{2-} and $S_2O_3^{2-}$ (SO_4^{2-} , SO_3^{2-} , S_2^{2-} , S^{2-}). Because the nature of the reaction was still debated at the beginning of this study, we could not use it to determine the polysulfide properties.

Addition of sulfur to sulfide.—The products of the reaction of S_8 with sulfide solutions strongly depend on the proportion of the reagents and on the temperature since two reactions are competing, the disproportionation reaction and the addition reaction. Without strictly controlled conditions, a complex mixture of S_2^{2-} , S_3^{2-} , SO_3^{2-} , and $S_2O_3^{2-}$ results. When sulfide is in large excess compared to sulfur, solution of S_2^{2-} free of oxyanion is obtained in presence of S^{2-} and traces of S_3^{2-} . However, we did not use this method because it was less quantitative than the electrochemical preparation.

Electrochemical oxidation of sulfide.—As shown in earlier (16), electrochemical oxidation of sulfide leads to S_2^{2-} solution when the electrolysis is stopped before 0.2 F/ S^{2-} and to S_3^{2-} after exchange of about 4/3 F/ S^{2-} . This method of preparation offers two important advantages: in each case, the polysulfide is obtained free of the other polysulfides and of oxyanions (but S^{2-} is present in the first case), and its concentration can be easily calculated. However, caution must be taken to get fast electrolysis because of the instability of S_3^{2-} . The obvious disadvan-

tage of this method is the complication of any electrochemical synthesis.

Unless otherwise mentioned, we used only the electrochemical preparation for the above reasons. Experimental details have been described elsewhere (16).

Other solutions.—Starting solutions of sulfide are prepared by adding to the NaOH-H₂O melt various amounts of solid Na₂S, recently titrated. Concentrated solutions of oxygenated compounds are prepared in water and added to the hydroxide melt, with a microsyringe to avoid volume correction. Experiments are carried out under nitrogen atmosphere.

Results and Discussion

Voltammetric properties of sulfur oxyanions.—Sodium sulfate and sulfite are neither oxidized nor reduced in the potential range accessible at a gold electrode in the equimolar NaOH-H₂O melt at 100°C or at 140°C. Thiosulfate presents no reduction wave, but can be oxidized at -0.05V, which is near the potential of oxidation of the gold electrode. This wave has not been studied further. Over a period of 2h or more, sulfite and sulfate solutions are stable, but thiosulfate decomposes even in an inert atmosphere, slowly at 100°C (less than 10% per hour) and more rapidly at 140°C. None of these compounds absorb in the UV range accessible in the melt.

UV spectra and voltammetric curves of sulfide, polysulfides (16), and oxyanions can be used as analytical tools to prove the presence of these species in the melt and measure their concentration. Qualitative criteria are gathered in Table I and can be summarized as follows: the presence of disulfide S_2^{2-} is shown by a higher absorption at 365 nm than at the arbitrarily chosen value 330 nm, and by the presence of two anodic waves. The trisulfide S_3^{2-} is obtained when absorption at 365 nm is lower than at 330 nm and only one anodic wave is present. In uncolored melt, one anodic wave means the presence of thiosulfate, and two anodic waves the presence of sulfide.

Reactions between polysulfides and oxyanions.—The general methodology includes preparation of polysulfide solutions via electrochemical oxidation of sulfide in order to get solutions free of oxyanions, then addition of various quantities of sodium thiosulfate, sulfite, or sulfate. Occurrence of a reaction is shown by the appearance or the disappearance of the sulfur compounds, which can be observed according to the analytical criteria of Table I. (Results are summarized in Table III.)

Cases of no reaction.—No other modifications of spectra or voltammetric curves than those due to instability (S_3^{2-} and $S_2O_3^{2-}$) are observed in the following cases: $S^{2-} + SO_3^{2-}$; $S_2^{2-} + SO_4^{2-}$; $S_3^{2-} + SO_4^{2-}$; $S^{2-} + SO_3^{2-}$; $S_2^{2-} + S_2O_3^{2-}$; $S_3^{2-} + S_2O_3^{2-}$. These results are easily proved except for the $S_2^{2-} + S_2O_3^{2-}$ reaction, because S_2^{2-} solution necessarily contains a five-fold excess of sulfide, which reacts with $S_2O_3^{2-}$ as detailed below. However, quantitative measurements at 365 nm or on the reduction wave of S_2^{2-} show that for equal initial S^{2-} concentrations, the same quantities of disulfide appear whether S_2^{2-} is initially present or not. Besides, the first anodic wave remains constant, which means that the total concentration in $S^{2-} + S_2^{2-}$ keeps a constant value. One can conclude that $S_2O_3^{2-}$ reacts with excess of S^{2-} , but not with S_2^{2-} .

Table I. Analytical characteristics of sulfur compounds in NaOH-H₂O equimolar melt at 100° or 140°C

	UV absorption	Anodic wave (below -0.2V)	Cathodic wave
S^{2-}	—	two	—
S_3^{2-}	$A_{365} > A_{330}$	two	one
S_2^{2-}	$A_{365} < A_{330}$	one	one
$S_2O_3^{2-}$	—	one	—
SO_3^{2-}	—	—	—
SO_4^{2-}	—	—	—

Consequently, in all the cases mentioned, we have been able to conclude that no reaction occurs.

Equilibrium between S^{2-} , S_2^{2-} , $S_2O_3^{2-}$, and SO_3^{2-} .—There exists an equilibrium between S^{2-} and $S_2O_3^{2-}$ on the one hand, and S_2^{2-} and $S_2O_3^{2-}$ on the other (it would be more exact to say: pseudoequilibrium, since three of the components are thermodynamically unstable)

This equilibrium has been proved by showing that the forward (1f) and backward (1b) reactions do exist and lead to the same proportion of components.

Backward reaction.—Arguments to assess the backward reaction are the following. Addition of sulfite to a disulfide solution leads to a decrease of the reduction wave (Fig. 1) and of the UV band at 365 nm (Fig. 2), which proves that S_2^{2-} disappears. At the same time, the first anodic wave keeps a constant value (Fig. 3), which proves that the concentration of $S_2^{2-} + S^{2-}$ remains constant: one S_2^{2-} is transformed into one S^{2-} .

The presence of $S_2O_3^{2-}$ is not simple to show because its anodic wave merges into the second anodic wave of S_2^{2-} and S^{2-} in excess. The reduction wave and absorption at 365 nm do not entirely disappear, even in presence of sulfite in excess.

Forward reaction.—Thiosulfate added to a sulfide solution leads to S_2^{2-} , as proved by the three following observations: appearance of yellow color with $A_{365} > A_{330}$, appearance of a reduction wave, and no decrease of the first anodic wave (Fig. 3). This last observation involves the substitution of one S^{2-} by one S_2^{2-} . No analytical method allows sulfite detection. Quantitative measurements show that the reaction is not total, even with $S_2O_3^{2-}$ in excess.

Reaction quotient.—The pseudoreaction quotient Q , defined above, has been determined by measuring the limiting current i of the reduction wave or the absorption A at 365 nm vs. the ratio $|S_2O_3^{2-}|/|S^{2-}|_i$ for the forward reaction and $|SO_3^{2-}|/|S_2^{2-}|_i$ for the backward reaction, the subscript i referring to the initial conditions. An example is given on Fig. 3.

Let x be either the absorption at 365 nm or the limiting current. Assuming that $x = x_T$ for a totally shifted forward

Fig. 1. Voltammetric curves at a rotating gold electrode during the addition of a $10^{-1}M$ sulfite solution to a S_2^{2-} solution in NaOH-H₂O (1-1) melt at 100°C in presence of sulfide in excess. Initial conditions: $S^{2-} = 2.2 \cdot 10^{-2}M$ electrolyzed up to 0.2 F/S²⁻. $SO_3^{2-}/S_2^{2-} = 0$ (curve 0), 0.5 (curve 1), 1.25 (curve 2), 3.75 (curve 4), 4.35 (curve 5), and 5.0 (curve 6).

Fig. 2. UV spectrum during the addition of a $10^{-1}M$ sulfite solution to a S_2^{2-} solution in presence of sulfide in excess. Initial conditions: $S^{2-} = 2.2 \cdot 10^{-2}M$ electrolyzed up to 0.2 F/S²⁻. $SO_3^{2-}/S_2^{2-} = 0$ (curve 0), 0.5 (curve 1), 1.0 (curve 2), 2.0 (curve 3), and 2.8 (curve 4).

Fig. 3. Intensity of the reduction wave (a, b), of the first anodic wave (c, d) and of the absorption at 365 nm (e, f) vs. the ratio y of the reagents. (Curve d: scale $\times 10$.) Curves a, c, and e: $y = |S_2O_3^{2-}| / |S^{2-}|_i$ with $|S^{2-}|_i = 5 \cdot 10^{-3}M$. Curves b, d, and f: $y = |SO_3^{2-}| / |S_2^{2-}|_i$ with $|S_2^{2-}|_i = 5 \cdot 10^{-3}M + |S^{2-}|_i = 4 \cdot 10^{-2}M$.

reaction, one easily calculates from balance equations that Q is given by

$$Q = \frac{x^2}{(x_T - x)(ax_T - x)}$$

For the backward equation, taking into account that S_2^{2-} is prepared in the presence of excess sulfide ($|S^{2-}|_i = 8|S_2^{2-}|_i$), one easily calculates

$$Q = \frac{x[ax_1 - (x_1 - x)]}{8x_1 + (x_1 - x)(x_1 - x)}$$

Results are given in Table II. Good agreement is obtained, whatever the reaction (forward or backward), the techniques or the ratio of the components (from 0.2 to 3). The mean value of $pQ = -\log Q$ is 0.8 ± 0.1 at 100°C.

Reaction of SO_3^{2-} on S_3^{2-} .—When sulfite is added to a S_3^{2-} solution, the reduction wave (Fig. 4) and the absorption at 330 nm (Fig. 5) characteristic of S_3^{2-} decrease in too large proportion to be simply explained by S_3^{2-} instability. After addition of a four-fold excess of sulfite, A_{330} does not yet equal zero, but is higher than A_{365} . It can be concluded that S^{2-} and not S_2^{2-} is finally obtained, but not

Table II. pQ at 100°C of the pseudoequilibrium [1]

Reaction	Method	$y = 0.2$	$y = 0.5$	$y = 1$	$y = 2$	$y = 3$
(1b)	spectrophotometry	0.94	0.77	0.75	0.76	0.80
	voltammetry	0.95	0.83	0.81	0.83	0.76
(1f)	spectrophotometry	0.44	0.68	0.70	0.85	0.97

Conditions for (1f): $y = |\text{S}_2\text{O}_3^{2-}|/|\text{S}_2^{2-}|$ and $|\text{S}_2^{2-}|_i = 5 \cdot 10^{-3}\text{M}$.
 Conditions for (1b): $y = |\text{SO}_3^{2-}|/|\text{S}_2^{2-}|$ and $|\text{S}_2^{2-}|_i = 5 \cdot 10^{-3}\text{M} + |\text{S}_2^{2-}|_i = 4 \cdot 10^{-2}\text{M}$.

quantitatively

It must be noticed that a minor concentration of S_2^{2-} seems present at the beginning of sulfite addition, since A_{365} remains constant or decreases less than A_{330} up to a ratio $|\text{SO}_3^{2-}|/|\text{S}_3^{2-}|$ equal to 0.5. The disulfide S_2^{2-} disappears further.

All reactions between polysulfides and sulfur oxyanions have been summarized in Table III.

Sulfur disproportionation.—Sulfur rapidly dissolves into the melt while a yellow color, characteristic of polysulfides, appears. Possible disproportionation reactions are given in Table IV (except for the less probable disproportionations into $\text{S}_2\text{O}_3^{2-}$, $\text{S}_2\text{O}_4^{2-}$, and $\text{S}_4\text{O}_6^{2-}$, which have not been taken into account). We have also given the recognition criteria based on the analytical properties of the polysulfides and the number of Faraday per sulfur atom required to reduce into S^{2-} the resulting polysulfides according to these reactions

If recorded shortly after the dissolution, voltammetric curves show at 100°C and 140°C a cathodic and only one anodic wave (Fig. 6, curve 0), while in the UV spectrum at 100°C, absorption at 330 nm is higher than at 365 nm (Fig. 7, curve 0). Limiting currents and UV absorption are proportional to the quantity of added sulfur. The UV absorption and the absence of the first anodic wave of S^{2-} or S_2^{2-} support the fact that the disproportionation of sulfur

leads first to trisulfide free of disulfide (S_2^{2-} begins to appear later on, after 1h at 100°C and a few minutes at 140°C because of the instability of S_3^{2-} and $\text{S}_2\text{O}_3^{2-}$). Reactions [2], [3], and [4] are ruled out.

The determination of the reaction has been accomplished via an electrolysis on the plateau of the cathodic wave at -1.15V, corresponding to the reduction of the polysulfide into sulfide. The number of Faradays per sulfur atom required for complete disappearance of the cathodic wave of a solution of dissolved sulfur has been experimentally found to be between 1.0 and 1.15 at 100°C.

This value excludes all the reactions of Table IV except for [5] and [6]. Reaction [6] may be eliminated because it has been seen above that S_3^{2-} reacts on sulfite to give S_2^{2-} : this anion is not detected just after the dissolution. Therefore, the disproportionation reaction of sulfur in the equimolar NaOH-H₂O melt at 100° and 140°C is reaction [5].

This reaction is also the most probable if one considers that it is the only one which agrees for its stoichiometry

Fig. 6. Voltammetric curves at a rotating gold electrode during the addition of sulfur to the NaOH-H₂O (1-1) melt in absence (curve 0) or in presence (curves 1-7) of $4.3 \cdot 10^{-3} M$ Na₂S. $S/S_i^{2-} = 0$ (curve 1), 0.46 (curve 2), 0.80 (curve 3), 1.15 (curve 4), 1.53 (curve 5), 1.93 (curve 6), and 3.14 (curve 7).

with the eight atoms of the sulfur ring. The disproportionation is fast since 95% is achieved in 2 min at 140°C. The rate is probably limited simply by agitation speed and diffusion into the bulk.

Addition of sulfur to sulfide.—Since the disproportionation reaction is fast in this melt, four reactions can compete when molecular S₈ is added to a S²⁻ solution, three addition reactions, and the S₈ disproportionation reaction

We shall show that when too little sulfur is added (typically $y = S/S_i^{2-} < 0.1$ in our conditions) reaction [8] does occur though not exclusively, while if addition is continued up to an excess of sulfur (typically $y > 2$), disproportionation reaction [5] is exclusively observed. In the intermediate range, both S₂²⁻ and S₃²⁻ are obtained via competition between reaction [8] and reaction [5], the prevailing reaction as S/S_i^{2-} increases.

Figures 6 and 7 show typical voltammetric curves and UV spectra recorded for successive additions of sulfur to sulfide solution. Plots of limiting currents or absorption at 365 nm vs. the quantity of added sulfur are given in Fig. 8 and 9. When $y < 0.1$, addition of sulfur leads to the onset of the reduction wave and the UV absorption of polysulfides, but the curves differ, depending on whether sulfide is present or not. Obviously, a reaction occurs with sulfide, which differs from the S₈ disproportionation obtained in its absence. Whatever the sulfide concentration, it leads to S₂²⁻, since $A_{365} > A_{330}$, whence it can be concluded that reaction [8] occurs.

When S₈ is added in excess ($y > 2$), variations of limiting currents and absorption are similar to the variations in absence of sulfide. It means that the disproportionation reaction [5] occurs, which is quite expected.

Completeness of the addition reaction.—Reaction [8] is not quantitative. As displayed in Fig. 8 and 9, the UV absorption is proportional to sulfur addition only for low values of y , and the reduction current does not increase with the

Fig. 7. UV spectra during the addition of sulfur to the NaOH-H₂O (1-1) melt in absence (curve 0) or in presence (curves 1-8) of $1.5 \cdot 10^{-2} M$ Na₂S. $S/S_i^{2-} = 0$ (curve 1), 0.02 (curve 2), 0.05 (curve 3), 0.09 (curve 4), 0.15 (curve 5), 0.19 (curve 6), 0.24 (curve 7), 0.30 (curve 8), 0.39 (curve 9), and 0.47 (curve 10).

theoretical slope. A clear break point is not observed on curves for $y = 1$, corresponding to the end of the addition and the beginning of the disproportionation.

When $y < 2$, disulfide and trisulfide are simultaneously formed, and for S₃²⁻ the question is by which reaction: [9], [10], or [5]? It is easily seen that reactions [9] and [10] do not occur. If they did, an increase in y would result in a decrease of the first anodic wave because of the substitution of the oxidizable S²⁻ by the electroinactive S₃²⁻, while the reduction wave would increase at the same rate as for $y < 0.2$ (reduction of x mol of S₂²⁻ via $2e$ of $x/2$ mol of S₃²⁻ via $4e$ leads to the same limiting current). Experiments are inconsistent with these conditions.

Reaction [10] is also ruled out by spectrophotometric measurements, since we do not arrive at a situation where $A_{365} \geq A_{330}$, as would be expected if S₂²⁻ were substituted by S₃²⁻ [cf. electrolysis experiments in Ref. (16) for valuable comparison].

It can be concluded that when $0.1 < y < 2$, competition between reactions [8] and [5] does occur, rather than reactions [9] or [10].

Quantitative measurements have not been performed to calculate the relative amounts of the two reactions because it depends on too many experimental parameters (initial concentration in sulfide, y value, temperature, etc.). Besides, quantitative measurements on S₃²⁻ concentration are difficult because of its instability (16). For instance, curves of Fig. 8 require hours to be performed in molten salt experiments, and the decomposition of the nonoxidizable S₃²⁻ into S₂²⁻ and S²⁻ explains the slight increase of the current of the first anodic wave observed for high values of y .

We shall just add that even for the smallest value of y which could be used with a convenient experimental precision ($[S^{2-}] = 1.5 \cdot 10^{-2} M$; $y = 0.07$), reaction [8] represents only 70% of the sulfur dissolution, using ϵ values determined in Ref. (16). Obviously, solid flowers of sulfur do not have the same structure and the same properties as the transitory electrogenerated *in situ* sulfur (16).

In our melt, sulfur disproportionation is fast and widely challenges the addition reaction on sulfide. Dissolution of sulfur is not accelerated by sulfide, especially as the rate-limiting step seems to be agitation speed and diffusion into the bulk. This would not be the case at lower temperatures or OH⁻ concentrations.

An important consequence results from the consideration of the first anodic wave shown on Fig. 6 and detailed on Fig. 8. If one does not take into account the slight decrease in the current (probably due to a smaller diffusion coefficient of S₂²⁻ as compared to S²⁻), these curves show

Fig. 8. Plot of the limiting current of the first anodic wave (X) and of the reduction wave vs. the amount of dissolved sulfur (in S atom l^{-1}) in absence (○) or in presence (●) of $3.68 \cdot 10^{-3} M S^{2-}$. Numbers on curve are the ratio $y = S/S_1^{2-}$.

Fig. 9. Plot of A_{365} vs. the amount of dissolved sulfur (in S atom l^{-1}) in absence (■) or in presence of $S^{2-} = 5.5 \cdot 10^{-3} M$ (○) and $1.5 \cdot 10^{-2} M$ (●). y values are indicated on each curve. Dotted line: theoretical curve assuming that reaction [8] is quantitative.

that the half-wave potential and limiting current remain roughly constant, as long as $y < 0.5$. Since one sulfide is substituted by one disulfide according to reaction [8], it means that S_2^{2-} is electro-oxidizable at the same potential as S^{2-} , and in the case of a rotating gold electrode with the same number of exchanged electrons.

This last assessment is inconsistent with an oxidation into S_3^{2-} , which requires $4/3$ electrons per sulfide against $2/3$ per disulfide. It does agree well with an oxidation in molecular sulfur (2 electrons in both cases). This fact has already been noted in Ref. (16).

Conclusion

When coupled with spectrophotometry, electrochemistry is a powerful tool for the study of chemical reactions in solution. With these two techniques, we obtained the

following results on the sulfur compounds in the equimolar NaOH- H_2O melt at 100° or $140^\circ C$.

1. Only two polysulfides exist in this melt: the disulfide S_2^{2-} and the trisulfide S_3^{2-} .
2. Voltammetric and spectroscopic characteristics of S_2^{2-} and S_3^{2-} have been described. They were used as analytical criteria allowing a distinction between S_2^{2-} and S_3^{2-} via UV absorption and presence of a first anodic wave.
3. There exist two anodic steps for sulfide oxidation at a gold electrode: the first one leads to S_2^{2-} , S_3^{2-} , or molecular sulfur depending on the time scale of the techniques, and the second to sulfite.
4. Disproportionation of sulfur is fast and quantitative. It leads to S_3^{2-} and $S_2O_3^{2-}$. On the contrary, addition of sulfur on sulfide to form S_2^{2-} is only partial.

5. Sulfite, thiosulfate, sulfide, and disulfide are related by a pseudoequilibrium.

Acknowledgment

This research, including that reported in Ref. (16), has been partly supported by Société Nationale Elf Aquitaine, which is gratefully acknowledged, especially for a grant to M.N.M. We wish to express our sincere gratitude to Dr. J. Badoz-Lambling, Director of ERA 953, for the fruitful discussions and helpful advice, and to C. Thibaut and M. Labat from SNEA for stimulating discussions and helpful suggestions.

Chemical, Electrochemical, and Technological Aspects of Sodium Chlorate Manufacture

K. Viswanathan* and B. V. Tilak*

Occidental Chemical Corporation, Hooker Research Center, Grand Island, New York 14072

ABSTRACT

A critical review of the chemistry, electrochemistry, and engineering principles involved in the production of sodium chlorate is presented. Various chlorate manufacturing technologies were discussed, with emphasis on materials of construction, and trends towards developing cost and energy effective methods for producing sodium chlorate.

One of the energy intensive electrolytic industries is the electrochemical production of sodium chlorate, wherein approximately 4500-5500 kWh of electricity is required to produce 1 short ton of sodium chlorate which may be compared to a value of 2700-2800 kWh/ton of chlorine using OCC's H-4 cells with DSA® anodes¹ and asbestos diaphragm (see Table I) (1). Electrosynthesis of chlorate dates back to 1802, when Hisinger and Berzelius (2) prepared sodium chlorate by electrolysis of sodium chloride. It was confirmed by Kolbe (3) who also prepared chloric acid from hypochlorous acid electrolytically.

Presently, about one million tons of sodium chlorate are produced annually, the U.S. share being about 0.25 MM tons. These figures may be compared to the annual chlorine production capacity of 30 MM tons, the U.S. production level being about 11 million tons. The anticipated growth of the chlorate industry is about 4%-5% per year, in contrast to the growth rate of 2%-2.5% for the chlor-alkali industry. These opportunities for growth in the chlorate industry appear promising in view of the following considerations: (i) environmental regulations arising from the formation of chlorinated organics may mandate the replacement of chlorine for bleaching purposes with alternate bleaching chemicals, such as ClO₂, for which NaClO₃ is the precursor. About 20%-25% of the paper mills appear likely to change their bleaching process to chlorine dioxide. (ii) Oxygen bleaching, which is now attracting commercial attention in pulp and paper industry, also uses ClO₂ and, hence, would require greater chlorate production.

* Electrochemical Society Active Member.

Keywords: chlorate formation, role of dichromate, unit operations, cathodes, chlorate manufacturing technologies.

¹ DSA is a registered trademark of Diamond Shamrock Technologies, S. A., of Geneva, Switzerland.

The end-use profile of NaClO₃ shows that approximately 82% of sodium chlorate is consumed by the pulp and paper industry. Other uses of sodium chlorate are in the agricultural industry as a defoliant and herbicide, as an oxidizer in uranium milling, and in perchlorate production.

The purpose of this article is to review the chemistry and electrochemistry involved in the production of chlorate, and outline the various technologies with emphasis on (i) the materials of construction and (ii) the trends towards developing cost-effective and energy-efficient sodium chlorate technology by improving current efficiency, lowering cell voltage, and minimizing capital costs.

Chemistry and Electrochemistry Involved in Chlorate Formation

Nature of the Overall Process

Sodium chlorate is produced by the electrolysis of NaCl and can be described by the overall chemical reaction

Table I. Comparison of chlorate and chlor-alkali industry

	Chlorate	Chlor-alkali
Power consumption (kWh/ton)	4500-5500	2700-2800
World production capacity (MM ton)	1	30
U.S. production capacity (MM ton)	0.25	15
Anticipated growth rate (%)	4-5*	2-2.5*

* Projected growth rates in 1983.

which requires 6 Faradays to produce 1 g mol of chlorate or 685 Ah/lb of chlorate (at 100% efficiency.)

Reaction [1] is endothermic (4), the overall heat of the reaction (ΔH) being 224 kcal/g mol (3745 BTU/lb; 1.1 kWh/lb) of chlorate. Therefore, the thermoneutral voltage, i.e., the voltage at which heat is neither required by the system nor lost by the system to the surroundings, would be $\sim 1.62\text{V}$, as calculated from Eq. [2]

$$-nFE = \Delta H \quad [2]$$

However, in practice, chlorate cells operate in the voltage range 3-4V, at an average current efficiency (CE) of $\sim 95\%$. This results in heat generation (q) to the extent of

$$q = \left[\left(\frac{100}{\text{CE}} \right) (138.36) E \right] - \Delta H (\text{cal/g mol}) \quad [3]$$

which, for a chlorate electrolyzer operating at 95% efficiency and 3.3V, would be ~ 250 kcal/g mol or 4250 BTU/lb of NaClO_3 . This heat, generated in cells operating at voltages $> 1.62\text{V}$, must be removed.

Reactions Involved in Chlorate Formation

The primary electrochemical reactions occurring in a chlorate cell are the discharge of chloride ions and H^+ ions to form H_2 and Cl_2 , respectively

Chlorine evolved at the anode dissolves in the boundary layer and hydrolyzes to form HOCl and OCl^- which, in turn, react in the bulk of the electrolyte to form chlorate. This series of reactions is shown in Eq. [6]-[9] with the equilibrium constants stated in parenthesis for Eq. [6]-[8] and rate constant for Eq. [9]

Reaction [9], which results in chlorate formation, proceeds very slowly with an optimal rate (7), when $[\text{HOCl}] = 2[\text{OCl}^-]$, which occurs at a pH value equal to $pK - \log 2$, where $pK = -\log$ (equilibrium constant) for reaction [8]. Thus, the pH values in industrial cells are controlled in the range of 5.9-6.7.

Kinetics of chlorate formation.—Two mechanisms are proposed in the literature to describe the formation of chlorate. The reaction sequence, proposed by Foerster (8) and confirmed by many others (6, 9, 10), is a third-order reaction involving 2 mol HOCl and 1 mol OCl^- , as represented by Eq. [9]. However, according to Lister (11), who examined the decomposition kinetics of hypochlorite in alkaline solutions, chlorate formation follows a bimolecular sequence

Eq. [10] being the slower of the above reactions.

Recent studies (12) addressed this controversy and showed the mechanism to conform with that proposed by Foerster. The apparent inconsistency in Lister's analysis (11) was traced to his method of determining the HOCl concentration which was subsequently used in the evaluation of the rate constant. Thus, the chlorate formation reaction is an apparent third order involving 2 mol HOCl

and 1 mol OCl^- , the third-order rate constant being $0.025 \text{ l}^2 \cdot \text{mol}^{-2} \cdot \text{s}^{-1}$ at 25°C in $4M$ NaCl solutions. The rate of chlorate formation is proportional to $[\text{HOCl}]^2 [\text{OCl}^-] V$ where V refers to the volume of the reactor, and, hence, as the concentration of $\text{OCl}^- + \text{HOCl}$ decreases, the rate falls significantly necessitating the use of large volumes (and therefore large retention times) to carry out the reaction.

Parasitic reactions affecting efficiency.—While reaction [9] leads to the formation of chlorate, several parallel reactions occur at the electrodes and within the cell, lowering the overall efficiency for ClO_3^- formation.

Anodic parasitic reactions.—Prior to the advent of metal anodes, the preferred anode material was graphite [see, however, Ref. (13) for historical details], which led to a chlorate efficiency of 80%-85% due to the oxidation of C to CO_2 and the lower overpotential for O_2 evolution compared to Cl_2 evolution on graphite. However, since the commercialization of metal anodes based on Pt-Ir and RuO_2 coatings on Ti substrates, the current efficiencies have increased to 93%-95%. This loss in current efficiency of 5%-7% can be traced to the chemical decomposition of HOCl and OCl^- to O_2 and Cl^- (which will be described below). The reactions described below are thermodynamically favored at potentials where Cl_2 is generated and can markedly lower the efficiency.

O_2 evolution.—Oxygen evolution reaction, represented by Eq. [12], is dependent

on the nature of the anode material and the pH of the medium. Typically, the current efficiency values for the O_2 evolution reaction vary from about 1% to 3% on noble metal based electrodes in the pH range 5.5-6.5.

Oxidation of OCl^- to ClO_3^- .—This reaction

under some conditions can occur lowering (14) the current efficiency for ClO_3^- formation to 66.67%.

Bulk parasitic reactions.—There are two reactions occurring in the bulk which can decompose the OCl^- essential for chlorate formation. These are represented by Eq. [14] and [15]

Addition of acid results in the release of Cl_2 and, hence, lowered cell efficiency. Another reaction favored at pH values less than 1 is the decomposition of chlorate to form chlorine dioxide (14).

Lister (15) made a careful study of the kinetics of O_2 evolution from solutions containing hypochlorite and found the mechanism of O_2 evolution to be of second order. The hypochlorite decomposition reaction proceeds at a rate of 1×10^{-5} g mol/l min at 40°C in pure solutions, and is greatly accelerated by Co, Ni, Fe, Cu, and Mn ions in the electrolyte in the following order

and also by light.

For current efficiency calculations, chlorate industries use the following formula (16)

$$\text{Chlorate efficiency} = \frac{100 - 3\% \text{ O}_2 - 2\% \text{ Cl}_2}{100 - \% \text{ O}_2 - \% \text{ Cl}_2} \quad [16]^a$$

by analyzing the exit gas stream. Material balance calculations show that Eq. [16] is adequate to describe the performance of a typical chlorate cell. However, implicit in

^a Uguine-Kuhlman uses the formula: chlorate efficiency = $100\% - 2\% \text{ O}_2 - \% \text{ Cl}_2$, with $\% \text{ Cl}_2 = 0.3-0.5$ and $\% \text{ O}_2 = 2-2.5$, which can be derived from Eq. [16] by simple binomial expansion.

the derivation of Eq. [16] are the following considerations: (i) 1 mol of O_2 generated corresponds to a loss of 4 Faradays of electricity, and (ii) 1 mol of Cl_2 escaped corresponds to a loss of 2 Faradays of electricity. Very often, the cell gas is scrubbed with caustic, and the scrubber liquor is recycled to the cell again.

Cathodic parasitic reactions—role of sodium dichromate during chlorate electrolysis.—The primary reaction at the cathode is the discharge of H^+ ions to form H_2 . However, thermodynamic and kinetic considerations favor OCl^- and ClO_3^- reduction reactions (Eq. [17] and [18])

The rates of these reactions are believed to be suppressed by the addition of sodium dichromate (in the 1-5 g/l range) during electrolysis.

Sodium dichromate is a conventional and multifunctional additive used routinely in the commercial production of sodium chlorate. Several roles are attributed to chrome, which include: (i) suppressing the corrosion of the Fe cathode (17-20), (ii) buffering (9, 21) the electrolyte in the pH range 5-7, where the chlorate formation rate is optimum, (iii) preventing the cathodic reduction of OCl^- and ClO_3^- ions by the " Cr_2O_3 " film formed by chromate reduction (22, 23), and (iv) inhibiting the O_2 evolution reaction at the anode (24, 25). It is of interest to note that the fluoride ion (26) is believed to play a similar role as dichromate during chlorate electrolysis with PbO_2 anodes. The relative importance of these functions is critically discussed in this section.

Inhibition of corrosion of steel cathode.—Cathodes made of steel are generally used in electrolytic chlorate cells, the electrolyte under operating conditions analyzing 450 g/l $NaClO_3$, 150 g/l $NaCl$, 4-5 g/l OCl^- , and 2-3 g/l $Na_2Cr_2O_7$ at $70^\circ C$ (pH \sim 5.9-6.7). If the role of dichromate is indeed one of suppressing the corrosion of steel under open-circuit conditions, then the open-circuit potential (E_{ocp}) should show significant differences in the presence and absence of dichromate. However, experimental measurements in the above solutions show the E_{ocp} to be -0.30 to $-0.32V$ vs. SCE in the presence and absence of dichromate, suggesting that the major role of $Cr_2O_7^{--}$ is not one of offering protection to steel from corrosion.

Enhancement of buffer capacity.—It was mentioned earlier that the preferred pH range of operation of a typical chlorate cell is in the range 5.9-6.7 to achieve optimal conversion of hypochlorite to chlorate. The system has a natural buffer capacity in this range due to HOC/OCl^- equilibrium represented by Eq. [8]. Taniguchi and Sekine (9) mentioned that chrome addition enhances the buffer capacity in this critical pH range due to the equilibrium reaction

pH titration data obtained in the presence of dichromate in solutions containing 150 g/l $NaCl$ and 450 g/l $NaClO_3$, at $70^\circ C$, in the absence of OCl^- , showed (12) that dichromate indeed buffers in the pH range 5.9-6.7. In the presence of OCl^- and $Cr_2O_7^{--}$, the buffer capacity was found to be directly proportional to the concentration of OCl^- and $Cr_2O_7^{--}$ and equal to the sum of the individual contributions from OCl^- and $Cr_2O_7^{--}$. Thus, it is definitively established (12) that dichromate enhances the buffer capacity in the pH region 5-7.

Inhibition of oxygen evolution.—One of the parasitic anodic reactions during chlorate electrolysis is oxygen evolution from either the discharge of water molecules (Eq. [12]) or the oxidation of OCl^- to ClO_3^- (Eq. [13]). It was stated in the literature (24, 25) that $Cr_2O_7^{--}$ suppresses the amount of oxygen generated during chlorate electrolysis. While one may rationalize this observation in terms of

blocking of sites for oxygen evolution by dichromate and/or complexation of hypochlorite decomposing catalysts (e.g., Fe, Co, Ni) by $Cr_2O_7^{--}$ (and/or CrO_4^{--}), further investigations are needed to understand the mechanistic aspects involved in this phenomenon.

Suppression of parasitic cathodic reactions.—In an electrolytic chlorate cell, there are two parasitic cathodic reactions (Eq. [17] and [18]) arising from the cathodic reduction of negatively charged ions, OCl^- and ClO_3^- . If these negatively charged ions are to be reduced cathodically, they have to approach the cathode by diffusion and convection against an adverse potential gradient. If the solution contains a large excess of supporting electrolyte, the adverse potential gradient is small and the transport of anions is affected only slightly. However, if an inert porous diaphragm is formed on the cathode that greatly counteracts the effect of convection, the approximate material balance equation for the species may be written as

$$N_i = -Z_i U_i F C_i \nabla \phi - D_i \nabla C_i \quad [20]$$

where N_i refers to the flux of species i , Z_i to the valence of the species, U_i to mobility, C_i to concentration, $\nabla \phi$ to the potential gradient, and D_i to the diffusivity of species i .

The first term on the right-hand side of Eq. [20] accounts for transport by migration (away from the cathode surface for anions) and the second term to the contribution from diffusion. If the potential gradient term is increased by increasing the local current density, then the transport of anions to a cathode can be completely suppressed. This may be achieved by forming an inert film with low porosity on the cathode. These facts were clearly expounded in a paper by Wagner (23). [See Ref. (27) for a historical perspective on the role of chromate during chlorate electrolysis.]

Dichromate is known to be cathodically reduced to form a " Cr_2O_3 " film on the cathode surface, which creates an adverse potential gradient that prevents the reduction of OCl^- and ClO_3^- ions. Polarization and mass-balance studies performed in the presence and absence of dichromate using steel and Pt cathodes clearly demonstrated (12) that the primary role of chromate is in the suppression of cathodic reduction of OCl^- and ClO_3^- via the establishment of an adverse potential gradient. Wagner's film theory is further substantiated using steel cathodes coated with Kalgard and Cr_2O_3 films in chlorate solutions, and by rotating disk electrode studies wherein $Fe(CN)_6^{3-}$ reduction was hindered by 0.1 g/l $Cr_2O_7^{--}$, while Fe^{3+} reduction was unaffected.

It is of interest to note that the limiting current density for $Fe(CN)_6^{3-}$ reduction is independent of rotation speed in the presence of $Cr_2O_7^{--}$, in contrast to the linear dependence as a function of square root of the rotation speed observed in the absence of $Cr_2O_7^{--}$. This suggests that the surface film dampens the convection effects significantly, resulting in the suppression of mass-transfer rates by a factor of $\gg 100$. To a first approximation, these effects may be expressed (28) by the relationship

$$Sh = 1.05 [Re/(1 + ld\epsilon)]^{0.93} \quad [21]$$

where l refers to the thickness of the porous film, d to the pore diameter and ϵ to the porosity, as shown by Roberston *et al.* (28). These results unequivocally suggest that the flow velocity in chlorate cells can at best only minimize the solution ohmic drop arising from void fraction of H_2 bubbles and in no way influences the kinetics of the hydrogen evolution reaction occurring via the discharge of H_2O molecules at pH values > 12 even though the bulk pH is ~ 6 and discharge of H_2 from H^+ ions is mass-transfer controlled at this pH value.

Energy Consumption and Components of Cell Voltage

Energy consumption (P) of a chlorate cell is a function of current efficiency (CE expressed as a fraction) and cell voltage (V in volts) as

$$P \text{ (kWh/ton)} = \frac{1372 \times V}{\text{CE}} \quad [22]$$

Current efficiency is a function of operating characteristics (*e. g.*, flow rate, pH, temperature, etc.) and cell design (*e. g.*, monopolar or bipolar), and is generally in the range 90%-95% for metal electrode cells. However, cell voltage is governed by the polarization characteristics of the anode and the cathode and conductivity characteristics of the electrolyte + gas mixture and can be expressed as

$$V = (\text{thermodynamic decomposition of the anode and the cathode}) + (\text{anodic overvoltage}) + (\text{cathodic overvoltage}) + (\text{ohmic drop between the anode and cathode due to the gas/electrolyte mixture}) + \text{ohmic drop across the hardware}$$

Typical energy requirements and components of a chlorate cell voltage are shown in Table II [see Ref. (1)].

Unit Operations in Chlorate Technology

The very nature of the formation of chlorate dictates the need for several unit operations for chlorate production as noted below.

Electrolysis zone.—In the electrolysis zone, the electrochemical reactions (Eq. [4] and [5]) take place along with the hydrolysis of Cl_2 . Escape of chlorine due to incomplete hydrolysis results in an imbalance of pH, and HCl has to be added to maintain the pH at the optimal value required for chlorate formation. (Pennwalt uses chlorine to maintain pH balance.)

Reaction zone.—Since a relatively large volume is required to carry out reaction [9], a reaction zone is needed.

Cooling zone.—Reaction [9] is exothermic, and the energy supplied to the cell exceeds the heat required to carry out the overall reaction [1], and hence a cooling zone is needed to remove the excess heat and control the operating temperature.

Circulation zone and means.—This is usually carried out by either a gas lift mechanism or by external pumping.

Acknowledging the need for the above, various manufacturers have developed their technologies judiciously by either separating or aggregating the four essential zones in their overall designs. Thus, while the chemistry and electrochemistry involved in chlorate formation appear relatively simple, eight to ten cleverly engineered technologies, distinctly different from each other, were developed during the past several years (see Table III). In spite of the distinguishing differences among the various technologies, emerged (i) as a consequence of the various permutations and combinations of patterns available to construct the cell circuits and (ii) as a result of patentability and economic considerations, there are several common features in these cell designs. In this sec-

Table II. Typical requirement of electrical energy for a chlorate cell (using steel cathodes and Pt-Ir anodes)*

Current density	1.9 A/in ²
Current efficiency	94%
Cell voltage components	
Thermodynamic decomposition voltage	1.71V
Anode overvoltage	0.05V
Cathode overvoltage	0.94V
Ohmic drops	0.80V (A/C gap: 3-5 mm)
Average cell voltage	3.50V

tion, an attempt is made to rationalize these differences showing the commonality among them in terms of system and electrode configurations.

System Configurations

The basic requirement in any chlorate cell operation is the need for four zones for achieving high efficiency and low cost. However, by judicious engineering, one can combine these unit operations to make the overall system cost effective, as shown in Fig. 1. Thus, DeNora, Eltech, OCC, Huron, and Canoxy-Squamish employ a single-vessel system wherein electrolysis, reaction, heat removal, and pumping by gas-lift are accomplished. Krebs, on the other hand, prefers to use a two-vessel system in which electrolysis is carried out in a separate vessel and the cell liquor is pumped by gas-lift to an external reactor to remove the heat and to allow the reaction to proceed to completion. Pennwalt, Ugine-Kuhlmann, Kemanord, and Krebskosmo designed their cell circuits in a classical fashion by using three separate vessel zones with liquor circulating from cell tank, to reactor, to circulating pump through the heat exchanger back to the cell bank. Chemetics, instead, pumps the electrolyte only through the heat exchanger and employs gas-lift to circulate liquor from the cell to the reactor. It may be pointed out here that Canoxy-Squamish technology is presently licensed by Chemetics.

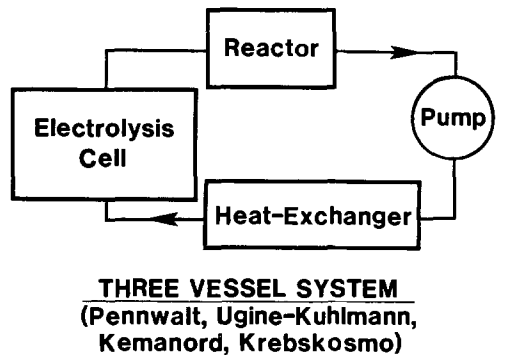

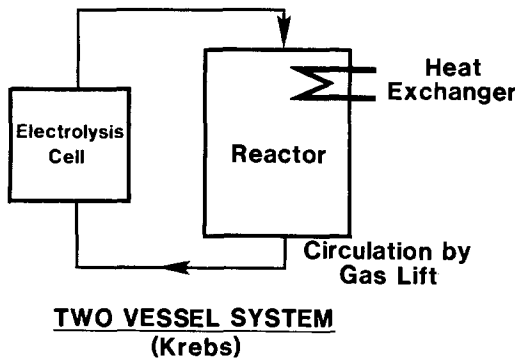

Electrode Configurations

Monopolar cells.—The basic design (see Fig. 2) in monopolar chlorate cells is the parallel plate configuration, the cathode plates being solid sheets in the case of OCC, Chemetics, and Krebs, and perforated in the case of Ugine-Kuhlmann and Pennwalt who claim lower cell voltage by this cathode design.

Bipolar cells.—Four different electrode designs are presently employed in bipolar cells, as shown in Fig. 3a and 3b. The simplest design is that of the OCC's D-cells at Columbus, which consists of parallel solid graphite plates. Improvements in the concept are introduced in the Eltech and Huron cells by employing bipolar plates of titanium cathodes and DSA anodes in electrical contact at the plastic partition at the top and bottom of the stack to separate the individual cells. The plastic used by Huron is PVC, and Eltech uses a fluoro polymer. Circulation is achieved in this design by gases generated during electrolysis flowing through the perforations. A similar design is used by Canoxy-Squamish, the differences being that the bipolar units are solid plates of Ti anode and Fe cathode bolted together and arranged vertically with spacers in between the bipolar elements.

DeNora achieves efficient gas-lift circulation in the cell by stacking the solid Ti-0.2% Pd cathodes/DSA anode bipolar elements vertically. Thus, cell height appears to provide high circulation rates in this design.

While, the OCC "D" at Columbus, Eltech, Huron, DeNora, and Canoxy-Squamish cell designs are truly bi-

(Chemetics pumps liquor only through the heat exchanger)

Fig. 1. System configuration

polar in character, the Kemanord design may be classified as a "pseudobipolar" system, since the bipolar stacks constituted of a Ti-Ag layer-steel composite sandwich provide current to the monopolar electrodes in between them (see Fig. 3a). [For details related to these technologies see Ref. (29-40).]

Materials of Construction

An overview of the materials of construction used in the chlorate industry presented in Tables IV and V shows that the materials used range from plastics (e.g., Huron) to exotic materials, such as Teflon and Ti, used by DeNora.

SOLID PARALLEL PLATES
(OCC [hollow cathodes], Chemetics, Krebs)

PERFORATED PARALLEL PLATES
(Ugine-Kuhlmann, Pennwalt)

Fig. 2. Electrode configurations for monopolar cells (sectional plan views).

The operating and capital costs of chlorate cell technologies differ from each other mainly because of the differences arising from system and electrode configurations and materials of construction of electrodes and cells. The differences in system and electrode configuration are reflected in power consumption, cell voltage, and overall cell efficiency variations. The differences in the nature of the materials of construction, system, and electrode configurations are presumably reflected in the capital cost variations among these cell technologies.

From the materials of construction point of view, the various chlorate technologies fall into three broad categories: (i) those which rely very heavily on plastics (e.g., Eltech, Huron, Chemetics). (ii) those which rely very heavily on Ti and Fe (e.g., Kregs, Pennwalt, Ugine-Kuhlmann, OCC at Taft), and (iii) those which attempt to find an economic medium (e.g. DeNora, Canoxy-Squamish, Kemanord).

The use of plastics (generally PVC or CPVC) limits the operating temperature and leads to high maintenance, whereas the use of Ti and Teflon increases the capital costs with low maintenance operations. Some of these aspects related to materials of construction in chlorate cells are addressed in the following sections.

Anodes (41, 42).—Graphite was extensively used as an electrode 80 to 90 years ago in monopolar and bipolar cells. However, it is not a satisfactory material because it is disintegrated by anodic oxidation and mechanical attri-

Fig. 3. Electrode configurations. a (left): bipolar cells. b (above): bipolar cells (stacked bipolar plates).

tion. As the electrodes wear away, the gap between the electrodes widens, resulting in an increase in the solution ohmic drop and, hence, the cell voltage. Furthermore, graphite imposes restrictions on the operating temperature of the electrolytic cell due to its rapid disintegration at elevated temperatures. An important development in recent years has been the use of metal anodes, which are essentially precious metal alloy or precious metal oxide coatings on valve metals. Titanium is the most commonly used substrate material, and the noble metal coatings are based on Pt, Ir, and Ru. These electrodes do not deteriorate like graphite electrodes, and are therefore termed dimensionally stable. In contrast to graphite electrodes, metal anodes can be operated at higher temperatures (70°-95°C) and higher current densities (2-4 A/in²) with high current efficiencies (90%-95%). These dimensionally

stable anodes operate close to the thermodynamic decomposition voltage for the Cl⁻ to Cl₂ reaction, thus resulting in significant energy savings with minimal maintenance and have, in a way, revolutionized the electrolytic chlor-alkali and chlorate operations making inroads into other electrochemical industries.

Cathodes.—Cathodes are most often Fe based, and many chlorate cells use steel cathodes, with the possible exception of DeNora cells, which employ Ti-0.2% Pd alloy, and Huron and Eltech cells, which use Ti cathodes. However, iron is a moderately good electrocatalyst for the hydrogen-evolution reaction, the activation overvoltage being 220-400 mV in the current density range 1.5-2.5 A/in². However, the hydrogen overvoltage on titanium is much higher than on Fe.

Chlorate cell liquor, which typically contains 450 g/l NaClO₃, 150 g/l NaCl, and 2-5 g/l NaOCl (at 70°-90°C) is one of the worst corrosive media since OCl⁻ to Cl⁻ is a thermodynamically favored reaction, with sufficient free energy to drive the oxidation of most metals below their reversible potentials under open-circuit conditions. The only metals that might withstand oxidation are probably noble metals which tend to establish the Nernstian potential for the OCl⁻/Cl⁻ and/or ClO₃⁻/Cl⁻ couple. While valve metals are also stable in this medium under open-circuit conditions, they tend to hydride easily during electrolysis, resulting in the loss of mechanical integrity due to lattice expansion and subsequent distortion.

Because of aforementioned limitations, chlorate cell technology is predominantly monopolar although there

Table IV. Materials of construction

Materials	Company
Plastics (PVC, Siliglas®* FRP, TFE-lined FRP)	Chemetics/Solvay, Huron, Eltech

are few bipolar cells, such as the ones used by Huron, DeNora, and Eltech. Thus, whenever steel cathodes are used, there is a need for cathodic protection to protect steel from corrosion during open-circuit conditions (or cell shutdown). The magnitude of the cathodic protection current should be so chosen that the potential of steel is well below the mixed potential set up by the hypochlorite reduction and the metal oxidation reactions.

Reactor.—The nature of the material chosen for the reactor should not only be stable to the “oxidative” chlorate cell liquor, but should also be able to withstand the temperature at which the cells are operated. For high temperatures of operation, the choice seems to be restricted to titanium or Teflon-lined materials. Krebs, Pennwalt, Ugine-Kuhlmann, and OCC use Ti reactors. DeNora, Eltech, and Chemetics/Solvay have experimented with Teflon-lined steel and Teflon-lined fiber glass, and Huron and Chemetics use plastics such as CPVC, Siliglas®, and FRP. These may however restrict the operating temperature of the cells. (Huron, however claims that Siliglas is suitable up to 65°-85°C.)

Cell cover and cell body.—Choice of cell cover includes: FRP, Teflon-lined FRP, rubber, titanium and Siliglas. The considerations involved in selection are very similar to that of the reactor. Cell body is typically steel in most cases and should be protected by making it cathodic under all conditions. Criteria for the selection of cell body material are similar to those involved for the reactors; this requires no further elaboration.

Energy Conservation in Chlorate Industry: Future Developments

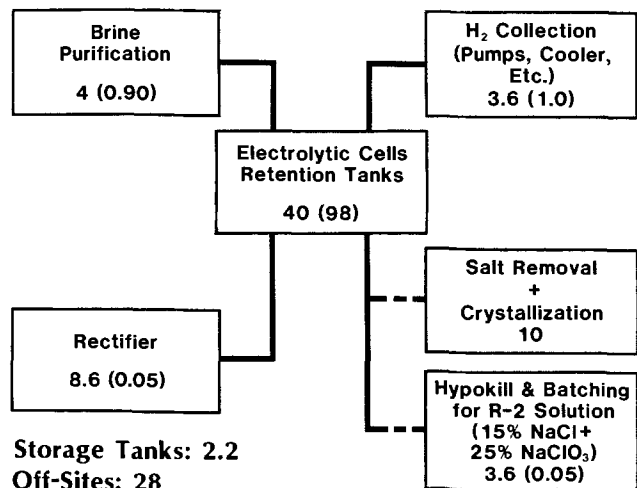

The opportunities to achieve energy savings in the chlorate industry can be generated by examining the flow sheet (1) describing the various unit operations involved in chlorate production. Figure 4 illustrates the general layout in a chlorate plant and shows the electrolytic stage to be the most capital and energy consuming unit in chlorate manufacture.

A closer look at the energy consumption requirements indicates that the majority of energy losses in electrolytic chlorate production are associated with (i) thermodynamic decomposition voltage and (ii) cathode potential. Some of these and other aspects related to the future developments in chlorate technology are discussed below.

Materials of construction.—It is pertinent to address the issue of why chlor-alkali diaphragm cells have certain characteristics different from those of chlorate cells. The reason for this primarily stems from the need to separate the anolyte from the catholyte via a diaphragm which re-

stricts major design variations. Removal of this constraint in chlorate cells has permitted development of a plethora of cell designs. If one now corrects for the effects of operating temperature, electrode gaps, and current densities, and compares them on a common basis, it can be safely assumed that there is little to choose among these different chlorate technologies even though each design is different (40) - the process conditions being mainly limited by the nature of the materials of construction. The development of a superior technology depends to a significant degree on finding cheaper materials of construction which will withstand the chlorate cell environment. This is elaborated upon in the following discussion.

In the chlorate industry, approximately 50% of the production costs are associated with the electrical energy and 30% in capital. To reduce the power consumption, one has to operate the cells at high temperatures to reduce the cell voltage, and this presently demands the use of expensive materials of construction. The dilemma now lies in increased capital cost, which demands higher current densities (and hence higher cell voltages) or increased product output. For operation at high temperatures, titanium is the preferred material of cell construction. However, its price in today's market is volatile. An economic replacement for the expensive titanium metal is needed, and possibilities exist, for example, via a more extensive usage of cathodically protected steel or

Fig. 4. Approximate capital and power requirements (expressed as percentage of total) for a 20,000 TPY chlorate plant using Krebs technology. Total power: 275,000 kWh/day. (Power requirements are stated in parenthesis for a solution (R-2) plant [from Ref. (1)].

cheaper stable coatings on metals. (For example, DeNora has examined Teflon-coated steel, and Huron proposed the usage of Siliglas®-lined steel.) Another advantage of using expensive metals like titanium lies in decreased downtime and maintenance of the cells. Use of plastics in this regard may be unsatisfactory with the possible exception of polyvinylidene difluoride (PVDF) or Teflon, which are also relatively expensive. Presently, no "low-cost" materials of construction capable of withstanding the corrosive environment of a chlorate cell have been identified.

Reduction in thermodynamic decomposition voltage.—Voltage savings of approximately 1V can be accomplished by using air-depolarized cathodes (43, 44) instead of the conventional H₂ cathodes. While this is not yet a commercial reality, a quantum leap in this area would be a significant technological advance (49). However, its impact on capital and operating costs require critical evaluation.

Cathode overpotential.—The cathode overpotential is presently about 1.0-1.2V, of which the contribution from the activation overpotential is about 0.3-0.4. The remainder is associated with the concentration overpotential and IR drop in the "chrome film." While the concentration overpotential cannot be reduced unless the mass-transfer coefficient in the cells surpasses an impossible value 10⁹ (see above), the activation overvoltage can be reduced by using "activated" cathodes (45, 46). However, one of the problems with steel-based cathodes is the corrosion of Fe-based materials, under open-circuit conditions due to OCl⁻ ion reduction; the conjugate reaction is the metal oxidation reaction. This imposes a serious restriction on the catalytic coatings (on steel) which provide the required high surface area for achieving low overvoltage. Thus, the search and/or development of materials exhibiting stability in OCl⁻ containing electrolytes in the pH region of 4-6 is the "slow-step" in the development of catalytic cathodes.

Ti cathodes, however, are stable in chlorate media but suffer from hydrogen embrittlement due to permeation of H₂ into the metal lattice, formation of TiH₂, and subsequent lattice distortion and degradation. While alloys of Ti containing 0.2% Pd (32) and rare-earth metals (47) and Ag-coated Ti (48) have been suggested to surmount the hydriding problem, the performance characteristics of these electrodes have not been firmly established. Moreover, an "understanding" of the factors involved in H₂ permeation kinetics into Ti during chlorate electrolysis and hydrogen embrittlement, required for the development of criteria for preventing and/or minimizing hydrogen entry, is presently lacking. A theoretical analysis of the nature and mechanism of H₂ entry into and discharge on Ti and other materials such as Ag, Pt, Au, etc., in chlorate solutions could provide a lead in developing non-hydrogen embrittling Ti-based cathodes. Nevertheless, it is a monumental task to develop materials that would replace steel.

Hydrogen recovery.—Except the Kemanord, Pennwalt, and Krebs locations which recover the hydrogen from chlorate cells for hydrogenation and NH₃ synthesis, respectively, all chlorate-recovered H₂ is presently used as a boiler fuel. Chemetics/Solvay also recover hydrogen for bottling purposes. While detailed economic information is not available at the present time, it appears worthwhile considering the fuel cell route for H₂ utilization, thus recovering some of the energy put into the electrolytic cells.

Acknowledgments

The authors wish to thank Occidental Chemical Company for permission to publish this paper. Our special thanks are due to Mr. L. Allais of Krebs, Dr. E. Hausmann of Krebskosmo, Mr. J. R. Hodges of Pennwalt Corporation, Dr. V. Tulkki of Oulu, Dr. J. Cormier of Ugine-Kuhlmann, Mr. D. Owens of Huron Chemicals Limited, Dr. R. Backstrom of Chemetics International Company, and Mr. L. C. Curlin of Eltech Systems Corporation for

critically reviewing the article, supplying technical information, and for permission to publish the data provided by them.

Manuscript submitted Oct. 4, 1983; revised manuscript received Jan. 9, 1984.

Occidental Chemical Corporation assisted in meeting the publication costs of this article.

Decomposition of Benzoate Ester Radical Anions

John H. Wagenknecht,* Richard D. Goodin,* Patrick J. Kinlen, and F. E. Woodard

Monsanto Company, Corporate Research Laboratories, St. Louis, Missouri 63167

ABSTRACT

The electrochemical reduction of benzoate esters in aprotic media leads to relatively stable radical anions. The radical anions decompose to electroinactive products in an initial EC mechanism. At long-time scales and/or higher concentrations, the benzoate esters begin to exhibit more complicated mechanistic behavior. The initial rates of decomposition of several benzoate ester radical anions have been determined by digital simulations of cyclic voltammograms, double potential step experiments, and rotating ring-disk techniques. On short-time scales, the reduction of *t*-butyl *p*-toluate is a good example of pure EC mechanistic behavior. The final decomposition products are many and complex for most of the esters studied, but *t*-butyl benzoate cleanly gives benzoate anion and *t*-butyl *p*-*t*-butyl benzoate.

The electrochemical reduction of benzoate esters has been studied by many workers. Coleman (1) recently reviewed the area and work is described in Baizer's (2) and Weinberg's (3) books. Horner (4) has reported the results of reduction of benzoate esters in aqueous medium. In aprotic media, benzoate esters may be reduced to radical anions which have been studied by ESR (5). Isolable products of the reduction of benzoate esters in aprotic media have been described by various workers. The reduction of phenylbenzoate led to cleavage of the carbonyl carbon-oxygen bond to form phenate and the dianion of benzil (6). Similar benzoate ester cleavage has been reported by Mairanovsky (7). Another example of cleavage of the same bond was reported in the reduction of methylbenzoate in acetonitrile to form benzoylacetonitrile (8). On the other hand, Gul'tyai has recently reported (9) that the reduction of methylbenzoate in dimethylformamide leads quantitatively to benzoate, *i.e.*, cleavage of the oxygen-methyl bond. Gul'tyai's report prompted us to report our results concerning the reduction of benzoate esters, which confirms that oxygen-alkyl bond cleavage is the major pathway of decomposition of benzoate ester radical anions in aprotic media.

Experimental

Methyl, ethyl (Eastman), *i*-propyl, and *t*-butyl benzoates (ICN Pharmaceuticals) were used as received. *t*-Butyl-*p*-toluate (bp 90°C at 3.2 torr) and *t*-butyl-*p*-*t*-butylbenzoate (bp 80°C at 0.1 torr) were prepared from the corresponding acid chlorides (Aldrich) and *t*-butyl alcohol. Tetraethylammonium perchlorate (Aldrich) was recrystallized from methanol before use. Tetraethylammonium fluoroborate (Southwestern Analytical) was used as received. Acetonitrile (Burdick & Jackson distilled in glass) was dried (10) over alumina (ICN Nutritional Biochemicals W 200 Neutral Activity grade Super 1).

*Electrochemical Society Active Member.

Coulometry was performed using a Princeton Applied Research Model 173 potentiostat with a Model 179 coulometer. GC analyses were performed with a Varian (Varian Associates, Incorporated) 3700 chromatograph with a 6 ft × 1/8 in. column packed with 10% OV-17 on 80/100 mesh Chromasorb W-AW. GC-mass spectral analyses were performed on a Finnigan-TSG GC-mass spectrometer.

Coulometry was performed in a 2.5 cm diam Nafion® 117 (E. I. du Pont de Nemours and Company) divided H cell with a 3 cm diam Hg pool cathode and 1 cm² Pt foil anode. The anolyte and catholyte were 50 ml of CH₃CN containing 0.1M Et₄N⁺ClO₄⁻. The catholyte contained ~0.5g of benzoate ester and 0.5g of phenetole (internal standard for chromatography). Electrolyses were run at -2.3V vs. SCE. The SCE was sheathed in a tube separated from the catholyte by a porous ceramic plug to minimize contamination of the catholyte with water and KCl.

At each 25C interval, a small catholyte sample was removed, treated with CH₃I, warmed a few minutes, and then analyzed by gas chromatography for remaining substrate and methylbenzoate.

The catholyte from the *t*-butyl benzoate reduction after 250C was analyzed by GC and found to contain a 35% yield of *t*-butyl-*p*-*t*-butylbenzoate, which was identified by comparison of the GC retention time and mass spectrum with an authentic sample. (Mass spectrum *M/e*(%): 163(100), 179(30), 161(18), 164(6.7), 57(5.4), 135(5.3), 178(5.2), and 91(4.1).)

All rotating ring-disk experiments were performed with a DT6 electrode from Pine Instrument Company with a platinum disk and platinum ring. The calculated collection efficiency (*N*) of this electrode is 0.176 (12). Digital simulation gives a value of 0.173. Using ferrocene as a model system, the experimental *N* value was found to be 0.173. Rotation was provided by a Pine Instrument ASR Rotator and potential control by a Tacussel (Ryaby Asso-

ciates) Bipotentiostat. The reductions were carried out in DMF, which was 0.1M in Bu_4NClO_4 and dried over activated neutral alumina. Kinetic rate constants for the decomposition of the anion radicals were determined from a working curve generated by finite difference digital simulation techniques assuming an EC mechanism (12).

The voltammetric cell was the same as the design of Buchta and Evans (13). All potentials are given with respect to a silver reference electrode (IBM Instruments) containing a filling solution of a 0.1M AgNO_3 in acetonitrile.

The hanging mercury drop electrode was of a design similar to that described by Evans *et al.* (14), while the planar platinum electrode (0.465 cm diam) was obtained from IBM Instruments.

A mercury-plated planar platinum electrode (0.290 cm diam, used for voltammetry of *i*-propyl benzoate) was prepared by alternatively oxidizing and reducing the platinum electrode above a pool of mercury. After five or six cycles at 0.1A, the negatively polarized platinum electrode was dipped into the mercury pool for approximately 5 min. The electrode was then removed from the pool while the negative potential on the electrode was maintained. Excess mercury was wiped carefully from the surface with a paper tissue. The electrode surface was renewed in this manner before each set of experiments.

The computer-controlled cyclic voltammetric apparatus consisted of an Apple II Plus[®] microcomputer (Apple Computer Incorporated), an ISAAC 9/A (Cyborg Corporation) data acquisition and control system, and an IBM Model EC/225 voltammetric analyzer. Standard IR compensation techniques were used. Figure 1 shows a

schematic diagram of the ISAAC/IBM interface. Binary outputs from the ISAAC are used to *reset* and start the voltammetric scans. The SWEEP/SWEEP signal from the IBM indicates the cyclic scan has started and triggers the ISAAC data acquisition. The fastest time interval for data acquisition is 1 ms, which matches the time constant for the IBM potentiostat. Current and potential outputs of the IBM are measured by the ISAAC in the differential mode. The potential ("X") output of the IBM is referenced to the initial potential. The gain of the A/D converters on the ISAAC is selected to optimize the full scale range of the current and voltage outputs (16). Normally, the current A/D range is $\pm 5\text{V}$, while the potential A/D range is $\pm 5\text{V}$ or $\pm 500\text{mV}$.

The double potential step experiments were performed using a microcomputer and data acquisition system developed at the University of North Carolina (15). The high speed potentiostat (constructed in-house) and electrochemical cell used in these experiments are described elsewhere (16). The electrodes were prepared by attaching a mercury drop to a Pt disk using a method reported by Bellamy (17). The excess mercury was then removed by shaking the electrode, leaving a thin mercury film.

Results and Discussion

Initial voltammetric studies of a series of benzoate esters showed the relative stability of the radical anions to be from most stable to least stable: ethyl \approx isopropyl, *t*-butyl (Fig. 2). Initial attempts to calculate the rate of decomposition of the radical anions using the technique of Nicholson and Shain (18) gave values for k_f , which varied

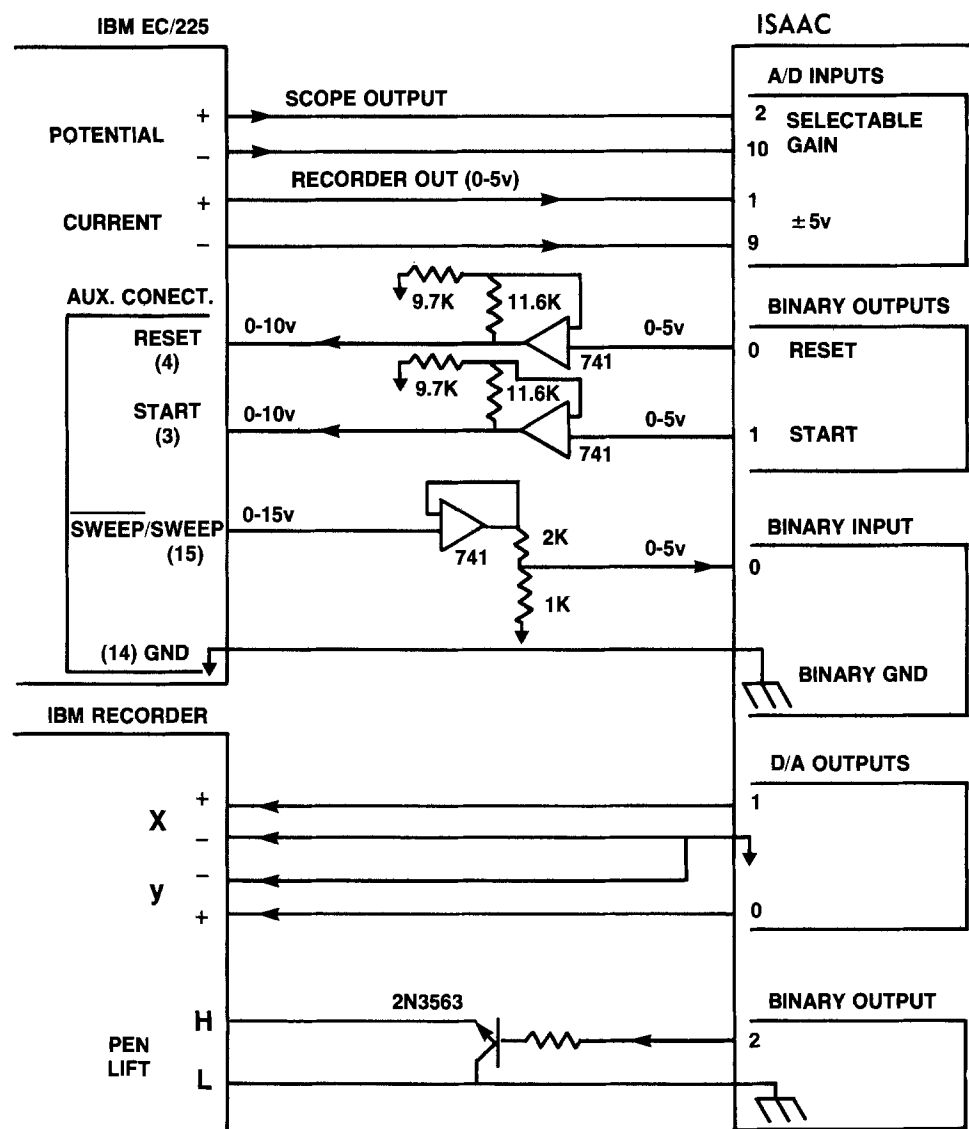

Fig. 1. Schematic diagram of the ISAAC 9/A—IBM EC/225 interface.

Fig. 2. Superimposed voltammograms of the reduction of various benzoate esters. The dashed line represents a total reversible system.

with sweep rate. This is thought to be due to the fact that the return peak current is difficult to measure accurately when the decomposition rate is fast.

The relative rates of decomposition of the radical anions were significant in that they suggest the following decomposition pathway

The reasoning is that the relative rates of decomposition of the radical anions are in the same order as the stability of the cleaved alkyl radical. If the cleavage led to benzoyloxy radical and alkyl anion

then the relative rates of cleavage ought to be reversed; *i.e.*, ethyl anion is a lower energy species than *t*-butyl anion and, therefore, the *t*-butyl ester radical anion should have been most stable.

Coulometric analyses of the electroreductions of *i*-propyl benzoate and *t*-butyl benzoate and *t*-butyl *p*-toluate were carried out with solution analysis at regular intervals during the electrolyses. Catholyte samples were removed, treated with methyl iodide, and analyzed by GC. By that method, the disappearance of starting ester and appearance of benzoate anion (analyzed as the methyl ester) were monitored. The results are shown in Fig. 3-5. Least squares plot of the ester concentration show 1.12 and 1.18 F/mol reduction, respectively, for the *i*-propyl benzoate and *t*-butyl benzoate.

Benzoate ion is formed at a yield much lower than the proposed mechanism would require. In the case of *i*-propyl benzoate, the yield of benzoate ion is only 25%. A complex mixture of other products is formed. A similar result was obtained in the reduction of methyl benzoate in DMF or acetonitrile. Again, only about a 30% yield of benzoate ion was obtained [as opposed to the 100% reported by Gul'tyai (9)], and a complex mixture of products was observed by gas chromatography. We were unable to detect benzoylacetonitrile in the reduction of methylbenzoate in CH_3CN as reported previously (8).

t-Butylbenzoate was better behaved, cleanly yielding about 65% of benzoate ion and about 35% of *t*-butyl *p*-*t*-butylbenzoate. A pathway for the formation of those products is shown in Fig. 6. The initially formed ester radical anion cleaves to form benzoate ion and *t*-butyl radi-

cal. In addition to other reaction pathways for *t*-butyl radical, it may attack unreduced ester. By some means, that initially formed adduct must lose a hydrogen and add an electron to give the observed product and allow for the observed 1F/mol disappearance of initial ester.

There are several possible means of meeting both requirements. The initial adduct radical may lose the 4-hydrogen atom to an acceptor, which is subsequently reduced at the electrode or by the ester radical anion. Another possibility is that the radical adduct is reduced to the corresponding anion, which could lose hydride to an

Fig. 3. Coulometry of *i*-propyl benzoate

Fig. 4. Coulometry of *t*-butyl benzoate

acceptor forming the product ester, or be protonated to the dihydro derivative shown. The dihydro compound might be oxidized on workup or in the gas chromatograph to the observed product, although we consider that quite unlikely.

Another possible reaction pathway is the reaction of the benzoate radical anion with *t*-butyl radical to form the ad-

Fig. 5. Coulometry of *t*-butyl *p*-toluateFig. 6. Reduction pathway for *t*-butylbenzoate

duct anion, which might be protonated to the dihydro derivative or electron transfer to substrate, forming the adduct radical.

As will be indicated later, *t*-butyl *p*-toluate is the best example of a simple EC mechanism by electroanalytical techniques at 1 mM concentration. The coulometry at 50 mM concentration is not as clean, giving 1.31 F/mol. This indicates reactions after radical anion cleavage, which lead to products that are also reduced. As shown in Fig. 5, the yield of *p*-toluate ion is only 65%.

Our first attempt at improving (compared to crude cyclic voltammetry) the kinetic data for benzoate ester radical anion decomposition was to use the rotating ring-disk technique. For *t*-butyl-*p*-toluate, a plot for disk diffusion limited current ($i_{D,1}$) vs. $\omega^{1/2}$ was linear at rotation rates of 500-3200 rpm with a correlation coefficient of 0.99996. Constant current was applied to the disk at levels corresponding to various points on the rising portion of the voltammetric wave. The collection efficiency at 1000 rpm was fairly constant (0.086 ± 0.0002) at $i_p/i_{D,1}$ ratios from 0.30 to 0.92. This behavior is indicative of a first order EC mechanism (19).

The collection efficiency was measured with the disk potential held on the limiting plateau at rotation rates of 500-3000 rpm. The rate constant for anion radical decomposition as determined from digital simulation working curves was $0.34 \pm 0.05 \text{ s}^{-1}$. For *t*-butylbenzoate, the rate constant for anion radical decomposition was determined in a similar manner to the toluate and found to be $(9.8 \pm 0.4) \times 10^{-2} \text{ s}^{-1}$.

Fig. 7. Voltammogram (XXX) and digital simulation (—) for ethyl benzoate.

Fig. 8. Voltammogram (XXX) and digital simulation (—) for *i*-propyl benzoate.

The rate constants determined by the rotating ring-disk method are significantly lower than those determined by electrochemical techniques described later. This may be due to an artifact which results from the necessity of using rigorously anhydrous solvents and very negative potentials to study these compounds. The Teflon shroud housing the electrode assembly showed darkly colored areas on the surface radiating outward from the electrode. We believe that this is due to reduction of the Teflon by the anion radicals. Reduction of polytetrafluoroethylene is known to yield surface carbon layers which can have appreciable conductivity in the reduced form (20). Reduction of the surface of the insulating spacer between the disk and ring electrodes could conceivably produce a resistive current leakage pathway, which could make the ring currents higher than expected and, thus, result in lower rate constants. This technique was abandoned for this application.

We then turned to digital simulation of cyclic voltammetry (22), carried out under more rigorously controlled conditions than had been done previously.

Fig. 9. Voltammogram (XXX) and digital simulation (—) for *t*-butyl benzoate.

Digital simulations were run assuming quasi-reversible electron transfer followed by a first-order chemical step. (Incorporation of slow electron transfer was required to obtain good fits for *t*-butyl benzoate and *t*-butyl-*p*-toluate.) Best fits were obtained visually, the important kinetic parameter being k_f/a , where k_f is the rate constant for the chemical step and a is related to the sweep rate, ν , by the expression $a = nF\nu/RT$.

The cyclic voltammograms for various esters and the digital simulation curves are shown in Fig. 7-10. For ethyl and *i*-propyl benzoate, scan rates of 50 mV/s or less were required to detect the effect of the chemical reaction of the reverse peak. At these low scan rates, spherical diffusion equations were required in the simulation to obtain good fits when using the HMDE. These are quite good fits, verifying that the reduction of benzoate esters involves a simple EC mechanism. The values of k_f are shown in Table I.

The results of the preparative experiments show that since *t*-butyl *p*-*t*-butylbenzoate is formed in the reduction of *t*-butyl benzoate, the reaction is not simply EC but

complicated by side reactions. It seems likely that the difference in results between preparative experiments and electroanalytical experiments may be explained by the large difference in concentration of the two types of experiments (50 mM for coulometry vs. 1 mM for electroanalytical experiments).

t-Butyl radical has been reported (23) to reduce in other systems between -2.8 and -3.0V (corrected to our Ag ref-

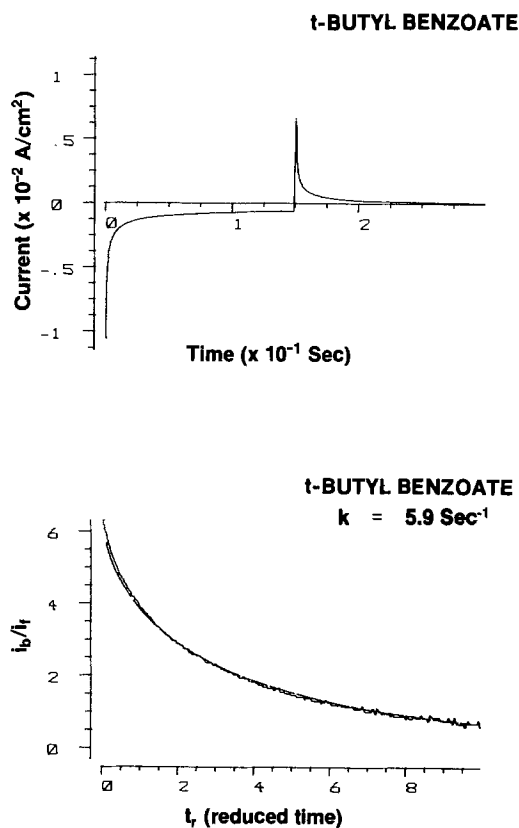

Fig. 11. (Top) Voltammogram of *t*-butylbenzoate showing E_i and E_f used in the double potential step equipment. (Center) Current/time trace from the double potential step experiment. (Bottom) Current ratio vs. reduced time. (Jagged line) data, (smooth line) least squares fit.

erence electrode). We see no evidence of this in our system either directly or as an ECE component. We have not reexamined the previous substrates in our system as a control; however, the absence of direct electrochemical evidence for *t*-butyl radical reduction, considering the modest reaction rates for our cleavage reactions, is not particularly disconcerting.

Double potential step experiments (15) were carried out to obtain independent verification of the EC mechanism and radical anion decomposition rate constants. Each potential step experiment was done both with and without the redox couple (i.e., the benzoate ester) present. This allowed the current/time profiles to be corrected for double layer charging and background faradaic processes.

The relaxation currents measured during double potential step experiments were analyzed by a method similar to that of Schwarz and Shain (21). The homogeneous rate constant was determined from a nonlinear least squares fit of the dimensionless current ratio (i.e., the current flowing after the forward step (I_f) divided by the reverse step current (I_b) at corresponding times after each step) plotted as a function of the reduced time (i.e., the time after each step divided by the duration of the forward step). Our method, which will be described in detail in a later paper, is an improvement over the method used by Schwarz and Shain in that the entire curve is used rather than just a single point. The nonlinear least squares fitting procedure, which was done on the UNC microcomputer, was complete in several minutes. A graphic display of the fit obtained during successive iterations was provided.

Figure 11 shows graphically the series of steps involved in obtaining the rate constant for *t*-butyl benzoate. Figure 12 shows the data and digital simulation fit for *t*-butyl *p*-toluate. The rate constants obtained were 5.9 and 10.0 s^{-1} , respectively, which were very near the results obtained for those two compounds by digital simulation of the cyclic voltammetry.

Fig. 12. (Top) Current/time trace from double potential step experiment with *t*-butyl-*p*-toluate. (Bottom) Current ratio vs. reduced time. (Jagged line) data, (smooth line) least squares fit.

The double potential step method is particularly attractive for measuring the homogeneous rate constant for EC systems because the number of variables used for fitting can be reduced to one. By stepping to a sufficiently forcing potential, the electrochemical reaction becomes diffusion controlled, and thus the charge transfer rate parameters have no influence on the relaxation currents. The dependence on electrode area as well as the dependence on the concentration and diffusion coefficient of the electroactive species is removed by using the ratio of the forward and reverse currents.

In conclusion, we have demonstrated by several methods (voltammetry, double potential step experiments, coulometry, and product isolation) that the reduction of benzoate esters in dilute (1 mM) nonaqueous medium involves an EC mechanism. The system becomes more complex at higher concentrations. The initially formed radical anion cleaves to form benzoate ion and alkyl radical. This is one of a very few examples of the reduction of organic compounds by an EC mechanism.

Rotating Ring-Disk Electrode Study of Competitive Photo-oxidation at α -Fe₂O₃ Photoanodes in Aqueous Solution

Menahem Anderman* and John H. Kennedy

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Competition reactions at α -Fe₂O₃ photoanodes were studied using the RRDE technique. It was found that iodide, bromide, and chloride ions were photo-oxidized in preference to water in acidic solutions. The competition ratio was measured as a function of halide-ion concentration, halide-ion flux, light intensity, electrode potential, and solution pH. A direct correlation between the disk photocurrent and the competition ratio at a given halide flux was demonstrated. A lack in selectivity for the dark current was also observed.

Photogenerated holes (h⁺) at an *n*-type semiconductor electrode/aqueous electrolyte interface are capable of oxidizing halide ions, as well as water and other reducing agents. The general scheme for such reactions is

Such reactions have been studied previously using bulk electrolysis (1, 2) as well as rotating ring-disk electrode (RRDE) techniques (3-6). General trends that have been observed include: (i) X⁻ is photo-oxidized in preference to water in acidic solutions, and (ii) the percentage of X⁻ oxidation (ϕ_{X_2}) decreases with increasing pH and decreasing X⁻ concentration. The only attempt to correlate competitive photo-oxidation with the disk electrode current was

carried out by Kobayashi *et al.* on an *n*-TiO₂ electrode (6).

We report here RRDE measurements of competitive photo-oxidation at α -Fe₂O₃ electrodes. In addition to testing the general trend described above for the α -Fe₂O₃ case, we have quantitatively correlated the disk current with the flux of X⁻ to the electrode surface. Questions probed were: (i) Does such a correlation exist? (ii) Can a simple kinetics scheme account for all available data? (iii) Do other parameters such as electrode potential or light intensity influence the competition, or is it only the overall availability of holes at the electrode surface that determines the competition at a given X⁻ flux? (iv) Does the dark current show the same competition characteristics as the photocurrent?

Experimental

Polycrystalline pellets of α -Fe₂O₃ (1 atom percent [a/o] SiC doped) were prepared as described previously (7). The procedure for assembling these disks into the RRDE has also been described in a previous publication (8). The

* Electrochemical Society Active Member.

Key words: α -Fe₂O₃ photoanode, competition reactions, photo-electrochemistry, rotating ring-disk electrode.

Pt ring was pretreated by polishing with fine alumina powder and washing with deionized water in an ultrasonic bath. Before taking measurements, the ring was cycled between the potentials for oxygen evolution and hydrogen evolution until reproducible I-V curves were obtained. The measured collection efficiency for the $\alpha\text{-Fe}_2\text{O}_3$ -disk/Pt-ring was $N_0 = 0.134 \pm 0.003$, while the collection efficiency for a Pt-disk/Pt-ring of the same size was 0.135. These values show fair agreement with the calculated collection efficiency of 0.143 using the formula of Albery and Bruckenstein (9). The disk area was 0.307 cm^2 .

It should be noted that the $\alpha\text{-Fe}_2\text{O}_3$ disk was somewhat porous and was not polished to avoid deleterious surface defects (8, 10). This created some operating limitations as follows:

1. Collection efficiency dropped at high rotation speeds, $\omega > 1000 \text{ rpm}$. Therefore, all quantitative studies were carried out at $\omega \leq 470 \text{ rpm}$, which was well within the satisfactory operating region.

2. At disk current densities above 2 mA/cm^2 , oxygen bubbles were adsorbed on the surface and disturbed solution flow to the ring, resulting in a drop in ring current.

3. Some I_2 , Br_2 , and Cl_2 apparently diffused into the $\alpha\text{-Fe}_2\text{O}_3$ pores. A few seconds of induction time were required before steady-state collection currents were observed. This problem was especially severe for iodine, which has been reported before (11).

The electrochemical cell was a 200 ml all-quartz cylinder, covered with a teflon lid. The cell included a SCE reference, Pt-wire counterelectrode separated from the main compartment by fritted glass, and gas entry tubes.

The electrochemical cell was a 200 ml all-quartz cylinder, covered with a Teflon lid. The cell included a SCE with two X-Y recorders to monitor both ring and disk currents. All experiments were conducted at ionic strength equal to 1.0, which was adjusted with NaClO_4 as the supporting electrolyte. Experiments in the pH range 2.0-6.4 were carried out in phosphate buffers (0.02-1M). It should be noted that carboxylic acid-based buffers can be oxidized at $\alpha\text{-Fe}_2\text{O}_3$ (12) and, therefore, are not suitable. Full light intensity of the 150W xenon lamp, filtered by an IR filter and focused with a quartz lens, was 500 mW/cm^2 at the electrode surface. Neutral density filters were used to reduce this intensity when desired.

Ring current-ring potential (I_R - V_R) scans were taken at a rate of 33 mV/s at constant disk potential (and constant disk current). Disk current-disk potential/ring current

scans (I_D - V_D/I_R) were taken at a rate of 2 mV/s at a predetermined ring potential. Alternatively, some I_D/I_R data were obtained pointwise with the disk potential stepped in 50 mV intervals.

Results

Bromide oxidation in 1M acid.—Ring current-ring potential (I_R - V_R) curves in $0.2M \text{ HBr}/0.8M \text{ HClO}_4$ solution are shown in Fig. 1 (curves 1-3). Curve 1 was recorded for an oxygen-free solution in the dark with zero disk current. Curve 2 was recorded for the same solution in the light with a disk current of $1000 \mu\text{A}$ ($1V$ vs. SCE). A diffusion-limited plateau for the collection of Br_2 at the ring is evident. The plateau extended from $+0.35V$ vs. SCE to $-0.15V$ vs. SCE, at which point reduction of water begins. Efficiency of bromine production at the disk is given by Eq. [4]

$$\phi_{\text{Br}_2} = \frac{I_D(2\text{Br}^- \rightarrow \text{Br}_2)}{I_{D,\text{total}}} = \frac{I_R(\text{Br}_2 \rightarrow 2\text{Br}^-)}{N_0 I_{D,\text{total}}} \quad [4]$$

Curve 3 of Fig. 1 is the I_R - V_R curve for an oxygen-saturated solution when $I_D = 0$. Oxygen detection at the ring begins at $+0.2V$ vs. SCE. Thus it is possible to detect both O_2 and Br_2 when they are produced simultaneously at the disk electrode, as shown in curve 4 of Fig. 1.

Bromine production efficiency was 100% for a $0.1M \text{ HBr}/0.9M \text{ HClO}_4$ solution at all light intensities studied (33 - 500 mW/cm^2) and for disk potentials of 0.3 - $1.4V$ vs. SCE.

Bromine production efficiency (ϕ_{Br_2}) as a function of disk photocurrent for a $0.01M \text{ KBr}/1M \text{ HClO}_4$ solution is shown in Fig. 2. It is clearly seen that production efficiency drops at high disk currents. The flux of Br^- to the disk electrode may be calculated by the well-known Levich equation

$$\text{Flux} = I_D^{\text{dl}} = 0.62 nAFD^{2/3} \nu^{1/6} C_b \omega^{1/2} \quad [5]$$

where I_D^{dl} is the diffusion limited current (mA), n is the number of electrons transferred in the reaction, F is the Faraday constant, A is the electrode area (cm^2), D is the diffusion coefficient (cm^2/s), ν is the kinematic viscosity (cm^2/s), ω is the angular velocity (rad/s), and C_b is the concentration of the diffusing species (M) in the bulk solution. At the Br^- concentration shown in Fig. 2, the calculated flux is $1920 \mu\text{A}$. For all disk currents below $1920 \mu\text{A}$, one would expect $\phi_{\text{Br}_2} = 100\%$ if flux of Br^- to the disk electrode is the controlling factor. Above $1920 \mu\text{A}$ the efficiency should be given by Eq. [6]

Fig. 1. Ring current-ring potential for $0.2M \text{ HBr}/0.8M \text{ HClO}_4$ (curves 1-3); and for $2 \times 10^{-3} \text{ HBr}/1M \text{ HClO}_4$ (curve 4). Rotation frequency = 470 rpm . Curve 1: oxygen-free solution, $I_D = 0 \mu\text{A}$. Curve 2: oxygen-free solution, $I_D = 1000 \mu\text{A}$. Curve 3: oxygen-saturated solution, $I_D = 0 \mu\text{A}$. Curve 4: oxygen-free solution, $[\text{Br}^-] = 2 \times 10^{-3}M$, $I_D = 1000 \mu\text{A}$.

Fig. 2. Bromine production efficiency as a function of disk current (I_D) for 0.01M KBr/1M HClO_4 . Curve 1: experimental data; \bullet full light, \circ 18% of full light, and \circ 6.7% of full light. Curve 2: calculated for 100% oxidation of Br^- flux.

$$\phi_{\text{Br}_2} = \frac{\text{Flux}(\text{Br}^-)}{I_D} \quad [6]$$

The calculated production efficiency is shown as curve 2 in Fig. 2.

The influence of mass transfer is more clearly seen in Fig. 3. Here, disk current-disk potential/ring current (I_D - V_D / I_R) curves are shown for a 10^{-3}M KBr/1M HClO_4 solution. At low current density at the disk, the ring collection current follows the disk current closely with $\phi_{\text{Br}_2} > 95\%$. At higher disk currents, the ring current tends to plateau. The Br^- flux for this solution calculated by Eq. [5] is 192 μA and the maximum ring current would be $0.134 \times 192 = 26 \mu\text{A}$. This compares well with the experimental value of 22 μA shown in Fig. 3.

The possible influence of light intensity and electrode potential on bromine production efficiency was checked with I_D - V_D / I_R curves taken at three different light intensities and shown in Fig. 4. It is apparent that neither light

Fig. 3. Disk current-ring current/disk potential for 10^{-3}M KBr/1M HClO_4 , 18% of full light. a: disk current. b: ring current. c: bromine production efficiency, ϕ_{Br_2} . d: calculated diffusion-limited plateau value for detection of Br_2 at the ring.

intensity nor electrode potential has any effect on the electrode reaction. Only the availability of holes at the surface (*i.e.*, the current density) will determine the competition ratio at a given Br^- flux. The solid line in Fig. 4 was calculated using Eq. [6], and the agreement with experiment is excellent.

Bromide oxidation at higher pH.— I_R - V_D / I_D curves for 0.02M KBr at pH 2.0 (phosphoric acid buffer) are given in Fig. 5. At low disk current, *i.e.*, 200 μA , $>95\%$ of production efficiency for bromine was observed (curve 2). Production efficiency dropped to 90% when I_D was 400 μA (curve 3) and to 60% when I_D was 900 μA (curve 4). For the last case, oxygen was also detected at the ring.

Bromine production efficiency as a function of disk current for various weakly acidic solutions is shown in Fig. 6. At pH 2.0, essentially the same results were obtained for the three different light intensities investigated. However, the Br^- flux to the disk for these conditions was 3840 μA , considerably higher than the maximum disk current at which ϕ_{Br_2} was still nearly 100%. The same qualitative picture was obtained at higher pH (curve b in Fig. 6) with ϕ_{Br_2} decreasing with increasing pH, as observed previously (3, 5).

For solutions containing 1M KBr ϕ_{Br_2} was 100% even at pH's as high as 4.2. Only at pH 6.4 was a decrease in ϕ_{Br_2} to 92% (curve c in Fig. 6) observed. Although this drop was small, it was outside experimental uncertainty, and, in addition, oxygen was detected at the ring.

At pH 12.2 no trace of Br^- oxidation was observed even for a 0.5M KBr solution. The I_R - V_D / I_D curves were not affected by the addition of Br^- to the solution. Plateau currents for oxygen reduction at the ring were observed (Fig. 7) with $\phi_{\text{O}_2} > 95\%$.

Chloride oxidation.—Photo-oxidation of chloride at $\alpha\text{-Fe}_2\text{O}_3$ electrodes competes effectively with water in strongly acidic solutions, as can be seen in Fig. 8 (curves 1 and 2). The production efficiency for Cl_2 in 1M HCl remained $> 95\%$ at all disk currents studied, but a small drop was seen at high current levels for 0.1M HCl/0.9M HClO_4 solutions (curve 2). This drop in efficiency was more pronounced when the concentration of chloride was decreased to 0.01M (curve 4). Also, ring voltammograms exhibited 3-4 reduction waves. For solutions containing $2 \times 10^{-3}\text{M}$ HCl/1M HClO_4 , in which chloride flux to the surface was equivalent to 330 μA , the dependence of ϕ_{Cl_2} on I_D was strong even at low disk current levels (curve 5).

As expected, ϕ_{Cl_2} dropped considerably as the pH was increased with efficiency values of 70-80% at pH 2.0 (curve 3 of Fig. 8) and $< 30\%$ and 200 μA at pH 4.0 (curve 6). No dependence on light intensity or electrode poten-

Curve 2: initially oxygen-free solution, $I_D = 500 \mu\text{A}$. Curve 3: air-saturated solution, $I_D = 0 \mu\text{A}$. Curve 4: initially oxygen-free solution, $I_D = 1000 \mu\text{A}$.

tial was observed. The I_R - V_R curve for 1M NaCl at pH 4.0 (Fig. 9, curve 2) shows the presence of O₂ as well as Cl₂, similar to the results presented earlier for bromide solutions.

Iodide oxidation.—Adsorption of iodine on the electrode surface (8) and possible diffusion of iodine into the bulk electrode along grain boundaries (11), complicated the RRDE measurements. By allowing time for the system to reach a steady state, it appeared, within experimental uncertainty, that 100% of the iodide flux could be oxidized to iodine at the disk in acidic solutions. No oxygen was detected at the ring as long as the iodide flux was higher than the disk current.

Dark currents.—At potentials $> 1.5\text{V vs. SCE}$, dark currents were observed at the α -Fe₂O₃ electrodes. Above 2.0V vs. SCE, the dark currents rose sharply as the semiconductor was driven to inversion. It was demonstrated previously (7) that oxygen was generated with 100% efficiency in the dark for 1M HClO₄ solutions. Addition of 0.1M Br⁻ or 0.1M Cl⁻ to the electrolyte was made, and electrolysis was carried out at 1.8-2.0V vs. SCE. For 0.1M KBr/1M HClO₄, production efficiency for Br₂ was $< 50\%$, and the ring currents were time dependent. Also, additional reduction waves were observed. It appears that both Br₂ and O₂ are produced in the dark along with at least one more product (such as HBrO or BrO₃⁻). Production efficiency for Cl₂ in the dark for solutions containing 0.1M KCl/1M ClO₄ was $< 50\%$, and the ring voltammograms were also complex.

Discussion

The competition reactions reported here at α -Fe₂O₃ electrodes follow the same general trend that has been observed at TiO₂ electrodes. The halides (I⁻, Br⁻, and Cl⁻) are oxidized in preference to water in acidic solution. However, because OH⁻ oxidation is kinetically favored over halide oxidation, the production efficiency for halogen decreases as the pH increases.

In Fig. 2-4, it was demonstrated that all Br⁻ reaching the electrode surface will be oxidized in preference to water in acidic solution. This is not true for Cl⁻ and for both Cl⁻ and Br⁻ in more basic solution.

A simple first-order kinetics scheme can be envisaged for the competition between halide and hydroxide ions. The halogen production efficiency is given by

$$\phi_{X_2} = \frac{k_X[X^-]}{k_X[X^-] + k_{OH^-}[OH^-]} \quad [7]$$

where k_X and k_{OH^-} are first-order rate constants for the oxidation of X⁻ and OH⁻, respectively. If we define a competition ratio: $k' = k_{OH^-}/k_X$, then Eq. [7] can be written as

$$\phi_{X_2} = \frac{[X^-]}{[X^-] + k'[OH^-]}$$

or

$$k' = \frac{[X^-] - \phi_{X_2}[X^-]}{\phi_{X_2}[OH^-]} \quad [8]$$

Fig. 8. Chlorine production efficiency as a function of disk current (I_D) for various chloride containing solutions. Curve 1: 1M HCl. Curve 2: 0.1M HCl/0.9M HClO₄. Curve 3: 1M NaCl, pH 2.0 (phosphoric acid buffer). Curve 4: 0.01M HCl/1M HClO₄. Curve 5: 0.002M NaCl/1M HClO₄. Fig. 9. Ring current-ring potential/disk current for 1M NaCl, pH 4.0 (phosphate buffer). Curve 1: oxygen-free solution, $I_D = 0 \mu\text{A}$. Curve 2: initially oxygen-free solution, 18% of full light, $I_D = 200 \mu\text{A}$. Curve 3: oxygen-saturated solution, $I_D = 0 \mu\text{A}$.

A simple test for the validity of Eq. [8] is if the same value of k' is obtained for various concentrations of X^- and OH^- . Such information is available from Fig. 6 for bromine production and from Fig. 8 for chlorine production. For the bromine case ($I_D = 700 \mu\text{A}$) the following values for k' are calculated: 9×10^9 (curve a), 4×10^8 (curve b), and 4×10^8 (curve c). For the chlorine case ($I_D = 200 \mu\text{A}$), k' values are: 3×10^{11} (curve 3), 1×10^{11} (curve 4), and 3×10^{10} (curve 6). Thus, the true kinetics is somewhat more complicated than this simplistic picture, but to an order of magnitude it is clear that $k'_{\text{Br}} \sim 10^8$ and $k'_{\text{Cl}} \sim 10^{11}$, which means that $k_{\text{Br}}/k_{\text{Cl}} \sim 10^3$.

It was demonstrated that the crucial parameter that determines the production efficiency in acidic solution is the ratio: flux X^-/I_D , relating the rate at which halide ions reach the electrode surface compared to the availability of holes at the electrode surface. Concentration of X^- , light intensity, and electrode potential only affect the production efficiency by their effect on this important ratio. In this respect, earlier publications (3-5) are somewhat misleading in that they disregarded this flux argument.

The complicated nature of these semiconductor electrodes is further demonstrated by the investigation of dark currents. The selectivity seen when $\alpha\text{-Fe}_2\text{O}_3$ is a photoanode is lost when operating in the dark. In fact, the behavior of $\alpha\text{-Fe}_2\text{O}_3$ in the dark resembles that of a metallic electrode. That is, mixtures of oxidation products for Br^- and Cl^- oxidation at high anodic potentials have been observed at metal electrodes (13). This similarity is not

too surprising when one recalls that the $\alpha\text{-Fe}_2\text{O}_3$ was driven to inversion to observe dark currents.

Conclusions

The following conclusions can be drawn from the observations reported here:

1. The general trends regarding competitive photo-oxidation at n -type semiconductor electrodes have been confirmed for $\alpha\text{-Fe}_2\text{O}_3$.

2. Quantitative agreement between the flux of Br^- reaching the electrode surface and the efficiency of Br_2 production has been demonstrated in acidic solution.

3. The critical factor in determining the competition ratio at a given pH is the flux $X^-/\text{disk current ratio}$.

4. A simple kinetics scheme does not fully account for the experimental data, but apparently Br^- is about 10^3 times more effective than Cl^- at capturing holes at the $\alpha\text{-Fe}_2\text{O}_3$ electrode surface, while OH^- is considerably more effective than either halide.

5. The dark current selectivity is considerably different than the photocurrent selectivity, with the $\alpha\text{-Fe}_2\text{O}_3$ electrode exhibiting more metallic-like behavior.

Photoelectrochemical Behavior of Iron Oxide/*n*-Si Heterojunction Electrodes with an Outer Pd Layer

Tetsuya Osaka,* Kiyomi Ejiri, and Naruya Hirota

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160 Japan

ABSTRACT

Iron oxide/*n*-Si heterojunction electrodes modified by an outer Pd layer were studied for its utility as an efficient photoanode. The addition of an evaporated Pd layer on the electrode greatly enhanced the photocurrent and shifted the onset potential from 0.5V (Hg-HgO) to the more cathodic side in a 0.2M KOH solution. A 100Å Pd layer showed the most cathodic onset potential of -0.36V (Hg-HgO). The unmodified iron oxide/*n*-Si electrode gave a relatively broad spectral photoresponse with the maximum region lying between 550 and 700 nm. With the addition of the Pd layer the quantum efficiency of spectral photoresponse from 400 to 800 nm became 20% higher. The addition of methanol enhanced the photocurrent up to 1.25 times at 0.6M concentration on the unmodified electrode, whereas on the Pd-modified electrode, the photocurrent decreased slightly by the addition of methanol. These phenomena are discussed in terms of various mechanisms for methanol oxidation.

A large number of oxide semiconductors have been investigated as photoanode materials because of their stability in the harsh conditions of oxygen evolution. Almost all oxide semiconductors have a large bandgap and even those with smaller bandgaps have been found to possess an unsatisfactory photocurrent onset potential (1). One of the oxide semiconductors, α -Fe₂O₃, has not been reported to show high energy conversion efficiency (2-9). An α -Fe₂O₃/*n*-Si electrode was reported to have stabilized *n*-Si semiconductor, and the heterojunction electrode showed broad spectral region of photoresponse (10-16). The photocurrent onset potential of α -Fe₂O₃/*n*-Si, however, is insufficiently cathodic. This paper reports the photoelectrochemical characteristics of Pd-modified iron oxide/*n*-Si electrodes for the purpose of improving the onset potential, as well as the effect of methanol on the electrodes with and without the Pd layer.

Experimental

Electrode preparation.—Single crystal *n*-Si semiconductors made by Shin-Etsu Chemical and possessing 0.85~1.15 Ωcm resistivity were used as substrates. A 400Å iron film was first vacuum-evaporated using a Hitachi electron beam evaporator onto a (100) plane *n*-Si substrate. The iron oxide was formed by heating in a vacuum furnace in an O₂ atmosphere of 0.1 torr at 400°C for 1.0h. The final thickness of iron oxide film was ca. 750Å, which was measured by a stylus technique (Rank-Taylor-Hobson Talystep I). The composition of the iron oxide was confirmed to be Fe₂O₃ by RBS (Rutherford backscattering spectroscopy) and XPS (x-ray photoelectron spectroscopy) methods, the data of which are to be published shortly (17). Pd layers were formed by two different methods: vacuum evaporation and the conventional Sn-Pd two-step activation wet process for electroless plating.

Photoelectrochemical measurements.—Electrochemical measurements were made potentiodynamically at 0.1 V·s⁻¹ in a 0.2M KOH solution in a purified Ar atmosphere at 25°C. Hg-HgO electrode in the same solution was used as a reference electrode. The photocurrent was measured using a 500W xenon lamp from Ushio Electric with an infrared filter. The spectral response of the photocurrent was measured between 400 and 800 nm using various spectral filters from Toshiba Glass. The total light intensity of the lamp, measured by a Tektronix radiant flux meter, was 0.085 W·cm⁻². The intensity at each wavelength was normalized for the spectral photoresponse. The differential capacitance of the semiconductor electrode was measured potentiodynamically at 5 mV·s⁻¹ by using a phase-sensitive impedance meter from Fuso-Seisakusho. Products of methanol oxidation on the

electrodes were qualitatively checked by a Hitachi gas chromatograph. Formaldehyde and oxygen gas were detected by using column packings of PEG 1000 and WG 100 (Gasukuro Kogyo Incorporated), respectively. The reproducibility was confirmed by using more than three electrodes for one matter. The stability of the electrodes was checked for about a one week term experiment.

Results and Discussion

Photoresponse of Fe₂O₃/*n*-Si heterojunction electrodes with Pd layer.—Figure 1 shows the characteristics of photocurrents for Fe₂O₃/*n*-Si electrodes with and without a 100Å layer of vacuum evaporated Pd in a 0.2M KOH solution. Photocurrent is greatly enhanced by the Pd layer. The photocurrent saturation point was observed at the region more anodic than 2.2V both with and without the Pd layer, but, the photocurrent of the Pd-modified electrode at the saturated photocurrent region is ca. 2.4 times larger than that of the unmodified electrode. A shift of the onset potential to the cathodic side was also observed as a result of Pd modification. Figure 2 shows the onset potential for electrodes with various thicknesses of Pd prepared by the two processes in a 0.2M KOH solution. With addition of a Pd layer, the photocurrent increased greatly and the onset potential also became more cathodic. In the case of the adsorbed layer of Pd prepared by the wet process, which may consist of adsorbed Pd particles of several tens of angstroms (18), the onset potential was not greatly improved. In the case of a Pd layer formed by vacuum evaporation, however, the photocurrent was significantly improved, especially at the low bias region, and the increase in photocurrent depends on the thickness of the Pd layer. The 100Å Pd layer gave the best improvement of onset potential (-0.36V) as can be seen in Fig. 2.

The relation between quantum yield (η) and the wavelength for the two cases, with and without a Pd layer, is plotted in Fig. 3. The spectral photoresponse for the Fe₂O₃/*n*-Si electrode shown in Fig. 3 shows the broad photoresponse between 400 and 800 nm, and the maximum photoresponse lies between 550 and 700 nm. The increase in the spectral photoresponse in the maximum response region may be caused by effective hole-injection from the Si to the electrode surface across the Fe₂O₃ film. The photoresponse of Fe₂O₃/*n*-Si heterojunction electrodes has been reported by Yazawa *et al.* (10-12), and they report that it has a broad photoresponse between 480 and 850 nm. There appears to be a slight difference between the spectral photoresponse obtained by Yazawa *et al.* (10) and ours. Since the characteristics of the photocurrent of the Fe₂O₃/*n*-Si depend strongly on the iron oxide states (16), the difference in spectral photoresponse may be due to the difference of the oxidized states of iron oxides which are formed by the differ-

Fig. 2. Photocurrent-potential curves for Pd-modified $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes in 0.2M KOH at $0.1\text{ V} \cdot \text{s}^{-1}$. Pd preparation, 2: wet process, 3,4,5: vacuum evaporation.

Fig. 3. Spectral dependence of quantum efficiency of anodic photocurrents for $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes both with and without Pd layer in 0.2M KOH in the saturated photocurrent region.

ent methods. The Pd-modified heterojunction electrode has almost the same response shape as $\text{Fe}_2\text{O}_3/n\text{-Si}$, but the quantum yield is about 20% higher, and at the maximum response region the quantum yield approaches 100%.

Figure 4a presents the capacitance behavior (C - E curves) at 1 kHz for $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes with and without Pd layer. The Mott-Schottky plots (Fig. 4b) were constructed from these curves in order to obtain flatband potentials and estimate band structure, though the Mott-Schottky plot which assumes a simple Schottky barrier does not necessarily give information about the exact flatband potential for such multilayered heterostructures. The plots in Fig. 4b indicate that the flatband potentials are apparently very close for two cases with and without the Pd layer. We assume that the introduction of the Pd layer results in a Schottky barrier electrode structure increasing its current collection efficiency, and that the increase in current collection efficiency due to Pd layer alters the onset potential in spite of the apparently closed flatband potentials. A relatively large extension of spectral range for photoresponse, improved by an outer metal layer, has been reported for $p\text{-GaP}$ (19, 20) and SrTiO_3 (21). Since the spectral photoresponse of the semiconductor itself, such as $p\text{-GaP}$ or SrTiO_3 , is in contrast with this heterojunction electrode, limited to shorter wavelengths, the introduction of surface metal layer is considered to effectively improve spectral photoresponse at longer wavelengths.

Effect of methanol on photocurrent in heterojunction electrodes with and without Pd layer.—Figure 5 shows the photocurrent vs. potential curves on the unmodified $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrode in a 0.2M KOH solution with various methanol concentrations. On this electrode the addition of methanol obviously causes an increase in photocurrent, but no shift in the onset potential. This effect with the unmodified electrode, well-known as "current doubling," was not observed on the Pd-modified electrode. The photocurrent ratio I_p/I_a vs. methanol concentration plots at 1.2V are shown in Fig. 6 for both electrodes, where I_p and I_a represent the photocurrents in the presence and absence of methanol in the solution. On the unmodified electrode, the photocurrent clearly increased with the addition of methanol and shows the maximum I_p/I_a ratio of 1.25 at 0.6M methanol, whereas on the Pd modified electrode, the photocurrent decreased slightly with an increase in methanol concentration. The photoelectrochemical oxidation of alcohols on $\alpha\text{-Fe}_2\text{O}_3$ was discussed by Miyoshi *et al.* (22), who claimed

Fig. 4. Capacitance behavior for $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes both with and without Pd layer in 0.2M KOH at 1 kHz . (a) Capacitance-potential curves and (b) Mott-Schottky plots.

Fig. 5. Effect of methanol on photocurrent of $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrode in 0.2M KOH at $0.1\text{ V} \cdot \text{s}^{-1}$. Methanol concentration, 1: 0M , 2: 0.08M , 3: 0.18M , 4: 0.45M .

that the addition of methanol did not cause an increase in the photocurrent despite their finding that the methanol was photoelectrochemically oxidized on the illuminated Fe_2O_3 . Accordingly, there is a large difference between Fe_2O_3 and $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes with regard to the effect of methanol on photocurrent. Moreover on the Pd-modified electrode, the current doubling effect of methanol was not observed.

In order to determine whether the methanol is photoelectrochemically oxidized on $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes with and without Pd layer, potentiostatic electrolysis at the saturated photocurrent region of 3.0V was performed for 10h in a 0.2M KOH solution under illumination. Gas chromatographic analysis showed that the main product of methanol in the solution on illuminated electrodes with and without Pd layer is formaldehyde and that the gas product is almost entirely O_2 . No production of CO_2 could be detected because CO_2 is absorbed by the KOH solution. Therefore, the methanol is concluded to be oxidized photoelectrochemically on the electrodes both with and without the Pd layer. It is generally accepted that the photoelectrochemical oxidation of methanol proceeds through a two-step mechanism for the case of accompanying the current doubling effect (22, 23)

Fig. 6. Plots of I_p/I_a vs. methanol concentration for $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes both with and without Pd layer in 0.2M KOH at 1.2V (Hg/HgO).

Fig. 7. Schematic diagram of current doubling process of methanol for $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrode.

The photoelectrochemical oxidation of organic compounds showing current doubling effect can be explained by electron-injection of the intermediate radical into the conduction band (Eq. [2]). Figure 7 shows a schematic diagram of the current doubling process, based on a tentative model of a possible energy diagram for the $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrode, proposed by Yazawa *et al.* (11, 12). The tentative model is assumed on the basis of efficient hole-injection that may be produced by the nice fit of the valence bandedge between outer and inner semiconductors. Miyoshi *et al.* (22) explained the oxidation of methanol on $\alpha\text{-Fe}_2\text{O}_3$ electrode by the assumption that the intermediate radical of methanol, produced by oxidation due to photogenerated holes, is further oxidized by the photogenerated holes instead of injecting the electron of the intermediate radical into the conduction band, since the energy level of intermediate radical is situated at the level lower than that of conduction band of Fe_2O_3 . On the unmodified $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrode, however, current doubling occurs, and furthermore this effect disappears on the Pd modified electrode. The following consideration is suggested in order to explain these results. On the unmodified $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrode, methanol is first oxidized to an intermediate radical by the photogenerated holes in the valence band as shown in Eq. [1], and further oxidation of the intermediate proceeds by electron-injection into the conduction band by the tunneling effect as shown in Fig. 7. The assumption of a tunneling effect, which is needed to explain the opposite results obtained from the Fe_2O_3 and $\text{Fe}_2\text{O}_3/n\text{-Si}$ electrodes, may be supported by the finding that the increase of photocurrent is merely 1.25 times. On the Pd-modified electrode, the intermediate radical, after the initial oxidation of Eq. [1], is further oxidized by the hole in the valence band as shown in Eq. [3]

since the hole density in the valence band becomes higher due to the effective hole generation by Pd layer.

Conclusion

The addition of a Pd layer on top of an $\text{Fe}_2\text{O}_3/n\text{-Si}$ heterojunction electrode caused quantum yield *ca.* 20% higher for the photoresponse between 400 and 800 nm, and made the onset potential more cathodic in a 0.2M KOH solution. The effect of methanol on photocurrent was studied, and the results obtained with and without the Pd layer were opposite. The characteristics of photoresponse and the mechanism of methanol oxidation for $\text{Fe}_2\text{O}_3/n\text{-Si}$ heterojunction electrodes both with and without Pd layer were discussed.

Dye Sensitization of Cuprous Thiocyanate Photocathode in Aqueous KCNS

Kirthi Tennakone, Mahendra Kahanda, Cyril Kasige, and Parakrama Abeysooriya

Department of Physics, Ruhuna University College, Matara, Sri Lanka

Ranmuthu H. Wijayanayaka and Padmananda Kaviratna

Department of Chemistry, Ruhuna University College, Matara, Sri Lanka

ABSTRACT

Cuprous thiocyanate (p-type semiconductor) is found to adsorb thiocyanated cationic dyes to yield high photoresponses in aqueous KCNS. The method of preparation and the performance of dye-sensitized CuCNS photocathodes are discussed.

Electrolytic photocells with semiconductor electrodes are attracting attention as economical devices for the conversion of solar energy (1-8). The additional advantage of these systems is the possibility of extending the spectral response by sensitization with dyes (9-13). It is also known that the dye-sensitized (DS) photocurrent is rather insensitive to impurities and defects in the semiconductor (14, 15); polycrystalline and amorphous materials with large bandgaps when sensitized yield high photocurrents. The sensitization is effective only if the dye is absorbed at the semiconductor surface (9-13). Thus, to produce practically useful DS cells, it is necessary to search for systems where the dye adsorption is optimized. We have found that cuprous thiocyanate (a p-type semiconductor) (16-17) readily adsorbs cationic dyes when CNS^- is the anionic ligand. In this paper, we describe our observations on DS CuCNS electrodes in aqueous KCNS.

Experimental

CuCNS photocathode is made by the following method. A copper plate 5×5 cm is anodically polished in 10% H_2SO_4 . An acidic solution of KCNS (0.25 mol l^{-1} in KCNS, 0.7 mol l^{-1} in acetic acid, solution pH ~ 3.5) is electrolyzed with the copper plate as the anode. The current density is kept at ≈ 2.5 mA cm^{-2} , and the plating is continued for ≈ 30 min. CuCNS deposits on the anode as a hard white layer firmly affixed to the copper substrate. (Unless a large excess of acetic acid is used, there is no risk of liberation of HCN in this process.)

To obtain an unbroken uniform coating, it is essential that the surface is free from patches of grease. The addition of 1-2 ml or propan-2-ol to 100 ml of the electrolyte enhances even deposition by removing grease. The dyes used in this investigation are mostly triarylmethane chlorides (BDH grade). CuCNS readily adsorbs these dyes

when Cl^- is replaced by CNS^- . The thiocyanated dyes (TD's) are prepared by the following method. A solution of the commercial dye in alcoholic KCNS (concentration > 2.5 mol l^{-1}) is boiled until most of the alcohol is expelled. The TD recrystallizes when the solution is cooled to room temperature (30°C). The crystals are separated by filtration, washed with KCNS solution, and dried at 80°C. CuCNS electrodes are made to adsorb the TD's by immersing them in the dye solution (0.1g per liter of water containing 10% ethanol, solution pH has no effect on the degree of adsorption) for 30 min. Rapid adsorption takes place, and the electrode acquires colors characteristic of the dyes (bluish-green, green, red for methyl violet, malachite green, and rosaniline). It is found that the best photoresponse is obtained when $\sim 10^{16}$ molecules of the dye/ cm^2 is adsorbed to form almost a monolayer (the amount of adsorbed dye is determined by extraction of the absorbed dye with ethanol and colorimetric estimation).

The absorption spectra of the dyes (in aqueous solution and adsorbed on solid CuCNS) are measured using Unicamp SP 500 Series 11 spectrophotometer. The light sources used in all experiments were tungsten filament lamps. Capacitance measurements indicate the flatband potential of CuCNS in aqueous KCNS is $\sim +0.2$ vs. SCE.

As they all perform better in the backwall mode, the anode used is a brass frame (same dimensions as the cathode) coated with copper sulfide. To obtain reproducible dark open-circuit voltages (≈ 0), it is prepared by the following procedure. The electrode is immersed in dilute HNO_3 (0.05 mol l^{-1}), H_2S is bubbled for about 10 min and kept in contact with the solution for 24h.

The electrolyte is an aqueous solution of KCNS (0.1 mol l^{-1}) containing $\sim 10^{-3}$ mol l^{-1} of thiocyanogen. Thiocyanogen is prepared by mixing a solution of Br_2 in diethyl ether with excess AgCNS (18). When the ethereal

solution of $(\text{CNS})_2$ is shaken, and aqueous KCNS and ether are allowed to evaporate, $(\text{CNS})_2$ passes into the aqueous medium. Thiocyanogen in aqueous solution undergoes partial decomposition and polymerization (19). However, in the presence of KCNS, a weak solution of $(\text{CNS})_2$ is almost completely stabilized (20) due to formation of $(\text{CNS})_2^-$. The presence of this ion can be easily demonstrated by its characteristic absorption peak at 475 nm (21). In fact, the oxidation of CNS^- by atmospheric oxygen always produces detectable quantities of $(\text{CNS})_2^-$ in aqueous solutions of KCNS.

Unlike in other DS cells, the dye does not diffuse into the electrolyte, and the solubilities of TD's are suppressed by the CNS^- ions.

Results and Discussion

The thiocyanates of Cu(I) and Ag show semiconduction at the optical absorption edge near 335 nm (see Fig. 1.) In the absence of sensitizers, a feeble photoresponse is seen

in the UV region (the material is completely photostable in aqueous KCN in the presence or absence of dyes). When the dyes are adsorbed, the photocurrent is enhanced by a factor more than 100, and the peak of the spectral response shifts towards the long wavelength region (Fig. 2, curve 3 gives the action spectrum of the cell in the optical region in the absence of UV component). The mechanism of dye sensitization is widely discussed in literature (4, 9-13). When these ideas are applied to the present system, the photoreaction occurring at the electrodes can be expressed as follows.

Photocathode

where D denotes a dye molecule, D^* an excited dye mole-

Fig. 2. Curve 1: diffuse reflectance spectrum of methyl violet adsorbed in CuCNS. Curve 2: absorption spectrum of an aqueous solution of methyl violet ($\approx 0.1 \text{ g dm}^{-3}$, cm cell). Curve 3: action spectrum when the photocathode is sensitized with methyl violet.

cule, and D^- a dye molecule that has lost one electron. The hole generated is transferred into the valance band.

Anode.—Near the anode, CNS^- ions discharge electrons yielding CNS free radicals, which combine with CNS^- ions in the solution to regenerate $(CNS)_2^-$ ions, *i.e.*

Thus, in principle, the cell is regenerative, because of the presence of the redox couple $CNS^-/(CNS)_2^-$ ($\sim +0.29$ vs. SCE).

It is interesting to note the close resemblance of the action spectrum of the photocurrent to the diffuse reflectance spectrum of the dye adsorbed on $CuCNS$ (Fig. 2). However, this is different from the absorption spectrum of the dye in aqueous solution. In the former spectrum,

the absorption peak is broader—a factor acting favorably on the performance of the cell. Compared to other DS systems, the efficiency of the cell (power produced/light energy incident per second) obtained from the plots of I vs. V and IV vs. V (Fig. 3 and 4) is high. The highest value, 2.8% (light source tungsten filament lamp at intensity of illumination 40 W m^{-2}), is obtained with methyl violet. The corresponding quantum yield, *i.e.*, number of electrons passed per second/number of incident photons per second in the wavelength region 450–600 nm (intensity distribution of the lamp is estimated using a bolometer coupled to a spectrometer), is $\sim 27\%$; other triarylmethane TD's give slightly lower efficiencies (Table I). The stability is also good and $CuCNS$ remains completely photostable; however, the dyes photodegrade slowly, decreasing the photocurrent at a rate $\approx 0.1 \mu\text{A cm}^{-2} \text{ h}^{-1}$ (Fig. 5). After about 48h of operation (light intensity 40 W m^{-2}), the dye degenerates, possibly because of the formation of re-

duced leuco-compounds. This is supported by the fact that when oxidizing agents are added, the photocathode regains the original color and photoresponse. The photo-reduction of the dyes could result from presence of the reaction.

in addition to reaction [1]. We have not succeeded in finding better redox electrolytes that do not react with the TD's. Apart from the triarylmethanes, other classes of cationic dyes (e.g., rhodamines, acridines) also show good adsorption. Unfortunately, they also suffer from the same defect.

Another interesting feature of the cell is the high open-circuit voltage (V_{oc}). Most dyes give a $V_{oc} \sim 800 \text{ mV}$ when the intensity of illumination is 40 W m^{-2} (Table I).

Although the efficiency of the system is comparable or slightly better than most efficient DS cells reported in the literature (13), the system in the present form does not have any practical value. Nevertheless, our investigations show that if methods are found for affixing dyes into high bandgap materials to optimize the photoresponse, DS cells would turn out to be practically useful systems (absorption of the dye is not the only criterion determining the performance of a DS cell, the stability of the dye towards repeated oxidation and reduction, the presence of an intense absorption band, and good electrical conductivity are also deciding factors). The V_{oc} of a photoelectrochemical cell depends on the bandgap of the material. The short-circuit photocurrent (I_{sc}) is determined by the number of photons converted into electron-hole pairs without recombinations (23). Thus, theoretically, DS cells

could have high efficiencies because I_{sc} can be controlled by the use of dyes, relevant to the desired spectral region.
