Our study shows that the diffusion of As in thermally grown SiO₂ is a complex phenomenon. In agreement with expectations from a simple model, one has to consider two consecutive process steps: restoration of the network structure damaged by implantation, and diffusion of As in the restored network. Both steps are likely to be ambient dependent.

The data presented in this paper suggest that two different oxide structures are obtained: an oxygen deficient one in N₂ (or Ar), and a fully oxidized structure in O₂. In both cases, As is incorporated into the network of the glassy oxide, and for N₂-annealed samples possibly additionally on interstitial sites.

The observation of a relatively high diffusion rate at high As concentrations and a very low one at lower concentrations in O₂-annealed samples leads to the conclusion that a separate high concentration liquid phase is formed in fully oxidized samples. The opposite behavior is exhibited by the N₂ heated samples. Again, a two-phase model is proposed, in this case with an immobile high concentration solid phase.

A report in the literature, claiming that a considerably enhanced rate of diffusion in O₂ is observed when simultaneously oxidation of the substrate takes place, could not be confirmed. However, we did find indications that the ambient affects the diffusion rate via the oxygen vacancy concentration in the system.

Characteristics of Ion-Implantation Damage and Annealing Phenomena in Semiconductors

J. Narayan* and O. W. Holland

ABSTRACT

The nature of ion-implantation damage in silicon and gallium arsenide as a function of implantation and substrate variables has been investigated using electron microscopy and Rutherford backscattering techniques. With no annealing effects, the crystalline-to-amorphous transition occurs at a critical energy of 12 eV/atom for silicon. By increasing the dose rate or the substrate temperature, "defect-free" regions with no dopant redistribution are obtained. There is a dose rate or substrate temperature window in which voids are formed, producing undesirable effects. The annealing effects at high dose rates are interchangeable with substrate temperature. A high fraction of dopants in both Si and GaAs is found to be in electrically active substitutional sites after high dose rate or high temperature implants. The origin and thermal annealing of underlying dislocation bands have been examined in detail. Subsequent annealing behavior of underlying dislocation bands is critically determined by the nature of the as-implanted states.

Ion implantation is now a well-established technique for a controlled introduction of dopants in semiconductors. Ion-implantation-induced damage must be removed in order to achieve a "complete" electrical activation of dopants and to recover carrier mobility (1). The conventional method of removing ion-implantation damage involves isothermal annealing treatments in a furnace in the temperature range of 900°-1000°C for about 30 min. Recently, more advanced methods based on rapid heating or annealing have been developed for removing ion-implantation damage. The annealing methods based on solid-phase and liquid-phase crystallization (2-6) have been successfully utilized to remove the damage. In both conventional and advanced annealing methods, the nature of ion-implantation damage before annealing is thought to determine the amount of residual damage and concomitant electrical activation and mobility achieved after annealing.

The purpose of this paper is twofold. The first purpose is to show that the nature of residual damage after ion implantation is a strong function of ion implantation and substrate variables. The ion-implantation variables of particular interest are the total dose, dose rate, and mass and energy of the incident ions. The substrate variables include the temperature and the mass. The second purpose of this paper is to show that different ion-implantation states exhibit different annealing behavior and electrical recovery of dopants. The mechanisms of dynamic *in situ* annealing during ion implantation and of subsequent annealing behavior are discussed for Si and GaAs. The correlations between residual ion-implantation damage and concentration of substitutional (electrically active) dopants in Si and GaAs specimens are presented. The paper is divided into the following sections: ion-implantation fundamentals; dose rate and substrate temperature effects in silicon; dose rate effects in different orientations; dose rate and substrate temperature effects in GaAs; thermal annealing of different ion-implantation states; and annealing effects in underlying dislocation bands and gettering.

Experimental

Single crystals of silicon having $\langle 100 \rangle$ and $\langle 111 \rangle$ orientations (500 μm thick, 2-6 $\Omega\text{-cm}$, Czochralski grown) were implanted with $^{28}\text{Si}^+$, $^{30}\text{Si}^+$, $^{75}\text{As}^+$, and $^{208}\text{Bi}^+$ ions. Implantation current varied from 1-500 $\mu\text{A cm}^{-2}$, ion energy from 100-250 keV, total dose from $1.0 \times 10^{14} \text{ cm}^{-2}$ to $5.0 \times 10^{16} \text{ cm}^{-2}$, and substrate temperature from liquid helium (He) to room temperature. No effort was made to heat-sink the samples during implantation. The $\langle 100 \rangle$ GaAs specimens were implanted with $^{28}\text{Si}^+$ ions using a similar range of implant and substrate variables. For some Si and GaAs specimens, *in situ* heating was applied while ion implantation was carried out at low dose rates. The ion-implanted silicon and gallium arsenide samples were analyzed by cross-sectional electron microscopy and Rutherford backscattering/channeling techniques at room temperature for a detailed determination of residual damage and lattice location of dopants. Lattice location of dopants is directly related to their electronic properties. The Si^+ -implanted GaAs samples were analyzed by MeV proton-induced x-ray excitation (PIXE) to determine the lattice location of silicon (7). For other studies, an analysis of the energy spectra of light ions backscattered from the sample under channeling and nonchanneling conditions is used for lattice-site determination. However, backscattering techniques are sensitive only to heavy impurities in light substrates and, therefore, are not suitable for GaAs work. The distinct separation of the Si characteristic x-rays from those of the host lattice makes lattice location studies possible in this material through the analysis of x-ray spectra (otherwise impossible using other ion scattering techniques). High resolution electron microscopy studies were conducted using a JEOL 200CX electron microscope operated at 200 kV with a spherical aberration coefficient (C_s) of 1.2 mm. The images were taken under axial illumination with optimum defocus, which is about 1.2 times the Scherzer defocus limit of -65 nm .

Results and Discussion

Ion-implantation fundamentals.—During ion implantation, when an energetic ion penetrates a solid, it collides with the electrons and nuclei of the solid. The energy lost in electronic excitations ultimately appears as heat. The initial energy of the primary ion can be partitioned into the amount lost in electronic excitations, and the remaining energy (E_D) goes into production of displacements. This displacement or ion-implantation damage is created as Frenkel (vacancy and interstitial) pairs, whose number is given by the modified Kinchin and Pease (8) expression $\kappa E_D/2E_d$, where κ (~ 0.8) is the displacement efficiency and E_d is the displacement threshold energy ($\sim 15 \text{ eV}$ for silicon) (9). The vacancies and interstitials accumulate as a function of implanted dose, and at a critical value of 12 eV/atom for E_D , there is a first-order phase transition from crystalline to amorphous phase. This value of 12 eV/atom, or $6.0 \times 10^{23} \text{ eV/cm}^3$ in silicon, is determined near 4 K, where annealing effects are negligible (10, 11). At higher temperatures, mobility of vacancies and interstitials becomes high enough that they annihilate each other or cluster to form dislocation loops. During ion implantation, if the regions of crystals exceed the critical energy for amorphization, they undergo a first-order phase transformation. It has been shown that for self-ions in silicon, overlap of damage produced by several ions is required because individual ions can deposit only about 3 eV/atom (11, 12). The ions, having mass equal to higher than that of antimony, can deposit 12 eV/atom or higher and, therefore, produce amorphous regions directly (11).

Figure 1A is a high resolution micrograph showing an amorphous region in a silicon specimen implanted with 100 keV, $1.0 \times 10^{14} \text{ cm}^{-2}$, $^{30}\text{Si}^+$ ions at liquid He temperature. The specimens that were implanted with $5.0 \times 10^{13} \text{ cm}^{-2}$ Si^+ (100 keV), at liquid He temperature or at room temperature, showed the presence of dislocation loops and not of amorphous regions. As the implanted dose was increased to $2.0 \times 10^{14} \text{ cm}^{-2}$, the small amorphous regions overlapped and created a large band of amorphous re-

gion. However, in this amorphous phase, the presence of microcrystallites is clearly delineated, as indicated by the arrow in Fig. 1B. Figure 1C shows a micrograph just below the critical dose of amorphization. There are many amorphous regions present at this dose, including a twinning partial dislocation, the core region of which is encircled in the micrograph. The line in the micrograph shows the trace of a twinning plane. Figure 1D shows a cross-section micrograph from a specimen implanted with a dose of $4.0 \times 10^{14} \text{ cm}^{-2}$, where the interface between crystalline and amorphous phase appears to be atomically sharp, confirming the first-order phase transition. Some microcrystallites (as shown by the arrow) are also present in this specimen. It is interesting to note that the amorphous-crystalline interface is fairly undulated, presumably because of ion-range straggling.

The displacements below the amorphous-crystalline interface are created because of ion-range straggling. The interstitials in this region can cluster at higher temperatures to form visible dislocation loops. The average size of the vacancy loops has been shown to be much smaller ($\sim 5\text{-}10\text{\AA}$) than that of interstitial loops (13), normally below the resolution limit of the strain-contrast imaging mode of the microscope.

The sequence of ion implantation as a function of increasing dose, discounting the annealing effects, can be described as follows. First, the region corresponding to the Gaussian damage peak turns amorphous after attaining 12 eV/atom of damage energy. This band then expands toward both the surface and deeper regions of the crystal with increasing implanted dose as these regions accumulate the critical energy for amorphization. Figure 2A shows a buried amorphous layer after a dose of $2.0 \times 10^{14} \text{ cm}^{-2}$ (100 keV, $^{30}\text{Si}^+$ ions). A high resolution micrograph from the near-surface region is shown in Fig. 2B, where the crystalline and amorphous boundary is clearly delineated. Although the amorphous-crystalline boundary is jagged, it is atomically sharp. The microcrystallites are present in the amorphous region. As the implanted dose is further increased, the amorphous-crystalline boundaries at both ends expand, ultimately creating amorphous layers followed by a band of dislocation loops. Figure 3 shows such layers for two different doses, 5.0×10^{14} and $5.0 \times 10^{15} \text{ cm}^{-2}$ (100 keV, $^{30}\text{Si}^+$). The thickness of the amorphous layer was found to increase from 2200-2660 \AA as the dose increased from 5.0×10^{14} (Fig. 3A) to $5.0 \times 10^{15} \text{ cm}^{-2}$ (Fig. 3B). Figure 3C is a microdiffraction pattern from $5.0 \times 10^{14} \text{ cm}^{-2}$ specimens, showing two clear rings, which correspond to the first and second neighbor distances, and a faint third ring. For a dose of $1.0 \times 10^{16} \text{ cm}^{-2}$, the thickness of the amorphous layer was found to be 2830 \AA . With further increase in dose, however, the increase in thickness was small because of saturation and the importance of sputtering effects.

Dose rate/substrate temperature effects in Si $^{28}\text{Si}^+$ implantation.—It has been shown that by increasing the ion-implantation current, the substrate temperature can be raised. Therefore, the annealing effects achieved by high dose rate implants (without additional sample heating) can be simulated by *in situ* heating of the substrate while implanting at low dose rates. By increasing the dose rate (ion-implantation current), it is possible to create "defect-free" regions near the surface, followed by a broad band of dislocation loops and tangles. An example is shown in Fig. 4A for a 200 keV Si^+ implant at 200 $\mu\text{A cm}^{-2}$ to a dose of $1.0 \times 10^{16} \text{ cm}^{-2}$. In this case, no additional heating was applied during implantation. The cross-sectional TEM micrograph shows a top 2100 \AA wide "defect-free" region, followed by a 3000 \AA wide region containing dislocation loops and tangles. The annealed layer has the same orientation as the underlying substrate. Figure 4B shows a random and $\langle 110 \rangle$ -aligned spectrum from these specimens. The aligned yield in the top 2100 \AA region is close to that of virgin crystals, which is in good agreement with TEM observations. The aligned yield increases below 2100 \AA , because of the presence of disloca-

Notice the presence of a microcrystallite in the amorphous region (indicated by arrow).

tions, but it does not reach the random or amorphous value. These results should be contrasted with low dose-rate Si^+ implants (see Fig. 19), where an amorphous layer followed by a band of dislocation loops is observed.

Figure 5 shows results from 80 keV $^{28}\text{Si}^+$ implants in silicon. After implantation to a dose of $1.0 \times 10^{16} \text{ cm}^{-2}$ at an implantation current of $120 \mu\text{A cm}^{-2}$, we found a buried amorphous layer, as shown in Fig. 5A. The cross-sectional

micrograph shows about a 350Å wide "defect-free" region, followed by a 700Å wide amorphous region. Below the amorphous layer, a 200Å wide defect-free layer is formed, which is followed by a 600Å wide region of dislocation loops and tangles. The RBS results from these specimens are shown in Fig. 5B. From the comparison of $\langle 110 \rangle$ -aligned spectra and random spectra, we find that the reduced yield in the top layer in as-implanted specimens is consistent with TEM observations. Below this region, the aligned yield approaches the random yield, corresponding to the presence of a 700Å wide amorphous layer. The aligned yield drops again, corresponding to the defect-free region below the amorphous layer. The yield increases again, owing to the presence of dislocations; however, the yield does not drop to a virgin value in the substrate, owing to previous dechanneling events. The as-implanted specimens containing buried amorphous layers were annealed at 550°C, and it was found that two amorphous-crystalline interfaces moved toward each other and ultimately produced a band of dislocation loops

Fig. 3. Cross-sectional electron micrographs showing an increase in amorphous layer thickness with dose. A: 100 keV $^{30}\text{Si}^+$, dose = $5.0 \times 10^{14} \text{ cm}^{-2}$. B: Dose = $5.0 \times 10^{15} \text{ cm}^{-2}$. C: Microdiffraction pattern corresponding to A.

near the center. This is consistent with a small peak in the aligned spectrum at a 700Å depth after annealing the as-implanted specimens for 50 min at 550°C. This peak was reduced or almost annealed out by further annealing at 850°C for 10 min, but the large dislocation loops in this layer, particularly in the underlying layer, remain. This is consistent with increased dechanneling in the aligned spectrum below 1200Å.

$^{75}\text{As}^+$ implantation.—Figures 6-9 show results from high dose-rate, 100 keV As^+ implants in $\langle 100 \rangle$ silicon. Figure 6A is a TEM cross-sectional micrograph at $200 \mu\text{A cm}^{-2}$ to a dose of $1.0 \times 10^{16} \text{ cm}^{-2}$; it shows a defect-free region ($\sim 500\text{Å}$ wide), followed by a band of dislocation loops and tangles ($\sim 1000\text{Å}$ wide). A microdiffraction pattern from the implanted layers of these specimens is shown in Fig. 6B, in which diffraction spots are sharp and regular, corresponding to a $\langle 110 \rangle$ orientation. At $40 \mu\text{A cm}^{-2}$, there is a 1100Å wide amorphous layer followed by a 150Å wide defect-free region and a 300Å wide dislocation band, as shown in Fig. 6C. A microdiffraction pattern from the amorphous band is shown in Fig. 6D, which contains the characteristic rings of amorphous phase. The defect-free region is formed by a solid-phase epitaxial growth process at this dose rate because of beam heating. It is apparent that by increasing the dose rate, the SPE

Fig. 4. A(top): Cross-sectional electron micrograph showing the formation of defect-free region in silicon-implanted (100) silicon (200 keV $^{30}\text{Si}^+$, $1.0 \times 10^{16} \text{ cm}^{-2}$, $200 \mu\text{A cm}^{-2}$). B(bottom): 2.0 MeV He^+ RBS spectra (random and $\langle 110 \rangle$ -aligned) from the specimen shown in A.

growth rate can be enhanced and annealing in the top region achieved. The dislocation loops and tangles are formed by clustering of point defects with number densities below that required for amorphous phase transformation. Figure 7 shows 2.0 MeV $^4\text{He}^+$ random and $\langle 110 \rangle$ -aligned spectra from high (Fig. 6a) and low (Fig. 6c) dose-rate implants and virgin crystals. The low dose-rate implants show $\sim 1500\text{\AA}$ thick defective layers. It should be noted that the 1500\AA wide defect-free band below the amorphous layer is not resolved in the aligned silicon spectrum for low dose-rate implants, presumably because of limited system resolution. The aligned silicon spectrum from high dose-rate implants shows reduced

Fig. 5. A(top): Cross-sectional electron micrograph showing a buried amorphous layer in silicon-implanted (100) silicon (80 keV $^{30}\text{Si}^+$, $1.0 \times 10^{16} \text{ cm}^{-2}$ with a dose rate of $120 \mu\text{A cm}^{-2}$). B(bottom): 2.0 MeV He^+ RBS spectra (random and $\langle 110 \rangle$ -aligned) after annealing at 550° and 850°C (from specimen shown in 1A).

yield in the top 500\AA wide region corresponding to the defect-free region in the cross-sectional TEM micrograph. From the aligned and $\langle 110 \rangle$ random spectra of arsenic, it was found that up to 90% of the arsenic in substitutional sites were in certain regions. It is most interesting to note that the arsenic depth distribution remains Gaussian and largely unchanged during high dose-rate implants. Hall measurements showed a high electrical activation of arsenic of up to 70%.

When the dose rate was increased to $400\text{--}500 \mu\text{A cm}^{-2}$, we observed the formation of voids in the top 500\AA wide region with a 50\AA average diameter. The voids in Fig. 8a exhibit a characteristic light contrast for overfocus conditions and a characteristic dark contrast for underfocus

Fig. 7. 2.0 MeV He^+ RBS spectra (random and $\langle 110 \rangle$ -aligned) from the high and low dose-rate specimens shown in Fig. 6.

Fig. 8. Formation of voids in high dose-rate implanted (100) silicon specimen (100 keV As^+ , 1.0×10^{16} , $\sim 400 \mu\text{A cm}^{-2}$) under different focusing conditions. C: Voids with light contrast in overfocus conditions at a higher magnification.

conditions (15) [Fig. 8b]. A small area at a higher magnification is shown in Fig. 8c, where voids are shown under a light contrast. Figure 9 is a plan-view micrograph showing voids in light contrast (overfocus conditions) in the top region. The formation of voids occurs because the in-

Fig. 9. Plan-view electron micrograph showing voids in light contrast (overfocus) conditions.

terstitials have faster mobility and are lost to the surface or other sinks. The vacancies, which in comparison with interstitials represent the slower moving species, cluster to form voids (16).

From these observations and a previous work (14), we have derived the following mechanism of annealing at high dose rates. During the initial phase of the ion implantation, buried amorphous layers or near-surface amorphous layers are formed, depending upon energy and mass of the incident ions and upon mass of the substrate. These variables determine the profile of the deposited damage energy. Lower energy of the incident ions and higher mass of the incident ions and substrate create amorphous layers near the surface. Buried amorphous layers are formed by higher energy of the incident ions and lower mass of the incident ions and substrate. For example, $100 \text{ keV } ^{28}\text{Si}^+$ tend to form buried amorphous layers, whereas $^{75}\text{As}^+$ ions form near-surface amorphous layers. The amorphous layers anneal by solid-phase epitaxial growth as the implantation is continued. The heat generated by the ion beam raises the substrate temperature. A typical substrate temperature of 750°C was measured during a $200 \mu\text{A cm}^{-2}$ (120 keV) Si^+ implant. Thus, SPE growth at high temperatures provides a primary mechanism of annealing at high dose rates. The kinetics of SPE growth have been extensively studied by RBS, TEM, and time-resolved reflectivity techniques (17). The interface velocity follows an Arrhenius relation $V = V_0 \exp(E_i/kT)$, where $V_0 \langle 100 \rangle = 3.07 \cdot 10^8 \text{ cm s}^{-1}$, and $E_a = -2.68 \text{ eV}$. The pre-exponential factor V_0 is orientation dependent, given by $(V_0 \langle 111 \rangle = 24 V_0 \langle 100 \rangle = 4 V_0 \langle 110 \rangle)$ (3). If the amorphous layers are not formed because the regions could not attain the critical energy of 12 eV/atom for amorphization, the recombination of interstitials and vacancies is a dominant mechanism of annealing. The cascades representing vacancy-rich regions may provide nuclei for void formation. It is noted that dopant depth profiles remain unchanged during high dose-rate implants. This is consistent because the average dopant diffusion distance ($\sqrt{2D\tau}$) during ion implantation (using the typical values of diffusion coefficients of arsenic in silicon at elevated temperatures, and using diffusion time, τ , the time of the ion implantation as the upper limit) is estimated to be less than 10 \AA .

Dose-rate effects in different orientations.—Since *in situ* solid-phase epitaxial (SPE) growth is a primary mechanism of annealing at high dose rates for high dose implants, it is interesting to study dose-rate effects in different orientations. The $\langle 111 \rangle$ Si specimens implanted with $^{75}\text{As}^+$ ions at a dose rate of $200 \mu\text{A cm}^{-2}$ contain an amorphous layer followed by a small defect-free region, similar to the microstructure obtained at $40 \mu\text{A cm}^{-2}$ in $\langle 100 \rangle$ specimens (shown in Fig. 6c). These results reflect a much smaller growth rate in $\langle 111 \rangle$ orientations than that in $\langle 100 \rangle$ orientations. The experimental results and theoretical models predict SPE growth rates to be slower by a factor of 24 in $\langle 111 \rangle$ orientations and a factor of 6 in $\langle 110 \rangle$ orientations, as compared with $\langle 100 \rangle$ orientations. Figure 10 shows a comparison between $\langle 100 \rangle$ and $\langle 111 \rangle$ orientations. These samples were implanted with 40 keV , $^{30}\text{Si}^+$ to $1.5 \times 10^{16} \text{ cm}^{-2}$ dose at liquid-nitrogen temperature at $\sim 5 \mu\text{A cm}^{-2}$ and then implanted with $120 \text{ keV } ^{28}\text{Si}^+$ to $1.0 \times 10^{16} \text{ cm}^{-2}$ dose at $\sim 200 \mu\text{A cm}^{-2}$. In $\langle 100 \rangle$ orientations, we found a 1700 \AA wide region to be fairly "defect free," except for a few polycrystalline regions near the surface. This region was followed by a 2000 \AA wide band of dislocation loops and tangles (Fig. 10a). A microdiffraction pattern from the recrystallized region is shown in Fig. 10c, where regularity and sharpness of diffraction spots are indicative of the perfection of the lattice.

The $\langle 100 \rangle$ Si results are in contrast to those of the $\langle 111 \rangle$ orientations, where we found 1700 \AA wide polycrystalline followed by a 2000 \AA wide band of dislocation loops and tangles (Fig. 10b). In the second region, a high number density of microtwins were also present.

Fig. 10. Comparison of high dose-rate effects in $\langle 100 \rangle$ - and $\langle 111 \rangle$ -oriented silicon specimens implanted with 40 keV $^{30}\text{Si}^+$ to $1.5 \times 10^{16} \text{ cm}^{-2}$ dose at LN_2 ($\sim 5 \mu\text{A cm}^{-2}$) and then implanted with 120 keV $^{28}\text{Si}^+$ to $1.0 \times 10^{16} \text{ cm}^{-2}$ dose. A: Cross-sectional electron micrograph, $\langle 100 \rangle$ Si specimens. B: $\langle 111 \rangle$ specimens. C: Microdiffraction pattern from A. D: Microdiffraction pattern from B.

Fig. 11. Substrate temperature effects in $\langle 100 \rangle$ GaAs after ion implantation with 120 keV $^{28}\text{Si}^+$ to a dose of $5.0 \times 10^{15} \text{ cm}^{-2}$. A: $\langle 110 \rangle$ cross-sectional electron micrograph with a dose rate $\sim 5 \mu\text{A cm}^{-2}$ while substrate is at room temperature. B: $\sim 5 \mu\text{A cm}^{-2}$ while substrate is at 200°C . C: $\langle 110 \rangle$ microdiffraction pattern from the specimens shown in B.

Figure 10d shows a microdiffraction pattern from the top layer, where diffraction rings are consistent with the polycrystalline structure of Fig. 10b. It is envisaged that SPE growth in $\langle 100 \rangle$ orientations is rapid enough to be completed before the nucleation of polycrystalline regions ahead of the crystallizing interface can occur (17). However, in $\langle 111 \rangle$ orientations, since the SPE growth rate is 24 times slower than that in $\langle 100 \rangle$ orientations, the crystallites can nucleate ahead of the crystallizing interface (3). Once these crystallites nucleate, interface-controlled growth cannot occur, and the whole layer turns polycrystalline.

Dose rate and substrate temperature effects in GaAs.—We have studied dose rate effects in $\langle 100 \rangle$ GaAs and compared the results with those obtained by heating the substrate during ion implantation. The ion implantation at low dose rates of $\sim 5\text{--}10 \mu\text{A cm}^{-2}$ typically results in the formation of amorphous layers followed by bands of dislocation loops. A typical example is shown in Fig. 11a, after 120 keV $^{28}\text{Si}^+$ implantation to a dose of $5.0 \times 10^{15} \text{ cm}^{-2}$. The number density of dislocation loops in the underlying dislocation band is found to be lower in this case than that found in silicon for the same implant condi-

Fig. 12. Characteristic x-ray spectrum from specimens shown in Fig. 11b, showing random and $\langle 100 \rangle$ -aligned x-ray yields.

tions. By heating the substrate to 200°C during implantation, we found a 1100Å wide, defect-free region followed by a 900Å wide band of dislocation loops, as shown in Fig. 11b. Figure 11c is a microdiffraction pattern from the annealed region; it shows sharp and regular diffraction, as corresponded with a $\langle 110 \rangle$ orientation.

Figure 12 shows a characteristic x-ray spectrum taken in random and $\langle 100 \rangle$ -aligned directions. The differences in aligned and random spectra of Ga and As confirm good annealing of the lattice. The $\text{SiK}\alpha$ yield in random and $\langle 100 \rangle$ -aligned directions shows that more than 90% of Si is in substitutional sites. Thus, these results indicate that high electrical activation of dopants can be achieved by implantation at high temperatures. The silicon profiles were found to be Gaussian from SIMS-measurements, similar to the as-implanted profile, which indicates that annealing does not involve long-range migration of defects. This is consistent with SPE growth and close-pair recombination of vacancies and interstitials.

The annealing results similar to those obtained by heating the substrate can also be obtained by increasing the dose rate. Figure 13 shows a TEM cross-sectional micrograph from specimens implanted at $160 \mu\text{A cm}^{-2}$ to a dose of $5.0 \times 10^{15} \text{ cm}^{-2}$ ($100 \text{ keV } ^{28}\text{Si}^+$ ions). The micrograph shows a $\sim 1100\text{\AA}$ wide, defect-free region followed by a 1000\AA wide band of dislocation loops. As is shown in Fig. 11, heating the sample to 200°C produces qualitatively similar results. Figure 14 shows RBS results from speci-

Fig. 13. Cross-sectional electron micrograph from (100) GaAs specimens implanted with $100 \text{ keV } ^{28}\text{Si}^+$ ions to a dose of $5.0 \times 10^{15} \text{ cm}^{-2}$ (dose rate = $160 \mu\text{A cm}^{-2}$).

Fig. 14. 2.0 MeV He^- RBS spectra (random and $\langle 110 \rangle$ -aligned) from $^{28}\text{Si}^+$ (120 keV , $5.0 \times 10^{15} \text{ cm}^{-2}$) implanted specimens at 120 and $160 \mu\text{A cm}^{-2}$ specimens.

mens implanted at high currents ranging from 120 to $160 \mu\text{A cm}^{-2}$. The dechanneling as a function of depth decreases with increasing dose rate, and the yields are close to virgin crystals for specimens implanted with $160 \mu\text{A cm}^{-2}$.

Thermal annealing of different ion implantation states.—We now present a detailed characterization of some ion implantation states and their subsequent annealing behavior. At low dose rates, we produce buried amorphous layers, which expand toward the surface and into the deeper regions of the crystal as the implanted dose is increased. At a certain dose, which is critically determined by the ion implantation and substrate variables, we obtain a continuous amorphous layer, which extends from the surface to a certain depth and is followed by a band of dislocation loops. In this section, we divide the discussion into two parts: (i) annealing of amorphous layers; and (ii) annealing of dislocation loops in the underlying dislocation band.

The annealing of amorphous layers occurs by an interface-controlled crystallization process commonly referred to as solid-phase epitaxial (SPE) growth. An example is shown in Fig. 15, where by annealing at 550°C for 25 min, the interface moved toward the surface by a distance of 1050\AA . The specimens after ion implantation ($100 \text{ keV } ^{30}\text{Si}^+$ to $5.0 \times 10^{15} \text{ cm}^{-2}$ dose) contained a 2830\AA amorphous layer followed by a band of dislocation loops. This band of dislocation loops is left behind during SPE growth.

Figure 16 shows an implantation state ($100 \text{ keV } ^{30}\text{Si}^+$ to $5.0 \times 10^{14} \text{ cm}^{-2}$ dose at liquid nitrogen temperature) where the amorphous layer does not extend to the surface entirely. Figure 16a shows a bright-field, cross-sectional TEM micrograph in which dark regions near the surface represent crystalline islands. The sample contains a 2150\AA wide amorphous layer followed by a band of dislocation loops. Figure 16b shows a high resolution micrograph of the near-surface region. The crystalline islands contain two sets of fringes corresponding to (111) and $(\bar{1}\bar{1}\bar{1})$ planes in $\langle 01\bar{1} \rangle$ orientation. The size of crystalline islands varies from 6 to 30\AA . It is interesting to note the presence of a 15\AA thick oxide layer above the crystalline islands. The structure of the oxide is noncrystalline. If such samples are annealed, the SPE growth occurs both from the front and back sides of the specimens, as shown in Fig. 16c. The thickness of the SPE-grown back and front layers is 750\AA and 450\AA , respectively. The front amorphous-crystalline interface is considerably more undulated than the back interface. However, both the front and back SPE-grown layers have exactly the same orientation as the substrate, as shown by the microdiffraction patterns in Fig. 17. Figures 17a and 17b are microdiffraction patterns of front and back SPE-grown layers, respectively, both of which have identical $\langle 110 \rangle$ diffraction patterns. A microdiffraction pattern from the amorphous layer is shown in Fig. 17c, which contains characteristic amor-

Fig. 15. Cross-sectional electron micrograph from $^{30}\text{Si}^+$ -implanted (100) Si specimen after annealing at 550°C for 20 min. The substrate was kept close to liquid He temperature and implanted with $100 \text{ keV } ^{30}\text{Si}^+$ to a dose of $5.0 \times 10^{15} \text{ cm}^{-2}$.

Fig. 16. A: Cross-sectional electron micrograph of as-implanted (100) Si specimens ($100 \text{ keV } ^{30}\text{Si}^+$, $5.0 \times 10^{14} \text{ cm}^{-2}$) containing crystalline islands near the surface. phous rings. As the time of isothermal annealing was increased to 40 min at 550°C , the front and back crystallizing interfaces were found to meet at a depth of about 880\AA . The dark line in Fig. 18a shows that defects associated with the interface at 880\AA are limited to within a 10\AA wide region. The nature of these defects was analyzed by plan-view electron microscopy, and the results are shown in Fig. 18b. The defects in this band consist of defect clusters and dislocation loops of interstitial nature. An approximate determination of concentration of point defects showed that the number of interstitials is equal to

Fig. 17. Microdiffraction patterns of the different regions of specimens shown in Fig. 16C. A: Front layer. B: Back layer. C: Middle amorphous layer.

the number of implanted Si^+ ions. Recent RBS experiments (14) on high dose-rate annealing have shown that if buried amorphous layers are formed during early states of ion implantation, the annealing occurs by SPE growth from both front and back sides.

Annealing effects in underlying dislocation bands and gettering.—We now discuss the nature and annealing of dislocation bands below the amorphous layers. The dislocation loops in the region are formed as a result of clustering of point defects that escape amorphous regions. Due to ion-range straggling, the number density of displacements in this region does not reach the critical value needed for amorphization. The number density of dislocation loops in this region is critically determined by ion implantation and substrate variables. The specific damage-energy density (the number of displacements per unit volume) and ion range straggling are primarily determined by the atomic mass of the projectile and substrate and the energy of the projectile. This, in turn, determines the number of point defects that can escape the amor-

Fig. 18. Defect microstructures of specimens shown in Fig. 16C after thermal annealing at 550°C for 40 min. A: Cross-sectional micrograph. B: Plan-view micrograph of dislocation loops and tangles.

phous regions. The mobility of defects and subsequent clustering into dislocation loops are determined by the substrate temperature. The dislocation loops are observed (by conventional TEM imaging techniques) to be of an interstitial nature. The size of vacancy loops is usually much smaller (5-10Å) than that of interstitial loops. The number density of dislocation loops decreases with decreasing substrate temperature. Figures 19a and 19b show a comparison between room temperature and liquid nitrogen temperature implants (200 keV $^{28}\text{Si}^+$ to $1.5 \times 10^{16} \text{ cm}^{-2}$ dose). These specimens were annealed at 550°C/5 min so that underlying dislocation bands could be delineated. The nature of the dislocation band also affects the defect density in the SPE-grown layers. In room temperature implants, the amorphous-crystalline interface intersects dislocation loops whose average size is much larger than that in the liquid nitrogen temperature implants. As a result, during SPE growth, these dislocations continue to grow with the interface and create a network of high number density of hairpin dislocations. The number density of loops in the underlying dislocation band also decreases with increasing mass of the projectile or the substrate. An example is shown in Fig. 19c for a bismuth implant (200 keV, $1.0 \times 10^{16} \text{ cm}^{-2}$ dose) in silicon. With increasing mass of the projectile, specific deposited damage energy increases, resulting directly in amorphous cascades and allowing the escape of a smaller number of defects to form loops.

The dislocation loops should be minimized or, preferably, removed because they are detrimental to electrical characteristics of p-n junctions. The dislocations with energy levels close to the middle of the bandgap provide efficient recombination centers. The dislocations are also known to provide trap centers via electronic and elastic interactions. The dislocations in these bands are particularly undesirable, owing to their close proximity to the metallurgical junction. The annealing characteristics of dislocation loops during heat-treatment are determined

Fig. 19. Cross-sectional electron micrographs showing defect microstructures as a function substrate temperature and incident mass. A: 200 keV $^{28}\text{Si}^+$, $1.5 \times 10^{16} \text{ cm}^{-2}$ at room temperature after isothermal annealing at 550°C/5 min. B: 200 keV $^{28}\text{Si}^+$, $1.5 \times 10^{16} \text{ cm}^{-2}$ at liquid nitrogen temperature after similar annealing treatment. by the average size and number density of loops. If the distance between two loops is less than twice the diameter of the larger loops, these two loops may coalesce by glide and climb processes and form larger loops (18). If the loops are farther apart, they shrink by a normal bulk diffusion process (19). Figure 20 illustrates the subsequent annealing behavior of two different ion implantation (100 keV As⁺, 1.0×10^{16} cm⁻² dose) states shown in Fig. 6a (high dose rate) and Fig. 6c (low dose rate). The dislocation tangles in the high dose-rate samples evolve into a complicated network of dislocations upon subsequent thermal annealing (at 850°C/30 min). It was found that the carrier concentration and mobility are degraded after the above annealing treatment, presumably because of segregation and trapping of dopants at the dislocations. In the case of low dose-rate samples, the amorphous layers grow by a solid-phase epitaxial growth process, and the loops coarsen by loop coalescence. Sometimes a network is generated by a well-known dislocation reaction: $a/2\langle 101 \rangle + a/2\langle 01\bar{1} \rangle \rightarrow a/2\langle 110 \rangle$, as shown by the 1 in Fig. 20b. The electrical properties (carrier concentration and mobility) of these specimens were found to improve continuously with subsequent annealing treatment after SPE growth.

The dislocations in the underlying dislocation bands provide effective impurity/dopant traps via elastic and electronic interactions. The dislocations can also be used to tie up or remove unwanted impurities by trapping them at the dislocations. We illustrate antimony trapping or segregation at the dislocations in Fig. 21. The (100) Si specimens were implanted with 200 keV, 4.4×10^{15} Sb⁺ cm⁻² dose; they were annealed at 550°C/20 min for SPE growth of the amorphous layers and subsequently heat-treated at 900°C for 30 min. After the latter heat-treatment, large precipitates were formed at the dislocations, making

Fig. 21. Plan-view electron micrograph showing gettering of antimony by dislocations after heat-treatment of Sb⁺-implanted (200 keV, 4.4×10^{15} cm⁻²) specimens, 550°C/20 min and 900°C/30 min.

them efficient traps for dopants. Figure 22 illustrates gettering of fluorine by dislocations in a BF₃⁺-implanted (100) Si, which was annealed at 1100°C for 5s in a rapid thermal annealing apparatus. The as-implanted specimens (50 keV BF₃⁺, 1.0×10^{15} cm⁻² dose) contained a 500Å wide amorphous layer followed by a band of dislocation loops. After the rapid thermal annealing treatment, the loops coarsened and gettered the fluorine, as indicated by the formation of fluorine bubbles near the dislocations (see bubbles as white spots in the micrograph). The secondary ion-mass spectrometry results on fluorine

Fig. 22. Plan-view electron micrograph showing gettering of fluorine by dislocations after rapid thermal annealing (1100°C for 5s) of BF₃⁺-implanted specimens (50 keV BF₃⁺, 1.0×10^{15} cm⁻²).

profiles show a peak corresponding to the dislocation band. It is interesting to note that loops are confined in a rather narrow band because the segregation of fluorine inhibits the glide of dislocations. It was found that, by further annealing, the dislocations and fluorine are removed simultaneously.

Conclusion

We have shown that the nature of ion implantation damage is a strong function of implantation and substrate variables. In silicon, crystalline to amorphous phase transformation occurs above a critical damage energy of 12 eV/atom if there are negligible annealing effects. This value is very close to the displacement threshold. For other materials, the critical specific damage energy is expected to scale according to the displacement threshold energy. By increasing the dose rate, the substrate temperature is increased, which enhances the SPE growth rate of amorphous layers and/or the recombination of close pairs of vacancies and interstitials. The as-implanted profiles in high dose-rate implants were found to be unchanged because of negligible diffusion distances of dopants, as estimated from time and temperature of implants. The specimens implanted at high dose rates contain defect-free, self-annealed layers followed by a wide band of dislocation loops. In the defect-free, self-annealed layers, up to 90% of the arsenic was found to be in substitutional (electrically active) sites. During high dose-rate implants, buried or near-surface amorphous layers are formed, the annealing of which involves SPE growth from both the front and back sides (buried layers) or growth from the back side (near-surface layers). At still larger dose rates, there is a region in the implantation current where we obtain undesirable void structure. A comparison of microstructures obtained at high dose rates and high substrate temperatures shows that these two parameters are interchangeable. The number density of dislocation loops in the underlying dislocation band can be manipulated by ion implantation and substrate variables. The average size and number density of loops play a critical role in the development of network of dislocations during subsequent annealing. These dislocations provide strong recombination and trap centers for impurities and dopants. By moving their locations away from the junctions, these dislocations can be used to getter unwanted impurities that adversely affect the p-n junction characteristics.

TEM Cross Section Sample Preparation Technique for III-V Compound Semiconductor Device Materials by Chemical Thinning

S. N. G. Chu* and T. T. Sheng

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A cross section sample preparation technique is described for the TEM studies of III-V compound semiconductor device materials. In this technique, a grid-masking method is introduced for selective-area perforation using chemical etching. By epoxy bonding a TEM specimen grid onto the surface of a face-to-face or face-to-back epoxy-bonded thin cross section sample stack, perforations by chemical etching are confined to the regions inside the meshes. Selective-area perforation can easily be achieved by accurately positioning the masking grid and monitoring the perforation under a microscope. Since many perforations can be made in the selected area, the chance of obtaining a cross section sample containing the device structure is greatly increased. Furthermore, the masking grid mechanically reinforces the perforated sample and hence eliminates problems associated with sample handling. Examples of the use of this technique for InP/InP(substrate) single-layer and p⁻-InGaAsP/p-InP/InGaAsP/n-InP/InP(substrate), multilayer laser device structures, grown by vapor-phase epitaxy, are demonstrated. The technique is also applicable to GaAlAs/GaAs multilayer structures, and, in addition, greatly facilitates the selective-area perforation of plan-view TEM samples.

Cross-sectional transmission electron microscopy (XTEM) has proven itself to be a powerful technique for the study of the generation and evolution of defect structures during heteroepitaxy of III-V compound semiconductor device materials (1, 2). In silicon integrated-circuit processing, XTEM is now routinely used for the characterization of process-related problems (3). The essential part of the XTEM technique, however, is the preparation of cross section samples containing the desired device structure.

Because most semiconductor devices consist of layers with thicknesses ranging from a few hundred angstroms to several microns near the surface of the wafer, reproducible XTEM samples are generally difficult to prepare. For example, sample preparation requires that the perforation, by ion milling or chemical etching, occur not only near the edge of the cross section, but right at where the desired device structure is located as well. Edge erosion of the sample is another problem. Unless the edge is well protected, the device structure is usually eroded before a perforation occurs.

These difficulties in the preparation of XTEM sample of silicon integrated circuits were overcome by Sheng *et al.* (3) using an epoxy embedding technique combined with large area ion milling. Direct application of this technique to InGaAsP/InP heterostructure-device materials, however, was found to be difficult simply because of the extreme fragility of the III-V materials compared with silicon. In this work, we report a new chemical thinning technique for the preparation of XTEM samples for III-V compound semiconductor device structures. We also introduce a grid masking method that allows us to control precisely the selected-area perforation. Finally, the XTEM for InP/InP single-layer and InGaAsP/InP multilayer structure materials are demonstrated.

Sample Preparation Technique

Thin cross section samples were cleaved from device wafers along a (011) plane. The cleaving process was facilitated by thinning the device wafer, from the back side, to less than 0.3 mm, using chemical-mechanical polishing in 2% Br₂-methanol solution. The cross section samples were epoxy bonded to form a stack with the device structures either face to face or face to back, as shown in Fig. 1, using extra-fast setting epoxy by Hardman, Incorporated (Belleville, New Jersey 07109). Excess epoxy was squeezed out between the samples. For best results in the subsequent thinning process, the thickness of the epoxy film was kept to a minimum. The cross section sample stack was then thinned by polishing it from both sides to a final thickness of about 20 μm.

*Electrochemical Society Active Member.

The details of the polish thinning process are as follows. The cross section stack was first bonded to a slide cover-glass, which in turn was bonded to a titanium disk (part of the sample polishing holder). A transparent crystal bond or soft wax can be used as a bonding material. The sample stack was surrounded with InP substrate wafers, as shown in Fig. 2, to prevent the edges of the stack from being rounded off during the polishing process. The stack was polished on one side to smooth the cross section surface and then turned over and polished to a final thickness of around 20 μm. Figure 3 shows Nomarski interference micrograph of a polished cross section sample stack.

Perforation by chemical etching immediately adjacent to the epoxy joint in the device region was accomplished by using a grid masking technique. A 100-mesh molybdenum grid was epoxy bonded onto the cross section stack, as shown in Fig. 4, using the same epoxy described before. Such grid masking requires careful alignment of the openings in the epoxy-coated grid to expose the device region, and can be done by using the grid-mounting jig shown in Fig. 5. With the cross section stack still on the titanium disk (Fig. 5), the disk is attached to the alignment block using double-sided adhesive tape. The sample

Fig. 1. Schematic diagram of face-to-face and face-to-back cross section sample stack bonded by epoxy.

Fig. 2. Schematic diagram of a cross section sample stack surrounded by InP substrate wafer, ready for initial polish thinning.

stack is centered by adjusting the four alignment screws on the grid mounting device. It is then visually aligned by moving one of the epoxy-bonded interfaces to the center of the device using the transparent alignment cover. An epoxy-coated 3 mm diam molybdenum grid is placed over a 2 mm diam hole inside the grid mounting cover, and is lightly held in place by the epoxy on the grid to the edge of the hole. The grid mounting cover is then turned over and slid onto the grid mounting device until it contacts the stop ring which prevents the grid from contacting the sample surface.

Precise alignment of the grid to expose the desired area is then accomplished under a stereo microscope by adjusting the position of the sample with respect to the grid. The stop ring is released and the grid mounting cover lowered until the grid rests on the surface of the sample. Gentle pressure on the grid mounting cover transfers the grid onto the surface of the cross section stack.

Two important points should be noted: (i) only a thin layer of epoxy should be applied to the grid. Excess epoxy tends to smear out and cover the openings of the

Fig. 3. Optical micrograph of the surface of a polished cross section couple. The dark strip is the epoxy.

grid. (ii) Any movement of the grid parallel to the surface must be prevented after the grid is transferred to the cross section stack. To avoid having the grid accidentally cover the entire device region, the edge of the cross section is aligned along the diagonal of the square mesh as shown in Fig. 4. The sample is then transferred with the cover glass onto a quartz disk.

The final perforation is done inside a crystalline dish by dripping 0.5% Br₂-methanol solution onto the masked-sample surface. A stereo microscope equipped with both reflection and transmission illumination is used to monitor the perforation. Because perforations are made only inside the meshes, each mesh becomes an individual sample. Grid masking, therefore, greatly increases the

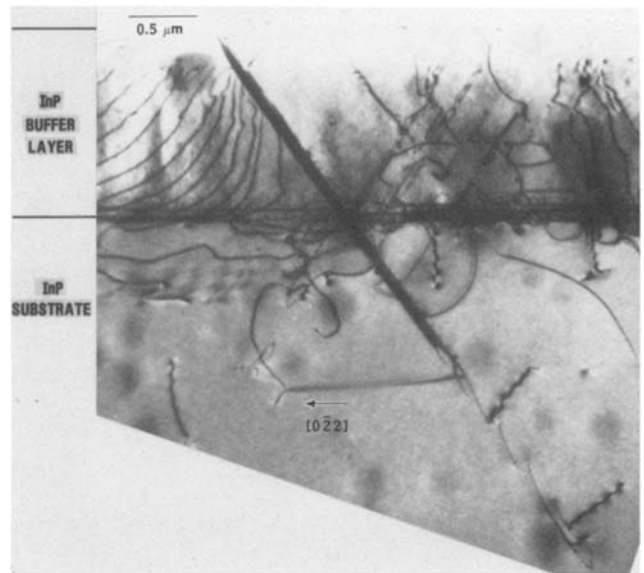

Fig. 7. XTEM of 1.3 μm InP buffer grown by VPE on InP substrate

success of obtaining a good XTEM sample. The etching process is stopped by applying a jet of methanol to the sample using a squeeze bottle. Small variations in thickness always exist across the polished cross section sample stack. As a result, perforations inside the mesh normally occurred progressively from mesh to mesh, starting from the thinnest area. It is important to stop the etching at the right moment, since the thin area around the perforation tends to be etched away very rapidly. The

Fig. 8. XTEM of a four-layer InGaAsP/InP laser structure grown by VPE

proper thickness at which to stop etching was judged by the transparency of the film as observed under the microscope using transmission illumination. When the proper transparency was achieved, the sample bonded to the grid was removed from the cover glass by soaking in acetone or trichlorethylene. Finally, the cross section sample is examined in the transmission electron microscope. Micrographs reported in this paper were taken using a JEOL 200-A instrument.

Results and Discussion

Figure 6 is an optical micrograph showing perforations that occur successively inside two meshes near the device structures. The semitransparent regions surrounding some of the perforations extend all the way to the device regions — a condition that is ideal for TEM studies. Since epoxy does not react with Br_2 -methanol, the epoxy film between the cross section remained as the semiconductors on both sides were etched away. The dark ribbon in Fig. 6 is the epoxy film that fell and covered one of the face-to-face epoxy-joined device structures.

A TEM cross section view of a $1.3 \mu\text{m}$ InP buffer layer grown by vapor-phase epitaxy on a (100) InP substrate is shown in Fig. 7. The InP epitaxial layer was contaminated by gallium during growth. It is therefore lattice mismatched to the InP substrate. This is shown by the presence of the straight interfacial-misfit dislocations oriented along the $[0\bar{1}1]$ direction. The dislocation networks on both sides of the interface were generated at the interface and propagated along the $\{111\}$ planes. Furthermore, the dark band oriented along the $[\bar{1}12]$ direction was verified to be a stacking fault. The detailed study of the gallium contamination of InP grown by vapor-phase epitaxy will be discussed in another paper (4).

The TEM cross section view of an InGaAsP/InP laser structure grown by vapor-phase epitaxy on a (100) InP substrate is shown in Fig. 8. The multilayer structure consists of $1.25 \mu\text{m}$ thick n-type InP buffer layer, a $0.34 \mu\text{m}$ thick undoped InGaAsP active layer, a $1.4 \mu\text{m}$ thick p-type InP cap layer, and a $0.56 \mu\text{m}$ thick p⁺-InGaAsP contacting layer. High density threading dislocations generated at the binary/quaternary interface, and threading through the quaternary layers can be seen in both active and p-contacting layers. These dislocations lie either in the $\{111\}$ planes or along a direction close to $[100]$. Furthermore, areas of diffuse dark contrast close to the $[100]$ orientation are also present, similar to those observed by Al-Jassim *et al.* (1) in InGaAs/InP VPE structures. An examination of the threading dislocation density between

the active layer and p-InP shows that the majority of the dislocations are either bent into the interface or recombined at the interface.

This bending and recombining is also seen in the tilted cross section view shown in Fig. 9. The threading dislocations recombine and form large dislocation tangles, only a few of which are propagated into the p-InP region. The lower interface shows a network of strain fields where the threading dislocations originate. The detailed characterization of the defect structure and the interfaces will be discussed in another paper. Similar quality of cross-sectional TEM samples have been achieved using the same technique on GaAlAs/GaAs and InAlAs/InGaAs/InP multilayer structures.

Conclusion

We have described a technique for preparing cross section samples for TEM studies of III-V compound semiconductor device materials using a chemical thinning technique. An essential aspect of the technique is the use of a grid masking method that makes it possible to exercise precise control over the selected-area perforation in the device regions. Since the perforation is confined to the area inside the mesh, each mesh becomes an individual sample, greatly increasing the probability of obtaining a good XTEM sample. The masking grid also mechanically reinforces the thin cross section of the sample, thereby alleviating sample handling problems. We have used the technique to prepare XTEM samples for InP/InP single-layer and InGaAsP/InP multilayer laser structures. The technique can also be applied to GaAlAs/GaAs and InAlAs/InGaAs/InP device structures, and, in addition, greatly facilitates the preparation of plan-view TEM samples.

Mass Spectrometric Transient Study of DC Plasma Etching of Si in NF_3 and NF_3/O_2 Mixtures

T. Honda¹ and W. W. Brandt

Department of Chemistry and Laboratory for Surface Studies, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin 53201

ABSTRACT

DC plasma etching experiments were performed on thin wafers of polycrystalline Si, using a pulse injection technique developed earlier, with NF_3 or NF_3/O_2 mixtures as etchants. The addition of O_2 was found to have no measurable effect on the etching rate, and steady-state concentrations of various radicals present in the plasma shifted relatively little. A fairly simple reaction scheme is presented which is consistent with these results. The NF_3 etching rates measured after oxidizing or nitriding the Si surface by plasma methods were explored to some extent as well.

It is very clear from the literature that plasma etching rates and related data obtained in different laboratories can normally not be compared in a quantitative fashion, since the experimental procedures, and, in fact, the quantities measured in each case, may differ. To arrive at reliable comparisons, the procedures must be standardized. At present, because of the large parameter space involved (1), this uniformity is an immediate and realistic objective only if the results which are to be compared are obtained in a single laboratory, using identical procedures, in short succession.

The present study represents such an attempt; the experimental procedures, including the sample preparation, were exactly the same as those used in several preceding studies (2, 3); only the etchant was changed, using NF_3 and NF_3/O_2 mixtures. The fragmentation of NF_3 in the plasma is likely to yield very few fragments, in contrast to SF_6 or SF_6/O_2 mixtures used earlier, judging from the published mass spectra of this gas (4-6). The tedious mass spectrometric fragmentation corrections needed to determine the concentrations of various excess species in the plasma are thus expected to be much simpler than those encountered in the earlier studies (2, 3, 7).

A second important reason for this study lies in that actinometric methods, based on optical emission measurements, are sometimes of no help in establishing the reaction mechanism of a system. For example, the plasma-etch rate of Si in NF_3/He mixtures fails to correlate with the concentration of electronically excited fluorine present in the plasma. Presumably the excitation transfer from $\text{He}^*(2^1\text{S})$ to NF_3 , with the simultaneous formation of excited F

becomes relatively important in certain mixtures, compared to direct electron impact excitation. There seem to be no actinometric results available on NF_3/O_2 mixtures thus far, but, eventually, such data, together with the results from this study, could help in determining the scope and reliability of actinometry in plasma etching studies (9, 10).

As an important by-product of this study, further information has been gathered concerning the detailed mass spectrometric procedures used in this and in previous studies (2, 3, 7), notably with respect to the unavoidable

random errors, and minor systematic errors which have been identified earlier.

Experimental

Most of the procedures used in this work are exactly the same as those used in the earlier studies (2, 3). Only the exposure of the polycrystalline Si sample to active O_2 and N_2 plasmas constitutes new types of experiments. The conditions are as shown in Table I.

Results and Discussion

Early during this study, it was recognized that the $m/e = 71$ and 52 signals, which are the major peaks in the NF_3 mass spectrum, and represent NF_3^+ and NF_2^+ , respectively, were always proportional to each other, and that their ratio was within the range of literature values (4-6). If plasma-generated NF_2 radicals were present, henceforth termed "excess NF_2^+ ," the NF_2^+ peak should be larger than that found in the standard NF_3 mass spectra. There was no such excess NF_2 outside the experimental errors, and, as a consequence, only the 52 peak was measured in the bulk of this study and taken to be a convenient measure of unfragmented or produced NF_3 present in the plasma.

The peak at $m/e = 85$, representing SiF_3^+ , served as a simple measure of the etch rate, as in earlier studies (2, 3). As illustrated in Fig. 1, this peak was found to be proportional (i) to the NF_2^+ signal, representing the unfragmented NF_3 in the plasma cell, and (ii) to the difference in the NF_2^+ peak before and after igniting the plasma, and thus to the amount of NF_3 fragmented in the plasma.

The signals at $m/e = 33$ and 14, representing NF^+ and N^+ , respectively, were corrected for the contributions from the NF_3 mass spectrum, and are also plotted in Fig. 1. The signals thus represent "excess NF^+ " and "excess N^+ ," respectively, which arise from NF and N radicals or ions formed in the plasma. The excess N^+ is seen to be proportional to the NF_2^+ and SiF_3^+ signals, and therefore to the etch rate, while the excess of NF^+ varies with the square of the NF_2^+ peak height (see Fig. 2).

Table I. Experimental conditions for O_2 - and N_2 -plasma treatment. Discharge voltage: 900V

Plasma gas	Pressure (torr)	Time (min)	Current (mA)
O_2	0.7	120	6.7
N_2	2.4	60	7.0

Fig. 1. Mass spectrometric signal maxima as a function of the amount of NF_3 injected with each pulse, as measured by the maximum of the NF_2^+ signal. \bullet : SiF_3^+ . \times : NF^+ . $+$: N^+ . Δ : (NF_2^+ signal maximum from the inactive cell) - (same quantity where plasma is ignited). The NF^+ and N^+ signals are corrected for the contributions arising from the mass spectrometric fragmentation of NF_3 .

Except for the last finding, one can summarize this as follows: there is essentially no measurable excess NF_2^+ , little excess NF^+ , and a somewhat larger excess N^+ —in short, the F-depleted fragments tend to accumulate in the plasma, as one would expect.

The results presented here are consistent with a relatively simple reaction scheme

Reactions [5] and [7] may well involve two separate steps which need not be discussed at length; the SiF_2 intermediate in the etching process has been documented by several spectroscopic studies (11, 12).

Reactions [6] and [8] are consistent with the fact that there is no measurable excess of NF_2 radicals in the plasma.

From the results analyzed in Fig. 2, one may postulate that in addition to the above reactions the disproportionation of NF_2

plays an important role. There are possible variations of this scheme which cannot be eliminated from the present data alone, such as a modified reaction [8]

Fig. 2. Residual signal maximum of NF^+ , after subtracting the estimated SiF_2^{++} contribution to the $m/e = 33$ signal from the measured signal height (see text), against the signal maxima of NF_2^+ (top), and against the same quantities squared (bottom).

Next, measured SiF_3^+ signal heights, which are considered a simple measure of the etch rate, are independent of the amount of oxygen added to the plasma, within experimental errors, as shown in Fig. 3. There is a slight decrease of the $m/e = 52$ signal, i.e., of the amount of unfragmented NF_3 present. A corresponding slight increase of the SiF_3^+ signals is to be expected, but this effect is smaller than the experimental uncertainties.

Related to this, the changes in mass signals 33, 14, and 19, representing NF^+ , N^+ , and F^+ , respectively, must be considered. Unfortunately, the F concentrations are too low to be measurable, but the trends in the 33 and 14, as shown in Fig. 3, lead to some insight.

The 33 peak has contributions from NF (radicals or ions) and SiF_2^{++} . NF probably reacts with plasma-generated O when O_2 is present, according to

The NF contribution to the $m/e = 33$ signal initially present in O_2 -free plasmas is thus expected to vanish as O_2 is added while the $m/e = 30$ peak, representing NO , increases at the same rate, as seen in Fig. 3. The $m/e = 33$ signal, which remains at high O_2 concentrations, presumably arises from the SiF_2^{++} peak in the SiF_4 mass spectrum; this is consistent with the measured SiF_3^+ signals and the literature spectra (4-6). The $m/e = 30$ signal continues to increase with increasing O_2 concentration in the plasma, balancing the previously mentioned increase in NF_3 fragmentation (decrease of NF_2^+ signal). In view of reaction [10], and within the experimental uncertainties, NF and F seem to be equally effective in the etching process.

The $m/e = 14$ signal as plotted in Fig. 3 is practically constant throughout this series; either reactions [6] and [8] are not shifted by the addition of oxygen, or the contri-

Fig. 3. Logarithm of signal maxima of various species against the signal maxima of O_2^+ , as a measure of the strength of the O_2 pulses injected. \circ : SiF_3^+ , \blacksquare , \square : NF_2^+ from the nonenergized plasma cell and in the presence of the plasma, respectively. \times , $+$, and \odot : signals at $m/e = 33, 14$, and 30 , respectively.

Contributions to the signal height from NO and NF are about equal, per unit concentration. In this context, one must recall that the contribution to the mass 14 signal arising from unfragmented NF_3 was subtracted earlier, and that NF_2 radicals are not present to a measurable extent.

Small $m/e = 44$ and 82 peaks were found in this study, both decreasing with increasing O_2 pressure. One can expect a small amount of $SiOF_2$ to form in this system, giving rise to SiO^+ and $SiOF_2^+$ signals, at 44 and 82 , respectively, but the concentrations of $SiOF_2$ should increase with O_2 concentration. Other unidentified traces may be involved here.

The sample surface and plasma cell walls remain very clean during the NF_3 and NF_3/O_2 etching experiments, so only volatile products are formed, except perhaps for small amounts of SiF_2 and $SiOF_2$.

Further support for the above interpretation is found in the kinetic results as presented in Fig. 4. As discussed in the earlier study (3), the apparent first-order constants determined from the slopes of the descending branches of the signal transients (2, 3) reflect the rate of the effusion process whenever one is dealing with chemically inert species. The NF_2^+ signals, representing unfragmented NF_3 present in the plasma cell, decay quickly, even somewhat faster than other inert species measured earlier regardless of whether the plasma indicated is ignited or not (see range b in Fig. 4). The SiF_3^+ apparent rate constants, by contrast, seem to be somewhat lower than the new NF_2^+ reference values, indicating some delay in the release of SiF_4 from the sample surface. This effect was just barely noticeable in the SF_6/Si system (2) and in the SF_6/O_2-Si system studied earlier (3).

NF^+ and N^+ signals also decay slowly, on this basis, and conceivably a portion of these species are formed, while the etching activities are dying down, after each injection

Fig. 4. Apparent rate constants, obtained from descending branches of transient signals, against natural logarithm of maximum signal. Data for low oxygen concentrations, corresponding to data near ordinate of Fig. 2. \blacksquare , \square : NF_2^+ before and after ignition of the plasma, respectively. \times , $+$, \odot : signals at $m/e = 33, 14$, and 30 , respectively. \circ : SiF_3^+ . B designates the range of other apparent rate constants in the absence of a plasma is shown, w.o. data point symbol. All data are corrected, according to Graham's law, to account for the different effusion rates. For this purpose, NF_2^+ is assumed to arise from NF_3 , NO^+ from NO , SiF_3^+ from SiF_4 , NF^+ from NF , and N^+ from N [see text, and Ref. (3)]. All corrections are relative to SiF_4 , as in Ref. (3).

of etchant gas. Possibly, NF_2 radicals, while present in the gas phase only in negligibly small amounts, are adsorbed at the surface undergoing etching, and cause reactions such as [6], [8], and/or [8a] to continue in the forward direction, even after the plasma activity ceased. Correspondingly, a small component of the SiF_3^+ signals, measured to evaluate the descending branches of the transient curves and to calculate the apparent rate constants, arises from that SiF_4 which is formed at the end of etching pulses. The fraction concerned is small: from Fig. 4, one obtains about 5%.

On the basis of these considerations, the overall reaction can be summarized approximately as

where NO appears in place of NF, whenever a sufficient amount of O_2 is present.

Finally, to gain some insight concerning the Si surface events, some plasma experiments were carried out to modify this surface. From Fig. 5, it appears that an oxide layer was created by exposure of the Si sample to an O_2 plasma, as described above. The layer is slowly removed by subsequent NF_3 etching, while Ar sputtering, under the conditions used, is quite ineffective for this purpose.

Fig. 5. Logarithms of maximum signals of SiF_3^+ , representing the etch rate, as a function of time. After the initial etching an O_2 plasma was produced for 120 min, at a pressure of 0.7 torr (see Table 1). Later on, a continuous Ar discharge was applied, modified by pulses of NF_3 , which resulted in the measured points. One ordinate division corresponds to a signal increase by a factor of 1.65.

Fig. 6. Same as Fig. 5, for N_2 plasma exposure, for 60 min at 2.4 torr (see Table I). Ordinate scale factor: 1.29.

The exposure to a N_2 plasma leads to the formation of a nitride layer which appears to be even more tenacious under NF_3 etching, except initially, where there is a rapid increase in etching rate after N_2 -plasma exposure (see Fig. 6). Intermittent Ar sputtering appears to render this layer even more resistant to etching.

The exploratory experiments described here essentially show the versatility and scope of the pulse etching procedure.

Conclusions

The pulse injection procedure developed earlier was used to gain some detailed insight into the chemistry of the plasma etching of polycrystalline Si under NF_3 or NF_3/O_2 mixtures.

As shown in reaction [11], aside from the principal product SiF_4 , small amounts of NF and N were formed during that process, and in addition NO , whenever O_2 was present in the mixture. NF_2 radicals were not present in the gas phase in measurable amounts, but from a consideration of probable reaction steps, reactions [2]-[10], and the apparent first-order rate constants for the disappear-

ance of various species after each pulse, it was concluded that NF_2 is probably adsorbed at the surface, during etching. Oxygen additions have no measurable effect on the etching rates, and little effect on the concentrations of most species measured, with the important exceptions of NF which decreases, and of NO which increases, with oxygen concentrations.

Acknowledgments

The authors are indebted to the National Science Foundation for support of these studies, and to Professor d'Agostino for valuable comments concerning the reaction mechanism.

Photosensitivity and Contrast Determination of Photoresist by Laser Interferometry

T. R. Pampalone,^{1,*} M. R. Hannifan, S. Jain, and C. D. Krieger

American Hoechst Corporation, AZ Photoresist Products, Somerville, New Jersey 08876

ABSTRACT

A laser interferometry technique was used to determine the photosensitivity and contrast values of positive photoresist. The precision of the technique was determined to be 2.7% (1 σ) for photosensitivity and 2.1% (1 σ) for contrast. The linear correlation of photosensitivity with film thickness was used to normalize the data. The utility of the technique as a quality control tool was demonstrated by analysis of 52 serially produced lots of 1350J photoresist.

Linewidth control during microlithographic fabrication of devices is critically dependent on the inherent photosensitivity of the resist. Some lot-to-lot variability in resist photosensitivity is expected by the device fabricator, and adjustments in exposure dose are routinely made on the line to compensate for this variability, most often using the critical dimensions of the device as the basis for the adjustment (1). Resist manufacturers do their best to minimize this lot-to-lot variability in photosensitivity by blending of raw materials or finished product to average out individual differences. However, one of the dif-

ficulties in achieving uniformity of photosensitivity is the variability of the test itself.

Several attempts to quantify the photosensitivity of a positive resist have been reported. One method measures the rate of photobleaching of the resist sensitizer, using monochromatic UV light as the irradiating source (2). The method assumes that the rate of photochemical conversion of sensitizer is a predictor of resist photosolubility, independent of processing conditions. This assumption is valid if the composition of the nonphotochemical components of the resist remain absolutely consistent so as not to change the physicochemical characteristics of the system. In practice, the latter situation seldom occurs. In or-

der to maintain consistent functional performance of the resist, resist manufacturers purposefully choose resins of varying molecular weight and developer solubility in the formulation to compensate for a particularly fast or slow sensitizer.

A functional measure of the photosensitivity of a resist is the "depth-of-penetration test" (3), which measures the thickness of resist film removed for a given amount of exposure energy under specific and controlled processing conditions. Recommended development time is 5 min. The thickness removed can be measured by a stylus measuring device if a ruled grating is used as the optical mask, and a plot of depth of penetration vs. exposure energy is constructed. From the plot, the minimum exposure energy to achieve complete dissolution of the film can be extrapolated. The precision associated with the test is $\pm 5\%$ (3), although for development times in the more-realistic 1-2 min range, the precision of the method is considerably less. A slight modification of the depth-of-penetration technique flood-exposes the sample and measures the thickness of film with an optical film thickness analyzer before and after development (4).

Rather than measure the thickness of film removed for a given exposure, one can measure the rate of film dissolution as a function of sensitizer photobleaching (5). Since for every resist there are inherent solubility rates for the dissolution of nonexposed and fully exposed resist, under fixed processing conditions, these solubility rates can be expressed as parameters to characterize the resist photosensitivity. A parameter related to contrast can then be calculated from the solubility parameters.

Although the approach has a good theoretical basis and generates functional data, it does not appear to be easily applicable to rapid resist characterization or have the rigor necessary for quality control.

In order to be useful to device fabricators, techniques to characterize the photosensitivity and contrast of photoresist must meet these criteria: (i) the results must be functional, derived under processing conditions the device actually undergoes; (ii) the results must be directly applicable to some device fabrication need, such as closely predicting the linewidth and edge acuity; (iii) the results must have good precision under production support conditions, which often differ considerably from the laboratory; and (iv) the technique must be responsive to small photoresist variations.

The laser interferometry technique described within has been under evaluation for over a year and meets these criteria. It functionally measures the dissolution properties of the total resist film, rather than the photochemical change of one component. In contrast, the Dill (7) procedure measures parameters (called "ABC") associated only with the photobleachability of the sensitizer (called photoactive compound, PAC) and neglects the contribution of the other components to dissolution rate. The Neureuther (5) technique uses laser interferometry to monitor development rate of the resist and generates data which can provide theoretical comparisons of resist lots. However, the data provided are not easily translated into the process-control parameters of interest to device makers. By comparison, the most useful application of the laser interferometry technique presented here appears to be quality control of photoresist on device fabrication lines. Contrast values indicate the attainable image resolution of the resist lot. Photosensitivity values provide a measure of lot-to-lot photosensitivity uniformity and can be used as a straightforward basis for making on-line exposure adjustments, if necessary. For instance, a $\pm 10\%$ variation in photosensitivity values determined by this technique results in linewidth variation of approximately $\pm 0.1 \mu\text{m}$ for a pattern generated with a Perkin-Elmer 220 Projection Aligner and consisting of $2 \mu\text{m}$ equal lines and spaces (6). The IC manufacturer, knowing that the photosensitivity value of a particular lot of photoresist is 10% higher than average, can increase exposure dose by 10% to maintain the same critical dimensions of the device.

Fig. 1. Exposure curve for determining photosensitivity and contrast values. D_p^o = Exposure dose where $NT_e = 0$ (mJ/cm^2). D_p^i = Exposure dose where $NT_e = 1.0$ (mJ/cm^2). NT_e = Normalized film thickness. Contrast = $|\log D_p^o/D_p^i|^{-1} = |\text{slope}|$. Photosensitivity = D_p^o (mJ/cm^2).

The purpose of this paper is to review the laser interferometry procedure for determining photosensitivity and contrast of photoresist and show application of the technique for quality control. The laser inter-

ferometry technique has been used widely by other workers (7) to characterize photoresist, and has been drafted into an ASTM test method (8).

Experimental

Determination of photosensitivity and contrast values.—The laser interferometry procedure is described fully in the ASTM method (8). Twelve 2 in. polished silicon wafers were spin coated at 4000 rpm with the 1350J photoresist and soft-baked 30 min at 90°C in an air circulating oven. The thickness variability for 12 wafers prepared in this manner was typically 0.008 μm (1σ). Each of the 12 wafers was exposed with a UV dose in the range 25-100 mJ/cm^2 , using an Oriel Corporation broadband 200W UV illuminator. The thickness of coated resist was measured in the center of each wafer using a Rudolf FTM (film thickness monitor). The wafers were each developed in 1:1 AZ Developer at 24°C, without agitation, and the loss of film was monitored by laser interferometry. From the resultant exposure curve of normalized film thickness remaining after 1 min development and the log exposure dose (Fig. 1), the photosensitivity and contrast values were determined for each of the 52 lots analyzed (Table I). The photosensitivity value (D_p^0) is the minimum UV dose required for complete film dissolution in the specified development time. In practice, the photosensitivity value is the exposure value when the linear portion of the exposure curve is extrapolated to zero normalized thickness. Contrast is the slope of the linear portion of the exposure curve (Fig. 1). Points within the linear limits of the exposure curve typically have a correlation coefficient of 0.98 or better. A reference 1350J resist was analyzed periodically to verify the reproducibility of the exposure and processing conditions.

Correlation of photosensitivity values with film thickness.—The photosensitivity values of 1350J (lot A), spin-coated at varying thicknesses, were determined and correlated with film thickness. Thicknesses from 3.3 to 1.6 μm were attainable by adjusting spin speed. After dilution to 26.5% solids, with AZ Thinner, coating thicknesses of 1.7-0.9 μm were attainable, and after dilution to 16.5% solids, coating thicknesses of 0.9-0.4 μm were attainable. The photosensitivity values obtained were recorded as a function of film thickness (Table II and Fig. 2). The correlation of photosensitivity value with film thickness was repeated for nine additional, randomly chosen lots of 1350J. For these additional runs, only six thicknesses were used, spanning the range of from 2.06 to 1.57 μm . The slope ($\text{mJ}/\text{cm}^2 \mu\text{m}$) of the least squares fit for each correlation, as well as the corresponding correlation coefficient, were calculated and statistically analyzed (Table III).

The contribution of substrate reflectivity to photosensitivity values.—The development rates of exposed resist

were monitored by laser interferometry to determine the contribution of the silicon substrate reflectivity to the photosensitivity values. The 1350J resist (lot A) was coated to thicknesses of 2.20, 1.45, and 0.49 μm on silicon wafers, with and without a proprietary antireflective coating. The antireflective coating was 1.88 μm thick and absorbed all of the normal incident light in the actinic range as determined by percent transmission measurements. After UV exposure with 25 mJ/cm^2 , the development rate of each wafer was monitored by laser interferometry, and the result plotted as film thickness removed vs. time (Fig. 3 and 4).

Results and Discussion

Photosensitivity values corrected for film thickness.—In Table III are listed the photosensitivity values obtained as a function of film thickness for 1350J (lot A) at 30.5% solids and after dilution to 26.5% and 16.5% solids. T_0 is the mean thickness of resist coated on the 12 wafers used for each photosensitivity determination. These results are plotted in Fig. 2. The slope of the least squares fit for a thickness range of 2.06-1.57 μm is statistically consistent for randomly chosen lots of 1350J, as shown in Table III. This consistency is not unexpected since the sensitizer and resin components are individually characterized and selected in formulating each resist lot. From the average

slope value of 113.8 mJ/cm² μ m for 1350J are calculated the photosensitivity values corrected for film thickness (D_{pc}°). For AZ 1350J spun at 4000 rpm, the average dry coating thickness is formulated to 1.760 μ m. Therefore, the corrected photosensitivity value (D_{pc}°) for 1350J is derived from the relationship

$$D_{pc}^\circ = D_p^\circ + (1.760 \mu\text{m} - T_0) (113.8 \text{ mJ/cm}^2 \mu\text{m})$$

where D_p° is the uncorrected photosensitivity value and T_0 is the mean film thickness for the 12 wafers used in the determination. The correction is best suited to small film thickness variations. The inherent 3% error in the correction factor (Table III) corresponds to an error in correction of less than 1 mJ/cm² for the thickness range under consideration. The thickness range for the 52 lots reported in this study (Table I) is 1.85-1.65 μ m.

Photosensitivity and contrast values for 1350J.—Presented in Table I are the photosensitivity and contrast values for 52 serially produced lots of 1350J resist. Each lot of resist was spun on 12 silicon wafers at 4000 rpm and the resultant mean thickness (T_0) was recorded. The photosensitivity values (D_p°) of all the lots were corrected (D_{pc}°) to a 1.760 μ m film thickness using the correction formula given above. From Table I, the mean corrected photosensitivity value (D_{pc}°) for the 52 lots is 100.4 mJ/cm² with a 5.7% (% RSD) lot-to-lot variability.

Fig. 4. Film thickness removed (μ m) vs. development time (min). Antireflective substrate. 25 mJ/cm² exposure. —: 0.49 μ m film. - - - -: 1.45 μ m film. —: 2.20 μ m film.

Precision of laser interferometry technique.—The repeatability precision of the laser interferometry technique was determined for 1350J (lot A) by the same operator using the same equipment. The statistical data and results are given in Table IV. The technique is shown to have a 1 σ precision of 2.7% (% RSD) for photosensitivity and 2.1% for contrast values.

Substrate reflectivity contribution to photosensitivity values.—As pointed out by Willson (9), the choice of method of defining resist sensitivity requires careful interpretation. His major concern is the contribution of substrate reflectivity, necessary to monitor film thickness loss, to the photosensitivity value. It is interesting to know how much, if any, of the reflected, actinic light affects the photosensitivity measurement. A direct observation of the reflectivity contribution was observed by analyzing the laser interferograms of 0.49, 1.45, and 2.20 μ m resist films after 25 mJ/cm² exposure. The plot of film thickness removed vs. development time (Fig. 3) illustrates the differential dissolution rates for the three films. (Deviation of the points from the curves is due mainly to standing wave effects.) The development rates for the 2.20 and 1.45 μ m films are similar; however, the 0.49 μ m film dissolves considerably faster. When the experiment is repeated, using an antireflective coating (Fig. 4), the dissolution rates of the 2.20 and 1.45 μ m film are unchanged; the 1.45 μ m film is now dissolving at the same rate as is the 2.20 μ m film, and the 0.49 μ m film is dissolving slower than before. Internal reflections and partial reflection at the photoresist-antireflective coating interface may still affect the dissolution rates despite the elimination of the reflection of normal incident light. The effect is more pronounced with thinner films owing to the higher relative intensity of incident light throughout the film and the interface. Residual solvent content of resist films after soft-bake is well known to affect dissolution rates (10). However, analysis of residual solvent in the 0.49 and 1.45 μ m resist films by quantitative infrared analysis (using transparent double-polished silicon wafers and scanning the 1720 cm⁻¹ carbonyl frequency) (11) showed that both films after soft-bake contained no detectable differences in percent ethoxyethyl acetate.

The data in Table II (photosensitivity value vs. film thickness) can be plotted as film thickness vs. log photosensitivity value. Each point on this curve represents a measured photosensitivity value for the respective film thickness on a substrate. In contrast, an exposure curve plot represents the film thickness removed after development for the respective log exposure dose. The plot of film thickness vs. log photosensitivity value (from Table II) superimposed upon an exposure curve of film loss vs. log exposure dose for a thick (3.2 μ m) film illustrates the contribution of substrate reflectivity to photosensitivity (Fig. 5).

In Fig. 5, the film thickness vs. log photosensitivity value plot (line no. 1) is superimposed upon the mean exposure curve for triplicate analyses of a 3.20 μ m film (line

no. 2). The divergence of the two lines reflects the magnitude of the contribution of substrate reflectivity to photosensitivity. Reflectivity contribution to resist photosensitivity has been well documented, especially for thin films on highly reflective substrates (12). Quantifying reflectivity effects is possible in this case because the light source is broadband and standing wave effects are minor. This would not be so for narrow bandwidth light sources such as projection aligners or steppers.

Determination of lot-to-lot photosensitivity uniformity.—From Table I, the standard deviation of corrected photosensitivity values (D_{pc}^0) is 5.7 mJ/cm², and from Table IV, the standard deviation of the laser interferometry technique is 2.7 mJ/cm². Using analysis of variance (13), which assumes the total variance is the sum of separate variances

$$\sigma_{\text{Total}}^2 = \sigma_1^2 + \sigma_2^2$$

the variance for resist photosensitivity (σ_R^2) can be approximated

$$(5.7)^2 = \sigma_R^2 + (2.7)^2$$

$$\sigma_R^2 = 25.2$$

The standard deviation for resist photosensitivity is

$$\sigma_R = 5.0 \text{ mJ/cm}^2$$

Therefore, the lot-to-lot photosensitivity uniformity for 1350J resist at the 1σ level is approximately $\pm 5 \text{ mJ/cm}^2$, or $\pm 5\%$ (σ), since $x = 100.4 \text{ mJ/cm}^2$. By the same analysis of variance procedure, the lot-to-lot contrast uniformity for 1350J at the 1σ level is ± 0.074 , or $+4.8\%$, since $x = 1.543$.

Conclusions

The laser interferometry technique can be successfully used to characterize the photosensitivity and contrast of positive resist. The 1σ precision for the technique was found to be 2.7% for photosensitivity and 2.1% for contrast values. A correction for film thickness can be applied in the normal working range of 1350J to improve the measurement. The technique is particularly well suited for lot-to-lot quality control (QC) testing of photoresist. QC analysis of 52 lots of 1350J photoresist showed the percent relative standard deviation (% RSD) for photosensitivity and contrast to be 5.7% and 5.2%, respectively. The % RSD for photosensitivity and contrast corrected by analysis of variance was 5.0% and 4.8%, respectively.

Research work is now underway to improve the precision of the laser interferometry technique and correlate photosensitivity and contrast values with critical dimensions, wall angles, and other lithographic outcomes. The techniques described here are being used to monitor and qualify raw materials and manufactured lots of photoresist.

Nonlinear Two-Step Diffusion in Semiconductors

D. Anderson

ABSTRACT

At high concentrations, impurity diffusion in semiconductors tends to be governed by nonlinear diffusion processes. Using similarity analysis, analytical solutions are here found for the impurity profile resulting from a two-step diffusion process where the drive-in step involves a nonlinear diffusion process. Comparison with previously published experimental results shows very good agreement.

In the fabrication of many semiconductor devices, solid-state diffusion is a common method for the introduction of impurities into the semiconductor material. The desired impurity profile is often established by means of a two-step process. In the first predeposition step, a certain total number of impurities is deposited in a shallow region close to the surface of the material, either by ion implantation or by an initial diffusion process. The second drive-in step involves a diffusive redistribution of the impurities, usually resulting in much deeper penetration into the material (1).

For low impurity concentration, the diffusion processes are governed by linear diffusion equations and exact solutions in terms of Gaussian or erfc functions are available. Although there has recently been some discussion about the most convenient approximation for the final impurity profile resulting from two-step diffusion processes (2, 3), the analytical understanding of the evolution of the impurity profiles is generally very good, owing to the extensive knowledge existing for the linear diffusion equations, cf. Ref. (4).

However, many modern semiconductor applications involve high impurity levels, in which case the corresponding diffusion processes may become strongly nonlinear, and the simple linear diffusion equation is well known to give results which are not in agreement with experimental results (5).

The physical mechanism causing nonlinear diffusion of impurities in, e.g., silicon has recently been summarized by Fair (6, 7). According to the vacancy model, the diffusion of substitutional impurities is a result of the interaction with vacant states in the silicon. These vacancies may be neutral or charged. The concentration of neutral states at any temperature is independent of the impurity concentration, C , while the number of charged vacancies depend on the impurity concentration. The intrinsic diffusion coefficient D_i , at low doping levels ($C < n_i$) may be written as

$$D_i = D^0 + D^+ + D^- + D^- \quad [1]$$

where D^0 , D^+ , D^- , and D^- represent the effective diffusivities under intrinsic conditions for the neutral, positive, singly, and doubly negative charged states, respectively. For extrinsic conditions, the diffusion coefficient may be written as

$$D = h[D^0 + D^+(n_i/n) + D^-(n/n_i) + D^-(n/n_i)^2] \quad [2]$$

where n is the electron concentration

$$n = \frac{C}{2} \left\{ 1 + \left[1 + \left(\frac{2n_i}{C} \right)^2 \right]^{1/2} \right\} \quad [3]$$

and h is the self electric-field enhancement factor

$$h = 1 + \frac{C}{2n_i} \left[\left(\frac{C}{2n_i} \right)^2 + 1 \right]^{-1/2} \quad [4]$$

Usually, at high doping levels, one of the charged-state diffusivities becomes dominant, so the effective diffusion coefficient may be written

$$D = 2D_i(C/n_i)^\gamma \quad [5]$$

where $\gamma = 1$ for boron and arsenic, and $\gamma = 2$ for phosphorous. However, the diffusion of phosphorous in silicon is complicated by the dissociation of the doubly negative charged vacancies at doping levels of about 10^{20} cm^{-3} . At lower levels, this dissociation results in an enhanced tail diffusion.

As compared to the linear case, the analytical understanding of nonlinear diffusion processes is strikingly poor, and resort is mostly taken to numerical computations (6). As far as we know, within the context of semiconductor applications, the only attempt towards an analytical investigation of nonlinear diffusion processes has been made by Nakajima *et al.* (9), Fair (10, 11), and Fair and Tsai (12, 13) for arsenic and boron diffusion. This approach relies on the approximation of the impurity profile by Chebyshev polynomials in the variable $x/t^{1/2}$ suggested by Nakajima *et al.* where x and t denote space and time coordinates, respectively (see Appendix A). This is a good approach for diffusion involving a constant surface concentration, but is not appropriate in the case of a two-step diffusion, where the diffusive redistribution occurs under the condition of a constant total number of impurities. The proper variable in this case turns out to be $x/t^{1/(\gamma+2)}$, i.e., $x/t^{1/3}$ and $x/t^{1/4}$ for $\gamma = 1$ and $\gamma = 2$, respectively.

The purpose of the present work is to demonstrate that similarity methods (14) provide a powerful and flexible tool for a systematic study of the nonlinear diffusion equations which occur in solid-state high concentration impurity diffusion. Furthermore, the analytic solutions which are obtained are exact, attractively simple, and yield very good agreement with experimental results.

Analysis

We restrict the present analysis to the case of a two-step process where the first step establishes a very shallow impurity profile containing a given total dose, Q_0 . For high impurity concentration, the second drive-in step is assumed to be governed by a diffusion equation of the form

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial C}{\partial x} \right) \quad [6]$$

where the diffusion coefficient, D , depends nonlinearly on the impurity concentration, C , as given by Eq. [5], i.e., $D_0 = 2D_i$,

$$D = D_0 \left(\frac{C}{n_i} \right)^\gamma \quad [7]$$

A systematic and very powerful tool for analyzing diffusion equations is similarity methods (14), which have the

attractive advantage of being equally applicable to linear and nonlinear equations. Following the similarity approach, we look for solutions of Eq. [6] and [7] in the form

$$C(x, t) \sim t^\alpha \phi(\xi) \quad [8]$$

where the similarity variable, ξ , is given by

$$\xi = \frac{x}{t^\beta} \quad [9]$$

The unknown function, $\phi(\xi)$, as well as the parameters α and β , are determined by inserting the expression into the diffusion equation and using the appropriate boundary or initial conditions. If the initial shallow impurity profile can be approximated as a delta function and the total number of diffusing impurities is assumed constant, the exact solution of Eq. [6] and [7] can be written in the suggestive form (see Appendix B)

$$C(x, t) = C_s(t) \left(1 - \frac{x^2}{x_F^2(t)}\right)^{1/\gamma} \quad [10]$$

where the surface concentration, $C_s(t)$, and the penetration depth, $x_F(t)$, are given by

$$C_s(t) = \left(\frac{\gamma}{2(\gamma+2)I_\gamma} \cdot \frac{Q_0^2 n_1^\gamma}{D_0 t}\right)^{1/(\gamma+2)}$$

$$x_F(t) = \left(\frac{2(\gamma+2)}{\gamma I_\gamma} \cdot \frac{Q_0^\gamma D_0 t}{n_1^\gamma}\right)^{1/(\gamma+2)} \quad [11]$$

In Eq. [10] and [11], I_γ is a numerical factor given by $I_1 = 2/3$ and $I_2 = \pi/4$.

In particular, we find from Eq. [10] and [11] for $\gamma = 1$ and $\gamma = 2$, respectively

(i) $\gamma = 1$

$$C(x, t) = C_s \left(1 - \frac{x^2}{x_F^2}\right) \quad [12]$$

where

$$C_s = \frac{3^{1/3}}{2} \left(\frac{Q_0^2 n_1}{D_0 t}\right)^{1/3} \cong 0.57 \left(\frac{Q_0^2 n_1}{D_0 t}\right)^{1/3}$$

$$x_F = 9^{1/3} \left(\frac{Q_0 D_0 t}{n_1}\right)^{1/3} \cong 2.62 \left(\frac{Q_0 D_0 t}{n_1}\right)^{1/3} \quad [13]$$

(ii) $\gamma = 2$

$$C(x, t) = C_s \left(1 - \frac{x^2}{x_F^2}\right)^{1/2} \quad [14]$$

where

$$C_s = \left(\frac{2}{\pi}\right)^{1/2} \left(\frac{Q_0^2 n_1^2}{D_0 t}\right)^{1/4} \cong 0.67 \left(\frac{Q_0^2 n_1^2}{D_0 t}\right)^{1/4}$$

$$x_F = \left(\frac{8}{\pi}\right)^{1/2} \left(\frac{Q_0^2 D_0 t}{n_1^2}\right)^{1/4} \cong 1.90 \left(\frac{Q_0^2 D_0 t}{n_1^2}\right)^{1/4} \quad [15]$$

We emphasize the characteristic time dependence of C_s and x_F involving $t^{1/3}$ and $t^{1/4}$ for $\gamma = 1$ and $\gamma = 2$, respectively, as opposed to the ordinary $t^{1/2}$ dependence of the conventional Boltzmann transformation. This feature has caused some confusion in previous investigations of nonlinear diffusion in semiconductors, cf. Ref. (11-13, 15).

The delta function approximation for the initial impurity distribution is a good approximation when the final width of the profile, as resulting from the drive-in step, is much larger than the width of the initial profile. Actually, the drive-in profile asymptotically approaches the similarity profile as t increases, irrespective of the form of the first impurity deposition. In situations where the width of the initial profile does play a non-negligible role, it can easily be incorporated into the analysis (see Appendix B).

In particular, Eq. [10]-[15] are still valid, provided we redefine the surface concentration and the penetration depth according to (cf. eq. [13] and [15])

(i) $\gamma = 1$

$$C_s = \frac{3^{1/3}}{2} \left(\frac{Q_0^2 n_1}{D_0 t}\right)^{1/3} \left(1 + \frac{x_0^3}{9Q_0 D_0 t/n_1}\right)^{-1/3}$$

$$x_F = 9^{1/3} \left(\frac{Q_0 D_0 t}{n_1}\right)^{1/3} \left(1 + \frac{x_0^3}{9Q_0 D_0 t/n_1}\right)^{1/3} \quad [16]$$

(ii) $\gamma = 2$

$$C_s = \left(\frac{2}{\pi}\right)^{1/2} \left(\frac{Q_0^2 n_1^2}{D_0 t}\right)^{1/4} \left(1 + \frac{\pi^2}{64} \frac{x_0^4}{Q_0^2 D_0 t/n_1^2}\right)^{-1/4}$$

$$x_F = \left(\frac{8}{\pi}\right)^{1/2} \left(\frac{Q_0^2 D_0 t}{n_1^2}\right)^{1/4} \left(1 + \frac{\pi^2}{64} \frac{x_0^4}{Q_0^2 D_0 t/n_1^2}\right)^{1/4} \quad [17]$$

and x_0 is the width of the initial profile.

Discussion

The general shape of the doping profile given by Eq. [10] is shown in Fig. 1 for $\gamma = 1$ and $\gamma = 2$, together with the Gaussian profile and the Chebyshev polynomial approximation (9-13). In this plot, the impurity concentration is normalized to the surface concentration and plotted against normalized junction depth. (For the Gaussian and Chebyshev profiles, the junction depth was chosen as the depth at which the concentration falls to 1% of the surface concentration.) As expected analytically, and also observed experimentally (8-13), the solutions to the nonlinear diffusion equations are much steeper, giving more abrupt junctions than the linear Gaussian profile.

For arsenic, only the neutral and singly negative charged vacancies are responsible for the impurity diffusion. The diffusivity of arsenic may then be written

$$D = D^0 + D^- \frac{n}{n_i} \quad [18]$$

but since $\beta = D^-/D^0 \cong 1$, the diffusion process is strongly nonlinear for $C \gg n_i$, and the resulting profile may be described by Eq. [10] and [11] where $\gamma = 1$. In Fig. 2, the

Fig. 1. Normalized doping profiles for $\gamma = 1$ and $\gamma = 2$. The Gaussian profile is given for comparison together with the Chebyshev polynomial approximation (9-13).

Fig. 2. Doping profile for shallow implanted arsenic compared with experimental results of Hill (16). The Gaussian profile for a constant diffusion constant is given for comparison.

doping profile of shallow ion-implanted arsenic, after 30 min of diffusion in argon at 1000°C , measured by Hill (13), has been compared to our theoretical curve calculated from Eq. [10] and [11]. Excellent agreement is found between the two curves. The Gaussian profile for the same conditions is also shown for comparison. In this plot, the value of $D_i = 24 \exp(-4.08/kT)$ has been used together with the value of n_i according to Morin and Maita (17).

The diffusion of ion-implanted arsenic in silicon has also been extensively studied by Fair and Tsai (12, 13), using secondary ion mass spectroscopy (SIMS). In Fig. 3, their experimental data for the surface concentration as a function of $(Q_0^2 n_i / D_i t)^{1/3}$ is compared to our theoretical result as given by Eq. [13]. Very good agreement is found. In particular, we note that for a given dose and temperature, the surface concentration will decrease as $t^{-1/3}$, as theoretically predicted by Eq. [13].

In Fig. 4, the junction depth, x_f , as described theoretically by Eq. [13], is plotted against $(Q_0 D_i t / n_i)^{1/3}$, together with the experimental data of Fair and Tsai (12, 13), in the

Fig. 3. The dependence of the surface concentration on time, temperature, and dose (Eq. [13]) for implanted As compared with experimental results of Fair and Tsai (13).

Fig. 4. The dependence of the junction depth of time, temperature, and dose (Eq. [13]) for implanted As compared with experimental results of Fair and Tsai (13) for dry ambients.

temperature range 1000°C - 1250°C . Again, good agreement is found, especially for deeper junction depths. In particular, the junction depth is clearly seen to increase as $t^{1/3}$.

Finally, Eq. [13] may also be rewritten as the following simple relation between surface concentration, dose, and junction depth, viz.

$$C_s = 1.5 Q_0 / x_f \quad [19]$$

This relation, together with the experimental data of Fair and Tsai, is shown in Fig. 5, again with good agreement.

The characteristic scaling of surface concentration and junction depth has previously been pointed out by Fair and Tsai (13), using a semiempirical approach. However, in this paper, we have demonstrated that the observed scalings are exact consequences of the properties of the nonlinear diffusion equation. The similarity method clearly shows that, for arsenic and boron diffusion at high impurity concentrations when the diffusion constant is concentration dependent (with $\gamma = 1$), the impurity profile is a function of $x/(D_i t)^{1/2}$ for diffusion with constant surface concentration and a function of $x/(D_i t)^{1/3}$ for diffusion with a constant number of shallow implanted impu-

Fig. 5. The surface concentration of implanted As vs. average doping compared with experimental data from Fair and Tsai (13).

urities. In earlier papers, this fact has only been obtained indirectly, as shown in Appendix A. Any function of $x/(C_s D_1 t/n_1)^{1/2}$, describing a doping profile with a constant surface concentration (and $\gamma = 1$), will be turned into a function of $x/(Q_0 D_1 t/n_1)^{1/3}$ if instead the total number of impurities are assumed constant, since integration of the impurity profile over x yields

$$Q_0 = \text{const.} \cdot C_s x_j \quad [20]$$

This constant is empirically determined by Fair and Tsai (13) to be 0.53 for arsenic, as compared to our theoretical value of 0.67 from Eq. [19], which is a 20% difference. For boron, this constant is 0.4 (11).

As shown in Fig. 2, the exact solution of the nonlinear diffusion equation is an excellent description of the arsenic doping profile, except very close to the surface. In this region, the theoretical profile tends to underestimate the surface concentration. This is also evident from the experimental data in Fig. 3. This is probably due to the reduced arsenic diffusivity at concentrations above 10^{20} cm^{-3} (6, 7). Hence, the implanted profile close to the surface is not redistributing as fast as theoretically expected, owing to complex impurity-vacancy pair formation, clustering, and strain effects. This effect is also more evident at lower diffusion temperatures.

This is probably also the explanation for why the Chebyshev approximation, with its nonvanishing slope at the surface, may result in just as good, or even better, doping profiles as compared to the theoretical solution in this paper. This is, then, not a natural result of the nonlinear diffusion itself, but rather a consequence of the deviations from ideal conditions, such as reduced surface diffusivity. The nonvanishing slope is, then, a residue of the originally implanted profile.

APPENDIX A

For nonlinear diffusion with $\gamma = 1$ and a constant surface concentration C_s , Nakajima *et al.* (9) approximated the doping profile with the Chebyshev polynomial

$$C/C_s = 1.00 - 0.87 Y - 0.45 Y^2 \quad [A-1]$$

where $Y = x/(8C_s D_1 t/n_1)^{1/2}$. This profile approximation may be simplified to

$$C/C_s = 1 - 0.70 \frac{x}{x_j} - 0.30 \left(\frac{x}{x_j} \right)^2 \quad [A-2]$$

where $x_j = 2.3 (C_s D_1 t/n_1)^{1/2}$ is the junction depth. This expression does not include the background concentration because of the large doping gradient at the diffusion front. Integrating Eq. [A-2] over x gives the total amount of dopants as

$$Q_0 = K C_s x_j \quad [A-3]$$

where K is a constant. This approximation is used by Fair and Tsai (13) also for the case of implanted arsenic diffusion with a constant amount of impurities. In this case, Q_0 is assumed constant in Eq. [A-3] instead of C_s , which is now assumed slowly varying. Insertion of Eq. [A-3] into the junction depth expression yields

$$x_j = 2(Q_0 D_1 t/n_1)^{1/3} \quad [A-4]$$

$$C_s = 0.94 (Q_0^2 n_1 / D_1 t)^{1/3} \quad [A-5]$$

which has turned the doping profile in Eq. [A-2] into a $t^{1/3}$ dependence instead of the original $t^{1/2}$ dependence.

For boron diffusion with $\gamma = 1$ and a constant surface concentration C_s , the doping profile may be approximated by (11)

$$C/C_s = 1 - \left(\frac{x}{x_j} \right)^{2/3} \quad [A-6]$$

where the junction depth $x_j = 2.45 (C_s D_1 t/n_1)^{1/2}$. Integrating Eq. [A-6] over x yields the total amount of boron im-

purities

$$Q_0 = 0.4 C_s x_j \quad [A-7]$$

Now assuming Q_0 constant for implanted boron diffusion, yields

$$C_s = 0.53 (Q_0^2 n_1 / D_1 t)^{1/3} \quad [A-8]$$

where 0.53 is an empirical constant.

APPENDIX B

The purpose of this Appendix is to give a more detailed presentation of the similarity approach as applied to the nonlinear diffusion equation obtained by combining Eq. [6] and [7], *i.e.*

$$\frac{\partial C}{\partial t} = D_0 \frac{\partial}{\partial x} \left(\left(\frac{C}{n_1} \right)^\gamma \frac{\partial C}{\partial x} \right) \quad [B-1]$$

It is convenient to normalize Eq. [B-1] by introducing $\tilde{C} = C/n_1$ and $\tau = D_0 t$. Equation [B-2] then becomes

$$\frac{\partial \tilde{C}}{\partial \tau} = \frac{\partial}{\partial x} \left(\tilde{C}^\gamma \frac{\partial \tilde{C}}{\partial x} \right) \quad [B-2]$$

In order to investigate Eq. [B-2] by similarity methods, we write the solution as (11)

$$\tilde{C}(x, \tau) = \tau^\alpha \phi(\xi)$$

$$\xi = \frac{x}{\tau^\beta} \quad [B-3]$$

Inserting this ansatz into Eq. [B-2] we find that the powers of τ match if α and β are related by

$$\alpha = \frac{2\beta - 1}{\gamma} \quad [B-4]$$

and the resulting equation for $\phi(\xi)$ is then

$$\alpha \phi - \beta \xi \frac{d\phi}{d\xi} = \frac{d}{d\xi} \left(\phi^\gamma \frac{d\phi}{d\xi} \right) \quad [B-5]$$

A further relation between α and β is obtained from the fact that the total number of diffusing particles is conserved, *i.e.*

$$\int_0^\infty \tilde{C}(x, \tau) dx = \tau^{\alpha+\beta} \int_0^\infty \phi(\xi) d\xi = \tilde{Q}_0 = \text{const.} \quad [B-6]$$

This obviously requires $\alpha = -\beta$, which, together with relation [B-4], determines α and β to be

$$\alpha = -\beta = -\frac{1}{\gamma + 2} \quad [B-7]$$

Note that constant surface concentration requires $\alpha = 0$ and consequently $\beta = 1/2$. With α and β given by Eq. [B-7], Eq. [B-5] for $\phi(\xi)$ can be integrated explicitly to yield

$$\phi(\xi) = \phi_0 \left(1 - \frac{\xi^2}{\xi_0^2} \right)^{1/\gamma} \quad [B-8]$$

where the characteristic penetration depth, ξ_0 , is related to the integration constant, ϕ_0 , by

$$\xi_0^2 = \frac{2(\gamma + 2)}{\gamma} \phi_0^\gamma \quad [B-9]$$

Furthermore, ϕ_0 is determined from the conservation condition, Eq. [B-6]. This yields

$$\phi_0 = \left(\frac{\gamma}{2(\gamma + 2) I_\gamma} \tilde{Q}_0^2 \right)^{1/(\gamma+2)} \quad [B-10]$$

where I_γ denotes the integral

$$I_\gamma = \int_0^1 (1 - x^2)^{1/\gamma} dx = \frac{\sqrt{\pi}}{2} \frac{\Gamma(1 + 1/\gamma)}{\Gamma(3/2 + 1/\gamma)} \quad [B-11]$$

and $\Gamma(x)$ is the complete elliptic integral. In particular, $I_1 = 2/3$ and $I_2 = \pi/4$.

Using Eq. [B-10] in Eq. [B-9], ξ_0 is obtained as

$$\xi_0 = \left(\frac{2(\gamma + 2)}{\gamma I_\gamma^\gamma} \bar{Q}_0^\gamma \right)^{1/(\gamma+2)} \quad [\text{B-12}]$$

Collecting our results, we find that $C(x, \tau)$ can be written

$$\bar{C}(x, \tau) = \bar{C}_s(\tau) \left(1 - \frac{x^2}{x_F^2(\tau)} \right)^{1/\gamma} \quad [\text{B-13}]$$

i.e., in terms of a decaying maximum concentration, $\bar{C}_s(\tau)$, given by

$$\bar{C}_s(\tau) = \left(\frac{\gamma}{2(\gamma + 2)I_\gamma^2} \frac{\bar{Q}_0^2}{\tau} \right)^{1/(\gamma+2)} \quad [\text{B-14}]$$

and a well-defined diffusion front at $x = x_F(\tau)$, where

$$x_F(\tau) = \left(\frac{2(\gamma + 2)}{\gamma I_\gamma^\gamma} \bar{Q}_0^\gamma \tau \right)^{1/(\gamma+2)} \quad [\text{B-15}]$$

In order to incorporate the feature of a finite width of the initial profile, we note that the fundamental nonlinear diffusion equation, Eq. [B-2], is invariant under time translations. This implies that a more general similarity solution is obtained through an arbitrary time translation of the previously obtained solution, i.e.

$$\bar{C}(x, \tau) = \phi_0(\tau + \tau_0)^{-1/(\gamma+2)} \left(1 - \frac{x^2}{\xi_0^2(\tau + \tau_0)^{2/(\gamma+2)}} \right)^{1/\gamma} \quad [\text{B-16}]$$

The arbitrary constant, τ_0 , can be related to the width of the original profile as follows: As $\tau \rightarrow 0$, the solution given by Eq. [B-16] does not approach a delta function, but rather

$$\lim_{\tau \rightarrow 0} \bar{C}(x, \tau) = \bar{C}(x, 0) = \phi_0 \tau_0^{1/(\gamma+2)}$$

$$\left(1 - \frac{x^2}{\xi_0^2 \tau_0^{2/(\gamma+2)}} \right)^{1/\gamma} \quad [\text{B-17}]$$

This implies that, for an initial profile of the form given by Eq. [B-17], the subsequent diffusive evolution is determined exactly by Eq. [B-16]. Admittedly, we cannot expect the initial profile to correspond to a similarity profile, as given by Eq. [B-17]. However, it is possible to approximate realistic initial profiles by functions of the form of Eq. [B-17], provided we choose τ_0 properly. Thus, Eq. [B-16] yields an approximate solution for the subsequent development, and, furthermore, this solution asymptotically approaches the correct solution, as the influence of the original profile width diminishes.

To be more specific, we note that if we characterize the initial profile simply by its width, x_0 , this determines τ_0 as

$$\tau_0 = (x_0/\xi_0)^{\gamma+2} = \frac{\gamma}{2(\gamma + 2)} \left(\frac{I_\gamma}{\bar{Q}_0} \right)^\gamma x_0^{\gamma+2} \quad [\text{B-18}]$$

which implies that the maximum concentration, C_s , and the location of the diffusion front, x_F , can be written as

$$C_s = \left(\frac{\gamma}{2(\gamma + 2)I_\gamma^2} \frac{\bar{Q}_0^2}{\tau} \right)^{1/(\gamma+2)} \left(1 + \frac{\tau_0}{\tau} \right)^{1/(\gamma+2)}$$

$$x_F = \left(\frac{2(\gamma + 2)}{\gamma I_\gamma^\gamma} \bar{Q}_0^\gamma \tau \right)^{1/(\gamma+2)} \left(1 + \frac{\tau_0}{\tau} \right)^{1/(\gamma+2)} \quad [\text{B-19}]$$

Carrier Lifetime Reduction in Silicon by Proton Implantation Through MOS Structures

A. Mogro-Campero* and R. P. Love

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

Ion implantation provides a versatile technique for lifetime control in silicon. Localized penetration and damage profiles provide means for the creation of regions of low lifetime within device structures. Protons of 80 keV were implanted 0.5 μm into silicon through a MOS structure, with doses up to 10^{14} cm^{-2} . The generation lifetime can be reduced by several orders of magnitude, and varies linearly with dose. Changes in oxide quality, surface generation velocity, and doping concentration were also studied. Low temperature annealing repairs the oxide degradation while maintaining substantial lifetime reduction.

The methods currently used to reduce carrier lifetime in silicon (the diffusion of gold or platinum, and electron irradiation) produce effects throughout the silicon wafer. Because of their well-defined range, implanted ions make possible the spatial localization of regions of reduced lifetime. Masking can be used to provide planar

*Electrochemical Society Active Member.

selectivity; depth control can be attained by energy selection or epitaxial overgrowth. Argon implantation provides an effective way of reducing lifetime, and is resistant to high temperature annealing (1-3). This makes it particularly appropriate for use during the early steps of device processing. In this paper, we explore the use of ion implantation to reduce lifetime in silicon during the late

stages of device processing. Depth control can be implemented by varying the energy of the ion. Most of the damage occurs near the end of range, so that a considerable degree of localization is still possible. Protons were used in our study; for singly ionized atoms and a given maximum implanter energy, they provide the greatest choice of depth. Since MOS structures are present in many of the devices of interest, the implantation was performed into the silicon through the metal and oxide layers.

Procedure

n-Type CZ silicon wafers of (111) orientation and doping density of 10^{15} phosphorus atoms cm^{-3} were used. The backs of the wafers were implanted with 10^{15} cm^{-2} phosphorus of 100 keV to ensure a low resistance contact to the back-side aluminum. 100 nm of dry oxide were grown at 1000°C. A set of 300 nm thick aluminum dots was then evaporated to form MOS capacitors, and sintered at 450°C for 30 min in nitrogen.

Using energy-loss and range tables (4), we calculate that the 80 keV protons implanted through the MOS structures penetrated $0.5 \mu\text{m}$ into the silicon. The maximum depletion depth under inversion is $1 \mu\text{m}$, so that the high frequency (1 MHz) capacitance-voltage and capacitance-transient measurements used in this experiment should be affected by the implantation. A portion of each sample was left unimplanted to serve as a control area. The damage produced by the protons has been estimated (5) to be such that at $0.35 \mu\text{m}$ into the silicon, the fraction of silicon atoms displaced from their crystalline positions is about 4×10^{-4} for the maximum proton dose of 10^{14}cm^{-2} used in this experiment.

Generation lifetime was measured at room temperature by the Zerbst technique (6, 7). A MOS capacitor is pulsed into deep depletion, and the formation of the inversion layer is observed via the capacitance transient. By this method it is possible to deduce the generation lifetime (τ_g) in the depleted zone, and the parameter s due to minority carriers whose current is independent of the time varying depth of the depletion zone. Because the lifetime is not constant with depth within the sampling volume, an average value dependent on depletion voltage will be obtained (3). The lifetime values reported here have been obtained with a -10V depletion pulse. The parameter s is the sum of the surface generation velocity and a term corresponding to diffusion of carriers into the depletion zone from the quasi-neutral regions (3). A typical variation of τ_g by a factor of 2 and parameter s by a factor of 3 was found across a given sample.

Results

Generation lifetime as a function of proton dose is shown in Fig. 1. Functional dependence with dose is close

Fig. 1. Generation lifetime vs. proton dose

to linear. At 10^{14}cm^{-2} , analysis by the capacitance transient technique was no longer reliable, but the duration of the capacitance transient continued to follow an inverse dose dependence, as shown by the dotted line extension in the figure. The superlinear dependencies (reverse leakage current of diodes approximately proportional to dose squared) for helium and carbon implantation within the range of doses in our experiment (8) were not observed.

The generation lifetime as a function of proton dose has been reported to drop more than three orders of magnitude in the dose range 10^{12} - 10^{13}cm^{-2} for similar experimental conditions (9). We find no evidence for this precipitous drop in lifetime. In that experiment, the lifetime was also deduced from a capacitance transient analysis, but the surface contribution was not taken into account. It has been shown that for irradiated samples, this procedure can lead to large errors (3).

The parameter s as a function of proton dose is shown in Fig. 2. Since the implantation damage region includes the oxide/Si interface, a linear dose dependence suggests the predominance of the surface generation velocity in the parameter s [the diffusion term would be either independent of dose if arising from deeper than the implant range, or proportional to the square root of dose if related to the lateral component (3)]. In a separate study of the temperature variation of τ_g and s for the sample with a dose of 10^{11}cm^{-2} , we have also come to the conclusion that the surface generation velocity is the dominant term in s at room temperature.

Doping profiles were obtained by a pulsed C-V method (10), using a pulse width of 1 ms. The result is shown in Fig. 3. The rise in doping density at shallow depths is most likely due to the interface proximity limitation (10). The rise in doping density due to the redistribution of

Fig. 2. Parameter s vs. proton dose

Fig. 3. Donor density vs. depth from C-V measurements. Portions of the curves have been omitted for clarity. All curves merge at depths $> 1.3 \mu\text{m}$. Curve a corresponds to a control sample and to a sample with a proton dose of 10^{10} cm^{-2} . Curves b-e correspond to proton doses 10^{11} - 10^{14} cm^{-2} .

phosphorus during thermal oxidation (11) is only a small effect in our case. The peaks in Fig. 3 correspond approximately to the expected range of the protons, and they indicate an increase in doping density with proton dose. However, interface traps can produce apparent changes in doping density profiles (10). Therefore, an average value of doping density within the equilibrium depletion depth under inversion (0.3 - $0.8 \mu\text{m}$ for doping densities 10^{16} - 10^{15} cm^{-3}) was obtained by the maximum-minimum C-V method, which is free of interface trap effects (10). A doping density increase is again observed (Fig. 4), but only for the highest proton dose.

Doping concentration changes after proton implantation into n-type silicon have been reported; carrier concentration decreases were found after implantation, but increases appeared after annealing at around 300°C (12). This indicates a competition between the dominance of deep and shallow levels, which should depend on the energy level spectrum within the silicon bandgap. Since various point defect complexes and/or defect-impurity associations are probably responsible for the levels, the details in a particular situation are bound to be different. It is important to note in this respect that we have used Czochralski samples, whereas the other experimenters (12) have worked with float-zoned material. It is well known that there is a large difference in impurity concentrations in these two types of crystals, notably with respect to oxygen concentration, which in Czochralski samples is many orders of magnitude higher (in the 10^{18}

Fig. 4. Doping density within the equilibrium depletion depth vs. proton dose (from C-V measurements).

Fig. 5. Charge associated with the oxide in units of the electron charge as a function of proton dose.

cm^{-3} range). Sample differences are presumably also partly responsible for the variety of energy levels reported by different investigators after proton bombardment (13).

Charge associated with the oxide was computed from flatband voltage shift (14); the results are shown in Fig. 5. The associated shift in threshold voltage for inversion is 2V for a dose 10^{14} cm^{-2} . C-V curves for a control sample, and one with a dose of 10^{14} cm^{-2} are shown in Fig. 6. The

Fig. 6. Capacitance normalized to the oxide capacitance vs. voltage. The arrows indicate the direction of the voltage sweeps (at a rate of 0.4 V s^{-1}). The top graph is for the control region of the sample, and the bottom one for a proton dose of 10^{14} cm^{-2} . Measurements are carried out in the dark, except that the sample is brought to equilibrium by a brief exposure to light after the positive-to-negative voltage sweep.

Fig. 7. Surface generation velocity and generation lifetime as function of annealing temperature for samples implanted with 10^{12} protons cm^{-2} . All anneals for 30 min. Average values are indicated with arrows for an unimplanted sample annealed at 450°C and for an implanted sample prior to annealing.

hysteresis and stretch out after irradiation are characteristic of interface charge trapping near the oxide/Si interface (15).

Annealing experiments in nitrogen were carried out for samples with a proton dose of 10^{12} cm^{-2} . Half-hour anneals showed that the oxide parameters referred to in the previous paragraph returned to their preimplanted condition after the 350°C anneal. The doping density increase deduced from the pulsed C-V method discussed earlier was reduced by the 150°C anneal, and disappeared after the higher temperature annealing treatments.

The results for annealing of the generation lifetime and surface generation velocity are shown in Fig. 7. Both parameters achieve stable values, but do not regain the unimplanted levels. It is interesting to note that the lifetime in the case of electron irradiation has returned to the unirradiated value after a 450°C anneal step for 30 min (16). Lifetime reduction by proton implantation is thus more thermally stable.

Further evidence for persistent lifetime reduction after annealing is provided in Fig. 8. For longer annealing times both τ_g and s move further away from the unimplanted values. This phenomenon of negative annealing has been observed in the reverse leakage current after carbon ion implantation in a similar temperature regime (8), and attributed to complexes that do not act to suppress lifetime annealing out at these temperatures, and freeing mobile defects which can recombine to form lifetime-active centers.

Conclusions

The generation lifetime of silicon samples can be reduced by several orders of magnitude by proton implantation, as deduced from measurements prior to annealing treatments. The implantation can be carried out near the end of the device processing sequence, so that only low temperature steps are left. Oxide degradation in MOS structures can be repaired with low temperature annealing treatments, which also serve to stabilize the lifetime. The relatively high value of surface generation velocity will tend to increase surface leakage current and decrease channel mobility. The severity of oxide and interface related effects will also depend on the ion energy used,

Fig. 8. Surface generation velocity and generation lifetime as a function of time at 350°C for samples implanted with 10^{12} protons cm^{-2} . Average values are indicated by arrows for an unimplanted sample annealed for 250 min and for an implanted but unannealed sample.

since ion energy-loss rates depend on energy. Well-defined range and damage profiles allow localization of regions of low lifetime within device structures, so that ion implantation is emerging as a versatile tool for lifetime control in silicon.

The System AgI-AgBr: Energetic Consequences of Defect Equilibria in Single-Phase and Two-Phase Regions

A. Khandkar,* V. B. Tare, A. Navrotsky, and J. B. Wagner, Jr.**

Center for Solid State Science, Arizona State University, Tempe, Arizona 85287

ABSTRACT

The enthalpy of solution of various single- and two-phase AgI-AgBr compositions in AgNO_3 at 518 K has been determined using a Calvet-type twin microcalorimeter. The enthalpy ($H_{518} - H_{298}$) of melted and unmelted mixtures of AgI and AgBr of various compositions within two-phase regions of the phase diagram has also been obtained using the same calorimeter. The effect of AgBr on the temperature and enthalpy of transformation of β -AgI to α -AgI has been investigated using a Perkin Elmer Differential Scanning Calorimeter. The terminal compositions at 518 K of the two-phase region of AgI-AgBr system has been found to be $\text{AgI}_{0.85}\text{Br}_{0.15}$ and $\text{AgI}_{0.3}\text{Br}_{0.7}$. The excess enthalpy, the difference in ($H_{518} - H_{298}$) values of the unmelted and melted mixtures in the two-phase region of the AgI-AgBr system, has been found to be maximum at the equivolume concentration of the two terminal phases and is suggested to be due to the generation of silver ion vacancies at the interfaces due to a space-charge layer.

During the past few years, several investigators have reported anomalous electrical conduction in materials containing finely divided particles dispersed as a second phase. The systems investigated include the dispersion of submicron-sized insulating particles in an ionically conducting matrix [$\text{LiI} + \text{Al}_2\text{O}_3$ (1), $\text{AgI} + \text{Al}_2\text{O}_3$ (2), $\text{AgCl} + \text{Al}_2\text{O}_3$ (3)], of insulating particles in materials with predominant electronic conduction [SiO_2 in TiO_2 (4)], of metallically conducting particles in a semiconductor [Ni_3S_2 (5) or Ni (6) in NiO], and of ionically conducting materials in an ionically conducting matrix [AgBr in AgI (7)]. The observed changes in the electrical conductivity could not be explained on the basis of classical theories alone. Several alternative explanations have been proposed (8-10); however, the explanation based on the presence of additional defects at the interface because of the space-charge layer appears to be most satisfactory (8). The AgI-AgBr system was chosen for the present study because of its relative physical and chemical simplicity and because of the extensive investigations carried out in this laboratory regarding its electrical conductivity (2, 7, 11). Silver iodide is known to exist in at least two stable crystallographic modifications with a transition at 420 K from a low temperature wurtzite β form to a high temperature, body-centered cubic α form. Silver bromide, on the other hand, is stable only in the rocksalt-type cubic structure up to its melting temperature.

Electrical conductivity of α -AgI is several orders of magnitude higher than that of β -AgI and AgBr. Partial replacement of iodine in AgI with bromine has been found to lower the transition temperature (11). Anomalous changes in electrical conductivity of several single-phase and two-phase compositions in the AgI-AgBr system have also been reported (7). Since the changes in the electrical conductivity are presumably associated with the changes in number and the mobility of the transporting species, present investigations were undertaken to see whether these changes are reflected in the energetics of this system as well.

Experimental

Sample preparation.—AgI and AgBr, (99.999% pure from Apache Chemicals) in powder form, were mixed together in appropriate proportions and sealed in 6 mm

* Electrochemical Society Student Member.

** Electrochemical Society Active Member.

diam evacuated silica tubes. The mixture was melted at 873 K for 1h. To ensure complete solution and homogenization, the melt was shaken from time to time. The sample was then quenched to room temperature, removed from the silica tube, and cut into small pieces of 500-600 mg each. Some of these pieces were annealed in air at 533 K for times varying from 2 to 15h before using them for drop calorimetry. Other pieces were ground to a fine powder (~200 mesh), and 50-60 mg of the powder was used for solution calorimetry in molten AgNO_3 . A few milligrams of the same powder was used in a Perkin-Elmer DSC-2 Differential Scanning Calorimeter.

Compositions of the samples were assumed to be the same as those of the starting mixtures. X-ray powder diffraction technique was used on samples at 298 K to confirm that no phases other than wurtzite-type AgI and rocksalt-type AgBr were present.

Calorimetry

Solution calorimetry.—A Calvet-type twin-microcalorimeter as described elsewhere (12), was used. Samples were dissolved in molten AgNO_3 at 518 K. 50g of AgNO_3 were premelted in silica crucibles and then put in each calorimeter chamber. The Ag(I, Br) samples (about 50 mg of powder) were placed in a platinum cup, which was suspended just above the solvent by means of a movable quartz assembly. After the system attained thermal equilibrium (as seen by a steady baseline signal), the platinum cup with the powder was immersed in the solvent and, after a quick up-and-down stirring action, raised to the original level above the solvent. This procedure was repeated several times until the baseline returned to the original value. The area under the peak representing the enthalpy changes associated with the dissolution process was proportional to the heat generated. Calibration was achieved by dropping pieces of platinum, of known weight and heat content, into the melt.

To check whether the stirring contributed to the heat, several experiments were performed using empty platinum cups. No change in baseline was detected, indicating negligible heat due to stirring. The heat effects in each experiment were approximately 0.1 cal; the heat of solution ranged from +1000 to -4200 cal/mol.

Heat content measurement.—($H_{518} - H_{298}$) was measured by dropping ~250 mg cylindrical samples from 298 K into

the same calorimeter at 518 K using empty crucibles. The calorimeter was calibrated by dropping Al_2O_3 rods of similar dimensions, the heat content of which is tabulated by Barin and Knacke (13).

Differential scanning calorimetry (DSC).—A Perkin-Elmer Differential Scanning Calorimeter Model DSC-2 was used to obtain the temperature and enthalpy of transformation of various AgI-AgBr samples. Since the transformation occurs at temperatures close to the melting of indium (429.6 K), the instrument was calibrated using the melting point of indium, which was found to be within ± 0.5 K of the reported value (13).

The heating rate of 5 K/min was found to be most suitable. The temperature was varied from 350 to 450 K at this rate. The enthalpy changes associated with the transformation were recorded on a strip chart recorder and integrated using a planimeter. The reproducibility of the temperature measurement was ± 0.5 K and of the enthalpy measurement ± 50 cal for at least ten different indium samples.

Results

The data ($H_{518} - H_{298}$) obtained by drop calorimetry for pure AgI and various AgI-AgBr compositions are listed in Table I. To see any effects of change in grain size or grain boundary structure during annealing, some of the samples were annealed for periods varying from 2 to 15h at 533 K. The enthalpy values obtained for annealed and unannealed samples were the same within experimental error. Our value of 4720 ± 125 cal/mol for pure AgI is comparable to 4558 cal/mol reported by Barin and Knacke (13).

Table II lists the excess enthalpy values which were obtained for two-phase mixtures by taking the difference between the experimentally determined ($H_{518} - H_{298}$) values for various compositions obtained by melting and the values estimated for the same composition by taking the weighted average of the experimentally determined values for the terminal solid solutions. The phase diagram of the AgI-AgBr system has been reported by Stasiw and Teltow (14). However, subsequent investigations are not consistent with the solubility limits reported in the phase diagram. Shahi and Wagner (11) suggested from the conductivity measurements that the end members of the two-phase region of the AgI-AgBr system are $AgI_{0.9}Br_{0.1}$ and $AgI_{0.3}Br_{0.7}$. These terminal compositions were therefore used to estimate excess enthalpy. The excess enthalpy values are shown in Fig. 1 as a function of mole percent (m/o) $AgI_{0.3}Br_{0.7}$. A maximum in excess enthalpy is observed at about 50 m/o $AgI_{0.3}Br_{0.7}$. The unmelted samples (mechanical mixtures) show no excess heat content.

The enthalpies of solution of various compositions in $AgNO_3$ at 518 K are listed in Table III. For some composi-

tions in the two-phase region, the enthalpies of solution were also obtained by preparing mechanical mixtures (without melting) of the end compositions. These values are also shown in this table. The difference in enthalpies of solution between the two-phase melted and unmelted compositions is within the experimental scatter.

The enthalpies of solution are plotted in Fig. 2 as a function of m/o AgBr. This figure indicates that the variation of the enthalpy of solution with composition shows some curvature in the AgBr-rich single-phase region, while it is approximately linear in the AgI-rich single-phase region. The enthalpy values of the compositions in the two-phase region fall approximately on a straight line joining the enthalpy values of the two terminal compositions.

The enthalpy and temperature of the β to α transformation of various compositions, as determined by

differential scanning calorimetry are listed in Table IV. For pure AgI, these values are 1420 ± 30 cal/mol and 420 ± 0.5 K, respectively, in excellent agreement with the literature value (13).

A plot of transformation temperature as a function of composition is shown in Fig. 3. The temperature varies linearly up to 15 m/o AgBr in AgI and then remains constant. A plot of transformation enthalpy per mole of composition shown in Fig. 4 also indicates that the enthalpy varies linearly with a change in slope occurring at 15 m/o AgBr. No transformation was detected for the composition 30 m/o AgI-70% AgBr. These data indicate that the terminal compositions of the two-phase region of AgI-AgBr system at 518 K are $\text{AgI}_{0.85}\text{Br}_{0.15}$, which undergoes the $\beta \rightarrow \alpha$ transformation at 403.5 K with a transformation enthalpy of 1200 cal/mol, and $\text{AgI}_{0.3}\text{Br}_{0.7}$, which does not undergo a crystalline transformation. The enthalpy values obtained for the composition in the two-phase region are therefore entirely due to the $\beta \rightarrow \alpha$ transformation of $\text{AgI}_{0.85}\text{Br}_{0.15}$ and are converted to values per mole of

Discussion

The results obtained by differential scanning calorimetry and solution calorimetry indicate that at 518 K the terminal compositions in the two-phase region of the AgI-AgBr system correspond to 15 m/o AgBr for the α -AgI type cubic phase and 70 m/o AgBr for the AgBr-type cubic phase. The excess enthalpy values shown in Fig. 1, therefore, need to be modified. Assuming a linear variation with composition in the AgI-rich single-phase region, the enthalpy of solution for the $\text{AgI}_{0.85}\text{Br}_{0.15}$ terminal composition was calculated. This value was used to estimate the modified excess enthalpy values which are also shown in the same figure. The maximum in excess enthalpy value is still around 50 m/o. $\text{AgI}_{0.85}\text{Br}_{0.15}$ and 50 m/o $\text{AgI}_{0.3}\text{Br}_{0.7}$. However, whatever terminal compositions are assumed for the solid solutions, the rather surprising observation remains that the enthalpy ($H_{518} - H_{298}$) is much larger for the melted and solidified two-phase mixture

Fig. 3. Transformation temperature as a function of composition. The break in the curve corresponds to the solubility limit of AgBr in AgI.

than for a mechanical mixture of the two terminal solid solutions, while the enthalpies of solution at 518 K are similar for both types of two-phase compositions. Since the maximum in excess heat content occurs near an equimolar mixture of the two-terminal solid solutions, and since their densities are not very different, the maximum also corresponds to 50 volume percent (v/o) of each. Because of the identical methods of preparation, the grain sizes in different compositions are expected to be similar. The maximum in excess enthalpy at equivalent concentrations of each of the terminal compositions suggests that the excess enthalpy may be related to changes at the interface between these two phases. Since interfacial enthalpies reported for other systems in the literature (15) are two to three orders of magnitude smaller than the values measured in the present investigation, an additional explanation for the origin of this enthalpy is necessary.

The measured enthalpy ($H_{518} - H_{298}$) for various compositions may be considered to be the sum of (i) the enthalpy change associated with the heating of the sample from 298 K to the transformation temperature, (ii) the enthalpy of the $\beta \rightarrow \alpha$ transformation, and (iii) the enthalpy change associated with heating the sample from the transformation to the calorimetric temperature, 518 K.

The measurement of the $\beta \rightarrow \alpha$ transformation enthalpy by DSC and the enthalpy of solution in AgNO_3 of melted

and unmelted samples in the two phase region at 518 K indicates that contributions from (ii) and (iii) are small. The excess enthalpy may therefore be considered to be predominantly due to the effects below the $\beta \rightarrow \alpha$ transition in the AgI-rich phase.

An anomalous increase in electrical conductivity in the two-phase region of the system at temperatures below the $\beta \rightarrow \alpha$ transformation was observed by Shahi and Wagner (2). The maximum in conductivity was reported to be at 20 m/o AgI-80 m/o AgBr. This enhanced conduction was suggested to be due to the presence of additional defects generated at the two-phase interface due to the space charge layer. AgI is an ionic conductor in which Frenkel-type defects predominate (16). Although the enthalpy of formation of silver interstitials and silver vacancies in AgI is not known, a comparison of similar values reported for AgCl suggests that the enthalpy of formation of silver vacancies is smaller than that of silver interstitials. The presence of silver vacancies as the predominant transporting species at lower temperatures has been suggested by Khandkar and Wagner (3) in the case of $\text{AgCl-Al}_2\text{O}_3$ composites and by Shahi and Wagner (2) in the case of $\text{AgI-Al}_2\text{O}_3$ composites. The latter authors inferred the predominance of silver vacancies from the sign of thermoelectric EMF.

The definite qualitative correlation observed between the anomalous conductivity enhancement and the excess enthalpy in the two-phase region suggests that the same mechanism may be responsible for both effects. It is suggested that the origin of this excess enthalpy is the excess vacancy concentration at the interface in the melted two-phase compositions of the AgI-AgBr system.

The observation that maxima in the electrical conductivity and in the excess enthalpy occur at different compositions suggests that the presence of a second phase not only affects the concentration of mobile species taking part in conduction, but also affects their mobility as well. Changes in mobility would not be reflected in the measured excess enthalpy, but could shift the maximum conductivity away from the composition of presumed maximum defect concentration and maximum enthalpy.

Enthalpies of solution of the AgI and the AgBr-rich single-phase compositions can be used to obtain enthal-

Fig. 5. Linear extrapolation of the enthalpy of solution of AgI-rich single-phase compositions to pure AgBr.

pies of solution of their metastable polymorphs by a method similar to that described by Davies and Navrotsky (17) for NiO-ZnO solid solutions. In this approach, one fits the enthalpy of solution within a single-phase region by an appropriate polynomial. Extrapolation to mole fraction of the solute equal to one gives the enthalpy of solution of the solute in the hypothetical polymorph having the structure of the terminal solid solution. The difference between that value and the heat of solution of the pure solute in its normal structure gives the enthalpy of transformation. A linear fit to the enthalpy of solution data implies that the solid solution is ideal when referred to standard states having the same structure; a quadratic fit that the solution is regular. The least squares computer fit for the data is shown in Fig. 5 and 6 for AgI-rich and AgBr-rich compositions, respectively. In each case the fit was obtained using all the data points for each composition rather than averages for each composition. Linear extrapolation of the data to pure AgBr gives a value for the enthalpy of solution of AgBr with the α -AgI-type cubic structure as -125 ± 150 cal/mol. From Table III, the enthalpy of solution of AgBr having rocksalt-type cubic structure is 870 ± 170 cal/mol. Therefore, the enthalpy of transformation of AgBr from its stable rocksalt-type cubic structure to α -AgI-type bcc structure is estimated to be 1000 ± 300 cal/mol. The variation of enthalpies of solution of AgBr-rich single phases with composition shows a small curvature. Because of the large scatter in the data obtained and small composition range of the single-phase region, the extrapolation of the data to pure AgI is quite uncertain. The linear fit (ideal solution) gives a near-zero enthalpy of transformation for AgI ($\alpha \rightarrow$ rocksalt). A quadratic fit implies negative heats of mixing in the rocksalt solid solutions and an enthalpy of transformation of 12,500 cal/mol. These two fits may represent an underestimate and overestimate, respectively, of the curvature of the data and may place a lower and upper bound on the enthalpy of transformation. Thus, ΔH for AgI ($\alpha \rightarrow$ rocksalt) may lie in the range 0-12 kcal/mol. No data are available for comparison.

Conclusions

1. The excess enthalpy, as defined by the difference in ($H_{518} - H_{298}$) values between the melted and solidified two-phase compositions and the mechanical mixtures of the terminal solid solutions of the AgI-AgBr system, exhibits maxima at equivolume concentrations of the terminal compositions and is suggested to be due to the excess silver ion vacancies generated at the interfaces due to the space-charge layer.

2. The terminal composition of the two-phase region of AgI-AgBr system at 518 K are $\text{AgI}_{0.85}\text{Br}_{0.15}$ and $\text{AgI}_{0.3}\text{Br}_{0.7}$.

3. The enthalpy of transformation of AgBr from its stable rocksalt-type cubic structure to α -AgI-type bcc structure is estimated to be 1000 ± 300 cal/mol, while the

Fig. 6. Linear and quadratic extrapolations of the enthalpy of solution of AgBr-rich single-phase compositions to pure AgI.

enthalpy for the transformation of α -AgI to the rocksalt structure lies between 0 and 12 kcal/mol.

Phase Relations and Thermochemistry of Iron-Aluminum-Sulfur System at 1173 K

P. C. Patnaik* and W. W. Smeltzer**

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

The compositions were determined of alloy and sulfide phases in the Fe-Al-S system equilibrated with one another at 1173 K. These evaluations were used to construct the ternary Fe-Al-S isotherm, which was comprised of three sulfide phases coexisting with alloy: FeS containing up to 0.61 atomic percent (a/o) Al, FeAl_2S_4 of Fe/Al ratio 0.766 to 0.518 in the alloy composition range 0.84 to 5.86 a/o Al, and Al_2S_3 containing 0.30 a/o Fe. These results were combined with available thermodynamic data to determine the ternary equilibrium diagram in the form of sulfur activity vs. aluminum metal atom fraction of the alloy and sulfide phases. The sulfur activity over the ternary univariant coexistence alloy + FeAl_2S_4 + Al_2S_3 is 5.35×10^{-6} .

Phase relations and thermodynamic properties of the Fe-Al-S solid-gas system at high temperatures are not known. In this investigation, the ternary Fe-Al-S isotherm at 1173 K is constructed using the compositions of equilibrated phases. The sulfur activities coexisting with aluminum sulfide and alloys were evaluated using the value for the standard free energy of formation of Al_2S_3 (1) and the available aluminum activity data for the binary Fe-Al alloys (2, 3). These sulfur activity evaluations, in conjunction with compositions of the sulfide and alloy phases, were utilized to construct the ternary equilibrium sulfur activity diagram.

Experimental

A number of ternary compositions in the Fe-Al-S system were synthesized from the elements. The starting materials were powders of iron and aluminum of 99.99% purity and sulfur of 99.999% purity supplied by Cerac, Incorporated. Several overall compositions (P1 to P6), as shown in Fig. 1, were chosen. In each case, the elements were thoroughly mixed, compressed to a pellet, and then placed in a high purity (99.9%) alumina crucible which was sealed in a quartz tube under vacuum (1-2 Pa). This method avoided SiO_2 contamination of the sample pellet resulting from its bonding to the quartz wall, which has been shown previously to occur (4).

Previous workers using aluminum and sulfur to obtain Al_2S_3 in a quartz ampul have encountered explosions while determining a suitable heating schedule (5). This behavior was due to the autocatalytic nature of aluminum sulfidation by which the exothermic sulfidation reaction increased the sulfur pressure in the ampul. With an increased sulfur pressure, the reaction rate increased, releasing additional heat, which led to excessive sulfur pressures and rupture of the quartz tube. This problem was not encountered in the present case, owing to rapid reaction between iron and sulfur. However, for a successful experiment, combinations of slow and step heatings were used.

Figure 2 shows a typical heating schedule of samples placed in alumina crucibles encased in quartz ampuls. Initially, they were heated for 2 days in steps at 423 and 509 K (total P_{S_2} at 509 K = 10^3 Pa) to permit combination of the sulfur with metals. All the samples contained 35 atomic percent (a/o) sulfur with varying amounts of the metals. The completeness of reaction was indicated by the absence of visible sulfur in the quartz tube. After approximately 240h at 1173 ± 2 K, the ampuls were quenched in water. The quenched samples were mounted for metallographic observation. In addition to metallography, x-ray powder diffraction with Ni-filtered CuK_α radiation was also employed to identify the various phases present in each sample. Compositions of various phases were determined using electron probe microanalyses (EPMA) with Fe-Al alloys, FeS, and FeAl_2S_4 of known

compositions as standards. These compositions could be determined to within ± 0.05 a/o.

Results

Figure 3 shows three equilibrated phases, FeS + Fe-0.84Al (a/o) + FeAl₂S₄. Table I summarizes the equilibrated phases in pellets P1 through P6 as identified by metallography and x-ray diffraction. The x-ray intensity plots *vs.* diffraction angle 2θ for several pellets are shown in Fig. 4. The correspondence of these diffraction patterns to ASTM standards for FeS, Al₂S₃, and Fe-Al alloys and to independent diffraction measurements made on synthesized FeAl₂S₄ support the inferences drawn from the metallographic observations (4, 6).

Compositions of alloys and coexisting sulfide phases determined by EPMA are reported in Table II. These analyses demonstrated the following findings of phase equilibria at 1173 K: (i) in the FeS + alloy + FeAl₂S₄ univariant equilibrium, FeS contained 0.61 a/o Al and the alloy contained 0.84 a/o Al, (ii) the double sulfide phase, (Fe_{1.24}Al_{1.618})S₄, in equilibrium with (Fe_{0.96}Al_{0.012})S and the Fe-0.84 Al alloy was rich in iron, and its iron content decreased to (Fe_{0.99}Al_{1.91})S₄ as the double sulfide was equilibrated with higher aluminum containing alloys, and (iii) the solubility of iron in Al₂S₃ equilibrated with double sulfide and alloy containing 5.86 a/o Al was 0.30 a/o. This solubility of iron in Al₂S₃ was found to decrease with increasing aluminum contents of the alloy.

Discussion

The Fe-Al-S isotherm, Fig. 5, was constructed from results of this investigation using the binary Fe-Al, Fe-S, and Al-S phase extents (3). Pure iron and aluminum dissolve up to 0.05 and 5 a/o of sulfur, respectively. These concentrations were used to represent the sulfur solubility in the alloy, as indicated by a dotted line on the ternary isotherm. Solubilities of aluminum and iron in FeS and Al₂S₃ were determined to be 0.61 and 0.3 a/o, respectively, when each phase was equilibrated with alloy and FeAl₂S₄. The phase field of double sulfide, (Fe_{1.24}Al_{1.618})S₄-

Fig. 5. The experimentally determined ternary Fe-Al-S isotherm at 1173 K.

6-80 a/o Al can be calculated as follows. If one considers the reaction

the equilibrium constant is given by

$$K = \exp - \frac{\Delta G_f^\circ}{RT} = \frac{a_{\text{Al}_2\text{S}_3}}{a_{\text{Al}}^2 P_{\text{S}_2}^{3/2}} \quad [2]$$

where $a_{\text{Al}_2\text{S}_3}$ and a_{Al} are the activities of Al_2S_3 and aluminum in the alloy, respectively, P_{S_2} is the dissociation pressure of Al_2S_3 , and ΔG_f° is the standard free energy of formation of Al_2S_3 . Since $a_{\text{Al}_2\text{S}_3} \approx 1$, the sulfur pressure relationship is given by

$$\log P_{\text{S}_2} (\text{Pa}) = \frac{2}{3} \left(\frac{\Delta G_f^\circ(\text{Al}_2\text{S}_3)}{2.303 RT} - 2 \log a_{\text{Al}} \right) + \log (101,300) \quad [3]$$

Upon substituting the most recently determined value for $\Delta G_f^\circ(\text{Al}_2\text{S}_3) = -507,883 \pm 500 \text{ J/mol}$ (1), the sulfur activity is given by

$$\log a_{\text{S}} = 1/2 [\log \{P_{\text{S}_2} (\text{Pa})/1.013 \times 10^5 (\text{Pa})\}] = -7.54 - \frac{2}{3} \log a_{\text{Al}} \quad [4]$$

Sulfur activities for alloy- Al_2S_3 equilibria were then calculated using the aluminum activity values and these evaluations are given in Table III.

An aluminum cation (or metallic) fraction of each phase is defined as

$$\xi_{\text{Al}} = \frac{g \text{ ions (atoms) of aluminum}}{g \text{ ions (atoms) of iron} + g \text{ ions (atoms) of aluminum}}$$

For the three-phase equilibrium, alloy + FeAl_2S_4 + Al_2S_3 , ξ_{Al} (alloy) was determined to be 0.059, corresponding to an activity of 3.9×10^{-4} . The corresponding sulfur activity was calculated to be 5.35×10^{-6} . It was not possible to evaluate the sulfur activity over the FeS + alloy + FeAl_2S_4 equilibrium because the free energy of formation of FeAl_2S_4 is unknown.

Figure 6 shows the sulfur activity equilibrium diagram, in a_{S} vs. ξ_{Al} , for the Fe-Al-S system at 1173 K. This diagram is semischematic and it has been compiled insofar as possible from the results given in Tables II and III. For clarity, dissociation pressures of the sulfides are also shown in this diagram.

Table III. The thermodynamic activity of Al in solid Fe-Al alloys (2) and the sulfur activities calculated from Eq. [4] for the alloy + Al_2S_3 equilibria at 1173 K

a/o Al	(ξ_{Al})		a_{Al} at 1173 K	$-\log a_{\text{S}}$
	$\frac{\eta_{\text{Al}}}{\eta_{\text{Al}} + \eta_{\text{Fe}}}$			
5	0.05		3.8×10^{-4}	
6	0.06		3.9×10^{-4}	5.27
10	0.10		8.1×10^{-4}	5.47
15	0.15		1.5×10^{-3}	5.65
20	0.20		2.5×10^{-3}	5.79
25	0.25		3.7×10^{-3}	5.91
30	0.30		5.5×10^{-3}	6.03
35	0.35		8.3×10^{-3}	6.15
40	0.40		1.4×10^{-2}	6.28
45	0.45		2.6×10^{-2}	6.47
50	0.50		5.5×10^{-2}	6.69
52	0.52		9.8×10^{-2}	6.86
60	0.60		9.8×10^{-2}	6.86
65	0.65		9.8×10^{-2}	6.86
67	0.67		1.3×10^{-1}	6.94
70	0.70		1.3×10^{-1}	6.94
75	0.75		4×10^{-1}	7.26
80	0.80		7×10^{-1}	7.42
100	1		1	7.54

The sulfur activity decreased from 1.2×10^{-4} imposed by the Fe-FeS coexistence to a lower value presently not determined associated with the univariant alloy + FeS + FeAl_2S_4 equilibrium. The fractions, ξ_{Al} , in each phase of this coexistence, are 0.0084, 0.012, and 0.566, respectively. The sulfur activity of the alloy + FeAl_2S_4 + Al_2S_3 coexistence was determined to be 5.35×10^{-6} . ξ_{Al} in each phase is 0.059, 0.658, and 0.992 respectively. FeAl_2S_4 equilibrated with alloys containing 0.84 to 5.86 a/o Al. The results indicate that Al_2S_3 exists with alloys containing greater than 5.86 a/o Al. Sulfur activity decreases with increasing aluminum contents of the alloy until it reaches 2.9×10^{-8} , corresponding to that of Al + Al_2S_3 equilibrium.

Summary

The ternary Fe-Al-S isotherm at 1173 K was constructed by determining the composition of equilibrated alloy and

Fig. 6. The ternary equilibrium sulfur activity diagram at 1173 K, $\log a_{\text{S}}$ vs. Al cation (metallic) fraction. The dissociation pressures calculated for the sulfides are given by

$$a_{\text{S}} = \{P_{\text{S}_2} (\text{Pa})/1.013 \times 10^5 (\text{Pa})\}^{1/2}$$

sulfide phases. Equilibrium sulfur activities were determined for the alloy + FeAl_2S_3 + Al_2S_3 univariant equilibrium and alloy + Al_2S_3 coexistences. These results in conjunction with thermochemical data for Fe-Al alloys and Al_2S_3 were used to determine the equilibrium diagram of sulfur activity as a function of aluminum metallic fraction of each phase.

Preparation and Properties of Amorphous Boron Films Deposited by Pyrolysis of Decaborane in the Molecular Flow Region

K. Nakamura

Department of Chemistry, Nihon University, Sakurajosui Setagaya-ku, Tokyo 156, Japan

ABSTRACT

Boron films of 0.1-1.5 μm thickness have been prepared on sapphire, silicon, and tantalum as substrates by the pyrolysis of decaborane ($\text{B}_{10}\text{H}_{14}$) in the molecular flow region ($\leq 10^{-4}$ torr) and in a temperature range of 350°-1200°C. It is found that the deposition rate of the boron films is proportional to the decaborane partial pressure and the substrate temperature. Below 416°C, the deposition rate D is given as a function of the substrate temperature and partial pressure of decaborane. This relation is

$$D = 7.16 \times 10^6 \cdot P \cdot \exp(-39000/RT_s)$$

where T_s is the substrate temperature, P is the pressure of decaborane, and R is the gas constant. The apparent activation energy for the decomposition of decaborane is found to be 39 kcal/mol. X-ray and electron diffraction study indicates that the films are amorphous. The electrical conductivities vary from $3 \times 10^{-5} \text{ S} \cdot \text{cm}^{-1}$ at 77 K to $30 \text{ S} \cdot \text{cm}^{-1}$ at 1000 K, and the activation energy is 1.07 eV in the intrinsic temperature range (700-1000 K). The maximum value of thermoelectric power is about $420 \mu\text{V} \cdot \text{deg}^{-1}$ at 700 K, and its polarity is positive between 500 and 1000 K. The absorption coefficient, refractive index, and extinction coefficient of boron films are obtained from the measured transmittance and reflectance. The energy of the indirect allowed transition is estimated to be $1.28 \pm 0.08 \text{ eV}$.

Boron is one of the elemental semiconductors. However, the resistivity of boron is several hundred times larger than that of Si and Ge at room temperature. Although many studies (1-3) on the properties of boron have been done, the physical properties reported are not in agreement with each other because it is very hard to obtain high-purity bulk boron. However, we can obtain pure and uniform boron in film form. Boron films have been prepared by means of chemical vapor deposition (4-6) or vacuum evaporation using electron bombardment of boron (7-9). Croft (10) has obtained high-purity boron films by pyrolysis of diborane. However, diborane is a very dangerous gas which requires much care in handling. Pentaborane (B_5H_9 ; -46.5°C mp, 60°C bp) and decaborane ($\text{B}_{10}\text{H}_{14}$; 99.6°C mp, 213°C bp) can be used as alternative boron hydride sources. Decaborane is safer and more stable than pentaborane and diborane. Furthermore, decaborane has advantages as a source material for boron films because high purity decaborane is easy to obtain with a sublimation purification process.

Many studies on the electrical (6, 11, 12, 14) and optical (8, 9, 13, 14) properties of boron films prepared by vacuum evaporation (12, 13) and CVD (5, 14) have been reported. However, reported properties scatter widely (e.g., the values of electrical conductivity and optical gap energy at room temperature).

In this report, high quality boron films have been prepared by pyrolysis of decaborane in the molecular flow region at temperatures between 350° and 1200°C. The deposition mechanism is discussed in terms of the depen-

dence of the deposition rate on the substrate temperature and the impingement frequency of decaborane molecules onto the substrate surface.

The temperature dependencies of the electrical conductivity and of the thermoelectric power of the boron films deposited on sapphire substrates have been measured. The energy-band gap and optical constant ($n \cdot k$) of boron have been estimated from the results of the optical transmittance and reflectance in the visible and infrared spectral regions.

Experimental

The schematic diagram of the apparatus in this study is shown in Fig. 1. The vacuum chamber was evacuated by an oil diffusion pump system, and the ultimate pressure was 2×10^{-6} torr. Sapphire and silicon were used as the substrates. The substrate was fixed on the tungsten sheet heater (0.05 mm thickness) and was heated from 600° to 1200°C (Fig. 2). Tantalum sheet was also used as a substrate and was heated between 350° and 700°C by direct resistance heating. The sapphire substrate temperature was estimated from the heater temperature, which was measured with an optical pyrometer. The relation between the substrate and the heater temperatures was previously obtained. The tantalum substrate temperature was measured directly by a welded thermocouple.

Decaborane (Arfa Product) was sublimated by heating at about 70°C and was introduced to the vacuum chamber through a variable leak valve. Boron films were deposited on the heated substrate by thermal decomposition of

Fig. 1. Schematic diagram of the apparatus used for deposition of boron films by pyrolysis of decaborane.

Fig. 2. Assembly of the substrate and the heater

the decaborane. The pressure of decaborane was measured as a corresponding of nitrogen pressure by a B-A type ionization gauge and was kept between 1×10^{-5} torr and 2×10^{-4} torr. Deposition time varied from 0.5-60 min, depending on the gas pressure and the substrate temperature. The thicknesses of the films on the sapphire substrates were measured with a multiple-beam interferometer and ranged from 442 to 4740 Å. In the case of the films deposited on tantalum, the film thickness could not be measured optically because of the rough surface of the tantalum substrate. The film thickness of the boron films on tantalum substrates was estimated from the measured x-ray fluorescence of boron deposited using EPMA with a 7 kV acceleration voltage, a 0.1A sample current, and a 100 μm beam-diameter. The relation between the x-ray intensity and the film thickness was previously obtained using boron films on a sapphire substrate.

The crystal structure of boron films was studied by reflection electron and x-ray diffraction techniques. The electrical conductivity and its temperature dependence were measured by a two-probe technique at temperatures ranging from 300 to 1000 K in vacuum. A gold film, deposited on the boron films by vacuum evaporation, was used as an electrode. Thermoelectric power of the films was measured by using a Pt-PtRh (10%) thermocouple

which was 0.2 mm in diameter. The distance between two thermocouples was 10 mm. The size of the boron films measured were $5 \times 13 \text{ mm}^2$, and the film thicknesses were 1.2 and 1.5 μm . The thermoelectric power could not be measured below 250°C because it was too small in comparison with the electrical noise in this temperature range.

The transmission and the reflection spectra of the boron films on sapphire were measured over a wavelength range of 200-2500 nm using a spectrophotometer MPS-50 (Shimadzu). In the transmission and the reflection measurements, an uncoated sapphire and an evaporated aluminum film were used as the references, respectively. Absorption coefficient, refractive index, and extinction coefficient of the boron films were calculated from the measured transmittance and reflectance at normal incidence.

Infrared transmittance at normal incidence on boron films deposited on high resistivity silicon wafers was measured in a wavelength range of 2.5-50 μm using an infrared spectrophotometer, DS-701G (Jasco).

Results and Discussion

Influence of the deposition parameters on the deposition rate.—The deposition rate of boron, D ($\text{\AA}/\text{s}$), is linearly dependent on the decaborane pressure, P (torr), as shown in Fig. 3, and is given as $D = 3.57 \times 10^{-3} \cdot P$ for substrate temperatures of 750° and 1000°C.

It is thought that the deposition rate of boron films obtained by pyrolysis of decaborane depends on the impingement frequency of decaborane onto the substrate. From gaseous molecular dynamics, the impingement frequency, S , of decaborane on the substrate surface is given as

$$S = P (M/2\pi RT_g)^{1/2} = 5.8 \times 10^{-2} \cdot P (M/T_g)^{1/2} \quad (\text{g}/\text{cm}^2 \cdot \text{s}) \quad [1]$$

where $R = 62.36 \text{ torr} \cdot \text{l}/\text{mol} \cdot \text{deg}$ is the gas constant, P is the decaborane pressure in torr, M is the molecular weight of decaborane, and T_g is the gas temperature considered to be at room temperature (*i.e.*, $T_g = 300 \text{ K}$).

The rate of chemisorption depends on the impingement frequency, S , of the decaborane molecules on the surface, the condensation coefficient, γ , and the fraction of collisions that take place at available sites $f(\theta)$, where θ is the fractional surface coverage. The rate of chemisorption, U is given as

$$U = S\gamma f(\theta) \exp(-E_c/RT_s) \quad [2]$$

Fig. 3. Deposition rates of pyrolytic boron films as a function of $\text{B}_{10}\text{H}_{14}$ pressure. The films were deposited at substrate temperatures of $T_s = 750^\circ\text{C}$ (●) and $T_s = 1000^\circ\text{C}$ (○).

where T_s is the substrate temperature, and E_c is the activation energy for chemisorption.

As shown in Fig. 3, the deposition rate is independent of temperature, and the chemisorption is nonactivated; hence, the activation energy $E_c = 0$. Under the experimental conditions, we suppose that $f(\theta) \approx 1$ and $\gamma \approx 1$, hence, the rate of chemisorption is equal to the impingement frequency, S . The theoretical deposition rate, D_t , in this high temperature range is

$$D_t = 1.66 \times 10^{-2} \cdot P \quad (\text{cm/s}) \quad [3]$$

taking into account the ratio of boron weight to decaborane molecular weight (0.9) and the density of boron (2.0 g/cm^3). Comparison with the experimental values of Fig. 3 shows that D_t must be multiplied by a factor of 0.22. This factor is due to either $f(\theta)$, γ , or the sensitivity difference of decaborane and nitrogen in the ionization gauge.

Figure 4 shows the temperature dependence of the deposition rate of boron films in a temperature range of 350°C to 700°C at two decaborane partial pressures, 2×10^{-5} torr and 8×10^{-5} torr. In each case, the deposition rate increases steeply, with an increase in temperature of up to 416°C , and then saturates.

In the low temperature range, $T_s \leq 416^\circ\text{C}$, the activation energy is found to be 39 kcal/mol from the slope, and the deposition rate is given as

$$D = 7.16 \times 10^9 \cdot P \cdot \exp(-39000/R \cdot T_s) \quad (\text{cm/s}) \quad [4]$$

The saturated deposition rate above 416°C can be explained by Eq. [2]. The activation energy of 39 kcal/mol is in agreement with 41.4 kcal/mol (15) and $41.6 \pm 0.5 \text{ kcal/mol}$ (16), both reported for the activation energy of the decomposition of decaborane at temperatures below 250°C .

Characterization of the films (structure, impurities).—The x-ray diffraction pattern of a boron film deposited on sapphire at a substrate temperature of 700°C and a decaborane pressure of 2×10^{-5} torr for 15 min is shown in Fig. 5. The x-ray and electron diffraction analysis indicates that the films are amorphous.

The ESCA spectrum of the boron film deposited at a decaborane pressure of 4.4×10^{-5} torr and a substrate temperature of 700°C is shown in Fig. 6. Figure 6 shows

Fig. 4. Logarithm of the deposition rate divided by the decaborane pressure as a function of reciprocal absolute temperature of the substrate. The films were deposited at decaborane pressures of $P = 2 \times 10^{-5}$ torr (●) and $P = 8 \times 10^{-5}$ torr (○).

Fig. 5. X-ray diffraction pattern of a pyrolytic boron film

Fig. 6. ESCA spectra of a pyrolytic boron film

the spectrum of the film before and after ion etching. The peaks at the binding energies of 191, 288, and 512 eV correspond to boron 1s, carbon 1s, and oxygen 1s, respectively. The amounts of carbon and oxygen at the surface were estimated from the observed peak intensities multiplied by the photo-ionization cross-section, factor (B: 0.486, C: 1.00, O: 0.293) and are shown in Table I. The table shows that oxygen decreases little by ion etching, even though the apparent carbon content decreases to almost one third its original content. These results indicate that it is difficult to remove oxygen from the film surface by ion etching alone. The boron films were analyzed by EPMA because this method was not influenced by surface impurities. The amounts of impurities in three films deposited on sapphire substrates at decaborane pressures of 1.4×10^{-5} , 3.3×10^{-5} , and 4×10^{-5} torr are shown in Table II. This table shows that carbon decreases with increasing deposition rate. Oxygen impurities in boron films on sapphire substrates cannot be analyzed by EPMA because the primary electrons penetrate the film and extend into the oxygen bearing substrate. On the contrary, no oxygen was found in the films on tantalum substrates by EPMA. The EPMA and the ESCA analyses suggest that oxygen impurity localized near the surface is due to the exposing air, while carbon impurities are incorporated in the films from a residual gas.

Electrical properties.—The conductivities of boron films as a function of reciprocal absolute temperature are shown in Fig. 7. Conductivity varied from $3 \times 10^{-3} \text{ S} \cdot \text{cm}^{-1}$ at room temperature to $30 \text{ S} \cdot \text{cm}^{-1}$ at 1000 K . The conductivity at room temperature is in agreement with that for amorphous boron films deposited by CVD and vacuum evaporation ($1 \times 10^{-3} \text{ S} \cdot \text{cm}^{-1}$) (12), but much larger than that of single crystal ($\approx 10^{-6} \text{ S} \cdot \text{cm}^{-1}$) (17, 18).

The conductivity decreases slightly with increasing deposition temperature and is not affected by the carbon impurities.

Generally, the conductivity of semiconductors in the intrinsic conduction region is written as

$$\sigma = \sigma_0 \exp(-E_g/kT) \quad [5]$$

where σ_0 is a constant, E_g the bandgap energy, k the Boltzmann constant, and T the absolute temperature. E_g can be determined from the slope of the straight line in the plot of $\log \sigma$ against $1/T$. By applying this method to Fig. 7, we obtained $E_g = 1.07$ eV. This value is in agreement with values reported for amorphous boron films (1.0-1.16 eV) (14, 19, 20), but is smaller than those for polycrystalline and single crystal boron (1.3-1.4 eV) (20-22). On the other hand, because the boron films obtained are amorphous,

Fig. 7. Temperature dependence of the conductivity of pyrolytic boron films. The films were deposited at substrate temperatures and $B_{10}H_{14}$ pressures of $T_s = 700^\circ\text{C}$ and $P = 1.4 \times 10^{-5}$ torr (\blacktriangle), $T_s = 700^\circ\text{C}$ and $P = 2 \times 10^{-5}$ torr (\bullet), $T_s = 800^\circ\text{C}$ and $P = 3.3 \times 10^{-5}$ torr (\blacksquare), and $T_s = 750^\circ\text{C}$ and $P = 1.5 \times 10^{-5}$ torr (\circ).

Fig. 8. Dependence of conductivity S on $T^{1/4}$; symbols correspond to those in Fig. 7.

the electric conduction is considered to be due to hopping conduction. Mott (23) has derived the equation for hopping conduction

$$\sigma = \sigma_0 \exp(-(T_0/T)^{1/4}) \quad [6]$$

where σ_0 and T_0 are constants.

The plots of $\log \sigma$ of the boron films as a function of $T^{1/4}$ are shown Fig. 8. The observed values show a good linear relation between $\log \sigma$ and $T^{1/4}$, and values of $\sigma_0 = 3.2 \times 10^{11}$ S·cm and $T_0 = 3.5 \times 10^{-8}$ K are obtained. According to Mott, T_0 is given as a function of the density of localized states at Fermi level, $N(E_F)$

$$T_0 = 16 \epsilon^3/kN(E_F) \quad [7]$$

where ϵ is the exponential decay factor of localized states ($\epsilon^{-1} \approx 5\text{\AA}$) (6), and k is the Boltzmann constant. From the value of T_0 and Eq. [7], $N(E_F) = 3.8 \times 10^{18}$ $\text{cm}^{-3} \cdot \text{eV}^{-1}$ is obtained. This value is in agreement with the value for amorphous boron films, 5×10^{17} - 10^{19} $\text{cm}^{-3} \cdot \text{eV}^{-1}$ (6), and the value for amorphous bulk, $\approx 10^{18}$ $\text{cm}^{-3} \cdot \text{eV}^{-1}$ (24). As mentioned above, the conduction of the boron films can be explained successfully by two conduction mechanisms. We cannot decide which mechanism is valid within our experimental accuracy.

Figure 9 shows the temperature dependence of the thermoelectric power of the films. All the films obtained show p-type conduction. The thermoelectric power increases rapidly from $107 \mu\text{V} \cdot \text{deg}^{-1}$ at 230°C to a maximum value of $400 \mu\text{V} \cdot \text{deg}^{-1}$ at 427°C ; it then decreases gradually to $310 \mu\text{V} \cdot \text{deg}^{-1}$ at 730°C . As the positive carrier concentration increases with increasing temperature, the thermoelectric power also increases with increasing temperature. However, at higher temperature, the thermoelectric power decreases with increasing temperature because the hole mobility decreases. The thermoelectric powers reported for bulk boron (17, 18, 25) show a large peak at a lower temperature, compared with those for the boron films we obtained ($420 \mu\text{V}$ at 700 K). These results can be explained by the assumption that the concentration of the impurities or defects in the boron films should be much higher than that in bulk boron. Middleton and Johnson have explained the same results for germanium by the higher concentration of aluminum (26).

Fig. 9. Temperature dependence of the thermoelectric power

The figure of merit for thermoelectric materials, Z , is given as

$$Z = r^2\sigma/\kappa \text{ (deg}^{-1}\text{)} \quad [8]$$

where r is the thermoelectric power, σ is the electrical conductivity, and κ is the thermal conductivity. The thermal conductivity of boron is assumed to be $0.05 \text{ W}\cdot\text{cm}^{-1}\cdot\text{deg}^{-1}$ (27, 28).

Fig. 10. EMF figure of merit Z of pyrolytic boron films as a function of absolute temperature.

Fig. 11. Absorption coefficient of pyrolytic boron films as a function of incident photon energy.

However, the Z values of the boron films are smaller than those reported for the amorphous bulk material (29). A figure of merit higher than 10^{-3} deg^{-1} is required for the material of a practical thermoelectric converter. Figure 10 suggests that boron films deposited by pyrolysis of decaborane are useful for thermoelectric devices at over 2000 K.

Optical properties.—The absorption coefficient of the boron films, α , is shown in Fig. 11 as a function of incident photon energy, $h\nu$. The absorption coefficient increases rapidly at about 1.3 eV.

It is well known that boron is an indirect energy-gap type material. The absorption coefficient α near the ab-

Fig. 12. The absorption edge fitted to the indirect allowed transition.

sorption edge E_g for the indirect allowed transition can be described as a function of the photon energy $h\nu$

$$\alpha h\nu \propto (h\nu - E_g)^2 \quad [9]$$

The variation of the square root of adsorption coefficient multiplied by photon energy $(\alpha h\nu)^{1/2}$ for the boron films with the incident photon energy is shown in Fig. 12. The figure shows that the boron film is an indirect energy-gap type material. The energy gap E_g is estimated to be 1.28 ± 0.08 eV by extrapolation of the linear part to the horizontal axis in Fig. 12. This value is larger than the value obtained by the electrical measurement (1.07 eV) and the values reported for amorphous films by Adirovich (19) and Morita (14).

The refractive index n and the extinction coefficient k of the boron films are shown as a function of wavelength in Fig. 13 and 14, respectively. These results agree well with the values obtained by Murphy (9) and Morita (14) for amorphous films deposited by vacuum evaporation. The hillock of the refractive index at the wavelength around $1 \mu\text{m}$ corresponds to the absorption edge. An increase in the extinction coefficient is also shown at wavelengths below $1 \mu\text{m}$.

Figure 15 shows the infrared transmission spectrum of the boron film deposited on a silicon substrate. As shown in Fig. 15, the absorption of the boron film in the IR spectral region increases at about $8 \mu\text{m}$ and reaches a maximum at $12.5 \mu\text{m}$. Blum (30) has studied the effect of impurities such as carbon and hydrogen on the infrared absorption of amorphous boron films and has shown that the narrow band at 2560 cm^{-1} observed in hydrogen-doped samples is due to B-H bond vibration. Also, the broad strong band from 1000 to 1200 cm^{-1} , which is correlated strongly with the amount of carbon in the films, is due to an overlapping and broadening of various B-C bond vibrations. Therefore, the absorption band from 8 to $12.5 \mu\text{m}$ observed in our films is not considered to be due to hydrogen and carbon impurities. Although many absorption bands caused by the complex crystal structure of boron have been reported, they are all in the wave-

Fig. 13. Refractive index of pyrolytic boron films as a function of wavelength.

Fig. 14. Extinction coefficient of pyrolytic boron films as a function of wavelength.

Fig. 15. Infrared transmission spectrum of a pyrolytic boron film deposited on a silicon substrate.

length region shorter than $8 \mu\text{m}$ (31). Werheit *et al.* (32, 33) have studied the optical properties of β -rhombohedral boron single-crystals in detail and have shown that absorption has a peak at $8 \mu\text{m}$. According to Decker (34), the absorption spectra of α -rhombohedral boron have absorption peaks at 18.2 , 10.9 , 9.3 , and $8.2 \mu\text{m}$. These absorption bands are not in agreement with those observed for boron films deposited by pyrolysis of the decaborane. On the basis of studies made by Golikova (21), it can be considered that the absorption at $12.5 \mu\text{m}$ is associated with the short-range lattice structure in the boron films.

Conclusion

Amorphous boron films have been deposited by pyrolysis of decaborane in the molecular flow region. On the assumption that the deposition rate of boron films is determined by the impingement frequency of the decaborane molecules onto the substrate surface, we have derived the equation for the deposition rate D at temperatures lower than 416°C . The equation, $D = 7.16 \times 10^9 \cdot P \cdot \exp(-39000/RT_s)$ (cm/s), explains the experimental results successfully.

Electrical conductivity of these boron films is $\approx 10^3$ larger than that for single-crystal boron and is in agreement with that for amorphous films deposited by CVD and vacuum evaporation. The influence of impurities on the conductivity is not clear. The activation energy for conduction of the boron films is estimated to be 1.07 eV in the intrinsic temperature range. The temperature dependence of the electrical conductivity can also be explained by a hopping conduction mechanism of amorphous materials. The plots of $\log \sigma$ against $T^{1/4}$ show a good linear relation, and the density of localized states at the Fermi level, $N(E_F)$, is estimated to be $3.8 \times 10^{18} \text{ cm}^{-3} \cdot \text{eV}^{-1}$. However, we cannot decide which mechanism is valid within our experimental accuracy.

The thermoelectric power of the boron films obtained shows a small peak at a higher temperature, compared with those for bulk boron. This may be attributed to the fact that the concentration of the acceptors in amorphous boron films is higher than that in boron crystals.

From the measurements of optical absorption, it is found that boron films are an indirect bandgap type material and have an energy gap of 1.28 ± 0.08 eV. The refractive indexes and the extinction coefficients of the boron films in the wavelength range of 0.27 - $2.5 \mu\text{m}$ were obtained. In the infrared spectral region, an absorption peak was observed at $12.5 \mu\text{m}$, which is considered to be associated with short-range order in the boron lattice.

Acknowledgments

The author would like to thank Professor K. Yoshimura and A. Itoh for suggesting this study and for their continuous encouragement. He wishes to express his thanks to S. Nakagawa, S. Misawa, and Dr. S. Gonda for helpful contributions and support of this work. Numerous valua-

ble and stimulating discussions with Professor A. Amano, Dr. S. Yoshida, and Dr. F. Shinoki are also acknowledged with many thanks.

Electrical Properties of Organometallic Chemical Vapor Deposited GaAs Epitaxial Layers

Temperature Dependence

Douglas H. Reep*¹ and Sorab K. Ghandhi*

Department of Electrical, Computer, and Systems Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

Electrical characteristics are presented for unintentionally doped GaAs epitaxial films, grown by the pyrolysis of trimethylgallium (TMG) and arsine at atmospheric pressure. The depositions were carried out on (100) substrates, from 450° to 1050°C, for a wide variety of growth conditions. Growth rates and morphology have been presented elsewhere. Films grown at 1050°C were found to be p-type, with the hole concentration falling at lower growth temperatures. Conversion to n-type occurred for growth below 975°C, independent of the arsine overpressure. At still lower temperatures, the film became increasingly n-type, with a peak in free electron concentration occurring at 850°C. Further reduction in growth temperature resulted in lower electron concentrations until eventually the films became p-type at around 550°C, depending on the arsine overpressure. The electrical behavior of these films correlates well with predictions from the growth model and thus provides additional insight into the organometallic growth process.

Much attention has been paid recently to the growth of thin epitaxial layers of GaAs by the organometallic CVD technique. Promising results have been obtained with the use of these layers for optoelectronic (1, 2), microwave (3, 4), and high speed digital applications (4). In addition, organometallic CVD grown layers which approach the purity and electron mobility of the best layers produced by the chloride-based techniques have been reported (4). The organometallic technique has also generated much interest due to its flexibility and its apparent simplicity.

Little has been published in regard to the mechanisms of growth by this process, as compared to the halide and hydride growth systems. In fact, the growth of GaAs films by this technique is generally described as a simple pyrolysis of trimethylgallium (TMG) and arsine. However, many complex processes and intermediate reactions are involved, and the subject is far from understood at the present time.

Recently, based on experiments employing different substrate orientations [(100), (110), (111)Ga, and (111)As] performed over a wide range of temperatures (450°-1050°C), we have proposed (5, 6) a growth model for this process. A brief review of this model is as follows: the dis-

*Electrochemical Society Active Member.

sociation activation energy for the first, second, and third (Ga-CH₃) bonds is 59.5, 35.4, and 77.5 kcal/mol, respectively (7). This fact, together with an analysis of the rate constant data for this dissociation, leads to the conclusion that the rate limiter for the thermal decomposition of TMG is in all probability the breaking of the last (Ga-CH₃) bond. Studies of the decomposition of AsH₃, in like manner, lead to the conclusion that the primary surface-adsorbed arsenic species is (As-H). The growth model which we have described is the result of a Langmuir-Hinshelwood-type reaction involving these species. Although the actual reactions which take place are very complex, and are still the subject of much controversy, this relatively simple model fits the observed growth characteristics for a wide range of crystal orientations, reactant partial pressures, and growth temperatures. Thus, it serves as a useful starting point for developing further insight into the growth process. In this paper, we describe the electrical characteristics of these layers. It is shown that they, too, can be explained in terms of this growth model. Thus, they provide support for it and help in its further development.

Experimental Procedure

Epitaxial layers of GaAs were deposited by the pyrolysis of arsine and trimethylgallium (TMG), using hydrogen as the carrier gas. Anhydrous hydrogen chloride was available for *in situ* etching of the substrates prior to layer growth. Layer deposition was performed at temperatures from 450°-1050°C, for input TMG partial pressures ranging from 4.6 to 37 × 10⁻⁵ atm. The arsine flow was varied over a wide range, corresponding to AsH₃/TMG ratios of 4.7-75 at the reactor inlet. The hydrogen carrier gas flow through the reaction chamber was fixed at 5 l/min for all of the data reported here.

Single-crystal, semi-insulating GaAs substrates^{2,3} used in this study were (100) oriented or 3° off (100) towards the [110] direction, and were received lapped and chem-mechanically polished on one side. Prior to loading into the epitaxial reactor, the wafers were degreased sequentially in trichloroethylene, acetone, and methanol. A chemical polishing etch of 1 min duration in hot (60°C) Caro's etch (H₂SO₄:H₂O₂:H₂O = 3:1:1 by volume) produced mirror-like surfaces, and removed 15-25 μm of material from the substrate surface. The substrates were quenched in DI water immediately following removal from the Caro's etch, rinsed with methanol, and blown dry in filtered nitrogen.

The epitaxial reactor consisted of an atmospheric pressure, horizontal, RF-heated, cold wall system of the type described previously (8). Gases were delivered to the 50 mm id quartz reaction chamber through 316 stainless steel or Monel tubing. The substrate temperature was monitored with a Pt/Pt-13% Rh thermocouple, sheathed in quartz, and inserted into a well in the back of the graphite susceptor.

A 10% mixture of arsine⁴ in hydrogen was used in this work. TMG⁵ vapor was provided by bubbling hydrogen through this liquid, which was held at 0°C in a stainless steel bubbler. A 1% mixture of electronic-grade hydrogen chloride in hydrogen⁴ was available for *in situ* etching of the substrates. Ultrapure hydrogen carrier gas was obtained by passing commercial-grade hydrogen⁴ through a Pd-Ag alloy purifier. In all cases, the reactant gases were thoroughly mixed prior to entry into the reaction chamber.

The substrate wafers were loaded into the reactor after chemical etching and microscopic inspection of the surface. The reaction chamber was evacuated and purged with argon,⁴ followed by hydrogen gas. Next, the required flows of hydrogen and arsine were set. For experiments involving an *in situ* etch prior to growth, the susceptor

was heated and stabilized at the etch temperature (typically 945°C). After a period of 5 min, which was sufficient to remove any surface oxide left by the chemical cleaning procedure (9), the wafers were given an *in situ* etch of the type described previously (10). The temperature of the susceptor was then reset and allowed to stabilize at the growth temperature for 2 min prior to commencement of growth by the introduction of the TMG vapor.

For experiments where no *in situ* etch was performed, the susceptor was heated to the growth temperature⁶ and stabilized there for a period of 5 min, before the TMG flow was established. At the end of the growth interval, the TMG flow was terminated, and the system held at the growth temperature for an additional 3 min. The susceptor and substrates were then cooled to 200°C in the AsH₃/H₂ ambient, followed by an argon purge of sufficient duration for the susceptor to reach room temperature.

The growth rate of the epitaxial layer was determined either by weight change, in the case of no pregrowth *in situ* etch, or by cleaving and staining, followed by inspection with an optical microscope fitted for Nomarski differential interference contrast. Surface morphology was studied using scanning electron microscopy.

The free carrier concentration and mobility of the GaAs films were measured using the Hall effect. In particular, the van der Pauw technique was employed. All of the results presented are calculated directly from the Hall coefficient, following the common practice of assigning a unity value to the scattering factor (*i.e.*, $r_H = 1$). Ionized acceptor and donor concentrations were determined from the free carrier and mobility measurements (11) at liquid nitrogen temperature (77 K) for the n-type layers.

Results and Discussion

Only the (100) orientation was considered, because of the extreme difficulty of growing device-quality layers of other orientations by OMCVD. Moreover, a study of this orientation is of greatest interest, since it is commonly used in device fabrication. All of the (100) layers (oriented as well as misoriented) exhibited smooth, specular surfaces over the full range of deposition temperatures. Moreover, the morphology was found to be essentially in-

⁶A minimum of 700°C was used for the pregrowth heat-treatment, as this is sufficient to remove any traces of surface oxide (9). Thus, for the depositions performed below 700°C, the susceptor temperature was dropped (from 700°C) and allowed 2 min to stabilize at the growth temperature.

dependent of the reactant flows over this temperature range, as was observed (6) for film growth at 700°C.

The majority of the epitaxial layers were grown for this investigation on substrates which were given no *in situ* etch, so that reliable growth rate data could be obtained. All of the data reported here were taken on layers which were 5-6 μm thick, so that the electrical measurements were not affected by the inclusion, or absence, of this etch step.

The electrical data reported here were made on samples grown using one lot of TMG and one cylinder of AsH_3 , so that meaningful comparisons could be made. In addition, the nature of the contaminants in the starting materials was first determined so that the results could be meaningfully interpreted.

Figure 1 shows the electrical properties of undoped samples grown at 700°C as a function of the arsine overpressure. Here, it is seen that N_D (the ionized donor concentration) increases with arsine pressure, where N_A (the ionized acceptor concentration) falls. These results are what would be expected if the primary contaminant in the starting chemicals came from column IV of the periodic table. Moreover, $(N_A + N_D)$ is independent of arsine pressure for these samples, indicating that the contaminant comes mainly from the TMG source, whose partial pressure was held constant for this series of experiments. Thus, to a first order, the inherent contaminant in the combination of starting chemicals used here can be attributed to column IV impurities⁷ related to the TMG, with relatively little contamination coming from the arsine. It is probable that silicon is this contaminant in our case, as this was detected by metallic impurity analysis.⁸ It has been shown that this dopant, although amphoteric, always results in n-type material in the OMCVD of GaAs (12).

We have proposed a growth model (5) based on the results of measurements made over a wide range of temperature, reactant partial pressures, and crystal orientations. Growth data, taken for the purpose of model development, is presented in Fig. 2 for the (100) orientation, and for AsH_3/TMG inlet pressure ratios from 9.3 to 36.9. A study of this figure, in the light of the growth model we have proposed, shows the following features: (i) at high temperatures (above the point A at 850°C), growth is limited by the desorption of (Ga-CH_3) from the surface since the presence of the methyl radical significantly reduces the effective Ga-As bond strength. The temperature at which the growth rate fall-off occurs is independent of the AsH_3/TMG ratio. (ii) At low temperatures, (below the point B at 600°C), the growth is limited by the decomposition of arsine, and by the increased desorption of (Ga-CH_3) resulting from this effect. (iii) Growth in the mid region, between A and B, is relatively independent of the temperature or the AsH_3/TMG ratio. Although this region is important from a device viewpoint, it sheds little light on the growth mechanism since diffusion through the boundary layer is the limiting factor, as opposed to surface dependent effects.

Figure 3 shows the electrical characteristics of layers grown on (100) GaAs for AsH_3/TMG ratios of 37, 19, and 9.3, respectively. (Here, the points A and B are the same as those indicated in Fig. 2.) As mentioned earlier, these divide the growth into three regions, which are now considered.

The high temperature region.—Here, falloff in carrier concentration (and peak value as well) occurs at the same temperature for all reactant partial pressure ratios. Even-

⁷As a point of interest, the usual situation at the present state of the art is that the TMG is considered to be relatively pure, and the contaminant is thought to come primarily from the arsine source. However, this was not the case with the sources used here. In fact, this controversy has received additional fuel recently with the identification of Ge as the dominant residual acceptor impurity in OMCVD GaAs, which as indeed traced to the TMG in at least one case (13).

⁸Contaminant data for TMG was 1 ppm Si, 2 ppm Al, and 1 ppm Fe with Mg and Zn not detectable. Data on the AsH_3 was not available.

Fig. 2. Growth rate vs. reciprocal temperature for (100) GaAs epitaxial layers, as a function of P_{AsH_3} and for $P_{\text{TMG}} = 1.8 \times 10^{-4}$ atm.

tually, the layer becomes p-type, at a conversion temperature which is also independent of the AsH_3/TMG ratio. This behavior can be explained as follows: both the gallium and arsenic vacancy concentrations increase with increasing temperature, from thermodynamic considerations (14, 15). Additionally, however, the V_{Ga} increases because of increasing desorption of (Ga-CH_3) as postulated in our previous growth model; this in turn leads to increased acceptor formation, by the well-established complexing reaction of gallium vacancies and donors

which has been confirmed by various workers (15, 16). Results of their annealing experiments on n-doped GaAs are reproduced in Fig. 4, and indicate that acceptor formation by this reaction is significant and can result in converting the layers to p-type. Moreover, the acceptor concentration is not a function of the arsenic overpressure for the range of growth conditions ($p_{\text{AsH}_3} \approx 1-5$ torr) reported in this paper. Hence, we can expect the falloff in electron concentration, as well as the conversion temperature (n \rightarrow p) to be independent of p_{AsH_3} . Note that the data of Fig. 4 are for thermal annealing of bulk samples for long times (8-16h). We believe the analysis is applicable to this situation as well, since the layer growth is carried out in a strong excess arsine overpressure environment.

Our model leads us to conclude that this falloff in growth rate is primarily due to increased desorption of (Ga-CH_3) . As a result, carbon contamination is most probably not the dominant factor at elevated temperatures. This has been verified by secondary ion mass spectroscopy (SIMS) data taken on a layer grown at 1000°C, and shown in Fig. 5. Here, the carbon level in the sample is the same as that of the substrate (except for a small perturbation at the epi-substrate interface).⁹ Thus, the amount of carbon incorporated during growth at these el-

⁹Layers grown with an *in situ* HCl etch did not show this peak. All the SIMS results in this paper are for layer growth without this etch step.

Fig. 3. 77 K carrier concentration vs. reciprocal temperature for (100) GaAs layers grown at $P_{\text{TMG}} = 1.8 \times 10^{-4}$ atm. a(top left): $P_{\text{AsH}_3} = 6.7 \times 10^{-3}$ atm. b(top right): $P_{\text{AsH}_3} = 3.3 \times 10^{-3}$ atm. c(left): $P_{\text{AsH}_3} = 1.7 \times 10^{-3}$ atm.

evated temperatures is below the detectability limit of the SIMS.

Low temperature region.—Here we note that the electron concentration falls for temperatures below A (Fig. 3a), with the layers eventually becoming p-type in the vicinity of, or slightly above, point B. This behavior differs from that in the high temperature region in many important respects. First, the $n \rightarrow p$ conversion point is a strong function of the arsine overpressure, and occurs at higher temperatures as p_{AsH_3} is decreased (Fig. 3b, 3c). Next, films grown at low temperatures are not entirely single

crystal in nature, with strong evidence of twinning noted by x-ray diffraction analyses (but were still shiny). Finally, there is direct evidence of a large amount of carbon incorporation in these films, as seen from the SIMS data of Fig. 6.

We believe that these observations can be explained as follows: the decomposition rate of arsine, and hence the arsenic overpressure, falls with falling temperature. This results in an increased residence time of (Ga-CH_3) on the surface of the slice, and an increased possibility of the strongly bonded carbon incorporating in the film. More-

Fig. 4. Acceptor density in heat-treated n-type GaAs, as a function of arsenic overpressure, annealing temperature, and initial free electron concentration. After Ref. (15).

Fig. 5. SIMS trace of relative ion intensity for gallium and carbon vs. depth into sample, for a 2.7 μm thick (100) GaAs epitaxial layer grown at 1000°C.

over, the reduction in effective arsenic overpressure at these temperatures increases the possibility of incorporating this carbon into arsenic sites, (increased V_{As} in this case) where it behaves as an acceptor and, in sufficient concentration, causes the layers to grow p-type. Finally, following the reactant attachment scheme previously proposed (6), we expect the methyl radical to occupy an arsenic site until the (Ga-CH₃) bond is broken, again supporting the high probability of carbon acceptor incorporation for low temperature growth.

Mid temperature region.—Here, both N_A and N_D fall with temperature. However, growth occurs in an excess arsenic overpressure, so that there is a net reduction in ($N_D - N_A$) with falling temperature. We believe that this explains the change in carrier concentration that we note over this temperature region, consistent with other reports in the literature (4, 17). Note, however, that an analysis of electrical behavior in this region sheds little light on the growth model, since the actual growth process is limited by diffusion through the boundary layer at these tem-

Fig. 6. SIMS trace of relative intensity for gallium and carbon vs. depth into sample for a 1.2 μm thick (100) GaAs epitaxial layer grown at 500°C.

peratures, and is independent of surface-related phenomena.

Summary

Gallium arsenide layers have been grown over a wide range of input reactant partial pressures, and for a broad range of deposition temperatures. Electrical properties of these layers have been measured, and are described in this paper. Reasons for their behavior with temperature and reactant partial pressure have been advanced; it has been shown that the observed behavior can be explained in terms of a growth model proposed earlier.

Conversion from n to p at high temperatures (> 975°C) is shown to result from an increased desorption of (Ga-CH₃) at these temperatures, and from acceptor formation by the gallium vacancy-donor reaction. Moreover, carbon incorporation is relatively unimportant at these temperatures, as compared to the complexing reaction.

It has also been shown that the electrical characteristics of films grown in the low temperature region shift from n → p type with falling temperature. This behavior can be explained by noting that arsine decomposition falls off at low temperatures, resulting in an increased possibility of carbon incorporation in the films. Evidence for this increased carbon incorporation is presented as well.

The electrical measurements thus support the growth model proposed earlier, and help to provide further insight into the growth process.

Low Pressure Chemical Vapor Deposition of Tungsten on Polycrystalline and Single-Crystal Silicon via the Silicon Reduction

K. Y. Tsao^{1,*} and H. H. Busta^{**}

Gould Research Center, Rolling Meadows, Illinois 60008

ABSTRACT

High purity metallic tungsten films are deposited on phosphorus-doped and undoped polycrystalline and single-crystal silicon by the silicon reduction of WF_6 . Depositions are performed in a commercial LPCVD hot wall reactor at temperatures ranging from 310°-540°C. Film formation is self-limiting, meaning that after a given film thickness any further reaction between WF_6 and the underlying silicon is inhibited. Obtainable film thickness depends strongly on the doping condition of silicon and on surface preparation prior to LPCVD. Conventional wet chemical cleaning limits the maximum obtainable film thickness to approximately 400Å, whereas with a low power argon plasma treatment approximately 900Å thick films can be obtained reproducibly. The resistivity of these films is $18.3 \pm 4.5 \mu\Omega\text{cm}$. This corresponds to a minimum sheet resistance of the thickest films of approximately $2 \Omega/\square$. The depositions are completely selective; no detectable amount of tungsten can be observed on thermal field oxide.

Low pressure chemical vapor deposition (LPCVD) of tungsten is currently under intense investigation for its potential application in VLSI circuits. These include shunting of polycrystalline silicon gate and interconnect lines with a lower resistivity tungsten film to reduce the interconnect RC time constant (1, 2), formation of a barrier between silicon and aluminum to reduce aluminum spike-induced failures (2, 4), planarization of the multilevel interconnect process (3, 4), low resistance contact formation to drain and source regions (1, 4), and formation of a Schottky barrier p-channel MOS transistor to form latch up-free CMOS (4).

An attractive feature of LPCVD tungsten is its selectivity. For appropriate deposition conditions, tungsten forms only on silicon and not on surrounding thermally grown SiO_2 . Thus, for polycrystalline gate shunting this eliminates one etching step in the processing sequence, as compared to shunting with a sputter-deposited silicide. However, some nucleation of tungsten can occur on thermally grown SiO_2 when films in excess of 2000Å are deposited (5) or when the SiO_2 is formed by sputter deposition, plasma-assisted CVD, or on borophosphosilicate glass (BPSG) (3).

Tungsten can be deposited via the hydrogen reduction of WF_6 (1-3, 6, 7, 9)

or the silicon reduction of WF_6 (3, 7-9)

With the hydrogen reduction, films of any thickness can be deposited, whereas with the silicon reduction the reaction ceases after formation of a given film thickness, because WF_6 cannot further react with the underlying silicon (9). Even in the hydrogen reduction, initial film growth proceeds via silicon reduction (3).

Since, according to reaction [2], 3 mol of silicon are needed to create 2 mol of tungsten, a certain thickness loss of silicon is experienced. It is given by

$$\frac{t_w}{t_{Si}} = \frac{2M_w \rho_{Si}}{3M_{Si} \rho_w} = 0.525 \quad [3]$$

and has to be taken into account during the device design stages. Here, t_w is the tungsten film thickness to be formed, t_{Si} the silicon thickness to be consumed, M_w , M_{Si} the molecular weights, and $\rho_w = 19.35 \text{ g/cm}^3$ and $\rho_{Si} = 2.33 \text{ g/cm}^3$ the densities of tungsten and silicon, respectively. Experimental verification of this fact is reported in Ref. (9).

In this paper, the LPCVD of tungsten using the silicon reduction method will be presented. The substrates are phosphorus-doped and undoped polycrystalline silicon and phosphorus-doped and undoped p-type single-crystal silicon.

The success of the LPCVD method in terms of obtaining reproducible films depends strongly on the surface preparation prior to film deposition (3) and hence on the native oxide characteristics (9). With the silicon reduction method, approximately 400Å thick films can be achieved at 350°C (3). By using standard wet chemical cleaning procedures we confirmed this result. With the addition of a low power argon plasma treatment, 900Å thick films can be deposited reproducibly with a sheet resistance of approximately $2 \Omega/\square$. Film properties as a

function of the argon plasma treatment and deposition parameters such as WF_6 flow rate, deposition time, and deposition temperature will be presented in the following sections.

Experimental

The apparatus used for the depositions is a commercially available 4 in. hot-wall LPCVD quartz reactor whose plumbing system has been modified to allow Ar, WF_6 , H_2 , HCl, and SiH_4 to enter the system through mass flowmeters (MFM). This is indicated in Fig. 1. Not shown in Fig. 1 is a heating tape wrapped around the WF_6 cylinder, the gas lines, and the mass flowmeter. This is necessary to prevent the WF_6 from liquifying. The temperature of the WF_6 is controlled to provide a pressure of approximately 7-10 psi.

Argon is used as a carrier gas with a flow rate of 335 cm^3/min and a pressure of 0.3 torr. For most experiments, the WF_6 flow rate is 12.4 cm^3/min . In some cases, where the sheet resistance as a function of flow rate is determined, it is varied from 1.55 to 24.8 cm^3/min . Deposition temperatures range from 310° to 540°C.

Sample preparation consists of growing approximately 1000Å of thermal SiO_2 on 3 in. diam silicon wafers. Approximately 4500Å thick polycrystalline silicon is then deposited via LPCVD at 610°C. For the phosphorus-doped samples, doping is performed at 950°C in PH_3 for 50 min, resulting in a sheet resistance of approximately 24 Ω/\square .

The single-crystal (100) p-type wafers used in this work have a boron concentration of approximately $2 \times 10^{15} cm^{-3}$. Doping is performed at 950°C in PH_3 for 50 min. This is followed by an *in situ* nitrogen anneal for 10 min, which results in a sheet resistance of approximately 15 Ω/\square .

For selectivity studies, standard photolithographic methods are used to delineate the polycrystalline silicon lines into the appropriate patterns. After photoresist (AZ1450J) stripping, the samples are cleaned at 95°C for 10 min in a mixture of three parts H_2SO_4 and one part H_2O_2 . This is followed by a 6s 10:1 HF etch, followed by a DI rinse and nitrogen spin dry.

Loading of the samples takes place within several minutes after the argon plasma treatment. The LPCVD reactor is at deposition temperature and is purged with argon at approximately 3 liter/min. After loading and sealing, the system is pumped to approximately 0.03 torr and then refilled with argon to approximately 1 torr. This is followed by one more pumping and refilling cycle. The argon flow and chamber pressure are then adjusted to the appropriate values. WF_6 is then metered into the system. After deposition, the WF_6 flow is turned off and the system is allowed to cool to approximately 250°C, at which point the wafers are removed from the system.

A conventional stylus thickness monitor and the Auger elemental depth profiling technique are used for film thickness evaluations and a four-point probe for sheet resistance measurements. For the stylus measurements, a tungsten step is etched using positive photoresist or protective wax and an alkaline ferricyanide solution at room temperature to etch the tungsten. The solution consists of 5g $K_3Fe(CN)_6$, 5g KOH, and 100 ml DI water. All the

samples are being etched for 1 min. After tungsten etching, the photoresist or wax are being stripped.

Results and Discussion

Polycrystalline silicon substrates.—Surface plasma treatment.—Initial experiments have been performed using the H_2SO_4/H_2O_2 and HF clean prior to the tungsten deposition. Depending on the surface conditions, *i.e.*, ion implanted *vs.* nonimplanted, different sheet resistances for identical deposition parameters have been obtained. From this, it has been conjectured that formation of a uniform distribution of nucleation sites will aid in the initiation of the surface reaction. Several wet and dry surface treatments have been investigated, and good results have been obtained with a short, low power argon plasma treatment in a barrel plasma etching system from which the shielding tunnel is removed. Some of the results are shown in Fig. 2. It shows five samples deposited at 410°C for 5 min at a WF_6 flow rate of 12.4 cm^3/min . Sample A is a phosphorus-implanted (50 keV, $5 \times 10^{15} cm^{-2}$) polycrystalline silicon substrate, sample B is the same as A except it is annealed in N_2 at 1000°C for 30 min after the implantation, sample C is phosphorus-doped polycrystalline silicon, sample D is undoped polycrystalline silicon, and sample E phosphorus-doped p-type single-crystal silicon. Sheet resistances range from approximately 5 to 24 Ω/\square , indicating a strong sensitivity of film formation to surface conditions. Sample F is from the same wafer as sample C but is subjected to a plasma treatment at 2W for 5 min. The sheet resistance differences of the samples are caused by different film thicknesses. This has been experimentally confirmed by stylus measurements. The corresponding film thickness scale is indicated on the right side of Fig. 2.

The power dependence of the plasma treatment on film thickness formation (sheet resistance) is shown in Fig. 3. From 2 to 50W, no change in sheet resistance can be observed, indicating that even at the lowest power enough nucleation sites are being created on the polycrystalline surface for optimum film formation. Little dependence of sheet resistance on plasma treatment time in the range of 1-10 min is observed. Figure 4 shows the effect of a 2W, 5 min argon plasma treatment on the sheet resistance as a function of WF_6 flow rate for phosphorus-doped polycrystalline silicon. The top curve shows the results without the plasma treatment.

Below a flow rate of 6.2 cm^3/min , not enough WF_6 is supplied to fully react with the available silicon, thus

Fig. 2. Sheet resistance of tungsten films deposited on different samples with the silicon reduction method. Samples A to E are deposited without the plasma treatment. Sample F is part of the same substrate as sample C, but is being subjected to the plasma treatment.

Fig. 3. Sheet resistance vs. argon plasma power for a phosphorus doped polycrystalline silicon sample. The tungsten deposition parameters are: 410°C, 5 min, WF_6 flow rate of 12.4 cm^3/min . The plasma treatment time per data point is 5 min.

causing thinner films. Above 6.2 cm^3/min , the difference in the sheet resistance between the treated and untreated samples is approximately a factor of three. This corresponds to a film thickness of approximately 900 Å for the treated and 300 Å for the untreated samples. Figure 5 shows the effect of a 2W, 5 min plasma treatment on sheet resistance as a function of the tungsten deposition time for phosphorus-doped polycrystalline silicon. The deposition is performed at a WF_6 flow rate of 12.4 cm^3/min . Otherwise, the same deposition parameters prevail as in Fig. 4. Very little dependence on deposition time is observed, indicating a self-limiting reaction. This is in agreement with the results presented in Ref. (9). Similar to Fig. 4, the difference in sheet resistances between the treated and untreated films is approximately a factor of 3, corresponding to thinner films (~300 Å) for the untreated samples. In addition to the possible creation of nucleation sites, the argon plasma treatment also changes the thickness of the discontinuous native oxide. Wafers removed

The tungsten deposition parameters are: 410°C, 5 min, Ar pressure of 0.3 torr. Above a flow rate of 6.2 cm^3/min , the thickness of the treated films are approximately 1000 Å, those of the untreated films 330 Å.

Fig. 5. Effect of the argon plasma treatment on sheet resistance as a function of tungsten deposition time for phosphorus-doped polycrystalline silicon. The tungsten deposition parameters are: 410°C, argon pressure of 0.3 torr, WF_6 flow rate of 12.4 cm^3/min .

from the storage container possess a native oxide of approximately $22 \pm 2 \text{ \AA}$ as measured with a Gaertner Scientific Instruments automatic ellipsometer. After cleaning and HF dip, this thickness is reduced to approximately $6 \pm 4 \text{ \AA}$. After the plasma treatment, the native oxide is approximately $14 \pm 4 \text{ \AA}$. At least qualitatively, this observation agrees with the discussion given in Ref. (9), where the argument is made that the thinner the native oxide the thinner a continuous tungsten film is formed, owing to a more homogeneous rate of reaction between WF_6 and silicon across the wafer surface. Similar results have been obtained with polycrystalline samples. Since the ellipsometer does not yield accurate results, the Auger technique has been used to estimate the thickness of the native oxide. HF-treated phosphorus-doped samples possess a discontinuous oxide of approximately 4-8 Å, which increases after the plasma treatment to approximately 8-16 Å. Results reported in the following sections are from substrates which have been subjected to a 2W, 5 min argon plasma treatment prior to tungsten deposition.

Deposition parameters.—Figure 6 shows resistance of tungsten/phosphorus doped polycrystalline silicon composite films at three different deposition temperatures as a function of deposition time. The data for the 367° and 419°C deposition temperatures show the self-limiting behavior, similar to the result shown in Fig. 5. At a deposition temperature of 469°C, the sheet resistance increases with deposition time. Stylus and Auger thickness measurements performed for the 5 and 30 min deposition time samples clearly indicate a decrease in the film thickness from approximately 330 to 235 Å during this time period. This result suggests a slow etching of the films (~4 Å/min) by WF_6 . Figure 7 shows the sheet resistance of tungsten/polycrystalline silicon composite films as a function of temperature for phosphorus-doped and undoped polycrystalline silicon. Deposition time in all cases is 20 min. In the undoped case, a shallow minimum is observed at approximately 420°C. Below this minimum, very little dependence on sheet resistance (film thickness) with deposition temperature is observed. Above the minimum, the sheet resistance increases from 2 to 4 Ω/\square . A strongly enhanced effect in terms of sheet resistance increase below and above a minimum is observed for the

Fig. 6. Sheet resistance of tungsten/phosphorus-doped polycrystalline silicon composite films as a function of deposition time.

phosphorus-doped case, indicating a strong participation of phosphorus in the kinetics of film formation.

From stylus and Auger thickness measurements taken of several samples below, above, and at the minima of the two curves shown in Fig. 7, a film resistivity of $18.3 \pm 4.5 \mu\Omega\text{cm}$ was deduced. This is in good agreement with the data given in Ref. (4) for film thicknesses ranging from 200 to 900Å.

To investigate film surface morphology at different deposition temperatures, SEM micrographs have been prepared for samples deposited on phosphorus-doped polycrystalline silicon at 367°, 419°, and 469°C, and for a sample deposited on undoped polycrystalline silicon at 419°C. These samples are marked as A, B, C, and D in Fig. 7. Figure 8 shows the 367°C deposited film (A), which is approximately 460Å thick. Figure 9 shows the 419°C deposited film (B, 740Å), and Fig. 10 the 469°C deposited film (C, 250Å). As can be seen, the roughness of the tungsten film and of the polycrystalline interface increases with increasing film thickness. Figure 11 shows the 419°C

Fig. 7. Sheet resistance of tungsten/phosphorus-doped and undoped polycrystalline silicon composite films as a function of temperature. Film deposition time is 20 min. The thickness of the polycrystalline silicon is approximately 4500Å.

Fig. 8. SEM micrograph of a 460Å thick tungsten film deposited on phosphorus-doped polycrystalline silicon at 367°C. The film has been etched with the alkaline ferricyanide solution described in the "Experimental" section. This is sample A in Fig. 7.

Fig. 9. SEM micrograph of a 740Å thick tungsten film deposited on phosphorus-doped polycrystalline silicon at 419°C. This is sample B in Fig. 7.

deposited film (D) on undoped polycrystalline silicon. The film thickness is 915Å. The roughness is similar to its doped counterpart (B). Auger elemental depth profiles (AEDP) of samples A, B, and C are shown in Fig. 12-14. Figure 12 shows the 367°C deposition temperature sample. Film thickness is defined at the 50% tungsten signal. The relatively broad interface between tungsten and polycrystalline silicon is an indication of film roughness, which, by taking the 10% and 90% points of the tungsten signal, is approximately equal to the film thickness. From Fig. 12, the consumption of polycrystalline silicon can also be deduced. According to Eq. [3], for a 460Å

Fig. 10. SEM micrograph of a 250Å thick tungsten film deposited on phosphorus-doped polycrystalline silicon at 469°C. This is sample C in Fig. 7.

Fig. 11. SEM micrograph of a 915Å thick tungsten film deposited on undoped polycrystalline silicon at 419°C. This is sample D in Fig. 7.

Fig. 12. Auger elemental depth profile of a tungsten/phosphorus-doped polycrystalline silicon/SiO₂ sandwich. The tungsten deposition is performed at 367°C. The deposition time is 20 min. This is sample A in Fig. 7.

thick tungsten film to be formed, approximately 900Å of silicon will be consumed. This then results in a thickness of the polycrystalline layer of $900 + 3250 = 4150\text{Å}$, in fair agreement with 4500Å, the initial polycrystalline layer thickness. Some uncertainty exists in defining the interface due to the film roughness. Figure 13 shows the 419°C deposition sample. The film thickness is 740Å, with a roughness of approximately the same value. Also, the consumption of the polycrystalline silicon, similar to the previous sample, can be seen. Figure 14 shows the 469°C deposition sample. The film is 250Å thick, and the interface is the smoothest of the three samples, which is in

Fig. 13. Auger elemental depth profile of a tungsten/phosphorus-doped polycrystalline silicon/SiO₂ sandwich. The tungsten is deposited at 419°C. The deposition time is 20 min. This is sample B in Fig. 7.

Fig. 14. Auger elemental depth profile of a tungsten/phosphorus-doped polycrystalline silicon/SiO₂ sandwich. The tungsten deposition is performed at 469°C. The deposition time is 20 min. This is sample C in Fig. 7.

agreement with the SEM micrographs shown in Fig. 8-10. In deducing the film thickness of these three samples, it was assumed that their density, and thus the sputtering rate, did not vary significantly from each other. From Fig. 12-14, it can be seen that some oxygen is incorporated into the films. A similar result is presented in Ref. (3). Assuming that this oxygen corresponds to the native oxide on the silicon surface prior to film formation (10), an estimate of its thickness can be performed. The area under the oxygen curve is determined and equaled to the height of the oxygen signal expected for SiO₂ times the thickness (sputtering time) of the to be determined native oxide layer. The height of the oxygen signal of SiO₂ is approximately 70% of the scaled signal scale. This can be seen in Fig. 12, where the polycrystalline silicon/SiO₂ interface is shown. The results yield approximately 30Å for sample A, 60Å for sample B, and 13Å for sample C. This agrees, at least qualitatively, with the conclusions made in Ref. (9) that film thickness and roughness depend strongly on the characteristics of the native oxide, with thinner tungsten films being formed for less native oxide. AEDP taken from other samples confirmed this observation: namely, that the oxygen incorporation is proportional to film thickness.

Figure 15 shows the SIMS phosphorus concentration profile of sample B in Fig. 7. Near the tungsten/polycrystalline silicon interface, the phosphorus concentration in

Fig. 15. Phosphorus concentration of a tungsten/phosphorus-doped polycrystalline silicon sample as measured by SIMS. The deposition temperature is 419°C. This is sample B in Fig. 7.

the tungsten film is approximately $1 \times 10^{20} \text{ cm}^{-3}$. The surface concentration is approximately $4 \times 10^{17} \text{ cm}^{-3}$. A similar profile has been obtained for sample A. Sample C exhibits a surface concentration of approximately $4 \times 10^{18} \text{ cm}^{-3}$. Within experimental error ($\pm 20\%$) the resistivity of the phosphorus containing tungsten films is not different from the undoped samples.

From the presented material it is clear that phosphorus takes an active part in tungsten film formation. From Fig. 7, it can be seen that at least two deposition mechanisms are present. For the undoped samples, the film thickness increases slightly, from 320° to 420°C , and then decreases from 420° to 540°C . A similar result is obtained for the films deposited on phosphorus-doped polycrystalline silicon except that it is accentuated. Film formation depends very strongly on the native oxide condition just prior to the WF_6 release into the LPCVD reactor. It is known that all the samples at the moment of insertion into the reactor have a native oxide of approximately 13 to 15 \AA . However, changes in oxide thickness can take place during pumpdown due to unavoidable oxygen traces present in the reactor. This change depends on temperature and sample doping conditions (11). This makes interpretation of the results shown in Fig. 6 and 7 difficult. Nevertheless, the results presented in these figures are very reproducible, sheet resistance across the 3 in. diam wafers do not vary by more than 5%. No film "cloudiness" or streaking phenomena are observed.

Single-crystal silicon substrates.—Similar results in terms of plasma treatment and film formation as described for polycrystalline substrates are obtained for p-type and phosphorus-doped p-type single-crystal substrates. Figure 16 shows the effect of the plasma treatment on n^+ -doped samples. Doping conditions are given in the "Experimental" section of this paper. The results are similar to Fig. 4, except that, without the plasma treatment, films of only approximately 200 \AA can be deposited under the given conditions of 410°C deposition temperature and a deposition time of 20 min. The sheet resistances of the plasma-treated samples (2W, 5 min) are almost identical to Fig. 4. Again, from stylus and Auger measurements, the thickness of the films has been obtained. The thickness scale is indicated on the right side of Fig. 16. The resistivity of the tungsten films is the same as of the tungsten films deposited on polycrystalline silicon, *i.e.*, $18 \mu\Omega\text{cm}$. Figure 17 shows the

Fig. 16. Effect of the argon plasma treatment on sheet resistance for phosphorus-doped p-type single-crystal silicon as a function of WF_6 flow rate. The tungsten deposition parameters are: deposition temperature of 410°C , deposition time of 5 min, Ar pressure of 0.3 torr. Argon plasma treatment: 2W, 5 min.

Fig. 17. Sheet resistance of tungsten deposited on phosphorus-doped p-type single-crystal silicon at three different deposition temperatures as a function of deposition time.

sheet resistance as a function of deposition time for n^+ -doped p-type samples. Strong similarity of the data with Fig. 6 is observed. For deposition temperatures of 367° and 419°C , the films form in less than 5 min after which film thickness is independent of deposition time. At a deposition temperature of 439°C , a strong decrease in film thickness from an initial value of approximately 500 \AA at 5 min to approximately 200 \AA at 30 min is observed. This again suggests etching of the films ($\sim 12 \text{ \AA}/\text{min}$) by WF_6 as a function of deposition time.

Figure 18 shows the sheet resistance for p-type single-crystal silicon as a function of temperature and for a film deposition time of 20 min. For the non-phosphorus-doped samples, very little change in sheet resistance and thus thickness is observed over the temperature range 330° - 460°C , which is similar to the undoped polycrystalline data given in Fig. 7. For the phosphorus-doped case, a minimum is reached at approximately 420°C . Above this minimum, a sharp increase in sheet resistance (decrease in film thickness) is observed. This decrease in film thickness is due to the onset of film etching above 420°C . The data in Fig. 18 are plotted for a deposition time of 20

Fig. 18. Sheet resistance of tungsten deposited on phosphorus-doped p-type and on p-type single-crystal silicon as a function of temperature. Film deposition time is 20 min.

Fig. 19. SEM micrograph of a 670Å thick tungsten film deposited on phosphorus-doped single-crystal p-type silicon at 419°C. This is sample A in Fig. 18.

min. According to Fig. 17, at this time period, etching of the film is already taking place for a deposition temperature of 439°C. This behavior is similar to the data shown in Fig. 7. Insufficient data exist at this time to explain the accentuated increase in film thickness from 320° to 420°C of the phosphorus containing samples (Fig. 7 and 17).

Figure 19 shows the SEM micrograph of a 670Å thick tungsten film deposited on phosphorus-doped single-crystal p-type silicon at 419°C. This is sample A in Fig. 18. The degree of surface roughness at the W/Si interface is similar to Fig. 9 and 11. The surface roughness of the tungsten film is less, probably owing to the smoother initial surface of single-crystal vs. polycrystalline silicon.

Selectivity.—From AEDP, it is verified that tungsten deposited by the LPCVD method is 100% selective. Prior to tungsten deposition, 5 μm wide polycrystalline lines are photoshaped and etched on top of thermally grown SiO₂ regions, and no tungsten (< 10Å) can be detected. Selectivity has been observed for all deposition conditions reported in this paper.

Applications.—The primary purpose of this work has been to develop deposition conditions yielding low sheet resistance for a W/phosphorus-doped polycrystalline composite film to be used for IC gate and interconnects. The best results are obtained using a deposition temperature of 420°C. This results in a 700Å thick film with a sheet resistance of approximately 2.6 Ω/□ (see Fig. 7, upper curve). The initial polycrystalline silicon thickness has to be at least 4500Å. Below this value, film lifting due to the stress created by the tungsten film is observed. Note that approximately 1400Å of the polycrystalline silicon are consumed during the tungsten film formation.

For low resistance source/drain contact formation to n⁺ silicon, a temperature of 420°C gives the lowest resistance films. However, to avoid film encroachment at the Si/SiO₂ pattern edges (3, 12) a deposition temperature of 350°C is needed. This results in a sheet resistance of approximately 4 Ω/□. However, the suitability of this approach has to be investigated by electrical measurements. Due to the tungsten protrusions into silicon, excessive leakage currents might result for Schottky barrier structures and tungsten on shallow n⁺ source/drain structures.

Summary

Tungsten films have been deposited via the silicon reduction of WF₆ in a low pressure chemical vapor deposition system on phosphorus-doped and undoped polycrystalline silicon and on phosphorus-doped p-type

and undoped p-type single-crystal silicon. Deposition temperatures range from 310° to 540°C.

For the non-phosphorus-doped substrates (polycrystalline and single crystal), film thickness of approximately 200-400Å can be obtained using a H₂SO₄/H₂O₂, HF dip clean prior to film deposition. With the introduction of a low power argon plasma treatment, film thickness can be increased, for the same deposition conditions, to a maximum of approximately 900Å. This treatment increases the native oxide thickness of all samples from 6Å (chemical clean only) to 14Å. Over the temperature range, the thicknesses of the tungsten films deposited on undoped polycrystalline silicon range from 500 to 900Å, those deposited on lightly p-type doped silicon from 800 to 1000Å.

A drastically different behavior is observed for the phosphorus-doped substrates. Here, a maximum film thickness of approximately 700Å can only be reached at 420°C. Below this temperature, film thickness decreases to approximately 400Å at 340°C for both substrates. Above 420°C, film thickness reduces to 200Å at 500°C (on polycrystalline silicon) and at 440°C (single-crystal silicon). This decrease is due to etching of the films by WF₆, which is catalyzed by the presence of phosphorus.

ABSTRACT

Polycrystalline cadmium selenide thin film electrodes prepared by coevaporation of the elements were investigated *in situ* by electrochemical photocapacitance spectroscopy (EPS) in aqueous basic electrolytes, with and without added polysulfide redox species. An interface state lying about 0.2 eV below the conduction bandedge was directly detected for material prepared at low substrate temperature and was demonstrated to mediate charge transfer between the semiconductor and the electrolyte.

Interface states are known to play an important role in charge transfer processes at both single-crystal and polycrystalline CdSe electrodes. For example, Fermi level pinning has been observed for n-CdSe in neutral sulfate electrolytes (1); for fast, one-electron redox species in nonaqueous electrolytes, the open-circuit voltage varies in a nearly ideal fashion as the redox potential is changed (over a limited range) (2). It has been proposed (3) that Fermi level pinning can result from interface-state densities as low as 10^{12} cm^{-2} . Interface-state effects in the thin-film n-CdSe/aqueous polysulfide system have been investigated by Rajeshwar (4). He reports that interface states associated with adsorbed sulfide ions mediate electron transfer and limit the open-circuit voltage; no change in V_{oc} was observed when the electrolyte composition was varied so as to change the redox potential over a 250 mV range.

In the present work, electrochemical photocapacitance spectroscopy (EPS) (5, 6) and ac impedance measurements were applied to further elucidate charge transfer processes associated with interface states at cadmium selenide electrodes prepared by coevaporation of the elements (7). Such thin film material was chosen for study because of its potential practical applications, *e.g.*, in photoelectrochemical cells. Results obtained previously for such electrodes in polysulfide electrolytes can be summarized as follows. Data are variable, but, in general, films prepared at low substrate temperatures ($\sim 100^\circ\text{C}$) yield higher photocurrents but lower open-circuit voltages ($\sim 100 \text{ mV}$ less) than those prepared at high substrate temperatures ($\sim 400^\circ\text{C}$) (8). For low substrate temperature films, the open-circuit voltage is increased by 50-100 mV and the fill factor is improved (with no loss in short-circuit photocurrent) when the electrode is soaked in ZnCl_2 solution and potential cycled (under illumination) in aqueous polysulfide (9). Based on Auger depth profile studies and impedance/polarization measurements, this improvement has been attributed to a negative shift in U_{FB} (flatband potential) caused by incorporation of Zn in the CdSe film.

Experimental Details

Thin film CdSe electrodes were prepared by vacuum coevaporation of Cd and Se from independently controlled sources, as described previously (7, 8). Two types of films were prepared (on titanium substrates). Low substrate temperature films were deposited at 100°C with a Se-to-Cd ratio in the vapor of 3:1. These films, which were only partially crystalline in the as-deposited state, were subsequently heat-treated at 400°C for 15 min in air to maximize their photovoltaic response. High substrate temperature films were deposited at 400°C with a Se-to-Cd ratio of 1:1. Although fully crystalline as deposited,

*Electrochemical Society Active Member.

these films still required heat-treatment at 450°C for 15 min for maximum photovoltaic output. After attachment of a wire lead to the titanium substrate with silver-epoxy resin, the electrode was sealed in Torr Seal® (Varian Associates, Palo Alto, California) so that the front (CdSe) face was exposed to the electrolyte. The geometric area of the electrodes ranged from 0.2-0.7 cm^2 . Before evaluation, films of both types were etched in 25% HNO_3 and dipped in polysulfide solution (0.1M S + 2.5M Na_2S + 1.0M KOH) to remove excess selenium from the surface.

The procedures and apparatus used to perform EPS measurements have been described previously (6). Impedance measurements were performed using the same apparatus.

Results and Discussion

For n-CdSe, which has a bandgap of 1.76 eV, four donor states (onsets at 1.04, 1.21,¹ 1.34, and 0.2 eV below the conduction bandedge) have been detected by EPS (10). As discussed in this earlier work, the 1.04 and 1.21 eV levels correspond to interface states associated with oxygen adsorption and play major roles in determining the electrical properties of CdSe devices. The 1.04 eV state predominates in aqueous solution and under vacuum conditions, resulting in a negative surface charge. At positive electrode potentials in acetonitrile solution, the 1.21 eV state occurs in higher concentrations, but can be electrochemically reduced to the 1.04 eV state at voltages near U_{FB} .

The 0.2 eV state in CdSe is of particular interest to the present work because it occurs in relatively high concentrations only in thin film materials prepared at low substrate temperature (100°C). As shown in Fig. 1a, this state ionizes at sufficiently positive electrode potentials and is detected as a sharp capacitance decrease beginning at about 1.5 eV (820 nm), corresponding to a transition from the valence band to the state. Such ionization, which increases the capacitance by increasing the positive charge at the interface (reduces the space charge thickness), is also reflected in Mott-Schottky plots as a sharp decrease in C^{-2} at more positive potentials. This is apparent above -0.5V in the plot given in Fig. 2; deviation from linearity, which apparently signals some ionization, is evident even at -0.7V . At potentials closer to U_{FB} , which according to Fig. 2 lies at -0.9V vs. SCE, the 0.2 eV state is nonionized in KOH solution and is, therefore, not detected. In this case, the capacitance is lower and the EPS spectrum (Fig. 1b) is similar to that for single-crystal electrodes; the 1.04 and 1.34 eV states are clearly evident, only slightly shifted in energy. As shown in Fig. 3, the 0.2 eV state is not detected at any appreciable concentration in coevaporated films prepared at high substrate temperature (400°C). This is an important result, indicating that the 0.2 eV

¹A slightly higher apparent onset is observed for this state in specimens having a high concentration of the 1.04 eV state.

level, by functioning as a charge transfer mediator/recombination center or by changing the interfacial potential distribution, is responsible for the observed limitations on the attainable open-circuit voltage for low substrate temperature material (8).

It should be mentioned that, as discussed previously (7), these thin film materials have a significant number of pinholes and cracks, through which a portion of the titanium substrate is exposed to the electrolyte. Thus, the measured capacitance includes a parallel contribution associated with the many small metal-electrolyte interfaces, which is likely to be large. In addition, the films are porous, so that the actual surface area of the electrode is much greater than the geometric area. Because of these combined effects, the capacitance values reported here tend to be large, even when the 0.2 eV state is nonionized. Hence, Mott-Schottky plots are of little value in determining carrier concentrations for these materials, but still provide useful information concerning the potential dependence of interfacial processes. Likewise, the absolute photocapacitance values reported have little quantitative significance.

Electrode porosity further complicates the situation by introducing frequency dispersion into the measured capacitance. Essentially, because of current distribution problems within pores, less of the surface of a porous electrode responds to the measurement perturbation at high frequencies, whereas the measured capacitance for an ideal planar electrode is frequency independent, that for an electrode with cylindrical pores that can

Fig. 2. Mott-Schottky plot (7 Hz) in 0.5M KOH for the same low substrate temperature CdSe electrode as in Fig. 1.

Fig. 3. EPS spectra (7 Hz) measured in 0.5M KOH at 1.0V vs. U_{FB} for coevaporated films prepared at low (100°C) and high (400°C) substrate temperatures.

be considered infinitely deep (in a given frequency range) decreases with increasing frequency. Specifically, the impedance for a porous electrode in this case is proportional to the square root of that for an ideal flat electrode (13). Consequently, low frequency measurements are preferable for porous electrodes because their capacitance behavior approaches that for ideal planar electrodes as the perturbation frequency is decreased. The relatively low perturbation frequencies used in the present work (7 and 70 Hz) were also chosen to provide optimum sensitivity to capacitance changes. Since it was not necessary, no attempt was made to normalize the data to permit determination of absolute densities of states.

The 0.2 eV state in CdSe apparently resides at the interface, since it is not observed for electrodes transferred from aqueous KOH to acetonitrile electrolytes, as shown in Fig. 4. An interface state is also consistent with the high associated EPS capacitance change (several $\mu F/cm^2$) and its potential dependence.

Because of the importance of the aqueous polysulfide for stabilization of CdSe photoanodes in photoelectro-

Fig. 4. EPS spectra (7 Hz) for the same low substrate temperature CdSe thin film electrode at 1.0V vs. U_{FB} in 0.5M KOH and in 0.1M tetraethylammonium perchlorate/acetonitrile solution.

chemical cells, appreciable effort was devoted to *in situ* investigation of various CdSe materials in the polysulfide electrolyte. Considerable quantitative variation in EPS results was observed from electrode to electrode (batch to batch), which can be attributed to differences in the material itself, since results for a given electrode were reproducible. In spite of the observed variation, some important general conclusions can be drawn from the data.

Exchange of electrons between the 0.2 eV state in CdSe and polysulfide species in solution is dramatically evident from the time dependence of the photocapacitance under intermittent illumination, as illustrated by the curves in Fig. 5. The response time for attainment of population/depopulation equilibrium for the state is on

Fig. 5. Transient photocapacitance (7 Hz) for a low substrate temperature CdSe thin film electrode with and without 720 nm illumination in 0.5M KOH solution (0.9V vs. U_{FB}) and in polysulfide solution (0.3V vs. U_{FB}), i.e., 0.1M KOH + 2.5M Na_2S + 1.0M S.

the order of hours in pure KOH solution, whereas in the presence of polysulfide, equilibrium is attained in less than 2s.

As is evident from the EPS spectra² in Fig. 6, the population of the 0.2 eV state in the presence of polysulfide is strongly dependent on the electrode potential. Ionized 0.2 eV states, which upon photoneutralization are reflected in a capacitance decrease beginning at 1.5 eV (820 nm), are not observed at -1.0V vs. SCE (Fig. 6a), are evident at -0.95 and -0.90V (Fig. 6b and 6c), are practically undetectable between -0.85 and -0.7V (Fig. 6d and 6e), but are present in very high concentration at -0.5V (Fig. 6f, note that absolute capacitance and photocapacitance are both large). It should be emphasized that all features of this complicated behavior are not observed for all specimens. This is not surprising since, as discussed below, the ionization/neutralization processes for the 0.2 eV state are complex and depend strongly on the density of states and U_{FB} , both of which vary appreciably from specimen to specimen.

The complex behavior illustrated in Fig. 6 can be understood in terms of interface-state (surface-state) reactions involving electron tunneling from the semiconductor bulk to ionized interface states (ss^+) or the reverse tunneling process from neutral interface states (ss^0), i.e.

and reactions involving the reduced (R_{red}) and oxidized (R_{ox}) redox species, i.e.

These reactions and the relative energies (approximately to scale) of the conduction band, semiconductor Fermi level, 0.2 eV interface states, and electrolyte redox level (E_R) are depicted for various bias voltages in Fig. 7. Based

²Note that the perturbation frequency in this case is 70 instead of 7 Hz; frequency dispersion effects are discussed below.

CdSe/POLYSULFIDE ENERGY LEVELS AT VARIOUS ELECTRODE POTENTIALS

Fig. 7. Energy level diagrams for n-CdSe showing the relative positions of the conduction band, Fermi level, and polysulfide redox potential for $U_{FB} = -1.5V$ at various electrode potentials: (a) -1.1 ; (b) -0.95 ; (c) -0.8 ; and (d) $-0.5V$ vs. SCE.

on photocurrent onset and ac impedance measurements for single-crystal CdSe, U_{FB} is taken as $-1.5V$ vs. SCE, which is also consistent with the highest open-circuit voltage reported for this system ($0.7V$) (11) and a redox potential of $-0.8V$; apparent variations from this value for polycrystalline electrodes are discussed below. It should be kept in mind that exchange of electrons between the 0.2 eV interface state and polysulfide species is conclusively evident from the much faster time constant for both ionization and neutralization of the state in the polysulfide electrolyte compared to pure KOH solution (Fig. 5). For Fig. 7a-7c, all of the electrode potential drop is assumed to fall within the semiconductor space-charge region, which is consistent with the relatively low capacitance values.

Population of the interface states is determined by the relative rates of reactions [1a] and [2a] compared to [1b] and [2b], which in turn are influenced by the electrode potential. At potentials of less than about $0.4V$ vs. U_{FB} (Fig. 7a), interface states are filled by electron tunneling through the relatively thin space-charge layer (Eq. [1a]) and by reaction with reduced redox species (Eq. [2a]); although some cathodic dark current is observed, transfer of electrons to electrolyte species is relatively slow (compared to the tunneling/capture rates) at this electrode potential so that no ionized interface states are detected (Fig. 6a). It is important to note that even when the formal E_R value lies far below the interface-state energy, electron transfer from reduced redox species (filled states) is still possible since the energy barrier is greatly reduced by the high local electric field associated with ionized interface states and by specific orbital interactions between the redox species and interface states. Because of such localized effects, E_R in the vicinity of interface states is effectively shifted negatively. At somewhat more positive potentials (Fig. 7b), electron tunneling is suppressed (Fermi level too low) so that some ionized states exist in equilibrium with electrolyte redox species (Fig. 6b-6c). When the Fermi level reaches the electrolyte redox potential (Fig. 7c), net electron transfer from reduced electrolyte redox species to the semiconductor is thermodynamically favored and the ionized interface states are filled (Fig. 6d

and 6e). As the electrode potential is made sufficiently positive of the redox potential (Fig. 7d), a large fraction of the interface states ionize by electron tunneling to the semiconductor bulk (Eq. [2b]), so that a large fraction of the electrode potential drops across the electrolyte Helmholtz layer, increasing E_R relative to E_F and giving rise to an appreciable anodic dark current. In this case, the tunneling process is again relatively fast compared to interfacial charge transfer, so that the overall capacitance is large and a high density of ionized 0.2 eV interface states is detected (Fig. 6f).

The lower open-circuit voltage obtained for materials containing a high concentration of the 0.2 eV interface state can readily be explained within this model. That is, at potentials closer to U_{FB} than depicted in Fig. 7a, the Fermi level energy rises above that of the interface states, greatly increasing the probability of electron transfer to electrolyte species and, consequently, the cathodic dark current. In this case, the semiconductor bands cannot unbend further because of charge leakage to the electrolyte, so that a voltage loss, corresponding to the energy of the interface states below the conduction bandedge (0.2 eV), results. This is also reflected in photocurrent onset measurements, which yield apparent U_{FB} values for low substrate temperature films of typically $-1.3V$ vs. SCE rather than the $-1.5V$ obtained for single-crystal material. Values of U_{FB} measured for such films by the ac impedance method ranged from -1.0 to $-1.4V$, apparently reflecting, at least to some extent, variations in the density of ionized interface states. It should be mentioned that Reichman and Russak (8) have previously reported that Mott-Schottky plots are of questionable value in determining U_{FB} for thin film materials of this type.

The dark current-voltage behavior of thin-film CdSe electrodes correlates well with the EPS results and the proposed charge transfer model. Typical plots of log current vs. electrode potential for low and high substrate temperature electrodes are given in Fig. 8. High temperature films, for which the 0.2 eV state is not detected by EPS, exhibit very low forward and reverse dark currents (comparable to those observed for single-crystal electrodes) over a wide potential range. At $-1.0V$ vs. SCE, the dark current for low temperature films is an order of magnitude greater, presumably because of conventional electron tunneling associated with the decreased band bending (shift in U_{FB}) for this type of material (8). This is consistent with the energy level diagram in Fig. 7a. Also, the fact that the forward dark currents for the both types of materials have the same ideality factor (1.5) indicates a simple change in barrier height, i.e., a shift in U_{FB} for the low temperature material. In addition, the dark saturation current for the low temperature film is $8 \times 10^{-9} A/cm^2$, as compared to $9 \times 10^{-9} A/cm^2$ for the high temperature material, indicating that the former passes more current at the zero bias point. The anodic dark current under re-

Fig. 8. Dependence of the dark current for low and high substrate temperature CdSe films in polysulfide electrolyte on the electrode bias potential (vs. SCE).

verse bias (-0.5V vs. SCE) is also much larger for the low temperature films, as expected from the proposed model (Fig. 7d).

Frequency dispersion of the photocapacitance also appears to reflect, in addition to porosity effects, the potential-dependent population/depopulation of the 0.2 eV interface state in aqueous polysulfide electrolytes. For example, in some relatively narrow potential regions, the photocapacitance decrease associated with this state was often much different in magnitude at the lower perturbation frequency (7 Hz) than at the higher frequency (70 Hz); in some cases, the 0.2 eV state was not observed at all at one of the frequencies. Such results indicate that the population of the interface state is affected by the perturbation voltage itself but only at sufficiently low frequencies for which electrons are induced to exchange between the state and electrolyte redox species or the semiconductor bulk (via tunneling). It should be mentioned that measurements of the photocapacitance frequency dispersion could ultimately yield rate constants for specific processes.

To further elucidate the role of the 0.2 eV interface state in charge transfer processes at n-CdSe electrodes, ac impedance measurements were performed over a broad frequency range (10,000 to 0.1 Hz), both in the dark and under illumination with 750 nm (1.65 eV) light. The data will be discussed in terms of the equivalent circuit given in Fig. 9, where R_s is the series resistance, C_p is the parallel capacitance, and R_{CT} is the charge-transfer resistance. Note that, ideally, C_p is a series combination of the space-charge (C_{sc}) and Helmholtz layer (C_H) capacitances, but in the present case there is also a contribution from the portion of the titanium substrate surface exposed to the electrolyte via pinholes and cracks in the CdSe film. In complex impedance plots of the imaginary (Z'') vs. real (Z') impedance components, generally R_{CT} is the diameter of the semicircle and $C_p = 1/2\pi f_m R_{CT}$, where f_m is the frequency at the maximum in the semicircle.

Complex impedance plots and calculated C_p and R_{CT} values for a low substrate temperature n-CdSe electrode in aqueous polysulfide at three electrode potentials are shown in Fig. 10, and the corresponding EPS spectra at two perturbation frequencies (7 and 70 Hz) are given in Fig. 11. At -1.0V, which is near U_{FB} , the semiconductor space-charge capacitance is relatively large and 0.2 eV states are readily filled via electrons tunneling from the semiconductor bulk. In this case, the 1.5 eV (820 nm) transition is not observed in the EPS spectrum for either frequency and well-defined semicircles, presumably associated with double layer charging and charge transfer/adsorption processes at the interface,³ are observed in the complex impedance plots. Although the subbandgap light (750 nm) has no appreciable effect on C_p , as expected when C_H is dominant, R_{CT} is decreased by almost a factor of two by such illumination. This effect is probably the result of electron-hole pair photogeneration, i.e., band tailing. Note that the presence of the 0.2 eV state might be expected to give rise to photocurrent band tailing associated with thermal emission of electrons photoexcited to

³Since no linear region, i.e., Warburg impedance, is observed, diffusional processes are apparently unimportant over the frequency range and light intensity studied.

Fig. 9. Simple equivalent circuit for n-CdSe/polysulfide system

Fig. 10. Complex impedance plots for a low substrate temperature n-CdSe electrode at three bias potentials in polysulfide solution (0.1M KOH + 2.5M Na₂S + 1.0M S), with and without 750 nm illumination.

the state from the valence band. This would explain the long wavelength difference in the action spectra for low and high substrate temperature material given in Fig. 12.

At -0.8V vs. SCE, the situation is quite different. In this case, the 0.2 eV state is at least partially ionized and the 1.5 eV (820 nm) transition is observed in the EPS spectra (note that the magnitude of the capacitance decrease is smaller at the higher perturbation frequency). In the dark, the complex impedance plot is a straight line inclined at 78°, indicating that the impedance is dominated by a somewhat "leaky" capacitor (an ideal nonporous capacitor would yield an angle of 90°), presumably the space-

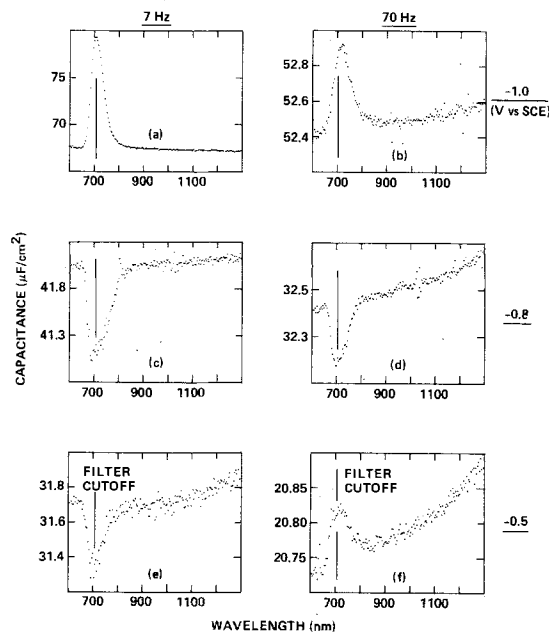

Fig. 11. EPS spectra (measured at 7 and 70 Hz) for n-CdSe at three bias potentials in polysulfide solution (same electrode and electrolyte as for Fig. 10).

Fig. 12. Spectral response of low and high substrate temperature CdSe materials in polysulfide electrolyte at $-1.0V$ vs. SCE.

charge capacitance (C_{sc}). This is consistent with the model presented above, according to which electron tunneling from the semiconductor bulk to 0.2 eV interface states does not occur at this bias voltage so that interfacial charge transfer processes are subdued. With 750 nm illumination, the complex impedance plot exhibits significant curvature (the radius corresponding to $10^5 \Omega$), presumably associated with interfacial reaction of electrons photoexcited to the interface states. Since photogenerated holes are rapidly consumed at the interface, such interfacial reaction of electrons corresponds to charge-carrier recombination via electrolyte species. These results, therefore, provide strong evidence for the participation of the 0.2 eV state in recombination.

At $-0.5V$ vs. SCE, which is positive of the polysulfide redox potential, faradaic processes once again dominate the impedance, yielding a well-defined semicircle in the complex impedance plots. In this case, electrons are transferred from the reduced redox species to the interface states, then tunnel to the semiconductor bulk, resulting in an anodic dark current. The lower value of C_p compared to that at potentials near U_{FB} indicates a significant contribution from C_{sc} ; under illumination, which populates and thus reduces the density of ionized interface states, the contribution is larger (C_p is smaller). Illumination also increases R_{CT} in this case because fewer sites are available for interfacial charge transfer, i.e., states are filled via the 1.5 eV phototransition. In addition, neutralization of the 0.2 eV state effectively increases the space-charge layer thickness, as seen by the decrease in C_p , which will inhibit tunneling and thus increase R_{CT} . Although the 0.2 eV state is detected in the EPS spectrum at 7 Hz (as expected), it is not observed at 70 Hz. This is probably a consequence of the relative rates of tunneling and charge transfer and the effect the perturbation voltage has in populating/depopulating the state.

EPS was also used to investigate the mechanism by which zinc treatment improves the performance of n-CdSe photoanodes (9). Although this treatment (soaking in 0.1M $ZnCl_2$ solution) apparently reduces the concentration of the 0.2 eV interface state in some cases — results of one set of experiments are summarized in Table I — the effect is not consistently observed and is apparently related only incidentally to the performance improvement. This interpretation is consistent with the findings of Reichman and Russak (9) that Zn, which is incorporated in the CdSe lattice, improves the open-circuit voltage by shifting U_{FB} negatively.

Table I. Effect of $ZnCl_2$ treatment on photocapacitance change for 0.2 eV state in thin film CdSe

Electrode preparation	$\Delta C(\mu F/cm^2)^*$
Untreated (etched/cycled in polysulfide)	-0.80
30 min soak in 0.1M $ZnCl_2$	-0.70
Additional 30 min soak in $ZnCl_2$ solution	-0.60

Some speculation concerning the origin of the 0.2 eV state is in order. A chemical impurity seems unlikely, since the 0.2 eV state is observed in small concentrations even for single-crystal material. Also, secondary ion mass spectroscopy (SIMS) profiling of low substrate temperature films indicated that impurity levels are as low as those of the best high substrate temperature films, for which the 0.2 eV state is not detected by EPS. Since the concentration of the state in single-crystal material is enhanced by mechanical polishing, participation of a lattice defect is implied. This is consistent with the findings of Brillson (12) that the feature corresponding to the 0.2 eV state in surface photovoltage spectra is enhanced by argon bombardment. Frese (1) has inferred the presence of an interface state in CdSe centered about 0.2 eV below the conduction bandedge and attributed it to excess selenium. Although free Se would be expected to dissolve in aqueous polysulfide, a Se species bound to a lattice defect would appear to be a likely prospect as the origin of the 0.2 eV interface state. The occurrence of such a selenium-defect state would not be surprising, because as-deposited low temperature films contain a 3:1 molar ratio of Se to Cd and are only partially crystalline. It is only after heat-treatment and removal of excess Se that such films are crystalline and exhibit favorable photovoltaic characteristics. This type of defect is also consistent with our inference that this state shifts U_{FB} anodic by interfering with polysulfide adsorption, which should be favored on Cd sites but inhibited on Se.

Activity Coefficients of Electrons and Holes in Semiconductors

Mark E. Orazem^{*1} and John Newman^{**}

Materials and Molecular Research Division of Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Dilute-solution transport equations with constant activity coefficients are commonly used to model semiconductors. These equations are consistent with a Boltzmann distribution and are invalid in regions where the species concentration is close to the respective site concentration. A more rigorous treatment of transport in a semiconductor requires activity coefficients which are functions of concentration. Expressions are presented for activity coefficients of electrons and holes in semiconductors for which conduction- and valence-band energy levels are given by the respective bandedge energy levels. These activity coefficients are functions of concentration and are thermodynamically consistent. The use of activity coefficients in macroscopic transport relationships allows a description of electron transport in a manner consistent with the Fermi-Dirac distribution.

The concentrations of holes and electrons in a semiconductor are given by the Fermi-Dirac distribution (1, 2). A Boltzmann distribution is frequently used as an approximation to this distribution in statistical-mechanical analyses of semiconducting systems. Dilute-solution transport equations with constant activity coefficients, consistent with a Boltzmann distribution, are also used in characterizing the behavior of semiconducting systems. These approximate methods are popular because of their relative mathematical simplicity, but are invalid when electron or hole concentrations are close to the respective site concentrations in any region.

Calculation of individual ionic activity coefficients for electrons and holes has been proposed as a means of identifying the regions in which these approximations are justified. Rosenberg (3), Panish and Casey, Jr. (4, 5), and Hwang and Brews (6) have presented activity coefficients for electrons and holes that are functions of potential as well as concentration. Harvey (7) discusses the separation of the activity coefficient into parts due to chemical and electrical effects. Landsberg and Guy (8) present an activity coefficient based upon an Einstein relation that includes within it the nonidealities associated with the activity coefficient (9).

Activity coefficients are derived here that are functions of concentration. This derivation is independent of the Einstein relation. These activity coefficients are thermodynamically consistent and can be used to check the validity of the Boltzmann function as an approximation to the Fermi-Dirac distribution. These coefficients can also be used in the application of macroscopic transport equations to semiconducting systems in a way that is generally valid.

Theoretical Development

The electrochemical potential of a given species can arbitrarily be separated into terms representing a reference state, a chemical contribution, and an electrical contribution (10)

$$\mu_i = \mu_i^0 + RT \ln (c_i f_i) + z_i F \Phi \quad [1]$$

where Φ is a potential which characterizes the electrical state of the phase and can be defined in a number of ways. The potential used here is the electrostatic potential which is obtained through integration of Poisson's equation (11). Equation [1] can be viewed as the defining equation for the activity coefficient, f_i .

Under the assumption of a dilute solution, the flux of an individual species within the semiconductor is driven by a gradient of electrochemical potential

$$N_i = -c_i u_i \nabla \mu_i \quad [2a]$$

or

$$f_i N_i = -u_i RT \nabla (c_i f_i) - z_i u_i F (c_i f_i) \nabla \Phi \quad [2b]$$

where N_i is the flux of species i . Introduction of $A = c_i f_i e^{z_i F \Phi / RT}$ yields

$$f_i N_i = -u_i RT e^{-z_i F \Phi / RT} \nabla A \quad [3]$$

Under equilibrium conditions, $\nabla A = 0$, and

$$c_i f_i = A e^{-z_i F \Phi / RT} \quad [4]$$

where A is a constant. Under the assumption of a constant activity coefficient, Eq. [4] is consistent with a Boltzmann distribution.

The distribution of electrons in a semiconductor is characterized by the Fermi-Dirac function

$$\frac{n_i}{g_i} = [1 + \exp [(E_i - E_f) / RT]]^{-1} \quad [5]$$

where n_i is the number of electrons within an energy level E_i with degeneracy g_i . The Fermi energy E_f is a statistical parameter given the units of J/mol and defined as the energy at which the probability of occupancy of a state is one-half. The Fermi-Dirac distribution enters into the transport development (Eq. [2], [3], and [4]) through introduction of individual ionic activity coefficients: one for electrons and one for holes.

Through Fermi-Dirac statistics the concentration of conduction electrons is given by

$$n = \int_{E_c}^{\infty} \frac{N(E)}{1 + \exp [(E - E_f) / RT]} dE \quad [6]$$

and the concentration of holes by

$$p = \int_{-\infty}^{E_v} \left[1 - \frac{1}{1 + \exp [(E - E_f) / RT]} \right] N(E) dE \quad [7]$$

The concentrations defined above are consistent with the concentrations c_i used in Eq. [1]-[4]. If the distribution of available energy levels is narrow or RT is small, the valence and conduction electrons can be characterized by single-valued energy levels, E_v (the highest energy level of the valence band) and E_c (the lowest energy level of the conduction band), respectively. Thus

$$n = \frac{1}{1 + \exp [(E_c - E_f) / RT]} \int_{E_c}^{\infty} N(E) dE \quad [8]$$

or

$$n = \frac{N_c}{1 + \exp [(E_c - E_f) / RT]} \quad [9]$$

where N_c is the concentration of conduction-energy sites for electrons. A similar term, N_v , is defined as the concentration of valence-band sites.

From the definition of the electrochemical potential, the chemical activity

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

¹Present address: Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia 22901.

$$a_i = c_i f_i \quad [10]$$

can be expressed as

$$a_i = \exp \left[\frac{\mu_i - \mu_i^0 - z_i \mathbf{F}\Phi}{RT} \right] \quad [11]$$

Note that the activity has units of concentration (see Eq. [1]). In Eq. [9], the concentration of conduction electrons is given as a function of the Fermi energy level. The energy E_c in this equation depends upon potential as

$$E_c = E_c^* + z_i \mathbf{F}\Phi \quad [12]$$

where E_c^* is a constant, independent of potential. The electrochemical potential of conduction electrons and the Fermi energy are related by an arbitrary constant

$$\mu_{e^-} = E_f + \mu_{e^-}^* \quad [13]$$

Equations [11] through [13] can be combined to yield

$$f_{e^-} = \frac{\exp[(\mu_{e^-}^* - \mu_{e^-}^0 + E_c^*)/RT]}{N_c} \left[\frac{1}{1 - n/N_c} \right] \quad [14]$$

where f_{e^-} is dimensionless. The secondary reference state quantities, E_c^* , $\mu_{e^-}^*$, and $\mu_{e^-}^0$, are chosen to allow the activity coefficient to approach unity as the concentration of conduction electrons approaches zero. Thus, the activity coefficient is obtained as a function of composition

$$f_{e^-} = \frac{1}{1 - n/N_c} \quad [15]$$

The activity coefficient of conduction electrons is equal to 2 for a dimensionless concentration n/N_c equal to 0.5.

A similar activity coefficient can be obtained for the holes as

$$f_{h^+} = \frac{1}{1 - p/N_v} \quad [16]$$

The assumption of unity activity coefficients is in harmony with the assumption of the Boltzmann limits to the Fermi-Dirac distribution. Use of the Fermi-Dirac distribution results in activity coefficients that are functions of concentration.

Discussion

Equations [15] and [16] are consistent with the form of the activity coefficients

$$f_{e^-} = \frac{N_c}{n} e^{(E_f - E_c)/RT} e^{\Delta E/RT}$$

presented by Hwang and Brews (6) and Landsberg and Guy (8). These authors include a term $e^{\Delta E/RT}$ for the shift in electron energy due to the occupation of energy levels above E_c at high electron concentrations (12). Under the assumption that $\Delta E = 0$, Eq. [15] is recovered by introduction of the Fermi-Dirac distribution function for electrons. Calculation of ΔE requires knowledge of the electron site distribution $N(E)$.

The activity coefficients defined above can be checked for consistency with the Fermi-Dirac function. Introduction of the activity coefficient presented for electrons in Eq. [15] into the respective Boltzmann distribution

$$n f_{e^-} = N_c e^{-(E_c - E_f)/RT} \quad [17]$$

recovers the Fermi-Dirac distribution

$$\frac{n}{N_c} = \frac{1}{1 + e^{(E_c - E_f)/RT}} \quad [18]$$

The same is true for the activity coefficient for holes.

A measure of internal thermodynamic consistency is obtained from the second cross-derivative of the Gibbs function, *i.e.*

$$\left(\frac{\partial \mu_i}{\partial c_k} \right)_{T,P,c_j \neq k} = \left(\frac{\partial \mu_k}{\partial c_i} \right)_{T,P,c_j \neq i} \quad [19]$$

where i and k represent components of the system that are not the solvent. This necessary condition for thermodynamic consistency is expressed for the system described here as

$$\frac{RT}{f_{e^-}} \left(\frac{\partial f_{e^-}}{\partial p} \right)_{T,P,n} = \frac{RT}{f_{h^+}} \left(\frac{\partial f_{h^+}}{\partial n} \right)_{T,P,p} \quad [20]$$

This condition is satisfied. (Equation [19] is properly stated in terms of mole numbers rather than concentrations. For the dilute systems involved here, lattice expansion is ignored, and the two are equivalent.)

Use of macroscopic relations for thermodynamics and transport in regions of nonzero electric charge density raises some interesting philosophical questions because transport and thermodynamic properties are not easily measurable as functions of composition including arbitrary departures from electroneutrality. Fortunately, the semiconductors of interest are extremely dilute compared to even dilute aqueous solutions, and theoretical expressions such as the Fermi-Dirac distribution can be used with some confidence. Note that individual ionic activity coefficients are here being introduced in regions of net charge.

The extreme dilution of the semiconductors is also a justification for using the simple transport Eq. [2a] rather than the multicomponent diffusion equation (10), which includes interactions of solute species, and for using the approximate thermodynamic test embodied in Eq. [19].

Conclusions

Activity coefficients are derived here that are functions of concentration. These activity coefficients are thermodynamically consistent and can be used to check the validity of the Boltzmann function as an approximation to the Fermi-Dirac distribution. These coefficients can also be used in the application of macroscopic transport equations to semiconducting systems.

The use of constant activity coefficients in modeling semiconductor systems is valid for dimensionless concentrations n/N_c and p/N_v less than 0.1. Use of the activity coefficients presented in Eq. [15] and [16] allows treatment of systems with dimensionless concentrations ranging from 0 to 1. This approach is restricted, however, by the assumption that valence- and conduction-band electrons are characterized by their respective bandedge energies. Relaxation of this assumption involves integration of Eq. [6] and [7] for a specific distribution of electron energy levels.

Polarization Effects in Polyimides

G. Samuelson

Solavolt International, Phoenix, Arizona 85040

S. Lytle*

Motorola, Incorporated, Mesa, Arizona 85202

Polyimide is a class of high temperature, stable organic polymers that has found widespread use in the semiconductor industry. It has been used as an interlevel dielectric in multilevel discrete transistors (1), and as a final passivant (2). More recently, its role in silicon and aluminum MOS integrated circuits has been demonstrated (3).

Some limited-reliability data on polyimide films have been described in the literature. For example, the effect of incomplete cure on device performance was discussed by Gregoritsch (4). The via resistance and leakage current of a multilevel bipolar LSI chip was reported by Mukai *et al.* (5). Finally, the effects of ionic contamination and electrical conduction in polyimide was discussed by Brown (6).

The present work extends the discussion of charge instability within polyimide films by using standard C-V techniques to probe charge effects that are inherent in the polyimide film or are induced by certain processes. Evidence is presented to show that differences in inherent polarizability of several commercially available polyimides exist. Evidence is presented to show that absorbed water causes increases in the polarization time constants. It may be possible to distinguish different kinds of water, based on the fact that different dehydration conditions are required to restore the original time constants of polarization, depending on the relative humidity to which the polyimide film was exposed. Finally, evidence is presented to show that plasmas routinely used in the semiconductor industry may influence the polarization of polyimide films. For example, standard isotropic O₂ plasma etching of polyimide was shown to cause a decrease in the polarization time constant and activation energy.

Experimental

Polarization effects intrinsic to polyimide.—MIS structures were constructed of 8-12 Ωcm phosphorus-doped Si, 1000Å thermally grown MOS-quality SiO₂, 0.8-4.8μ polyimide (du Pont PI2545, PI2555, PI2562, PSH61453, and Hitachi PIQ-13), and 4000Å pure evaporated aluminum, patterned using conventional lithographic techniques. The resulting test wafer was subjected to a 200°C, 20 min dehydration bake immediately prior to measurement. The measurement system consisted of a Temprotronic TP350A thermally controlled chuck, an HP4275A LCR meter, and a Fluke 8502A multimeter. A "standard" room

temperature trace was performed at 100 kHz from -100V to +100V using a ramp rate of 1 V/s. The stress conditions used to compare measured ΔV_{FB} values against ΔV saturation calculated from classic polarization theory were -5V, 200°C, and 20 min, with cooling to room temperature under bias. At room temperature, the "standard" trace was repeated and the ΔV_{FB} measured. The stress conditions used to determine the time constants of polarization were -5V, 200°C, and times varying from 1 to 40 min, depending on the polyimide under test. Following stress, the MIS structure was cooled to room temperature under bias, the "standard" trace was repeated, and ΔV_{FB} was measured.

Humidity effects on polarization.—C-V analysis was performed on MIS structures which consisted of 4-7 Ωcm p-type Si substrates, 1000Å thermally grown MOS quality SiO₂, 1000Å CVD Si₃N₄, and 1.5μ polyimide, followed by 12 kÅ of sputtered Al-Cu-Si. An MDC computerized semiconductor measurement system consisted of a Boonton 72B capacitance meter, a HP7010B XY recorder, current monitors, and power supplies supported by an 8080S microcomputer system. Standard C-V traces of unstressed samples were made at room temperature over a voltage range of -75 to +25V at 1 MHz. Stressing was done at 225°C under a +5V bias for times ranging from 2 to 20 min. The MIS structure was brought to room temperature under bias, and the ΔV_{FB} was measured as a function of stress time. The time constant of polarization, τ, was calculated from the slope of the ln ΔV_{FB} vs. time curves for MIS structures exposed to various humidity ambients. 100% humidity ambient was achieved by placing wafers in an airtight wafer box with water. At no time was the water in contact with the polyimide. All other relative humidities were obtained by exposing wafers to the clean room ambient. Typically, control wafers were stored at 200°C at N₂.

Results and Discussion

Polarization effects vs. polyimide chemistry.—It has been noted by Brown (6) that charge effects in polyimide can cause inversion of underlying silicon and consequent undesired communication between doped areas. An effort was made to distinguish among the various commercially available polyimides with respect to charge instabilities by subjecting them to -5V, 200°C, and 20 min stress, conditions which mimicked realistic operating conditions for certain devices. The ΔV_{FB} of the stressed

61453	1.95	78	88.6	0.880	40.000
PI2545	1.68	80	76.4	1.000	47.600

profile was compared with the ΔV_{FB} of the unstressed profile. The results are presented as ΔV_{FB} , measured in Table I for numerous polyimides. The saturating shift was calculated from classic polarization theory where

$$\Delta V_{sat} = - (k_o x_p / k_p x_o) V_p^2$$

V_p is the polarizing voltage, k_o and k_p are the dielectric constants of oxide and polyimide, respectively, and x_p and x_o are the thicknesses of polyimide and oxide. The ratio of the ΔV_{FB} measured and the calculated ΔV saturation is a reflection of the relative polarizability of the polyimides tested, as is the parameter ΔV_{FB} measured/ μm . From Table I, it is clear that PI2566 is the least polarizable. du Pont PI2545 and PSH61453 are both rapid polarizers, and the other polyimides fall intermediately between these two extremes.

An attempt was made to measure the time constant of polarization. Figure 1 shows the C-V trace under $-5V$, 200°C stress for times varying from 1 to 15 min for PSH61453. The undulating C-V profiles made it difficult to measure a single meaningful time constant. An attempt was made to "freeze" out polarization events by reducing the stress temperature to as low as -10°C . Even under these conditions, the most rapid polarizers continued to exhibit nonlinear $\ln \Delta V$ vs. time curves. In fact, under conditions of no applied stress other than that imposed by the standard trace, considerable hysteresis in the C-V characteristics was observed for all polyimides, except for the slowest polarizer, PI2566. Figure 2 shows the comparable family of C-V traces for PI2566, also stressed at $-5V$ and 200°C , though now for 15-40 min. The family of curves exhibits uniform, conventional C-V behavior. A plot of $\ln \Delta V$ vs. time, as shown in Fig. 3, gives a straight line with correlation coefficient 0.984. The time constant τ was determined from the slope of the curve in Fig. 3 and the equation

$$\Delta V = \frac{K_o x_p}{K_p x_o} V_p (1 - e^{-t/\tau})$$

The calculated τ for PI2566 was 840 min.

Polarization effects due to absorbed water.—The specific contribution of water to polarization effects in poly-

Fig. 1. C-V characteristics for PSH61453 stressed at $-5V$ and 200°C for 1-15 min.

imide films was studied. MIS structures using PIQ or PI2566 were "soaked" for varying times in either a clean room environment where the relative humidity varied from 17 to 35% or a 100% relative humidity environment. The structures were stressed at $+5V$ and 225°C following humidity exposure, and C-V profiles were measured as a function of stress time. Figure 4 is an example of the results for a MIS structure using PIQ and SiO_2 where the stress times were 2-16 min. The figure illustrates the typical finding that, initially, a rapid shift in ΔV_{FB} occurred which correlated directly with the relative humidity of the soak period. The term ΔV_{H_2O} was defined as the ΔV_{FB} that arose between the zero-stress C-V profile for a dehydrated film (the dotted line in Fig. 4) and the zero-stress C-V profile for a water-"soaked" film. The magnitude of ΔV_{FB} appeared to be a direct function of the relative humidity and the time of exposure to that humidity, as indicated in Fig. 5. The ΔV_{H_2O} occurred almost instantaneously upon temperature and bias stressing and disappeared following a 200°C , 30 min dehydration bake in dry N_2 . After ΔV_{H_2O} occurred, a family of C-V curves resulted, with continued stressing from which ΔV_{FB} values could be measured and used to calculate a time constant of polarization, τ . If such a time constant was measured as a function of exposure time in a 100% RH ambient, τ was seen to increase, as shown in Fig. 6 for PIQ MIS structures. Samples which exhibited increasing τ with time at 100%

Fig. 2. C-V characteristics for PI2566 stressed at $5V$ and 200°C for 15-40 min.

Fig. 3. $\ln \left(\frac{K_o x_p}{K_p x_o} V_p - \Delta V \right)$ vs. time for PI2566 stressed at $-5V$ and 200°C .

Fig. 4. C-V characteristics of PIQ-3 exposed to a 17% RH ambient for 22h and stressed at +5V and 225°C for 2-16 min.

Fig. 5. Magnitude of ΔV_{H_2O} vs. exposed time for PIQ-13 at 100% RH and clean room humidity, varying as indicated in the parentheses.

RH did not revert to the original τ values following 200°C dehydration bake in dry N_2 atmosphere for as long as 72h. They did, however, revert to original τ values following 450°C dehydration bake in dry N_2 for 30 min. Such high temperature dehydration conditions were consistent with the release of H-bonded water. Samples exposed to lower relative humidities (i.e., 17-35%) for as long as 120h also

Fig. 7. Arrhenius plots for untreated, plasma-etched, and passivated PIQ-13 films.

exhibited increased τ values which reverted to original values on lower temperature, 200°C dehydration bake.

Processing effects on polarization.—A brief study was done to determine the effects of highly energetic UV irradiation associated with plasma processing on the polarization behavior of polyimide films. Two plasma processes were performed on deposited polyimide films: plasma etching of the polyimide film itself and passivation with a plasma-enhanced CVD film of silicon oxide.

Films with a thickness of $\sim 3.0 \mu m$ of cured PIQ-13 polyimide were etched to half their original thickness in a Dionex 3000 barrel reactor. Etching took place at 150°C and 0.5 torr in an O_2 plasma at 500W. The approximate etching time was 30 min. After etching, $1.5 \mu m$ of Al-Cu-Si was deposited, and C-V analysis was performed as previously described. For passivation, a 1000Å-thick film of plasma oxide was deposited on wafers which had $1.5 \mu m$ of cured PIQ-13 and Al-Cu-Si metallization. Passivation was performed in an AMT Plasma II reactor at 300°C and 0.3 torr. A plasma energy of 150W was used to react SiH_4 and N_2O in a carrier gas to form the silicon oxide film. Deposition time was approximately 5 min. The plasma oxide film was then selectively removed from the metal-patterned polyimide film, and C-V analysis was done.

Figure 7 shows Arrhenius plots for untreated, plasma-etched, and passivated PIQ films. While no significance beyond measurement error could be attributed to the differences in activation energy between the passivated film and the untreated control, there was a significant lowering of the activation energy for the plasma-etched film. In addition, this effect increased with increasing exposure and/or intensity of the plasma. This change in polarization could not be reversed by annealing the plasma-treated films at 450°C in N_2 for 1h.

Oxygen plasma treatments have been shown in the literature to affect other properties of polymer films, particularly in a 1-10 μm thick region at the surface. For example, general trends of increases in wettability and decreases in molecular weight have resulted for a number of different polymer films (8). Also, mechanical strength of surface layers has been altered as a result of exposing polypropylene to O_2 -containing and N_2O -containing plasmas (9). In general, the mechanism responsible for changes in these properties has been scissioning of polymer chains due to UV irradiation, with subsequent rapid termination of free radicals with oxygen (8). Such a mechanism may have been responsible for the changes in polarization behavior which occurred in the thin polyimide films studied.

Dependences of Magnetron-Sputtered SiO₂ Film Properties on Argon Pressure

Toshiaki Yachi and Tadashi Serikawa

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, 3-9-11 Midori-cho, Musashino-shi, Tokyo 180, Japan

Planar magnetron-sputtered SiO₂ films have been found to be desirable as insulating materials in integrated circuits, such as aluminum multilevel interconnections, because of their high deposition rates, very low deposition temperature, and good step coverage (1). Some studies on deposition rates and step coverage, as well as on applications for device fabrication, of such planar magnetron-sputtered SiO₂ films have been reported (2-5). However, dependences of the film properties on deposition conditions have yet to be made sufficiently clear (6). This note describes the dependences of the RF planar magnetron-sputtered SiO₂ film properties on argon pressure.

Experimental

SiO₂ film about 1 μm thick was deposited on (100)-oriented p-type 10 Ω cm resistivity silicon wafers of 3 in. diam by a RF planar magnetron sputtering apparatus with two targets. The system was pumped down to 3 × 10⁻⁴ Pa prior to in-bleeding of the argon, and sputtering was carried out at 0.3-2.0 Pa in argon. The barrel-type substrate holder, electrically at floating potential, had a 10 rpm rotation rate during deposition. The minimum spacing between the substrate and the target was 50 mm, and the targets used were 99.99% pure SiO₂ sheets, 5 × 15 in. and 1/8 in. thick. The RF forward power was held at 2.0 kW/target. The substrate temperature was also kept at 200°C. Some samples were annealed at 900°C for 20 min in nitrogen gas.

Film properties were evaluated by etching rate, transmission electron microscope (TEM) surface replica observation, and stress. Etching rates were determined by the film thickness decrease in 15:10:1 (H₂O:NH₄F:HF) buffered hydrofluoric acid solution at 30°C, which was measured by creating a step and then using the Talystep Height Reader. Film stresses were determined by comparing wafer curvatures before and after deposition, which were measured by the Newton rings method. Film densities were also measured by a gravimetric technique.

Results and Discussion

The SiO₂ film deposition rate vs. argon pressure is shown in Fig. 1. The deposition rate is maximum at 0.40 Pa. At an argon pressure above 0.40 Pa, the deposition rate decreases with regularity with an increase in argon pressure. The deposition rate at 2.00 Pa amounts to only about 60% of its maximum. At the higher pressures, this drop is due mainly to increased sputtered-particle scattering resulting from the discharge gas (7).

The dependence of the buffered HF etching rate on argon pressure is shown in Fig. 2, where the samples indica-

ted are deposited and annealed. The etching rates change markedly at the "critical pressure" of about 0.5 Pa. In the as-deposited samples, the etching rate of the film depos-

Fig. 1. SiO₂ film deposition rate vs. argon pressure

Fig. 2. SiO₂ film etching rates vs. argon pressure

Fig. 3. TEM micrographs of as-deposited SiO₂ films.

ited at an argon pressure of 0.95 Pa is about 12 times greater than that for the film deposited at a pressure of 0.33 Pa. Although these etching rates are reduced over the entire argon pressure by annealing, the etching rate still exhibits a marked dependence on argon pressure.

TEM micrographs for as-deposited film before and after slight etching by buffered HF are shown in Fig. 3. Before slight etching the surfaces of the films deposited at both 0.33 and 1.05 Pa argon pressures show partial undulation. The surface of the film deposited at 1.05 Pa, however, has very small, shallow pits. The slightly etched film surfaces are markedly different for the two pressures. The film surface deposited at 0.33 Pa (below the critical pressure) shows comparatively shallow spherulike pits of about 0.1 μm diam, while the surface of the film deposited at 1.05 Pa (about the critical pressure) shows a deep leaflike roughness of about 0.5 μm overall.

TEM micrographs of annealed film before and after slight etching are also provided in Fig. 4. The films prior to etching indicate a scalelike surface, corresponding to the undulations in the as-deposited film surface. After

slight etching, the surface of the annealed film deposited at 0.40 Pa shows spherulike pits as in the as-deposited film, while the surface of the annealed film deposited at 2.00 Pa shows a marked roughness.

The SiO₂ film density also depends on the argon pressure. The density of film deposited at 0.33 Pa is 2.23 g/cm³, while the density of film deposited at 2.00 Pa is 2.10 g/cm³. Film density at 0.40 Pa corresponds to the thermally oxidized film density of 2.2 g/cm³ (8).

TEM micrographs and film density suggest that the marked increase in the etching rate of film deposited above the critical pressure arises mainly from the large amount of internal surface area associated with the microvoids present in these films.

The dependence of SiO₂ film intrinsic stress on argon pressure is shown in Fig. 5. The stresses are compressive. The stress also changes greatly at the critical pressure of about 0.5 Pa.

In a sputter deposition system the sputtered particles are emitted from the target, follow the cosine emission distribution and have an energy value of a few electron

Fig. 4. TEM micrographs of annealed SiO₂ films.

Fig. 5. SiO₂ film stress vs. argon pressure

volts (9). The energy of the emitted particles is reduced, and the direction of the particles changes as a result of gas-phase collisions with the argon atoms, as indicated in Fig. 1, and then reach the substrate. In this way, the energy of the sputtered particles is finally reduced so that it corresponds to the thermal energy of the gas.

Westwood calculated the distances which the particles travel normal to the sputtering target before their energies are reduced to the thermal energy of the gas. The distance increases with the mass and energy of the sputtered particle and with a decrease in argon gas pressure; for a 5 eV particle with a mass 60, the distance is about 8 cm at an argon pressure of 0.5 Pa (10).

The distance of 8 cm is near the space between the target and the substrate. At an argon pressure below the critical pressure 0.5 Pa, many SiO₂ particles reaching the substrate have an energy higher than the thermal energy of the gas. These SiO₂ particles with a higher energy migrate on the substrate; thus, the film contains few microvoids, and the film density increases. At an argon pressure above the critical pressure 0.5 Pa, however, the SiO₂ particle energy is thermalized before the particles reach

the substrate and the SiO₂ incident angle distribution is broad. This broad incident angle distribution produces a self-shadowing effect (11). The SiO₂ films contain microvoids, on account of both the low energy of the SiO₂ particle reaching the substrate and the self-shadowing effect. Thus, film density is low. Owing to etching along the microvoids, the films deposited at an argon pressure above the critical pressure 0.5 Pa have a markedly large etching rate. These microvoids can be partially removed by annealing.

In conclusion, the following results are demonstrated: (i) The SiO₂ films deposited below the critical pressure are dense (2.23 g/cm³) and have a low etching rate. (ii) The SiO₂ films deposited above the critical pressure contain many microvoids and film density decreases to 2.10 g/cm³. Moreover, the etching rate of the films deposited by buffered HF is 12 times greater than that of films deposited below the critical pressure. (iii) The stress of SiO₂ film is compressive and increases rapidly with the critical pressure.

The Growth of Epitaxial Layers of Ga_{0.47}In_{0.53}As by the Vapor-Phase Epitaxy-Hydride Method Using a Gallium-Indium Alloy Source

Thomas E. Erstfeld and Kenneth P. Quinlan*

Rome Air Development Center, Solid State Sciences Division, Hanscom Air Force Base, Massachusetts 01731

Epitaxial structures of the ternary system, Ga_{0.47}In_{0.53}As, have found wide application in the fields of optoelectronic and microwave devices. These epitaxial layers have been prepared by various techniques: liquid-phase epitaxy (1), vapor-phase epitaxy (2), molecular beam epitaxy (3), and metal-organic chemical vapor deposition (4). All these methods have produced Ga_rIn_{1-r}As layers with room temperature mobilities in the 10,000 cm²/V-s range, with a high of 13,000 cm²/V-s for the liquid-phase epitaxy (3, 5-7). Carrier concentrations ranged from 10¹⁵ cm⁻³ to the mid-10¹⁶ cm⁻³.

The vapor-phase epitaxy (VPE) technique uses either AsCl₃ (chloride method) or AsH₃ (hydride method) as the source of arsenic. Higher mobilities have usually been achieved with the chloride method (8, 9) but the hydride method has many advantages that the chloride method

*Electrochemical Society Active Member.

lacks, e.g., ease of control, group V reactants are gaseous, etc. Most work with the VPE-hydride technique for the preparation of Ga_{0.47}In_{0.53}As have concentrated on the use of separate metallic sources for the group III elements with a double-barrel reactor. The use of an alloy source in the VPE-hydride technique offers two distinct advantages over the use of two separate metal sources: (i) the flow of hydrogen chloride over the source does not have to be as finely controlled as is necessary with separate metallic sources, and (ii) only a single-barrel reactor is needed. A study of the preparation of Ga_rIn_{1-r}As ternaries using an alloy source (Ga-In) with the VPE-hydride technique was carried out in order to evaluate the technique. This paper reports the effect of various parameters, e.g., source composition, hydrogen chloride pressure, deposition temperature, and operation time on the ternary compositions and growth rates.

The use of an alloy source for the preparation of $\text{Ga}_r\text{In}_{1-r}\text{As}$ by the VPE technique has been studied by a number of investigators. In 1965, Minden (10) used an alloy source of gallium and indium in a modified VPE-chloride method to prepare epitaxial layers of the ternary. Recently, Chatterjee *et al.* (11) studied the use of the alloy with a modified VPE-chloride technique and presented a thermodynamic model describing the system. They demonstrated that a low doped, lattice-matched gallium indium arsenide epilayer could be obtained in a reproducible and controlled manner. Kordos *et al.* (12) studied the growth of $\text{Ga}_r\text{In}_{1-r}\text{As}$ with the VPE-hydride system using a Ga-In alloy. Their results differ from those reported in this paper.

Experimental

The preparation of the epitaxial layers of the ternaries, $\text{Ga}_r\text{In}_{1-r}\text{As}$, was studied in the quartz reactor previously described (9). The quartz reactor has three temperature zones, source, mixing, and deposition, which are heated by "clam shell" resistance heaters. The reactor has three inlet flow systems for AsH_3/H_2 , HCl/H_2 , and H_2 . The flow rates are regulated by Tylan mass flow controllers. The reactants are the highest purity products obtainable: arsine (99.998%), as a 10% mixture in hydrogen (99.999%), hydrogen carrier gas (99.999%), hydrogen chloride (99.995%), indium (99.9999%), and gallium (99.9999%). The hydrogen carrier gas was further purified by a hydrogen purifier (Palladium Diffusion Process-Engelhard). The alloys were prepared by putting the appropriate amounts of the metals into a quartz boat. The masses of the alloys used varied between 99 and 107g. The surface areas of the alloys in the quartz boats were approximately 26 cm^2 . The alloys were prebaked for 50h in a hydrogen atmosphere before any runs were performed. This procedure as reported by Kordos *et al.* (12) lowers the carrier concentrations in the resulting epitaxial layers.

Compositions of the grown ternaries of $\text{Ga}_r\text{In}_{1-r}\text{As}$ were determined from Vegard's law plots of lattice constants *vs.* compositions. The lattice constants were determined by x-ray diffractometry with the $\text{CuK}\alpha$ irradiation using InP as an internal standard. Microprobe analyses verified this method of determining the composition. The growth rates were determined from the surface area of the substrate, mass of deposit, density of the ternary, and time duration of growth. The time of growth was usually 225 min.

The substrates were prepared from a liquid-encapsulated Czochralski (LEC)-grown InP(Fe-doped) boule. Slices were cut 3° off the (100) plane towards the (111) plane. The preparation of the InP substrates are described in Ref. (9).

Carrier concentrations (n) and mobilities (μ) were obtained from resistivity and Hall measurements at room temperature with the van der Pauw technique (13). A permanent magnet provided a field of 3 kG for the Hall measurements.

The residual compositions of the Ga-In alloys were determined by atomic absorption spectroscopy. The alloys for the analyses were remelted and quenched at 0°C to prevent formation of Ga-In solid solutions. During the course of a series of runs, the alloy becomes richer in indium content.

Results and Discussion

Various parameters were studied initially to determine the parameter values which produce high quality epitaxial layers with consistent growth rates. Superior quality epitaxial layers of the ternary, $\text{Ga}_r\text{In}_{1-r}\text{As}$, were obtained when the source, mixing, and deposition temperatures were 800°C , 850°C , and 700°C , respectively. The partial pressures of hydrogen chloride in these preliminary experiments were in the vicinity of 233 Pa. The partial pressure of AsH_3 was 1013 Pa, while the flow rate of hydrogen carrier gas was $980\text{ cm}^3/\text{min}$. The arsine and hydrogen were maintained at these values throughout the study. The x-ray diffractometry studies used for the determina-

tion of the lattice constants showed that the layers were normally of high quality and uniform composition. After these preliminary results were obtained, the determination of the alloy composition required to give a specific ternary composition of $\text{Ga}_r\text{In}_{1-r}\text{As}$ was undertaken. Growth rates of the ternary systems were determined as function of hydrogen chloride partial pressure and deposition temperature.

Figure 1 shows the composition of the ternary, $\text{Ga}_r\text{In}_{1-r}\text{As}$, obtained as a function of the alloy composition. The values depicted are for a deposition temperature of 700°C and a hydrogen chloride partial pressure of 233 Pa. The plot of the experimental data intersecting the $\text{Ga}_{0.47}\text{In}_{0.53}\text{As}$ composition line gives a value of 12.2 mole percent (m/o) gallium-87.8 m/o indium as the alloy necessary to prepare this ternary. The theoretical curve (Fig. 1) calculated from thermodynamic data shows that kinetic factors probably play a role in the deposition process. The differences between theory and experiment may not only be due to kinetic factors but may also be due to errors in the literature used in the calculation of thermodynamic values. Faktor and Haigh (14) have shown that errors in the literature can result in derived thermodynamic values that are inaccurate. Kordos *et al.* (12) reported that 7 m/o in the alloy produces the $\text{Ga}_{0.47}\text{In}_{0.53}\text{As}$ ternary. This large discrepancy between 7 m/o and that found in the present work (12.2 m/o) is not understood.

The compositions of the ternaries were studied as a function of the number of runs with an alloy. The plots obtained are shown in Fig. 2 and are typical of the ternary composition found for various alloys. Figure 2 shows the ternary compositions obtained from the two alloy compositions, 11.5 m/o Ga and 11.9 m/o Ga. The data show that the average composition of the ternaries exhibits a slight increase in the indium content as more runs are performed. An increase in the indium content of the ternary was expected since an analysis of an alloy after 30h of reaction time showed that the mole fraction of indium had increased by 4%. This is in agreement with the extrapolated value of 2% from the data of Chatterjee *et al.* (11). The data presented in Fig. 2 show that at least 14 samples lattice-matched to InP can be obtained with the same alloy.

Epitaxial layers with a value of $|\Delta a/a| < 10^{-3}$ are considered to be lattice-matched to InP. These values of $\Delta a/a$ correspond to $\text{Ga}_r\text{In}_{1-r}\text{As}$ layers that range in composition from $\text{Ga}_{0.45}\text{In}_{0.55}\text{As}$ to $\text{Ga}_{0.49}\text{In}_{0.51}\text{As}$. Inspection of Fig. 1 illustrates that alloy compositions with a gallium content between 11.9 and 12.9 m/o are capable of producing

Deposition temp. = 700°C ; mixing temp. = 850°C ; source temp. = 800°C .

Fig. 2. Mole fraction of indium in $Ga_xIn_{1-x}As$ as a function of the number of runs. \circ — \circ : Alloy composition = 11.5 m/o Ga + 88.5 m/o In. \triangle — \triangle : Alloy composition = 11.9 m/o Ga + 88.1 m/o In. $AsH_3 = 1013$ Pa; $HCl = 233$ Pa; $H_2 = 980$ cm^3/min . Deposition temp. = $700^\circ C$; mixing temp. = $850^\circ C$; source temp. = $800^\circ C$.

$Ga_xIn_{1-x}As$ epitaxial that are lattice-matched to InP. The series of runs shown in Fig. 2 with an alloy composition of 11.9 m/o gallium produced epitaxial films that were lattice-matched to InP only one-third of the time. The values for the indium mole fraction in these samples ranged from 0.48 to 0.60, indicating the lack of reproducibility in these types of experiments. An important aspect of this type of work is depicted in these results, where a certain amount of scatter is observed in the composition of the epitaxial layers from one run to the next. This scatter may be attributed to the free radical nature of these reactions. Various workers (15) have shown that changes in the surfaces of a reactor greatly influence the course of free radical reactions. The surfaces of the reactors used for epitaxial growth undergo constant change when the different parameters of the system are varied. This scatter may account for the lack of observation of the increase in indium content for the ternaries obtained in the series of 25 runs reported by Kordos *et al.* (12).

The growth rates of the ternary, $Ga_xIn_{1-x}As$, were determined as functions of the source hydrogen chloride partial pressure and deposition temperature. Hydrogen chloride reacts with gallium and indium in the alloy to form $GaCl(g)$ and $InCl(g)$. The metal chlorides react with $As_4(g)$ at the InP-substrate surface in the deposition zone to form $Ga_xIn_{1-x}As$. The growth rates of various epitaxial layers grown from different alloy compositions as a function of HCl partial pressure are shown in Fig. 3. These results were obtained at a source temperature of $800^\circ C$ a mixing temperature of $850^\circ C$, and a deposition temperature of $700^\circ C$. The decrease in growth rate below ~ 233 Pa is probably due to the corresponding decrease in the concentration of the monochlorides of the group III elements being formed. The decrease in growth at HCl partial pressures greater than ~ 233 Pa may be due to the occupancy of the available arsenic adsorption sites by either the metallic monochlorides or hydrogen chloride molecules or both which inhibit the deposition reactions. This mechanism has been clearly described by Shaw (16, 17).

The maximum growth rates for the ternaries were obtained when the partial pressure of the hydrogen chloride was in the vicinity of 233 Pa. These growth rates for the various ternary compositions were investigated at $700^\circ C$ and $725^\circ C$, and the results are presented in Table I. The growth rate increases when the temperature is increased from 700° to $725^\circ C$, indicating that the growth is occurring in the kinetic-limited region. The table shows that the growth rates of $Ga_xIn_{1-x}As$ ternaries having indium mole fractions of 0.42-0.63 remain relatively constant at the two temperatures. These ternaries were prepared from alloy source compositions ranging from 15.9 to 11.1 m/o gallium. The ternaries, $Ga_{0.29}In_{0.71}As$ and $Ga_{0.08}In_{0.92}As$, produced from alloy sources of 6.9 and 3.2 m/o gallium, respectively, exhibited higher growth rates. InAs (18) has been shown to have a higher growth rate than GaAs (19)

Fig. 3. Growth rate of epitaxial layers of $Ga_xIn_{1-x}As$ as a function of source HCl partial pressure using different alloys. $AsH_3 = 1013$ Pa; $H_2 = 980$ cm^3/min . Deposition temp. = $700^\circ C$; mixing temp. = $850^\circ C$; source temp. = $800^\circ C$. Compositions of layers prepared from the various alloys given in Table I.

in their homoepitaxial growth by the VPE-chloride technique.

Data showed that varying the partial pressure of the source hydrogen chloride had no effect on the composition of the epitaxial layer which is formed. This would be expected, because the ratio of $GaCl(g)$ to $InCl(g)$ would be independent of HCl partial pressures. No definite trend could be found in our work for the effect of deposition temperature on the composition of the epitaxial layer. Experiments carried out at $750^\circ C$ showed no effect on the composition. This was not surprising since the temperature coefficient of the compositional ratio of GaAs/InAs is very small (11). Kordos *et al.* (12) reported a 0.1% increase in gallium content of the ternary per degree.

The average energy of activation for the data presented in Table I is 170 kJ/mole. Activation energies of the formation of the epitaxial layers were obtained from Arrhenius plots of growth rates vs. reciprocal of the deposition temperatures. A value of 180 kJ/mol was found for the energy of activation for $Ga_{0.53}In_{0.47}As$ prepared from a 12.3 m/o Ga alloy. This value is in close agreement with the value of 44 kcal/mol (184 kJ/mol) reported by Hyder *et al.* (20). These authors used the VPE-hydride technique with separate metal sources.

Table I. Growth rates of $Ga_xIn_{1-x}As$ formed from various alloy compositions at two deposition temperatures. HCl partial pressure = 233 Pa, AsH_3 partial pressure = 1013 Pa, and H_2 flow rate = 980 cm^3/min . Source temp. = $800^\circ C$, mixing temp. = $850^\circ C$, and deposition temp. = 700° and $725^\circ C$.

Alloy composition (m/o Ga)	$Ga_xIn_{1-x}As$	Growth rate at $700^\circ C$ (μ/min)	Growth rate at $725^\circ C$ (μ/min)
15.6	$Ga_{0.58}In_{0.42}As$	0.08	0.13
12.3	$Ga_{0.53}In_{0.47}As$	0.08	0.14

Table II. Carrier concentrations (n) and mobilities (μ) of various ternaries at room temperature

Ternary	n (cm ⁻³)	μ (cm ² /V-s)
Ga _{0.56} In _{0.41} As	2.6×10^{15}	3982
Ga _{0.52} In _{0.48} As	4.4×10^{15}	4164
Ga _{0.51} In _{0.49} As	2.0×10^{15}	6601
Ga _{0.45} In _{0.55} As	2.4×10^{15}	5947
Ga _{0.41} In _{0.59} As	5.6×10^{15}	3064
Ga _{0.41} In _{0.59} As	3.4×10^{15}	7204
Ga _{0.40} In _{0.60} As	5.8×10^{15}	4991
Ga _{0.39} In _{0.61} As	8.4×10^{15}	3722

The carrier concentrations (n) and mobilities (μ) were determined for a series of samples and are reported in Table II. The results represent the average of a number of determinations for many of the ternaries. The carrier concentrations all fall in the vicinity of 4.0×10^{15} cm⁻³, while the mobilities range 3064-7204 cm²/V-s. A plot of the mobility vs. layer composition exhibits a curve with the appearance of two maxima. Whiteley and Ghandhi (21) reported a similar-type plot with less pronounced maxima and observed their highest mobility with a layer composition corresponding to Ga_{0.42}In_{0.58}As. The best values obtained in the present study for n and μ were 2.8×10^{15} cm⁻³ and 8852 cm²/V-s, respectively, for a sample whose composition was Ga_{0.41}In_{0.59}As. These higher mobilities when In > 0.53 have been attributed to less dislocation formation in layers under compressive stress (22). The present results compare favorably to the values previously reported: Kordos *et al.* (12) reported a value of 4000 cm²/V-s for the mobility for the Ga_{0.41}In_{0.59}As. Towe (23, 24) obtained a value of 9400 cm²/V-s for the mobility with a carrier concentration of 6.4×10^{15} cm⁻³ at room temperature for the composition Ga_{0.47}In_{0.53}As. Towe prepared the ternary with the VPE-hydride technique using two metal sources. Cheng and Cho (3) prepared Ga_{0.47}In_{0.53}As (Si-doped) by the MBE method and reported values of $\mu = 8500$ cm²/V-s and $n = 1 \times 10^{16}$ cm⁻³ at room temperature. A high value of 13,800 cm²/V-s for the mobility (with $n = 1.9 \times 10^{15}$ cm⁻³) at room temperature has been reported by Oliver and Eastman (6) for LPE prepared Ga_xIn_{1-x}As. The MOCVD technique for the growth of Ga_{0.47}In_{0.53}As used by Whiteley and Ghandhi (21) gave values of 5800 cm²/V-s and mid- 10^{16} cm⁻³ for μ and n at room temperature, respectively. These comparisons show that the system using the alloy source can be used to grow high quality Ga_xIn_{1-x}As epitaxial layers.

Recent analyses of the different techniques to grow epitaxial layers of the III-V compounds have shown that the roles of VPE, MOCVD, and MBE are expected to increase greatly (25) in the future. The present study shows that the VPE-hydride technique can be simplified by the use of an alloy source with no loss in the quality of the epitaxial layers. Further work with this system should give carrier concentrations and mobilities equal to those produced by the LPE technique.

Acknowledgments

The authors gratefully acknowledge the help provided by Jane A. Horrigan in performing x-ray analyses of these samples. Van der Pauw measurements were performed

by Joseph P. Lorenzo and Captain Kenneth J. Soda. Single-crystal InP substrates were grown and polished by Brian S. Ahern. The authors also wish to acknowledge the help and advice obtained from William D. Potter and John K. Kennedy through discussions with them. Finally, the authors wish to thank the team of A. K. Chatterjee, M. M. Faktor, M. H. Lyons, and R. H. Moss and the team of P. Kordos, P. Schumbera, M. Heyen, and P. Balk, both of whom were kind enough to send us preprints of their work on the growth of InGaAs from an alloy source.

Manuscript submitted Nov. 14, 1983; revised manuscript received June 11, 1984. This was paper 344 presented at the San Francisco, California, Meeting of the Society, May 8-13, 1983.

Hot Wall Si-CVD at Reduced Pressures

C. Domínguez,¹ G. Pastor, E. Lora-Tamayo, and E. Domínguez

U.E.I. Microelectrónica, I.E.C. (C.S.I.C.), Madrid, Spain

In this technical note, results are given for silicon deposition in a hot-wall reactor at basic pressures of 10 and 76 torr and a temperature of 1223 K. Various initial gas mixtures were used (SiH_2 , $\text{Cl}_2/\text{HCl}/\text{H}_2$, $\text{SiH}_2\text{Cl}_2/\text{SiHCl}_3/\text{SiCl}_4/\text{HCl}/\text{H}_2$, $\text{SiHCl}_3/\text{H}_2$, and $\text{SiH}_2\text{Cl}_2/\text{H}_2$).

The system used for our experiments consisted of a reaction chamber, a vacuum system, and a gas system. The reaction chamber contained a 100 mm id quartz tube heated by a conventional diffusion furnace. The four heating zones this system provided guaranteed constant temperature over a length of 70 cm (with variations below 0.2%). The temperature profile was measured using a thermocouple (Pt-Pt 10% Rh) located inside the reactor under deposition conditions. The vacuum system consisted of a rotary pump in series with a variable-speed roots blower with a throttle valve. This provided a wide range of working pressures. The pressure was measured using two Baratron MKS pressure gauges, one for high ranges and one for low ranges. Chlorosilanes used for our experiments were SiH_2Cl_2 , SiHCl_3 , and SiCl_4 , as well as HCl and H_2 . Flow was measured and regulated using a mass-flow controller for gases and a vaporizer-type controller for liquid sources. All gases used were electronic-grade pure. For H_2 , a palladium cell purifier was used.

The depositions were made at a maximum flow of 2500 sccm, total pressures of 10 and 76 torr, and a gas temperature of 1223 K. Wacker Chemitronic silicon (100) wafers were placed vertically parallel or perpendicular to the gas flow, and no significant variations in the growth rate were observed.

The experiments were performed taking as a base the results obtained through a model (1) analogous to the one used by Sirtl and Hunt (2) and Van der Putte *et al.* (3). This program calculated the partial pressures of all the components of a gaseous mixture in equilibrium with solid silicon for the Si-H-Cl system. Results were obtained through the solution of a nonlinear system of equations generated by the application of the mass-action law to the formation reactions of the different components, starting from the elements. The pressure, temperature, and Cl/H ratio were used to define the composition of the gaseous phase.

To determine which type of thermodynamic equilibrium existed in the Si-H-Cl system, different series of experiments were performed, based on data provided by the model.

Series A: $\text{SiH}_2\text{Cl}_2/\text{HCl}/\text{H}_2$.—For the first group of experiments, a mixture of SiH_2Cl_2 , HCl, and H_2 was introduced into the system at the appropriate flow, under the equilibrium condition for each Cl/H ratio, and under successive situations of Si supersaturation at normal pressures of 10 and 76 torr. None of the experiments, despite having reached Si supersaturation levels [values above the equilibrium given by the model (1)] of close to 100%, revealed appreciable deposition or significant etching of the wafers. These results did not agree with model (1) for these conditions.

Series B: $\text{SiH}_2\text{Cl}_2/\text{SiHCl}_3/\text{SiCl}_4/\text{HCl}/\text{H}_2$.—These compounds were introduced simultaneously in the reactor in a proportion that anticipated this equilibrium (although the Si supersaturation was gradually increased). The experiments in this case continued to provide negative results.

Series C: $\text{SiH}_2\text{Cl}_2/\text{H}_2$.—Figure 1 shows the silicon growth rate for different SiH_2Cl_2 and H_2 flows (without HCl) at a

total pressure of 10 torr. Growth rates were much higher than those observed when HCl was present.

Series D: $\text{SiHCl}_3/\text{H}_2$.—Figure 2 shows the results of these experiments, together with those of SiH_2Cl_2 and H_2 at 76 torr. We found growth that was different from the series $\text{SiH}_2\text{Cl}_2/\text{H}_2/\text{HCl}$ under the same total pressure, temperature, and Cl/H ratio conditions. The crystalline structure was determined using x-ray diffraction, and polycrystalline silicon was obtained in every case.

It can be deduced from the analysis of prior experiments that, at equal or lower pressures of 76 torr, the growth rate is almost zero in the presence of HCl in the initial mixture and is considerably higher in the absence of HCl. Hence, the introduction of HCl in the initial mixture can be said to cause a drastic decrease of the growth rate.

We found that the growth rate, G , depends on the total flow in equilibrium, C_T^e , and on partial pressures of SiCl_2 , H_2 , P_{SiCl_2} , and P_{H_2} . The dependence can be expressed as

$$G = k(C_T^e)^\beta (P_{\text{SiCl}_2})^\gamma (P_{\text{H}_2})^\delta \quad [1]$$

where e expresses equilibrium values, k is a constant that depends on nucleation, and β , γ , and δ are exponents to be determined. Total flow in the equilibrium can be expressed as

$$C_T^e = C_{\text{SiCl}_2}^e + C_{\text{H}_2}^e \quad [2]$$

where $C_{\text{SiCl}_2}^e$ is equal to the initial dichlorosilane flow because, under experimental conditions, the equilibrium dissociation constant of equation

Fig. 1. Silicon growth rate under hydrogen flows for different dichlorosilane flows at 10 torr and 1223 K.

¹Present address: Department of Inorganic Chemistry, Complutense University, Madrid, Spain.

Fig. 2. Silicon growth rate under a Cl/H ratio for dichlorosilane-hydrogen and trichlorosilane-hydrogen at 76 torr and 1223 K.

is 3.322, and the degree of dissociation, without hydrogen and with it, is about 100%. $C_{H_2}^e$ is therefore

$$C_{H_2}^e = C_{H_2}^i + C_{DCS}^i \quad [4]$$

In other words, it is the sum of the initial hydrogen flows, i , and those obtained from the dissociation of

dichlorosilane as a result of the dissociation reaction [3]. Equation [1] can be expressed as

$$G = k' C_T^{e\beta} \left(\frac{C_{SiCl_2}^e}{C_T^e} \right)^\gamma \left(\frac{C_{H_2}^e}{C_T^e} \right)^\delta \quad [5]$$

where $(C_T^e)^\beta$ reflects diffusion dependence, and $(C_{SiCl_2}^e/C_T^e)^\gamma (C_{H_2}^e/C_T^e)^\delta$ reflects superficial adsorption of $SiCl_2$ and H_2 . The experimental values of the exponents are $\beta = 0.54$, $\gamma = 0.56$, and $\delta = 1$.

In summary, it has been confirmed that, at low pressures, the presence of HCl in the initial mixture produces silicon growth rates that are practically nil or negative for a supersaturation range of 0% to 120%. This result does not agree with the data based on the classic model of calculating the equilibrium for the Si-H-Cl system. In addition, a change in the silicon growth rate has been noted, according to the source of the silicon used in the initial mixture, so that a growth rate three times higher is obtained when SiH_2Cl_2/H_2 mixtures are used instead of $SiHCl_3/H_2$.

Finally, the silicon growth rate has been studied at a pressure of 10 torr and a temperature of 1223 K, with SiH_2Cl_2/H_2 mixtures and an LPCVD system modified in accordance with experimental conditions. The experimental results make it possible to determine the dependence of the silicon growth rate on the total flow and the partial pressures of $SiCl_2$ and H_2 in equilibrium. We have assumed that $SiCl_2$ comes mainly from the thermal decomposition of SiH_2Cl_2 .

Sputter-Etching Planarization for Multilevel Metallization

H. Kotani, H. Yakushiji, H. Harada, K. Tsukamoto, and T. Nishioka
(pp. 645-648, Vol. 130, no. 4)

J. H. Thomas III and J. L. Vossen:¹ We should like to point out that the model employed by the authors for the variation of the sputtering yield with the angle of incidence of the bombarding ions is not applicable as a general model for all materials and bombarding species and energies.

The Sigmund theory² predicts a change in sputtering yield that rises as the angle of incidence increases, peaks, and then falls to zero at glancing incidence. The rate of increase and the angular position of the peak value depend upon the energy of the incident ions, the mass of the incident ion (as compared to the target atoms), and the target material. It has been verified both by computer simulation and experiment that the angle at which the peak sputtering yield occurs is between about 45° and 80°, depending on the conditions and materials involved.³

The authors' finding that the 45° facet angle developed in their experiment should be considered specific to the material being etched (SiO₂) and to the bombarding conditions used (which were not specified), and should not be extrapolated to other materials and bombarding conditions.

H. Kotani, H. Yakushiji, K. Tsukamoto, T. Nishioka,⁴ and H. Harada:⁵ We agree with the comments that the values of our results are specific and are not necessarily applicable to all materials and bombarding conditions. We consider the exact value of the facet angle in our experiments insignificant. It should be emphasized that the sputter etching in our experiment provides smooth surfaces and develops facets with angles of around 45°.

Electrical Properties of Post-Annealed Thin SiO₂ Films

S. S. Cohen

(pp. 929-932, Vol. 130, no. 4)

P. A. Heimann:⁶ The author of this paper does not mention any checks for the presence of sodium, which might be present since the oxidations were done without HCl. In fact, the hysteresis of the C-V curves is in the direction which would be expected for mobile ions in the oxide. He assumes that this hysteresis is due to a layer of SiO at the oxide/silicon interface. However, stoichiometric SiO is not known to exist in the solid phase. The author does not give any reason for expecting that an oxygen-deficient layer (SiO_x) should contain "slow" charge trapping sites.

The author describes a cold trap for removing residual water from the oxygen, but he does not mention whether any other precautions were taken to keep water out. For instance, a double-walled quartz tube is often used to prevent atmospheric moisture from diffusing through the hot fused-silica furnace tube. Irene⁷ has shown that low concentrations of moisture can improve the breakdown voltages of thin oxides. This effect becomes probable for the very long annealing times described in this paper, so it is uncertain whether the improvement seen here is due to the annealing ambient or to trace moisture. This residual moisture could also affect the results of the second oxidation step, even if dry oxygen is being used.

The author might be underestimating the actual breakdown fields by choosing a breakdown definition of 1 μA. It is easy to pass currents much greater than 1 μA through thin oxides by Fowler-Nordheim tunneling without having catastrophic breakdown. The author should use a breakdown criterion that distinguishes between Fowler-Nordheim tunneling and irreversible breakdown.⁸ The breakdown histograms in his Fig. 3-5 probably should show higher breakdown fields.

S. S. Cohen:⁹ The following clarifications are provided to answer the comments made by P. A. Heimann about my paper.

1. Routine bias-temperature stress measurements were made in the course of the investigations to demonstrate that sodium was at a low level of $\approx 10^{10}$ cm⁻². Also, one who carefully reads the paper would notice that a re-oxidation treatment removed the observed hysteresis. Such a treatment is not known as capable of driving sodium out of the oxide film.

⁸P. A. Heimann, *IEEE Trans. Electron Devices*, To be published.

⁹General Electric Company, Corporate Research and Development, Schenectady, New York 12301.

2. The possibility that water molecules made part of our ambient atmosphere was not ignored; it was clearly mentioned in the paper. The effects of these on the breakdown field was also discussed in view of Irene's paper.

3. Like most of the researchers in this field, we are well aware of the ability of thin SiO_2 films to withstand high level tunneling currents without suffering a destructive breakdown.¹⁰ We have, therefore, verified experimentally

that in our case a $1 \mu\text{A}$ current level could only be obtained after an irreversible breakdown of the MOS capacitors under study.

Oxygen Reduction on Ruthenium Electrode Modified by Foreign Metal Adsorbates

R. R. Adžić, N. A. Anastasijević, and Z. M. Dimitrijević¹

Institute of Electrochemistry, ICTM and Center for Multidisciplinary Studies, University of Belgrade, Belgrade, Yugoslavia

Ruthenium is a metal of considerable importance in electrochemical technology, especially in combination with an oxidized Ti substrate as an electrocatalyst for Cl_2 evolution (1). A few studies of oxygen reduction on Ru(2) and RuOx/Ti (3) and RuO₂ (4) electrodes have been reported. Under certain conditions its activity for oxygen reduction is similar to that of the other noble metals (2). The oxidized surface of Ru, which would be encountered at potentials of practical oxygen cathodes, is completely inactive for O₂ reduction (2). This has been confirmed in the present work. Improving electrocatalytic properties of Ru for O₂ reduction appears interesting from both academic and practical viewpoints. In this work we have shown that a completely inactive surface of oxidized Ru can be modified by thallium and lead adsorbates in such a way as to show a pronounced activity for O₂ reduction. Also, these adsorbates catalyze O₂ reduction on the Ru surface which shows a high activity when cycled in the potential range encompassing H adsorption/absorption. The effects are of fundamental interest in developing an understanding of the relation of O₂ electrocatalysis to the surface oxide properties. They could furnish also some information on the properties of ruthenium oxides per se. Considering the importance of Ru as an electrode material these effects seem to have an applicative side.

Ru rod 99.999%, 4 mm diam x 6 mm was supplied by Metal Crystals Ltd, Cambridge, England. It was embedded in a Teflon holder to serve as a rotating electrode and polished in the standard way with a final polishing perfor-

med with 0.3 μm diamond paste. The solution, 0.1 M NaOH, was prepared from triply distilled water and "carbonate free" Barker's NaOH.

Fig. 1 gives a comparison of O₂ reduction on Ru and Ru modified by Tl adsorbate. An oxidized Ru surface, obtained by a repetitive cycling in the potential range (-) 0.7 V < E < 0.1 V does not show any activity for O₂ reduction. Almost identical curves have been obtained in the presence of N₂ or O₂ in this electrolyte. At high rotation rates a small reduction current is observed at the negative potential limit. Upon addition of Tl⁺ into the electrolyte the adatoms of Tl are formed at E = -0.6 V. At more positive potentials the Tl⁺ ions adsorb on the surface oxide layer. These two adsorbates change the properties of the oxide layer sufficiently to make it a good catalyst for O₂ reduction. A similar effect is caused by addition of Pb ions to the electrolyte (Fig. 2).

Fig. 3 shows O₂ reduction on Ru electrode when cycled in the potential range encompassing hydrogen adsorption/absorption. Under these conditions Ru shows a pronounced activity. This is in agreement with the data reported in reference (2). Tl adsorbates cause an enhancement of the reaction rate, causing a shift of half-wave potential by ~0.1 V. Oxygen reduction is strongly influenced by foreign metal adatoms obtained by underpotential deposition. The adatoms of Pb, Tl and Bi catalyze O₂ reduction on Au (5-9) and Pt (10). Besides adatoms, it has been shown that ions of the above metals, interacting with the oxidized layers of Au (6) and Pt (10), also cause a catalytic effect. This has been ascribed to the modification of the oxidized layers of Au and Pt which become better catalysts for O₂ reduction.

Permanent address: Institute of Chemical Power Sources, Belgrade, Yugoslavia.

Key words: oxygen reduction, ruthenium, modified surfaces, adatoms.

Fig. 1. O_2 reduction on Ru and Ru/Tl^{ad} in 0.1 M NaOH and 0.1 M NaOH + 1×10^{-4} M Tl⁺. Sweep rate 50 mVs⁻¹.

Fig. 2. Same as in Fig. 1 but for 1×10^{-5} M Pb²⁺ in 0.1 M NaOH.

Fig. 3. Same as in Fig. 1 but for 1×10^{-5} M Pb²⁺ in 0.1 M NaOH and $E_{cat} = -0.95$ V.

These data show, for the first time, that foreign metal adatoms can modify an oxidized surface completely inactive for O_2 reduction and present further strong evidence of the modification of the oxide layer by ionic adsorption. Further work is in progress to determine the nature of the interaction of the oxidized Ru with foreign metals adsorbates, the extent of modification and kinetics and mechanism of O_2 reduction on such surface.

A New Transition-Metal Penta-Chalcogenide Cathode for Secondary Lithium Cells

S. Okada, H. Ohtsuka, and T. Okada

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki-ken, 319-11, Japan

INTRODUCTION

Low-dimensional van der Waals-bonded materials have been intensively studied for cathodes of secondary batteries based on rechargeable Li intercalation. In particular, transition-metal poly-chalcogenides, MX_n (M: transition-metal, X: chalcogen), have been supplying many candidates by combination of the elements (M,X) and stoichiometry (n). Dichalcogenides, typified by TiS_2 , exhibit relatively deep rechargeability and high rate capability due to the presence of straight Li diffusion pathways (1). On the other hand, higher chalcogenides such as $NbSe_3$ and $NbSe_4$ tend to exhibit highly specific capacities due to the presence of polychalcogen bonds which are reducible for Li intercalation (2).

Here, we report $ZrTe_5$ and $HfTe_5$ cathode properties in MX_5 for the first time. MX_5 ($ZrTe_5$ and $HfTe_5$) is the highest chalcogenide in MX_n and the atomic arrangement induces some expectation for a rechargeable high-capacity cathode material. MX_5 contains both layer and chain structures with the extra " X_2 " atoms linking the " MX_3 " chains into layers (3). These layers are weakly held together by van der Waals type forces. Correspondingly, a single crystal has cleavage properties along the a-c plane (X_2 -layer) with the longest dimension parallel to the a-axis (MX_3 -chain). Furthermore, $ZrTe_5$ and $HfTe_5$ show the lowest resistivity along the a-axis, $\sim 7 \times 10^{-4} \Omega cm$ at room temperature (4), and anisotropy in the a-c plane, $\rho_c / \rho_a = 2 \sim 3$, is quite small compared with that of typical MX_3 , e.g., 16 of $NbSe_3$ (5).

EXPERIMENTAL

MX_5 was synthesized from stoichiometric amounts of 99.9% Zr (99.8% Hf) and 99.999% Te by iodine vapor transport (5 mg per cc of the quartz ampule volume) in a $470 \sim 420^\circ C$ thermal gradient for a month. Most of the material were confirmed by X-ray powder

diffraction analysis as $ZrTe_5$ ($HfTe_5$) with the same lattice parameters given by Furuseth et al (3), that is, $a = 3.9876 \text{ \AA}$, $b = 14.502 \text{ \AA}$ and $c = 13.727 \text{ \AA}$ for $ZrTe_5$, $a = 3.9743 \text{ \AA}$, $b = 14.492 \text{ \AA}$ and $c = 13.730 \text{ \AA}$ for $HfTe_5$.

The cathode pellet (250 mg/cell) was prepared by mixing the sieved MX_5 powder (35 mesh) with carbon powder (Ketjen black) and polytetrafluoroethylene powder in a weight ratio of 78:20:2. The surface area of the cathode pellet in a coin type cell (23 mm diameter, 2 mm thickness) was 2 cm^2 . The Li content in each cell was 200 mAh. The electrolyte, used here, was 1M $LiClO_4$ -propylene carbonate/1,2-dimethoxyethane (1:1 vol%) with a water content of less than 50 ppm. The cell properties were measured galvanostatically and the open circuit voltages (OCV) were determined by discharge at regular intervals (discharging at 0.5 mA/cm^2 for 7 hr and resting for 50 hr). All set-up operations and measurements were carried out in a dry box filled with Ar gas.

RESULTS AND DISCUSSION

Figure 2 shows open circuit voltages and several discharge curves of $ZrTe_5$. Though the cell capacity above 1.5 V gradually decreased (260, 200, 100 and 50 Ah/kg) with an increasing current density (OCV, 0.5, 1.5 and 5 mA/cm^2), there are intrinsic similarities in each profile. In addition, the profiles of $HfTe_5$ agree with those of $ZrTe_5$.

This common $ZrTe_5$ and $HfTe_5$ behavior suggests that the MX_5 structure itself plays an important role in the cell reaction. The first plateau region on the open circuit voltage curve corresponds to 7 Li/ MX_5 (260 Ah/kg- $ZrTe_5$, 230 Ah/kg- $HfTe_5$), compared with 5 Li/ MX_4 (e.g., $NbSe_4$), 3 Li/ MX_3 (e.g., $NbSe_3$) and 1 Li/ MX_2 (e.g., $NbSe_2$) (6). The stoichiometry of Li/ MX_5 is accounted for by reduction of both the chalcogenide and the metal ions as follows;

Key Words: $ZrTe_5$, $HfTe_5$, Secondary Li cell, Intercalation.

Although the cell reaction mechanism beyond 7 Li/MX₅ is not clear, MX₅ cathodes show rechargeability for several cycles at least within this depth. The typical cycling behavior of ZrTe₅ at 1 Li/ZrTe₅ depth and 0.5 mA/cm² rate is given in Fig. 3. In terms of rechargeability, ZrTe₅ and HfTe₅ were also much the same. The cycle number was about 20 times to 2 Li/MX₅, but to 1 Li/MX₅ it exceeded 180 times. Commonly, most higher chalcogenides except NbSe₃ show over 100 cycles within the limits of 1 Li/MX_n. This good rechargeability to 1 Li/MX₅ may be mainly attributed to metal ion reduction/oxidation (M⁴⁺ ⇌ M³⁺) with Li intercalation/deintercalation.

In summary, the cathode properties of MX₅ are shown in Table I, compared with the other types of MX_n. It is worth while noting that the capacity of MX₅ reaches 7 Li/MX₅ for the 1.5 V cutoff, though a rechargeability of over 100 times is so far restricted to 1 Li/MX₅. This result involves a new possibility, that is, if a lighter MX₅ like TiS₅ can be synthesized and reacted with up to 7 Li in the same manner as ZrTe₅ or HfTe₅, the theoretical capacity is estimated to be 900 Ah/kg for TiS₅. Such MX₅ cathode properties are still open to future study.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. A. Yamaji, C. Uemura, M. Kakuchi and A. Shibukawa for their helpful discussion. We are also grateful to Prof. T. Sambongi and Assistant Prof. M. Ido of Hokkaido University for their kind support.

Electrochemical Conversion of CrO₂

D. Fousse, V. Jovancicevic,¹ and F. Tissier

Centre de Recherches du Fer Blanc, 57103 Thionville, France

Despite a number of interesting properties, such as ferromagnetism and "metallic" electrical conductivity ($10^4 \Omega^{-1} \text{cm}^{-1}$), CrO₂ is not well known by the electrochemists. This situation may be explained by relative chemical and electrochemical instability of the oxide and by difficulty in the preparation of the solid electrodes. One can suppose that its oxido-reduction properties (chromium valence IV) and/or metallic character can play a role in the electrocatalysis or in the chromate-passivated films behavior.

In the solid state chemistry, CrO₂ formed by the thermal decomposition of CrO₃ was extensively studied (1 - 3). In particular, the interconversion of CrO₂ to CrOOH and/or Cr₂O₃ was examined as a function of the temperature and is summarized by means of the equation :

The interconversion process was explained by the analogy between a tetragonal structure of CrO₂ and an orthorhombic distortion of rutile structure of CrOOH (2).

Besides, some literature results on the composition of the passive film on chromium (4) and chromate-passivated film on iron (5) allow to design a non-stoichiometric close to CrO₂ and a double layer chromium oxide structure, respectively. Nevertheless, a

1. Present address : Texas A & M University, College Station, Texas 77843

Key words : chromium dioxide, chromium-passivated film, electroconversion.

prevalent model of chromate passivation films is chromium trivalent oxide-hydroxide structure (6 - 8). In XPS spectroscopy, it is fairly difficult to obtain conclusive evidence of CrO₂ presence in the film since this compound is easily reduced to Cr₂O₃ by electron, ion or prolonged X-ray bombardment (9).

As a part of investigation on the composition of the electrolytically chromium coated steel (an industrial packaging material), the electrochemical behavior of CrO₂ in neutral NaH₂PO₄ (pH = 7) solution have been studied in the relation with those of Cr₂O₃ and Cr(OH)₃, using cyclic voltammetry. Considerable attention has been paid on the procedure of preparation of the oxide layers. The specimens were made from pressed (greater than 98 % pure) powder on platinum "soft" substrate to provide a 0.1 mm thin solid layer. The chromium dioxide (CrO₂) was obtained by courtesy of Kodak Pathé France.

The cyclic voltammograms on CrO₂ are shown in Fig. 1. In the region preceding oxygen evolution reaction at 0.35 V/SSE one can observe two characteristic features relative to CrO₂ layer ; an oxido-reduction process at about 0.2 V/SSE (sweep increasing currents) and a reduction process at - 0.2 V/SSE (sweep decreasing current) in the oxide. The "steady state" voltammetric curve obtained after ten sweeps (Fig. 1b) indicated that two steps reversible oxido-reduction reactions take place. No cathodic reduction peak at -0.2 V/SSE means that the transformation of the oxide produced in the course of the potential cycling is stopped. The same voltammogram was obtained with the previously potentiostatically reduced (- 0.2 V/SSE) CrO₂.

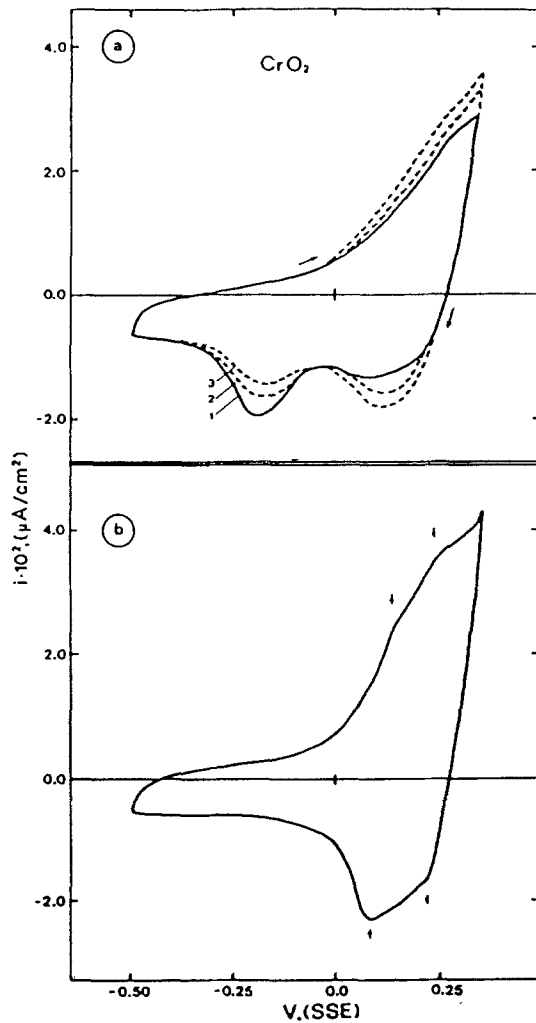

Fig. 1 : Cyclic voltammograms of CrO₂ for three first sweeps (a) and "steady state" curve after ten sweeps (b) ; scan rate = 20 mV/sec.

The double-peak feature of CrO₂ (arrows in Fig. 1b) was examined in relation with the cyclic voltammograms on Cr₂O₃ and Cr(OH)₃ oxides obtained in the same conditions (Fig. 2). Cr₂O₃ shows the same marked less than 0.05 V reversible double-anodic peak (second peak is more reversible than the first one). Conversely, Cr(OH)₃ presents only double layer behavior.

Two steps reversible oxidation of Cr₂O₃ can be assigned to the consecutive oxidation to CrO₂ and CrO₃.

Then the electrochemical conversion (Fig. 1) of CrO₂ can be summarized in terms of the following reactions :

the first one is irreversible reduction of CrO₂ and the second one is a reversible oxido-reduction of formed Cr₂O₃. The chromium dioxide participates in both reactions, as a bulk oxide and an intermediate oxide product, respectively. At the beginning of the cycling of the potential (Fig. 1a), the reduction of CrO₂ is produced at two different potentials separated by 0.35 V. One can assume that this difference is due to the different crystallographic structures of CrO₂.

Fig. 2 : Cyclic voltammograms of Cr₂O₃ (a) and Cr(OH)₃ (b) ; scan rate = 20 mV/sec.

In this paper we give the evidence of the electrochemical stability of CrO₂ and the role that it can play as a component of the chromate passivation film. In the case of chromium coated steel a subsequent anodic oxidation allows to reduce the porosity of the chromium oxide film, more than by ten times (10). The improvement of the passivating properties may be ascribed

to the formation of the high conducting CrO_2 .

Besides, the metallic conductivity of CrO_2 and its electrochemical stability could be used to promote it, for example, as an electrocatalyst for oxygen evolution reaction.

Cation-Vacancy Model for MnO₂

Paul Ruetschi*

Leclanché S. A., 1400 Yverdon, Switzerland

ABSTRACT

A cation-vacancy model for electrochemically active manganese dioxides (γ -MnO₂ and ϵ -MnO₂) is presented. According to this model, the crystal structure, composed of closely packed O²⁻ ions which are octahedrally coordinated to Mn²⁺ ions, the [MnO₆] octahedra sharing edges and corners, contains [Mn] vacancies. Each vacancy is coordinated to, and electrostatically compensated by, four protons. The protons are present in the form of OH⁻ ions, these latter replacing O²⁻ in the lattice, without noticeable change in lattice parameters. Many hitherto unexplained phenomenological and experimental facts, relating to chemical composition (water content), density, electrochemical capacity, proton-transfer rate, electronic conductivity, and electrode potential of MnO₂, can be reconciled, and quantitatively predicted, on the basis of the present theory. In particular, electrochemical reactivity of MnO₂ in battery electrodes is shown to be due to the presence of cation vacancies in the lattice.

The large-scale use of MnO₂ for battery electrodes is continuing and is extending today also to nonaqueous lithium cells. Annual worldwide consumption for battery electrodes is now estimated at 400,000 tons. Although progress has been made in the characterization of MnO₂, with respect to structure and electrochemical behavior (1, 2), some aspects, relating in particular to the property called "electrochemical reactivity," remain unexplained. The reasons why certain forms of MnO₂, for instance, the γ and ϵ modifications, are highly reactive and may undergo electrochemical reduction at high rates, while other forms, for instance, the β modification, are relatively inactive, are still not fully understood (3).

The fact that the electrochemically active forms (γ - and ϵ -MnO₂) always contain in the crystal structure a considerable amount (typically 4% per weight) of "structural," "chemically bonded," or "combined" water, has been recognized for a long time (4-11). This structural water appears to be distributed over a wide range of "absorption energies" and can be removed progressively by heating to increasing temperatures in the range from about 100° to 400°C (12-17). It can thus be clearly distinguished from water which is physically adsorbed on the surface of the crystallites and which may be desorbed by applying vacuum at room temperature, or by heating without vacuum to just above 100°C. Chemisorbed water at the surface (surface OH⁻ groups) should have a binding energy approaching that of the structural bulk water. A large portion of the structural water may be removed by heating without apparent change in the x-ray powder diffraction patterns (18, 19). The presence of structural water influences not only electrochemical reactivity (4-9, 11, 20, 21), but also other properties, such as density (22, 23), electronic conductivity (14, 21, 24), and electrode potential (20, 25). However, to date, there is no clear understanding of the relation between water content and these properties.

The structural water in γ - and ϵ -MnO₂ modifications has been thought to be present, at least partially, in the form of OH⁻ ions, replacing O²⁻ in the lattice (7, 8, 19, 26-29). This requires, for charge balance, an equivalent number of Mn³⁺, replacing Mn²⁺ (30-34). However, there is, in total, always more structural water present than could be accounted for by the average state of oxidation (or val-

ency) of manganese. Thus, additional water, in the form of "interstitial" H₂O, or surface-adsorbed H₂O in a "high density state," or H₂O in "microcrevices" or "closed pores," was postulated. These explanations are unsatisfactory for the following reasons: "interstitial" water is not compatible with the accepted lattice structure of γ - or ϵ -MnO₂, in view of the dense packing of O²⁻ ions in these structures. The problem of how to locate interstitial H₂O has been struggled with by Freund *et al.* (35) and Parida *et al.* (36). Surface-adsorbed H₂O, or H₂O in microcrevices or closed pores, would not explain its influence on the physical bulk properties mentioned above. Chemisorbed H₂O at the surface, (as calculated from the BET area) could not account for the total quantity of structural water observed.

Koshiba and Nishizawa (37) proposed that a large number of "lattice dislocations" were present in γ -MnO₂, as well as structurally bonded water, associated with Mn²⁺ ions. The high electrochemical reactivity of γ -MnO₂ was attributed to the presence of such defects. However, the presence of Mn²⁺ in the lattice is unlikely, in view of its large size (Table I).

Recently, Burns (38, 39) suggested that naturally occurring and synthetic γ -MnO₂ phases, used in batteries, might contain lattice defects such as "stacking faults, dislocations, chain defects, multidimensional tunnels (for instance T(3, n) tunnels) and other irregular voids," and that "H₂O, impurity ions, etc., may be accommodated in such lattice defects." He also suggested that such defects might account for the high water content and the high electrochemical reactivity of γ -MnO₂. However, also relatively well-crystallized γ -MnO₂, in which the presence of

Table I. Ionic radii in MnO₂

* Electrochemical Society Active Member.

large tunnels or voids has not been proven, shows a relatively high structural water content and a high electrochemical reactivity.

In a recent study, Turner and Buseck (40), using structure imaging by high resolution transmission electron microscopy (HRTEM) have demonstrated that naturally occurring nsutite (γ - MnO_2) contains T(1, 3) tunnels, as well as other structural defects and isolated larger voids or tunnels. However, it must be pointed out that T(1, 3) tunnels are too small to contain H_2O molecules and that larger voids or tunnels might not be present in sufficient number to account for the total quantity of structural water.

In view of the above facts, the presently accepted formula for MnO_2 (30-34)

is unsatisfactory. It distinguishes between water in form of "acid" OH^- groups, associated with Mn^{3+} ions, and "neutral" water molecules, but gives no picture or explanation as to the physical state of the m "neutral" water molecules.

The above expression is formally equivalent to

or

where n is the "degree of oxidation" ($2n$ = average valency) and where $(2 - n + m)$ represents the total structural water.

Preisler (14) reports for electrochemically deposited, fibrous ϵ - MnO_2 a composition (after drying for 2h at 120°C) of

This corresponds to $n = 1.96$ and $m = 0.19$. As Preisler points out, the value of n can only account for $(4 - 2n) = 0.08$ OH^- , that is, 0.04 moles of H_2O per mole of Mn, while an additional quantity of $m = 0.19$ moles of H_2O per mole of Mn would have to be present "interstitially." This is indeed not realistic from the crystallographic point of view, and a new explanation must, therefore, be found as to how this water can be present.

Lattice-Vacancy Model of γ - or ϵ - MnO_2

In this paper, I present a cation-vacancy model for MnO_2 . This model removes the previous lack of understanding concerning the state and quantity of structural water. The possibility, that cation vacancies could be present in MnO_2 , has been mentioned previously (3, 41), but, up to now, a complete and self-consistent vacancy model has not been developed.

My model is based on the following considerations.

1. Each manganese ion in the MnO_2 structure is octahedrally coordinated to six nearest oxygen ions, and each oxygen ion is coordinated to three nearest manganese ions. The (slightly distorted) MnO_6 octahedra are arranged in the crystal as to share edges and corners. Since O^{2-} ions are much larger than Mn^{4+} ions (Table I), the lattice resembles a dense packing (nearly hexagonally close-packed) of O^{2-} ions, with the small Mn^{4+} ions more or less orderly arranged in edge-shared MnO_6 octahedra-chains between O^{2-} layers (3, 19, 39, 42). This is the accepted crystallographic description.

2. A fraction x of Mn^{4+} ions is missing in the Mn^{4+} sublattice. Each empty Mn^{4+} site is, for charge compensation, coordinated to four protons, the latter being present in form of four OH^- ions. The OH^- ions replace O^{2-} in the lattice without significant volume change of the unit cell, the ionic radii of O^{2-} and OH^- being very similar (43). Normal unit cell parameters are thus maintained.

3. A fraction y of the Mn^{4+} ions are replaced by Mn^{3+} . This fraction determines the degree of oxidation (average valency) of the manganese ions. For each Mn^{3+} present, one proton is introduced for charge compensation. These

protons form further OH^- ions, replacing O^{2-} in the lattice. Substitution of Mn^{4+} by Mn^{3+} leads to lattice distortion (lattice expansion) and an increase in the volume requirement of the unit cell, as observed experimentally during electrochemical or chemical reduction (44-48).

4. The lattice is thus composed of O^{2-} , OH^- , Mn^{4+} , and Mn^{3+} ions, and Mn vacancies. All the structural water is present in form of OH^- ions, associated with either Mn vacancies, or Mn^{3+} ions. The vacancies are immobile. They will localize protons in surrounding OH^- groups. These protons can jump to adjacent O^{2-} sites, if they are being replaced at their previous location by introduction of further protons, as Mn^{4+} are being reduced to Mn^{3+} . Protons associated with Mn^{3+} are mobile.

5. The presence of Mn^{2+} in the lattice is considered unlikely on thermodynamic (49), as well as sterical grounds (46, 50).

6. Surface-chemisorbed H_2O is considered to be present in form of surface OH^- groups. The surface is treated as a "continuous layer of Mn^{4+} vacancies," two "surface vacancies" being equivalent to one "interior vacancy" (regarding structural water).

7. Electronic conductivity arises from delocalized electrons, tunneling or hopping from one Mn^{4+} orbital to the next. Vacancies increase the tunneling distance.

In the following, I shall present the phenomenological predictions, which can be derived from this model, with respect to the chemical composition (water content), density, theoretical (maximum) electrochemical capacity, proton transfer rate, electronic conductivity, and electrode potential of electrochemically active (γ - and ϵ -) MnO_2 .

Chemical Composition (Water Content)

The proposed cation vacancy model leads to the following formula for manganese dioxide

The parameters x (fraction of vacancies) and y (fraction of Mn^{3+} ions) in expression [1] are related to the parameters n and m of the formula given in the above by the set of equations

$$x = \frac{m}{2 + m} \quad [2]$$

$$y = \frac{4(2 - n)}{2 + m} \quad [3]$$

and

$$n = \frac{4(1 - x) - y}{2(1 - x)} \quad [4]$$

$$m = \frac{2x}{1 - x} \quad [5]$$

Thus, the example cited above, a composition $\text{MnO}_{1.96} \cdot 0.23\text{H}_2\text{O}$ (structural water content 4.58%) corresponds to

$$x = 0.087$$

and

$$y = 0.073$$

This example illustrates how surprisingly large quantities of structural water may be explained by seemingly small vacancy fractions x . Preisler reported this composition to be typical for ϵ - MnO_2 (FEMD). Our interpretation implies that about one out of 12 Mn^{4+} would, for this material, be missing in the lattice (or would be situated at the surface), and about one out of 14 Mn^{4+} ions would be substituted by Mn^{3+} . For γ - MnO_2 (EMD and especially CMD), the structural water content, and thus the vacancy fraction x , would typically be somewhat smaller, but of the same order. In comparing expression [1] with other chemical formula for manganese dioxide, one has to keep in mind that expression [1] contains in total only $(1 - x)$ moles of manganese, while in the past the chemical composition was normally expressed per one mole of total manganese.

Using Eq. [1], the total structural water content may be expressed by

$$\% \text{H}_2\text{O} = \frac{18.016(4x + y)}{2 \text{ MW}}$$

where MW is the molecular weight of formula [1]. (MW depends on x and y .)

The above expression is plotted, for the cases $y = 0$ and $y = 0.10$ as a function of x , in Fig. 1.

A structural water content of 4%, for instance, would imply at $y = 0$ a vacancy fraction of $x = 0.092$, and at $y = 0.1$ a vacancy fraction of $x = 0.068$. From Fig. 1, one derives for $y = 0$ and $x < 0.1$ the following approximately linear relation between weight percent (w/o) H₂O and vacancy fraction x

$$\text{w/o H}_2\text{O} \approx 44x \quad [6]$$

Density

The crystallographic unit cell parameters a_0 , b_0 , and c_0 , of different MnO₂ modifications, and those of α -MnOOH, are listed in Table II.¹ Also shown in this table are unit cell volumes (v), stoichiometric numbers per unit cell volume (z), and x-ray densities (d) calculated with these unit cell parameters.

According to the present model, introduction of vacancies into the Mn⁴⁺ sublattice, and associated substitution of 4 O²⁻ by 4 OH⁻, does not lead to a noticeable change in lattice parameters. However, owing to missing Mn⁴⁺ ions, the density will decrease with increasing vacancy fraction x . The decrease of density with x may be calculated with

$$d = \frac{\text{MW}}{V}$$

where MW is the molecular weight of formula [1] and where V is its molecular volume.

For $y = 0$, the density varies then with x as follows

$$d = \frac{54.94(1 - x) + 32 + 1.008(4x)}{V_0}$$

This relation is plotted in Fig. 2 for $V_0 = 30.2 \text{ \AA}^3 \cdot 6.02 \cdot 10^{23} = 18.18 \text{ cm}^3$, corresponding to a density of 4.78 g/cm^3 at $x = 0$ (x-ray density of ramsdellite or ϵ -MnO₂, see Table II), and for $V_0 = (1/4) 118.3 \text{ \AA}^3 \cdot 6.02 \cdot 10^{23} = 17.805 \text{ cm}^3$, corresponding to a density of 4.88 g/cm^3 at $x = 0$ (x-ray density of γ -MnO₂, see Table II).

When calculating densities for $y > 0$, one must take into account lattice expansion, resulting from replacement of Mn⁴⁺ by the larger Mn³⁺ ions. The corresponding volume increase amounts empirically (44-48) to about $V(y) = V_0 + 3y$. For $y = 0.1$, the correction to V_0 is only about 1.7%, however, as illustrated in Fig. 2, it leads already to a measurable difference in density.

Combining the results of Fig. 1 and 2, one deduces readily a theoretical relation between water content and density, as presented in Fig. 3. This relation may be experimentally verified. For a structural water content of 4%, for instance, the theory predicts at $y = 0$ a density of 4.52 g/cm^3 for the ϵ -MnO₂ structure, and a density of 4.62 g/cm^3 for the γ -MnO₂ structure. Interestingly, the same values are calculated for $y = 0.1$. The calculated values are in excellent agreement with experimental pycnometric data (22, 23).

When removing structural water by means of heating, the density will increase, since \square vacancies would tend to "heal out" by cation self-diffusion (Mn⁴⁺ sublattice rearrangement). Protons will then be moving from the interior to the surface, where they would be leaving the crystal in form of H₂O, after combining with surplus O²⁻. It should be possible to follow experimentally the annealing of vacancies by HRTEM techniques (40).

Thermal treatment could, theoretically, lead also to the formation of \square vacancies in the O²⁻ sublattice

Fig. 2. Density as a function of Mn⁴⁺ vacancy fraction x for the ϵ - and γ -MnO₂ structures.

Fig. 3. Density as a function of structural water content

However, this process is likely to occur only at the surface of the crystal. Its influence on density would probably in any case be masked by the density increase due to cation (vacancy) diffusion.

Theoretical (Maximum) Electrochemical Capacity

The theoretical (maximum) electrochemical capacity deliverable per unit weight (C_w), or unit volume (C_v), calculated on the basis of expression [1] for a solid-state, one-electron reduction process [7], where (aq) and (c) designate "aqueous solution" and "crystalline" phase, respectively

is given by

$$C_w = \frac{(1-x-y) \cdot 26.80}{\text{MW}} \quad (\text{Ah/g})$$

and

$$C_v = C_w \cdot d \quad (\text{Ah/cm}^3)$$

C_w and C_v designate the capacity per unit of initial weight and per unit of initial volume of active material present.

The calculated values are plotted for $y = 0$ as a function of x in Fig. 4. This figure serves to illustrate that the theoretical maximum capacity must decrease with increasing x , that is, with increasing water content. This is a fact confirmed by practical experience. "Hydrous oxides," for example, containing up to 10% water, show notoriously poor capacity per unit weight or volume. In view of Fig. 2, the capacity is also predicted to decrease with decreasing density, which is also confirmed experimentally (51). This conclusion applies, of course, only when comparing MnO_2 materials containing no (or the same quantity) of heavy foreign ions. Figure 4 also shows that the capacity per unit volume decreases with increasing water content much more drastically than the capacity per unit weight.

While a high percentage of structural water is thus undesirable as regards to capacity, a certain amount of structural water is a necessity for a fast proton transfer, as discussed in the next section. In practice, most applications require that the capacity must be deliverable within a relatively short time. This is only possible if the proton-transfer rate is high.

Proton-Transfer Rate

The reduction of γ - or ϵ -manganese dioxide, according to reaction [7], involves the introduction of protons into the crystal lattice. This process occurs in a single phase, whereby the lattice expands with increasing degree of reduction (44-48). The "diffusion coefficient" for protons in MnO_2 has been reported to have a value of about

$$D = 6 \cdot 10^{-10} \text{ cm}^2/\text{s} \quad (52)$$

Fig. 4. Theoretical electrochemical capacity per unit weight (Ah/g) and per unit volume (Ah/cm³) as a function of Mn⁴⁺ vacancy fraction for $y = 0$ (undischarged state).

According to the present model, the OH^- ions incorporated into the lattice as a consequence of cation vacancies, will act as donors for and provide thus an initial concentration of protons for solid-state proton transfer. In terms of reaction-rate theory, one may then express the probability of proton transfer by

$$P_t = \nu \cdot [\text{OH}^-] \cdot [\text{O}^{2-}]$$

where ν is a "jump frequency," depending exponentially on temperature

$$\nu = \nu_0 \cdot \exp(-A_p/kT)$$

and where $[\text{OH}^-]$ represents the "concentration" of proton-occupied sites, and $[\text{O}^{2-}]$ the "concentration" of available, suitable empty sites for proton transfer.

If the $[\text{OH}^-]$ and $[\text{O}^{2-}]$ concentrations are expressed as number of ions per molecular volume, one derives in view of reaction [1]

$$[\text{O}^{2-}] = 2 - 4x - y \quad [8]$$

and

$$[\text{OH}^-] = 4x + y \quad [9]$$

The expression

$$[\text{OH}^-] \cdot [\text{O}^{2-}] = (4x + y) \cdot (2 - 4x - y)$$

is plotted in Fig. 5 as a function of x , for the condition $y = 0$. This figure serves to illustrate that the electrochemical reactivity of (undischarged) manganese dioxide increases with x , that is, with structural water content. The curve of Fig. 5, reaches a maximum at $x = 0.25$ and would decrease thereafter to zero at $x = 0.5$, as all the O^{2-} sites are occupied, even at $y = 0$.

In formulating the above expressions, it has been (temporarily) assumed that all the O^{2-} sites are sterically equivalent and equally accessible to protons during the reduction process. It has further been (boldly) assumed that all the protons, that is those in the OH^- ions coordinated to Mn vacancies, as well as those in the OH^- ions associated with Mn^{3+} ions, behave kinetically in an equivalent manner. This is not necessarily the case. For $y > 0$, the above expressions are thus, at best, a first approximation, if applicable at all.

It should also be remembered that, in total, not more than one proton per Mn^{4+} ion, that is not more than $(1-x)$ protons, can be taken up during single-phase reduction. In order to derive a measure for the overall rate of reduction, the rate of proton transfer would have to be multiplied with the fraction of Mn^{4+} ions present, that is with $(1-x-y)/(1-x)$.

The proton-transfer process shall now be detailed for the case of the ramsdellite structure. Two types of O^{2-} sites must here be distinguished: the "planar" and the "pyramidal" configuration, with respect to the three next-neighbor Mn^{4+} ions (53). It has been suggested by Maskell *et al.* (54) that only the "pyramidal" O^{2-} are suitable sites for proton-uptake. Protons introduced during reduction would thus occupy pyramidal sites only. The lat-

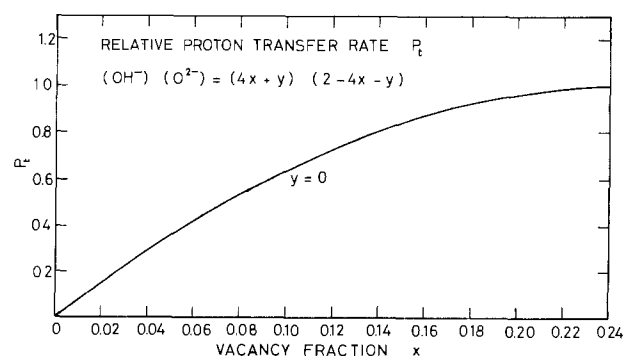

Fig. 5. Relative proton transfer rate in MnO_2 as a function of Mn⁴⁺ vacancy fraction x .

ter are arranged in strings along the [100] direction, along which the protons could be thought to move freely (direction vertical to the (001) plane).

However, protons present as a result of $\overline{\text{Mn}}$ vacancies, must occupy both, planar and pyramidal sites.

Depending on the spacial distribution of the four OH⁻ ions, present around a vacancy, either 1, 2, or 3 OH⁻ ions must occupy a pyramidal site. The remaining, free, accessible pyramidal sites are thus given by

$$[\text{O}^{2-}]_p = 1 - px - y \quad [10]$$

whereby p can assume values of 1, 2, or 3.

The number of pyramidal occupied sites becomes

$$[\text{OH}^-]_p = px + y \quad [11]$$

and the number of "planar" occupied sites is

$$[\text{OH}^-]_{pl} = (4 - p)x \quad [12]$$

These latter might play kinetically a particularly important role as proton "bridges," connecting neighboring strings of pyramidal occupied sites.

The proton transfer rate could thus be visualized as being proportional to

$$[\text{OH}^-]_{pl} \cdot [\text{OH}^-]_p \cdot [\text{O}^{2-}]_p \\ = (4 - p)x \cdot (px + y) \cdot (1 - px - y)$$

This expression is plotted in Fig. 6 as a function of x , for $p = 2$, and for several values of y as parameter. It is of importance to point out that for the case $p > 1$, the rate of proton transfer falls to zero before all the Mn⁴⁺ ions are reduced, because of the lack of free suitable O²⁻ sites. This might reduce the electrochemical capacity to a value smaller than that calculated theoretically (see previous section) on the basis of the Mn⁴⁺ ions present.

The cation vacancy model as developed in this paper sheds a completely new light on the property called "electrochemical reactivity." The reason, why γ -MnO₂ and ϵ -MnO₂ are electrochemically much more active than β -MnO₂ is shown to be due to the presence of $\overline{\text{Mn}}$ vacancies and a corresponding water content, providing an initial starting concentration of protons for the transfer process. In contrast, β -MnO₂ contains almost no vacancies and thus very little structural water. Electrochemical (and chemical) reactivity arises primarily from the presence of (proton-compensated) $\overline{\text{Mn}}$ vacancies, and not primarily from a special lattice structure, e.g., a pyrolusite-ramsdellite intergrowth lattice as assumed previously. This latter might, however, be particularly apt to contain and might possibly even be stable only in presence of vacancies.

Since the surface may be regarded as a "layer of vacancies," β -MnO₂ should also become reducible in a single phase, at least to some extent, if the surface is sufficiently large and if the crystallites are correspondingly small, e.g., only a few atomic layers thick.

Lattice expansion will certainly occur with less strain next to vacancies. In fact, Mn³⁺ present initially (in

Fig. 6. Relative proton transfer rate as a function of Mn⁴⁺ vacancy fraction x for the special case of a ramsdellite structure.

nonreduced MnO₂) might in general be located adjacent to a vacancy (or in the surface). This is also borne out by the similarity in the values for x and y in the example discussed earlier.

The discontinuity in the lattice expansion, and in the distortion of MnO₆ octahedra, observed during reduction (46-48), at degree of reduction corresponding to about MnO_{1.75}, may reflect the greater strain required, as all the Mn⁴⁺ next to vacancies (or surfaces) are already reduced to Mn³⁺.

Electronic Conductivity

In this section, it will be shown how the experimental observation concerning the decrease of electronic conductivity with increase of structural water content (14, 21, 24) can be explained on the basis of the present vacancy model.

Manganese dioxide is an n-type semiconductor, with relatively high charge carrier concentration. For β -MnO₂, Euler *et al.* (55) reported a carrier concentration of $n = 10^{17} \text{ cm}^{-3}$ and Preisler (14) reported for γ -MnO₂ a value of $n = 1.5 \cdot 10^{16} \text{ cm}^{-3}$.

For electrochemical reduction, an electron, as well as a proton, must be available at the reaction site. In order to minimize ohmic voltage drops, and in order to achieve a discharge profile as uniform as possible, a high electronic conductivity is of advantage. According to a suggestion of Preisler (14), the probability of electron tunneling, and thus electronic conductivity σ , depends exponentially on the average electron tunneling distance, a_t , from one manganese orbital to another

$$\sigma = \sigma_0 \exp(-2\kappa a_t) \quad [13]$$

where σ_0 and κ are constants and a_t is the average tunneling distance (length of potential energy barrier). In a lattice containing $\overline{\text{Mn}}$ vacancies, the average, effective tunneling distance a_t will increase with increasing vacancy fraction x according to

$$a_t = a_0 \cdot \frac{1}{1-x} = a_0 (1 + x + x^2 + \dots) \quad [14]$$

For small values of x , one derives with Eq. [13] and [14]

$$\frac{d(\ln \sigma)}{dx} = -2\kappa \cdot a_0 \quad [15]$$

Since x is proportional to the water content, expression [6], Eq. [15] expresses the linear relation between logarithm of conductivity and water content, observed experimentally (14).

The relation

$$\frac{d(\log \sigma)}{d(\% \text{H}_2\text{O})} = \frac{-2\kappa}{44 \cdot 2.3} \cdot a_0 \quad [15a]$$

is plotted in Fig. 7, using the experimental results of Preisler (14).

Fig. 7. Logarithm of electronic conductivity of MnO₂ as a function of structural water content. From the slope one calculates, with $a_0 = 2.85 \text{ \AA}$, from Eq. [15a] $\kappa = 8.9 \text{ \AA}^{-1}$ and from Eq. [18a] $\theta = 0.45 \text{ eV \AA}^{-1}$, or $10.3 \text{ kcal \AA}^{-1}$.

It is interesting to note that an equivalent expression to Eq. [15] and [15a] can also be derived from the Arrhenius relation for electronic conductivity (21)

$$\sigma = \sigma_0 \cdot \exp(-A_e/kT) \quad [16]$$

when assuming that the activation energy A_e depends linearly on the average transfer distance a_t for the electrons between neighboring manganese electronic orbitals

$$A_e = A_0 + \theta (a_t - a_0) \quad [17]$$

where θ is a factor relating activation energy to transfer distance and where a_0 is the transfer distance at $x = 0$. Then, with Eq. [14], [16], and [17], one has, for small values of x

$$\frac{d(\ln \sigma)}{dx} = -\frac{\theta}{kT} \cdot a_0 \quad [18]$$

and with Eq. [6]

$$\frac{d(\log \sigma)}{d(\%H_2O)} \approx \frac{-\theta}{kT \cdot 44 \cdot 2.3} \cdot a_0 \quad [18a]$$

It should also be pointed out that similar reasoning could be used to explain the drastic decrease of electronic conductivity with increasing y , that is with increasing degree of reduction. As Mn^{3+} ions are substituted for Mn^{4+} ions, the average tunneling distance a_t will increase. The density of (delocalized) electrons is presumably very low around Mn^{3+} ions. These latter might thus constitute "voids" for the conduction electrons and one would have, analogous with Eq. [14]

$$a_t = a_0 \cdot \frac{1}{1-x-y} \quad [19]$$

When introducing this expression into Eq. [13], one deduces a sharp decrease of conductivity with increasing y , that is increasing degree of reduction. At $y \rightarrow (1-x)$ the resistivity would, according to Eq. [19], reach infinity.

Electrode Potential

In the following, it shall first be discussed, how the free enthalpy of formation of a cation-deficient, electrochemically active (γ - or ϵ -) MnO_2 depends on the vacancy fraction x (and thus on the water content).

Let us consider a vacancy-formation process as follows

The free enthalpy of this reaction, ΔG_v , corresponds to the energy required to form 1 mol of \overline{Mn} vacancies under uptake of 2 mol of water.

When transforming 1 mol of vacancy-free (and water-free) MnO_2 into a cation-deficient oxide, having a vacancy fraction x , the above process would have to occur $x/(1-x)$ times

This transformation can be visualized as removal of a fraction x of Mn^{4+} ions from the interior of the crystal lattice, transport of the removed ions to the surface, and formation thereon of a corresponding quantity of $x/(1-x)$ mol of additional (defective) manganese dioxide, whereby the required protons and oxygen ions are stemming from the water taken up in the reaction.

When considering now vacancy formation in an oxide containing also Mn^{3+} ions, that is in an oxide having an average valency of

$$\frac{4(1-x-y) + 3y}{1-x} = \frac{4(1-x)-y}{1-x}$$

the free enthalpy of vacancy formation is a function of y . (Arguments that ΔG_v depends approximately linearly on y will be presented in a future publication.)

The free enthalpy of vacancy formation determines the electrode potential difference between a vacancy-free oxide and a cation-deficient oxide. If a single-phase, solid-state electrochemical reduction according to reaction [7] is potential determining (neutral or alkaline solutions), the electrode potential difference is obtained by differentiating the free enthalpy of vacancy formation with respect to y (54). One derives then, at constant y , the following dependence of the electrode potential on x

$$E_\gamma = E_{\gamma_0} - \frac{x}{1-x} \cdot \frac{1}{F} \cdot \frac{d(\Delta G_v)}{dy} \quad [20]$$

For small values of x , the electrode potential is then shown to depend linearly on x . In view of Fig. 1 and Eq. [6], the electrode potential is predicted to increase linearly with water content [$d(\Delta G_v)/dy$ being negative]

$$E_\gamma \approx E_{\gamma_0} - \frac{\%H_2O}{44} \cdot \frac{1}{F} \cdot \frac{d(\Delta G_v)}{dy} \quad [21]$$

This prediction is in agreement with the experimental results of Preisler (25).

In order to examine the question of how the electrode potential depends on y (the degree of reduction), it is helpful to depict the number of the various species present in the crystal lattice as a function of y . This is done in Fig. 8 for the case of $x = 0.1$.

Applying now methods of statistical thermodynamics, as suggested recently by Atlung *et al.* (56) and Maskell *et al.* (54, 57), and limiting the discussion to the configurational partition function, the cation-vacancy model leads to the following situation: at a fixed vacancy fraction x , there are in total $(1-x)$ Mn^{4+} sites available for distributing therein y Mn^{3+} ions (in effect distributing y electrons to transform Mn^{4+} to Mn^{3+} under lattice expansion). For each configuration, y protons can be distributed independently into $(2-4x)$ O^{2-} sites, if, according to Eq. [8], all the O^{2-} sites are equally available, or, on the other hand, into $(1-px-y)$ O^{2-} sites, if, according to Eq. [10], only the pyramidal oxygen sites are available for proton uptake during reduction. Neglecting interaction

Fig. 8. Variation of $[Mn^{4+}]$, $[Mn^{3+}]$, $[O^{2-}]$, and $[OH^-]$ as a function of y , that is, as a function of discharge, for the case $x = 0.1$.

Fig. 9. Variation of electrode potential with y , (degree of reduction) according to Eq. [22] and [23], for $p = 2$ and $x = 0.08$.

terms, the following expressions are then derived for the electrode potential

$$E_{\gamma} = E'_{\gamma_0} + \frac{RT}{F} \ln \frac{1-x-y}{y} + \frac{RT}{F} \ln \frac{2-4x-y}{y} \quad [22]$$

or, respectively

$$E_{\gamma} = E''_{\gamma_0} + \frac{RT}{F} \ln \frac{1-x-y}{y} + \frac{RT}{F} \ln \frac{1-px-y}{y} \quad [23]$$

These equations, in which y may vary from 0 to $(1-x)$, or from 0 to $(1-px)$, respectively, are plotted in Fig. 9. These equations can fit the experimental results concerning the dependence of voltage on degree of reduction, as reported, for instance, by Kozawa (58), Maskell *et al.* (57), or Ohzuku and Hirai (59). A possible refinement of Eq. [22] or [23], including interaction energies, will be discussed in a future paper.

Conclusions

The cation-vacancy model for MnO₂, as presented in this paper, is able to quantitatively explain for the first time many aspects of MnO₂ electrochemistry, which have puzzled investigators in the past. In particular, the model predicts correctly the following observations regarding electrochemically active (γ - or ϵ -) MnO₂: (i) quantity of structural water, (ii) decrease of density with structural water content, (iii) decrease of theoretical electrochemical capacity (Ah/g and Ah/cm³) with structural water content, (iv) increase in proton-transfer rate (electrochemical reactivity) with structural water content, (v) decrease of electronic conductivity with structural water content, (vi) increase of electrode potential with structural water content, and (vii) dependence of electrode potential on degree of reduction.

The theory presented in this paper constitutes a breakthrough in our understanding of the physical, chemical, and electrochemical behavior of electrochemically active MnO₂. It will also have implications for the interpretation of the behavior of other oxide electrodes, for instance, PbO₂ and NiOOH.

Manuscript submitted Feb. 27, 1984; revised manuscript received June 27, 1984.

A Rechargeable Battery Employing a Reduced Polyacetylene Anode and a Titanium Disulfide Cathode

Josip Čaja,^{*1} Richard B. Kaner,^{*} and Alan G. MacDiarmid^{*}

Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

Novel rechargeable battery cells have been constructed using a reduced form of the conducting organic polymer, polyacetylene, as the anode, the inorganic intercalating material, titanium disulfide as the cathode, and either 1.0M LiClO₄ in THF or 1.0M NaPF₆ in THF as the nonaqueous electrolyte. A feasibility study of the cells is described. It includes constant current discharge characteristics, stability, and rechargeability. The cells exhibited good stability and reversibility. Their performance was cathode limited, owing to the method used for fabricating the TiS₂ electrode.

Considerable interest has been shown during the past four years in the use of conducting organic polymers as electroactive materials (1). The prototype conducting polymer, polyacetylene, (CH)_x, can be reversibly oxidized or reduced electrochemically and has been studied primarily as a cathode-active material in rechargeable cells employing a lithium anode (2). Since the reduced form of (CH)_x, e.g., [Li_y⁺(CH)^{-y}]_x, is stable up to a reduction level of ~10 mole percent (m/o), i.e., y = 0.1, in an electrolyte of 1.0M LiClO₄ in tetrahydrofuran (3), it has potential for use as an anode-active material, in conjunction with a suitable cathode, in a rechargeable battery.

Inorganic intercalating materials, primarily titanium disulfide, TiS₂, have also been extensively studied as the cathode in rechargeable lithium cells (4, 5). The feasibility of combining an inorganic intercalating cathode, such as TiS₂, with a conducting organic polymer anode, such as reduced (CH)_x, is reported in the present study. A cell of this type has the advantage of avoiding the major problems associated with a lithium anode, specifically, reaction of the lithium electrode with the organic electrolyte and inadequate cycle life due to the growth of lithium dendrites.

The terms "doping," "intercalation," and "oxidation/reduction" have often been used interchangeably when referring to the process which increases the conductivity of an organic polymer, such as (CH)_x, by introducing small quantities of foreign species into the organic polymer matrix. In order to avoid confusion, it is desirable to distinguish between these three terms. The doping of an organic polymer, such as (CH)_x, is different from the doping of a classical semiconductor, such as silicon. If,

for example, a crystal of silicon is n-doped by replacing a silicon atom with a phosphorus atom (which has one valence electron more than Si), the phosphorus represents a negative site in so far as the crystal lattice is concerned, even if no charge transfer between silicon and phosphorus were to occur. However, the n-doping of a conducting organic polymer, such as (CH)_x, refers to the addition of a given number of electrons to the polymer chains together with a corresponding number of counter cations needed to maintain electrical neutrality. Conducting polymers generally require much higher doping levels than classical inorganic semiconductors in order to effect comparable electronic changes. Intercalation refers to the orderly insertion of a molecule or ion into the crystal lattice of a layered "host" material. Oxidation or reduction of the host material by either chemical or electrochemical means may occur during this process. Intercalation of lithium or sodium into TiS₂, for example, has been shown (5) to involve an almost complete electron transfer from the alkali metal with concomitant reduction of the TiS₂ to give species such as M_y⁺(TiS₂)^{-y} (y < 1; M = Li or Na). Throughout this paper, the incorporation of lithium or sodium cations into TiS₂ will be termed "intercalation," while the incorporation of lithium or sodium cations into (CH)_x will be termed "reduction."

When carrying out electrochemical studies on *trans*-polyacetylene, a semiconductor, it is important to note that pure, neutral (CH)_x can exhibit an open-circuit voltage, V_{oc}, lying in the range between 1.8V, below which significant reduction begins to occur, and 3.1V, above which significant oxidation begins to occur (6). These potentials are given with respect to the Li⁺/Li couple in 1.0M LiClO₄ in THF for the reduction reaction and in 1.0M LiClO₄ in propylene carbonate for the oxidation reaction. This variation in potential results from the slightly differ-

^{*} Electrochemical Society Active Member.

ent ways in which the film has been previously stored or handled. The sensitivity of the potential to the previous history of the film is caused by the extremely small number of molecular orbitals (*i.e.*, density of states) lying between the highest filled pi bonding molecular orbital (at the top of the valence band) and the lowest empty pi antibonding molecular orbital (at the bottom of the conduction band) with which reduction or oxidation processes are associated. Thus, the transfer of an infinitesimally small number of coulombs into or out of the $(\text{CH})_x$ can lower its potential toward 1.8V or raise its potential toward 3.1V, respectively.

Experimental

Materials and reagents.—*cis*-Rich $(\text{CH})_x$ film was prepared as previously described (7). Tetrahydrofuran (THF) (Fisher Scientific Company) was freshly distilled from sodium benzophenone *in vacuo* and was used to make a 1.0M solution of LiClO_4 and a 1.0M solution of NaPF_6 . Anhydrous LiClO_4 (Alfa Ventron) was dried by melting under a dynamic vacuum. Anhydrous NaPF_6 (Aldrich Chemical Company) was dried by heating at 120°C under a dynamic vacuum for 24h. Titanium disulfide, TiS_2 , was synthesized directly from elemental titanium and sulfur in an evacuated, sealed silica hot/cold tube at 500°-900°C by chemical vapor transport (8). Lithium metal (Alfa Ventron) and sodium metal (J. T. Baker Company) were scraped with a knife in a dry argon atmosphere immediately before use. Glass filter paper (Reeve Angel 934AH), dried at 600°C for 24h, was employed as the separator.

Cell construction.—All measurements were performed using cells, shown in Fig. 1, constructed in a dry argon atmosphere by placing separators between the electrodes, squeezing the assembly into $4 \times 10 \times 50$ mm rectangular glass tubing (Vitro Dynamics, Incorporated), adding the electrolyte, freezing the cell contents with liquid N_2 , and sealing the cell under vacuum across the protruding electrode leads. The $(\text{CH})_x$ electrode was made from a 2.5 ± 0.1 mg strip of $(\text{CH})_x$ film (~ 0.7 cm²) mechanically pressed onto 52 mesh platinum gauze, to which had been spot welded a platinum wire lead. The lithium or sodium electrode was made by pressing a (~ 0.7 cm²) piece of 0.13 mm thick lithium ribbon or a (~ 0.7 cm²) strip of sodium into a 189 mesh nickel grid (Delker Corporation), to which had been spot welded a nickel-chromium wire lead. The TiS_2 electrode was made by pressing a TiS_2 /Teflon mixture in the form of a flat sheet (~ 0.1 mm thick) into the center of a nickel grid, to which had been spot welded a nickel-chromium wire lead. The TiS_2 /Teflon flat sheet was made by mixing and then pressing a two-to-one mixture, by weight, of TiS_2 powder and Teflon powder onto the bottom of a mortar by means of a pestle. The $(\text{CH})_x$ electrode was placed in the center of the cell with the TiS_2 electrode on one side and the alkali metal electrode on the other side. The electrodes were separated from each other by the glass filter paper separators.

Fig. 1. Construction of the $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell. Lithium or sodium metal serves as a reference electrode.

Preparation of the reduced polyacetylene anode.—The $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_r$ ($\text{M} = \text{Li}$ or Na) anode was prepared *in situ* in a cell of the type described above by electrochemically reducing the *cis*-rich $(\text{CH})_x$ to $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_r$ at a constant current of 0.1 mA (~ 2 m/o reduction/h) applied between the $(\text{CH})_x$ electrode and the alkali metal electrode. *cis*-Rich $(\text{CH})_x$ was used in the cell construction since it is more flexible than the *trans*-rich isomer. The reduced $(\text{CH})_x$ was then oxidized at a constant current of 0.1 mA until a voltage of ~ 2.4 V (*vs.* Li), characteristic of neutral $(\text{CH})_x$, was reached. Electrochemical reduction followed by oxidation back to neutral $(\text{CH})_x$ converts *cis*-rich $(\text{CH})_x$ to the more thermodynamically stable *trans*-rich $(\text{CH})_x$ (9). The *trans*-rich $(\text{CH})_x$ so formed was then reduced to a 10.0 m/o reduction level using the same conditions as described above and was permitted to stand for 12h, in order to permit diffusion of the alkali metal cations throughout the 200Å diam $(\text{CH})_x$ fibrils, before commencing with the electrochemical studies.

The $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_r$ ($\text{M} = \text{Li}$ or Na) obtained in this way and the TiS_2 electrode constituted the cell in its charged state. The alkali metal electrode thus served a dual role: first in the preparation of the reduced $(\text{CH})_x$ anode, and second as a reference electrode during the studies described below. All discharge studies were carried out to 0 V between the $(\text{CH})_x$ anode and the TiS_2 cathode and were performed at room temperature. All voltages are given with respect to a lithium or sodium reference electrode. The first discharge/charge cycle of each cell was ignored.

Results

Discharge/charge characteristics of $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cells.—These studies were carried out on two $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cells containing different molar ratios of $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r$ and TiS_2 . The use of different molar ratios permitted the final intercalation level, y , in $\text{Li}_y^+(\text{TiS}_2)^{-y}$, obtained after discharge, to be varied as desired. Cells of this type displayed an open-circuit voltage, V_{oc} , of ~ 1.65 V.

Use of a 1:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell.—The net electrochemical reaction taking place during the discharge process is given by Eq. [1]

The relationship between cell discharge voltage, V_d , and time for representative discharges to 0 V at constant currents of 0.2 and 0.1 mA are shown in Fig. 2, curves 1 and 2, respectively. Each charge was carried out first at a constant current to 1.8V and then at a constant applied potential of 1.8V for 48h. The 1.8V charging potential was used to complete the conversion of the electrode material to $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r$ and TiS_2 . Each cell discharge was completely reversible, as can be seen from Table I by comparing the coulombs involved in a discharge process,

Fig. 2. Relationship between the discharge voltage, V_d and time, during the discharge of a 1:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell at 0.2 mA (curve 1) and 0.1 mA (curve 2).

^a Per kg of $[M_y^+(CH)^{-y}]_x$ and TiS_2 used in constructing a cell.

^b Based on the weights of $[M_y^+(CH)^{-y}]_x$ and TiS_2 used in constructing a cell. The number of moles of $[M_y^+(CH)^{-y}]_x$ used in constructing each cell was approximately the same.

^c $Q_{(out)}$ is the number of coulombs liberated during constant current discharge of the cell to 0 V.

^d The $[Li_{0.10}^+(CH)^{-0.10}]_x$ cells were charged at a constant potential of 1.8 V for 48h; the $[Na_{0.10}^+(CH)^{-0.10}]_x$ cell was charged at a constant potential of 1.9 V for 48h.

$Q_{(out)}$, to the coulombs involved in a charge process, $Q_{(in)}$. Note however, from the extent of a given cell reaction (Table I), that the discharge reactions were not entirely complete when 0 V had been reached. Additional discharge/charge cycles at 0.1 and 0.2 mA gave similar results.

Use of a 10:1 molar ratio $[Li_{0.10}^+(CH)^{-0.10}]_x/TiS_2$ cell.—The electrochemical reactions taking place at the TiS_2 cathode, the $[Li_{0.10}^+(CH)^{-0.10}]_x$ anode, and the net cell reaction during the discharge process of this cell are given by Eq. [2], [3], [4], respectively

The relationship between cell potential, V , and coulombs transferred, Q , during a 0.1 mA constant current discharge process and charge process is shown in Fig. 3, curves C and C', respectively. The respective TiS_2 and $[Li_{0.10}^+(CH)^{-0.10}]_x$ electrode potentials on discharge are given in Fig. 3, curves A and B. The corresponding potentials on charge are given in curves A' and B'. Curves A, B, and C correspond to Eq. [2], [3], and [4], respectively. The cell was then charged at a constant current of 0.1 mA for 1h. The charging was completed by applying a constant potential of 1.8 V for 48h.

Fig. 3. The relationship between the voltage, V and the charge transferred, Q for the $Li_y^+(TiS_2)^{-y}$ cathode (vs. Li) (curves A and A'), the $[Li_y^+(CH)^{-y}]_x$ anode (vs. Li) (curves B and B'), and the 10:1 molar ratio $[Li_{0.10}^+(CH)^{-0.10}]_x/TiS_2$ cell (curves C and C') during 0.1 mA discharge and charge processes, respectively (see text).

The cell reaction was completely reversible, as can be seen from Table I by comparing the $Q_{(out)}$ and $Q_{(in)}$ values. Note, however, from the extent of a given cell reaction (Table I), that the discharge reaction was not entirely complete when 0 V had been reached. Additional discharge/charge cycles at 0.1 mA gave similar results.

Discharge/charge characteristics of a $[Na_{0.10}^+(CH)^{-0.10}]_x/TiS_2$ cell.—The studies were carried out on a 4:1 molar ratio $[Na_{0.10}^+(CH)^{-0.10}]_x/TiS_2$ cell. The net electrochemical reaction taking place during the discharge process is given by Eq. [5]

It has been reported that $Na_y^+(TiS_2)^{-y}$ undergoes a phase change at $y > \sim 0.4$ (10). Therefore, the present study has been restricted to $Na_y^+(TiS_2)^{-y}$ for $y < 0.4$, in which region the reaction given by Eq. [5] is believed to be reversible.

The relationship between cell discharge voltage, V_d , and time for representative discharges to 0 V at constant currents of 0.2, 0.1, and 0.05 mA are shown in Fig. 4, curves 1, 2, and 3, respectively. Each charge was carried out at a constant potential of 1.9 V for 48h. The 1.9 V charging potential was used to complete the conversion of the electrode materials to $[Na_{0.10}^+(CH)^{-0.10}]_x$ and TiS_2 .

The cell discharges at 0.05 and 0.1 mA were completely reversible, as can be seen from Table 1 by comparing the coulombs involved in a discharge process, $Q_{(out)}$, to the coulombs involved in a charge process, $Q_{(in)}$. However, the cell discharge at 0.2 mA was not completely reversible. Additional discharge/charge cycles at 0.05, 0.1, and 0.2 mA gave similar results.

Characteristics of the $[M_y^+(CH)^{-y}]_x/TiS_2$ cells.—Data from the studies described in the previous sections for the three cells investigated were used to compile the information in Table I. Included are the three cells containing $[M_{0.10}^+(CH)^{-0.10}]_x$ and TiS_2 in the molar ratios

Fig. 4. The relationship between the discharge voltage, V_d and time, during the discharge of a 4:1 molar ratio $[Na_{0.10}^+(CH)^{-0.10}]_x/TiS_2$ cell at 0.2 mA (curve 1), 0.1 mA (curve 2), and 0.05 mA (curve 3).

1:1, 10:1, and 4:1 and their corresponding discharge reactions together with the number of coulombs calculated for 100% discharge, $Q_{\text{out, calc.}}$, of a cell if all the $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_r$ and TiS_2 employed in the cell construction underwent reaction. The coulombs liberated in the experimental discharge, Q_{out} , is given next, followed by the extent of the cell reaction, $[Q_{\text{out}}/Q_{\text{out, calc.}}]100$. An average discharge voltage, \bar{V}_d was calculated by integrating the area under each discharge curve, $(V_d \times Q_{\text{out}})$, (Fig. 2, curves 1 and 2; Fig. 3, curve C; Fig. 4, curves 1 and 3) and dividing this value by Q_{out} . Energy densities given in the table were obtained by integrating the area under each discharge curve, $(V_d \times Q_{\text{out}})$ and dividing this value by the combined weight of $[\text{M}_y^+(\text{CH})^{-y}]_r$ and TiS_2 employed in each cell construction. This value was then divided by 3600 to convert W-s/kg to W-h/kg.

Stability.—After the discharge/charge cycles described above were completed, the relationship between V_{oc} and time for the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell was monitored and is shown in Fig. 5, curve 1. The cell showed an initial decrease from 1.75 to 1.64V during the first 15 days, followed by a very gradual decrease to 1.59V after 3 months. Its capacity on discharge after this time was 69% of that obtained from a discharge carried out immediately after completion of a charge cycle. The relationship between V_{oc} and time for the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell is shown in Fig. 5, curve 2. This cell showed an initial decrease from 1.65 to 1.50V after 5 days, followed by a much more gradual decrease to 1.43V after 20 days. Its capacity on discharge after this time was 88% of that obtained from a discharge carried out immediately after completion of a charge cycle.

Discussion

Since, as described above, neutral $(\text{CH})_r$ can have a potential in the range 1.8-3.1V (*vs.* Li) and since $\text{Li}^+(\text{TiS}_2)^-$ has a potential of 1.9V (*vs.* Li), it is apparent that when a 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell is completely discharged to 0 V such that the electrodes attain the compositions $(\text{CH})_r$ and $\text{Li}^+(\text{TiS}_2)^-$, as given by Eq. [4], both electrodes will have a potential of 1.9V (*vs.* Li). Experimentally, this can be seen in Fig. 3, for the discharge of this cell to 0 V, by the intersection of curve A (the potential of the $\text{Li}_y^+(\text{TiS}_2)^{-y}$ cathode *vs.* Li) and curve B (the potential of the $[\text{Li}_{0.10(1-y)}^+(\text{CH})^{-0.10(1-y)}]_r$ anode *vs.* Li), which occurs at 1.9V (*vs.* Li). Although the potential of 1.9V (*vs.* Li) is consistent with the formation of $\text{Li}^+(\text{TiS}_2)^-$ and neutral $(\text{CH})_r$ the reaction is only 49% complete based on Q_{out} , the coulombs liberated during cell discharge and the weights of TiS_2 and $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r$ employed in the cell construction (see Table I). This is due to polarization of the $\text{Li}_y^+(\text{TiS}_2)^{-y}$ and $[\text{Li}_y^+(\text{CH})^{-y}]_r$ electrodes under the applied current densities and to incomplete diffusion of Li^+ ions from the surface of the TiS_2 to its interior and from the interior of the $(\text{CH})_r$ fibrils to its surface during the time in which the discharge studies were performed. These effects can readily be seen, for example, after the

10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell was discharged to 0 V and then disconnected for 1 min. The V_{oc} increased to 0.3V as Li^+ ions diffused into the interior of the TiS_2 and toward the surface of the $(\text{CH})_r$ fibrils. These effects may be related, at least in part, to the fabrication of the TiS_2 electrodes' being poorer than that obtainable by the best state of the art procedures.

When comparing discharge cycles at different current densities for a given cell, it can be seen from Table I that the extent of cell reaction decreased with increasing discharge current density. This is consistent with increased polarization and less complete diffusion at higher current density discharges, which occurred in a shorter time period. Comparing the 1:1 and 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cells at the same discharge current density (0.1 mA for 0.7 cm² of $(\text{CH})_r$), it can be seen that the extent of the cell reaction (78% *vs.* 49%, respectively) is less complete for the 10:1 molar ratio cell. This is consistent with the fact that both cells employed approximately the same amount of $(\text{CH})_r$ so that the 10:1 molar ratio cell contained only one-tenth the amount of TiS_2 . The correspondingly smaller surface area of TiS_2 will, therefore, increase the effects due to polarization.

The 1:1 and 10:1 molar ratio cell reactions were essentially reversible, as can be seen in Table I by comparing Q_{out} , the number of coulombs liberated during discharge, to Q_{in} , the number of coulombs involved during the charging process. Since these quantities were nearly the same in all cases, these reactions are considered to be essentially reversible even though they do not proceed to completion. The incompleteness of these reactions is believed to be due to incomplete diffusion during the time of the discharge, so that, in effect, the interior portions of the TiS_2 particles and the interior portions of the $(\text{CH})_r$ fibrils do not actively enter into the reaction processes.

Since the value of Q_{out} for the 0.05 mA discharge of the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell, whose reaction is given by Eq. [5], was close to the value of Q_{in} (see Table I) obtained in the subsequent charge, this reaction may also be considered essentially reversible. However, when the discharge was carried out at the higher current of 0.2 mA, the value of Q_{out} was significantly larger than the value of Q_{in} . This may be due to the formation of some $\text{Na}_y^+(\text{TiS}_2)^{-y}$ ($y > 0.4$) phase at the surface of the TiS_2 , during the rapid discharge process, from which it is believed Na^+ ions may not be readily removed during the charging process (11).

In order to better understand the discharge curve shown in Fig. 3, curve C for the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell, whose reaction is given by Eq. [4], a theoretical curve based on equilibrium data has been constructed. This theoretical curve, shown in Fig. 6, curve C, was constructed from (i) Fig. 6, curve A, which gives the equilibrium V_{oc} values of a $\text{Li}/\text{Li}_y^+(\text{TiS}_2)^{-y}$ cell as a function of increasing intercalation of Li^+ ions into the $\text{Li}_y^+(\text{TiS}_2)^{-y}$ ($0 \leq y \leq 1$) electrode as reported by Whittingham (12) and (ii) Fig. 6, curve B, which gives the equilibrium V_{oc} values of a $\text{Li}/[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r$ cell as a function of decreasing reduction, *i.e.*, removal of Li^+ ions from the $[\text{Li}_y^+(\text{CH})^{-y}]_r$ ($0.1 \geq y \geq 0$) electrode, as we have reported previously (3). Curves A, B, and C in Fig. 6 correspond to the equilibrium potentials for the reactions given by Eq. [2], [3], and [4], respectively. The calculated equilibrium cell potential (Fig. 6, curve C) is thus based on the difference between curves A and B as given by Eq. [6]

$$V_{\text{cell}} = V_{\text{cathodic}} - V_{\text{anodic}} \quad [6]$$

Figure 6, curve C represents a hypothetical discharge carried out under no load, infinitely slowly, thus eliminating polarization and diffusion effects.

Figure 6, curve B' is an experimental curve obtained from a $\text{Li}/[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r$ cell (employing 3.1 mg of $(\text{CH})_r$), when the $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r$ electrode was oxidized at a constant current of 0.17 mA/cm² of $(\text{CH})_r$ (3). If curve B' is combined with curve A using Eq. [6], then curve C'

Fig. 5. Relationship between the open-circuit voltage, V_{oc} and time for a $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{NaPF}_6(\text{THF})/\text{TiS}_2$ cell (curve 1) and a $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{LiClO}_4(\text{THF})/\text{TiS}_2$ cell (curve 2).

Fig. 6. Potential of: (A) $\text{Li}_y^+(\text{TiS}_2)^{-y}$ cothode vs. Li at equilibrium [Ref. (4)]; (B) $[\text{Li}_{0.10(1-y)}^+(\text{CH})^{-0.10(1-y)}]_r$ anode vs. Li at equilibrium [Ref. (3)]; (B') $[\text{Li}_{0.10(1-y)}^+(\text{CH})^{-0.10(1-y)}]_r$ electrode vs. Li during oxidation of $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r$ to $(\text{CH})_r$ [Ref. (3)]; (C) $[\text{Li}_{0.10(1-y)}^+(\text{CH})^{-0.10(1-y)}]_r/\text{Li}_y^+(\text{TiS}_2)^{-y}$ cell calculated at equilibrium; (C') $[\text{Li}_{0.10(1-y)}^+(\text{CH})^{-0.10(1-y)}]_r/\text{Li}_y^+(\text{TiS}_2)^{-y}$ cell calculated for discharge (see text).

is obtained. This gives a closer approximation than curve C to what could be expected experimentally during discharge of the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell, since one of the curves (curve B') represents a discharge under actual load conditions.

Curve C in Fig. 6 is reproduced as curve 2 in Fig. 7. For comparative purposes, the experimental discharge curve for the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell (Fig. 3, curve C) is reproduced as curve 1 in Fig. 7. It can be seen that these curves have a similar general shape, but that, owing to polarization and diffusion effects, the observed cell discharge reaction (curve 1, Fig. 7) is only 49% complete.

A theoretical V vs. Q curve based on equilibrium data has also been constructed for the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell. This theoretical curve shown in Fig. 8, curve 2 is constructed from (i) equilibrium V_{oc} values of a $\text{Na}/\text{Na}_y^+(\text{TiS}_2)^{-y}$ cell as a function of increasing intercalation of Na^+ ions into the $\text{Na}_y^+(\text{TiS}_2)^{-y}$ ($0 \leq y \leq 0.4$) electrode as reported by Winn *et al.* (10) and (ii) equilibrium V_{oc} values of a $\text{Na}/[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r$ cell as a function of decreasing reduction, *i.e.*, removal of Na^+ ions from the $[\text{Na}_y^+(\text{CH})^{-y}]_r$ ($0.1 \geq y \geq 0$) electrode (13).

For comparative purposes, the experimental discharge curve for the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell (Fig. 4, curve 3) is reproduced as curve 1 in Fig. 8. From Fig. 8, it can be seen that the experimental curve also follows the general shape of the theoretical curve for the $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell, but, again, owing to polarization and diffusion effects, the observed cell discharge reaction (curve 1, Fig. 8) is only 64% complete.

Comparing the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell data given in Fig. 7 with the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell data given in Fig. 8, it is apparent that the potential of the $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell falls continually as the discharge reaction proceeds to completion, while the potential of the $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell decreases more gradually and then falls rapidly during the last ~10% of its discharge. This difference in the behavior of the cell potentials is consistent with the fact that the equilibrium potential of the $\text{M}_y^+(\text{TiS}_2)^{-y}$ electrode for differing values of y is dependent on the intercalant used with respect to a common reference (*e.g.*, vs. Li) (10, 12), while the potential of the $[\text{M}_y^+(\text{CH})^{-y}]_r$ electrode for differing values of y is independent of the dopant used (3, 13). Since the potential of $\text{Na}_y^+(\text{TiS}_2)^{-y}$ is greater than the potential of $\text{Li}_y^+(\text{TiS}_2)^{-y}$ for $y \leq 0.4$ vs. a common ref-

Fig. 7. Change in voltage of a 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell as a function of percent Li intercalation in $\text{Li}_y^+(\text{TiS}_2)^{-y}$ during a 0.1 mA discharge (curve 1) and at equilibrium (curve 2).

erence electrode (10, 12), the $\text{Na}_y^+(\text{TiS}_2)^{-y}$ electrode would therefore be expected to exhibit a larger potential than the $\text{Li}_y^+(\text{TiS}_2)^{-y}$ electrode, vs. a $[\text{M}_y^+(\text{CH})^{-y}]_r$ electrode. For example, at $y = 0.4$, the potential of a $\text{Na}_y^+(\text{TiS}_2)^{-y}$ electrode is 2.00V (vs. Na), *i.e.*, 2.33V (vs. Li),² while the potential of the corresponding $\text{Li}_y^+(\text{TiS}_2)^{-y}$ electrode is 2.20V (vs. Li). Also note that when $y = 0$, the V_{oc} of TiS_2 vs. Na is 2.3V, *i.e.*, 2.63V (vs. Li),² while the corresponding V_{oc} of TiS_2 vs. Li is 2.45V (see Table II).

The V_{oc} , theoretical energy density, and specific energy of reactant materials are given in Table II for each of the following cells: the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell, the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell, a $\text{Li}/\text{Li}_y^+(\text{TiS}_2)^{-y}$ cell, a $\text{Na}/\text{Na}_y^+(\text{TiS}_2)^{-y}$ cell, a $\text{Li}/[\text{Li}_y^+(\text{CH})^{-y}]_r$ cell, and a $\text{Na}/[\text{Na}_y^+(\text{CH})^{-y}]_r$ cell. The theoretical energy densities are based on the area under the equilibrium V_{oc} vs. Q curves for each reaction divided by the total weight of anode and cathode material employed in the cell construction. For example, the theoretical energy densities for the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell and the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell are obtained from the area under curve 2, Fig. 7 and curve 2, Fig. 8, respectively, and from the weights of $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_r$ and TiS_2 employed in each cell. The experimental energy densities are based on the area under a V_d vs. Q curve during a constant current discharge and the total weight of an-

² Assuming that the difference in the E_{red}^0 potential between Na (2.711V vs. SHE) and Li (3.045V vs. SHE), *i.e.*, 0.334V, will have approximately the same value in the electrolytes used in the present studies.

Fig. 8. Change in voltage of a 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_r/\text{TiS}_2$ cell as a function of percent Na intercalation in $\text{Na}_y^+(\text{TiS}_2)^{-y}$ during a 0.05 mA discharge (curve 1) and at equilibrium (curve 2).

Table II. Energy densities of selected cells employing polyacetylene and titanium disulfide electrodes

Cell discharge reaction	V_{oc} (V)	Theoretical energy density (Wh/kg)	Discharge current density (mA/cm ²)	Specific energy of reactant materials (Wh/kg)

^a This work.^b Ref. (4).^c Calculated from data in Ref. (10).^d Calculated from data in Ref. (14).^e Ref. (3).^f Ref. (13).^g Ref. (15).^h Calculated from data in Ref. (11).

ode and cathode material employed in the cell construction. For example, the experimental energy densities for the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cell and the 4:1 molar ratio $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cell are obtained from the area under curve 1, Fig. 7 and curve 1, Fig. 8, respectively, and from the weights of $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_x$ and TiS_2 employed in each cell.

The Li/TiS_2 and the $\text{Li}/(\text{CH})_x$ cells have significantly higher experimental energy densities than the corresponding Na/TiS_2 and $\text{Na}/(\text{CH})_x$ cells (see Table II). This is due to the lower atomic weight and higher reduction potential of lithium as compared to sodium. However, the $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cell has an experimental energy density (30.1 Wh/kg, close to that of the $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cell (27.1 Wh/kg). This is due to the higher potential of the $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cell during discharge, as discussed above.

As can be seen in Fig. 3, curve C', the charging of the 10:1 molar ratio $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cell could not be completed at a constant current of 0.1 mA. From Fig. 3, curve A', it can clearly be seen that the main cause of this is polarization of the TiS_2 electrode, resulting in a cathode-limited reaction. Thus, the applied charging current caused the $\text{Li}_y^+(\text{TiS}_2)^{-y}$ electrode potential to rise rapidly; the charging was therefore completed at a constant potential of 1.8V applied between the anode and the cathode.

Improved methods for constructing TiS_2 electrodes have allowed others to successfully cycle TiS_2 cathodes at high current densities (16, 17). Adopting some of these methods to the present cells could (i) improve the $[\text{M}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cells by enabling complete charging at high current densities and (ii) improve the energy densities by enabling the cell reactions to proceed further to completion. Improvements in fabricating the TiS_2 electrodes include a hot bonding technique (11), improved binders such as ethylenepropylene-diene terpolymer (16), and employing a reduced weight ratio of binder to TiS_2 . All these improvements have been shown to reduce polarization effects at the TiS_2 electrode and to improve its overall performance in a battery cell.

Improved electrolytes could be useful in the $[\text{M}_y^+(\text{CH})^{-y}]_x/\text{TiS}_2$ cells. For example, 1.0M LiAsF_6 in 2Me-THF has been shown to increase the recyclability of Li/TiS_2 cells (17). Since this electrolyte is compatible with the $[\text{Li}_y^+(\text{CH})^{-y}]_x$ electrode (18), it could be advantageously employed in a $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_x/\text{TiS}_2$ cell.

Other intercalating inorganic materials might be substituted for TiS_2 as the cathode-active material in these cells. For example, the electrochemistry of the sulfides and selenides of vanadium, niobium, and tantalum and transition metal oxides such as V_2O_5 , MoO_3 , and MnO_2 , has been investigated (4). To determine which materials could be used in practical cells, theoretical V vs. Q curves, such as

those given in Fig. 7, curve 2 and Fig. 8, curve 2, should be constructed, and the electrochemical characteristics of those showing the most promise could be investigated.

Analogously, other conducting organic polymers might be substituted for polyacetylene as the anode-active material in these cells. Polyparaphenylene (19) and polyquinolines (20), both of which can be reduced electrochemically, are the most promising candidates.

Conclusions

This feasibility study of cells comprised of the conducting organic polymer anode—reduced polyacetylene and the inorganic intercalating cathode—titanium disulfide has shown some promise for practical cells. The major problems associated with lithium anodes are avoided. Two cells employing differing molar ratios of $[\text{Li}_{0.10}^+(\text{CH})^{-0.10}]_x$ and TiS_2 as anode- and cathode-active materials, respectively, and one cell employing a $[\text{Na}_{0.10}^+(\text{CH})^{-0.10}]_x$ anode and TiS_2 cathode have exhibited promising energy densities and electrochemical reversibility. Improvements in the fabrication of the TiS_2 electrode are needed to overcome the observed cathode limitations of the present cells. Other modifications, such as the use of new conducting organic polymer anodes or other inorganic intercalating cathodes, may show even greater technological promise.

Methodology for Predictive Testing of Fuel Cells

D. N. Patel, H. C. Maru,* M. Farooque,* and C. H. Ware¹

Energy Research Corporation, Danbury, Connecticut 06810

ABSTRACT

A perturbation testing method has been developed and tested for predictive testing of fuel cells. This method involves application of small changes to the operating conditions of the cell in a predetermined sequence. The resultant response of the cell is then measured and statistically correlated with the corresponding test conditions. This method has been applied to the phosphoric acid fuel cell, and the effect of operating and cell-component variables on cell-performance degradation has been studied. A strong effect of the cell temperature and cathode potential on fuel-cell-performance degradation has been observed. A cell-performance degradation model has been formulated, and the unknown parameters in the model have been estimated by a regression analysis of the experimental data. A reasonable agreement between the fuel cell performance predicted by this model (derived from the perturbation experiments) and the unperturbed test data supports the applicability of the perturbation method.

The phosphoric acid fuel cell being developed for electricity generation is expected to have a long operating life (typically 40,000h for use in utility power plants). A fuel cell aging model is therefore very useful in a cost-effective component evaluation and an optimization of design conditions minimizing the life-cycle cost. The techniques used most often in electrochemical studies for developing aging models are steady-state life testing and accelerated testing. Steady-state life testing of fuel cells offers limited information, is very expensive, and is time consuming. In accelerated testing, the cell is run at very severe operating conditions (e.g. a cell temperature of 200°C and a cathode voltage of 0.9V) to accelerate decay, and the large changes made in operating conditions to accelerate decay may cause a shift in the decay mechanism. Hence, the decay mechanism during accelerated testing may not be representative of design conditions. Accelerated testing is also expensive, as a large number of tests are required. This paper describes an alternative predictive testing approach—the perturbation testing technique—and describes its application to the phosphoric acid fuel cell (PAFC).

Theoretical

Perturbation testing technique.—This technique involves the investigation of a system response, utilizing small, careful changes in the operating conditions to ensure the representative behavior of the decay mechanism. It is an adaptation of "Evolutionary Operation" (EVOP) (1, 2), originally applied to optimization of plant operation. In this technique, changes are made in important variables of the plant to find conditions that would in-

crease its performance and provide the direction for further improvement. The changes are kept small to permit plant operation with an acceptable product. Because in the perturbation testing technique several perturbations in operating variables are applied to a single cell, fewer tests are required than in accelerated testing. Furthermore, perturbations on the same cell enable cell-to-cell, variation-free estimation of model parameters. Thus, the perturbation testing technique is cost effective, quick, and reliable.

Decay modes.—In this study, the perturbation testing technique is applied to phosphoric acid fuel cells (PAFC). The PAFC are operated in the temperature range of 165°-200°C. At temperatures lower than 165°C, the poisoning of the Pt catalyst by CO in the fuel increases, and at temperatures higher than 200°C, the material stability is affected. The basic reactions occurring in the PAFC are

The PAFC electrodes consist of platinum, carbon, and Teflon. The carbon support provides a conductive and highly dispersive base for the Pt (catalyst) crystallites; the Teflon mainly imparts hydrophobicity to the structure. The phosphoric acid (electrolyte stored in the matrix layer) provides a conductive path for H⁺ ions, and electricity is produced by an electrochemical reaction between H₂ from fuel and O₂ from air. The primary fuel for the PAFC is pure hydrogen. However, impure hydrogen (containing CO₂) may also be used as fuel.

Knowledge of possible decay modes and important parameters affecting the decay is desirable (and even essential to predict relative contributions of various decay

*Electrochemical Society Active Member.

¹Present address: World Energy Systems, Rocky Mount, VA 24151.

rates) in performing cost-effective and efficient predictive testing. The primary decay modes limiting the PAFC lives appear to be related to cathode performance decay (3). In this study, two primary decay modes are considered

A: Platinum deactivation (4)

- Catalyst surface area loss by platinum crystallite growth
- Platinum dissolution in the electrolyte

B: Increase in diffusion polarization

- Corrosion of the carbon support

- Teflon degradation

Possible secondary decay modes, such as anode poisoning, matrix-bubble pressure loss, and bipolar plate corrosion, are not studied. The electrolyte-loss decay mode is experimentally eliminated by providing a constant supply of electrolyte.

Experimental design.—Experimental variables which influence the cell-performance degradation through modes A and B are chosen next. Cell temperature, cathode potential, and average water partial pressure at cathode are selected as the operating variables (5). Catalyst loading and Teflon content of cathode are selected as the cell component (build) variables. The levels of these variables (see Table I) are decided after preliminary experiments. The criteria for the selection of levels is to have the "high" levels low enough to prevent material problems (and other problems) and to have the "low" levels high enough to provide a measurable decay in each perturbation period.

A variation on the Balanced Incomplete Block Design (BIBD) (6) has been selected for this study. The traditional application of an incomplete block design is one in which there are too many treatments (too many variables, which create the need for too many test runs) to be studied in a single block (a test cell, in this case). A balanced incomplete design is one in which every pair of treatments occurs the same number of times. One purpose of the perturbation experiments is to study the effects of cell operating and build variables on catalyst deactivation, which results in cell performance degradation. Since the catalyst utilization (effectiveness of the cathode catalyst) changes with time, the effects of variables has to be estimated in the presence of this uncontrolled variable (catalyst utilization). Hence, in the selected design, an important consideration is given to time. The balanced incomplete block designs permit the experimenter to obtain a small block of information which can be efficiently integrated into a large picture. The particular design chosen utilizes 2×2 factorial design as a block. BIBD is selected to obtain a snapshot of the effects of two variables (T and V_c) in a relatively short period of time (the 2×2 factorial) and then return to the same factorial design at a later time when catalyst utilization is different. The analysis of the results of each 2×2 factorial design yields the effects of the independent variables (T , V_c , P_{H_2O}) on decay rates. In addition, a comparison of these effects at two different catalyst utilization levels (different times) yields the mutual interaction between the operating variables and the catalyst utilization.

The use of a second block (2×2 factorial) at a later time does not only obtain the foregoing comparison. It is a vir-

Table I. Experimental variables and their levels

Levels	Operating variables			Build type	Cell component variables	
	T , °C	V_c , Volts	P_{H_2O} , kPa		CL, mg/cm ²	TFE, %
High	191	0.81	42	I	0.3	40
Center	184	0.77	35	II	0.6	40
Low	177	0.73	29	III	0.3	45
				IV	0.6	45

tual necessity to reduce the effect of changing catalyst utilization on the experimental results and, therefore, the estimates of the model coefficients. By making the second block a mirror image of the first, the confounding of catalyst utilization with operating variables can be eliminated if catalyst utilization is linear with time; if not, it can be reduced.

Balanced Incomplete Block Designs have another advantage. Unlike factorial designs, there is no test run with all variables at the most severe condition and at the least severe condition. By avoiding the most severe condition, material problems can be eliminated; by avoiding the least severe condition, a measurable decay can be obtained in a reasonable period of time.

A complete perturbation cycle is shown in Table II. The design is symmetrical with respect to Period 11. The operating sequence of the design consists of a 2×2 factorial in the cell temperature and cathode voltage, followed by single variable perturbation in water-vapor partial pressure. The fourth variable is assigned as a dummy variable to provide for orthogonal blocking in the design. This allows cell-to-cell, variation-free estimation of the model parameters.

It should be noted that this ($T \times V_c$, P_{H_2O}) is only one of three possible combinations. The other two combinations are

- 2×2 factorial in cathode voltage and water partial pressure, followed by single variable perturbation in cell temperature ($V_c \times P_{H_2O}$, T)
- 2×2 factorial in water partial pressure and cell temperature, followed by single-variable perturbation in cathode voltage ($P_{H_2O} \times T$, V_c)

If all three combinations are to be executed, too many test cells will be required. Also, the replicates are needed to estimate the experimental error. Hence, only one combination is used, and replicates are provided in the experiments to accomplish the objectives with a minimum number of test cells. The $T \times V_c$, P_{H_2O} combination is preferred because it offers $T \times V_c$ interaction, which may be stronger than $T \times P_{H_2O}$ and $V_c \times P_{H_2O}$ interactions.

The duration of the perturbation periods (Table II) are chosen after the preliminary experiments. They are selected to keep the change in catalyst utilization, CU , approximately equal in all periods in order to keep $\text{Var}(\ln r_u)$ comparable.

Testing

Test facility.—A test facility consisting of 22 high-quality test stands was designed and constructed for the pre-

dictive testing. Digital high-precision meters were used. The temperature controller for the cell had a dual set point: one to control cell temperature and the other to remove the load and to shut off the heating system when the temperature increased beyond a preset level. This protected the cell from excessive heating. For the oxidant, the facility provided air during the break-in period of the cell, O₂ during the perturbation runs, and an O₂-N₂ mixture during the limiting current measurements.

Perturbation testing.—Eighteen subscale cells (25 cm²) comprising the four buildtypes were assembled for the perturbation testing. Excellent reproducibility of the performance parameters was established (Table III) in the test cells to obtain statistically meaningful results. Cell-to-cell variation in the Ir-free performance fell within ± 5 mV for each buildtype. Perturbation testing was then initiated. The operating conditions established during the testing were

Pressure:	101 kPa (1 atm)
Temperature:	As required by the perturbation cycle
Cathode voltage:	
Fuel:	
Oxidant:	O ₂ [humidified, when required, to produce desired water partial pressure at cathode (see perturbation cycle)]
Fuel utilization:	75%
Oxidant utilization:	50%

The operating pressure, fuel (H₂) utilization, and oxidant utilization were maintained constant during the perturbation testing. The cell temperature, cathode voltage, and average water-vapor partial pressure at the cathode were maintained constant during each perturbation period. After each period, their values were changed to those corresponding to the next period (Tables I and II). The new period was initiated soon after the cells were stabilized at the new values. The catalyst loading and Teflon content at the cathode were kept approximately constant by using the same cell throughout the perturbation cycle.

Measurements made during the perturbation testing were

- Current, cell voltage, open-circuit voltage, and cell resistance (measured daily)
- Limiting current (measured at the beginning and the end of each perturbation period)
- Complete polarization measurements [measured when the cell was operating at center levels (at the end of periods 6, 11, 16, and 21)]

From these measurements, the current and the limiting current measurements were used in the data analysis. The rest of the measurements were taken for diagnostic purposes.

The planned 21 perturbation runs were completed in about 3000h. About 85% of the perturbation data obtained was used in the data analysis. The data from perturbation periods 20 and 21 for buildtypes III and IV, and from periods 18 through 21 for buildtypes I and II were not used in the analysis because of an unplanned disturbance in testing. This did not affect the data analysis because the lost data represented only 15% of the total.

Unperturbed testing.—Four base line cells of buildtype IV were operated constantly at centerpoint conditions to generate long-term base line performance data for evaluation of the aging model. The testing continued up to about 5500h.

Data Analysis

Computation of decay rates.—Catalyst utilization (CU) and limiting current density (i_L) are selected to represent the cell performance degradation via modes A and B, respectively. The limiting current-density data obtained during perturbation experiments are measured using dilute O₂ (4%O₂ + 96%N₂). The data, therefore, are corrected as follows

$$i_L (\text{corrected}) = i_L (\text{measured}) \times [P_{O_2} (\text{pert. cond.}) / P_{O_2} (i_L \text{ meas. cond.})]$$

Catalyst utilization values are computed from the cell current data and the limiting current data collected during perturbation tests, using the phosphoric acid fuel-cell performance model (see Appendix A). The performance model and the detailed computation procedure are given in Appendix A. Once the CU and i_L values are obtained for each perturbation period, $-dCU/dt$ and $-di_L/dt$ decay rates are computed using the least squares method. A typical decay plot is shown in Fig. 1. It can be observed that the effect of cell temperature and cathode voltage on Pt deactivation is predominant. Further discussion on this is presented later in the section.

Correlation of decay rates.—The correlation of decay rates with the corresponding operating conditions is then pursued. To begin with, a simple aging model is constructed

For platinum deactivation (mode A)

$$\tau_u = -\frac{dCU}{dt} = k_{u0} \exp(-E_u/RT) CU^{\alpha_u} \exp(\beta_u V_c/T) P_{H_2O}^{\gamma_u} \quad [2]$$

For increase in diffusion polarization (mode B)

$$\tau_i = -\frac{di_L}{dt} = k_{i0} \exp(-E_i/RT) i_L^{\alpha_i} \exp(\beta_i V_c/T) P_{H_2O}^{\gamma_i} \quad [3]$$

The above model is transformed to a logarithmic form for simplicity in correlating the decay rates. The detailed derivations are presented in Appendix B. The logarithmic form of the model is presented below

For platinum deactivation (mode A)

$$\ln \tau_u = \ln \tau_{u0} - E_u/R (1/T - 1/\bar{T}) + \alpha_u (\ln CU - \overline{\ln CU}) + \beta_u (V_c/T - \overline{V_c/T}) + \gamma_u (\ln P_{H_2O} - \overline{\ln P_{H_2O}}) \quad [4]$$

For increase in diffusion polarization (mode B)

$$\ln \tau_i = \ln \tau_{i0} - E_i/R (1/T - 1/\bar{T}) + \alpha_i (\ln i_L - \overline{\ln i_L}) + \beta_i (V_c/T - \overline{V_c/T}) + \gamma_i (\ln P_{H_2O} - \overline{\ln P_{H_2O}}) \quad [5]$$

- t = time

Initially, the average (for each period) of data from cells 101 to 106 (buildtype IV) is fitted to the logarithmic model by regression analysis. Though a good fit is obtained, a high uncertainty is observed in the estimated coefficients. To lower the uncertainty, data from individual cells (rather than average cell data) are fitted to the model. However, the F-test indicates a lack of fit. The residual analysis reveals a step change between periods 11 and 12 for a few cells (this upset is caused by an unplanned H₂ outage during these periods). The above data are excluded from further analysis. Also, the estimates of model coefficients and 95% confidence intervals show

that the CU, i_L , and P_{H_2O} terms are very small and have a high uncertainty. Hence, these terms are deleted from the model.

Finally, a good fit is obtained when data from the first six periods are fitted to the model. The model coefficients, standard deviations, and 95% confidence intervals are listed in Table IV. The last column in this table is the overall activation energy, which is a function of V_c . Although the estimates of $E_u, \beta_u, E_i,$ and β_i are statistically significant (because their mean value estimates are relatively much larger than the corresponding standard devi-

ations), when they are combined in an overall activation energy the two factors tend to cancel each other out, leaving a number which is relatively small compared to its standard deviation. This result, however, does not diminish the significance of the two parameters, E and β (see Table IV).

The strong effect of V_c on $-dCU/dt$ is analyzed for a proper interpretation. The voltage term ($\beta_u V_c/T$) of the decay model can be compared with the $\alpha F V_c/RT$ term from the Tafel equation. After multiplying both the terms by RT/V_c and after rearranging, α can be represented as $\beta_u R/F$. Based on $\beta_u = 8100 \text{ K/V}$ (see Table IV), α is computed to be 0.7, which agrees with α values obtained from the corrosion study of the Vulcan XC-72 carbon (used in this study as the catalyst support material) at ERC (unpublished work). It is an interesting result, because it suggests that the effectiveness (*i.e.*, activity and/or catalyst surface area) of the cathode catalyst is significantly affected by the cathode voltage, probably via carbon-support corrosion (see Eq. [1]).

The final form of the aging model for each of the four buildtypes is shown in Table V. The decay-rate equation accounting for the diffusion loss is discarded because the diffusion polarization is negligible for the test duration. The effects of the build variables are lumped in the decay-rate constants. A relative comparison of the decay-rate constants shows that the cathode with 0.6 mg/cm² Pt loading and 45% Teflon content decays much slower than the rest of the electrodes. This is expected because a cathode with higher Teflon content may be more resistant to acid attack and, hence, provide better wetproofing to prevent flooding. An evaluation of the model is discussed in the following section.

Table V. Final form of the aging model^a

• Buildtype I (0.3 mg/cm ² , 40% TFE)	$r_u = -dCU/dt = 0.0232 \cdot \exp[-10770(1/T - 0.0022)] \cdot \exp[6200(V_c/T - 0.0017)]$
• Buildtype II (0.6 mg/cm ² , 40% TFE)	$r_u = -dCU/dt = 0.0255 \cdot \exp[-3523(1/T - 0.0022)] \cdot \exp[7400(V_c/T - 0.0017)]$
• Buildtype III (0.3 mg/cm ² , 45% TFE)	$r_u = -dCU/dt = 0.0213 \cdot \exp[-9461(1/T - 0.0022)] \cdot \exp[5900(V_c/T - 0.0017)]$
• Buildtype IV (0.6 mg/cm ² , 45% TFE)	$r_u = -dCU/dt = 0.0134 \cdot \exp[-8505(1/T - 0.0022)] \cdot \exp[8100(V_c/T - 0.0017)]$

^a T - temperature, K; V_c - cathode voltage, V; CU - catalyst utilization, %; t - time, h.

Evaluation of the Aging Model

To evaluate the validity of the aging model (see Table V) the performance predicted by the model (for buildtype IV) is compared with the base line performance data. Because the model does not contain CU and i_l terms, it predicts a linear decay. The base line performance data shows an exponential decay. This indicates that the CU and i_l terms are necessary and should be included in the model. The model parameters are therefore re-estimated after including the CU and i_l terms. Though the F-test shows a good fit, the uncertainty in the estimates of the parameters increases because of the limited data available to estimate CU and i_l parameters (first six periods only).

Different values of the decay-rate constants and α within a 95% confidence interval are used to predict the

Fig. 2. Comparison of cell performance predicted by aging model derived from perturbation experiments, with unperturbed test data

performance. The minimum values of the decay-rate constants and the maximum values of α yield a reasonably good agreement between the predicted and the experimental curves (Fig. 2). The fact that parametric values for the best fit lie within the 95% confidence limits of the estimates supports the applicability of this approach. Because of a large uncertainty in the parametric values, however, it is weak evidence, and further experiments are needed to strengthen these findings.

Summary

A methodology for predicting long-term fuel-cell performance from short-term testing, utilizing a perturbation testing technique, has been developed and tested on phosphoric acid fuel cells. The initial series of perturbation tests appears to be reasonably successful. The perturbation levels and the periods selected are sufficient to obtain measurable decay. A reasonable agreement between the performance predicted by the simple aging model derived from the perturbation experiments and the unperturbed test data of base line cells supports the applicability of the perturbation technique and the methodology used. The methodology developed for perturbation testing of PAFC should be further refined and applied to other fuel cells, batteries, and electrochemical systems.

The following effects of the operating and cell-component variables on the phosphoric acid fuel-cell decay have been observed

- Cell temperature and cathode voltage are the dominant parameters in the platinum deactivation. The observed effect of cathode voltage on the activity and/or catalyst surface area of the cathode catalyst may be related to a corrosion of the carbon support.
- No significant effect of water partial pressure on cell decay is observed.
- The cathodes with 0.6 mg/cm² Pt loading and 45% Teflon content decay much slower than the electrodes having lower Pt loading and/or Teflon content.
- For the entire test duration, the limiting current density remains sufficiently high and, consequently, the diffusion polarization is found to be negligible.

APPENDIX A

Phosphoric Acid Fuel-Cell Performance Model and Estimation of Catalyst Utilization

Performance model.—The fuel cell terminal voltage, V , can be expressed as

$$V = E - Ir - \eta_{\text{anode}} - \eta_{\text{cathode}}^{\text{act}} - \eta_{\text{cathode}}^{\text{dif}} \quad [\text{A-1}]$$

In perturbation testing, cathode voltage, V_c , is kept constant during a period. Hence, substituting V_c for $V + Ir + \eta_{\text{anode}}$ in Eq. [A-1] gives

$$V_c = E - \eta_{\text{cathode}}^{\text{act}} - \eta_{\text{cathode}}^{\text{dif}} \quad [\text{A-2}]$$

where the Nernst potential or reversible EMF is

$$E = 1.2605 - 0.00025 T + RT/2F \ln (P_{\text{H}_2} P_{\text{O}_2}^{1/2} P_{\text{H}_2\text{O}}^{-1}) \quad [\text{A-3}]$$

activation polarization at cathode is

$$\eta_{\text{cathode}}^{\text{act}} = RT/F \ln (i \times (i_0 \times CL_0 \times SA_0 \times CU) - 1) \quad [\text{A-4}]$$

³Where, $CU = CU_0[(SA_0/SA_0)(CL_0/CL_0)]$ and $i_0 = 0.12 \exp(-12,795/RT) P_{\text{O}_2}^{3/4} P_{\text{H}_2\text{O}}^{1/2}$

and diffusion polarization at cathode is

$$\eta_{\text{cathode}}^{\text{dif}} = RT/2F \ln (i_L \times (i_L - i)^{-1}) \quad [\text{A-5}]$$

In the model, CL and SA are treated as the initial catalyst loading and initial surface area. Any changes in CL and SA with time, thus, are automatically lumped in the CU term.

Estimation of CU .—The Nernst potential, E , and diffusion polarization, $\eta_{\text{cathode}}^{\text{dif}}$, are computed by substituting i , i_L , T , P_{H_2} , P_{O_2} , and $P_{\text{H}_2\text{O}}$ (maintained constant during a perturbation period) in Eq. [A-3] and [A-5]. Activation polarization at the cathode, $\eta_{\text{cathode}}^{\text{act}}$, is then estimated by substituting E , $\eta_{\text{cathode}}^{\text{dif}}$, and V_c (kept constant during a perturbation period) in Eq. [A-2]. Finally, catalyst utilization, CU , is computed by substituting $\eta_{\text{cathode}}^{\text{act}}$, T , i , i_0 , CL_0 , and SA_0 , in Eq. [A-4].

APPENDIX B

Transformation to a Logarithmic Decay Model

The simple aging model represented by Eq. [2] and [3] (in the text) can be transformed to a logarithmic form below

$$\ln \tau_u = \ln k_{u0} - E_u/RT + \alpha_u \ln CU + \beta_u V_c/T + \gamma_u \ln P_{\text{H}_2\text{O}} \quad [\text{B-1}]$$

$$\ln \tau_i = \ln k_{i0} - E_i/RT + \alpha_i \ln i_L + \beta_i V_c/T + \gamma_i \ln P_{\text{H}_2\text{O}} \quad [\text{B-2}]$$

The most general logarithmic form is obtained by expanding $\ln \tau$ in a Taylor series in terms of $1/T$, $\ln CU$, $\ln i_L$, V_c/T , and $\ln P_{\text{H}_2\text{O}}$ about the center point

$$\begin{aligned} \ln \tau_u = & \ln \tau_{u0} + a_1 (1/T - \overline{1/T}) + a_2 (\ln CU - \overline{\ln CU}) \\ & + a_3 (V_c/T - \overline{V_c/T}) \\ & + a_4 (\ln P_{\text{H}_2\text{O}} - \overline{\ln P_{\text{H}_2\text{O}}}) + \frac{1}{2} a_{11} (1/T - \overline{1/T})^2 \\ & + \frac{1}{2} a_{22} (\ln CU - \overline{\ln CU})^2 + \frac{1}{2} a_{33} (V_c/T - \overline{V_c/T})^2 \\ & + \frac{1}{2} a_{44} (\ln P_{\text{H}_2\text{O}} - \overline{\ln P_{\text{H}_2\text{O}}})^2 + a_{12} (1/T - \overline{1/T}) \ln (CU - \overline{\ln CU}) \\ & + a_{13} (1/T - \overline{1/T}) (V_c/T - \overline{V_c/T}) + a_{14} (1/T - \overline{1/T}) (\ln P_{\text{H}_2\text{O}} \\ & - \overline{\ln P_{\text{H}_2\text{O}}}) \\ & + a_{23} (\ln CU - \overline{\ln CU}) (V_c/T - \overline{V_c/T}) + a_{24} (\ln CU - \overline{\ln CU}) \\ & (\ln P_{\text{H}_2\text{O}} - \overline{\ln P_{\text{H}_2\text{O}}}) + a_{34} (V_c/T - \overline{V_c/T}) (\ln P_{\text{H}_2\text{O}} - \overline{\ln P_{\text{H}_2\text{O}}}) \\ & + \text{higher order terms} \quad [\text{B-3}] \end{aligned}$$

Most general forms for $\ln \tau_i$ can be obtained similarly. However, quadratic, interaction, and higher order terms are neglected in order to have a simple linear model. The simplified model is

$$\ln \tau_u = \ln \tau_{u0} + a_1 (1/T - \overline{1/T}) + a_2 (\ln CU - \overline{\ln CU}) + a_3 (V_c/T - \overline{V_c/T}) + a_4 (\ln P_{\text{H}_2\text{O}} - \overline{\ln P_{\text{H}_2\text{O}}}) \quad [\text{B-4}]$$

and

$$\ln \tau_i = \ln \tau_{i0} + a_1' (1/T - \overline{1/T}) + a_2' (\ln i_L - \overline{\ln i_L}) + a_3' (V_c/T - \overline{V_c/T}) + a_4' (\ln P_{\text{H}_2\text{O}} - \overline{\ln P_{\text{H}_2\text{O}}}) \quad [\text{B-5}]$$

or

$$\ln \tau_u = \ln k_{u0} + a_1 \frac{1}{T} + a_2 \ln CU + a_3 V_c/T + a_4 \ln P_{\text{H}_2\text{O}} \quad [\text{B-6}]$$

and

$$\ln \tau_i = \ln k_{i0} + a_1' \frac{1}{T} + a_2' \ln i_L + a_3' V_c/T + a_4' \ln P_{\text{H}_2\text{O}} \quad [\text{B-7}]$$

Comparison of [B-6] and [B-7] with [B-1] and [B-2], respectively shows

$$a_1, a_1' = -E_u/R, -E_i/R$$

$$a_2, a_2' = \alpha_u, \alpha_i$$

$$a_3, a_3' = \beta_u, \beta_i$$

$$a_4, a_4' = \gamma_u, \gamma_i$$

Substituting the above relationships into Eq. [B-4] and [B-5] gives

$$\ln \tau_u = \ln \tau_{u0} - E_u/R (1/T - \overline{1/T}) + \alpha_u (\ln CU - \overline{\ln CU}) + \beta_u (V_c/T - \overline{V_c/T}) + \gamma_u (\ln P_{\text{H}_2\text{O}} - \overline{\ln P_{\text{H}_2\text{O}}}) \quad [\text{B-8}]$$

and

$$\ln \tau_1 = \ln \tau_{i_0} - E_i/R (1/T - 1/T) + \alpha_i (\ln i_i - \ln i_0) + \beta_i (V_c/T - \bar{V}_c/T) + \gamma_i (\ln P_{H_2O} - \ln \bar{P}_{H_2O}) \quad [B-9]$$

LIST OF SYMBOLS

CL_0	initial catalyst loading at cathode
CL_t	catalyst loading at time t
CU_0	initial catalyst utilization
CU	$CU_0 [(SA_t/SA_0) (CL_t/CL_0)]$
E	Nernst potential
E_i	activation energy for the decay reaction in mode B
E_u	activation energy for the decay reaction in mode A
F	Faraday's constant
I	current
i	current density
i_L	limiting current density
i_0	exchange current density
k_{i_0}	decay rate constant in mode B

Some Characteristics of PbO_2 Doped with Various Elements

A. Delmastro and M. Maja*

Dipartimento di Scienza dei Materiali ed Ingegneria Chimica, del Politecnico di Torino, 10129 Torino-Italia

ABSTRACT

The doping effect of various elements (Ag, As, Co, Ge, Mn, Ni, Sb, Se, Sn, Te, and Zn) on the O/Pb ratio, on morphology, and on self-discharge of alpha and beta lead dioxide have been investigated. These dopants increase the O/Pb ratio and, with the exception of As, Te, Sn, and Mn in the beta form, lower the self-discharge rate. The effects on the morphology are evident only for Ge and Sn at concentrations greater than 100 ppm in the solution.

It is well known that alloying elements in the lead of positive grids and inorganic compounds added to active material during manufacturing of plates of Pb-Ac batteries can affect the behavior of cells in various ways. The impurities in sulfuric acid used for plates' conversion and during battery service life can also have a noticeable influence (1). In fact, the alloying constituents of positive grids can enter the lattice of oxides that form during corrosion, thus influencing the electrical characteristics of contact between active material and the grid. Moreover, alloying elements that dissolve in electrolyte and the impurities of sulfuric acid can dope both allotropic forms of PbO_2 during cycling of the batteries, thereby promoting a stabilization of some structures and changing some active material properties.

Years ago, our research group began a systematic study concerning the electrochemical characteristics of alpha and beta lead dioxide doped with various elements. Some results regarding the influence of antimony have been reported (2, 3). In this work, the study is extended to other elements which can be present in lead-acid batteries, both as alloying constituents of grids and as impurities of electrolyte.

Studied in particular is the influence of Ag, As, Co, Ge, Mn, Ni, Sb, Se, Sn, Te, and Zn, inserted as doping ele-

ments in the lattice of lead dioxide, on stoichiometry deviation, crystal morphology, and self-discharge.

The effect of 24 contaminant ions on the gas generation rate of the lead-acid cell has been examined by Pierson *et al.* (4) in order to determine the permissible impurity concentration levels in a maintenance-free battery. They find that only five elements (As, Co, Ni, Sb, and Te) have a drastic effect on gassing during constant overcharge tests.

Mahato and Tiedemann (5) have studied the effect of trace As, Co, Ni, Sb, and Te ions on linear potential sweep curves of lead-acid battery electrodes. By considering the hydrogen and oxygen overvoltage change, these authors show the dangerous effects of As, Sb, and Te on negative plates and of Co and Ni on positive ones.

Experimental

According to the method referred to in the literature (6), various samples of the two allotropic forms of lead dioxide had been prepared. Alpha lead dioxide was electrodeposited on Pt electrodes from a 2M KOH solution saturated with PbO at a current density of 10 mA/cm². Beta lead dioxide was electrodeposited on Pt electrodes from a 0.5M lead-nitrate solution containing 0.15M nitric acid at a current density of 100 mA/cm². The solutions were stirred and maintained at 30°C.

* Electrochemical Society Active Member.

Doping of PbO₂ was achieved by adding to the pure electrodeposition solution known amounts of doping elements: As, Ge, Sn, Te, Sb, Se, and Zn for the alpha form; and Ag, As, Co, Ge, Mn, Ni, Sb, Se, Sn, Te, and Zn for the beta form. The doping elements were added to the solution as nitrates or as oxides dissolved in KOH. By increasing the concentration of some doping elements in the electrolyte above 100 ppm, the current efficiency for lead dioxide deposition abruptly decreased yielding powdery deposits (Fig. 1). For this reason, the maximum concentration of the studied elements was limited to 100 ppm. This finding was evidence of the influence of the considered elements.

After electrodeposition, the electrodes were washed in ammonium acetate and in distilled water; then they were dried in air. The influence of doping elements on the morphology of lead dioxide crystals was determined by observing with a scanning electron microscope (SEM) the surface of some anodic deposits obtained from solutions containing up to 200 ppm of dopant.

In order to determine the characteristics of the dioxide, the anodic layers were detached from the Pt substrates and carefully ground in a mortar to obtain a fine homogeneous powder. The phase purity and crystallinity of powder samples were tested by means of x-ray diffraction. The true surface area was determined by the standard BET method using nitrogen adsorption. A sample of the powder was analyzed to determine the amount of the doping element and the deviations from the stoichiometry (O/Pb ratio) of lead dioxide. The amount of doping elements was determined by means of inductively coupled plasma spectrophotometry, while the O/Pb ratio was measured by iodometric titration of active oxygen (7).

The self-discharge of lead dioxide was studied by measuring the oxygen evolution-rate at the rest potential of the dioxide in sulfuric acid, employing an apparatus similar to that described by Ruetschi (8). For this purpose, 1.5g of powder was introduced in a small glass tube for a microvolumetric gassing test; the tube was then filled with pure sulfuric acid having a density of 1.4 g/cm³ and was maintained at a temperature of 30° ± 0.05°C.

During these tests, which lasted 10 days, the amount of oxygen developed was periodically measured, and self-discharge equivalent currents of lead dioxide were calculated from the data collected.

Results and Discussion

Doping and stoichiometry deviation.—The analytical method employed to measure the stoichiometry of PbO₂ permits the determination of the amount of tetravalent lead ions in the lattice of this compound. The same method, applied to doped PbO₂, also takes into account the amount of doping elements having an oxidation number at which they behave as an oxidant in respect to chloride ions.

The doping elements considered in this work can have a variable valency, and the deposition potential of lead dioxide assures their codeposition with tetravalent lead ions in one of their oxidized states. Because the doping elements can have a different oxidation-number variation during the iodometric analysis, they do not behave the same way with respect to chloride ions. However, considering that the O/Pb ratio increase, calculated from the amount of doping elements present in the lattice at their highest oxidation number, will be markedly lower than the measured values, the O/Me ratio obtained by iodometric titration can be taken as the effective atomic ratio value of the doped dioxide.

In the case of pure alpha and beta forms, in agreement with the data reported in the literature (9), the analysis shows that their O/Pb ratios are equal to 1.87 and 1.93, respectively. These values for the doped lead dioxide will increase if the doping element, with an oxidation number greater than two, substitutes the bivalent lead ions in the lattice or occupies metal vacancies or if the lattice content of hydrogen or hydroxyl ions decreases as a consequence of doping.

Fig. 1. Current efficiency for PbO₂ electrodeposition from solutions containing As³⁺ ions as impurity.

The data concerning the O/Pb ratio for the doped allotropic forms and the amount of doping elements in the lattice are reported in Fig. 2 and 3 and in Tables I and II. Under the same conditions of temperature, current density, and concentration of doping elements in the electrolyte, the ion which codeposits in the greatest amount in the alpha allotropic form is antimony, followed in decreasing order by Zn, Sn, Ge, Te, Se, and As. For the beta lead dioxide, the following decreasing series has been established: Sb, Ge, Te, Mn, As, Sn, Ag, Se, Co, Zn, and Ni. The results show that the O/Pb ratio for both the alpha and beta lead dioxide increases with the doping element amount in the lattice and that the increasing of the stoichiometry in the case of the alpha form is higher than that observed for the beta form. The alpha lead dioxide doped with Ge, Se, and Te presents an O/Pb ratio nearly equal to that of the pure beta form.

By comparing the amount of doping elements which can be codeposited with tetravalent lead ions from both alkaline and acid solutions (Table I) at the same concentration of doping ions added to the electrolyte used in anodic electrodeposition of PbO₂, it is possible to order these elements in the following decreasing series: Sb, Zn, Ge, Te, Sn, As, and Se.

Fig. 2. O/Pb ratio vs. dopant content in the electrolyte

Fig. 3. O/Pb ratio vs. dopant content in the electrolyte

In order to ascertain the influence of the various dopants on the lead dioxide stoichiometry, the data corresponding to the same concentration of doping element in the PbO_2 lattice are compared. For this purpose, the experimental O/Pb ratio data are interpolated to calculate the value for a given dopant concentration (0.01%). The elements are ordered according to the following decreasing series: Te, Ge, Se, Zn, Sn, As, and Sb for the alpha lead dioxide; and Co, As, (Se, Sn, Mn, Zn), (Te, As, Ge), and Sb for the beta lead dioxide. It is interesting to observe the opposite positions occupied by As and Te in these series. The positions can only be explained by supposing that, according to the allotropic form, two different action mechanisms for these elements must be taken into account. Moreover, the great influence of the studied elements on the O/Pb ratio, compared with their concentration in the lattice, reveals that the stoichiometry deviation of the dioxide can be attributed to the decreasing of hydrogen and hydroxyl ions in the lattice as a consequence of doping.

By considering the above reported results, it is possible to determine that the major effect of Sb on the properties of alpha PbO_2 is strictly connected with the higher level of doping which may be obtained with this element.

Finally, SEM observation of electrodeposited anodic layers shows that, while the effect of the dopants is practically negligible in the case of beta PbO_2 , the elements codeposited with lead from solutions containing up to 100

ppm of dopant cause a small reduction of the crystal size of alpha PbO_2 without substantially modifying the crystal morphology. A comparison of the structures of pure alpha PbO_2 and Ge- and Sn-doped alpha PbO_2 anodic layers is shown in Fig. 4-6.

For impurity concentration greater than 100 ppm, the current efficiency of PbO_2 electrodeposition decreases, as previously described, and the anodic layers formed are powdery. In the case of Ge- and Sn-doped alpha PbO_2 obtained from solutions containing impurity concentration of 200 ppm, the SEM observation of the anodic layers shows a "soap bubble" structure, as in the case of Sb-doped alpha PbO_2 (2). These results indicate that, generally, the impurities, entering the lattice of alpha PbO_2 , change the oxygen overpotential and the crystal morphology by increasing the active areas for the oxygen evolution. As a consequence, the oxygen evolution is the main process above a critical impurity concentration at which the PbO_2 anodic layers cannot form any more.

Self-discharge.—It is well known that lead dioxide is not thermodynamically stable in sulfuric acid solutions because of the high value of its standard potential of reduction with respect to the oxygen/hydroxyl ion couple. In spite of that, the reaction rate of self-discharge $\text{PbO}_2 + \text{H}_2\text{SO}_4 = \text{PbSO}_4 + \text{H}_2\text{O} + 1/2 \text{O}_2$ is very slow. Because the lead dioxide reduction occurs in sulfuric media at a very low overpotential, it is easy to forecast that the self-discharge reaction, in the absence of a reductive agent, is a process controlled by oxygen evolution. The recent developments in electrocatalysis concerning the oxygen evolution reaction on conductive oxides (10) take into ac-

count various parameters such as geometrical factor, adsorption and desorption energy of intermediates, O/Me ratio, and surface activity. This reaction is extensively studied in the case of PbO₂ electrodes.

Ruetschi *et al.* (11) shows that the kinetics of oxygen evolution on the two forms of lead dioxide are different for both Tafel slope (0.07 for the alpha form and 0.12 for the beta form) and exchange current density ($1.77 \cdot 10^{-16}$ and $6.2 \cdot 10^{-10} \text{ A/cm}^2$, respectively). Thus, while the overpotential differences become smaller at open circuit near the reversible potential of the dioxide/sulfate couple, the oxygen overvoltage on beta dioxide is higher than the value on the alpha form at high current density. On the other hand, Makrides (12) claims that no difference exists between the two forms if a nonporous film of the dioxide is deposited on Pt electrodes. The same results are also reported by Vuorio (13) and Hyvarinen (14). This disagreement can be resolved by considering the possibility that the alpha lead dioxide, in acid media, can transform to the more stable beta form.

The increase in activity of alpha lead dioxide with respect to beta has been attributed to different surface lattice spacing (10). Moreover, the position of lead dioxide on the "volcano curve" (10) indicates that the oxygen vacancies in the dioxide are responsible for its activity and that the decrease in nonstoichiometry, involving a weaker adsorption intermediate, produces a decrease of electrocatalytic activity of the dioxide. In regard to the surface activity, it must be pointed out that the physical-chemical methods used to measure the true surface of a specimen do not give information on the electrochemical

active surface which can otherwise be obtained by means of capacitance measurements. And finally, the literature refers to some evidence concerning the adsorbed species on lead dioxide (15). It is generally accepted that atomic oxygen, OH radicals, sulfate ions, and water molecules are present on the dioxide surface according to the applied potential.

In order to study the reaction rate of self-discharge, some microvolumetric determinations of oxygen evolved from a known amount of pure and doped lead dioxide ground and put into a sulfuric acid solution are carried out. Doped lead dioxide samples are prepared from solutions containing the same concentration of the doping element (100 ppm). They have different stoichiometry and various compositions, as it has been shown above. The specific area of the samples is reported in Table III.

It must be noted that while specific areas of alpha PbO₂ agree with the data in the work of Voss and Ruetschi (8, 16), the results for beta lead dioxide do not agree with the data in the literature. On the other hand, the tests show that the pure and doped beta allotropic forms, produced by anodic deposition and powdered as described above, have in all examined cases the same granulometry of the alpha form, but a lower BET area. Capacitance data obtained from impedance measurements on pure and antimony-doped alpha and beta electrodeposited PbO₂ seem to agree with BET data (17).

The collected experimental data, with daily measurements made for ten days, have been transformed using regression linear analysis, to the mean values of self-discharge current and self-discharge current density, as reported in Table III. For these data, varying behavior of doped alpha and beta lead dioxide occurs, and some remarks on the influence of the doping elements can be made. The values of self-discharge current density for the two pure lead dioxide forms are about the same. In the doped alpha form, all such values are smaller than those for the pure form. Whereas the dopants always decrease the self-discharge current for alpha PbO₂, three groups of elements having different effects can be depicted for doped beta PbO₂: As, Mn, and Sn increase the self-discharge current values, while Co and Te exhibit an almost null effect; and all the remaining elements show smaller values for self-discharge current density than in the case of the pure forms.

To study the effect of the doping elements on the self-discharge current density, some tests with lead dioxide specimens containing different concentrations of dopants are performed. In the range of dopant concentrations considered in this work, the results of these tests seem to in-

dicate a proportionality between the doping element concentration and the self-discharge current density.

As a consequence of interpolating the experimental data, the self-discharge current densities corresponding to the same concentration of dopants in the PbO_2 lattice (e.g., 0.01%) are calculated, and the following series is obtained, in which the elements are in a decreasing self-discharge current density order: As, Ge, Se, Te, Sn, Sb, and Zn with lowering effect in doped alpha PbO_2 ; Sn, As, and Mn with enhancing effect; Co and Te with negligible effect; and Zn, Se, Ag, Ge, and Sb with lowering effect in doped beta PbO_2 . It is interesting to note the opposite positions occupied by Zn and Ge in this series, the same approximate locations of Se in the sets, and the smallest values of self-discharge current density (always showed by lead dioxide doped with Sb).

Except for the results of beta PbO_2 doped with As, Mn, Sn, and Te, for which an increase in stoichiometry corresponds to a fairly important increase in self-discharge current density, the catalytic activity of oxygen evolution tends to reduce in all other cases when the O/Pb ratio values are increased. This agrees with recent discussions (10) on the electrocatalytic activity of the oxygen evolution process on oxides.

When comparing our results concerning the effect of Co and Ni with the literature data (5, 18) which report a decrease of the oxygen overvoltage when Ni and Co are added to the Pb-acid battery electrolyte, it appears that these impurities act according to a catalytic mechanism (18) involving the ions present in the solutions and not as a consequence of doping.

Conclusions

Some general conclusions can be drawn from the results discussed above.

- 1) By considering the dopants which can be present both in alpha and in beta PbO_2 , the alpha allotropic form incorporates greater amounts of Sb, Sn, and Zn, whereas the beta form incorporates greater amounts of As, Ge, Se, and Te.
- 2) The doping of alpha PbO_2 produces an increase in the O/Pb ratio which always corresponds to the decrease in oxygen evolution rate, according to ideas of electrocatalysis theory concerning the relation between oxygen overpotential and oxide stoichiometry.
- 3) Doping of beta PbO_2 produces a small increase in stoichiometry, and only in the case of Ag, Co, Ge, Ni, Sb, Se, and Zn is an increase in oxygen overpotential observed.
- 4) The greatest effect of doping elements on self-discharge current density occurs for Sn in the case of beta PbO_2 and for Ge in the case of alpha PbO_2 .

- 5) In regard to crystal morphology of PbO_2 , the effect of dopants on beta lead dioxide is practically negligible, whereas the elements codeposited with lead in the alpha form cause a small reduction of crystal size up to 100 ppm concentration; moderate variations of the crystal habitus of alpha PbO_2 occur at Ge and Sn concentrations greater than 100 ppm.

ABSTRACT

The electrochemical doping process of polyacetylene has been investigated in lithium cells using lithium perchlorate in propylene carbonate as the electrolytic solution. The kinetics and the cyclability of this process have been examined by cyclic voltammetry, charge-discharge curves, and EPR analysis. The results show that, for film-type polyacetylene electrodes, the kinetics are controlled by the diffusion of the dopant species throughout the polymer. This diffusion appears particularly slow from the bulk to the surface of the polymer so that constant-current charge-discharge cycles of polyacetylene film electrodes may sustain only low rates (*i.e.*, in the range of microamperes per square centimeter), and have a poor coulombic efficiency (*i.e.*, of the order of 50%). Much better performance is offered by foam-type polyacetylene electrodes, where the intrinsic high porosity produces an improved surface morphology, which in turn favors the diffusion of the dopant species. Indeed, constant-current, charge-discharge cycles at reasonably high rates (*i.e.*, in the range of milliamperes per square centimeter) and reasonably good coulombic efficiencies (*i.e.*, of the order of 85%), have been obtained with lithium cells using this type of polyacetylene electrodes.

Much interest has lately been devoted to polyacetylene (PA) films and to their application as electrodes in lithium-organic electrolyte batteries (1-4). However, the results so far published are somewhat controversial. MacDiarmid and co-workers (1, 5) have reported that PA can be oxidized and reduced with nearly 100% coulombic efficiency in the LiClO_4 -PC electrolyte and that this cycling process may be repeated several times (5). However, such high cycling efficiency was only obtained by a constant current charge followed by an extended, controlled-potential discharge. MacDiarmid and co-workers also reported that the electrochemically oxidized, PA-doped electrodes do not spontaneously lose their charge, thus showing very good stability and long shelf-life (1). Other authors have also observed that only about 50% of the charge stored in the oxidized PA can be recovered in a constant-current cycle, and the remainder is only accessible by the extended controlled-potential discharge (4, 6). But, they also presented convincing experimental indications that the electrochemically oxidized PA electrodes do suffer a considerable loss of charge upon standing in the nonaqueous electrolyte (4, 7).

Coulombic efficiency and stability are obviously crucial aspects in the characterization of electrode materials for batteries. Therefore, we have considered it important to carry out a systematic study on the electrochemical behavior of PA electrodes in nonaqueous electrolytes, in an attempt to clarify whether the apparently contradictory results are related to intrinsic properties of the polymer or to external, controllable factors, such as *cis-trans* conformation ratio, surface morphology, preparation technique, experimental procedure, and so forth.

In this paper, we discuss the kinetics and the cyclability of various types of PA electrodes in the LiClO_4 -propylene carbonate electrolyte, on the basis of cyclic voltammetry, polarization, and EPR studies.

Experimental

Shirakawa-type polyacetylene films about 0.005 cm thick were synthesized according to the procedure described by Ito *et al.* (8). The specific characteristics of these films are: (i) apparent density ranging from 0.7 to 0.9 g/cm³; (ii) specific conductivity in the range of 10^{-9} to

10^{-5} ($\Omega \cdot \text{cm}$)⁻¹, depending on the *cis-trans* conformation ratio.

The PA foam samples were prepared following the procedure recommended by Wnek *et al.* (9). Pressed foam samples about 0.1 cm thick were obtained using a gel as an intermediate synthetic step (9). The apparent density of these pressed samples was about 0.4-0.6 g/cm³, and their electrical characteristics, both in the undoped and in the doped state, were similar to those of the PA films.

The *cis-trans* ratio of all the PA samples was varied by temperature-induced polymerization.

In view of the sensitivity of PA to impurities, particular care was devoted to the preparation of the electrolyte solution, and to the assembly of the cell under controlled environmental conditions.

Propylene carbonate (PC), a Merck reagent-grade product, was distilled twice under vacuum and then percolated through activated alumina. Lithium perchlorate, LiClO_4 , a Ventron pure product, was used as received. The 1M LiClO_4 -PC electrolyte solution was prepared in a dry box and further purified by percolation through activated alumina.

The electrochemical measurements were carried out in a glass cell having three compartments separated by porous glass walls (4). The PA electrodes (approximately 1 cm² surface) were sandwiched in a platinum mesh and housed in the central compartment of the cell. The Li reference and Li counterelectrodes were located in the two side compartments. The lower part of the cell was first filled with a layer of activated alumina and then by approximately 10 cm³ of the LiClO_4 -PC solution.

The electrochemical stability of this solution was tested in the same cell using the platinum mesh as the indicator electrode.

All the experimental procedures were performed in a controlled-atmosphere dry box. Standard electrochemical equipment was used for the cyclic voltammetry and the polarization studies.

The EPR spectra were recorded on a Varian E-X4 band spectrometer with an ancillary temperature-control unit. The maximum hyperfrequency power was 5 mW. The experimental tests were performed on 100% *trans* PA samples in order to avoid isomerization effects on the EPR linewidth.

Fig. 1. A: cyclic voltammetry of the LiClO₄-PC electrolyte. (Pt mesh electrode.) B: cyclic voltammetry of a cis-rich PA film electrode in the LiClO₄-PC electrolyte. Scanning rate: 0.4 mV/s.

Results and Discussion

As already pointed out in the experimental section, particular care was devoted to the preparation and the purification of the LiClO₄-PC solution. Figure 1A shows the voltammetric response of a Pt mesh electrode in this electrolyte. The low residual current is a good indication of the purity of the electrolyte, whose reduction and oxidation voltage limits are about 2.5 and 4.0V, respectively, vs. Li.

The cyclic voltammogram of a cis-rich PA film electrode in the LiClO₄-PC electrolyte is shown in Fig. 1B. The voltammogram reveals two oxidation peaks, at about 3.6 and 3.8V, respectively, vs. Li. The two oxidation peaks suggest a two-stage mechanism for the electrochemical doping process of PA in LiClO₄-PC. Indeed, McKinney and Burrow (7), obtained a similar two-peak cyclic voltammogram of PA film electrodes in lithium perchlorate-sulfolane electrolyte and suggested the presence of two different sites in the PA structure available for the electrochemical p-doping process.

Figure 2 compares the cyclic voltammograms of the cis-rich PA film electrodes in LiClO₄-PC under different scanning rates. Notice that as the scanning rate increases, the separation between the peaks vanishes and finally only one peak becomes detectable. Furthermore, the increased scanning rate causes a decrease in the reversibility of the overall process. Therefore, the

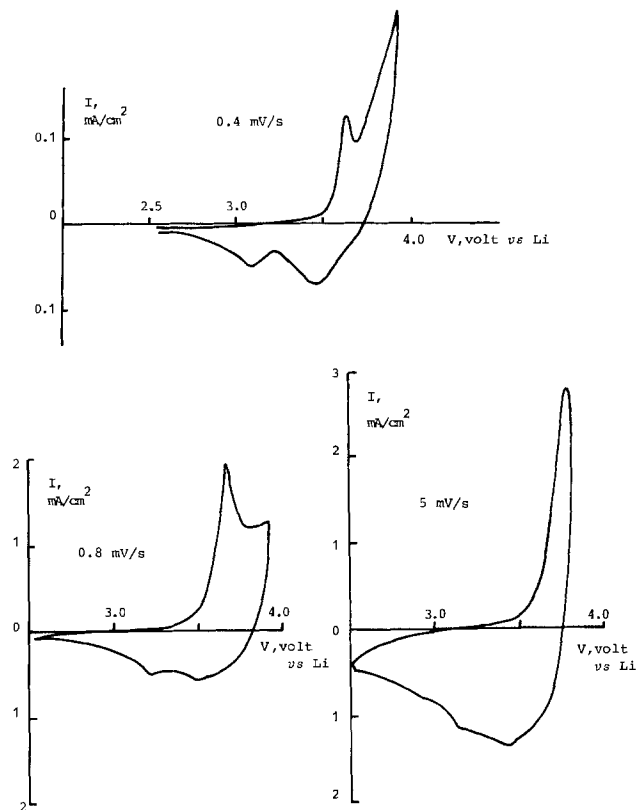

Fig. 2. Cyclic voltammetry of cis-rich PA film electrodes in the LiClO₄-PC electrolyte at various scanning rates.

voltammetric results indicate that the anodic charging (p-doping) process of PA in LiClO₄-PC is characterized by two steps, whose kinetics are strongly controlled by the diffusion of the dopant ClO₄⁻ species throughout the polymer.

In fact, Farrington *et al.* (4) and Abe *et al.* (10) have found two plateaus in the charging curve of a Li/LiClO₄-PC/PA cell. To the contrary, Kaneto *et al.* (2) reported the open-circuit potential of ClO₄⁻ doped, cis-rich PA electrodes increases smoothly with the doping level. This apparent difference may be explained by the diffusion-controlled kinetics of the electrochemical doping process of PA, whose characteristics can vary considerably with the experimental conditions.

On the basis of Fig. 2, one may reasonably expect that at high rates the charge curve of the Li/PA cell may reveal only one plateau and the charge-discharge coulombic efficiency may remain low. This is indeed what we have observed with cells using the same type of PA film electrodes to which Fig. 2 refers.

As illustrated in Fig. 3, the constant current charge-discharge cycles of these cells show a single-plateau charge curve and a poor coulombic efficiency (around 50%), even at moderate rates, such as 0.05 mA/cm². Low efficiency seems to be a typical characteristic of PA film electrodes; it remains around 50% for each constant-

Fig. 3. Constant-current (0.05 mA/cm²) charge-discharge cycles of a Li/PA film cell at 25°C. The number of cycle and the coulombic efficiency (η) are indicated in the figure.

Fig. 4. Micropolarization tests of the PA film electrode at various stages of a constant-current ($0.05 \text{ mA}/\text{cm}^2$) charge-discharge cycle of a Li/PA cell.

current cycle and does not improve upon cycling. Similar results have been obtained by various other authors (2, 4,

6, 10), and thus it is reasonable to assume that the low coulombic efficiency of PA film electrodes in $\text{LiClO}_4\text{-PC}$

Fig. 5. Constant-current ($0.05 \text{ mA}/\text{cm}^2$) charge-discharge cycle of a Li/PA film cell. Only about 50% of the dopant species are removed by the discharge. Complete removal is obtained only by an extended, controlled-potential discharge.

Fig. 6. EPR analyses of *trans*-rich PA film electrodes at various stages of a constant current charge and of a following constant current plus constant potential discharge process, of the type of that illustrated in Fig. 5. ΔH_{pp} = linewidth. η = percent of recovery of the original linewidth of the pristine sample.

is ascribable to the diffusion of the dopant ClO_4^- species, which appears especially slow from the bulk to the surface of the polymer.

In Fig. 4, micropolarization curves from the PA film electrodes at various stages of a constant current, charge-discharge cycle of the type discussed for Fig. 3 are shown. Fast kinetics and good reversibility (revealed by the linearity of the anodic and cathodic micropolarization scans), are obtained only during the last part of the charge and the beginning of the discharge. Apparently, only the dopant species residing near the surface of the polymer are easily removed by the constant-current discharge process. The remainder, which has diffused toward the bulk, is observed in the second oxidation step, and is not readily available; thus a poor coulombic efficiency is obtained over the entire cycle. The complete removal of the dopant species and therefore the full reversibility of the electrochemical PA doping process may be obtained only

by adding to the constant current discharge, an extended, controlled-potential (2.5V vs. Li) process, as illustrated in Fig. 5.

This conclusion is further supported by EPR analyses of the PA film electrodes, run at various stages in the cycle of Fig. 5. As shown in Fig. 6, the electrochemically doped PA samples after charge (B) show EPR spectra with a linewidth (ΔH_{pp}) narrower than that associable to the pristine sample (A). The EPR spectra related to the sample after the constant-current discharge (C) reveals only 25% recovery of the original linewidth. Only after the extended, controlled-potential process (D), does the recovery reach 86%. With constant potential, charge-discharge cycles, efficiencies on the order of 85%-95% have been obtained for Li/PA cells by various authors (2, 4). This type of cycling, however, does not appear very

Fig. 7. Cyclic voltammetry of *trans*-rich PA film electrodes in the $\text{LiClO}_4\text{-PC}$ electrolyte at various scanning rates.

Fig. 9. Cyclic voltammety of *cis*-rich PA foam electrodes at various scanning rates.

useful in practice, where constant rates are generally required.

To determine whether the *cis-trans* conformation ratio of the polymer could be in part responsible for the kinetic limitation, we have considered the cyclic voltammety of *trans*-rich PA film electrodes. The results, obtained at various scanning rates, are shown in Fig. 7. The voltammetric response is similar to that observed for *cis*-rich electrodes (compare Fig. 2). Here again, the height of the first peak and the reversibility of the overall process depends on the scanning rate. Therefore, a poor coulombic efficiency for the *trans*-rich electrodes is to be expected in constant current, charge-discharge cycles, as was experimentally verified. The *cis-trans* ratio does not influence the kinetics of the electrochemical p-doping process of PA in the LiClO₄-PC solution. This is not surprising and is consistent with the fact that *cis-to-trans* isomerization takes place anyway during the electrochemical doping process, without apparently affecting its characteristics (11).

The kinetics may be more likely influenced by the morphology of the polymer, since diffusion of the dopants from the surface of the electrode seems to effect the efficiency so much. To investigate the role of the surface morphology on the electrochemical behavior of PA, we have considered the response of foam-type samples. In fact, the PA foam, even if retaining the typical mat-of-fibers structure of the PA film, has a much more extended surface area (9).

The cyclic voltammogram of a PA foam electrode in LiClO₄-PC, shown in Fig. 8, reveals the two typical oxidation peaks, at about 3.55 and 3.75V vs. Li, respectively. However, the response appears more reversible, both in terms of voltammetric peak resolution and current density, than the PA film electrodes under comparable conditions (compare Fig. 2B).

In Fig. 9 cyclic voltammety curves of foam PA electrodes are shown at various scanning rates. The behavior is again qualitatively similar to that of PA film electrodes (compare Fig. 2 and 7) since the increase in the scanning rate is accompanied by a broadening of the peaks. This, however, appears to be smaller in the case of the PA foam electrodes which, at high rate, assume the usual one-peak characteristic, but still maintain an acceptable degree of reversibility and a high current density response.

These results indicate that the kinetics of the electrochemical doping process of PA foam electrodes is still controlled by the diffusion of the dopant species in the polymer, but the extended surface allows reasonably high charge and discharge rates at good coulombic efficiencies.

This conclusion is further supported by examining the response of PA foam electrodes after prolonged charge-discharge cycles, obtained under diversified conditions both in terms of current density (ranging from 0.2 to 1.25 mA/cm²) and doping level (ranging from 0.5% to 4.2% mole percent [m/o]). The results, related to three different Li cells using the LiClO₄-PC electrolyte, are summarized

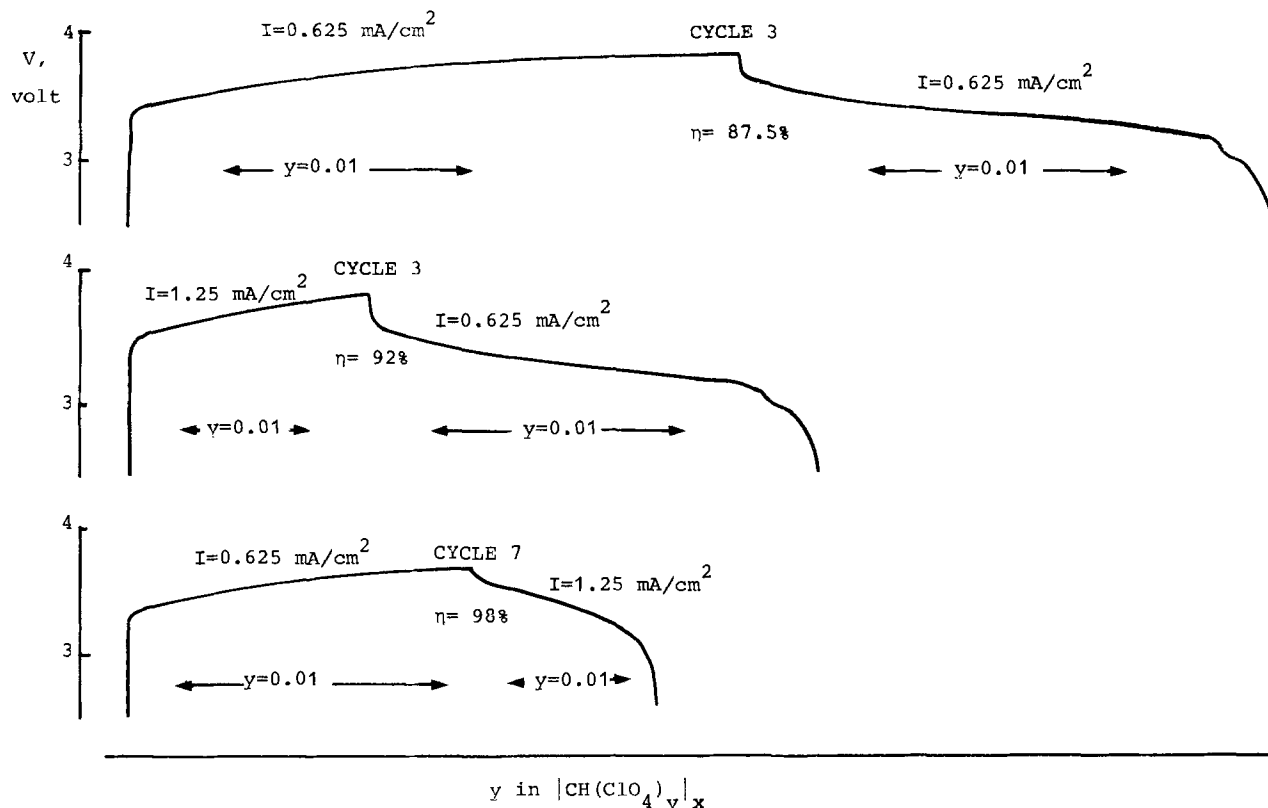

Fig. 10. Constant-current, charge discharge cycles of a Li/PA foam cell at 25°C. The number of cycle, the charge-discharge rates (mA/cm^2), and the coulombic efficiency (η) are indicated in the figure.

in Table I and illustrated in Fig. 10. The cycling behavior confirmed the voltammetric response, since the PA foam electrodes are indeed able to sustain comparatively high rates with reasonably good efficiencies.

This is clearly shown in Fig. 11, where the coulombic charge-discharge efficiencies obtained in each cycle of the three cells tested are progressively displayed. The first cycles generally have a lower efficiency than the following ones. This is not uncommon in lithium batteries; low initial coulombic efficiencies have often been reported for systems using intercalation electrodes. Such observations have been interpreted assuming that the initial intercalated species are strongly bound to the host structure and thus difficult to remove (12). These strongly bound species expand the layers of the

intercalating compound, thus facilitating further insertion and enhancing reversibility as the concentration increases (12). Since the electrochemical doping of PA may be regarded as similar to an intercalation process (4), a similar explanation may also hold in this case.

In contrast to what is observed with film-type electrodes, the efficiency of the foam type improves after the first cycles, as expected on the basis of the above-mentioned activating mechanism. After the two initial cycles, average coulombic efficiencies between 83% and 88% are obtained for the three Li/PA foam cells tested (see Fig. 11). These values, even if not yet completely satisfactory, are certainly much more encouraging in view of practical applications, than those reported for cells based on PA film electrodes, under comparable characteristics of cycling regimes and doping levels.

Conclusions

The above results show that the electrochemical p-doping process of PA in the $\text{LiClO}_4\text{-PC}$ electrolyte solution is controlled by the diffusion of the ClO_4^- dopant species in the polymer. For PA film electrodes, this diffusion appears particularly slow from the bulk to the surface, and this situation induces poor charge-discharge coulombic efficiencies for the Li/PA batteries.

Experimental results obtained by various authors (2, 4, 10, 13) confirm the kinetic limitation of the film electrodes. Slow diffusion may explain the drastic loss of capacity reported by various authors (4, 7) under open-circuit conditions. This effect may be related to the difficulty in removing the dopant species, which, upon standing, have diffused into the interior of the polymer electrode.

While the kinetic limitations of PA are independent of the *cis-trans* conformation ratio, the surface morphology does play a key role in the electrochemical doping process. Foam-type electrodes, which are characterized by a porous surface structure, can sustain much higher cycling rates and offer much better coulombic efficiencies than film-type electrodes, which are characterized by low porosity and smooth surfaces. Further study is certainly necessary to confirm this and to establish the long-term

Fig. 11. Charge-discharge coulombic efficiency (η) of PA foam electrodes in the $\text{LiClO}_4\text{-PC}$ electrolyte, under the conditions listed in Table I.

behavior of the foam-type electrodes, especially in terms of a number and depth of cycles and stability. However, the results reported in this work, even if preliminary, allow us to infer that disordered, porous morphology should be preferred for polyacetylene if it is to be used as cathode in rechargeable lithium batteries.

ABSTRACT

Optically and polarographically measured initial photoreduction rates of methylviologen on polycrystalline TiO₂ (anatase) electrodes at open circuit are shown to compare well with reduction rates calculated from the currents at the intersection of photocurrent and inverted dark current *i-E* curves. Such rates measured at single electrodes are then used to predict reduction rates on particle suspensions. The role of light intensity, pH, and platinization on reduction rates of various relays is discussed.

Redox reactions on illuminated semiconductor electrodes and on particle suspensions have been extensively studied in the last few years. One main interest lies in the photoelectrosynthetic applications, *i.e.*, the oxidation and reduction products that are formed by the charge carriers (electrons and holes) generated by light absorption in the semiconductor. In the case of a photoelectrochemical cell, one charge carrier is channeled through a wire to a counterelectrode which may be separated by an ionic conducting membrane. This is one of the main advantages of such a cell. The short-circuit current and, hence, the product formation rates can be measured and calculated from the current of the intersection of the anodic and cathodic current-potential (*i-E*) curves measured potentiostatically for the constituent electrodes of the cell (1).

Photoelectrosynthesis on semiconductor particle suspensions or colloids is less well understood because the individual reactions cannot be separately studied. The counterelectrode is directly attached to the photoelectrode (*e.g.*, in the form of a catalyst) or is identical to the latter. No electrical contact can be made on small particles, and the product formation rates can only be measured by chemical analysis. Interestingly, both products (reduction and oxidation) sometimes emerge from

the same (illuminated) surface; the same behavior has recently been seen in electrodes and 40 μm CdS particles embedded in a membrane (2).

In this work, we aim to predict product formation rates on single illuminated semiconductor electrodes suspended in solution and operated at open circuit from electrochemical measurements at the same electrode in a separate experiment. Such an electrode mimicks a semiconductor particle suspension consisting of only one large particle. We will use this principle to make the first attempts at a quantitative understanding of photoelectrosynthesis in semiconductor particle suspensions. Phenomenologically, in such suspensions, each particle consists of two short-circuited microelectrodes able to carry out a reduction and an oxidation. The concept has already successfully been applied in understanding corrosion phenomena (3) and redox catalysis by metallic particles (4). The idea is to extrapolate electrochemical data of macroelectrodes into the area of particle suspensions or colloids. If the material of the two electrodes is the same, and if one reaction only occurs under illumination, it is sufficient to study, in the dark and under illumination, on one electrode the current-potential (*i-E*) curves that are thought to be representative of the individual cathodic and anodic reactions. Product formation at a single sand-

wiched electrode under illumination (5) and the correlation between the deposition rate of silver (6) and reduction rate of methylene blue (7) and the currents in TiO_2 crystals have been reported in the literature.

Since redox reactions on semiconductors usually exhibit high overvoltage, much research has been done on the improvement of kinetics by attaching noble metal catalysts to the surface of semiconductor electrodes and powders (2, 8-11). New features can be observed because of the specific interaction of metals surface attached to the support (12, 13) or adsorption of relays on the catalyst (14). It is also the purpose of this work to explain on the basis of i - E curves whether (and if so, why?) catalytic deposits can increase product formation rates in the dark and under illumination. Experiments with TiO_2 (anatase) as the semiconductor and methylviologen as the relay will be reported, and the influence of various factors such as relay concentration, light intensity, and platinization on the rates of product formation will be investigated.

Experimental

n - TiO_2 (anatase) electrodes were prepared by thermal decomposition of TiCl_4 (10) on titanium sheets ($0.75 \text{ cm} \times 0.75 \text{ cm}$) cleaned with 30% HNO_3 /4% HF . The thickness of the TiO_2 layer, which was varied by varying the number of deposited layers prior to the final annealing procedure, was 10-40 μm , as estimated by weighing. Photoplatinization was carried out by UV irradiation ($\lambda > 350 \text{ nm}$, 8-80 min) in argon degassed solution ($\text{pH} = 2.43$) containing $8.2 \times 10^{-3} \text{ M K}_2\text{PtCl}_6$, at open circuit, in the absence of a deliberately added hole scavenger. One electrode was photoplatinized for 8 min at +0.342V, the potential initially established under irradiation at open circuit. From the integrated charge, a thickness of 20 \AA could be estimated, assuming a homogeneous layer. The morphology of the deposit will be discussed below. The back sides of the electrodes were insulated with plastic paint, unless otherwise indicated. TiO_2 powder "P 25" was obtained from Degussa.

The irradiation equipment consisted of a 450W Xe lamp (Oriel) operated at 22.2A, an 8 cm water filter (to remove IR light), a 350 nm cutoff filter (in its absence, direct photolysis of methylviologen occurred), a shutter, a slit, and the irradiation cell (shown in Fig. 1).

Fig. 1. Lower part of irradiation cell. (quartz) cell, W) working electrode (TiO_2), R) reference electrode, C) counterelectrode (Ti), P) electrode for polarographic detection of product (Pt), L) actinic light, AL) analyzing light, PD) photodiode, B) tube for bubbling with gas, M) separating membrane (cellulose).

Figure 1.—The total liquid volume was 2-3 ml. The solutions (made up in twice-distilled water, then filtered) were purged with Ar 4N8 (unless otherwise indicated) before and sometimes during the experiments, then they were stirred. Currents and potentials were measured with a Wenking POS 73 potentiostat. (All potentials are quoted vs. NHE.) Identical electrochemical pretreatment (potential at which the electrode is held before starting a scan, illumination, etc.) was necessary to obtain reproducible i - E curves in the region of the photocurrent onset. Production rates of reduced methylviologen, MV^+ , were measured by two ways: via its absorbance of light of a He-Ne laser at 632.8 nm ($\epsilon = 8060 \text{ M}^{-1} \text{ cm}^{-1}$); or by reoxidation on a polarographic detector electrode (Pt) held at 0V. The purpose of the latter method was to allow measurements of production rates in turbid solutions (particle suspensions) for which the same experimental setup was used. In front of the cell, a mask having the same surface and form as the TiO_2 electrodes used was attached to maintain the number of incident quanta.

Results

Figure 2.—Three types of measurements carried out at single n -type TiO_2 electrodes are compared in Fig. 2.

1) The i - E curves in the dark and under illumination have been recorded potentiodynamically, separately or simultaneously, using chopped light. i_d is the current for the reduction of the relay, MV^{2+} , in the dark, and i_d' is $-i_d$. i_i is the current under illumination, and the net photocurrent, i_{ph} , equals $i_i - i_d$.

2) A second experiment has been made at open circuit. The potential has been recorded as a function of time (E_t). When the light is switched on, the potential rapidly de-

Fig. 2. Current-potential and photopotential- t curves and product formation rates for $\text{MV}^{2+}/\text{MV}^+$ on TiO_2 (anatase). 0.1 N NaOH , $6 \times 10^{-3} \text{ M MV}^{2+}$, Ar bubbling, stirring, $\lambda > 350 \text{ nm}$, scan rate -0.5 mV/s . i_t , i_c) intensity of transmitted analysis light and current on the polarographic detection electrode, respectively, as a function of time.

creases. Both charge carriers react on the surface of the electrode. When the photopotential, i_{ph} , is reached, the photocurrent (corresponding to an oxidation process carried out by holes in the valence band) equals the dark current (reduction of the relay), as indicated in Fig. 2 by the intersection point S, where $i_{ph} = -i_d = i_{sc}$. The production rate is then calculated from the current at the intersection

$$v_e = i_{sc}/F \quad [1]$$

For experiments where reduced methylviologen, MV⁺, is the reduction product, it turns out to be better to calculate i_{sc} using i_{ph} in the absence of the relay, since the photocurrents tend to decrease when MV⁺ is accumulated at slow scan rates. This also leads to the slow increase of E_t with time.

3) The increase in concentration of the photoproduct (MV⁺) is simultaneously measured photometrically (I_o) and polarographically (i_c). The current on the collector electrode, i_c , is proportional to the concentration of the reduced relay and can be calculated using the optical data (I_o)

$$v_a = \frac{V}{t\epsilon} \log \frac{I_o}{I_t} \quad [2]$$

Photoproduction rates tend to level off at prolonged irradiation time. The initial production rates V_{ap} and v_e are dependent on several factors, the influence of which on the individual (dark, light) i - E curves is shown in the following.

Figure 3.—There is a well marked dependence of production rates on concentration. The dark reactions which are thought to be responsible for this behavior are therefore recorded as a function of potential and relay concentration (Fig. 4).

Figure 4.—The dependence of plateau photocurrents on the TiO₂ electrodes on light intensity (I) is found to be linear in the range studied ($d \log i_{ph}(\text{plateau})/d \log I = 1$ over several orders of magnitude). A more complex dependence is expected for the currents at the intersection of inverted dark current i - E curves that occur in the falloff region of the photocurrent near the onset potential. As a consequence, the photopotential, E_{ph} , usually changes with the logarithm of the light intensity (18). This is also the case for "dry diodes." The photopotential of TiO₂/MV²⁺ shifts by 60 mV per decade of light intensity, as predicted for a one electron relay by Gomes *et al.* (18) (Fig. 5).

Figure 5.—At very high light intensities, the curve will reach a limiting value because the photopotential cannot

exceed the flatband potential. The intersection current at the photopotential which determines the photoproduction rate must therefore also show saturation behavior as shown in Fig. 5 (see also Fig. 7b below). At no value of the intensity does $d \log i_{sc}/d \log I$ reach 1, in contrast to plateau photocurrents.

Platinized TiO₂ electrodes show a markedly different behavior with respect to their i - E characteristics in the dark for various relays, but, also, the light curves are somewhat changed (Fig. 6).

Figure 6.—Only a small decrease (<10%) of the photocurrent is noticed in the plateau region. The relative decrease of photocurrents in the onset region (curves 7-10), however, is much more important. As with unplatinized electrodes, photocurrents decrease at high relay concentration. In Fig. 6, curves 9 and 6 intersect the baseline (continuation not shown), and the net effect becomes photocathodic.

In the presence of EDTA, H₂ is formed on platinized electrodes at a rate of 1.1×10^{-10} mol/s. Only trace quantities are detected without EDTA.

In Table I, data for production rates at a single TiO₂ electrode and for suspension of TiO₂ powder (same illumination area) are collected.

Discussion

First, the production rates on a TiO₂ electrode and the parameters influencing them will be discussed. The initial production rate $v_{a,0}$ compares well (Fig. 3) with values of the production rate v_a obtained from i - E curves on the same electrode. It thus seems possible to predict, from electrochemical data, production rates on electrodes at

Fig. 6. Influence of platinumization of TiO_2 electrodes on i - E curves for various relays. (—) before platinumization, (---) after platinumization. 1, 2) Ar saturated solution, dark; 3, 4) oxygen saturated solution, dark; 5, 6) $6 \times 10^{-3} \text{M MV}^{2+}$, Ar saturation, dark; 7, 8) Ar saturated solution, light; 9, 10) $6 \times 10^{-3} \text{M MV}^{2+}$, Ar saturation, light; 11) Ar saturation, $8.2 \times 10^{-3} \text{M K}_2\text{PtCl}_6$, pH 2.43; 12) as 11, but scan recorded after 11. Scan rates: -0.5 mV/s for curves 1-10; -2 mV for curves 11 and 12, 0.1N NaOH; stirring.

open circuit. There are several factors responsible for the leveling off of the curves at high MV^{2+} . From Fig. 2, it can be seen that a doubling of reduction current will not result in a doubling of the current at the intersection point, for a purely geometrical reason (considering the given form of dark and light i - E curves).

Second, the dark reduction currents are not proportional to relay concentration. This effect has already been noticed by Memming *et al.* (15) on Fe_2O_3 and by Vandermolen *et al.* (16) on TiO_2 , and it is explained by the transfer of electrons to be occurring via surface states. Another reason for the leveling off of the rates calculated from i_{sc} is the decrease of the net photocurrents, i_{ph} , with increasing relay concentration. i_{ph} even becomes negative at sufficiently negative potential (Fig. 6). This has also been called "photocathodic" effect (17). However, before the net photocurrent turns cathodic, photoinduced reduction currents flow and lower i_{ph} . The contribution of this effect is relatively small for $\text{MV}^{2+}/\text{TiO}_2$ because intersection of i - E curves occurs at potentials where the photoreduction effect is of minor importance.

The dependence of production rates (insert Fig. 3) on pH can be explained as follows. A band shift of usually 59

(b) Calculated value for electrode with 4 times larger surface, but the same irradiated surface.

mV per pH unit is caused by the dissociation of surface OH groups on oxide semiconductors. Since the redox potential of methylviologen is independent of pH, the balance of reaction rates of injection of electrons from the reduced relay into the conduction band of the semiconductor and vice versa will depend on pH. From this, an attempt has been made to calculate the Fermi level of TiO_2 (as powder suspension) in redox systems at pH = 0, by flash photolysis (19) or by polarographic product analysis during illumination (20). However, the Fermi level is not always close to the potential of the conduction band edge, the value of which one usually obtains to characterize a semiconductor. Nor can a simple linear or logarithmic dependence for product formation rates or yields on pH be derived from theory. From the point of intersection of photocurrent potential curves, which shift 59 mV per pH unit toward more positive potentials, with dark current potential curves (i_a vs. E), it can be seen that the current and the production rate become zero at the pH where the onset of the i_{ph} - E curve occurs at the potential at which the dark current is zero. This potential may be identical to the redox potential of the relay, considering relative concentrations of oxidized and reduced form, if the relay shows rapid kinetics on the electrode, as it does for methylviologen [this is an exception for dark currents on semiconductors (21)]. Even then, if the experimentally measured reduction rates are initial rates, the Nernst potential changes rapidly in the beginning stages after the light is switched on, because the concentration of the reduced form of the relay is very small. This means that no reliable reference point is available to calculate the Fermi level.

For methylviologen on TiO_2 (anatase) electrodes, we find that the reduction rates become zero at pH 9 (insert, Fig. 3). Because no hole scavenger is employed, oxygen formed by valence band holes will start to consume MV^+ when it is accumulated. The reaction rate of oxygen with MV^+ certainly increases with decreasing pH, and we think that the fall off of reduction rates at relatively high pH [compared to a system in which a hole scavenger (acetate) is present (20)] is due to this back reaction. It is surprising that MV^+ is formed at all when a highly oxidizing anodic product is evolved. The reason might be that, shortly after switching on the light, photoproduct oxygen is adsorbed on TiO_2 and is reacted slower in this form with MV^+ being formed at other sites on the electrode and that the probability of reaction with MV^+ molecules already escaped into the solution will be smaller. Later, the leveling off of product formation is a consequence of the reaction of MV^+ with O_2 and valence band holes.

One of the most important factors influencing product formation is the presence of a catalyst on the semiconductor surface. This is mainly due to an influence on dark currents, as can be seen in Fig. 6. As expected, the reduction curve for water (curves 1, 2) shifts toward much more positive potentials (by 570 mV) when Pt is present at the surface. The shift for oxygen reduction (curves 3, 4) is smaller (250 mV), but still higher than that for the reduction of the one electron relay, methylviologen (60 mV, curves 5, 6). Undoubtedly, this effect is of catalytic nature for water and oxygen reduction, whereas the small shift for methylviologen reduction could be partially explained by the increase in surface when platinum is deposited. This has also been proposed by Kobayashi *et al.* (9). Preliminary experiments (electron micrographs) show that the metallic deposit is built up in the form of islands (preferentially at damaged areas). Generally, if no sites will be available where the electrolyte can reach the semiconductor surface, no photoeffect should occur, since a poreless metal film represents a perfect shunt for light-separated charges [ohmic contact provided, which is usually the case for Pt on TiO_2 (25)]. This has often been overlooked when discussing deposition on semiconductor surfaces. However, photodeposition can continue until almost the whole surface is covered (22). In the case of photodeposition of silver on WO_3 (23), photoactivity is

maintained, even when a visible deposit (plates perpendicular to the surface, as shown by electron micrograph) is present on the surface. An affirmation for nonhomogeneous coating lies in the fact that a rapidly decreasing overpotential is observed for the deposition of the first grains of metal on the surface [see also Ref. (8)]. During potentiostatic deposition of Pt in the dark (curves 11 and 12) and under illumination, the decrease in overpotential is caused by increasing dark reduction currents due to deposition on already existing sites (note that the i - E curve 12, obtained in the second scan for TiO₂ in K₂PtCl₆, lies 300 mV more positive than the one of the first scan, curve 11).

Photoreduction rates of methylviologen are not enhanced on platinized electrodes, although the dark reduction i - E curves shift toward more positive potentials. This is due to the decrease in photocurrents in the onset region, which is a result of metal islands serving as recombination centers for electrons and holes. The effect is also noted for a deposit of RuO₂ on WO₃ (24). Because of this, as little platinization as is necessary to obtain a catalytic deposit is recommended. The decrease in i_{ph} is smallest for the shortest platinization time used, 8 min. Note that at high relay concentration, the decrease in photocurrents is less pronounced (curves 8 and 10).

The situation is different for hydrogen generation on unbiased electrodes. From the current potential curves, it can be seen that there is no intersection of the inverted curve 1 (H₂O reduction on an unplatinized electrode) and curve 7. With a platinized electrode, the onsets of the curves 2 and 7 just touch each other, and hydrogen is detected only in trace amounts by gas chromatography. However, in the presence of a hole scavenger (EDTA), the curve i_{ph} vs. E (curve not shown) is shifted toward more negative potentials [transients which usually occur when the light is switched on or off are suppressed, probably due to the enhancement of the hole transfer rate and/or to specific binding in the form of a complex (26)], and the formation rate of hydrogen is corresponded to an intersection current of 20 μ A.

Comparison of reduction rates at single electrodes and particle suspensions.—The foregoing discussion of the influence of several parameters on product formation rates on unbiased electrodes using electrochemical data (i - E curves) shall now enable us to understand the photoelectrochemical performance of a semiconductor particle suspension that can be thought to consist of a high number of such electrodes (of much smaller surface, but exhibiting the same electrochemical features as a single macroelectrode). As would be expected from the doubling of the dark currents, the reduction rate of an electrode that is also covered on the back side with TiO₂ is already found to be higher (1.26 times, Table I). Even higher reduction rates are observed on illuminated powder suspensions (3.5 times, as compared to a single electrode) for > 2.5g TiO₂/l (the decrease in rate for amounts of TiO₂ < 2.5 g/l is due to the incomplete light absorption).

On a spherical particle, the surface available for dark reactions may be four times larger than its cross section because in a simplified approach, a light beam of cross section $r^2\pi$ would be entirely absorbed by a particle of radius r , surface $4r^2\pi$. However, as we have seen above (discussion of Fig. 1), an increase in dark current is not reflected in a proportional increase in current at the intersection of the i - E curves (a factor of 1.45 is calculated from the i - E curves for quadrupling the surface of the electrode; see data in Table I).

Refining the model, we must consider that light is also absorbed by particles lying partially in the shadow of the particles nearest to the window (for which the current density at a large part of the illuminated surface will be close to that on a flat single electrode), giving rise to smaller light currents, but making their entire surface available for the dark reaction.

Figure 7.—The total surface which can be used will thus be much higher, though the contribution is not addi-

Fig. 7. Model for illumination of particle suspensions: (a, left) irradiation geometry; (b, right) i - E curves on particles, schematic.

tive, because the intersections of the i - E curves (i_{ph} and i_d') have to be calculated individually for each particle, and only the currents at the intersection points can be summed up (Fig. 7b). In any case, the following relation holds

$$i_{sc,t} = \sum_f f(I)_i m_i > f(I)_t \quad [3]$$

where $\sum_i I_i = I_t$, $i_{sc} = f(I)$ for constant particle surface and relay concentration. $i_{sc,t}$ is the total production current, I is the light intensity, I_i is the intensity at an individual particle, I_t the total absorbed light intensity, and m_i is the number of particles experiencing the light intensity I_i . The function f has a form like that in Fig. 5. From Eq. 3, it also follows that the same amount of light absorbed by smaller, therefore more transparent and more numerous (if total absorption is achieved in the vessel) particles should lead to higher reduction rates. In addition, light that is not entirely absorbed by the particle first hit (especially near the poles) will be absorbed by particles located at longer distance from the window. The derivation of an exact solution or analytical representation of the above problem is beyond the scope of this article, but we think that the above considerations can explain an increase in reduction rates like those observed in particle suspensions (compared to single electrodes). At the same number of quanta absorbed by the suspension as for the macroelectrode, the main topological difference is the fact that the light is absorbed by a great number of particles in the suspension, involving a larger total surface. The rates on single electrodes are of the same order of magnitude, which proves that the study of i - E curves on electrodes is a useful tool in predicting the possibility of reactions occurring in particulate systems and in predicting their rates.

Compositional Changes of Anolyte on Electrolyzing Stainless Steel in High Temperature Chloride Media

K. Tanno* and M. Aizawa¹

Department of Applied Chemistry, Faculty of Engineering, Iwate University, Ueda, Morioka 020, Japan

ABSTRACT

In connection with crevice corrosion of stainless steel in high temperature water, Type 304 stainless steel was anodically electrolyzed in 0.5N or 0.05N NaCl solution at temperatures up to 250°C with determination of compositional changes of the anolyte. Components of the steel dissolved as Fe²⁺, Cr³⁺, and Ni²⁺ and lowered the pH of the anolyte by hydrolysis of the dissolved ions. pH measured at room temperature decreased with increasing amounts of charge. During electrolysis at temperatures above 150°C, lower pH values and much more precipitates were obtained, and at 200° and 250°C hard films, which were mainly composed of CrOOH and scarcely dissolved in hot HCl, were formed on the specimens. In the electrolysis at 250°C, lower pH values were obtained in concentrated Cl⁻ solutions. These pH changes of the anolyte were well described with the experimental results of hydrolysis of Cr³⁺ solutions. At 200° and 250°C, local corrosion of the steel in the anolyte occurred.

Because of its technological importance, crevice corrosion of stainless steel in chloride media has been studied frequently and compositions of occluded solutions have been examined. Much evidence (1-3) shows that the occluded solution has a higher concentration of hydrogen ion and chloride ion than the bulk solution. Concentration of hydrogen ion is caused by hydrolysis of metal ions, and that of chloride ion is due to migration of the ion from the bulk solution due to an active-passive cell formed, respectively, inside and outside the crevice. Therefore, some authors (4) examined compositional changes of a simulated anolyte on electrolyzing stainless steel in chloride media.

However, most of these investigations have been conducted near room temperature, and there are few studies conducted at temperatures above 100°C, in spite of its practical importance. Taylor *et al.* (5-8) reported some results at 288°C relating to stress corrosion cracking of stainless steel in nuclear plants.

In the present study, compositional changes of electrolyte were examined when stainless steel specimens were dissolved anodically in chloride media at the temperature ranging from 25° to 250°C. In connection with the pH changes of the anolyte, hydrolysis of chromium chloride solutions at high temperatures were conducted.

Experimental

Electrolysis.—Austenitic stainless steel of Type AISI 304 was used for test specimens. All specimens were 1

mm thick, 10 × 10 mm in area, and have the following composition by percent weight: Cr = 18.77, Ni = 9.18, C = 0.08, Mn = 1.34, Si = 0.52, Mo = 0.19, and Fe to 100. They were mechanically polished with emery paper and washed with acetone and alcohol.

Figure 1 shows the electrolysis cell made of Teflon. The anodic and cathodic compartments are separated by a sintered SiC disk filter made of particles of an average size of 2 μm with a porosity of about 43%. The counter-electrode is platinum or Type 304 stainless steel plate. Sodium chloride solutions of 0.5 or 0.05N were used as electrolyte. Volumes of anolyte and catholyte were 30 and 175 cm³, respectively.

For electrolyses conducted above 100°C, this cell was set in an autoclave in the atmosphere and heated to definite temperatures. The electrolysis was performed at a constant current density of 12 mA/cm². After electrolysis, the autoclave was cooled and the anolyte and catholyte were filtered through no. 5C filter paper. Iron, chromium, and nickel were measured by atomic absorption spectrometry and chloride ion was determined by the Volhard method.

Hydrolysis.—In the experiment, 90 ml of 3.3 × 10⁻² mol/liter CrCl₃ solution with various concentrations of Cl⁻ in a titanium autoclave was heated to 150°, 200°, or 250°C for 24h, which is enough to get a steady state. The solution was then cooled quickly and filtered through a Millipore filter paper (pore size 0.8 μm), and pH and chromium content of the filtrate were measured. The composition of precipitate was examined by x-ray diffraction, IR spectrometry, and thermogravimetry. The test solutions were prepared from reagent-grade CrCl₃ and pure water,

Fig. 1. Electrolysis cell

and their Cl^- contents were adjusted by adding reagent-grade NaCl.

Results and Discussion

Electrolysis.—Figure 2 shows enrichment of chloride ion in the anolyte with charge passed at various temperatures. Data at 200° and 250°C were omitted, as the diffusion of chloride ion from the anolyte to the catholyte was noticeable, as estimated from separate experiments. Chloride ion concentration increased proportionally to the charge and decreased slightly as the temperature rose, which led to slightly smaller transport numbers with temperature (9).

Figure 3 shows the pH of the anolyte at room temperature after electrolysis at various temperatures. The pH decreased almost logarithmically with charge. The pH of the anolytes electrolyzed at 25°, 50°, and 80°C were the same. However, those above 150°C decreased as the temperature of the electrolysis rose. The anolyte pH of the 0.5N solution electrolyzed at 250°C, showed a limiting value of 1.6 over the range of 13 C/ml. When 0.05N NaCl solution was used, the pH was higher than that of the 0.5N solution. As

Fig. 2. Enrichment of chloride ion in the anolyte on electrolyzing stainless steel in 0.5N NaCl solution.

Fig. 3. Anolyte pH values on electrolyzing Type 304 stainless steel in NaCl solution.

for the appearance of the electrolytes and specimens after electrolysis, there were no visible precipitates nor films on specimens for electrolysis below 80°C, whereas there was some precipitate in the anolyte at 150°C, and there were considerable precipitate and hard films on specimens at 200° and 250°C. These films were hard to dissolve even in hot hydrochloric acid.

Figure 4 shows pH changes of the anolytes when they were held at room temperature after electrolysis at various temperatures. Whereas slight pH changes were observed in the anolytes electrolyzed at 80° and 150°C, pH of those electrolyzed at 200° and 250°C scarcely changed. The reason for this will be discussed later.

Table I shows amounts of metal existing in the anolyte and the catholyte after electrolysis equal to a charge of 20 C/ml. During electrolysis at 80°C, most of the dissolved metals existed in the anolyte, and a portion of that diffused into the catholyte through the SiC disk and precipitated there. Results at 25° and 50°C were similar. During electrolysis above 150°C, precipitates formed. As the temperature for the electrolysis increased, much more precipitation occurred. Moreover, at 200° and 250°C, hard films formed on the specimens, as described above.

Figure 5 shows amounts of metal dissolved during electrolysis in 0.5N NaCl solution, expressed as equivalents of Fe^{2+} , Cr^{3+} , and Ni^{2+} , respectively. Bold straight lines are calculated values from quantity of charge. As shown in Fig. 5a, both the measured and calculated values coincide at 150°C. So, it is ascertained that constituents of stainless steel dissolve as Fe^{2+} , Cr^{3+} , and Ni^{2+} in the experimental conditions. Results of electrolysis at 25°, 50°, and 80°C

	250	—	2.5×10^{-4}	—	2×10^{-6}	—	4.6×10^{-5}

Charge: 20 C/ml.
0.5N NaCl solution.

were the same. At 200°C (Fig. 5b), the measured values of Ni almost coincide with the calculated values, those of Fe were a little larger than the latter, but the measured values of Cr were significantly less than the calculated values. At 250°C, the measured values of Ni almost coincide with the calculated ones and the measured values of Fe were larger than the calculated ones up to about 20 C/ml and smaller above 20 C/ml (Fig. 5c). However, Cr was scarcely detected. Similar results were obtained for the 0.05N NaCl solution. From these results, it is assumed that the hard films formed on the specimen at 200° and 250°C contain mainly chromium compounds.

The hard films were removed by immersing the specimens in a boiling alkaline permanganate solution (NaOH 30 + KMnO₄ 2 + H₂O 68 weight percent [w/o]) for 2h, followed by an acidic hydrogen peroxide solution (conc. HNO₃ 25 + 35% H₂O₂ 5 + H₂O 70 w/o) for 3h at 60°C, and the specimens were weighed. A blank weight loss for this treatment was negligible. Figure 6 shows the results for specimens electrolyzed at 200° and 250°C. Whereas weight losses of specimens with film (line B) were smaller than those of the calculated values (line A) from the charges, weight losses after removing the films (line C) were larger. This larger weight loss after removing films might be due to a self-corrosion caused by low pH at the high temperatures.

Hydrolysis of Cr³⁺ solutions.—As for the hydrolysis of metal ions at temperatures below 100°C, there have been many studies (3, 4) connected with localized corrosion. Hydrolysis of metal ions lowers the anolyte pH mainly due to the hydrolysis of Cr³⁺ (reaction) [2]

However, hydrolysis products are oxides or oxyhydroxides in high temperature solutions. In the case of chromium, CrOOH was ascertained, as described later. So, the following equilibria were taken into account, and their equilibrium constants at 150°, 200°, and 250°C were calculated (Table II)

The calculation was conducted utilizing Criss and Cobble's entropy correspondence principle. The free energies and entropies for the substances were taken, whenever possible, from Latimer's and Pourbaix's compilations (10, 11). The heat capacities were taken from Kelley (12) and from Wicks and Block (13). The data for CrOOH, which was not available in these compilations, was taken from Lee's estimation (14). From the table, it is ascertained that the main factor of decreasing pH is the hydrolysis of Cr³⁺.

As the next step to understanding the pH changes of the anolyte, the hydrolysis of Cr³⁺ solutions was examined experimentally. Figure 7 shows the pH and the chromium

contents of the filtrates taken from the hydrolyzed 3.3×10^{-2} mol/liter Cr³⁺ solutions with various amounts of Cl⁻. As the temperature of hydrolysis increased, the pH of the filtrates decreased. As the Cl⁻ concentration increased, the pH of the filtrates treated at 200° and 250°C decreased, whereas the pH at 150°C increased. So, the differences of pH of the solutions treated at 150° and 250°C were larger in the more concentrated Cl⁻ solution. Chromium contents of the filtrates decreased with the temperature of hydrolysis and increased with the Cl⁻ concentration. In the case of 150°C and 3 mol/liter Cl⁻ concentration, the most chromium in the initial solution was found in the filtrate. But, the pH of the filtrate was 1.55, and this meant that the most of Cr³⁺ had hydrolyzed.

Figure 8 shows x-ray diffraction patterns of the precipitates. The precipitate obtained at 250°C was identified as CrOOH, while those at 200° and 150°C were amorphous. Infrared absorption spectra of the precipitates showed an absorption maximum at 3400 cm⁻¹ due to OH groups.

Figure 9 shows weight losses of the precipitates during thermogravimetric analysis. When the precipitates were heated to 500°C in an argon atmosphere, all of them gave Cr₂O₃. Assuming that the weight losses on heating were due to vaporization of water, repeated measurements showed that compositions of the precipitates obtained at 150°, 200°, and 250°C were CrOOH · (0-0.5)H₂O, CrOOH · (1-1.5)H₂O, and CrOOH · (1.5-2)H₂O, respectively.

Absorption spectra in the ultraviolet and visible region showed that the dissolved Cr³⁺ in the filtrate treated at high temperature existed as [Cr(H₂O)₆]³⁺, while those in the original solution as [Cr(H₂O)₆Cl₂]⁺ (15).

As the compositions of precipitates formed from hydrolysis of Cr³⁺ solutions were examined, the weight losses of the specimens with films in Fig. 6 were evaluated and compared with the measured values. Line D in Fig. 6b and lines E and F in Fig. 6a show weight losses of the specimens with film calculated from the lines C, assuming the film compositions as CrOOH, CrOOH · H₂O, and CrOOH · 2H₂O, respectively. As line B in Fig. 6a exists between line E and F and that in Fig. 6b near line D, it is assumed that the film formed at 250°C is composed of CrOOH with little or no water, and that formed at 200°C is CrOOH with one to two water molecules. These agree with the compositions of precipitates from Cr³⁺ solutions.

During electrolysis at 200° and 250°C, self-corrosion of the specimens was suggested to occur. Then, additional dissolution of Fe and Ni was calculated from weight loss due to the self-corrosion, the differences between lines A and C in Fig. 6, and the total dissolved Fe are shown as fine lines in Fig. 5b and 5c. In the case of Ni, the correc-

Fig. 5. Amounts of metal in solution after electrolyzing Type 304 stainless steel anode at (a) 150°, (b) 200°, and (c) 250°C in 0.5N NaCl solution (symbols are measured values plotted as Fe^{2+} , Cr^{3+} , and Ni^{2+} , bold lines are calculated values from the charges, and fine lines are calculated values of Fe corrected for self-corrosion).

tions were negligible. The results support the above assumption except for charges greater than 20 C/ml in Fig. 5c, where a part of the dissolved Fe might precipitate.

According to the knowledge of coordination chemistry (16), Cr^{3+} ion in aqueous solution forms aquo complexes and tends to hydrolyze and polymerize. Forms of complex in chloride media at room temperature are $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$, $[\text{Cr}(\text{H}_2\text{O})_5\text{Cl}]^{2+}$, and $[\text{Cr}(\text{H}_2\text{O})_4\text{Cl}_2]^+$, depending on the chloride concentration and history of the solution. The aquo complexes hydrolyze, behaving as acid like

Fig. 6. Weight losses of specimens electrolyzed in 0.5N NaCl solution at (a) 200°C and (b) 250°C: \circ : Measured values with film; \times : Measured values without film. Line A: Calculated value from the charge as Fe^{2+} , Cr^{3+} , and Ni^{2+} . Line B: Fitted line for the measured values with film (\circ). Line C: Fitted line for the measured values without film (\times). Line D, E, and F: Assumed values with film composed of CrOOH , $\text{CrOOH} \cdot \text{H}_2\text{O}$, and $\text{CrOOH} \cdot 2\text{H}_2\text{O}$, respectively.

Heating shifts the equilibrium to the right, and more of the coordinated water molecules are converted to OH^- groups. Here, ololation and oxolation occur, resulting in formation of polynuclear complexes consisting of chains or rings of $\text{Cr}(\text{III})$ ions connected by bridging OH and O^- groups. Oxolation gives protons like

The ultimate consequences of ololation and oxolation are the formation of colloids and precipitates. Continued heating brings a remarkable decrease in reactivity of the colloids and precipitates.

This knowledge about aquo complexes is well suited to the observations in this study. The experimental results show that increasing temperature up to 250°C accelerates hydrolysis and polymerization, resulting in lower pH and more precipitates. The same phenomena were also observed for nickel and other metals (17). Acceleration of the hydrolysis of aquo complexes at high temperature is related to changes in the physical properties of water, and the most important change is the decrease of the dielectric constant (18).

Experimental results show that ololation or oxolation is inhibited in concentrated Cl^- media. Nevertheless, the

Fig. 7. pH (a) and Cr content (b) of the filtrates on hydrolyzing Cr^{3+} solutions at various temperatures. Initial concentration of Cr^{3+} : 3.3×10^{-2} mol/l.

pH of the filtrates is low. Generally, activity coefficients of H^+ are larger in concentrated Cl^- media, but those in 0.5N NaCl solution are not so large compared to those in 0.05N NaCl solution (19). The reason for such low pH in the concentrated Cl^- filtrate is not clear at present; further fundamental studies are needed.

Fig. 8. X-ray diffraction patterns of precipitates

Fig. 9. Thermogravimetric analysis curves

Finally, the lower pH values of the anolyte electrolyzed at higher temperature (Fig. 3) are brought about by the accelerated hydrolysis and oxolation described above. When most Cr^{3+} ion is hydrolyzed and the activity coefficient of H^+ is constant with varying Cl^- concentration, the slope of pH against the log of charge should be -1 . Smaller slopes at higher temperature would be due to retardations of the hydrolysis in concentrated Cl^- solution, diffusion of H^+ into the cathodic compartment through the SiC disk during electrolysis and cooling, and consumption of H^+ by the local corrosion.

Conclusions

When Type 304 stainless steel specimens were electrolyzed anodically, the pH of the anolyte decreased with charge passed. As the temperature of electrolysis increased in the range above 150°C, lower pH values and more precipitates were obtained, and hard films were formed on the specimens at 200° and 250°C. The films were mainly composed of the hydrolysis product of chromium, CrOOH , which was the main factor for lowering the pH. During electrolysis at 250°C, lower pH values were obtained in concentrated Cl^- solution. These pH changes of the anolyte were well described with the experimental results of hydrolysis of Cr^{3+} solution. Heating of Cr^{3+} solutions at high temperatures accelerates hydrolysis and polymerization and brings low pH values.

Acknowledgments

Nonlinear Current Response of Electrochemical Systems

Martin W. Kendig*

Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

Laplace analysis of the electrochemical response of an iron electrode in 1.0N H₂SO₄ containing 20 mM propargylic alcohol demonstrates the existence of a discontinuity in the potential at the inner Helmholtz plane (IHP) as a function of applied potential. This result is consistent with previous results reported by Lorenz and Mansfeld and demonstrates the utility of Laplace analysis for evaluating systems where adsorbed species give rise to discontinuous behavior of the effective potential at the IHP due to shielding by the adsorbed phase.

The Laplace transform of a current responding to an applied potential pulse can provide the frequency dependence of the electrochemical impedance (1), a function useful for the analysis of electrochemical kinetics. The Laplace transform is an integral transformation which takes a function of time into the frequency domain. The ratio of the Laplace transform of potential to that of the current, $\Delta E(s)/\Delta I(s)$, defines the frequency dependent electrochemical impedance $Z(s)$ by substituting $j\omega$ for the Laplace variable, s , where ω is the frequency (radian/s) and $j^2 = -1$. The assumptions involved in the definition of impedance include the assumption of causality and the assumption of linearity (2). Causality implies a cause and effect relationship between the respective current and potential variations ΔE and ΔI , and linearity requires the current transient, $\Delta I(t)$, to be proportional to the amplitude of the applied potential step. Electrochemical systems can meet these criteria for most cases through the careful control of experimental conditions. However, in the case of iron in dilute sulfuric acid containing propargylic alcohol (PGA) the current-potential behavior remains nonlinear down to very low potentials, as correctly analyzed by Lorenz and Mansfeld (3). Despite this presence of fundamental nonlinearities in certain electrochemical systems, transform analysis can provide a means for characterizing the electrochemical kinetics. Using this approach, the system iron in 1N H₂SO₄ containing 20 mM PGA has been analyzed to give details of the interfacial structure responsible for the nonlinear response.

Theoretical Considerations

In general, nonlinear current vs. potential behavior results from the fact that the free energy of activation for an

elementary charge-transfer process is proportional to the applied potential. Hence, the current varies exponentially with potential. This nonlinearity can always be excluded by using an appropriately small ΔE (< 10 mV) and is not the subject of this discussion. However, the existence of stored charge or the dielectric shielding of interfacial charge at the interface, produced by irreversible electro-sorption, can cause a discontinuity in the effective potential seen by the electroactive species at the inner Helmholtz plane (IHP) as a function of applied potential. Specific adsorption of molecular dipoles or ions can increase or decrease the potential of the IHP virtually independently of the electrode potential relative to a reference electrode (4). Such is the case of electrocrystallization when a sharp change in overvoltage occurs upon conversion of a surface phase (5). The anomalous dissolution of metals at cathodic potentials has been attributed to modification of the potential at the IHP due to shielding by adsorbed surface complexes (6). The model proposed here for this effect (Fig. 1) places an internal potential source, E_i , in series with the faradaic charge transfer resistance, R , and capacitance of the double layer, C . Usually E_i is insignificant or varies weakly with the applied potential, E , such that the potential fluctuation across R and C resulting from the external application of ΔE is identical, or at least varies linearly with ΔE . However, in the case that the potential at the IHP, that is, the internal potential E_i , contains a discontinuity at the potential E_0 where the pulse, ΔE , is applied as schematically shown in Fig. 1, a nonlinear ΔI vs. ΔE relationship follows. A discontinuity in the potential seen at the IHP as a function of electrode potential can lead to the apparent existence of a multiplicity of steady states (MSS) due to metastability resulting from a slow time dependence for the adsorption-desorption behavior which would extend the current

*Electrochemical Society Active Member.

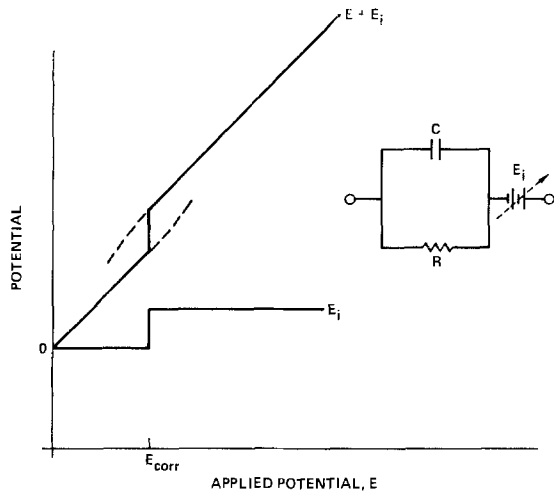

Fig. 1. Schematic for an electrochemical interface containing a discontinuity at the IHP as a function of applied potential.

voltage response along the dotted lines in Fig. 1. Analogous discontinuities in the potential at the IHP can also occur as a function of the chemical potential of surfactants where $\mu = \mu^0 + RT \ln a_s$, where a_s is the activity of the surfactant in the bulk solution. For example, discontinuities in the potential at the IHP as a function of inhibitor concentration can give rise to catastrophic transitions from one level of corrosion rate to the other across the discontinuity. These catastrophic transitions can occur as a function of time or location on the electrode surface and will cause the noted scatter in observed corrosion rates (7) or pitting (8), respectively. Sato uses a model containing a discontinuity in the IHP to explain passivity (9).

An electrochemical system with a discontinuity in the potential seen at the IHP influences the observed impedance behavior (3). The quantitative height of the discontinuity can be discerned, however, through Laplace analysis of the current responding to positive and negative pulses at E_0 across the discontinuity (Fig. 1). The analysis produces an observed effective impedance, $Z^{eff}(s)$ describing the electrochemical response, which provides a means for determining the magnitude of the discontinuity. Unlike a true impedance, $Z^{eff}(s)$ depends on the magnitude, ΔE , of the potential step.

An expression for $Z^{eff}(s)$ may be written in closed form, provided the contribution of ΔE_i to the total potential fluctuation ($\Delta E + \Delta E_i$), across the R and C takes an assumed time dependence. The transformation from the one state to the other at the discontinuity is assumed to result from a first-order process. Thus, upon stepping ΔE across the discontinuity (Fig. 1), $\Delta E_i(t)$ is assumed to take the following form

$$\Delta E_i(t) = E_i(1 - e^{-kt}) \quad [1]$$

The effective impedance $Z^{eff}(s)$ will be by definition $\Delta E(s)/\Delta I(s)$, where $\Delta I(s)$ is the transform of the observed current which flows across the RC network as a result of the application of $\Delta E(t) + \Delta E_i(t)$. Therefore

$$Z^{eff}(s) = \frac{\Delta E(s)}{\Delta I(s)} = \frac{\Delta E(s) Z(s)}{\Delta E(s) + \Delta E_i(s)} \quad [2]$$

where $Z(s)$ is the impedance of the RC network

$$Z(s) = R/(1 + RCs) \quad [3]$$

The Laplace transform of the pulse of amplitude ΔE gives $\Delta E(s)$ equal to $\Delta E/s$. Adding $\Delta E_i(s)$ to the transform of Eq. [1] and including the resulting $\Delta E(s) + \Delta E_i(s)$ into Eq. [2] gives

$$Z^{eff}(s) = \frac{(s + k)R}{\left(s + k\left(1 + \frac{\Delta E_i}{\Delta E}\right)\right)(1 + RCs)} \quad [4]$$

This analysis shows that Z^{eff} depends on ΔE . Furthermore, Z^{eff} has the same functional dependence on frequency as an equivalent circuit containing an inductance in series with a resistance, R, and in parallel with a capacitance, C_p

$$Z_{RLC} = \frac{R + sL}{1 + sC_p R + s^2} = \frac{P_1(s)}{P_2(s)} \quad [5]$$

where $P_n(s)$ is the nth-order polynomial function of s.

Experimental Approach

An iron specimen prepared as described previously (3) was held in a Stern holder and placed in a stagnant air-equilibrated 1N H_2SO_4 + 20 mM PA and allowed to equilibrate for a constant open-circuit potential. A Princeton Applied Research 173 potentiostat with a Model 176 coulometer was used to apply a ± 10 mV step about the corrosion potential. The current response was recorded on a fast responding strip chart recorder or a digital oscilloscope. The potential transform was taken as 0.010 V/s, where $s = -j\omega$ (radian/s), and the current response was estimated using the algorithm of Pilla (1) with the following modification. The Laplace integral between current points that increased with time were obtained by fitting the current-time curve at the interval $\{t_i, t_{i+1}\}$ to a cubic equation

$$I(t) = A_1 + A_2t + A_3t^2 + A_4t^3 \quad [6]$$

Hence, the integral, I_i of the interval

$$I_i = \int_{t_i}^{t_{i+1}} e^{-ts} I(t) dt = \sum_{j=1}^4 I_{ij} \quad [7]$$

could readily be calculated from evaluating the known integrals, I_{ij}

$$I_{ij} = \int_{t_i}^{t_{i+1}} A_j e^{-ts} t^{j+1} dt \quad [8]$$

using an established formula (10). The impedance, $Z(s)$, was calculated then as the transform of $I(t)$ [i.e., $I(s)$] divided by the respective transform of a 10 mV potential step.

Results and Discussion

Figure 2 shows a plot of the Laplace transformed data for a dummy cell consisting of a resistor R_p equal to 10,030 Ω in parallel with a capacitor C_p equal to 3138 μF both in series with a resistor R_s equal to 1002 Ω . The actual values for the impedance elements of the dummy cell were determined by conventional TFA analysis (11). The transformed data (solid circles) are superimposed on the calculated transform for the dummy cell (open circles), which demonstrates the validity of the transform. Significant errors can exist at the highest frequencies as a result of risetime of the potentiostat and current recorder. For this reason, frequencies $> 0.1/t_1$, where t_1 is the first time interval measured, have been ignored.

Fig. 2. Comparison of Laplace analysis with the transform calculated from the component values for a dummy cell determined using the TFA.

Fig. 3. Laplace transform and TFA impedance data determined for iron in stagnant 1N H_2SO_4 and 20 mM PGA.

The curves in Fig. 3 represent data for the observed impedance, Z^{eff} , of the iron in sulfuric acid-PGA solution. It must first be restated that these are not true impedances owing to the nonlinear nature of the system. As a result, Z^{eff} depends on the mode of measurement. Curve 1, for example, shows the impedance measured using the TFA. The region where the impedance increases with increasing frequency implies an inductive component. The low frequency Laplace transform analysis of the response to a 10 mV anodic potential pulse was obtained by computer analysis of a current transient and appears as curve 2 in Fig. 3. The time response of the recorder limits these data to low frequencies. Curve 2 shows a lower effective dc resistance than that indicated by curve 1. However, the Laplace analysis of a current response to a potential step, $\Delta E = 10$ mV cathodic to E_{corr} , shows no inductive behavior and a dc limit close to that obtained from the ac measurement (curve 3). The response to a second anodic potential pulse at a later time (curve 4) again represents a low dc resistance, but is only slightly higher than the previous response to an anodic pulse (curve 1), showing that there is a slow overall time dependence in the system behavior.

These results clearly indicate that the magnitude of ΔE influences the observed impedance as predicted by the model and observed by Lorenz and Mansfeld (3). The use of ac impedance analysis for inherently nonlinear systems, such as the PGA-inhibited Fe in sulfuric acid system, shows that care must be taken in defining the potential excitation which produces the current response. Despite the fact that true impedance can only result for linear systems, the true impedance R and C can, in principle, be extracted by using Eq. [4]. The effective impedances of 1.37 and 27.6 Ω evaluated for the limit as $s \rightarrow 0$ for $\Delta E = +10$ mV and $\Delta E = -10$ mV, respectively, and Eq. [4] allow calculation of the value for R as 3 $\Omega \cdot cm^2$, and ΔE_i due to the discontinuity as 9 mV. The value for ΔE_i is small, but represents a significant discontinuity since its magnitude compares with the ac modulation of ± 10 mV typically assumed to produce a linear response. A ΔE_i of 9 mV certainly is significant in light of its influence on the dc limits for Z^{eff} , which vary by over a factor of 10 de-

pending on whether the potential is pulsed in the positive or negative direction away from the open-circuit potential. Depending on the proximity of the electrokinetic plane of shear to the IHP, $E_i \cong E - \zeta$, where ζ is the zeta potential (12). Hence $\Delta E_i \cong -\Delta \zeta$. Since zeta potentials typically range between ± 50 mV, a difference of -9 mV represents a significant discontinuity in the zeta potential of the steel surface as a result of inhibitor desorption.

Summary

Electrochemical impedance in highly irreversible and nonlinear systems is not defined. However, the theoretical treatment presented here allows extraction of the true ac impedance from effective impedances obtained from Laplace transform of the current response of nonlinear systems. Furthermore, the model of a system undergoing an irreversible adsorption-desorption predicts an effective impedance containing an inductive component. The effective impedance depends on the amplitude of the applied-potential step. The present discussion explains the inductive behavior previously obtained for the system iron/ H_2SO_4 + PGA. The results are consistent with the presence of a discontinuity in the potential at the IHP of 9 mV as a function of applied electrochemical potential.

Impedance Model for a Concentrated Solution

Application to the Electrodeposition of Copper in Chloride Solutions

Bernard Tribollet¹ and John Newman*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

From the Stefan-Maxwell equations, a model has been developed which describes the distribution of concentration of each species in the solution. This model has provision for an arbitrary number of simultaneous homogeneous and heterogeneous reactions and is used to treat the steady state and the impedance of an electrochemical interface. As an example, this method is applied to the anodic dissolution of a rotating disk of copper in chloride solutions.

The rate of many electrochemical processes is governed by the transport of reactant species to the electrode surface by diffusion and convection. The dilute-solution theory has been applied to many electrochemical problems and is adequate for analytic solution. The limits of application for the dilute-solution theory are not really clear, and these limits may be different for the steady state and the nonsteady state. Nevertheless, this theory breaks down in concentrated solution; first of all, because migration and diffusion fluxes must be defined with respect to some average velocity of the fluid, and the flux relations so defined must be consistent with this choice. In a concentrated solution, it is not only the solvent velocity which contributes to the average velocity.

A careful definition of transport properties also requires, except at infinite dilution, the application of the theory for concentrated solutions. In this theory, the dilute flux relation for each solute species is replaced by the multicomponent diffusion equation (1). This last equation involves many parameters, and an analytic solution is too complicated; but, if our aim is a numerical solution, it is possible to consider an analysis which includes variable physical properties and has provision for an arbitrary number of simultaneous homogeneous and heterogeneous reactions. This analysis should be able to deal with the steady state, and it was used with success for modeling silicon deposition on a rotating disk (2). In this paper, we use this model to treat not only the steady state but also the impedance of an electrochemical interface. The comparison of the numerical results from the theory for concentrated solutions with the analytic results from the dilute-solution theory allows one to define clearly the limits of this last theory.

The described method is applied to the anodic dissolution of a rotating disk of copper in chloride solutions. The rotating-disk electrode has been used in this study because the hydrodynamics and mass-transfer characteristics of this system are relatively well understood.

Theoretical Analysis

The multicomponent diffusion equation

$$\frac{c_i \nabla \mu_i}{RT} = \sum_{j \neq i} \frac{c_i c_j}{c D_{ij}} (v_j - v_i) \quad [1]$$

describes the motion of species i relative to the surrounding fluid. In this equation, μ_i is the electrochemical potential of species i and v_i is the velocity of species i (so that the flux density of species i is $N_i = c_i v_i$). The total concentration is $c = \sum_i c_i$, where the sum includes the solvent, and D_{ij} is a diffusion coefficient describing the interaction of species i and j ($D_{ij} = D_{ji}$).

Equation [1] is similar to the Stefan-Maxwell equation (3). By using the mole fraction

$$x_i = \frac{c_i}{c} \quad [2]$$

at constant temperature, the gradient of the electrochemical potential may be defined as

$$\nabla \mu_i = z_i F \nabla \Phi + RT \frac{\nabla x_i}{x_i} \quad [3]$$

where Φ is the electrostatic potential.

For a mixture of n species, the local mass-average velocity v is defined as

$$v = \frac{\sum_i \rho_i v_i}{\sum_i \rho_i} \quad [4]$$

The molar flux relative to the mass-average velocity v is

$$J_i = c_i (v_i - v) \quad [5]$$

With these parameters, the Stefan-Maxwell Eq. [1] becomes

$$x_i \frac{\nabla \mu_i}{RT} = \sum_{j \neq i} \frac{x_i J_j - x_j J_i}{c D_{ij}} \quad [6]$$

The number of independent equations with the form of Eq. [6] is one less than the number of species. If we consider the relation among the molar fluxes

$$\sum_i M_i J_i = 0 \quad [7]$$

we have a set of n equations which can be written in a matrix form

$$\frac{1}{RT} \begin{pmatrix} 0 \\ x_2 \nabla \mu_2 \\ \vdots \\ x_1 \nabla \mu_1 \\ \vdots \\ x_n \nabla \mu_n \end{pmatrix} = \begin{pmatrix} M_1 & \dots & M_k & \dots & M_n \\ \frac{x_2}{c D_{21}} - \sum_{j \neq 2} \frac{x_j}{c D_{2j}} & \dots & \frac{x_2}{c D_{2k}} & \dots & \frac{x_2}{c D_{2n}} \\ \vdots & & \vdots & & \vdots \\ \frac{x_1}{c D_{11}} & \dots & - \sum_{j \neq 1} \frac{x_j}{c D_{1k}} & \dots & \frac{x_1}{c D_{1n}} \\ \vdots & & \vdots & & \vdots \\ \frac{x_n}{c D_{n1}} & \dots & \frac{x_n}{c D_{nk}} - \sum_{j \neq n} \frac{x_j}{c D_{nj}} & \dots & \frac{x_n}{c D_{nn}} \end{pmatrix} \begin{pmatrix} J_1 \\ \vdots \\ J_k \\ \vdots \\ J_n \end{pmatrix} \quad [8]$$

or

$$\frac{1}{RT} x \nabla \mu = \underline{b} J \quad [9]$$

The material balance is described by

*Electrochemical Society Active Member.
¹Present address: Groupe de Recherche number 4 du CNRS, "Physique des Liquides et Electrochimie," associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France.

$$\nabla \cdot J_i = \sum_l R_{i,l} - \nabla \cdot (vc_i) - \frac{\partial c_i}{\partial t} \quad [10]$$

$R_{i,l}$ is the net rate of production of species i by reaction l ; it is regarded as the difference between the rates of forward and backward rates and can be presented as

$$R_{i,l} = k_{if} \prod_j x_j^{\nu_{ji}} - k_{ib} \prod_j x_j^{-\nu_{ji}} \quad [11]$$

where k_{if} and k_{ib} are the rate constants for forward and backward reactions, respectively. The first product (Π) is over reactants ($\nu_{ji} > 0$) and the second product (Π) is over product species ($\nu_{ji} < 0$).

The law of conservation of mass can be expressed as (1)

$$\frac{\partial \rho}{\partial t} = - \nabla \cdot (\rho v)$$

When the density is constant in space and time, this expression reduces to

$$\nabla \cdot v = 0$$

This is frequently an adequate approximation for dilute liquid solutions. A solution without this approximation may be obtained, but it would be necessary to solve the Navier-Stokes equations and the conservation of mass equation together with the Stefan-Maxwell equations.

The inverse of Eq. [8] and so the flux expression is

$$J_i = \sum_{k=2}^n b_{ik}^{-1} \left(\nabla x_k + \frac{z_k F}{RT} x_k \nabla \Phi \right) \quad [12]$$

The divergence of the Stefan-Maxwell Eq. [6] is

$$\begin{aligned} \nabla^2 x_i + \frac{z_i F}{RT} \nabla x_i \cdot \nabla \Phi + \frac{z_i F}{RT} x_i \nabla^2 \Phi \\ = \sum_{j \neq i} \nabla \left(\frac{x_j}{cD_{ij}} \right) \cdot J_j - \nabla \left(\frac{x_j}{cD_{ij}} \right) \cdot J_i \\ + \sum_{j \neq i} \frac{x_j \nabla \cdot J_j - x_j \nabla \cdot J_i}{cD_{ij}} \end{aligned} \quad [13]$$

Since $\nabla \cdot J_i$ and J_i are given by Eq. [10] and [12], Eq. [13] becomes

$$\begin{aligned} \nabla^2 x_i + \frac{z_i F}{RT} \nabla x_i \cdot \nabla \Phi + \frac{z_i F}{RT} x_i \nabla^2 \Phi \\ - \sum_{j \neq i} \frac{x_j \sum_l R_{jl} - x_j \sum_l R_{il}}{cD_{ij}} + cv \cdot \sum_{j \neq i} \frac{x_j \nabla x_j - x_j \nabla x_i}{cD_{ij}} \\ + c \sum_{j \neq i} \frac{x_j \frac{\partial x_j}{\partial t} - x_j \frac{\partial x_i}{\partial t}}{cD_{ij}} - \sum_{j \neq i} \nabla \left(\frac{x_j}{cD_{ij}} \right) \\ \cdot \sum_{k=2}^n b_{jk}^{-1} \left(\nabla x_k + \frac{z_k F}{RT} x_k \nabla \Phi \right) \\ + \sum_{j \neq i} \nabla \left(\frac{x_j}{cD_{ij}} \right) \cdot \sum_{k=2}^n b_{ik}^{-1} \left[\nabla x_k + \frac{z_k F}{RT} x_k \nabla \Phi \right] = 0 \end{aligned} \quad [14]$$

The concentration dependence of D_{ij} may be taken into account in Eq. [14], if we know the concentration-dependence expression.

The relationship among the mole fractions is

$$\sum_i x_i = 1 \quad [15]$$

and the equation of electroneutrality is

$$\sum_i z_i x_i = 0 \quad [16]$$

With $n - 1$ equations of the form of Eq. [14] plus these two equations, we have a set of $(n + 1)$ equations with $(n + 1)$ unknowns (n mole fractions and Φ , the electrostatic potential). This set may be resolved with the corresponding boundary conditions set forth below.

1. Far from the disk, the composition approaches that of the bulk fluid, equilibrated with respect to homogeneous reactions.

2. At the interface, one or more heterogeneous reactions occur. A single-electrode reaction can be written in symbolic form as

Then the flux of a species is related to the partial current densities related to these heterogeneous reactions

$$J_i = - \sum_l \frac{s_{i,l}}{n_i F} i_l \quad [18]$$

and the total electrode current density is the sum of partial current densities ($i = \sum_l i_l$).

At the interface, Eq. [6] becomes

$$\begin{aligned} \nabla x_i = - \frac{z_i F}{RT} x_i \nabla \Phi \\ - \sum_{j \neq i} \frac{x_j \sum_l \frac{s_{j,l}}{n_j F} i_l - x_j \sum_l \frac{s_{i,l}}{n_i F} i_l}{cD_{ij}} \end{aligned} \quad [19]$$

The partial current densities can be expressed by the kinetic equation

$$\begin{aligned} \frac{i_l}{n_l F} = k_{al} \exp \left[\frac{(1 - \beta_l) n_l F}{RT} V \right] \prod_i x_i^{s_{i,l}} \\ - k_{cl} \exp \left[- \frac{\beta_l n_l F}{RT} V \right] \prod_i x_i^{-s_{i,l}} \end{aligned} \quad [20]$$

Again, the first product (Π) is for anodic reactants ($s_{i,l} > 0$ for $n_l > 0$), and the second product (Π) is for cathodic reactants ($s_{i,l} < 0$). Nonelectrochemical, heterogeneous reactions can be described similarly, but with no potential dependence and with $i_l/n_l F$ replaced by the rate of the heterogeneous reaction (in Eq. [18] as well as [20]).

At the electrode, $(n - 1)$ Stefan-Maxwell relations (Eq. [19]) are used together with the relationship between mole fractions (Eq. [15]) and the electroneutrality equation (Eq. [16]) in order to obtain $(n + 1)$ boundary conditions at the interface.

The steady-state solution may be obtained with $\partial x_i / \partial t = 0$. Then the transient solution may be obtained from the steady-state solution for a sinusoidal perturbation. If the amplitude of perturbation is low enough, each mole fraction may be written as

$$x_i = \bar{x}_i + \text{Re} \{ \tilde{x}_i \exp(j\omega t) \} \quad [21]$$

where \bar{x}_i is the steady-state solution and \tilde{x}_i is a complex function of distance from the disk.

By the same way the current and potential may be written as

$$i = \bar{i} + \text{Re} \{ \tilde{i} \exp(j\omega t) \} \quad [22]$$

$$V = \bar{V} + \text{Re} \{ \tilde{V} \exp(j\omega t) \} \quad [23]$$

The expression of the electrochemical impedance is independent of the choice of the regulation

$$\tilde{i} = \sum_l \tilde{i}_l \quad [24]$$

At the interface, Eq. [19] becomes

$$\begin{aligned} \nabla \bar{x}_i &= -\frac{z_i \mathbf{F}}{RT} \bar{x}_i \nabla \Phi - \frac{z_i \mathbf{F}}{RT} \bar{x}_i \nabla \phi \\ &- \sum_{j \neq i} \frac{\bar{x}_i \sum_l \frac{s_{j,l}}{n_l \mathbf{F}} \bar{i}_l - \bar{x}_j \sum_l \frac{s_{i,l}}{n_l \mathbf{F}} \bar{i}_l}{c D_{ij}} \\ &- \sum_{j \neq i} \frac{\bar{x}_j \sum_l \frac{s_{j,l}}{n_l \mathbf{F}} \bar{i}_l - \bar{x}_i \sum_l \frac{s_{i,l}}{n_l \mathbf{F}} \bar{i}_l}{c D_{ij}} \end{aligned} \quad [25]$$

For the nonsteady solution, with $2(n-1)$ equations of the form of Eq. [14] plus two equations of the form of Eq. [15] and two of the form of Eq. [16], we have a set of $2(n+1)$ real equations and two $(n+1)$ unknowns [$(n+1)$ for the real components and $(n+1)$ for the imaginary components]. This set may be resolved with the corresponding boundary conditions: (i) far from the disk, each concentration tends towards zero, and (ii) at the interface, $2(n-1)$ Stefan-Maxwell relations (Eq. [25]) are used together with the two relationships between mole fractions (Eq. [15]) and two electroneutrality equations (Eq. [16]).

The electrochemical impedance is defined as

$$Z = \frac{\bar{v}}{\bar{i}} = \frac{\bar{v}}{\sum_l \bar{i}_l} \quad [26]$$

From Eq. [20]

$$\bar{i}_l = n_l \mathbf{F} k_{al}$$

$$\begin{aligned} &\exp \left[\frac{(1-\beta) n_l \mathbf{F}}{RT} \bar{v} \right] \sum_l \left(s_{i,l} \bar{x}_i^{s_{i,l}-1} \bar{x}_i \prod_{j \neq i} \bar{x}_j \right) \\ &- n_l \mathbf{F} k_{cl} \exp \left[-\frac{\beta n_l \mathbf{F}}{RT} \bar{v} \right] \\ &\sum_l \left(-s_{i,l} \bar{x}_i^{-s_{i,l}-1} \bar{x}_i \prod_{j \neq i} \bar{x}_j \right) + R_{t,l}^{-1} \bar{v} \end{aligned} \quad [27]$$

with

$$R_{t,l}^{-1} = \sum_l R_{t,l}^{-1} \quad [28]$$

and

$$\begin{aligned} \frac{R_{t,l}^{-1}}{n_l \mathbf{F}} &= \frac{(1-\beta) n_l \mathbf{F}}{RT} k_{al} \\ &\exp \left[\frac{(1-\beta) n_l \mathbf{F}}{RT} \bar{v} \right] \prod_l \bar{x}_i^{s_{i,l}} \\ &+ \frac{\beta n_l \mathbf{F}}{RT} k_{cl} \exp \left[-\frac{\beta n_l \mathbf{F}}{RT} \bar{v} \right] \prod_l \bar{x}_i^{-s_{i,l}} \end{aligned} \quad [29]$$

Then

$$\begin{aligned} Z &= R_t - \frac{R_t}{\bar{i}} \sum_l \left(n_l \mathbf{F} k_{al} \exp \left[\frac{(1-\beta) n_l \mathbf{F}}{RT} \bar{v} \right] \right. \\ &\quad \left. \sum_l (s_{i,l} \bar{x}_i^{s_{i,l}-1} \bar{x}_i \prod_{j \neq i} \bar{x}_j) - n_l \mathbf{F} k_{cl} \right. \\ &\quad \left. \exp \left[-\frac{\beta n_l \mathbf{F}}{RT} \bar{v} \right] \sum_l \left(-s_{i,l} \bar{x}_i^{-s_{i,l}-1} \bar{x}_i \prod_{j \neq i} \bar{x}_j \right) \right) \end{aligned} \quad [30]$$

Anodic dissolution of copper in chloride solutions.—At low current densities and for Cl^- concentration higher than 0.05M, copper dissolves anodically in acidic chloride

solution to form CuCl_2^- (4, 5). At high current densities, a mechanism involving the formation of CuCl and dissolution of this precipitate with the diffusion of CuCl_2^- has been suggested (5, 6). In this paper, we consider the case of low current densities for which there is a good agreement among the published experimental data (4-8); and we compare the results from the two models: infinitely dilute solution and concentrated solution.

Steady state

With this electrochemical reaction, Eq. [20] may be written as

$$\begin{aligned} \frac{i}{\mathbf{F}} &= k_a c_{\text{Cl}^-} \exp \left[\frac{(1-\beta) \mathbf{F}}{RT} V \right] \\ &- k_c c_{\text{CuCl}_2^-} \exp \left[-\frac{\beta \mathbf{F}}{RT} V \right] \end{aligned} \quad [32]$$

In the infinite dilution theory

$$\frac{i}{\mathbf{F}} = \frac{D_{\text{CuCl}_2^-}}{\delta_{\text{CuCl}_2^-}} (c_{\text{CuCl}_2^-} - c_{\text{CuCl}_2^-, \infty}) \quad [33]$$

$$\frac{i}{\mathbf{F}} = \frac{1}{2} \frac{D_{\text{Cl}^-}}{\delta_{\text{Cl}^-}} (c_{\text{Cl}^-} - c_{\text{Cl}^-, \infty}) \quad [34]$$

The expression of the current density may be obtained by solving this set of Eq. [32], [33], [34]. With the assumptions: $c_{\text{CuCl}_2^-, \infty} = 0$ and $c_{\text{Cl}^-, \infty} = c_{\text{Cl}^-}$, this expression is

$$\frac{i}{\mathbf{F}} = \frac{k_a c_{\text{Cl}^-} \exp \left\{ \frac{\beta \mathbf{F}}{RT} V \right\}}{1 + \frac{\delta_{\text{CuCl}_2^-}}{D_{\text{CuCl}_2^-}} k_c \exp \left\{ -\frac{(1-\beta) \mathbf{F}}{RT} V \right\}} \quad [35]$$

For the low rotation speeds

$$\frac{\delta_{\text{CuCl}_2^-}}{D_{\text{CuCl}_2^-}} k_c \exp \left\{ -\frac{(1-\beta) \mathbf{F}}{RT} V \right\} \gg 1 \quad [36]$$

and then

$$\frac{i}{\mathbf{F}} = \frac{D_{\text{CuCl}_2^-}}{\delta_{\text{CuCl}_2^-}} \frac{k_a}{k_c} c_{\text{Cl}^-} \exp \left\{ \frac{\mathbf{F}}{RT} V \right\} \quad [37]$$

and when the rotation speed tends towards infinity

$$\frac{i}{\mathbf{F}} \xrightarrow{\Omega \rightarrow \infty} k_a c_{\text{Cl}^-} \exp \left\{ \frac{\beta \mathbf{F}}{RT} V \right\} \quad [38]$$

Expression [35] is in good agreement with the experimental data given in Ref. (5, 7) and in particular with Smyrl's results (8). By using these last data we can determine the values of β , k_a , k_c , and $D_{\text{CuCl}_2^-}$

$$\beta = 0.5, k_a = 6 \text{ cm}^4/\text{s}, k_c = 10^{-3} \text{ cm/s},$$

and

$$D_{\text{CuCl}_2^-} = 5.4 \times 10^{-6} \text{ cm}^2/\text{s}$$

The value of D_{Cl^-} is given in Ref. (1): $D_{\text{Cl}^-} = 2.032 \times 10^{-5} \text{ cm}^2/\text{s}$; the values of k_a and k_c correspond to V relative to a saturated calomel electrode.

At first, we consider the case of low concentration in acidic chloride: $c_{\text{HCl}} = 0.1M$ and low potential $V = -0.205 \text{ mV/SCE}$.

From expression [35] we find $i = 0.00526 \text{ mA/cm}^2$ for $\Omega = 600 \text{ rpm}$ (10 Hz) and $T = 293.15 \text{ K}$ and by using the Stefan-Maxwell Eq. [2], the numerical integration gives 0.00527 mA/cm^2 . The agreement is very good, and the infinitely dilute solution theory may be used.

In Fig. 1 we give the mole fraction variation of each species vs. the distance from the electrode. These results were obtained from the integration of the Stefan-Maxwell Eq. [1].

In the second case, we consider a higher concentration in acidic chloride $c_{\text{HCl}} = 2.0M$ and a higher potential: $V = -0.085 \text{ mV/SCE}$. Expression [35] cannot be used because

Fig. 1. Variations of the mole fraction of each species vs. the distance from the copper electrode. The concentration in HCl is 0.1M, and the potential is -0.205 mV/SCE.

Fig. 2. Variations of the mole fraction of each species vs. the distance from the copper electrode. The concentration in HCl is 2.0M, and the potential is -0.085 mV/SCE.

the assumption $c_{Cl-i} = c_{Cl-\infty}$ is not valid. Therefore, we must solve the set of Eq. [32], [33], [34]; for $\Omega = 600$ rpm (10 Hz) and $T = 293.15$ K, we find $i = 115$ mA/cm², and by using the Stefan-Maxwell Eq. [1] $i = 119$ mA/cm². By using the numerical integration of the Stefan-Maxwell equation, we obtained the values of $\nabla\Phi$ and c_{Cl-s} , and thus we verified that the difference between the two previous results ($i = 115$ mA/cm² and $i = 119$ mA/cm²) is due to the effect of migration

$$D_{Cl-} c_{Cl-s} \frac{F^2}{RT} \nabla\Phi = 4 \text{ mA/cm}^2$$

In Fig. 2, we give the mole fraction variation of each species vs. the distance from the electrode. At the interface, the concentration of $CuCl_2^-$ is only five times less than the concentration of Cl^- ; that explains the effect of migration on the current.

The effect of the migration program [appendix C in Ref. (1)], or variations of it, could have been used with success here. The Stefan-Maxwell approach was used because we already had a nonelectrochemical version [silicon deposition (2)] with arbitrary homogeneous and heterogeneous reactions, and because of its ultimate validity when we get to problems (electropolishing, conditions of pitting corrosion), where even the viscosity and the pH of solution can vary dramatically near the electrode. We visualize adding surface coverages to the computer program at a later date.

Impedance.—For a low amplitude of perturbation, each variable may be written as in Eq. [21].

From Eq. [32]

$$\tilde{i} = R_t^{-1} \tilde{V} + 2 F k_a \bar{c}_{Cl-s} \exp \left[\frac{(1-\beta)F}{RT} \tilde{V} \right] \tilde{c}_{Cl-s} - F k_c \exp \left[-\frac{\beta F}{RT} \tilde{V} \right] \tilde{c}_{CuCl_2-s} \quad [39]$$

with

$$R_t^{-1} = \frac{(1-\beta)F^2}{RT} k_a \bar{c}_{Cl-s}^2 \exp \left[\frac{(1-\beta)F}{RT} \bar{V} \right] + \frac{\beta F^2}{RT} k_c \bar{c}_{CuCl_2-s} \exp \left[-\frac{\beta F}{RT} \bar{V} \right] \quad [40]$$

R_t is the usual charge-transfer resistance.

Equations [33] and [34] become

$$\tilde{i} = -F D_{CuCl_2-} \frac{\partial \tilde{c}_{CuCl_2-}}{\partial z} \Big|_{z=0} \quad [41]$$

$$\tilde{i} = \frac{1}{2} F D_{Cl-} \frac{\partial \tilde{c}_{Cl-}}{\partial z} \Big|_{z=0} \quad [42]$$

Then the faradaic impedance is

$$Z_f = R_t + Z_D \quad [43]$$

with

$$Z_D = R_t \left\{ 4 \frac{k_a \bar{c}_{Cl-s}}{D_{Cl-}} \exp \left[\frac{(1-\beta)F}{RT} V \right] \frac{\delta_{Cl-}}{-\theta'_{Cl-}(0)} + \frac{k_c}{D_{CuCl_2-}} \exp \left[-\frac{\beta F}{RT} V \right] \frac{\delta_{CuCl_2-}}{-\theta'_{CuCl_2-}(0)} \right\} \quad [44]$$

Z_D is the diffusion or convective Warburg impedance and $\{-1/\theta'(0)\}$ is the dimensionless convective Warburg impedance for the species i . The variation of $\{-1/\theta'(0)\}$ vs. the frequency was studied by several authors (9-11) with the assumptions of infinite dilution theory. If we assume $c_{Cl-i} = c_{Cl-\infty}$ and then $\tilde{c}_{Cl-i} = 0$, Eq. [44] becomes

$$Z_D = R_t \frac{k_c}{D_{CuCl_2-}} \exp \left\{ -\frac{\beta F}{RT} V \right\} \delta_{CuCl_2-} \left(-\frac{1}{\theta'(0)} \right)_{CuCl_2-} \quad [45]$$

Fig. 3. Variation of the real and imaginary part of the normalized convective Warburg impedance for two particular conditions. ($c_{\text{HCl}} = 0.1\text{M}$ and $V = -0.205\text{ mV}$; and $c_{\text{HCl}} = 2.0\text{M}$ and $V = -0.085\text{ mV}$).

For $V = -0.205\text{ mV}$, $c_{\text{HCl}} = 0.1\text{M}$, and $\Omega = 600\text{ rpm}$ (10 Hz), the results from the infinite dilution theory (Eq. [45]) and the Stefan-Maxwell equation are very close. In Fig. 3, we have reported the variation of the real and imaginary part of the impedance vs. the frequency. In this figure, the curves from the concentrated solution theory and from the infinite dilution theory cannot be distinguished.

For $V = -0.085\text{ mV/SCE}$, $c_{\text{HCl}} = 2.0\text{M}$, and $\Omega = 600\text{ rpm}$, the results from the infinite dilution theory are given by Eq. [36] and are shown in Fig. 3 as a dashed line. The translation of this curve compared to the previous curve shows the effect of the Cl^- diffusion. The Schmidt number for CuCl_2^- is 1670, and for Cl^- is 4380, then the curve from Eq. [44] is identical to a curve from Eq. [45], corresponding to an apparent Schmidt number between 1670 and 4380 (here, approximately 2750).

When the frequency tends towards zero, the difference between the impedance derived from the infinite dilution theory and the impedance from the concentrated solution theory is 4%, in good agreement with the steady-state result. The variation of the dimensionless impedance derived from the concentrated solution theory is plotted in Fig. 3.

The curves are translated from the infinite dilution theory curves towards high frequency. In the concentrated-solution theory, the curves are identical to curve from Eq. [45], corresponding to an apparent Schmidt number of 1150, which is outside the average value of the CuCl_2^- Schmidt number and Cl^- Schmidt number. Then, in this case, the effect is very important, and an analysis of experimental data with the infinite-dilution theory (Eq. [44]) gives a wrong result for the Schmidt number determination.

ABSTRACT

This paper reports SIMS analysis of passive layers. Pure Fe disks are used in borate buffers of $\text{pH} = 8.4$. Pre-electrolysis is carried out to remove trace impurities. Potential step control of the electrode is utilized. Two types of experiments are carried out. In one, passive layers are prepared and then exposed to chloride ions for various times. In the other, films are heated at various temperatures for preselected times. The passive layers subjected to these treatments are exposed to SIMS analysis. The distribution of OH^- with depth, from SIMS analysis, shows an exponential-like decrease away from the electrode/solution interface for passive films exposed to $0.5M$ buffered chloride solutions for various times or heated at a given temperature for a predetermined period of time. The OH^- peak heights at a fixed depth in passive layers decrease in a similar manner with increasing exposure time to chloride ions or with increasing annealing temperature for a given time period. Cl^- peak heights for films exposed to chloride ion-containing borate solutions increase rapidly for times up until breakdown, decrease sharply after breakdown, and then level off at times much longer than breakdown. O^- peak heights decrease exponentially with depth for samples exposed to chloride ions and decrease linearly for specimens annealed at various temperatures for a number of different times. Corresponding Fe^+ peak height data display a linear decrease with depth for chloride-treated films and an almost constant value for layers subjected to thermal treatments. Positive SIMS O^+ peak heights increase sharply for thermally treated films over a surface region of approximately 7\AA , remain constant in the bulk regions, and decrease rapidly in the film/metal interfacial regions. Homogeneous films are indicated with a thickness of about 25\AA . Detailed mechanistic discussions of the two principal models of passivity show that the results are in greater agreement with the amorphous hydrated polymeric oxide model than with the crystalline oxide model, in which water is considered only in terms of adsorbed water on the surface of the passive film.

Two kinds of approaches have been used in the past to characterize the passive film formed electrochemically on iron in neutral solutions (1, 2). The first includes *in situ* techniques such as ellipsometry (3, 4) and Mossbauer spectroscopy (5, 6). The second involves the use of high-vacuum spectroscopic methods such as electron diffraction (7, 8), XPS (9, 10), and Auger (11, 12). Both approaches have their drawbacks (difficulty of interpretation of Mossbauer spectra and the removal of the sample from its environment and potential control with *ex situ* techniques); however, a considerable wealth of information has been collected concerning the nature of the passive film.

At present, two models are utilized in interpreting the data obtained on passive films on iron (2, 13). In one view (7, 8, 14-16), the film is considered polycrystalline and an-

hydrous, the only water in the film being that adsorbed in the surface region (9, 17). Passivity in this model is understood in terms of the nature of the crystalline oxide present (either a duplex layer consisting of an inner layer of Fe_3O_4 and an outer layer of $\gamma\text{-Fe}_2\text{O}_3$ (7) or $\gamma\text{-Fe}_2\text{O}_3$ alone (8, 14)). In the second model (5, 18, 19), the passive layer is regarded as an amorphous hydrated ferric oxide represented by $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ (12). According to this model, the bound water is the essential element in the passive film, cementing the polymeric iron oxide chains together (20). Passivity is understood in terms of the difficulty of lattice cation diffusion through the film as a result of the network formed by the bound water molecules.

A key problem to be resolved, therefore, is the location of hydrogen or hydrogen containing species, *e.g.*, OH^- and H_2O , in the passive layer. Secondary ion mass spectroscopy (SIMS) is uniquely suited for this problem be-

* Electrochemical Society Active Member.

cause of its ability to detect hydrogen and its isotopes in association with depth profiling. An early application of SIMS to this problem has given results which are inconclusive (9, 21, 22). Preliminary work in this laboratory (20, 23) shows the presence of water throughout the thickness of the passive layer and relates the loss of passivity in aggressive environments such as chloride solutions to displacement of the bound water molecules by the latter, eventually leading to pitting.

In this paper, a SIMS investigation of passive films on iron, both exposed and nonexposed to chloride ions, as well as those post-thermally treated in an inert gas atmosphere, is described.

Experimental

Working electrodes were iron disks (1 mm thick and 6 mm \times 6 mm square, 99.99% pure; Alfa Ventron Corp., Danvers, MA) mechanically polished to a mirror finish, washed with methanol and thrice-distilled water, dried, and stored *in vacuo*. Electrode specimens were prepared fresh with a fine-grade diamond paste prior to use. Samples were fixed in a Teflon electrode holder, as described previously (10). The counterelectrode was a piece of platinum gauze of an area about 100 times that of the iron disk working electrode and was situated in a manner to avoid depolarization of the latter. The reference electrode was a Hg/HgO, 1N KOH electrode.

Buffer solutions (pH = 8.4; 0.275M sodium tetraborate mixed with 0.15M boric acid) were made up, using thrice-distilled water and analytical-grade reagents. Prior to experimental runs, all solutions were pre-electrolyzed for about 15h at a current density of 20 $\mu\text{A cm}^{-2}$, using two large platinum gauze electrodes.

Air-formed oxide films on iron disks were removed by cathodic polarization at -0.74V (NHE) (24) for 30 min, followed by replacement of the contaminated borate electrolyte (from an attached reservoir) while maintaining the cleaned electrode surface under a nitrogen gas atmosphere. Electrodes prepared by this procedure were used afterward in experimental runs.

Passive films were formed in all cases by means of a potentiostatic step from the resting potential of the cleaned electrode to $+0.3\text{V}$ (NHE), the time of film growth being 50 min.

At this stage in one set of experiments, the solution of film growth was pressed out of the cell by means of nitrogen pressure and replaced with a chloride ion containing (0.5M) borate buffer solution from an attached reservoir. Passivated electrodes were exposed to this solution at the potential of film growth for various times prior to, during, and after breakdown. On completion of each experiment, the test solution was pressed out of the cell, quickly filled with thrice-distilled water from an attached reservoir, and released by nitrogen gas pressure. Washing with thrice-distilled water was repeated. The cell with the electrode still in place under a nitrogen gas atmosphere was placed in a glove box. On opening the cell, the electrode was removed, washed thoroughly again with thrice-distilled water, and transferred to a glass vial. The glass vials, which were filled with nitrogen gas, were carefully sealed with Teflon tape and a screw-on cap.

In another set of experiments, electrodes after film growth were put in a glove box as described above and placed individually in cleaned Pyrex glass tubes under a nitrogen gas atmosphere. The tubes were then placed in a furnace and heated at a number of temperatures for various times under a flowing inert gas atmosphere. On completion, tubes with specimens inside were returned to the glove box, and electrodes were removed and placed in glass vials.

Samples were opened under inert gas conditions and placed in the target chamber of a Gatan Model 591C SIMS-SIPS ion microprobe at the Materials Research Laboratory, Pennsylvania State University. In this instrument, the ion beam consists of a Colutron ion source, a Wein mass filter, and two electrostatic lenses. The ion gun chamber is pumped with a turbomolecular pump.

The target chamber can be evacuated to 10^{-10} torr with a second turbomolecular pump and titanium sublimation pump.

The typical operating parameters used in this work were probe ion beam $^{40}\text{Ar}^+$, beam voltage of 7 keV, beam current of 90 nA, and a sample chamber pressure during analysis of 5×10^{-9} torr. The ion beam of $\sim 70 \mu\text{m}$ in diameter was rastered over an area of 1.2×1.2 mm. The signal was gated, so the data were collected over a central area of 0.36×0.36 mm. The sputtering rate was found to be 0.3 \AA sec^{-1} , using a $102\text{\AA SiO}_2/\text{Si}$ standard. The sputtering rate for the passive film was taken to be the same as that for the SiO_2/Si material.

Results

A convenient measure of hydrogen containing species, including water, in passive films can be obtained from monitoring the negative SIMS OH^- peak heights with depth into the films. In Fig. 1, the OH^- peak height, which is related to water content as a result of OH^- ion formation from the fragmentation of water within the films on ion bombardment, is presented as a function of annealing temperature for passive films grown at $+0.3\text{V}$ (NHE) and subsequently annealed for 15 min at various temperatures in a flowing inert gas atmosphere.

The outer regions of the passive films (*i.e.*, where the aqueous solution is in contact with the films), for all temperatures, are richer in water than the bulk layers. In the former regions, an exponential-like decrease in water content can be observed from room temperatures of up to 200°C .

The OH^- peak heights for passive films formed at $+0.3\text{V}$ (NHE) and exposed afterward to a 0.5M chloride ion containing borate buffer solution at the latter potential for various times are shown in Fig. 2a for a number of film depths. Peak heights decrease sharply, particularly in the outer regions, for exposure times of up to 163s. At 163s, which is observed (20) to be the breakdown time for the passive film on iron under the experimental conditions employed, a minimum is to be noted in the OH^- peak heights for all depths. For exposure times greater than breakdown, namely 205 and 420s, an exponential-like increase in the OH^- peak heights occurs and is particularly large in the outer surface regions.

The corresponding Cl^- peak heights as a function of exposure time to chloride ions for the passive films described above are illustrated in Fig. 2b. Peak intensities increase sharply for exposure times up to breakdown, reach a maximum at breakdown, then decrease in an exponential-like manner. This behavior is opposite to that observed for the OH^- peak heights (Fig. 2a). Chloride ions penetrate into the interior of passive layers, up to the

Fig. 1. Variation of OH^- peak height with annealing temperature for passive films formed in borate buffer solution at 0.3V (NHE) and then thermally treated in an inert gas atmosphere.

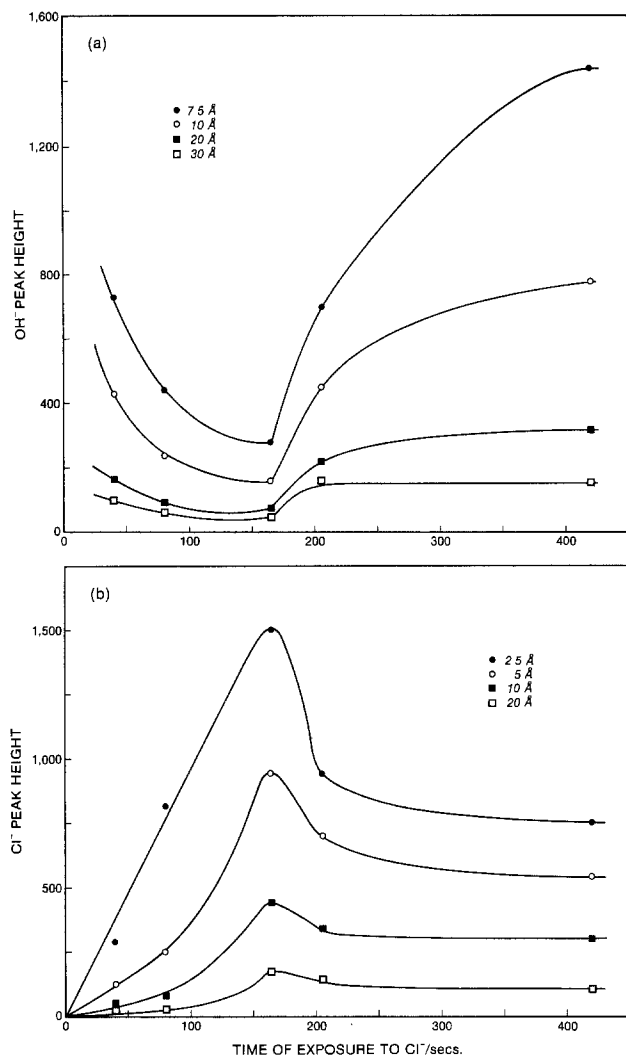

Fig. 2. (a) OH⁻ peak height as a function of the time of exposure to chloride ions for passive films formed in borate buffer solution at 0.3V (NHE) and then exposed to a chloride containing borate solution at this potential. (b) Variation of Cl⁻ peak height intensities with time of exposure to chloride ions for passive films formed in borate buffer solution at 0.3V (NHE) and then exposed to a 0.5M chloride containing borate solution at this potential for various times

metal/metal oxide interface. The local concentration of chloride ions is highest in the outer regions for all exposure times and decreases with depth into the films.

The treating of passivated iron specimens to chloride solutions or to annealing atmospheres also has an effect on the O⁻ peak heights, the latter being associated with lattice oxide ions. The latter are plotted as a function of depth in Fig. 3a for passive films annealed under an inert gas atmosphere at various temperatures for a number of different times. The oxide ion concentration decreases in a linear fashion in practically all cases, the decrease being lowest for those films annealed at the higher temperatures.

The Fe⁺ peak heights, obtained from positive SIMS, for the thermally annealed films are shown in Fig. 3b as a function of depth. After a sharp initial increase over the first 1-2 Å of the outer surface region, an approximately constant signal is obtained for all films throughout the bulk. At the metal/metal oxide interface (about 25 Å), a decrease in peak heights is observed.

The positive SIMS O⁻ peak heights arising from thermally treated passive films are illustrated in Fig. 3c as a function of depth into the films. A rapid signal increase occurs over the first 5-7 Å, followed by a plateau region which terminates as the metal/metal oxide interface is approached. Temperature effects are seen.

The variation of O⁻ peak heights with depth for passive films exposed to chloride ions for various times is pre-

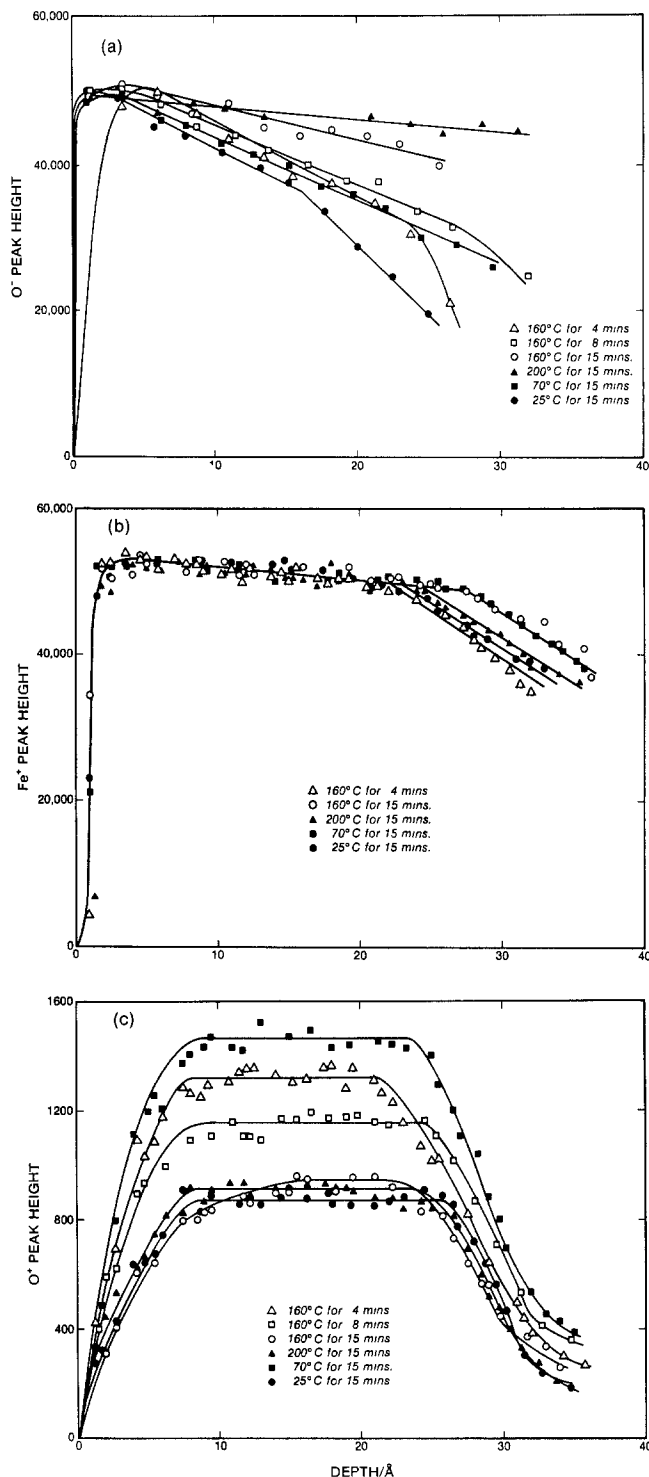

Fig. 3. (a) O⁻ peak height as a function of depth into passive films grown in borate buffer solutions at 0.3V (NHE) and then thermally annealed in an inert gas atmosphere at various temperatures for different times. (b) Fe⁺ peak height as a function of depth into passive films formed in borate buffer solution at 0.3V (NHE) and then thermally treated in an inert gas atmosphere. (c) O⁻ peak height as a function of depth into passive films which were thermally treated at a number of different temperatures for various times.

sented in Fig. 4. The profiles give rise to an initial sharp increase, followed by a sharp decrease in the outer surface regions of the films and, thereafter, a more gradual decrease in the bulk. A sharp drop in peak heights occurs in the interfacial region between the metal and the metal oxide. An increase in the O⁻ signal with exposure is observed at a given depth.

Fe⁺ data for films exposed to chloride solutions are presented in Fig. 5. Compared with the data in Fig. 3b, the outer surface regions in this case are much broader, of the

Fig. 4. Variation of O^- peak height with depth for passive films grown in borate buffer solutions at 0.3V (NHE) and then exposed to a chloride containing borate solution at this potential.

order of 1-7Å. Following an initial maximum at the latter depth, the Fe^+ signals decrease with depth, this being more pronounced for films with the shortest exposure time to chloride ions. Variations in ion yields per unit depth in the bulk and in the interfacial region are given in the inset in Fig. 5 as a function of exposure time.

Discussion

Effect of heating passive films.—*In situ* Mossbauer spectroscopy studies (5, 6, 25), *ex situ* Auger analysis under controlled conditions (12), and *ex situ* EXAFS investigations (26, 27) under an inert gas atmosphere support the hydrated amorphous polymeric ferric oxide nature of the passive film on iron. Data from Auger (12), tritium radiotracer measurements (28), and a recent combined XPS-ISS study (29) are consistent with a structure of the passive film corresponding to $Fe_2O_3 \cdot H_2O$. These observations are consistent with the formation of polymeric species and structures with oxy and hydroxy bridges on hydrolyzing ferric salts (30). However, electron diffraction data (8, 14), ellipsometric spectroscopy (4), and ac impedance studies (31) indicate that the passive film is composed of an anhydrous ferric oxide.

Naturally occurring and synthetic amorphous hydrated oxides of iron (III) subjected to thermal treatments in a variety of atmospheres have been well characterized (32-36). However, similar conditioning of thin passive oxide layers on iron has been little investigated (6, 37). Utilization of Mossbauer spectroscopy (6) reveals that thermally annealing passive films give rise to a change in the Mossbauer parameters: the parameters change from those typical of a hydrated amorphous polymeric ferric oxide film to those typified by anhydrous crystalline $\gamma-Fe_2O_3$. The SIMS analyses of thermally treated passive layers reported here (Fig. 1) can be interpreted along similar lines. Thermal expulsion of water takes place at temperatures of up to 200°C for weakly chemisorbed water and structural water from the outer surface regions and for structural or lattice-bound (38) water from the bulk of the films, giving rise to the formation of an anhydrous crystalline oxide, possibly $\gamma-Fe_2O_3$. This view may be compared with that concerning the dehydration behavior of a tungsten oxide hydrate, $WO_3 \cdot 1/3 H_2O$, which has been observed (39) to follow two steps: emission of adsorbed water, without a change in structure, followed by loss of structural water and the formation of anhydrous crystalline WO_3 .

The enthalpy, ΔH , associated with water removal from passive films, may be obtained from a van't Hoff type of

Fig. 5. Variation of Fe^+ peak height with depth for passive films exposed to 0.5M chloride containing borate buffer solutions for various times.

expression (40) by plotting the log of the OH^- peak heights (Fig. 1), which are proportional to the concentration of water, C_{H_2O} , in the layers, against the inverse of the absolute temperature. However, the qualitative nature of SIMS data (41) must be borne in mind, and any value of ΔH must be regarded as approximate.

From a plot of the relevant data (Fig. 6), $\Delta H \sim 2.0$ kcal mol^{-1} . This low value may be interpreted in terms of the hydrated polymeric oxide model of passivity in the following way: the amorphous Fe_2O_3 should be bonded in some fashion to H_2O , and after breaking this bond by thermal treatments, it is reasonable to expect a chemical bond strength to be involved, *i.e.*, a heat of reaction, ΔH , of the order of 20-100 kcal mol^{-1} . What actually happens is that, in the overall process, two compensating reactions are taking place—an endothermic bond-breaking reaction involving water removal and an exothermic crystallization reaction associated with the formation of a stable, anhydrous, crystalline lattice, probably $\gamma-Fe_2O_3$. These two compensating reactions can be represented by the equation

The heat of crystallization, given off during the formation of $\gamma-Fe_2O_3$, almost provides the heat required to expel water from passive layers—only 2 kcal mol^{-1} more are required. With this interpretation of events, the small calculated value of ΔH is rational.

With the crystalline oxide model of passivity, the low value of ΔH , 2 kcal mol^{-1} , could be understood in terms of the desorption of weakly adsorbed water on the outer surface of passive films, where the short-range forces involved are of the order of 1-10 kcal mol^{-1} . However, the distribution of water throughout the thickness of passive films (Fig. 1) strongly supports the first interpretation and the hydrated polymeric oxide model of passivity.

It must also be pointed out that the passivated samples, described in Fig. 1, are heated under a flowing inert gas atmosphere for only 15 min. In the case of many hydrated oxides or salts, a much longer thermal treatment of the order of 10-20h is needed to remove the last traces of bound water. For the passivated iron disks, the film thicknesses are low, approximately 30Å, so a shorter time

Fig. 6. Plot of log of OH⁻ peak height (relevant data taken from Fig. 1) vs. the inverse of the absolute temperature.

may suffice. However, the state of equilibrium achieved may not lie completely to the right of Eq. [1], i.e., in the purely crystalline state.

The O⁻ peak heights, which arise from lattice oxide ions, display for thermally treated films (Fig. 3a) a qualitative similarity to those of OH⁻, which give a measure of the water content (Fig. 1) with respect to depth into the films. The general tendency of O⁻ peak heights to decrease with increasing depth (Fig. 3a and 4) may result from a change in the oxide matrix with increasing annealing temperatures and give rise to differences in ion yields on performing SIMS analyses (42).

Effect of exposing passive films to chloride containing solutions.—An interesting comparison, with regard to the water content of passive films, can be made between thermally treated films (Fig. 1) and films exposed to chloride containing solutions (Fig. 2a). In Fig. 2a, the decrease of OH⁻ peak heights for exposure times of up to 163s is associated with events leading to breakdown of the passive films.

Figure 2b implies a permeation of chloride ions through the passive layer over a time period of about 160s. Using the relation (43)

$$\Delta^2 = 2Dt \quad [2]$$

and having $\Delta = 50\text{\AA}$ yield a value of the order of $10^{-15} \text{ cm}^2 \text{ s}^{-1}$ for the diffusion coefficient of chloride ions, D , through the passive film on iron. With the hydrated polymeric oxide model of passivity, it may be thought that the permeation occurs along certain paths (Fig. 7) where bound water molecules coordinated to lattice Fe³⁺ cations are located. Such a view is supported by the results shown in Fig. 2a and 2b, from which it can be seen that the progress of the chloride ions into the lattice is followed by a diminution of H₂O up to the critical time at which breakdown occurs. Penetration of chloride ions (but not nitrate ions) throughout the bulk of synthetic hydrated oxides of iron by expulsion of water molecules from the structures and by replacement by chloride ions was found to occur by Ellis *et al.* (44). Correspondingly, in mixtures consisting of a hydrated ferric oxide and goethite ($\alpha\text{-FeOOH}$) with KCN, rapid room temperature solid-state substitution reactions occur (45) involving replacement by cyanide ions of only the water molecules in the hydrated ferric oxide, the reaction going to completion. Rapidity of the reaction is attributed (45) to the greater π -acceptor properties of cyanide ion, as compared with water and the ease of CN⁻ diffusion due to the presence of water in the structure.

In the crystalline oxide model of passivity, chloride ion penetration may be accounted for in terms of ion ex-

Fig. 7. Schematic representation of chloride penetration channels in terms of the amorphous hydrated polymeric oxide model of passivity.

change processes, e.g., Cl⁻ for lattice O²⁻ (46), via cation vacancies (47), or point defects (48). However, the correlation shown here between water content and chloride ion permeation through passive films (Fig. 2a and 2b) favors the hydrated polymeric oxide model.

The increase in OH⁻ peak heights after breakdown (about 160s) (*cf.*, Fig. 2a) may be thought to arise from the precipitation of corrosion products, e.g., Fe(OH)₂ or FeOOH, at the outer surface regions of the unprotective oxide film, as well as from porous plugs within the chloride ion permeation channels (Fig. 7). Using the solubility product of ferrous hydroxide, it can be shown that at a pH of 8.4 and at local current densities of 1 mA cm^{-2} , the solubility of Fe(OH)₂ will be exceeded. Precipitation of corrosion products in the outer film surface regions is supported by the enhanced OH⁻ peak heights obtained at a film depth of 7.5\AA (Fig. 2a), as compared with those observed at times well before breakdown.

The decreasing chloride ion peak heights observed for times after breakdown (Fig. 2b) could be due to chloride removal of some Fe³⁺ cations from within the film in the form of chloro complexes. Thus, the density of the resulting $\gamma\text{-Fe}_2\text{O}_3$ is likely to be substantially greater than that of the amorphous passive film. Support for the hypothesis of chloride removal of Fe³⁺ cations can be found by comparing the data presented in Fig. 3b and 5. A decrease in Fe³⁺ peak heights increasingly exposed to chloride ions (Fig. 5) is observed, whereas for passive films not exposed to chloride ions (Fig. 3b), almost constant Fe³⁺ peak heights are observed. Furthermore, the rotating ring-disk work of Heusler and Fischer (49) demonstrates the existence of Fe³⁺ species in solution after exposing passivated iron disks to chloride solutions.

The O⁻ peak profiles obtained for passive films exposed to chloride ions (Fig. 4) are similar in outline to those observed for thermally treated films (Fig. 3a) and, again, they indicate matrix effects. The increasing O⁻ ion yields at a given depth with increasing exposure time to chloride ions (Fig. 4) are probably due to a change in the oxide matrix (42) as a result of events leading to breakdown, subsequent corrosion, and corrosion product buildup on the outer surfaces.

Thickness and uniformity of passive films.—From the data presented in Fig. 3b, the interfacial region between the passive film and the underlying metal occurs at around $27 \pm 3\text{\AA}$. The lower Fe³⁺ ion yields in the interfacial regions are probably due to irregularities in the position of the metal/metal oxide interface and a change in the matrix in going from a predominantly oxide lattice to a metal one. Supporting evidence can be obtained from the related data shown in Fig. 5.

The change in ion yields per unit depth with time [(b) in the inset in Fig. 5] indicates that the bulk regions of chloride-exposed passive films undergo a change in cation environments with time of exposure to chloride ions. This is due to the aforementioned chloride removal and replacement of bound water and the chloride removal of some Fe^{3+} cations from the passive films. However, the almost constant ion yields obtained for exposure times greater than 200s indicate homogeneous layers for films after breakdown; this probably corresponds to $\gamma\text{-Fe}_2\text{O}_3$ (6).

The almost constant ion yields per unit depth with time of exposure of passive films to chloride ions in the metal/metal oxide interfacial region [(a) in the inset in Fig. 5] point to a uniform structure in this region for all films. This would correspond to the increasingly metallic region indicated at depths greater than 25Å. The same behavior is found for the interfacial region of thermally treated films (Fig. 3b).

The positive SIMS O^+ peak heights for passive films thermally treated (Fig. 3c) again indicate a passive film thickness of about 25Å. Also, the constant O^+ signal values, corresponding to the bulk of each film investigated, indicate homogeneous layers, though the layers differ from each other according to the degree of thermal treatment. Similar SIMS O^+ peak profiles are obtained for passivated iron disks exposed to chloride ions (29). A thickness of about 25Å for passive films grown under the conditions used compares very well with the ellipsometric data of Sato *et al.* (50) and Brusica *et al.* (51).

It is not at all obvious why the passive film treated at 25°C (Fig. 3c) should depart from the trend observed; it is unlikely that the matrix for this film is the same as that for films annealed at the highest temperatures, 160° and 200°C. This aspect requires further clarification.

ABSTRACT

Amorphous metallic films of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ and $\text{Mo}_{82}\text{B}_{18}$ have been prepared by magnetron sputtering, and their corrosion behavior was investigated and compared with amorphous liquid-quenched $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ and crystalline Mo in acidic and basic solutions. Sputtered $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ showed lower corrosion rates compared with liquid-quenched $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$, owing to the superior surface smoothness and uniformity of the former. Amorphous $\text{Mo}_{82}\text{B}_{18}$ showed low corrosion rates in both acidic and basic aqueous solutions. Comparison of the corrosion properties of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ with $\text{Mo}_{82}\text{B}_{18}$ and Mo demonstrates the roles of the alloys' constituents. Ru significantly extends the passive region to high anodic potentials, but, at less anodic potentials, $\text{Mo}_{82}\text{B}_{18}$ has the lowest corrosion rate.

The extraordinary corrosion resistance exhibited by many amorphous metals (metallic glasses), owing to their chemical homogeneity, has led to much interest in their properties and applications. The majority of studies of their corrosion behavior have focused on materials produced by the widely employed liquid quenching technique, which yields samples in the form of powders, wires, foils, or ribbons. Amorphous metals can also be prepared by electroless or electrochemical deposition, solid-state diffusion reactions, and by a variety of vapor quenching techniques, in particular, sputtering. Sputtering techniques offer the greatest opportunity for variation of amorphous metal composition even beyond the bulk solubility limits, and are also attractive as a means for producing amorphous metals as protective coatings with good adhesion to substrates. The magnetron sputtering technique has met with increasing acceptance in large-scale industrial deposition applications owing to its high deposition rates, minimum substrate heating, ease of scale up, and extreme versatility (1). It is routinely used for commercial deposition of chromium and antireflection coatings on large area substrates. However, studies of the chemical corrosion behavior of sputter-deposited amorphous metallic films are quite limited. One study by Diegle and Merz comparing the corrosion resistance of triode sputter-deposited and liquid-quenched $\text{Fe}_{45}\text{Ni}_{30}\text{Cr}_2\text{V}_2\text{P}_{15}\text{B}_6$ and $\text{Fe}_{31}\text{Ni}_{30}\text{Cr}_{16}\text{V}_2\text{P}_{15}\text{B}_6$ concluded that the two amorphous materials were generally similar to the liquid-quenched samples in their corrosion behavior, but that the triode sputter-deposited film exhibited higher anodic current densities in some potential regimes and was thus somewhat inferior in its corrosion resistance (2). However, these authors did not discuss in detail the influence of surface roughness and bulk microstructure on the corrosion characteristics of these alloys.

We have undertaken a systematic and comparative study of the corrosion resistance of liquid-quenched and magnetron-sputtered early transition metal-based amorphous alloys in order to understand the role of alloy constituents and composition as well as bulk microstructure and surface features in determining corrosion properties. A second goal was the preparation of amorphous alloys, which are inaccessible by current liquid quenching technology, but could be readily prepared by magnetron sputtering. The amorphous alloy $(\text{Mo}_{0.6}\text{Ru}_{0.4})_{82}\text{B}_{18}$, or $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$, was selected for the comparative study because its physical properties have been thoroughly examined and because it has a comparatively high crystallization temperature (800°C), high mechanical strength, and thus represents a potentially important class of nonferrous-metal-based amorphous alloys derived from early

transition metals and metalloids (3). $\text{Mo}_{82}\text{B}_{18}$ was selected in order to demonstrate that this technique can be used to prepare refractory amorphous alloys, which cannot be prepared by liquid quenching. Moreover, the corrosion and thermal behavior of this alloy was expected to provide a useful comparison with $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$, allowing an improvement in our understanding of the effects of the individual constituents. The preparation of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$, liquid-quenched and magnetron-sputtered amorphous metallic alloys, and the influence of sputtering parameters on microstructure and corrosion behavior of this alloy have already been briefly reported elsewhere (3-6). The corrosion behavior in acidic and basic aqueous solutions, as well as thermal properties of these alloys are reported here in more detail.

Experimental Details

Sputtering targets were fabricated by hot pressing thoroughly mixed powders (325 mesh) of high purity ($\geq 99.99\%$) elements in the desired composition at ~ 3000 psi and 1200°C. The hot-pressed targets were then machined to the exact size to fit the magnetron sputtering gun (Sputtered Films, Incorporated). Films 2-10 μm thick were deposited by magnetron sputtering onto precleaned glass or freshly cleaved mica substrates under conditions described elsewhere (3, 4, 5). Films were analyzed by energy dispersive analysis (EDS) and ion microprobe depth profiling in order to confirm uniformity of chemical composition. Differential thermal analysis (DTA) and differential scanning calorimetry (DSC) were carried out on the samples, scraped from the substrates, in order to measure temperatures at which relaxation and crystallization processes occur in the materials. X-ray diffraction patterns were measured before and after annealing experiments using either a powder diffractometer or a Guinier camera in order to unambiguously characterize the nature of transitions observed by DTA and DSC. The preparation and characterization of liquid-quenched $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ alloys have been described previously (6). Electrodes for electrochemical studies were prepared by attaching leads to samples with indium-zinc solder, and covering leads and edges of the sample with epoxy. Potentiostatic and potentiodynamic polarization data were obtained in 1.0N aqueous solutions of HCl and H_2SO_4 , and 0.1N NaOH, using a Princeton Applied Research Model 173 potentiostat and a Model 376 log-current converter with Ag/AgCl and Hg/HgO reference electrodes in acidic and basic solution, respectively. Potentiodynamic data were collected at scan rates of 1-100 mV/s, but a 10 mV/s scan rate showed passivation behavior best. Potentiostatic measurements were made after holding the electrode at each potential in the passive region for 20-180 min, until a

* Electrochemical Society Active Member.

steady response was obtained. At potentials where corrosion was very rapid, measurements were made after 1-20 min since thin film integrity was short lived at high current densities. Corrosion measurements were also performed on liquid-quenched $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ and molybdenum sheet (Alfa, 99.9%) for purposes of comparison.

Results and Discussion

$\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ films deposited under low pressures of argon gas ($\leq 5 \times 10^{-3}$ torr) exhibited a very smooth surface finish and a uniform tensile fracture cross section. Under higher Ar pressures ($35\text{--}75 \times 10^{-3}$ torr), the surface roughness increased and a distinct vertical columnar structure was seen in cross section. Scanning electron microscope photographs of the cross sections of films produced in both of these pressure ranges are shown in Fig. 1.

The films deposited under 5×10^{-3} torr Ar were slightly variable from batch to batch and displayed slightly different behavior when deposited on different substrate materials. Films deposited on glass substrates could be easily removed, intact, by immersion of the sample in concentrated HCl, but the films tightly coiled as they separated from the glass substrate, indicating high stress density in the as-deposited films. Films on mica substrates generally exhibited better adhesion and

Fig. 1. Tensile fracture cross sections of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ films sputtered under Ar pressures of: $< 5 \times 10^{-3}$ torr (A), and $> 35 \times 10^{-3}$ torr (B). The films are each about $2.5 \mu\text{m}$ thick.

somewhat better corrosion resistance than most of the films deposited on glass. Clearly, complete optimization of the deposition process on different substrates must involve characterization of crystallinity and short-range order, microstructure, surface morphology, and the frozen-in internal, as well as interfacial stresses of the film. Figure 2 shows DTA plots for both liquid-quenched and magnetron sputter-deposited metallic amorphous alloys. Relaxation processes occur at 350° and 650°C for $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ and $\text{Mo}_{82}\text{B}_{18}$, respectively. Crystallization occurs at $\sim 800^\circ\text{C}$ for $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ and begins at $\sim 950^\circ\text{C}$ for $\text{Mo}_{82}\text{B}_{18}$ (3). X-ray powder diffraction patterns of the amorphous $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ show broad, diffuse lines which shift slightly to shorter d spacings after relaxation. These peaks are further shifted and greatly sharpened after crystallization and the diffraction pattern became more complex. The diffuse diffraction pattern of $\text{Mo}_{82}\text{B}_{18}$ changes substantially after annealing for one day at 650°C without a significant increase in the distance over which order exists (7). Segregation as well as relaxation apparently occurs at 650°C , since three of the diffuse lines agree with the d spacings of Mo 110, 200, and 211 vectors within $1.5 \times 10^{-3}\text{\AA}$, and several new diffuse lines appear at 650°C , clearly indicating short-range structural changes. More new lines appear and all diffraction lines become sharp after annealing at 950°C for 20 min. The diffraction pattern of a sample annealed to 950°C was assigned to a mixture of crystalline Mo and a previously unknown Mo-B phase (8).

Annealing $\text{Mo}_{82}\text{B}_{18}$ at 650°C results in a decrease in the d spacing of the first strong diffraction peak, from 2.249\AA in the unannealed sample to 2.227\AA in the annealed sample, but this diffraction peak remains diffuse, even after annealing for 24h. These d spacings are clearly too small to be the nearest neighbor distances for Mo in an alloy, but are close to the 110 distance in crystalline Mo. Assuming short-range structure in $\text{Mo}_{82}\text{B}_{18}$ is similar to that in crystalline Mo, the nearest neighbor distance is 2.754\AA before annealing and 2.728\AA after annealing. There is no further change in this d spacing after annealing at 950°C for 20 min, but this and all other diffraction peaks sharpen, indicative of formation of long-range crystalline order in the sample. Similarly, sputtered $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$

Fig. 2. (a): DTA plots showing crystallization exotherms of sputtered and liquid-quenched $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ at $780^\circ\text{--}790^\circ\text{C}$. Inset shows DSC plot of sputtered films showing exotherm due to relaxation at 400°C . (b): DTA plot of $\text{Mo}_{82}\text{B}_{18}$ shows exotherm at 600°C due to relaxation/segregation and at $\geq 950^\circ\text{C}$ due to crystallization.

crystallizes at $\sim 790^\circ\text{C}$, but exhibits a thermal relaxation at 450°C , which is reflected in a decrease in the first nearest neighbor distance from 2.73 to 2.71 Å, the latter distance also being characteristic of liquid-quenched $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$.

Potentiostatic and potentiodynamic data are presented in Fig. 3-5. This data represents measurements on films prepared in argon at pressures less than 5×10^{-3} torr. Films prepared under these conditions were fairly reproducible and showed good passivation behavior, whereas films prepared at higher pressures or in the presence of nitrogen or oxygen showed higher corrosion rates at all potentials, and in some cases disintegrated immediately on contact with electrolyte solutions (5). The magnetron sputter-deposited films of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ showed passive behavior from ~ -0.4 to $\sim +1.1\text{V}$ in acid solutions (1.0N HCl and H_2SO_4), from ~ -0.6 to $\sim +0.4\text{V}$ in 0.1N NaOH. The presence of ruthenium, which is not oxidized until quite anodic potentials, results in a greatly reduced corrosion rate in $\text{Mo}_{42}\text{Ru}_{33}\text{B}_{18}$ in the range $+0.4$ to $+1.1\text{V}$ vs. Ag/AgCl. Corrosion studies of crystalline molybdenum-ruthenium alloys have also demonstrated the reduction of the corrosion rates in the range of $+0.4$ to $+1.1\text{V}$ vs. Ag/AgCl by addition of small percentages of ruthenium to molybdenum (9).

The first anodic passivation process at $\sim -0.2\text{V}$ vs. Ag/AgCl is common to $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$, $\text{Mo}_{82}\text{B}_{18}$, and crystalline Mo, and can be tentatively ascribed to formation of a passivation film containing Mo in mixed valent oxide of average oxidation state Mo^{+4} based on analogy to corrosion studies of other Mo containing alloys (9, 10). Likewise, the anodic process at $+0.4\text{V}$ vs. Ag/AgCl is common to all of the alloys and probably results in a Mo^{+5} - Mo^{+6} containing film.

This oxidation occurs at -0.3 to -0.4V vs. HgO/Hg in 0.1N NaOH, but at about $+0.2\text{V}$, potentiostatic current time curves show a minimum current of $\sim 10 \mu\text{A}/\text{cm}^2$ after several minutes, followed by a gradual increase to a steady-state current of $\sim 100 \mu\text{A}/\text{cm}^2$ after several hours. This may be explained by the high solubility of Mo^{+6} , i.e., as molybdate, in basic solution, and implies that the passive film is fairly completely converted to Mo^{+6} compounds at this potential. The highest potential anodic

Fig. 4. Potentiostatic polarization data for $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ in 1N HCl. (○): Liquid-quenched foil. (□): liquid-quenched foil, after polishing. (△): Sputtered film.

Fig. 5. Potentiodynamic polarization data for sputtered films of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$, $\text{Mo}_{82}\text{B}_{18}$, and Mo in 0.1N NaOH. Scan rate: 10 mV/s.

process exhibited by $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ occurs at a potential where no anodic waves are exhibited by $\text{Mo}_{82}\text{B}_{18}$ or Mo; it is presumably due to oxidation of Ru(O) to $\text{Ru}^{3+}/\text{Ru}^{4+}$. A brown-black film is observed to form at the onset of transpassive behavior at $\sim +1.0$ - 1.1 vs. Ag/AgCl, and gas evolution (presumably O_2) is only observed at still more anodic potentials. The lack of good resolution of waves in the voltammograms at scan rates of 1 to 100 mV/s is ascribed to the formation of a continuous range of mixed-valent molybdenum oxides. The potentiostatic and potentiodynamic behavior of magnetron-sputtered films and liquid-quenched foils of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ show similar corrosion responses, but the corrosion rate is somewhat greater for the liquid-quenched samples, as shown in Fig. 4. Polished samples of the liquid-quenched foils show a lower potentiostatic corrosion rate than unpolished samples, but the magnetron-sputtered films are still somewhat better. It appears that the very smooth, uniform surface of the sputtered films is responsible for its favorable corrosion response; the liquid-quenched samples, by contrast, have fairly rough surfaces. There is a small difference in the structure of liquid-quenched vs. sputtered $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$, as shown by the difference in the nearest neighbor spacing and minor differences in the thermal analytical data. However, since the differences in electrochemical behavior manifest themselves only in the magnitude of the currents observed, and polished liquid-quenched samples are not greatly different than sputtered samples, it is clear that most of the difference is due to surface uniformity. Amorphous $\text{Mo}_{82}\text{B}_{18}$ is similar to crystalline Mo in its corrosion response in acid 1.0N H_2SO_4 , but shows significantly lower anodic current density in the passive regime from -0.3 to $+0.3\text{V}$, and is also superior to amorphous $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ within a limited potential regime.

In order to verify that pitting corrosion plays no important role in the corrosion of $\text{Mo}_{49}\text{Ru}_{33}\text{B}_{18}$ films, even in the transpassive regime several films were cycled from the passive regime to the active anodic corrosion regime and then taken to more cathodic potentials with agitation of the solution until the thick anodic film was dislodged. Invariably, the smooth mirror surface was retained for sputter-deposited films and no evidence of pitting corrosion was observed for either sputtered or liquid-quenched samples. In fact, the corrosion behavior of unpolished liquid quenched samples was improved by cycling in this manner, owing to an electropolishing effect, since no localized corrosion processes occurred, owing to the homogeneity of the bulk alloy.

Conclusions

Magnetron sputtering can be used to prepare amorphous alloys having compositions not easily accessible by liquid quenching techniques because existence of a deep eutectic of solid solubility is not a prerequisite. This technique may be especially useful for depositing protective coatings of amorphous metallic alloys with good adhesion as well as corrosion resistance. $\text{Mo}_{82}\text{B}_{18}$ is an example of such a high crystallization temperature alloy which has not yet been successfully prepared by liquid quenching.

Vapor-quenched amorphous metal films prepared under optimum deposition parameters show superior corrosion resistance, as compared with liquid-quenched samples, owing to the superior surface uniformity of the former. However, the sputtered films show poorer corrosion resistance if sputtering conditions which give rise to columnar deposits are used (5). The fundamental electrochemical reactions occurring during corrosion of liquid- and vapor-quenched amorphous alloys of similar composition are apparently identical since the potentials at which corrosion reactions are initiated are the same. The important differences between vapor-quenched (sputtered) and liquid-quenched amorphous alloys are due largely to the higher quenching rate, $\sim 10^{11}$ K/s for sputtering vs. $\sim 10^6$ K/s for liquid quenching. The liquid quenched samples have a possibility of inhomogeneity due to a cooling rate profile within the sample (11). Some chemical segregation is possible, and microstructural order may vary in the sample. Differences in composition have been observed between the top and bottom of liquid-quenched ribbons (12). More rapid quenching rates eliminate these diffusion-related inhomogeneities. These results are in basic agreement with the results of Diegle and Merz, who indicated that the thermal properties at their sputtered films of amorphous iron-based metallic alloys were virtually identical to the properties of melt-spun alloys and that the triode-sputtered films exhibited somewhat higher corrosion rates, but with overall corrosion behavior similar to the melt-spun alloys (2). It is apparent that vapor deposition techniques can yield films with widely varying corrosion behavior, depending on the deposition parameters employed and resultant variations in bulk and surface properties, such as microstructure, adhesion to substrate, and internal stress.

Magnetron sputtering offers a unique opportunity for synthesis of amorphous alloys of very refractory compositions, based on early transition metals and metalloids. Deposition of these alloys in adherent form on a variety of substrates is possible. Also, since compositions are not limited to those near eutectic compositions and quenching rates are high, systematic exploration and exploitation of a complete range of alloy compositions is possible. However, microstructure, thermal properties, and interfacial stress between film and substrate are all dependent on the deposition process, and understanding

and control of these properties of the films requires more detailed studies of the deposition process.

ABSTRACT

The effect of fluid flow on transport of reaction products from dissolving cavities was investigated theoretically in order to establish regions of parameter space where the solution within the cavity may be above, or below, the saturation concentration. Situations where such phenomena are important include etching of masked devices and pitting corrosion. Steady laminar convective transport was analyzed in smooth-walled two-dimensional cavities (trenches) of several shapes. The fluid flow patterns within the cavities were obtained in the Stokes flow region. The convective diffusion problem was solved for values of the Peclet number between 1 and 500. Two types of boundary conditions were investigated: (i) uniform dissolution of the cavity surface, and (ii) uniform concentration along the cavity surface. Numerical calculations were carried out with a commercial, general-purpose finite element code. It was found that for $Pe \leq 1$, the entire cavity volume had a concentration in excess of 90% of the saturation value while for $Pe \geq 100$, the electrolyte within the cavity was substantially free of dissolution products.

Dissolution of small active sites on a surface exposed to flowing fluid will lead eventually to recession of the active surface below the surrounding plane, to formation of cavities occluded from the exterior flow region, and to secondary fluid flow patterns within the cavities. Situations where such phenomena are important include pitting corrosion, etching of masked device surfaces, electrochemical machining and electropolishing, and heat/mass transfer from rough surfaces. In general, the velocity of secondary fluid motion within cavities (*i. e.*, trapped eddies) will increase as the size of the cavity increases, that is, as dissolution proceeds. Therefore, in early stages of cavity formation, mass transport by diffusion may well control the rate of dissolution, but, as cavity size increases, transport by convection will increase and will eventually predominate over diffusion processes. Thus, the evolution of cavity shape is accompanied by a change in the controlling transport process. The purpose of this investigation was to study theoretically the effect of fluid flow on mass transfer within small cavities dissolving at such high rates that precipitation of dissolution products may occur.

While there are numerous applications of dissolution from small cavities, the present investigation evolved from a study of flow effects of pitting corrosion. General reviews of pitting are available (1-4) as are qualitative discussions of the effect of flow on corrosion (5-7). Efforts to model quantitatively the effect of fluid flow on corrosion have also recently been summarized (8).

Evidence that mass transport controls pitting corrosion of stainless steel (SS) has been reported by Isaacs (9) and by Rosenfeld *et al.* (10). Flow effects in pit-like geometries were studied by Beck (11) with the use of a flow channel, in one wall of which was an artificial cavity containing an electrode. It was found that fluid velocity influenced the dissolution rates of Al, Ti, and Fe electrodes. More recently, Beck and Chan (12) studied real pits on pure Fe and 304 SS in chloride solutions and found that there was a threshold velocity, above which fluid flow was important, and also a critical velocity, above which the current became limited by ohmic resistance rather than by convective transport. It was also found that stainless steel repassivated at flow rates above the (upper) critical velocity.

It has come to be generally recognized that the composition of solution within corrosion pits is substantially dif-

ferent from the exterior solution and, in particular, that salts of metal dissolution products may exceed saturation levels (13) and precipitate as metal salt films (10, 14-20). Based on transport equations, Beck and Alkire (21) predicted that the current density at small corrosion sites (10) could exceed 10^3 A/cm² and could therefore cause precipitation of salt films within 10^{-4} s following pit nucleation.

Weisbrod studied the repassivation of Fe, Co, and carbon steel in flowing sulfuric acid (22) and found that there was a critical velocity above which the specimens would not repassivate, a result which was opposite from that observed in chloride systems (12). It was found that the effect was due to rinsing off of precipitated sulfate salt films which formed on the surface during the repassivation sequence. Alkire and Cangelari (23) predicted theoretically the flow conditions under which such metal salt films would be rinsed away from a dissolving surface coplanar with the wall of a flow channel.

While a unified treatment of pitting corrosion has not yet emerged at the fundamental level, the foregoing discussion indicates that mass-transfer processes and precipitation of surface films are intimately coupled with the phenomenon. As a consequence, a general treatment of the effect of fluid flow past cavities within which salt films may precipitate would clearly be helpful.

The behavior of fluid flow (24-27) and of heat- and mass transfer (28-33) within cavities has been vigorously studied for a variety of geometries. In addition to pitting corrosion, there are many other processes where convective mass transfer from cavities controls the rate of dissolution (47), including electrochemical machining (34), chemical etching of masked device surfaces (35), heat- and mass transfer from rough surfaces (36), clot formation in flowing blood (37), and aerodynamic applications (38).

The goal of the present investigation was to develop an improved method of analysis which would be sufficiently robust that it could be expanded at a later time to include more factors than just mass transfer. The finite element method (FEM) was selected (39). The FEM has been applied to a small number of electrochemical applications to data (40-43), and has been found to be particularly effective for situations which involve curved boundaries and shape change.

Theoretical Information

The geometry of the systems studied in the present work are shown in Fig. 1. These geometries represent a range of shallow, cylindrical, and deep cavities. The uppermost diagram illustrates the general configuration un-

* Electrochemical Society Active Member.

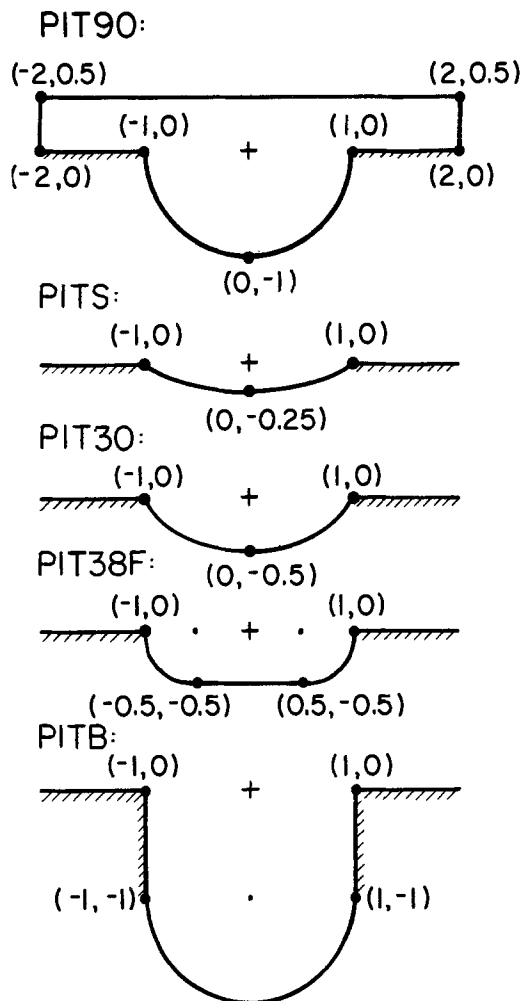

Fig. 1. Two-dimensional cavity geometries under study. The uppermost diagram illustrates the entire region over which solutions were obtained. The other diagrams depict the cavity shapes which were investigated, i.e., the lower surface of the region.

der study; a rectangular region in one wall of which is a two-dimensional semicircular cavity, or trench. Four other cavity configurations were also studied, as also shown in Fig. 1. Each cavity shape is specified by the coordinates with respect to the center cross given on the diagrams. While analysis of flow past an axisymmetric (hemispherical) cavity would be more representative of a real corrosion pit, the problem would then correspond to a three-dimensional situation which would increase computation cost and difficulty significantly. The present analysis of flow past a two-dimensional trench represents progress toward this goal.

Fluid enters the region through the left-hand boundary, flows past the cavity opening, and leaves through the right-hand boundary. The upper boundary of the region was set far enough away, for the region of interest in this study, that the fluid flow was a constant along its surface. The use of dimensionless equations and variables in this study enables the results to be applied to any system for which the configuration and assumptions are valid.

Dissolution occurs along the curved interior surface of the cavity. In Fig. 1, the hatched areas represent unreactive regions of the solid surface. The particular application to which this study was originally directed corresponded to dissolution of a small cavity on an otherwise passive metal immersed in flowing corrosive solution. For this reason, simplifying assumptions will be introduced in order to confine the scope of the assumptions to mass-transfer variables. The finite element method used in this study, however, is flexible and robust and could therefore be expanded in the future to include additional features.

Assumptions.—The cavity was assumed to have a smooth wall. Because interest was directed toward small cavities, the fluid flow in the immediate vicinity of the cavity wall was assumed to be laminar, although the possibility of turbulent flow at a distance was not precluded by the method of analysis. Further, constant property Stokes' flow was assumed ($Re < 0.1$). Since the Schmidt number for aqueous electrodes is approximately 2000, the range of Peclet numbers ($Pe = ReSc$) for which calculations are strictly valid is $Pe < 200$. In the results presented below, the interesting behavior was found to occur over the range $1 < Pe < 100$.

When a system is under mass-transfer control, other possible limitations are less important; therefore charge-transfer and ohmic resistance effects were neglected in this analysis, as was hydrolysis of solvated metal cations. It was assumed that the current efficiency for metal dissolution was 100% so that the local dissolution rate along the surface was proportional to the concentration gradient normal to the surface.

While dissolution causes gradual increase in cavity size, it was assumed that this process is slow enough that a pseudo-steady-state analysis of invariant cavity shapes would be useful. Indeed, it may be shown that the time constant for shape change is significantly longer than the time constant for fluid recirculation within the cavity.

Migration of dissolved metal species was assumed to be negligible owing to the presence of supporting electrolyte, and the physical properties of the system were assumed to be constant. These two assumptions may be questionable if the metal salt has a high solubility, since large metal ion concentrations can then arise within the diffusion region. The effect of migration of, say, divalent metal ions and divalent anions serves to increase the mass flux by a factor of up to two, depending upon the ratio of supporting cations to total anion concentration (44). However, an increase in concentration also serves to decrease the diffusion coefficient. Thus the two questionable assumptions tend fortuitously to offset each other (22).

Two mass-transfer situations were investigated. In the first, it was assumed that the surface was coated with a metal salt film so that the metal ion concentration immediately adjacent to the dissolving surface was assumed to be a constant, equal to the saturation concentration. In the second, the cavity was assumed to maintain a self-similar, semicircular shape during dissolution, according to which the dissolution rate was assumed to have the same value everywhere along the cavity surface.

Equations.—The dimensionless equation for Stokes' flow of a Newtonian fluid is

$$\nabla^2 U (=) Re \nabla P$$

where Re is the Reynolds number. With respect to Fig. 1, the following boundary conditions were used

$$\begin{aligned} U_y &= 0 \text{ on all boundaries} \\ U_x &= 0 \text{ on lower boundary} \\ U_x &= A \text{ on upper boundary} \end{aligned}$$

$$\frac{\partial U_x}{\partial x} = 0 \text{ on left- and right-hand boundaries} \quad [2]$$

These equations are independent of the concentration field and therefore may be solved to obtain the hydrodynamic flow and pressure field. Because the equations are linear in velocity, the results may be scaled to any value of Re for which the Stokes' approximation is valid.

The dimensionless equation of convective mass transfer is

$$UVC = \frac{1}{Pe} \nabla^2 C \quad [3]$$

where Pe is the Peclet number. Two cases of boundary conditions were investigated. In the first case, the surface was assumed to be covered with a metal salt, and the incoming fluid was assumed to contain no dissolved

metal salt

$$C = 1 \text{ on cavity surface}$$

$$C = 0 \text{ at } X = -2, \text{ where fluid enters} \quad [4]$$

$$\frac{\partial C}{\partial n} = 0 \text{ on other boundaries}$$

In the second case, the surface was assumed to dissolve at the same rate everywhere into a fluid which contained no dissolved metal salt.

$$\frac{\partial C}{\partial n} = -Sh \text{ on cavity surface}$$

$$C = 0 \text{ at } X = -2, \text{ where fluid enters} \quad [5]$$

$$\frac{\partial C}{\partial n} = 0 \text{ on other boundaries}$$

where Sh is the Sherwood number.

Method of solution.—The computer code used for calculations in this study was FIDAP, a versatile finite element code for solving fluid dynamics problems including convective heat-transfer applications. FIDAP solves transient or steady-state forms of the momentum and thermal energy equations in two- or three-dimensional finite element domains. The elements may be linear or quadratic elements of isoparametric form. The physical properties of the fluid may depend on time and fluid temperature, or may be constant. By using standard heat- and mass-transfer analogies, the program is also capable of solving problems of convective mass transfer. Boundary conditions can take on a variety of forms. Details of use of the program may be found in Ref. (45), as well as the appendixes of Ref. (46).

Referring to Fig. 1, configurations (a) and (b) were meshed with nine-noded quadratic elements, while the other configurations were meshed with eight-noded quadratic elements produced by the mesh generation package FIMESH (45). Table I gives mesh statistics and representative run times for solving the equations on a Cyber 175 computer. Since an out-of-core solver was used in the program, the central memory used by the program could be controlled by the user. In this study, 143,000 octal words of central memory were used for execution. It was found that computation costs were typically \$0.60/CPU second.

Results and Discussion

Hydrodynamic flow field.—The flow pattern in a cavity of given geometry needs to be determined only once for all Reynolds numbers in the Stokes regime. By substituting the Stokes solutions into the constant-property Navier-Stokes equations via the FIDAP algorithm, it was found that the norm of the error vector divided by the norm of the Stokes' solution vector was less than 0.2%. That is, inertial effects are negligible and the computed results are accurate. Table II provides input velocities (constant A in Eq. [2]), and the velocities at the center of the cavity mouth (u_0) which were used in normalizing the flow fields.

Figure 2 illustrates the velocity vectors for the flow field in each of the cavity configurations under study. It was found that a single recirculating flow eddy existed in all but the shallowest cavity configuration. No secondary eddies were observed.

Concentration fields, constant concentration at cavity wall.—The solution of the convective diffusion equation for various values of Pe is shown in Fig. 3 in the form of metal ion concentration contour plots. The lettered contours correspond to lines of constant metal ion concentration, expressed in fractions of the saturation concentration, as given in the figure caption. Since the Peclet number contains both velocity and cavity size, the progression from Fig. 3(a) to Fig. 3(e) corresponds either to a sequence of increasing fluid flow, or to a sequence of increasing cavity sizes.

For $Pe = 1$ [Fig. 3(a)], the concentration contours near the top of the region are not realistic because the boundary condition on that surface forces the concentration gradients to the value of zero. However, modification in the

Fig. 3. Effect of Peclet number on metal ion concentration for PIT90 configuration when the concentration at the cavity wall is equal to the saturation value everywhere ($C = 1$). Equiconcentration contours are shown for various fractions of the saturation value as given in the accompanying key.

boundary condition on the upper surface would not be expected to change the observation that, for $Pe = 1$, the solution within the cavity is within 90% of the saturation concentration throughout. That is, the fluid flow external to the pit does not substantially influence the transport of dissolution products within the pit. Indeed, the contours A and B indicate clearly that there is substantial diffusion in the upstream direction, against the direction of fluid flow. Because the concentration field inside such pits is disrupted to only a minor extent by the action of fluid flow, it is concluded that very small pits are insensitive to external flow conditions even when there may be substantial superficial flow velocities outside the pit.

For $Pe > 1$, the metal ions were swept out the right-hand side of the region, and the anomalous behavior at the upper surface was not significant. For $Pe = 100$, Fig. 3(c), it may be seen that the electrolyte just outside the cavity mouth is essentially free of metal ions. That is, the effect of fluid flow has increased to substantial proportions. In addition, the effect of the recirculating flow pattern within the cavity can clearly be seen to influence the mass-transfer process.

For $Pe = 500$, the mesh size is too large for generation of smooth contours in the center of the cavity, a problem which could be eliminated by remeshing. The numerical jitter does not influence the observation that the concentration variation becomes confined to a thin region adjacent to the cavity surface.

Reference (46) contains additional results for other cavity configurations. These results indicate that the effect of recirculating flow becomes more pronounced as the pit becomes deeper, and that the influence of external flow on the ion concentration profile near the bottom of the pit decreases as the pit shape becomes deeper.

In all cases where there is a recirculating flow, the consequence is to cause the dissolution rate to have the greatest value along the downstream surface of the cavity. Such results are consistent, for example, with the experimental observation of "flow tails" in nickel pitting at high current densities under high electrolyte flow as seen in Fig. 5 of Ref. (34b) and Fig. 6 of Ref. (34c). In the shallowest cavity studied, there was no recirculation pattern, and the dissolution rate was highest at the upstream edge of the cavity.

Concentration profiles, constant flux at the cavity wall.—Under certain conditions, corrosion pits are known to exhibit hemispherical shapes, which implies that the dissolution rate is constant along the interior dissolving surface, a condition which may be simulated mathematically by the boundary conditions expressed in Eq. [5] above.

Figure 4 illustrates results for the semicircular cavity configuration for five values of Pe over the range 1-500 while holding Sh constant at 1.31. This sequence therefore corresponds to a variation of velocity while holding the average dissolution rate constant. The lettered contour lines indicate surfaces of constant concentration, expressed as fractions of the saturation concentration as given in the key associated with each figure. Since there is no physical limitation in the model on the value of the concentration, it is possible for the concentration to rise above the saturation value (1.0). For the conditions shown in Fig. 4, it may be seen that the entire cavity region contains supersaturated solution at $Pe = 1$, while for $Pe = 100$ the cavity region is everywhere below the saturation concentration. In addition, it may be seen that the region where the concentration is highest shifts from the downstream portions of the cavity surface (for small Pe) to the upstream region (for large Pe). In the shallowest cavity, where no recirculation eddy was present, the maximum concentration was always on the downstream portion of the cavity surface.

Similar concentration field plots are available for other cavity configurations in Ref. (46).

Critical flow conditions for salt film precipitation.—Based on the foregoing calculations, it is possible to map out generalized conditions under which saturation concentration will be found in cavities exposed to flowing fluid. For a cavity of certain shape experiencing electrolyte flow of a given velocity, there is a value of current density which must exist in order to sustain a saturated solution along the cavity surface. That is, for a given Pe , there exists some value of Sh which will result in $C_{max} = 1.0$ somewhere along the surface. In addition, there exists another value of Sh which will result in a $C_{max} \geq 1.0$ everywhere along the surface.

Figure 5 illustrates critical flow conditions for all of the cavity configurations investigated (46). For each configuration, two lines are indicated in the graph; the symbols in Fig. 5 represent values for which computations were carried out with use of Eq. [5]. The left-hand group of lines gives, for each of the five configurations, the critical conditions where the entire surface is below the saturation level everywhere along the cavity surface. Above and to the left of the line corresponds to flow conditions and dissolution rates where the solution at the cavity surface cannot exceed saturation. The right-hand group of lines gives, for the five configurations, the critical condi-

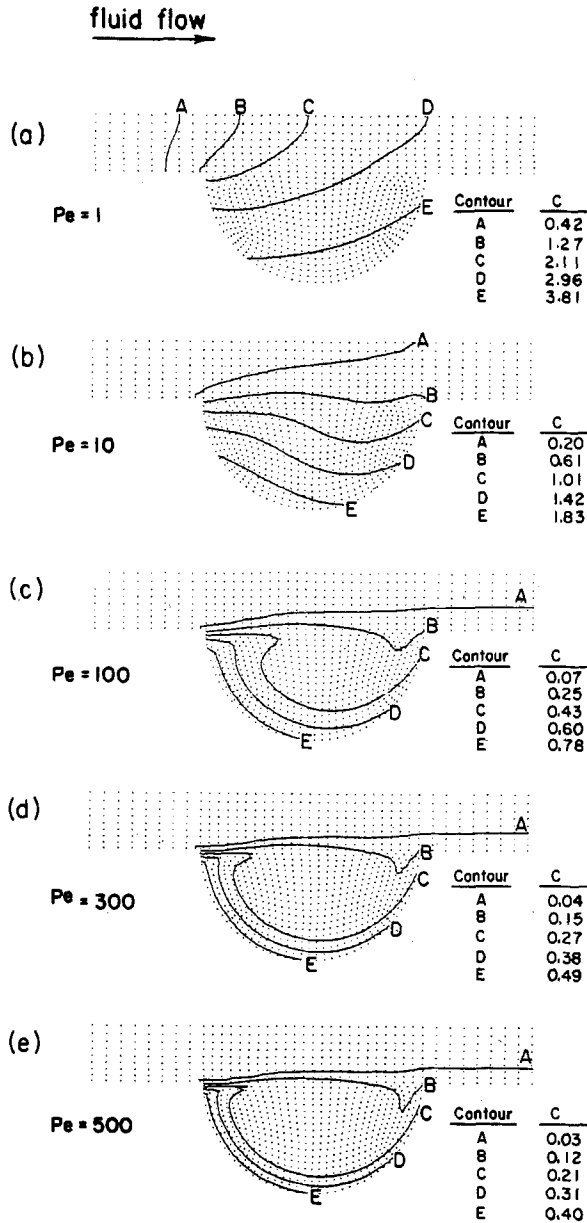

Fig. 4. Effect of Peclet number of metal ion concentration for PIT90 shape when the dissolution rate is constant over the cavity surface ($Sh = 1.31$). Equiconcentration contours are shown for various fractions of the saturation value as given in the keys associated with each figure.

Fig. 5. Critical convective transport conditions for removal of dissolution products from cavities of various shapes. Δ : PIT38F. \square : PIT30. \circ : PIT90. \bullet : PITB.

tions where the entire surface is above the saturation level. Below and to the right of these lines corresponds to the region of parameter space where precipitation of dissolution products would be expected to occur.

In Fig. 5, the region between the two lines corresponds, for each configuration, to the region where some portion of the solution within the cavity would be at or above saturation (deep within the cavity interior), while other portions would be at or below saturation (nearer the cavity entrance).

Figure 5 illustrates that if a cavity is dissolving at a higher rate, it takes a higher flow rate to wash it out. Also, as a cavity becomes deeper, it becomes more difficult to rinse it out. For the configurations investigated, Fig. 5 indicates that an eightfold increase in depth to diameter (PITS vs. PITB) requires a fiftyfold increase in Pe to accomplish complete rinsing of the cavity. In addition, the geometry of the cavity entrance region influences the ease of rinsing: PIT30 and PIT38F are the same depth, but it takes a higher flow rate to rinse out PIT38F than PIT30.

Conclusions

A flexible, robust, commercially available finite element code has been used to predict mass-transfer behavior within cavities during dissolution in the presence of fluid flow. Analysis of the concentration distribution within small cavities has led to a general criterion for predicting conditions under which precipitation of sparingly soluble dissolution products may be expected to occur on the dissolving surface. Early stages of cavity growth were found not to be influenced by external flow owing to the small size of the cavity which impedes fluid circulation. As dissolution continues, however, fluid flow effects become increasingly significant and could eventually rinse out the cavity.

Situations where such phenomena are important include etching of masked surfaces and also pitting corrosion. Disruption of electrolyte in the interior of corrosion pits has been linked by other investigators to the repassivation of active pits, particularly in chloride solutions. It may thus be anticipated that a young corrosion pit would grow to a certain size, at which it would become susceptible to being washed out and thus repassivated. If such a pit were not completely rinsed out while relatively shallow, then it may partially passivate, in the entrance region, but remain active in the more remote regions. Such events could thus lead to evolution of steadily deeper and thus more shielded configurations, which would be increasingly more difficult to repassivate by rinsing. The analysis presented here gives a limiting case of performance against which the behavior of real systems may be compared.

Hydrodynamic strategies for corrosion prevention have not been fully explored to date. The damage of materials by corrosion in the presence of impingement, erosion, wear, cavitation, and other flow-related phenomena represents a research field of vital importance. Of special value would be improved understanding of flow conditions under which inexpensive materials of construction could be used with confidence in corrosive environments.

Structural Studies of Electroless Thin Co-P Films¹

R. O. Cortijo and M. Schlesinger

Department of Physics, University of Windsor, Windsor, Ontario, Canada N9B 3P4

ABSTRACT

The microstructure of thin electroless Co-P films is studied using electron microscopy with radial distribution function (RDF) analysis of electron diffraction patterns. It is concluded that, depending on metalizing bath chemistry, films may grow with their component crystallites, having their c-axis prefer to be perpendicular to the plane of the film. No evidence of an fcc phase is found in these films.

Chemically (electroless) deposited thin cobalt film (Co-P) can be considered as a binary system of cobalt and phosphorus. They have been regarded as a potential digital recording medium ever since their discovery by Brenner and Riddell (1). For recording applications, one seeks a thin layer ($\sim 500\text{\AA}$) with appropriate magnetic properties. In Co-P, the magnetic properties are strongly dependent

¹ Work supported by the Natural Sciences and Engineering Research Council of Canada.

upon the microstructure, and the microstructure, in turn, is markedly influenced by the plating conditions and the substrate.

In the past (2), the nucleation and growth of Co-Ni-P and Co-P films have been studied. It has been found that mixed cobalt-nickel films form an fcc structure like nickel. This is not surprising, as it is known to be one of the simplest systems formed by cobalt, and nickel can form a complete series of solid solutions with fcc cobalt.

Of more complexity are the results pertaining to Co-P. It has been conjectured that the films constitute a mixture of fcc and hcp phases and that increasing the phosphorus content tips the balance toward the hcp phase.

The aim of the present work is to elucidate the nature of the microstructure of thin Co-P. Here, transmission electron microscopy, electron diffraction, and reduced radial distribution curves are employed. It is concluded that thin Co-P deposits on Formvar form microcrystals possessing an hcp structure which has a degree of preferred orientation dependent on the phosphorus content. No evidence for the presence of an fcc phase, as stated previously, has been found.

Experimental

Films in this investigation were grown on microscope slide glasses coated with Formvar (4g polyvinylformal in one liter of ethylene dichloride). Standard sensitizing (Sn II), activating (Pd II), and metalizing (as in Ref. 2) procedures were followed in their preparation. The films were floated off the glass substrate in distilled water. They were subsequently placed in the sample holder of a JEOL Model JEM-100CX electron microscope. The electron microscope was operated at 100 kV, and electronmicrographs and selected area diffraction patterns (camera length of 236 mm) were recorded photographically.

The diffraction patterns were scanned by a microdensitometer whose output was fed into an ADC of a PDP 11/03 minicomputer. The reduced radial distribution functions (RDF) were obtained as described recently (3, 4). A combined smoothing and averaging technique was used to reduce random noise errors. A number of procedures were adopted to eliminate the effects of systematic errors. We will present reduced RDF curves given by

$$G(r) = 8\pi \int_0^{\infty} i(s) \sin(2\pi sr) ds$$

with

Fig. 1. Electron micrographs of two Co-P films: (bottom) sample grown with 10 g/l hypophosphate; (top) sample grown with 5 g/l hypophosphate (magnification = $\times 14,000$).

$$s = \frac{2 \sin \theta}{\lambda}$$

where $i(s)$ is the reduced interference function.

Results and Discussion

In Fig. 1, we present electron micrographs corresponding to two (out of a dozen or so on which measurements were carried out) typical samples. One has grown in a metalizing bath with a sodium hypophosphite ($\text{NaH}_2\text{PO}_2 \cdot \text{H}_2\text{O}$) content of 10 g/l and the other has grown in a bath containing 5 g/l sodium hypophosphite. In Fig. 2 we present their respective selected area diffraction (SAD) curves after subtracting the background in the SAD patterns. This background is due to nonelastic collisions and, as it has the form of a slowly varying function, the procedure for its elimination is rather simple. We have indicated the Miller (hkl) indexes on the different peaks (rings).

In Table I we summarize the hkl and corresponding $d(\text{\AA})$ values of the curves in Fig. 2, along with the corresponding bulk cobalt values. These values are determined directly from the photographic plates, using a traveling microscope, and the curves in Fig. 2 represent the densitometer's output. The former is a somewhat more sensitive method; it yields, for instance, a value for a (002) ring, while no such peak is identifiable on the corresponding SAD curve (Fig. 2a). A close comparison of Fig. 2a and 2b shows differences in the relative intensities of some peaks. One such difference is between the (101) peak and stronger (100) peak in 2a and the (100) peak and stronger (101) peak in 2b. Another difference is between

Fig. 2. Diffraction patterns corresponding to the films shown in Fig. 1: (a) phosphorus rich sample; (b) phosphorus poor sample.

Table I. Spacing [$d(\text{\AA})$] values corresponding^a to SAD curves in Fig. 2

hkl	$d(\text{\AA})$ High P	$d(\text{\AA})$ Low P	$d(\text{\AA})$ Bulk Co
100	2.162	2.127	2.165
002	2.038		
101	1.913	1.883	1.910
102	1.478	1.482	1.480
110	1.249	1.234	1.252
103	1.148	1.135	1.149
112	1.068	1.048	1.066
201	1.045		1.047

^a Values in table were determined directly from photographic plates.

the relative intensities of the (110) and, say, the (112) peaks.

It is proposed that curve 2a is an hcp structure with random crystallite orientation. It is further proposed that 2b is an hcp structure with crystallites, where the c -axis prefers to be (but is not exclusively) perpendicular to the plane of the films. These proposals are based on a number of considerations. In Fig. 2b, it is the peaks with index $l = 0$ that are observed to be enhanced. These are the reflections from planes having no intercept (*i.e.*, parallel) with the c -axis. These planes are expected to be in "grazing angle" position relative to the electron beam, being more likely to fulfill the Bragg condition if our proposal is valid. It is the same consideration which should explain the complete absence of the (002) reflection (see Table I) from the low P content film, because it represents a plane perpendicular to the c -axis.

In order to lend further support to our proposal and rule out the possibility that Fig. 2b represents the existence of an fcc phase, we have carried out a series of experiments in the electron microscope. The film corresponding to Fig. 2b was tilted by 45° in the sample holder, and its SAD was recorded. Next, it was rotated and tilted about the z and y axes, respectively, by 45° , and its SAD was recorded again; the process continued as such. Eight pictures were taken making sure that the SAD was taken each time exactly from the same film area. Figure 3 is the average (background subtracted) of these eight SAD patterns. Note that, now, the relative intensities more closely resemble those of Fig. 2a, *i.e.*, the proposed case of a random orientation of crystallites. The reduced RDF from the curves of Fig. 2a and Fig. 3 have been calculated and found to be very similar, as shown in Fig. 4a and 4b, respectively. Specifically, both indicate a nearest neighbor distance of 2.5\AA and a second nearest neighbor distance of 4.0\AA . These values agree well with the cobalt bulk values of $a = 2.507\text{\AA}$ and $c = 4.070\text{\AA}$. From Table I, one can also

Fig. 3. Diffraction pattern of the phosphorus poor sample, taken as an average of eight different film orientations.

Fig. 4. Reduced radial distribution curves: (a) calculated from Fig. 2(a); (b) calculated from Fig. 3.

Fig. 5. Electron micrographs of a phosphorus poor Co-P film: (bottom) bright field; (top) dark field (magnification = $\times 20,000$).

infer a set of values as follows. For the P-rich sample, $a = 2.497\text{\AA}$ and $c = 4.081\text{\AA}$; for the P-poor film, $a = 2.482\text{\AA}$ and $c = 3.980\text{\AA}$.

Finally, a crystallite size range can also be inferred from either the RDF or the diffraction patterns. Figure 4a would seem to correspond to a "long" range order of about 15\AA . The further peaks tend to smear out, indicating a lack of longer range order or that any further points are usually beyond a given crystallite. Figure 4b corresponds to a range of order of about 20\AA . It is perhaps not surprising that the sample richer in phosphorus possesses a slightly shorter order range (3) (smaller crystallites). The diffraction patterns yield a very nearly identical crystallite size value of about 18\AA for both samples. This is inferred from the width of the Bragg diffraction peak Δs and its relation to the crystallite size (3, 4). The nearly equal crystallite sizes of phosphorus rich and phosphorus poor samples should be contrasted with their markedly different metal island sizes, as seen in Fig. 1a and 1b. The difference between metal island and crystallite size is best illustrated by a dark field electron micrograph. Figure 5a is the bright field and 5b the dark field electron micrograph of a phosphorus poor Co-P film. The dark field is due to the (110) reflection, and it clearly shows the sizes of component crystallites to be much less than the sizes of metal islands.

Conclusion

Electroless-plated cobalt films should be considered α -cobalt with a hexagonal lattice composed of crystallites about 20\AA in size. These create groups forming metal islands. Depending on phosphorus content, films may

grow with their component crystallites, having their c-axis prefer to be perpendicular to the plane of the film. It is noteworthy that in the low-phosphorus deposit, the $\langle 0001 \rangle$ direction is already preferentially perpendicular to the surface in the very early stages of deposition. Frieze *et al.* (5) have performed experiments similar to the present ones, but they have not analyzed the electron diffraction patterns in the way this work does or found that thicker deposits produced in an electrolyte with the same hypophosphite concentration also have a $\langle 0001 \rangle$ texture. Co-P deposits produced in solutions with higher hypophosphite concentration have a $\langle 1010 \rangle$ texture. Finally, no evidence is found for the presence of β -cobalt with fcc lattice. Nor do the films exhibit the presence of cobalt phosphide phases such as Co_2P with orthorhombic lattice. Electrodeposited films do show (6) its presence after heat treatment.

Electrochemical Etching of the Semiconductor Lead Tin Telluride

Patrick G. Barber*

Longwood College, Farmville, Virginia 23901

Roger K. Crouch*

NASA-Langley Research Center, Hampton, Virginia 23665

ABSTRACT

Convective currents during the Bridgman growth of a compound semiconductor lead to temperature fluctuations at the solid-liquid interface. These temperature fluctuations in turn lead to microscopic compositional variations in the solid. Electrochemical principles have been applied to develop three etches which delineate the variations in the compound semiconductor, lead tin telluride, and allow optical studies of the growth kinetics of this material. Use of these etches has shown periodic lines during the initial growth, with indications of oscillatory instabilities developing in later stages of growth, and, finally, complete breakdown of the interface.

With the increased use of remote sensing systems utilizing infrared detectors, there is a need for materials suitable for large area arrays. One material that possesses properties suitable for such detectors is the narrow bandgap semiconductor, lead tin telluride ($\text{Pb}_{1-x}\text{Sn}_x\text{Te}$), which can be prepared as an infrared detector in which the peak detectivity can be chosen to be any wavelength from 5 to $17\ \mu\text{m}$ by changing the ratio of the lead to the tin (1). As part of NASA's Microgravity Science Program at Langley Research Center, studies are being carried out on the effects of convection on microscopic inhomogeneities in the compound semiconductor lead tin telluride (LTT). Crystals have been grown in quartz ampuls using the Bridgman technique (2). Natural convection during the growth of this material results in temperature fluctuations at the solid-liquid interface, which consequently results in microscopic variations in the composition of the solid as the growth progresses. Since these fluctuations are small, accurate quantitative analysis of the resulting crystals is difficult. The development of

etching techniques which delineate these variations making optical studies possible are very desirable.

The literature provides several chemical etches for materials like LTT. These chemical etches are typically solutions of strong, corrosive chemicals, such as concentrated nitric acid, hydrofluoric acid, liquid bromine, hydrobromic acid, or concentrated potassium hydroxide (3-8). Such corrosive etches do attack the LTT, but they do not do so selectively, so that the fine interface demarcations are not made visible reproducibly and reliably. This report describes the development of a mild etching procedure for LTT by applying electrochemical principles. Three different solutions were successfully used for this particular application, but the procedure may have more general applicability in the semiconductor industry and in materials research. Etches do not have to be corrosive reagents to be effective.

Experimental

A review of the thermodynamics quickly reveals why strong, corrosive reagents could not be used for LTT.

*Electrochemical Society Active Member.

Chemical reagents that solubilize the component ions of LTT create a thermodynamic dilemma, for once the metallic cations and telluride anions are in solution, they should react with each other to form the respective metals. The standard electrode potentials, shown in Tables I and II, indicate that these reactions should go to completion, since the equilibrium constants are very large. Consequently, as fast as strong corrosive etchants dissolve the semiconductor surface, the component ions react in solution to form a precipitate that plasters over the surface to be viewed in the optical microscope. The fact that the surface features are sometimes more visible after a light polishing than immediately after etching tends to support this hypothesis. Such a polishing procedure, using strong, corrosive reagents, is not reproducible or reliable.

Electrochemical procedures were applied to selectively dissolve the lead and tin tellurides and, at the same time, quickly sweep away the resulting ions before the subsequent chemical reactions forming the obscuring deposits can occur. Electrochemical cells were set up as shown in Fig. 1, and mild chemical etching solutions were used. The particular geometry of the cell did not appear to be crucial, for reproducible results were obtained on samples regardless of whether the platinum cathode was vertical or horizontal, whether it was near or far from the surface of the sample, or whether the sample itself was vertical or horizontal. The usual configuration of having the sample horizontal and the cathode vertical was selected for ease of assembly. The position of the platinum contact on the sample was not critical. Contacts were made at different sites on the LTT surface and at the edge of the sample. Reproducible patterns occurred in all cases. To enhance the removal of the solvated ions from the surface of the semiconductor and to retard their subsequent self-oxidation and reduction, the ionic strength of the solution was increased, thus reducing the thickness of the electrical double layer. Chelating agents were also added to the solution to tie up the liberated ions. This did prevent further chemical reactions and reduced the deposit formed back over the semiconductor surface.

Three mild electrochemical etching solutions were developed for lead tin telluride. The compositions of these solutions are given in Table III. The colloidal sulfur, mild Norr (composition 1 in Table III), and ethylenediamine tetraacetic acid (EDTA) solutions gave the most informative and reproducible results on the samples of LTT. The mild Norr was developed by reducing the concentration

Fig. 1. Electrochemical cell for etching lead tin telluride

of the corrosive reagents in that etch described in the literature. The other two solutions were developed by considering the inorganic and electrochemical factors described in the previous paragraph. Sulfur will react quickly with both lead and tin to form precipitates; and the rationale was that if these elements formed precipitates with sulfur, they would not be available to form the obscuring plaster on the surface of the semiconductor. The EDTA solution was developed using the ability of this chelating reagent to complex with lead and tin ions in solution. If the ions were locked in an inorganic complex, they would not be as readily available to react with the telluride ions and to form the plaster. All three of these rationales lead to successful solutions.

The procedure followed in all cases was the same even though the sample orientations and etching solutions were changed. The LTT single crystals were in the form of cylindrical boules when they were removed from the Bridgman furnace. These were cut into slices along their long axis, and they were mounted and carefully polished using a series of decreasing grit sizes from 600 grit to 0.05 μm as the final mechanical polish. The sample was then polished on a soft cloth using an alkaline, silica solution. These samples were placed one at a time in an electrochemical cell, shown in Fig. 1, and arranged in such a way that the sample was the anode and the ribbon of platinum was the cathode. A magnetic stirring bar assured rapid mixing in the solution, which covered the sample. A small voltage was applied, on the order of 1-3V, and the current was monitored. Currents were normally kept at values less than 50 mA. Within these current and voltage limits, the exact current density did not appear to be critical in developing the etch patterns, since these patterns seemed to be independent of sample size and voltage. Etch rates and current densities were not measured. Samples were etched for approximately 1 min. Then the power supply was turned off, at which time, due to the decay characteristics of the power supply, a reversed current flow of about 5 mA was observed for approximately 2-4s. The current would again rise to about 15 mA for 1-2s before decaying back to zero in about ten more seconds. However, if the voltage applied to the sample initially was too large, the solution itself would begin to electrolyze, and the desired surface features would be obscured by

the plaster coat. These steps were repeated until the desired degree of etching was achieved. A successful etching could easily be monitored visually while regulating the applied voltage.

Results

Use of these electrochemical etching procedures have revealed microscopic inhomogeneities in samples grown in a thermally unstable Bridgman configuration. Examples of the etch patterns are shown in Fig. 2 and 3. These patterns were reproducible in the sense that an etched sample could be polished and etched again and the same patterns would appear. The patterns seem to indicate that an oscillatory growth occurs in the sample and that the solid-liquid interface is concave into the solid. As the growth progresses, oscillatory perturbations begin to occur along the interface, and eventually the interface appears to break down completely. A more complete description and analysis of the crystal growth and morphology will be published later.

Concluding Remarks

Electrochemical principles have been combined with thermodynamics and inorganic chemistry to develop a new etching procedure for the compound semiconductor lead tin telluride. These etches have been shown reproducibly to enhance microscopic inhomogeneities in LTT and to offer the potential of studying interface

Fig. 3. Etched sample showing apparent breakdown of interface

growth kinetics. It is believed that the same principles used in the development of these etches can also be used in the development of etches for other semiconductor materials.

Photoelectrochemical Study of SnS₂ in Aqueous Solution

A. Katty, B. Fotouhi, and O. Gorochov

Laboratoire de Physique des Solides, CNRS, 92195 Meudon, France

ABSTRACT

n-Type SnS₂ with a layered structure has been grown by chemical vapor transport using phosphorus as doping agent. It has a resistivity of 1 Ω cm and an energy gap of 2.2 eV. It is characterized by very low dark current under anodic polarization. The material is not stable under prolonged illumination in aqueous acidic and basic solutions. However, the stability can be improved considerably in acidic solutions containing potassium iodide. The voltammograms under illumination indicate that the photocurrent onset potential, particularly in alkaline solutions, depends on redox reagents used. Photopotentials do not vary as expected with different redox couples.

Metal dichalcogenides have been the subject of intensive work during the past six years (1-14). Among these materials, WSe₂ and MoSe₂ have received most attention. Characterization of new materials continues; some of them might be durable and efficient materials. Among metal dichalcogenides, tin sulfide has not yet received attention in photoelectrochemistry, but has been characterized by reflection data. The energy gap is given as 2.21 eV for the first indirect transition (15-16). At higher energies (ca. 2.88 eV) a direct transition is reported.

SnS₂ has a CdI₂-type C₆ structure (D_{3d}³ - P3̄m1) composed of planes of hexagonal close packed S atoms interleaved with planes of Sn atoms to give the stacking sequence S—Sn—S S—Sn—S in c direction of the unit cell. This C₆ structure is characterized by adjoining planes of weakly bound S atoms allowing a cleavage in [001] direction. Sn has in this structure a characteristic sixfold octahedral coordination (17).

The semiconducting nature of SnS₂ has been predicted assuming that Sn forms a resonating sp^{3d} bonds. Calculated electronic band models have shown a good agreement with optical reflectivity spectra and confirm the existence of an indirect gap around 2.2 eV (15-16). The conduction band as well as the valence band should exhibit essentially s-p like character.

Experimental

SnS₂ single crystals doped with phosphorus were grown by chemical vapor transport method in a closed silica tube. The transporting agents were bromine and iodine. The temperature of the transport and growth zones were, respectively, 600° and 530°C. Yellow reddish crystals (~3 × 3 × 0.1 mm) were obtained both with bromine and iodine within a week.

The tube initially contained stoichiometric amounts of tin and sulfur plus 5 atomic percent (a/o) of phosphorus. Microprobe analysis, however, indicate that the amount of phosphorus incorporated in the crystal bulk was less than 0.5%. The excess phosphorus stayed either unreacted in the tube or distributed in some crystals as a black localized phase (dark points).

Typical transport properties (from resistivity and Hall voltage) at room temperature were a resistivity of ~ 1 Ω cm and a carrier density of 5 × 10¹⁷ cm⁻³.

Electrochemical measurements were performed using standard potentiostatic system and a classical three-electrode cell. A 75W tungsten halogen lamp was used as light source. Samples were illuminated by monochromatic light (λ = 480 nm) using a Jobin-Yvon H20 monochromator. The lock-in amplifier method was used to perform capacitance measurements between 200 and 1500 Hz. Analytical-grade chemicals and deionized water were used for the preparation of the solutions.

Contacts were achieved by using Ga/In eutectic and Johnson Matthey silver paste. Samples were mounted on a copper plate and then insulated by Dow Corning glue.

All potentials are referred to the saturated calomel electrode.

Electrochemical Results

Figure 1 demonstrates the behavior of an n-type SnS₂ single crystal in the dark and under illumination in solutions of three different pH values. The electrode shows nearly perfect blocking characteristics over all pH values in the dark, the dark current being equal to 10⁻⁷ A cm⁻² over a wide range of potentials. Under illumination, the photocurrent onset depends on the pH of the solution. It shifts to more negative potentials as the pH of the solution increases. The photocurrent onset potential in solutions of sulfuric acid pH = 0, KCl pH = 5.5, KOH pH = 14 are, respectively, + 0.2V, 0V, and -0.35V.

Capacitance measurements also indicate that the flat-band potential shifts to more negative values with increasing pH of the solution. Mott-Schottky plots are linear and are extrapolated to the same potential independent of frequency (between 200 and 1500 Hz). Figure 2 shows the Mott-Schottky plots in acidic and basic media. The corresponding slope gives a carrier number of 3.7 × 10¹⁷ cm⁻³ (assuming ε = 10), which is in agreement with Hall measurements.

When redox couples such as Fe(CN)₆^{4-/3-} and I⁻/I₂ are added to the alkaline solution, a shift in photocurrent onset potential is observed. For instance, in alkaline solutions, the addition of Fe(CH₃)₆^{4-/3-} and I⁻/I₂ shifts the photocurrent onset to a more positive value, whereas the addition of S²⁻/S₂⁼ produces a negative shift. The photocurrent onset in solutions containing I⁻/I₂ and Fe(CN)₆^{4-/3-} is at -250 mV; for the one containing S²⁻/S₂⁼ it is at -450 mV (Fig. 3).

In acidic solutions, the addition of I⁻/I₂ produces a negative shift of the photocurrent onset potential (Fig. 4), whereas other couples, such as Fe(CN)₆^{4-/3-}, Fe^{2+/3+}, do not have any effects.

Capacitance measurements (18) also indicate a shift in flatband positions (a positive shift in alkaline solutions containing I⁻/I₂ and Fe(CN)₆^{4-/3-} and a negative shift in acidic solution containing I⁻/I₂). Table I shows the photopotential values obtained in a molar solution of sulfuric acid in the presence of different redox reagents. These values remained almost unchanged in different redox media.

SnS₂ is not stable in aqueous acidic and basic solutions and decomposes gradually under prolonged anodic polarization (4h at +1V) and white light illumination (≈ 200 mW cm⁻²). Decomposition products were a yellow layer, which covered the electrode surface and was proved to be elemental sulfur by x-ray analysis, and dissolved tin, which was found by the analysis of the solution.

The decomposition reaction can be prevented when I⁻ is present in acidic solutions.

The addition of I⁻ in sufficiently high concentration (0.1M) to the acidic solution improves to a great extent the stability of the electrode. The oxidation of iodide to triiodide in an argon-purged solution can be observed during the photoelectrolysis as the solution's color changes to reddish brown. The experiment was performed in a cell in which the counterelectrode was separated by a glass frit. The solution was bubbled with argon

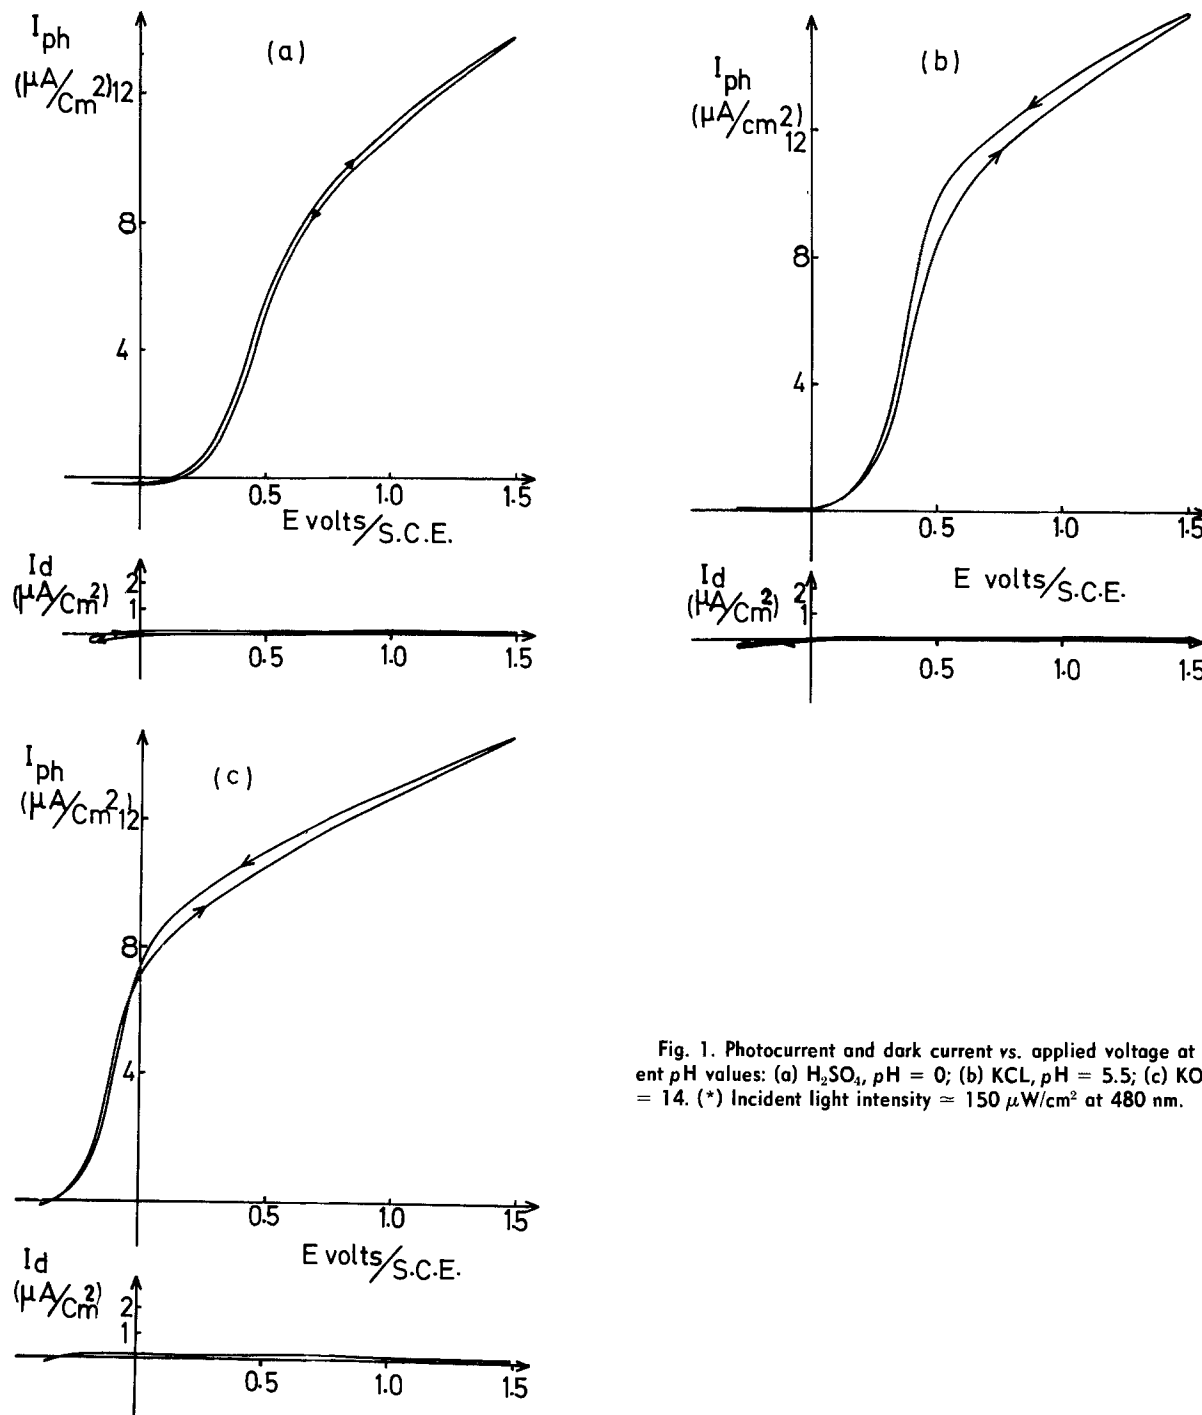

Fig. 1. Photocurrent and dark current vs. applied voltage at different pH values: (a) H_2SO_4 , pH = 0; (b) KCl, pH = 5.5; (c) KOH, pH = 14. (*) Incident light intensity = $150 \mu W/cm^2$ at 480 nm.

for several hours before the addition of KI. The electrode was polarized at +1V ($V_{FB} = 0.05V$) under white light ($\approx 200 mW cm^{-2}$). The current, after initial variation, remained constant during the experiment (Fig. 5), and no change on the electrode surface was observed.

The analysis of the solution did not show any trace of tin. The triiodide formed during the photoelectrolysis was titrated potentiometrically with sodium thiosulfate, and its concentration corresponded within the experimental

error to 95% of the total charge produced during the experiment. Table II shows, at pH = 0 and 14 with and without addition of I^- , the percentage of total charge consumed in electrode photodecomposition reaction calculated from the ratio of the concentration of dissolved tin found in the solution and the total charge produced during the experiment.

It is noted that Ce^{3+} and $Fe(CN)_6^{4-}$ do not improve the electrode stability.

Table I. Photopotential values obtained for 1M H_2SO_4 in the presence of various redox couples

Redox couples	Photovoltage
I^-/I_2	0.205V
$Fe(CN)_6^{4-\beta-}$	0.218V
$Fe^{2+/\beta+}$	0.204V

The spectral dependence of the photocurrent at constant photon flux is shown in Fig. 6. Using the general theoretical relation between the photocurrent and light energy (19), assuming that I_{ph} is directly proportional to α and that L_p is small

Fig. 4. Photocurrent vs. applied voltage (a) in 1M H₂SO₄ and (b) in 1M H₂SO₄ + 0.05M I⁻ and 0.001M I₂.

Fig. 5. Photocurrent variation as a function of time at constant potential (+1V/SCE) in 1M H₂SO₄ + 0.1 KI.

$$h\nu I_{ph} \propto (h\nu - E_g)^{n/2}$$

where $n = 1$ for a direct gap and $n = 4$ for an indirect gap, the linear extrapolation of $(h\nu I_{ph})^{1/2}$ as a function of $h\nu$ yields the value of 2.21 eV as the first indirect transition.

The relative energy scheme for SnS₂ and redox potentials of the couples in H₂SO₄ and KOH can be constructed (Fig. 7).

Fig. 6. Spectral response of SnS₂ in 1M H₂SO₄: (a) I_{ph} vs. light energy and (b) $(h\nu I_{ph})^{1/2}$ vs. light energy (at different scale).

Fig. 7. Energy scheme of SnS₂ in H₂SO₄ (pH = 0) and in KOH (pH = 14).

As it can be seen from Fig. 7, hydrogen couple redox potential is situated above the conduction band edge. At cathodic polarizations (ca. more negative than -0.3V), hydrogen evolution does not take place and the cathodic current is mostly due to the electrode decomposition. This leads to the formation of hydrogen sulfide and a black layer on the surface of the electrode. X-ray analysis indicates that this layer corresponds to the formation of tin oxide (SnO).

Discussion

The voltammograms, in the dark, indicate that tin sulfide is characterized by very low anodic current. The first indirect transition determined from the spectral response is in complete agreement with values found in the literature. This value corresponds to 2.2 eV. Although oxygen evolution under illumination is energetically possible (Fig. 7), photoinduced holes are partly consumed in the electrode-decomposition reaction in acidic solutions, while in KOH the decomposition rate is much higher. The decomposition product is a yellow layer which covers the electrode surface. X-ray analysis indicates that the layer is composed primarily of elemental sulfur. However, dissolved tin was found in the solutions, which indicates that tin passes into the solution both in acidic (pH = 0) and basic (pH = 14) media. The following anodic decomposition reactions, in acidic and basic solutions, respectively, can be considered

It seems that the decomposition mechanism of tin sulfide is similar to that of ZrS₂, for which the anodic decomposition product is also elemental sulfur (20). In contrast, the cathodic decomposition mechanism is not the same. In the case of ZrS₂, for example, hydrogen sulfide and zirconium metal are the cathodic decomposition products in acidic solution (20); in the case of SnS₂, the cathodic decomposition product is hydrogen sulfide and the lower oxide of tin (SnO). The following reaction may be considered as the cathodic decomposition reaction in acidic solutions

SnO is also formed during the cathodic polarization in basic solutions, but it dissolves (probably oxidizes to SnO₃⁻) when the polarization is stopped.

As it has been already mentioned, the oxidation of iodide to triiodide is the main photoanodic reaction in acidic solutions, and therefore considerable improvement is obtained in the stability of the electrode.

An interesting feature of Fig. 5, which shows the variation of current under anodic bias of SnS₂ in acidic solution containing I⁻, is the increase in photocurrent at first before further stabilization. This may be caused by the negative flatband shift due to the production of triiodide. The gradual formation of I₃⁻ during the electrolysis and its accumulation shifts the flatband potential to more negative values, and the photocurrent increases at first.

Fig. 8. Energy scheme of SnS₂ in the dark and under illumination. The role of surface states in preventing the flattening of the bands is illustrated.

The peak disappears when iodine is intentionally added to the solution before experiment.

The addition of I⁻/I₂ to acidic solution also shifts the photocurrent onset potential to a more negative value. The negative shift of the flatband position due to the adsorption of triiodide ion (21, 22) has already been shown in the case of MoSe₂ and MoS₂. The phenomenon has been interpreted by the introduction of a large number of acceptor states on the surface. Our results indicate that the same behavior can be assumed in the case of SnS₂. The introduction of surface states with accumulation of negative charge on the surface provokes changes in the field of the Helmholtz double layer. On the contrary, the addition of other couples such as Fe^{2+/3+} and Fe(CN)₆^{4-/3-} has no effect on the photocurrent onset potential and the flatband position.

The addition of redox reagents such as I⁻/I₂ and Fe(CN)₆^{4-/3-} to alkaline solutions provokes a positive shift of the photocurrent onset potential. But, the shape of the photocurrent voltage curve remains unchanged, and the decomposition of the electrode is the main photoanodic reaction. The positive shift of the photocurrent onset potential arises from the dependence of the flatband position on the above redox agents. The flatband potential is more positive in alkaline solutions containing I⁻/I₂ and Fe(CN)₆^{4-/3-} and it becomes more negative in those containing S²⁻/S₂²⁻ (23). The positive shift in flatband position has been discussed elsewhere (18), and it has been shown that the shift arises from the interaction of the oxidized form of the redox couples with the negatively charged surface states. On the contrary, S²⁻/S₂²⁻ couple increases the negative charge on the surface.

Shifts in photopotentials can be explained either by band edge movement or by the existence of surface states close to the conduction band edge (Fig. 8). Electrons which are excited into the conduction band fall into these surface states and prevent the flattening of the band. A similar effect was observed with ZrS₃ (24). Surface states below the conduction band edge should also be responsible for the existence of cathodic dark currents when solutions contain redox reagents. At all pH values, when solutions contained redox reagents, a cathodic dark current was observed at potentials positive to the flatband position.

Conclusion

It has been demonstrated that SnS₂ doped with phosphorus has a diode-like behavior. Under illumination, the electrode is not stable in acidic and basic media and the photoelectrochemical reactions are mostly due to the decomposition of the semiconductor. However, the electrode can be stabilized in acidic solutions containing iodide. The main photoanodic reaction in this case is the oxidation of iodide to triiodide.

Electrodialytic Water Splitting

Conversion of Dilute Sodium Acetate or Acetic Acid into Concentrated Acid

John Kassotis and Harry P. Gregor

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

Frederick P. Chlanda

Allied Corporation, Corporate Research Group, Morristown, New Jersey 07960

ABSTRACT

Electrodialytic water splitting is an energy-efficient and inexpensive means to produce relatively concentrated solutions of weak acids and bases from feed solutions of the corresponding salts. With contaminated feedstreams, ultrafiltration is a necessary prerequisite. A 6% solution of sodium acetate was readily resolved into 35% acetic acid and about 8% sodium hydroxide. The degree of concentration achieved is determined by the electro-osmotic coefficients of the ions involved. This process can also serve to concentrate relatively dilute solutions of weak acids and weak bases, ones too weak to be capable of concentration by direct electrodialysis. The water splitting process has unusual advantages for the treatment of the products of fermentation in closed-loop systems.

The extensive development of ion-exchange membranes has led to increased interest in the phenomenon of water splitting. In the electrodialytic processes when a critical current density is reached wherein the concentration of electrolyte at the membrane surface approaches zero, the water in or at the membrane surface starts to dissociate at a rate such that the transport of hydrogen and hydroxyl ions in opposite directions becomes significant. This phenomenon was first observed by Bethe and Toropoff (1, 2), who observed that equal amounts of acid and base were produced, presumably from water.

The development of bipolar membranes and their study has led to several rather detailed analyses of water splitting processes. It also became evident that bipolar membrane systems could be used for the production of acids and bases from neutral solutions. Accordingly, the preparation of bipolar membranes of industrial utility has been a topic of study for some years. For a bipolar membrane to be useful industrially, the following properties must be realized: high permselectivity; stability and efficacy under high current densities; stable physical properties; and low ohmic resistance.

Several techniques have been employed. Frilette (3) fused monopolar membranes together and used them in

electrodialytic processes. De Korosy (4) made bipolar membranes from a single sheet of polyethylene by sulfochlorination from one side and amination from the other. Benjamin *et al.* (5) improved the cementation technique. Most recently, Liu *et al.* (6-12) prepared bipolar membranes which have demonstrated operational characteristics suitable for large-scale utilization.

Benjamin (13) studied three different applications of bipolar water splitting membranes: namely, the preparation of KOH and HCl from KCl, of Mg(OH)₂ and H₂SO₄ from MgSO₄, and the decomposition of ammonium bicarbonate to form CO₂ and ammonia. It was found that in the production of 0.2N KOH and HCl the coulombic efficiency was 90%. In the production of Mg(OH)₂ and H₂SO₄ current efficiencies fell to 85% and 65%, respectively, attributed to the low mobility of the large bisulfate ion. Fused monopolar membranes were used in these studies.

Chang (14) evaluated the feasibility of electrodialytic water splitting for the conversion of ferrous chloride-HCl pickling solutions into the insoluble hydroxide and free acid, and demonstrated feasibility at the laboratory level. Chang (15) also applied water splitting to the conversion of hydroxylamine hydrochloride into hydroxylamine nitrate.

Chlanda *et al.* (11) characterized the Allied bipolar membranes by producing 1N HCl and NaOH from NaCl at a current efficiency of 93% for the base and 80% for the acid. Most of the loss in efficiency was attributed to leaks in the flanking monopolar membranes.

Experimental

Preparation of bipolar membranes.—The fused bipolar membranes deteriorate after prolonged use due to their separation, probably as a result of electro-osmotic forces. Improved bipolar membranes were made using the gluing technique of Benjamin and Chang, wherein Ionac MC3470 and MA3475 membranes of the heterogeneous monopolar type were used. A solution of linear polystyrenesulfonic acid in DMF was applied as a thin film across each surface face, and the two fused together for 3 min in a hydraulic press at 200° F and 2000 psi pressure, the optimal conditions.

Measurement of electrolysytic and water splitting efficiencies.—A batch recirculating device (Fig. 1) was employed to determine water splitting efficiencies; it had six cells (Fig. 2) in series, each connected to individual 2 × 15 in. Pyrex cylinders calibrated for volume measurement. Four compartments (two for feed and one each for base and acid delivery) had individual micropumps, and the two end electrode compartments had a joint feed stream and pump. For water splitting, the membranes used were, from left to right in Fig. 1, + (cation permeable), +, - + (bipolar), - (anion permeable), +. Two cell compartments had an in-line heat exchanger to maintain stream at 25°-35°C. Prior to each experiment, distilled water was circulated to test for leaks because no materials can be lost if accurate current efficiencies are to be calculated. Solutions were prepared with reagent-grade chemicals and deionized water.

After the insertion of feed solutions, circulating pumps were started, and their rheostats regulated for proper flows and cell liquid levels. Zero time samples were taken for analysis and then current was passed with the voltage properly adjusted. The device was operated for the time intervals necessary to achieve a given concentration charge, then current was stopped, samples of acid

and base were taken, and volume changes recorded. The base concentration was maintained near 0.5M to keep diffusible losses low; different initial concentrations of acetic acid were used to allow one to measure membrane efficiency over a wide range of concentrations.

When straightforward concentration by electrolysis (ED) was desired, one concentrate cell was used between two feed cells, with the membrane sequence: +, +, -, +.

There are several fermentation routes to make acetic acid. In one, the almost pure acid is produced at the 3%-10% levels, depending upon the feedstock, organism, and rate of fermentation desired. In general, rates of conversion decrease with increasing product concentration, owing to product inhibition. Jeffries (16) and Omstead (17) have shown that when product levels are kept well below the maximum which can be attained, fermentation rates are substantially increased, often as much as five-fold. In the anaerobic digestion of primary sewage sludge, for example, Naughton (18) obtained detention times 0.1 of the usual (1.5 cf. 15 days) by the use of concomitant ultrafiltration.

Wang (19) has shown that biomass is an effective feedstock to produce at neutral pH levels 6% or 0.73M sodium acetate, corresponding to 4.4% acetic acid. It is usually converted to glacial acetic acid by treatment with sulfuric acid; solvent extraction then removes the acid which is concentrated by distillation.

Thus, there are several possible routes to glacial acetic acid by the use of membrane processes, including the straightforward electrolysytic concentration of acetic acid or that of sodium acetate, but little is gained by concentrating the salt.

Results

Electrolysytic concentration of acid.—A feed of 4.8% acetic acid was electrolysytically concentrated at 17.3 mA/cm² with AMV and CMV membranes of the Asahi Glass Company at 35°C. The concentration of acid was carried to the 19.8% level (Table I). The current efficiency was fairly high ini-

Fig. 1. Laboratory cell and auxiliary equipment

tially; it fell to 53% when approximately 20% acetic acid is reached.

The transport efficiency of acetic acid is influenced by the electro-osmotic water carried along with the acid which dilutes it in the concentrate stream; it is lowered by back-diffusion of acid. Water splitting taking place at the surface of the anion-permeable membrane in the dilute solution feed lowers current efficiency, where generated hydroxide ions pass through the membrane, with hydrogen ions going into the deionate.

Asahi Glass membranes are among the tightest available commercially. When looser Ionac membranes were employed at 20 mA/cm² and starting with 0.6% acid, when a concentration of 4.9% was reached the current efficiency fell to 27%. Thus, the nature of the membranes used is important.

The extent of electroolytic water splitting is appreciable here because the concentration of ionized species in solution is low. For example, in 0.73M acetic acid at the 4.4% level, the concentration of hydrogen ions is 0.0038M and its specific resistance 667 Ω-cm. Water splitting could be minimized by operating at low current densities, but this increases the relative contribution of back-diffusion and makes for increased equipment costs.

The limiting current before water splitting is readily calculated from Nernst-Planck as equal to $2DC/\delta$, where D and C are diffusion coefficient and concentration of transported species and δ the boundary layer thickness. Since the diffusion coefficient of acetate is 1×10^{-5} cm²/s at a concentration of 0.004M and a boundary layer thickness of 100 μm (as measured in these cells), the limiting current density is 0.8 mA/cm². With high convection the boundary layer resistance can be lowered by two-thirds, but a current of 2.4 mA/cm² requires too much investment in equipment.

The rate of back-diffusion of acid through the much more permeable cation membrane is readily calculated.

Fig. 3. Electrolytic water splitting to convert salts of organic acids into bases and organic acids.

For a membrane thickness of 200 μm and an effective diffusion coefficient of acetic acid in it of 10^{-6} cm²/s, if the concentration of acetic acid on one side is 20% acid and zero on the other, the flux is 1.5×10^{-7} mol/cm² s, corresponding to a current of 15 mA/cm². It is evident, therefore, that a high current density must be employed, something precluded by the low concentration of ionized species present and resultant water splitting. Thus, we cannot use a low current density nor a high one.

Conversion of sodium acetate to acetic acid.—Consider electroolytic water splitting in a bipolar cell (Fig. 3). Because of the high mobility of the hydroxide ion, we do not allow the concentration of the base stream to rise above 0.5M, but raise the concentration of acetic acid in its product stream as high as possible. If a high concentration of base is desired, conventional ED can produce 15%-40% base, depending on the membrane used.

In the initial series of experiments, cemented Ionac bipolar membranes were employed at a current density of

* Calculated by subtracting calculated solution resistance from total resistance.

20 mA/cm². Monopolar membranes of the Ionac variety were used. Figure 4 shows that the current efficiency was high when a dilute solution of acid was obtained, but it fell to about 27% when 5% acid was reached. Varying the current density to higher and lower values did not lead to improved current efficiencies, probably because the heterogeneous monopolar Ionac membranes show a rather large leak to acetate and acetic acid.

The allied bipolar membrane was first measured as to its current-voltage characteristics in a similar 11 cm² cell between 0.5M sodium sulfate solutions at room temperature and at 0.05-1.2A current. The voltage drop across the membrane and solution and across the solution itself was measured, and that across the membrane was calculated. Probe electrodes inserted in the two solutions flanking the membrane were used. The voltage drop across the membrane increased from 0.7 to 1.1V as the current density was varied by a factor of about 24, as shown in Table II. The decrease in membrane resistance with increasing current is typical for bipolar membranes which act like p-n junctions in generating current carriers proportional to current density. This membrane was designated ACBM-3 bipolar membrane, its preparation is given in Chlanda *et al.* (11), and its properties were quite similar or identical with those of Ref. (6-12).

The water splitting conversion of 6% sodium acetate was performed in the 11 cm² cell, starting with 0.5 NaOH and 6% acetic acid in the product compartments. A constant current density of 109 mA/cm² was maintained, and the flanking membranes were the C322 (similar to ones of AMF) and the ASV membranes of the Asahi Glass Company. To reduce the overall IR drop in the receiving acid compartment, small amounts of sodium acetate were added to the acid product compartment initially. Some sodium acetate also entered this compartment due to the leak of salt.

In a first run (Table III), acetic acid was concentrated from 6.00% to 7.54% at a current efficiency of 89.7%. Subsequently, the acid product stream was raised to 27.3%, and the current efficiency remained fairly high through-

out. However, the current efficiency fell to 38% when a concentration of 36.6% acetic acid was reached by initial addition, probably because the maximum concentration of acid that could be reached (as dictated by electro-osmotic transport of water) was exceeded. Table IV gives salt levels in acid product stream.

A final series of steady-state experiments was performed, wherein the process was continued until a constant concentration of acid in the product stream was reached. In water splitting, the device "pumps" both acid and water (plus a small amount of salt) into the product stream; if this is allowed to overflow, a steady-state concentration is obtained. Table V gives results at 1.2A for the 11 cm² cell, at 109 mA/cm² or 101 A/ft². The maximum level of acid reached in ten separate experiments varied from 33% to 41% acetic acid.

Discussion

Water splitting technologies can convert fermentation product streams of salts of weak acids into solutions of base, with the acids in a concentrated solution. The highest level of acid obtainable is dictated by electro-osmotic water transport across the anion-permeable membrane. For a given ion, the electro-osmotic coefficient is primarily a function of the effective pore diameter of the membrane, and increases rather sharply with pore size. The anion-permeable membranes used here had osmotic coefficients of 8 mol of water per Faraday; finer pore membranes allowing but 5-6 mol of water could be developed to obtain a 50% acid solution, one which is probably the upper limit.

There are few limitations to this process. The upper MW level of permeating solutes is about 500. The concentration of the feedstock plays no role other than to dictate the IR drop across the feed compartment. If dilute feedstocks must be employed, they can be readily concentrated by membrane processes at low cost to the point where the overall cost of the process is minimized. For example, solutions of salts of organic acids at the 1000-5000 mg/liter levels and produced by the fermentation of sewage sludge under membrane-facilitated conditions have been treated first by ultrafiltration to remove fouling components, then by reverse osmosis for concen-

tration, and then by water splitting to produce concentrated acids.

Reliable costs for this process can be estimated. For a relatively small plant producing 1000 gal/h of a 6% sodium acetate feed, a plant having a total area of about 800 ft² effective area for each of the three membrane types would be required, operating at a current density of 100 A/ft². The investment costs would be approximately \$50,000; larger plants cost somewhat less. These are total plant costs including the power source, module and pumps but not interest on investment. For this small plant, the cost of device per square foot of cell area was taken as \$62.50; according to Liu *et al.* (8), one having an area of 18,750 ft² costs \$28.50 per ft², so appropriate consideration was given to the economies of scale which prevail in this field.

For this plant, the production of 35% acetic acid is about 0.1 lb/s. Taking the standard amortization rate of this equipment (5 yr average, 3 on membranes and 7 on the remainder) the total equipment cost would be approximately 0.2¢/lb of acid. With power at 5¢/kWh and with a dilute feed (0.5%) requiring a total voltage of 3V, the cost is 3.4¢/lb acetic acid. With a more concentrated feedstock of the type studied here (3%-10% salt) and electricity at 3.5¢/kWh, the voltage drop is 2V and the power required is approximately 1.6¢/lb of acid produced.

The water splitting process can be applied to a wide range of electrolytes of different kinds for the double purpose of converting these into their corresponding acids and bases and also producing concentrated product streams. The current efficiencies obtainable and the maximum current densities which can be utilized depend upon the nature and concentration of the feed substances. In the present study, the relatively large molecular size of the acetic acid product and its relatively low diffusivity through the membranes allowed for a high current efficiency, with little loss of acid by diffusion. If the product were formic acid, somewhat higher losses would be encountered, as would occur if ammonia were the base produced. Solutes of higher molecular weight, particularly those which are poorly ionized in the acid or base form, make for the highest current efficiencies and the smallest losses by diffusion.

Water splitting can also serve to concentrate weak electrolytes. As was observed, the electrochemical concentration of acetic acid was impractical. Somewhat stronger acids such as malic acid can be electrochemically concen-

trated to up to 30% efficiently from a 5% feedstock as demonstrated by Liu (20).

The concentration of dilute acetic acid to the 35%-40% level by electrochemical water splitting can be readily achieved. The acid feedstock is first neutralized and the salt used as feed, with the base recycled for neutralization of feed. At a feed level of 1000 GPM of 4.4% acetic acid (the same molarity as 6% sodium acetate), the membrane plant has the same area and cost as with salt conversion.

If a product stream entirely free of excess sodium acetate were desired, straightforward electrochemical with little loss of free acid would reduce it to the 0.01M or 500 mg/liter level. Or, direct cation exchange using a strong acid regenerant would remove all traces of sodium and produce pure acid at nominal cost.

Acknowledgments

This work was supported in part by two research contracts from the United States Department of Energy, the first from the Office of Energy from Municipal Wastes (DF-AC 01-78CS-20400), the second through the Solar Energy Research Institute (XB-9-8161-1); the authors express their thanks for this support. We also thank Allied Corporation for its cooperation and permission to use its facilities.

A Homogeneous/Agglomerate Model for Molten Carbonate Fuel Cell Cathodes

H. R. Kunz,* L. J. Bregoli, and S. T. Szymanski

United Technologies Corporation, Power Systems Division, South Windsor, Connecticut 06074

ABSTRACT

A molten carbonate fuel cell cathode model was developed which enables the estimation of performance as a function of cathode electrolyte content. This model is neither a thin film nor a conventional agglomerate model, but involves the calculation of the effective agglomerate diameter, porosity, tortuosity, and number based on knowledge of the electrode's pore spectrum and electrolyte content. Calculated electrode performance and experimental results are compared for cathodes of different pore spectra over a range of electrolyte contents.

The cathode of present molten carbonate fuel cells consists of porous, lithiated nickel oxide, which, during operation, is partially filled with electrolyte. Its structure consists of microporous nickel oxide particles clustered to form macropores, as shown in Fig. 1. The degree of saturation of the cathode with electrolyte depends upon the total amount of electrolyte in the cell and the pore-size distributions and volumes of the cell anode, cathode, and matrix. When good performance is being attained, the larger electrode pores are open to allow gas-phase diffusion of reactants into the cathode and reduce the path length for liquid-phase diffusion. Enough electrolyte is present to facilitate the electrochemical reactions and ionic conduction. Good electronic conductivity should be provided by the catalyst particles.

Such an electrode configuration has been modeled in the past using a thin film model (1-3), whereas a cylindrical agglomerate model would be more appropriate (4-6). Both of these approaches, however, are deficient in that neither the electrolyte film thickness nor the agglomerate diameter is known with any accuracy, and they are frequently used as fitting parameters to the experimental data. The uncertainties are compounded when the performance is desired as a function of the amount of electrolyte in the electrode. In order to avoid these uncertainties, a new model was developed, which is basically a cylindrical agglomerate model with the agglomerate diameter, number, porosity, and tortuosity calculated from a knowledge of the pore size distribution and electrolyte content.

In conjunction with the theoretical analysis, experimental performance data were obtained for four cathodes of different pore structure using a half-cell rig containing a reference electrode. Electrolyte was added and removed from these cathodes to obtain performance as a function of electrolyte content. These experimental results were used to evaluate the capabilities of the model.

Theory

If an electrode is completely filled with electrolyte and a gas pressure is applied in excess of the liquid pressure, liquid is forced out of the electrode into adjacent liquid containing regions. Most of the PdV work done in this expulsion increases the vapor-liquid interfacial free energy, σdA . This relationship is used to determine the surface area of a porous body using mercury intrusion porosimetry (7). Here P is the pressure difference between the gas and liquid, V is the volume of the gas in the electrode, σ is the surface tension, and A is the vapor-liquid interfacial area. This is not an exact relationship in this case because of solid-gas and solid-liquid interfacial free energies, the effect of vapor-liquid interfacial curvature on the free energy, the effect of film thickness on surface free energy, chemical effects, and the process by which the electrode is filled. However, if the electrolyte is considered to completely wet the catalyst and form a relatively thick film, the equality of PdV and σdA may provide an

*Electrochemical Society Active Member.

equation which enables the prediction of gas-liquid interfacial area. If this area is known and the cylindrical agglomerate concept is retained, this area becomes the gas surface area of all the agglomerates.

An assumption must be made that the measured pore-size distribution is suitable for use in this analysis. Most pore spectra are obtained using mercury intrusion porosimetry, in which nonwetting mercury is forced into the porous body. In the fuel cell case, a wetting liquid is wicked into or forced from the body, which results in somewhat different pore spectra, since hysteresis effects are known to be present in pore spectra.

Agglomerate properties.—If all of the above assumptions are made, the agglomerate radius, number, and po-

Fig. 1. Scanning electron micrograph of oxidized cathode

rosity can be calculated from the pore spectrum as follows

$$(P_G - P_L) dV = -\sigma dA \quad [1]$$

where V is now the volume of liquid in the electrode. Since

$$(P_G - P_L) = 2\sigma/r \quad [2]$$

it follows that

$$dA = 2dV/r \quad [3]$$

where $r(V)$ is the pore radius on the pore-size distribution graph. Therefore

$$A = \int_{V_{\text{filled}}}^{V_{\text{total}}} \frac{2dV}{r} \quad [4]$$

V_{total} is the total void volume of the electrode and V_{filled} is the volume of electrolyte in the electrode.

For a cylindrical agglomerate

$$A/V_{\text{filled}} = (2Nr_o \pi \tau_E \delta \theta) / (N\pi r_o^2 \tau_E \delta \theta) \quad [5]$$

where N is the number of agglomerates, r_o the agglomerate radius, τ_E the agglomerate tortuosity, θ the porosity, and δ the electrode thickness.

Then

$$A/V_{\text{filled}} = 2/r_o \quad [6]$$

Eliminating A between Eq. [4] and [6] yields

$$r_o = V_{\text{filled}} \int_{V_{\text{filled}}}^{V_{\text{total}}} \frac{dV}{r} \quad [7]$$

This equation can be used to obtain the agglomerate radius from the pore-size distribution curve.

The number of agglomerates, N , is calculated assuming the agglomerates are cylindrical using the equation

$$N = (V_{\text{filled}} + V_{\text{solid}}) / (\pi r_o^2 \tau_1 \delta) \quad [8]$$

where V_{solid} is the volume of solid in the electrode. The agglomerate porosity, θ , is

$$\theta = V_{\text{filled}} / (V_{\text{filled}} + V_{\text{solid}}) \quad [9]$$

and the tortuosity for ionic migration, τ_1 , is

$$\tau_1 = [(V_{\text{total}} + V_{\text{solid}}) / V_{\text{filled}}]^{0.75} \quad [10]$$

using an Archie's law relationship (8) found to hold for molten carbonate fuel cell matrices. These equations predict that the radius of the agglomerate decreases and the number of agglomerates increases as the electrolyte content of the electrode is decreased. This is due to the increase of the vapor-liquid interfacial area. The model also predicts that the porosity of the agglomerates decreases from the overall porosity of the electrode when it is completely filled to zero when it is empty of electrolyte.

Agglomerate model description.—Figure 2 is an idealized illustration of the model. The agglomerates are assumed to consist of an array of right-circular cylinders of radius r_o in which nickel oxide catalyst particles and electrolyte are homogeneously dispersed. The agglomerate radius and number are calculated by Eq. [7] and [8], respectively, for a specified pore spectrum and electrolyte content. During steady-state operation, reactant gases at the surface of the cylinder dissolve in the electrolyte and diffuse radially with simultaneous reaction on the catalyst particles. Ionic current is assumed to conduct only in the axial direction.

Additional assumptions include the following: (i) electrolyte is saturated with reactant gas at the gas-electrolyte interface, (ii) all activities are equal to concentrations (i.e., all activity coefficients are assumed equal to one), (iii) transport parameters are constant, and (iv) the electrode operates at a uniform temperature.

The model includes the effects of activation polarization, liquid-phase diffusional resistance in the electrolyte,

Fig. 2. Homogeneous/agglomerate model

ionic resistance in the electrolyte, and electronic resistance in the nickel oxide structure. Gas-phase diffusional losses were not considered. Previous results indicate that these losses may be significant (6). For a given overall electrode current density, the model calculates the axial variation of electrode and electrolyte potentials and the radial and axial variations of reactant concentrations and local current density.

Mechanism.—The geometric configuration presented above was used with the following reaction sequence occurring within the agglomerate.

The correct mechanism to use for an actual fuel cell cathode is uncertain at this time (9), so this mechanism was used to evaluate the concept of the homogeneous/agglomerate model. The above reaction sequence assumes that oxygen dissolves as molecular oxygen. In the actual case, molecular oxygen dissolves as superoxide and peroxide if these dissolution reactions are adequately fast. The relative contents of superoxide and peroxide depend on the electrolyte and oxidant composition and the relative rates of the dissolution reactions. The rate of homogeneous reaction (III) may also be slow enough to be controlling.

Activation polarization.—Using the above reaction sequence, the local current per unit of real catalyst surface area, $i(x, r)$ is

$$i(x, r) = i_o \left\{ \left(\frac{P_{CO_2}^o}{P_{CO_2}} \right)^2 \exp \left[\frac{(3 + \beta)F\eta}{RT} \right] - \left(\frac{P_{O_2}}{P_{O_2}^o} \right) \exp \left[\frac{-(1 - \beta)F\eta}{RT} \right] \right\} \quad [11]$$

where i_o is the exchange current density (A/cm^2), $P_{CO_2}^o$, $P_{O_2}^o$ the bulk gas partial pressures at the gas/agglomerate interface, P_{CO_2} , P_{O_2} the equivalent reactant partial pressure at the reaction site, η the local overpotential (V), and β the symmetry factor for rate-determining step.

The exchange current density is given by

$$i_o = k(T) [P_{O_2}^o]^{3/4 + \beta/4} [P_{CO_2}^o]^{-1/2 - \beta/2} \quad [12]$$

where $k(T)$ is the cathodic rate constant for the rate-determining step and is a function of temperature.

In this analysis, the reference state is taken to be that of the local conditions along the agglomerate under load. Hence $P_{CO_2}^o/P_{CO_2}$ and $P_{O_2}^o/P_{O_2}$ are measures of the liquid-phase diffusional polarization.

The overpotential $\eta(x)$ is defined as

$$\eta(x) \equiv E(x) - \phi(x) - E_{o/c} = E(x) - \phi(x)$$

$$-\frac{RT}{2F} \ln \left[\left(\frac{P_{CO_2}^o}{0.67} \right) \left(\frac{P_{O_2}^o}{0.33} \right)^{1/2} \right] \quad [13]$$

where $E(x)$ is the potential of the electrode solid (V), $\phi(x)$ the electrolyte potential (V), and $E_{o/c}$ the reversible or open-circuit potential measured relative to a 2:1 $CO_2:O_2$ reference (V).

Liquid-phase diffusional polarization.—To determine the liquid-phase diffusional losses, the following approach is taken. Assuming Henry's law to hold for both oxygen and carbon dioxide

$$P_{CO_2}/P_{CO_2} = H_{CO_2} P_{CO_2}^o/[CO_2] \quad [14]$$

and

$$P_{O_2}/P_{O_2}^o = [O_2]/H_{O_2} P_{O_2}^o \quad [15]$$

where factors in brackets represent molar concentrations and H is Henry's law constant.

Since step (III) in the overall mechanism is in equilibrium at all points within the agglomerates according to the equation

$$K = (CO_3^-)/(O^-) P_{CO_2} = (CO_3^-)^o/(O^-)^o P_{CO_2}^o$$

Therefore

$$P_{CO_2}/P_{CO_2} = [CO_2]^o/[CO_2] = (O^-) (CO_3^-)^o/(O^-)^o (CO_3^-)$$

The mole fractions are related to molar concentrations by the molar density, D_M

$$(O^-) = [O^-]/D_M$$

Since $(CO_3^-)^o/(CO_3^-) = 1$, then

$$P_{CO_2}/P_{CO_2} = [CO_2]^o/[CO_2] = [O^-]/[O^-]^o \quad [16]$$

The $[O^-]/[O^-]^o$ factor can be determined by taking into account the oxygen and carbon atom fluxes through the agglomerate

$$\begin{aligned} \text{O atom flux } 5 \cdot 2D_{O_2} \frac{\partial [O_2]}{\partial r} + D_{O^-} \frac{\partial [O^-]}{\partial r} \\ + 2D_{CO_2} \frac{\partial [CO_2]}{\partial r} + 3D_{CO_3^-} \frac{\partial [CO_3^-]}{\partial r} = 0 \end{aligned} \quad [17]$$

$$\text{C atom flux } 5 \cdot D_{CO_2} \frac{\partial [CO_2]}{\partial r} + D_{CO_3^-} \frac{\partial [CO_3^-]}{\partial r} = 0 \quad [18]$$

where D is the diffusion coefficient of a species.

Differentiating Eq. [16]

$$\frac{\partial [O^-]}{\partial r} = \frac{-[O^-]^o [CO_2]^o}{[CO_2]^2} \frac{\partial [CO_2]}{\partial r} \quad [19]$$

Substituting Eq. [18] and [19] into [17], simplifying, and then integrating between limits yield

$$[CO_2] = \frac{(\alpha - \epsilon) + \sqrt{(\epsilon - \alpha)^2 + 4\gamma\beta}}{2\gamma} \quad [20]$$

where

$$\alpha = \{D_{CO_2}[CO_2]^o - D_{O^-} [O^-]^o\}/2D_{O_2}$$

$$\beta = D_{O^-} [CO_2]^o [O^-]^o / 2D_{O_2}$$

$$\gamma = D_{CO_2} / 2D_{O_2}$$

$$\epsilon = [O_2]^o - [O_2]$$

$$[O^-]^o = D_M H_{CO_2} / K [CO_2]^o = D_M / KP_{CO_2}^o$$

Equation [20] expresses $[CO_2]$ only as a function of $[O_2]$ and a series of constants.

Substituting Eq. [14], [15], and [20] into [11] results in an expression for the current density $i(x, r)$ which is a function only of $[O_2]$ at a fixed value of x .

The diffusion of dissolved oxygen through the agglomerate with simultaneous consumption due to current generation is given by the steady-state continuity equation using Fick's law

$$\frac{\partial^2 [O_2]}{\partial r^2} + \frac{1}{r} \frac{\partial [O_2]}{\partial r} + \frac{\tau_1 S_g \rho (1 - \theta) i(x, r)}{nFD_{O_2} \theta} = 0 \quad [21]$$

with boundary conditions

$$\frac{\partial [O_2]}{\partial r} = 0 \text{ at } r = 0, [O_2] = [O_2]^o = H_{O_2} P_{O_2}^o \text{ at } r = r_o$$

where $n = 4$, the number of electrons in the overall reaction, S_g is the surface area of catalyst (cm^2/g), and ρ is the catalyst density (g/cm^3).

Equation [11] can then be substituted into [21], resulting in a second-order, nonlinear, partial differential equation. The solution of this equation in conjunction with Eq. [16] and [20] gives $[O_2]$, $[O^-]$, $[CO_2]$, and i as functions of r and x for a given value of η .

Ohmic effects.—The electrolyte potential, ϕ , is taken as zero at $x = 0$, the matrix side of the electrode, and decreases as x increases. $d\phi/dx$ reaches 0 at the end of the agglomerate on the gas side of the electrode.

The effect of the ohmic potential gradient within the electrolyte can be taken into account by relating the ionic current, J_i , developed in the axial direction in the agglomerate, to the ohmic potential gradient in the electrolyte by Ohm's law

$$J_i = \frac{\sigma_1 \pi r_o^2 \theta}{\tau_1} \frac{\partial \phi}{\partial x} \quad [22]$$

Because of the current generated by the electrochemical reaction

$$dJ_i/dx = -2\pi S_g \rho (1 - \theta) \int_0^{r_o} i r dr \quad [23]$$

where σ_1 = ionic conductivity, $\Omega^{-1} cm^{-1}$.

Differentiating Eq. [22] and setting it equal to Eq. [23] yields

$$\frac{d^2 \phi}{dx^2} = \frac{-2\tau_1 S_g \rho (1 - \theta)}{\sigma_1 \tau_o^2 \theta} \int_0^{r_o} i r dr \quad [24]$$

The total current generated for the entire agglomerate, J_T , can be found by evaluating Eq. [22] at $x = 0$

$$\left. \frac{d\phi}{dx} \right|_{x=0} = \frac{J_T \tau_1}{\sigma_1 \pi r_o^2 \theta} \quad [25]$$

J_T is the overall current, I , divided by the number of agglomerates of radius r_o .

As stated above

$$\phi|_{r=0} = 0 \quad [26]$$

$$\left. \frac{d\phi}{dx} \right|_{x=L} = 0 \quad [27]$$

At each point along the agglomerate, the sum of the ionic current, J_i , and the electronic current, J_E , must be equal to the total current

$$J_T = J_i + J_E \quad [28]$$

at

$$x = 0 \quad J_i = J_T, J_E = 0; \text{ at } x = L, J_i = 0, J_E = J_T$$

The change in the electrode solid potential, E , with distance is related to the electronic current by

$$\frac{dE}{dx} = \frac{J_E \tau_E}{\sigma_E \pi r_o^2 (1 - \theta)} \quad [29]$$

where σ_E = electrode conductivity, $\Omega^{-1} cm^{-1}$.

Substituting Eq. [28] into [29] gives

Table I. Pore spectra characteristics of four pre-oxidized nonlithiated cathodes

Cathode designation	Thickness (mil)	Porosity (fraction)	Surface area (m ² /g)	Mean pore diameter (μm)
A	21	0.40	0.9	0.74
B	30	0.39	0.4	2.25
C	35	0.60	0.3	16.00
D	30	0.48	1.5	2.95

$$\frac{dE}{dx} = \frac{J_T \tau_E}{\sigma_E \pi r_0^2 (1 - \theta)} - \frac{\tau_E \sigma_1 \theta}{\tau_1 \sigma_E (1 - \theta)} \frac{d\phi}{dx} \quad [30]$$

From Eq. [25] and [27] it follows that

$$\left. \frac{dE}{dx} \right|_{x=0} = 0 \quad [31]$$

$$\left. \frac{dE}{dx} \right|_{x=L} = \frac{J_T \tau_E}{\sigma_E \pi r_0^2 (1 - \theta)} \quad [32]$$

The values of $E(x)$ and $\phi(x)$ are calculated by the above equation and used in Eq. [13] and [11].

Experiments

Performance data were obtained on four cathodes fabricated by sintering nonlithiated nickel oxide powders. The thicknesses, porosities, surface areas, and mean pore sizes of these cathodes are shown in Table I. The surface areas listed there were obtained by mercury intrusion porosimetry. Pore spectra are shown in Fig. 3. As can be seen, the properties of these cathodes were considerably different. For each of these cathodes, the cathode potential was measured as a function of current density in a half-cell apparatus using 62 mole percent (m/o) Li₂CO₃, 38 m/o K₂CO₃ electrolyte, and 67 m/o CO₂, 33 m/o O₂ oxidant. The use of this gas composition eliminated gas-phase diffusional losses, which were not included in the model. Electrolyte was added and removed from these cathodes to obtain data as a function of electrolyte content using the techniques described in Ref. (6). Post-test analyses of the electrodes were used to verify the electrolyte contents.

Results

The performance characteristics of the four cathodes are shown in Fig. 4-7, where the overpotential at 160 mA/cm² is plotted as a function of the percentage of the open pore volume that is filled with electrolyte (percentage fill). Because of excessive polarization, the "estimated" point shown in Fig. 6 was obtained by a small extrapolation of the overpotential vs. current density sweep curve to 160 mA/cm². The arrows on the lines connecting the data points indicate the sequence used in obtaining the data. In some cases, a considerable hysteresis in performance is evident.

The mathematical model described in this report was fit to each of the experimental data curves using a value for symmetry factor determined in a previous study. The

Fig. 4. Performance characteristics of cathode A

three diffusion coefficients (D_{CO_2} , D_{O_2} , and $D_{O^{2-}}$) and exchange current density were used as fitting parameters.

In the investigation that was conducted to define the symmetry factor, experimental performance data from a 10.8 cm² molten carbonate cell were compared to the results of a thin film model using the same rate-determining step as the present model. The analysis was a modification of that presented in Ref. (2). Best agreement was obtained using a value of β equal to zero. This unlikely value for β is an indication that further studies are needed on the reaction mechanism.

The same diffusion coefficients were found to result in good agreement in all cases

$$D_{CO_2} = 8.8E-7, D_{O_2} = 1.7E-6, D_{O^{2-}} = 3.4E-6 \text{ cm}^2/\text{s}$$

These diffusion coefficients have not been measured but are about the values that might be expected based on the specie ionic radii and the diffusion coefficient of Ni²⁺,

Fig. 5. Performance characteristics of cathode B

Fig. 6. Performance characteristics of cathode C

which has been measured as $4.86 \times 10^{-6} \text{ cm}^2/\text{s}$ (10) and estimated to be $1.2 \times 10^{-5} \text{ cm}^2/\text{s}$ (11).

The values obtained for the exchange current densities are presented in Table II. Although the same value of exchange current density was not obtained for all four cathodes, the values are considered to be nearly equal considering the hysteresis present in the performance curves and the accuracy with which the surface areas were determined.

Cathode C, which had the smallest mean pore size and low porosity, was very intolerant to percentage fill and had much higher overpotential at optimum fill.

In order to demonstrate the features of the present model, the agglomerate properties were calculated for cathode A over a range of percentage fills. The changes in the agglomerate number and agglomerate radius as a function of the percentage of cathode void filled with electrolyte are shown in Fig. 8. Here, the number of ag-

glomerates decreases by seven orders of magnitude as the percentage fill increases from 10% to 90%. However, the radius increases by four orders of magnitude over the same fill range.

Figure 9 illustrates the effect of electrolyte content on the relative agglomerate diameter. The relative agglomerate diameter is defined as the ratio of the calculated agglomerate diameter to the pore diameter obtained from a pore spectra curve at a given fill state. For the case of the cathode A, the ratio is less than or equal to one for electrolyte contents below 40%. As the electrode continues to fill, the ratio rapidly increases beyond this point. Since the number of agglomerates decreases and the agglomerate radius increases with electrolyte content, greater liquid-phase diffusional polarization results. At the same time, the agglomerate porosity is increasing, as shown in Fig. 10, and ionic tortuosity is decreasing, as shown in Fig. 11. These decreases would tend to reduce ohmic losses. At a fill state of approximately 40%-50%, these effects balance out, resulting in an optimum in performance as presented in Fig. 4.

Reference (6) indicates that the current density of an *in situ* oxidized nickel cathode structure at optimum elec-

tolerance to percentage fill both increase as the cathode thickness increases, the tolerance of the cathode to electrolyte content increases greatly as the thickness of the cathode is increased. This feature is of great significance in molten carbonate fuel cells, since loss of electrolyte is a major cause for performance decay.

Calculations were also performed using the present model and the structure of cathode A to determine the electrolyte volume tolerance as a function of the cathode thickness. These results are shown in Fig. 14. As can be seen, not only does the cathode overpotential decrease initially as the cathode is thickened, but also the volume tolerance increases. Since the electrolyte volume and tol-

erance to percentage fill both increase as the cathode thickness increases, the tolerance of the cathode to electrolyte content increases greatly as the thickness of the cathode is increased. This feature is of great significance in molten carbonate fuel cells, since loss of electrolyte is a major cause for performance decay.

Conclusions

The homogeneous/agglomerate model of fuel cell cathodes was found to suitably describe the performance characteristics of cathodes as a function of electrolyte content and cathode thickness. These results indicate that an optimum electrolyte content is present in a cathode, with the tolerance of the cathode to electrolyte content depending upon the cathode structure. An optimum thickness also exists for a cathode of given pore structure, with that optimum thickness providing a higher degree of electrolyte volume tolerance than cathodes thinner than the optimum. Further modeling is required in order to account for the true reaction process in a cathode so the effects of reactant composition and pressure can be predicted and further electrode optimization performed.

Conductivity of the LiBF_4 /Mixed Ether Electrolytes for Secondary Lithium Cells

Yoshiharu Matsuda,* Masayuki Morita, and Tooru Yamashita

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwa-dai, Ube, Yamaguchi, Japan

ABSTRACT

Electrolytic conductivity of LiBF_4 has been studied in the mixed system of 1,3-dioxolane with 1,2-dimethoxyethane or with tetrahydrofuran. Relative permittivity (dielectric constant) of the solvents suggested the formation of associated ion pairs in the systems, but the conductivity measured was higher than that expected from the viewpoint of ionic association. Conductivity maxima were observed in the solutions containing about 1:1 (by volume) mixed solvents. Viscosities of the solvent and the solution were also measured, and their contribution to the conductivity change with the solvent composition was discussed. Solute concentration dependence of the molar conductivity was specific for the ether solutions. Apparent activation energy for conduction, which was determined by the temperature dependence of the conductivity, varied with LiBF_4 concentration. Structural specificity of the mixed ether solutions was discussed with these parameters and ^1H NMR spectra of the solutions.

In the development of secondary lithium cells, the choice of a suitable electrolyte system is of great importance (1). It is necessary to secure as high an electrolytic conductivity as possible in order to obtain high charge and discharge currents in practical secondary cells.

* Electrochemical Society Active Member.

Mixed solutions of propylene carbonate (PC) with 1,2-dimethoxyethane (DME), γ -butyrolactone (BL) with tetrahydrofuran (THF), and the like have been used as the solvent of the electrolytic solution in primary lithium cells (2-5). One of the reasons for this is that the improvement of electrolytic conductivity has been realized by

using these mixed solvents (6, 7). However, Besenhard and Eichinger (8) reported that solutions containing PC as a main component were not suited for the electrolytes of secondary lithium cells, because the reaction of the solvents with active Li deposited during charge lowered the cycling efficiency of the Li electrode. Koch and Young (9) pointed out that aliphatic cyclic ethers like THF, which do not have reactive C=O bonds, were better solvents for the secondary cells. Recently, Koch *et al.* (10, 11) showed that 2-methyltetrahydrofuran (2-MeTHF) was much less reactive toward Li than THF, and that higher Li cycling efficiency was obtained in 2-MeTHF containing LiAsF₆. Other ethers (or acetals) such as DME (12, 13), 1,3-dioxolane (DOL) (12-15), and polymethoxy-methanes (16) have also been proposed as the solvents of secondary lithium cells. Sometimes mixed solvents have been used to improve solubility of electrolytic salts. For instance, mixed systems of diethylether (DEE)-THF (17, 18), DEE-DME (18), DEE-DOL (18), THF-DME (19), DME-DOL (12, 13, 19), and THF-2-MeTHF (20) have been examined.

Up to the present, basic properties of these electrolytic solutions, which might relate to the charge-discharge performance of the cell, have not been clarified, except for the solution stability. The authors have studied physico-chemical properties of mixed systems of PC-THF (21, 22), PC-DME (23-25), and BL-THF (26) for primary lithium cells. The mixing effects of the solvents on the conductance and the ionic behavior in the mixed systems were discussed. This paper is concerned with the mixed ether solutions of DOL-THF and DOL-DME as the solvents of secondary lithium cells. Ether-based electrolytes should have different properties from those of PC- or BL-based electrolytes for the primary cells. It is necessary to consider the ionic behavior in the mixed ether solutions since solvent mixing effects on the charge-discharge characteristics of Li and TiS₂ electrodes were really observed in DOL-THF containing lithium tetrafluoroborate (LiBF₄) (27). Polarization of Li and TiS₂ electrodes in LiBF₄/DOL-THF was smaller than that in LiBF₄/DOL or LiBF₄/THF, and the charge-discharge curves of the Li electrode in the mixed electrolyte solution showed stable potential-change during the cycle (27). It has been reported that salts of Lewis acids such as LiAsF₆ decompose DOL (1, 28) and that the use of LiBF₄ lowers cycling efficiency of Li in THF (9). These faults in the use of DOL and LiBF₄, however, would be overcome by mixing ether solvents. The mixed LiBF₄ (1 mol dm⁻³)/DOL-THF solution did not practically polymerize, and the Li cycle efficiency in that solution did not appreciably lower with increase in the cycle number (27). In this work, the electrolytic conductivity of LiBF₄ was measured in the mixed solutions of DOL-THF and DOL-DME. The relation between the conductance and other properties such as viscosity, permittivity, and NMR spectra of the solutions was investigated, and the ionic behavior in the mixed ether systems was discussed.

Experimental

The solvents, DME (Mitsubishi Petrochemical) and THF (Toyo Soda Manufacturing) were purified by the methods described previously (24-26). DOL (Tokyo Kasei Kogyo) was refluxed over CaH₂ for 48h and then fractionally distilled at 75°C. The fraction was stirred over metallic Na for 48h, degassed under reduced pressure, and then distilled at 75°C again (27). LiBF₄ (Morita Chemical Industries, >98%) was used as a supporting electrolyte after drying under reduced pressure at 80°C for 24h. For comparison, LiClO₄ (Ishizu Pharmaceutical) was also used.

The electrolytic conductivity was measured with an impedance bridge using 10 kHz ac (bridge: DRZ-2M, Ando Electric; oscillator: Model 417RC, Kikusui Electronics; synchroscope: DS5016, Iwatsu Electric). The viscosity was measured with a modified Ostwald viscometer or with a B-type (rotator-type) viscometer (BL-type, Tokyo Keiki). The relative permittivity (dielectric constant) was determined by a bridge method using 10 kHz ac (bridge:

TR-1C; oscillator: WBG-9; detector: BDA-9, Ando Electric). The NMR spectra of the solvents and the solutions were measured under 100 MHz field. These measurements were mainly carried out at 30°C, except for temperature dependence experiments. In most cases, the data will be graphically described with marks of appropriate size in which standard deviations of individual points are included.

Results and Discussion

In general, electrolytic solutions with high conductance should be realized when solvents with high permittivity and low viscosity are used (29). Ether solvents have low viscosity but have low permittivity, compared with PC or BL. Figure 1 shows the relative permittivity, ϵ_r , against the solvent composition, in mole percent (m/o), for the mixed systems of DOL-THF and DOL-DME at 30°C. The relative permittivity decreased almost linearly with DOL concentration in the solvent for both systems, though a little deviation from linearity was observed in DOL-DME. In these mixed ether systems, an additive property of each solvent determines almost the relative permittivity of the mixed solvent. This is similar to the results obtained for the mixed systems containing PC (22, 23, 25).

According to the ion association model by Bjerrum (30), the critical distance for ion-pair formation, q , is given by Eq. [1]

$$q = \frac{|z_i z_j| e^2}{8\pi\epsilon_0 \epsilon_r kT} \quad [1]$$

where ϵ_0 is the permittivity of a vacuum, z 's are charge numbers of ions, and other symbols have their usual meanings. For a 1:1 electrolyte in DOL-THF and DOL-DME, q 's were calculated, and the results are shown in Table I. The values are about four times larger than those in the PC-based electrolytes, which are 0.5-1 nm in DME (or THF) concentration of 0%-70% (22, 25). The degree of association is given by Eq. [2] (30, 31)

$$1 - \alpha = \frac{4\pi Nc}{1000} \int_a^q \exp\left(\frac{|z_i z_j| e^2}{4\pi\epsilon_0 \epsilon_r kT} \frac{1}{r}\right) r^2 dr \quad [2]$$

where α is the degree of dissociation, a is the distance of closest approach of two ions, r is the distance from the center of ion j , N is the Avogadro constant, and c is the molar concentration of the salt. The degree of association, $1 - \alpha$, was calculated as a function of α . The results are

Fig. 1. Relative permittivity (ϵ_r) of the mixed solvent at 30°C

Table I. Relative permittivity (ϵ_r) and critical distance for ion-pair formation (q) in DOL-THF and DOL-DME systems at 30°C

vol% DOL	DOL-THF		DOL-DME			
	mol% DOL	ϵ_r	q/nm	mol% DOL	ϵ_r	q/nm
0	0.0	7.51	3.67	0.0	7.21	3.83
25	28.1	7.31	3.77	33.3	7.08	3.89
50	53.9	7.12	3.87	60.0	6.97	3.95
75	77.8	6.97	3.98	81.8	6.83	4.07
100	100.0	6.74	4.09	100.0	6.74	4.09

shown in Fig. 2. The a in the LiBF₄ solution was not practically determined, but would be less than 1 nm for a moderate concentration of the electrolyte (22, 25, 27). Thus, the relatively large values of q in DOL-THF and DOL-DME suggest that the ion-pair formation, or the ion association, is liable to occur in these systems.

Figures 3 and 4 show the viscosities, η , of the solvents and of the 1 mol dm⁻³ LiBF₄ solutions, respectively. The variations of the solvent viscosity deviated slightly in the negative direction from straight lines which correspond to the additive property. The viscosities of the electrolytic solutions also varied nonlinearly with the solvent compositions, and increased markedly in high DOL concentration regions. These are similar to the results obtained in mixed systems of PC-DME and PC-THF (22, 23, 25), but the values in the present systems are much smaller than those in the PC-based systems. This fact means that the present systems would be preferable to the ionic mobility than the PC-based systems.

The molar conductivities, Λ , of the 1 mol dm⁻³ LiBF₄ solutions at 30°C are shown in Fig. 5. The conductivity in the mixed solvent was higher than that in each pure solvent. The conductivity became maximum at about 40 m/o DOL in DOL-DME and at about 60 m/o DOL in DOL-THF. The DOL-DME solutions had much higher conductivity than the DOL-THF solutions. The maximum conductivities were 4.1 and 2.5 S cm² mol⁻¹ in DOL-DME and DOL-THF, respectively. These values were higher than those expected from the relative permittivity of the solvents. It is considered that ionic behavior in these ether systems could not be expressed by Bjerrum's classical model. As shown in Fig. 2, low permittivity of the solvents seemed to lead to extremely high degree of association, if Bjerrum's model is adopted. However, the observed molar conductivity suggested that considerable amounts of mobile ions exist in these ether-based electrolytes. The degree of dissociation, α , can also be estimated from the ratio of Λ and Λ_0 (Λ_0 : molar conductivity under the infinite dilution condition). In the present systems, however, Λ_0 of LiBF₄ was not determined because of complicated concentration dependence of Λ , which will be mentioned later. Thus, α of LiBF₄ in mixed DOL-DME or

Fig. 3. Viscosity (η) of the solvent at 30°C

DOL-THF could not be discussed quantitatively. As DME and THF have high donicities (32), Li⁺ ion would be firmly solvated by coordination in the DME- or THF-based electrolyte. This is one of the reasons for which the present electrolyte systems show considerably high conductance in spite of the low permittivity of the solvents. As another contribution to the high conductance in these ether-based electrolytes, the formation of conductive ion triplets was also taken into account, which will be discussed in a later part of this section.

Figure 6 shows the molar conductivities of 1 mol dm⁻³ LiClO₄ solutions. The conductivity maxima were observed in these solutions like in the LiBF₄ solutions. The conductivity of LiClO₄/DOL-DME and LiClO₄/DOL-THF were 9.1 and 4.9 S cm⁻² mol⁻¹, respectively, which were about twice those of the LiBF₄ solutions. However, these LiClO₄ solutions containing DOL would not be suited for practical use, owing to the possibility of explosion (33).

Sometimes DEE has been mixed with THF, DME, DOL, and 2-MeTHF for the purpose of raising LiAsF₆ solubility (17, 18). However, the conductivity decreased gradually with increasing DEE concentration in LiAsF₆/DEE-THF (17). The variations in the molar conductivities of LiBF₄/DEE-THF and LiBF₄/DEE-DOL are shown in Fig.

Fig. 4. Viscosity (η) of the mixed solution containing 1 mol dm⁻³ LiBF₄ at 30°C.

Fig. 5. Molar conductivity (Λ) of the mixed solution containing $1 \text{ mol dm}^{-3} \text{ LiBF}_4$ at 30°C .

7. Solubility of LiBF_4 decreased by DEE addition and it became less than 1 mol dm^{-3} at 75 m/o DEE in DEE-THF and at 25 m/o DEE in DEE-DOL. The molar conductivities of LiBF_4 were relatively low in the DEE-based solutions, and no conductivity maximum was observed either in DEE-THF or in DEE-DOL, in contrast to DOL-DME and DOL-THF. On the other hand, it has been reported that, in 2-MeTHF-THF, the conductivity of LiAsF_6 varied almost linearly with THF concentration (20). Thus, the conductivity maxima observed in the present mixed-

ether systems might be peculiar to such systems as DOL-DME and DOL-THF.

Figure 8 shows Walden products, $\Lambda\eta$, for $1 \text{ mol dm}^{-3} \text{ LiBF}_4$ in DOL-DME and DOL-THF, as a function of solvent composition. The Walden products had also maxima in the mixed solvents. This is probably due to changes in size of the ions with solvent composition. In general, the size of solvated ion is closely associated with donor and acceptor properties of the solvent (34). The donicity (DN) of solvent is concerned in the solvation of cation and the acceptor number (AN) of the solvent determines the solvation of anion. The DN and AN of DOL have not been measured, but it can be assumed that they are not greatly different from those of dioxane (DO) whose structure is analogous to that of DOL. According to Gutmann's data (32), the order of DN becomes $\text{DME}(24) > \text{THF}(20.0) > \text{DOL}(\text{DO}: 14.8)$ and the order of AN is $\text{DOL}(\text{DO}: 10.8) > \text{DME}(10.2) > \text{THF}(3.9)$. This suggests that, in the systems of DOL-DME and DOL-THF, DME and THF acting as donors mainly interact with Li^+ ion, and DOL acting as an acceptor mainly interacts with the anions. These differences in the donor and acceptor properties of the solvents probably cause the conductivity maxima observed in the mixed solvents and the difference in the conductivity between the solutions of LiBF_4 and LiClO_4 .

The molar conductivities at -20°C are shown in Fig. 9. The conductivities of the LiBF_4 solutions did not appreci-

Fig. 8. Walden product ($\Lambda\eta$) for the mixed solution containing $1 \text{ mol dm}^{-3} \text{ LiBF}_4$.

ably lower at low temperature. Their maximum values at -20°C are 70%-80% of those at 30°C . This is probably due to low viscosity of the ether solvent even at -20°C . The relatively high conductance of these electrolytes at low temperature is a very attractive property from the standpoint of practical use. Abraham and Goldman (20) have examined mixed 2-MeTHF-THF system in order to gain high conductance of the LiAsF₆ solution even at low temperature.

Figure 10 shows the LiBF₄ concentration dependence of the molar conductivity at 30°C . The mixed solvents used here are DOL-DME (1:1 volume = 60 m/o DOL) and DOL-THF (1:1 volume = 54 m/o DOL). Specific conductances, κ , of 3 mol dm⁻³ LiBF₄ were 9×10^{-3} S cm⁻¹ in DOL-DME and 6×10^{-3} S cm⁻¹ in DOL-THF. In the present systems shown in Fig. 10, the profiles of the concentration dependence were similar to each other. The molar conductivity in the low concentration range did not linearly vary with a square root of LiBF₄ concentration. That is, the conductivity variation did not follow the Onsager equation as shown in strong electrolytes. LiBF₄ in these solvents acted as a weak electrolyte, and accurate estimates of Λ_0 were impossible. In every case, a maximum of the molar conductivity appeared in the high concentration range of 1.0-1.5 mol dm⁻³. Similar variations in molar conductivity have been reported in sodium tetrabutylaluminate (NaAlBu₄)/THF (35) and LiBF₄/THF (36). These phenomena might be interpreted by some changes in the conduction mechanism from high concentration to low concentration. On the basis of molecular weights of the solvents and densities of the solutions, the concentration of solvent in the 1 mol dm⁻³ LiBF₄ solution was estimated to be 10-15 mol dm⁻³. This means that the molar ratio of the solvent molecule to Li⁺ ion in the 3 mol dm⁻³ LiBF₄ solution would be about 4-5:1.

In the NaAlBu₄/THF solution, the following equilibrium has been proposed (35)

At low Na⁺ concentration, Na⁺ ion is solvated by four THF molecules and forms a stable 1:4 complex. The fraction of the 1:1 complex increases with increasing Na⁺ concentration because of lowering in the relative concentration of free THF. Similar equilibria would be present in the LiBF₄/THF system (37). If the solvation number at low concentration is different from that at high concentration, the ionic mobility should be markedly influenced by the electrolyte concentration. On the other hand, it is believed that equilibria between nonconducting ion pairs and conductive ion triplets, such as Eq. [4], are present in solvents of relative permittivity below 10 (36, 38).

James (36) suggested that the maximum at 1.0-1.5 mol dm⁻³ in molar conductivity of LiBF₄/THF was associated with these equilibria and with the sharply increased solution viscosity at high concentration. Consequently, it is possible that two above-mentioned effects, i.e., change in solvation of Li⁺ ion and conversion of ion pairs to ion triplets, exist in the present mixed ether systems.

Temperature dependence of the molar conductivity was measured in the range of 20°C - 40°C . Typical Arrhenius plots are shown in Fig. 11. The conductivities increased normally with increasing temperature in the solutions of high LiBF₄ concentration (1.5 mol dm⁻³). At low LiBF₄ concentration (0.01 mol dm⁻³), however, the slopes of the plots had opposite sign. This means that the conductivities of the low concentration solutions have negative activation energies. The apparent activation energies for conduction were calculated from the

Fig. 9. Molar conductivity (Λ) of the mixed solution containing 1 mol dm⁻³ LiBF₄ at -20°C .

slopes of the $\log \Lambda$ vs. T^{-1} plots for the LiBF₄ concentration of 0.01, 0.05, 1.0, and 1.5 mol dm⁻³. Reasonable values from the viewpoint of ionic motion were obtained in 1.5 mol solutions [4.16 kJ mol⁻¹ for THF, 4.77 kJ mol⁻¹ for DME, 4.43 kJ mol⁻¹ for DOL-THF(1:1), 4.48 kJ mol⁻¹ for DOL-DME(1:1)]. The activation energy tended to decrease with decreasing LiBF₄ concentration. At 0.05 and 0.01 mol dm⁻³, the calculations gave negative activation energies. It was impossible to interpret the negative energies quantitatively, but the drops in the activation energy with lowering salt concentration were probably due to the equilibria for the Li⁺ ion solvation and/or for the ion pair-ion triplet conversion. It was thought that ion conduction occurred mainly in the forms of the 1:1 complex, $[\text{Li} \cdot \text{THF}]^+$, and/or of the ion

triplets, $[\text{Li}_2\text{BF}_4]^+$ and $[\text{Li}(\text{BF}_4)_2]^-$, in the solutions of high LiBF_4 concentration. At lower concentrations, the equilibria should be displaced, so that the components of 1:4 complex and/or the ion pairs increased with decreasing LiBF_4 concentration. Thus, it was considered that the negative activation energies appeared since the equilibria are dependent on temperature.

The ^1H NMR spectra of the mixed ether solutions were measured, so as to obtain further information on the solution structure. Typical spectra of the mixed solvents and the effects of LiBF_4 concentration on the spectra are shown in Fig. 12 and 13 for DOL-DME and DOL-THF, respectively. The spectra shifted to the lower field (higher δ values) at high LiBF_4 concentration (1.5 mol dm^{-3}). Similar results have been reported in the case of the spectra of $\text{LiB}(\text{CH}_3)_4$ ($0.5\text{--}2.2 \text{ mol dm}^{-3}$)/DOL system (14). These changes in the proton chemical shifts to the lower magnetic field show that the increase in electrolyte concentration increases the number of the solvated ether molecules where the electron density around the proton is reduced by the solvation or the complex formation. The changes in the chemical shifts of DME were larger than those of DOL in DOL-DME. The shift of α -proton in THF (c in Fig. 13) changed most remarkably in DOL-THF. It is presumed that DME or THF solvates to Li^+ ion more strongly than DOL does, though the magnitude of the change in the chemical shift does not quantitatively correspond to the strength of the coordination bond. These results are consistent with the previous discussion based on the donicities and acceptor numbers of the solvents. It is thought that the contribution of the solvation or the ion-solvent interactions to the conductivity play a large part in the ether-based electrolyte like the present systems. However, further information concerning their solvation chemistry is required.

Summary

Electrolytic conductivity and other physicochemical properties were measured for LiBF_4 solutions of DOL-THF and DOL-DME mixed systems. The results obtained are summarized below.

1. In spite of low permittivities of the solvents, the conductivities of the solutions were moderately high.

Fig. 12. ^1H NMR spectrum of the DOL-DME mixed system (1:1 volume = 60 m/o DOL). (A): a typical spectrum of the solvent. (B): LiBF_4 concentration dependence of the proton chemical shifts in DOL-DME.

2. The maximum conductivities were obtained in the solutions consisting of the mixed solvents (about 1:1 by volume).

3. The salt concentration dependence and the temperature dependence of the molar conductivity suggested that

Fig. 13. ^1H NMR spectrum of the DOL-THF mixed system (1:1 volume = 54 m/o DOL). (A): A typical spectrum of the solvent. (B): LiBF_4 concentration dependence of the proton chemical shifts in DOL-THF.

the solvation of Li⁺ ion and/or the ion-pair formation varied with salt concentration.

4. The changes in the proton chemical shifts which were probably caused by the coordination of the solvents to Li⁺ ion were observed in the solutions of high LiBF₄ concentration.

Electrode Kinetics of Fuel Oxidation at Copper in Molten Carbonate

S. H. Lu* and J. R. Selman**

Department of Chemical Engineering, Illinois Institute of Technology, Chicago, Illinois 60616

ABSTRACT

Copper appears to be a promising anode material for the molten carbonate fuel cell, as an alternative to nickel. Therefore, polarization data have been obtained for oxidation of fuel gases on a fully immersed copper rod. The electrode-kinetic parameters have been determined using the potential-step technique. The reaction mechanism on copper appears to be similar to that on nickel, and the exchange current density only slightly less than that on nickel. The importance of a correct extrapolation technique to obtain the time-zero current response is emphasized.

In molten carbonate fuel cell (MCFC) development, exploration of suitable materials for the electrode is a persistent effort. A good electrode material must be cheap, stable, durable, and compatible with other cell components. After testing, many materials in terms of performance and stability, and surveying the availability and cost of each prospective material for commercialization, the

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

conclusion is that no one material shows definite superiority over the others in all respects. The decision is a tradeoff and depends on what is critical with respect to its use: whether high catalytic activity is necessary; whether the cost of material is a primary consideration; whether the worldwide supply/demand is the first concern; etc.

The currently used anode material is porous sintered nickel, stabilized with 2-10 weight percent (w/o) chromium to inhibit sintering. These nickel anodes exhibit

good, stable electrochemical performance. However, nickel-based anodes are relatively high cost components. In addition, questions arise regarding the availability of nickel in the quantities required for commercialization of MCFC power plants. Exploratory polarization data for hydrogen oxidation have shown relatively little dependence on the nature of the metal (1, 2).

Copper is presently being considered as an alternative anode material based upon its greater domestic availability, significantly lower cost, and expected chemical stability in the fuel cell anode environment. The objective of this work was to ascertain the electrode-kinetic suitability of copper as an alternative anode material. Since extensive data were available for nickel (3), a comparative study was made of copper and nickel, using the same techniques and procedures in both cases.

Apparatus and Procedure

The experiments were conducted in a hermetically sealed cylindrical closed-end alumina tube (AD-998, nominally 99.8% recrystallized Al_2O_3), containing an alumina crucible (Coors Porcelain Company, Golden, Colorado) of 250 ml capacity. The crucible was hung on Pt-Pd hooks from alumina supports fitted with pierced baffles to minimize temperature gradients. The whole assembly was suspended from a metal header attached to a leveling table and placed in a vertical tubular furnace. After assembly, the crucible rested on a piece of alumina firebrick placed at the bottom of the outer alumina jacket. The most important feature of the apparatus was its vacuum tightness; otherwise, the gas composition above the melt, and consequently the electrode potentials, would become inaccurate, owing to effects such as the diffusion of air from outside, as well as thermal dissociation of the molten carbonates. The apparatus was rendered vacuum tight by means of O-rings between the alumina jacket and the stainless steel header. Similarly, the outer sheaths of the working and reference electrodes, and the gas bubbler tube were sealed by O-rings.

The configuration of the cell is shown in Fig. 1. The working electrodes were made of pure nickel and copper rods. The nickel and copper were Marz grade with purity of 99.995% and 99.999%, respectively (Materials Research Corporation, Orangeburg, New York). The dimensions of the electrodes were measured by micrometer to within ± 0.01 mm. The surface area was 4.25 ± 0.05 cm². The rod was threaded at the center and screwed to a lead wire of the same material, which was sheathed in an alumina tube constructed in such a way as to prevent meniscus effects. The working electrode was completely immersed in the melt which was about 5 cm deep. The counterelectrode was a gold sheet fitted as an inner liner of the alumina crucible so as to surround entirely the working electrode and, thus, ensure uniform current distribution. A gold wire in equilibrium with a 33.3% O_2 -66.7% CO_2 gas mixture inside an alumina tube served as the reference electrode. Electrolyte in the tube communicated with the bulk melt through a tiny hole (0.038 cm diam) at the bottom of the tube. Since the tube was pressed against the flat bottom of the crucible, diffusive and convective mixing between the reference and the bulk electrolyte was restricted. The end of the gold wire was ca. 2.5 cm above the bottom of the tube; this location was found to be very important to ensure stable potential readings. The reference gas mixture was supplied through the inner alumina tube (which also carried the gold wire) and escaped through the annulus between the inner and outer tubes of the electrode. The flow rate was kept at 2 ml/min. Two reference electrodes with separate gas supplies were used as an insurance against accidental occurrence of plugging and instability. Under normal conditions, their readings were within 2 mV of each other.

Electrolyte mixtures were prepared from Li_2CO_3 and K_2CO_3 (Fisher analytical reagent). The composition used in this study was 62 mole percent (m/o) Li_2CO_3 , 38 m/o K_2CO_3 . The melting point of this eutectic mixture is 761 K (488°C). Fuel gas mixtures were purchased premixed from

Fig. 1. Configuration of cell

Matheson Gas Company (Joliet, Illinois); the gas compositions were verified by gas chromatographic analysis. The fuel flow rate was kept at 50 ml/min, adjusted by pressure regulators and capillary flowmeters. Humidification of the inlet gas was performed by passing it through a column of water in a large tube, and from there to the gas bubbler in the working electrode compartment. The saturator efficiency was checked by gas-chromatographic analysis of the humidified gas, as reported previously (3). The gas line from the humidifier to the bubbler was kept at 403 K (130°C) to prevent condensation of water. A long nickel wire was inserted in the gas line to facilitate the water-gas shift reaction.

The whole apparatus was heated up slowly (100°C/h). Because of the tendency of the melt to creep along the surfaces in direct contact with the molten carbonate, care was taken to turn on the reference and fuel gases before the melting point was reached; if this was not done, plugging of the tubes was likely to occur. A Universal Programmer (Model 175, Princeton Applied Research, Princeton, New Jersey) was used to control the potentiostat (Wenking, Model ST72, Gerhard Bank Elektronik, Germany). The output voltage was monitored by a Fluke Type 8020A Digital Voltmeter (John Fluke Company, Seattle, Washington). Steady-state currents were recorded on an Omnigraphic 2000 X-Y recorder (Houston Instrument, Austin, Texas). The transient response following a potential step was displayed on a Nicolet Explorer II Digital Oscilloscope (Nicolet Instrument Company, Madison, Wisconsin), which has a risetime of 50 ns or less with 5 μV resolution.

Feed Gases and Their Equilibrium Potentials

In accordance with the envisaged application of the molten carbonate fuel cell, five typical fuel gases (4) were chosen for these experiments, ranging from high Btu to very low Btu. These feed gases were produced from various initially dry mixtures by saturation with water at different dewpoints. Dewpoints were chosen in such a way as to prevent carbon formation at lower temperatures encountered by the gas during heating to cell temperature.

Two reactions are involved in establishing the equilibrium compositions of these gas mixtures: the water-gas shift reaction

and the steam reforming reaction

$$K_s = \frac{P_{\text{H}_2} P_{\text{CO}_2}}{P_{\text{CO}} P_{\text{H}_2\text{O}}}$$

and

$$K_m = \frac{P_{\text{CO}} P_{\text{H}_2}^3}{P_{\text{CH}_4} P_{\text{H}_2\text{O}}} \quad [3]$$

can be found in the literature [$K_s = 1.96$, $K_m = 2.68$ at 923 K (650°C)] (5). The compositions of the dry gas mixtures, the compositions corresponding to complete shift equilibrium and those corresponding to simultaneous equilibrium of the shift and the steam reforming reactions, are listed in Table I. The open-circuit potentials based on these gas compositions, as well as the experimentally measured open-circuit potentials are shown in Table II. The observed open-circuit potentials are in good agreement with the theoretical values obtained, assuming simultaneous equilibrium of the shift and the steam reforming reactions (6).

Steady-State Results

Steady-state polarization curves for high Btu fuel gas at nickel and at copper in $\text{Li}_2\text{CO}_3/\text{K}_2\text{CO}_3$ eutectic at 923 K (650°C) are shown in Fig. 2 and 3, respectively. In these figures, measurements made under conditions of continuous bubbling (50 ml/min) are compared to those made in the quiescent melt. Nickel supports a higher current density than copper at the same polarization. In both cases, much higher current densities are obtained with the melt subjected to continuous bubbling. The difference is obvious even in the low polarization region (20 mV). This demonstrates that the electrode process is under partial diffusion (mixed) control. The persistent presence of diffusion control in the anode process can be explained either by depletion of the reactant (H_2) or buildup of the re-

action products (H_2O and CO_2) near the electrode surface, or both. Equating activation overpotentials to steady-state potentiostatic measurements would give too low a value for the exchange current density. Near-equilibrium resistances (7), composed of kinetic and mass-transfer effects if ohmic potential drop is neglected, can be calculated from the current densities at a total polarization of 20 mV under identical conditions of continuous bubbling

$$R_{\text{Ni}} = \frac{\Delta \eta}{\Delta i} = 1.4 \times 10^2 \Omega\text{-cm}^2$$

$$R_{\text{Cu}} = \frac{\Delta \eta}{\Delta i} = 3.3 \times 10^2 \Omega\text{-cm}^2$$

The resistance for nickel is lower than that of copper. Under the same hydrodynamic conditions, the mass-transfer contributions to these resistances are equal ($RT/nF i_{\text{lim}}$). Comparing the above resistances, nickel appears to support a larger exchange current density than copper.

Potential-Step Transient

Technique and interpretation.—The potential step technique with appropriate IR compensation has been proven to be valid for separating activation (kinetic) and mass-transfer effects under mixed control conditions (3). In the cell configuration used here, an appreciable distance separates the reference and working electrodes (Fig. 1). The ohmic resistance (typically 5Ω) causes a potential drop which contributes significantly to the controlled potential. In order to control the potential drop across the working electrode/solution interface accurately, one must resort to an IR-compensation technique. An external voltage divider was used to pick up part of the voltage at the current recording terminal of the potentiostat, and feed this back into one of the potentiostat control inputs. The

positive feedback voltage was then adjusted until the system became almost unstable. This resulted in a maximum obtainable compensation of the ohmic resistance, which was confirmed by the current interruption technique. A typical oscilloscope trace obtained using this technique is shown in Fig. 4. The effect of positive feedback can be seen, where the upper trace is with compensation, and the lower one without. With appropriate IR compensation, the capacitive current can be clearly distinguished from the faradaic current; it has become negligible at 0.2 ms (Fig. 4).

Determination of the kinetic parameters of an electrode reaction by the potential step technique generally involves two difficulties, namely (i) superposition of activation and diffusion polarization in the presence of a double-layer charging current, and (ii) occurrence of a multistep reaction mechanism.

Upon application of a potential step to the working electrode, direct observation of the faradaic current is at first prevented by the double-layer charging current which, however, as noted above, decays rapidly. Therefore, if one only uses data points obtained after a period of time long enough for the charging current to become negligible, and makes a plot of current density vs. some appropriate function of time, then the activation current, free from the effects of mass transfer, may be obtained by backextrapolation of the transient current to time zero.

The second difficulty cannot be overcome by experimental means, and will be discussed in some detail below. First, however, an important aspect of the treatment of potential-step data needs to be considered.

An analytical solution is available only for first-order kinetics involving a single reacting species and product (8). The current-time relationship for the reaction

is, as shown by Gerischer and Vielstich

$$i = i(0) \exp(\lambda^2 t) \operatorname{erfc}(\lambda \sqrt{t}) \quad [5]$$

Here $i(0)$ is the "kinetic" current density corresponding to the potential step, η , and the expression for λ can be found in Ref. (8). For small time periods, this solution can be linearized

$$i = i(0) \left(1 - \frac{2}{\sqrt{\pi}} \lambda \sqrt{t} \right) \quad \text{for } \lambda \sqrt{t} < 1 \quad [6]$$

Thus, the current density is a linear function of \sqrt{t} for small time periods, and \sqrt{t} appears to be the appropriate simple function of time for backextrapolation to $i(0)$. Several papers discuss the criteria of satisfactory extrapolation, and possible improvements (9, 10). However, in the literature, two other techniques of extrapolation are found. They were devised either for ease of use, or for assumed high precision. These techniques are: (i) linear extrapolation. This technique, adopted by Ang and Sam-

mells, (3) is the easiest way to process the data. The near-linear initial section of the oscillogram following decay of capacitive current is selected and extrapolated back to time zero, which yields $i(0)$. (ii) Analysis in Laplace space. Some authors have analyzed their experimental data in Laplace space (11). This has certain advantages of accuracy and versatility, as it utilizes the entire time span of the transient and avoids approximation (12). It should be especially useful in cases where the inverse Laplace transformation cannot be performed, or where the inverse form can only be handled by approximation.

To compare the results obtained by these techniques with the simple \sqrt{t} extrapolation, the time variation of current density following a potential perturbation of +100 mV from the rest potential, is treated by each of the three methods. Figure 5 shows the oscillogram of the current density and the results of linear and \sqrt{t} extrapolation. The kinetic current, $i(0)$, is obtained by extrapolating currents between 0.3 and 0.5 ms to time zero. The trace of the \sqrt{t} extrapolation, bending up near $t = 0$, yields a higher kinetic current than does linear extrapolation. In this particular case, the results are 100.5 and 76.4 mA/cm², respectively.

In the case of Laplace-space analysis, although the data span the entire period of 0-1s, the first charging-free datum point is at $t = 0.8$ ms. Since the current density is weighted by an exponential function in the Laplace transformation, neglecting the initial portion of the transient will cause a significant error. Although analysis in Laplace space utilizes more points in the transient, the precision of this approach is limited by the double layer charging period. To remedy this problem, currents before 0.8 ms were generated by \sqrt{t} extrapolation and included in the integration. The results are shown in Fig. 6. The kinetic currents for three time intervals are 47.9, 104.7, and 291.0 mA/cm², respectively. Linearity is satisfied for all cases, but the kinetic currents are very sensitive to the time interval used for extrapolation. Comparing methods of reducing potential-step data, we conclude that: (i) Extrapolation vs. t (linear) yields too low a value of $i(0)$, (ii) extrapolation vs. \sqrt{t} (theory) yields satisfactory values of $i(0)$ if the time interval is 0.3-0.5 ms, and (iii) Laplace-transform taken over 0.2-1000 ms yields $i(0)$ identical with extrapolation vs. \sqrt{t} , but including data at less than 0.2 ms yields too high a value of $i(0)$.

Application to nonlinear kinetics.—Strictly speaking, the procedures described above are valid only for a generalized redox reaction Eq. [4]. Although such a reaction can take place in any number of chemical and electrochemical elementary steps, one of these is assumed to be rate determining so that the current is determined solely by semi-infinite linear diffusion of the reactant and product of this step, and by the first-order kinetics of the step. It is also assumed that: (i) none of the species taking part in the reaction sequence is strongly adsorbed on the electrode surface, and (ii) the intermediates are not diffusing

Fig. 4. Variation of current with time at a copper electrode. The upper trace is with IR-compensation, the lower one without compensation.

Fig. 5. Extrapolation of potential-step response vs. \sqrt{t} (upper) or t (lower).

Fig. 6. Analysis of data in Laplace space

into the bulk solution. However, many reactions involve multiple components and multistep charge transfers. These kinetic complications frequently generate fractional reaction orders for reactants and products (3). Clearly, the previous procedures are not *ipso facto* applicable directly to potential step data for such a case. A more extensive analysis should be made. This analysis may well lead to a different but more appropriate technique for data treatment technique; or, on the other hand, it may show that the basic features of the Gerischer-Vielstich analysis (8) are applicable.

To investigate the effect of fractional reaction order on the current-time behavior, consider a general electrode reaction

where p and q are reaction orders for S_r and S_o , respectively. At $t = 0$, a potential step is applied to the working electrode. Following the same procedures as Newman (13), the boundary value problem can be described by the following equations

$$\frac{\partial C_o}{\partial t} = D_o \frac{\partial^2 C_o}{\partial x^2}, \quad \frac{\partial C_r}{\partial t} = D_r \frac{\partial^2 C_r}{\partial x^2} \quad [8a, 8b]$$

with the boundary and initial conditions

$$C_o(x, 0) = \bar{C}_o, \quad C_r(x, 0) = \bar{C}_r \quad [9a, 9b]$$

$$C_o(\infty, t) = \bar{C}_o, \quad C_r(\infty, t) = \bar{C}_r \quad [10a, 10b]$$

$$pD_o \left(\frac{\partial C_o}{\partial x} \right)_{x=0} + qD_r \left(\frac{\partial C_r}{\partial x} \right)_{x=0} = 0 \quad [11]$$

$$i = \bar{i}_o \left[\left(\frac{C_r}{\bar{C}_r} \right)^p \exp \left(\frac{\alpha n F}{RT} \eta \right) - \left(\frac{C_o}{\bar{C}_o} \right)^q \exp \left(- \frac{(1-\alpha)nF}{RT} \eta \right) \right] \quad [12]$$

Here x is the distance from the electrode surface, \bar{C}_o and \bar{C}_r are the initial concentrations of the substances S_o and S_r , respectively, D_o and D_r are the respective diffusion coefficients, and α is the symmetry factor. η is the overall overpotential which consists of surface (η_s) and concentration (η_c) overpotentials. \bar{i}_o is the exchange current density at the bulk concentration.

Equations [8]-[12] have been solved numerically assuming the following set of parameters for illustration purposes

$$D_r = D_o = 1.0 \times 10^{-5} \text{ cm}^2/\text{s}, \quad \bar{C}_r = 1.0 \times 10^{-5} \text{ mol/cm}^3\text{-atm}$$

$$\bar{C}_o = 4.0 \times 10^{-6} \text{ mol/cm}^3\text{-atm}, \quad \eta = 0.1V, \quad \bar{i}_o = 10 \text{ mA/cm}^2$$

$$T = 923 \text{ K}, \quad n = 1$$

The following procedure is used to obtain the systematic errors caused by the linear and the square-root-of-time extrapolations. Data points (i - t pairs) are generated by solving Eq. [8]-[12] for the time span 0.3-0.5 ms. The initial current (current at $t = 0$) is then obtained from these data points by either linear or \sqrt{t} extrapolation. The true and extrapolated initial currents are compared to obtain the systematic errors.

The numerical method which was employed in solving Eq. [8]-[12] has been described by Feldberg (14). The accuracy of this numerical approach was demonstrated by comparing the numerical results with the analytical solutions in the case of $p = q = 1$, and the results differed by less than 0.02%. The systematic errors caused by the two extrapolation procedures for various values of p and q are evaluated and listed in Table III. The maximum error found for square-root-of-time extrapolation is about 3%. However, the value estimated by linear extrapolation is more than 10% lower than the exact value. This result is not surprising; in the conventional trial-function expansion method for solving the differential equations, the known solution of a simplified problem is often used as a first approximation (15), since it usually has similar behavior in a limited range. In the present case, since the linearized form (Eq. [6]) is a good approximation for the first-order reaction, it is reasonable to assume that the same functional form (\sqrt{t} dependence at short times) is applicable to the case of fractional reaction orders.

Table III. Numerical solutions for various values of fractional reaction order p , assuming $p = q$, and relative errors caused by two extrapolation procedures

$i(0)$ = Initial current density (10^{-2} A/cm 2).
 t = Time (ms).

This investigation, therefore, leads to the conclusion that the square root of time is an appropriate form for short time extrapolation, even in the case of fractional reaction orders. The value obtained by the linear extrapolation is likely to be too low. The conclusions of this analysis are applied in the following sections.

Results.—Kinetic parameters for the hydrogen-oxidation reaction on nickel have been reported previously by Ang and Sammells (3). Some of their measurements were repeated in this work, using the same procedure as these authors, for a more direct comparison with the data at copper. Exchange current densities for high and intermediate-Btu gases at nickel electrode were measured. The kinetic current, $i(0)$, was obtained by linear extrapolation of the current between 0.3 and 0.5 ms, to time 0. In this manner, the activation polarization curve was obtained in the -100 to $+100$ mV overpotential region; from this, the Allen-Hickling plot was constructed and the exchange current density calculated. At least three measurements were taken at each overpotential, and sufficient time was allowed to let the open-circuit potential return to normal (usually 15 min). The measurements were taken in the absence of gas bubbling. The raw data were fed into a regression analysis program to get the mean value and the standard deviation. Exchange current densities for high and intermediate-Btu fuel gas were 37 and 44 mA/cm², respectively. These values compare well with those of Ang and Sammells, who obtained 35 and 42 mA/cm², respectively, under the same experimental conditions and using the same potential-step technique.

However, if the dependence of current density is assumed to be with the square root of time, in agreement with the theory, the extrapolation leads to higher values of i_0 at nickel than given by Ang and Sammells. The exchange current densities at nickel are 51 and 59.5 mA/cm² for high and intermediate Btu gases. The corresponding Allen-Hickling plot for intermediate Btu fuel at nickel is shown in Fig. 7.

The true (activation) polarization curve and Allen-Hickling plot at copper in the Li/K eutectic at 923 K (650°C), using intermediate Btu fuel, are shown in Fig. 8 and 9, respectively. For this gas composition, the i_0 value at copper was found to be 28.7 mA/cm². Five different gas compositions ranging from high Btu to very low Btu fuel gas were thus measured. The corresponding i_0 values are tabulated in Table IV.

From the known values of the exchange current density for the five different gas compositions, the dependence of the exchange current density, i_0 , on fuel composition can be determined. Since equilibrium conditions exist in the melt, the CO content can be determined from the respective concentrations of H₂, CO₂, and H₂O, using the equilibrium constants. The dependence of exchange current density on gas composition is assumed to be

Fig. 7. Allen-Hickling plot for nickel electrode in Li/K eutectic with intermediate Btu fuel (42.8% H₂). Assumed: $\alpha_a + \alpha_c = 2$.

Fig. 8. Activation polarization for copper in Li/K eutectic with intermediate Btu fuel (42.8% H₂) at 923 K (650°C).

Fig. 9. Allen-Hickling plot for copper in Li/K eutectic with intermediate Btu fuel (42.8% H₂) at 923 K (650°C). Assumed: $\alpha_a + \alpha_c = 2$.

$$i_0 = i_0^0 [\text{H}_2]^a [\text{CO}_2]^b [\text{H}_2\text{O}]^c \quad [13]$$

where i_0^0 is the standard exchange current density (mA/cm²) at 1 atm partial pressure of each reactant.

Using the i_0 values at copper obtained with fuel gas compositions corresponding to high, intermediate, low, and very low Btu, and assuming shift equilibrium, Eq. [13] has the parameters

$$i_0^0 = 69.50 \pm 2.28 \text{ mA/cm}^2, a = 0.34 \pm 0.01 \\ b = 0.13 \pm 0.01, c = 0.31 \pm 0.02 \quad [14]$$

If both steam reforming and shift equilibria are assumed, one finds

$$i_0^0 = 71.12 \pm 2.14 \text{ mA/cm}^2, a = 0.33 \pm 0.01 \\ b = 0.14 \pm 0.01, c = 0.33 \pm 0.02 \quad [15]$$

The difference is not significant, as is to be expected for one atmosphere pressure data. Ang and Sammells reported for the nickel electrode

$$i_0^0 = 104.7 \text{ mA/cm}^2, a = 0.26, b = 0.28, c = 0.18 \quad [16]$$

Table IV. Exchange current densities, i_0 , and transfer coefficient, α_c , for copper in Li/K melt at 923 K (650°C) using various feed gases

Feed gas	i_0 (mA/cm ²)	α_c
High Btu	26.6 ± 0.41	1.31
Intermediate Btu	29.2 ± 0.37	1.31
Low Btu 1	21.1 ± 0.23	1.33
Low Btu 2	23.4 ± 0.23	1.30
Very low Btu	16.6 ± 0.24	1.27

The standard exchange current density for copper is lower than that for nickel. However, if one corrects the data of Ref. (3) for the underestimation caused by linear extrapolation, the actual value of the standard exchange current density at nickel may be as high as 138 mA/cm² at 923 K (650°C).

The kinetic results at both nickel and copper indicate that the anodic activation polarization of anode is very small in the molten carbonate fuel cells; also, the electrode metal has little effect on the polarization. These results are consistent with the low anode polarization of lab-scale (3 cm²) cells using a porous copper anode [fabricated by Gould laboratories and stabilized at IGT (16)].

Discussion and Conclusions

The exchange current density at copper measured in this study is very encouraging from a practical point of view. The standard value (i_0) of 71.1 mA/cm² at 923 K (650°C), is of the same order of magnitude as, but somewhat lower than, that for nickel. The previously determined value of i_0 at nickel appears to underestimate the actual value due to an inappropriate extrapolation technique; it may be as large as 138 mA/cm² at 923 K (650°C).

This study confirms the electrode-kinetic suitability of copper as an alternative anode material to nickel. Performance studies of porous copper anodes in small cells at IGT have led to the same conclusion.

Several reaction mechanisms have been considered to interpret the dependence of i_0 on gas composition (17). Ang and Sammells suggest that a good representation of their experimental results, Eq. [16], is given by

In deriving the theoretical expression for the current, they assume that Eq. [18] is the rate-determining step, and thus the preceding and following steps are in quasiequilibrium. It should be noted that the proposed mechanism also assumes that the reaction steps must take place consecutively and that the intermediates do not diffuse toward or away from the electrode surface. Since the intermediate hydroxide ions are quite stable in molten carbonate, their concentration may be determined from the hydrolysis equilibrium

The hydrolysis constant of reaction [20] is reported to be $K_h = 1.79 \times 10^{-4}$ for 923 K (650°C) (18). Because of the existence of an appreciable amount of OH⁻ ions in the melt, the rate of reaction [19] is not limited by the rate of supply of OH⁻ ions from reaction [18]. Under the circumstances, a more rigorous analysis of the anodic process requires the treatment of reactions [18] and [19] as simultaneous reactions rather than as consecutive steps of a simple reaction. Also, separate conservation equations must be set up for each species to account for their diffusion, and possibly convection. If reaction [18] occurs rather slowly, most of the OH⁻ ions consumed in reaction [19] are produced by reaction [20] and the reaction rate, *i.e.*, the current density, will have a strong dependence on H₂O partial pressure. As observed experimentally (see Eq. [15]),

the exchange current density is more sensitive to H₂O than to CO₂.

Equation [7] represents a general overall reaction on the electrode. This simplified form was used to show the applicability of the extrapolation scheme to fractional kinetics. As a matter of fact, an electrode kinetic analysis must consider the overall reaction in terms of several elementary steps. Such an analysis is complicated by the need to account for the transport process and kinetics for each step. This rigorous approach, in which complications from the multistep mechanism and the diffusion of multiple components are taken into consideration, will be discussed in a follow-up paper (19).

ABSTRACT

A bench scale experiment with a 50A cell equipped with a Nafion membrane has been conducted. Electrolyte is a mixture of HCl and CuCl₂. Chlorine is generated at the graphite anode, and cupric chloro-complex ions are reduced at the graphite cathode. The catholyte effluent is sent to the packed tower, where the cuprous ions are oxidized by chlorine in the waste gas. The cost evaluation for chlorine production in full-scale plants of various sizes is also described.

It is estimated that 2-3% of the chlorine produced by brine electrolysis is being wasted by the liquefaction unit as a dilute gas because the cell gas contains a small amount of oxygen, nitrogen, hydrogen, and others, depending on the cell design and the operating conditions of the electrolyzers and the liquefaction plant. Although most waste gas is treated by caustic soda solution to convert it into hypochlorite, it would be profitable if concentrated chlorine could be recovered. Hooker has developed an adsorption-desorption process using pressurized water, whereas Diamond Shamrock uses chlorinated solvents such as carbon tetrachloride (1, 2).

Hine *et al.* has studied electrolysis of the mixed solution of CuCl₂ and HCl where chlorine is liberated from the anode and cupric chloro-complex ions are reduced at the cathode. The catholyte leaving the cell is oxidized in a separate reactor by waste chlorine and recycled to the electrolytic cell (3, 4). This process consumes a relatively small amount of electricity because the decomposition voltage and the anodic and cathodic overvoltages are small. The chemical reactions involved in this process are relatively simple and have already been clarified (5-8).

This paper deals with a bench scale experiment of the electrolytic process with a 50A cell. The cost estimation for 0.5-5.0 ton-Cl₂/day units is also discussed.

Outline of the Process

The electrolytic cell is equipped with the graphite anode and cathode, and a Nafion membrane is located between them. The electrolytic solution consists of a mixture of 6M HCl and 1.5M CuCl₂, in which cupric ions may form chloro-complex CuCl_m^{-(m-2)}. The chloride ions are oxidized at the anode (reaction [1]), and cupric chloro-complex ions can also discharge as a side reaction (reaction [2])

At the cathode, cupric ions are reduced into cuprous

where *m* is the coordination number of Cl⁻ with respect to a cupric ion, its possible number in 6M HCl being 3. Tetrachloro-complex is a stable form of cuprous ions (5). Consequently, reactions [2] and [3] are followed by the homogeneous reactions [4] and [5] in the anode and cathode compartments, respectively

and

where *n* is the coordination number of Cl⁻ with respect to a cuprous ion.

*Electrochemical Society Active Member.

Although the Nafion membrane rejects the anions, H⁺ can pass through the membrane from the anode side to the cathode side. It causes depletion of HCl in the anode compartment, whereas the HCl concentration in the cathode compartment increases during electrolysis.

The catholyte liquor leaving the cell is sent to the oxidation tower, and it reacts with the waste gas containing chlorine. A possible reaction is

Also, reaction [8] may take place because the waste gas contains air or oxygen, as well as chlorine (7)

Polarization Studies

It is well known that an oxide-coated Ti anode such as DSA is the best selection for chlor-alkali cells because of its low chlorine overvoltage and corrosion resistance in concentrated NaCl solutions. An oxide-coated Ti anode composed of 1 part RuO₂ and 2 parts TiO₂ in mole ratio (OCTA, hereafter) was prepared and electrolyzed in a mixed solution of 6M HCl and 1.5M CuCl₂ at 100 A/dm². The chlorine overvoltage remained low for about 3 months, then after 6 months the oxide layer degraded and the overvoltage increased considerably. The service life was extended somewhat by addition of a third element such as Ir.

However, the graphite anode was resistant to concentrated HCl, and its chlorine overvoltage was acceptably low, *e.g.*, about 0.1V at 20 A/cm². Also, the chlorine overvoltage was lowered by addition of cupric ions in concentrated HCl solutions, as shown in Fig. 1, though its mechanism was unclear. Consequently, graphite was used as the anode material. The Ti screen and/or perforated electrodes coated with noble metal oxide were also examined in some cases for the convenience of the cell design.

The main reaction at the cathode was the conversion of cupric chloro-complex ions into cuprous ions, as shown by reaction [3]. However, copper deposition could have taken place and been troublesome if the cathode was polarized more negative than 0V vs. SCE. The cathodic polarization curves of various materials are shown in Fig. 2. The rotating-disk electrode was used because the cathodic process under consideration was diffusion-controlled. Because an undivided cell was employed, a part of the chlorine generated from the anode was reduced at the Pt cathode at the potentials more negative than 0.5V vs. SCE and was also controlled by diffusion. The cathodic reduction of cupric chloro-complex ions (reaction [3]) took place at the same potential range. This reaction

Fig. 1. Polarization curves of the graphite anode in HCl solutions with and without CuSO_4 at 40°C .

Fig. 2. Polarization curves of various cathode materials in $6\text{M HCl} + 1.5\text{M CuCl}_2$ at 70°C .

was limited by mass transfer. Further polarization would have caused copper deposition on the cathode.

A fresh oxide-coated Ti electrode showed almost the same behavior as the Pt cathode, but the oxide coating was degraded gradually by cathodic reduction. Other metallic specimens such as Cu, Ti, and Hastelloy C were corroded, even when they were polarized cathodically from their static potential in the solution under discussion.

Graphite was, of course, corrosion resistant, and its cathodic polarization was the same as that of the Pt cathode. Consequently, a graphite cathode was considered to be the best selection.

Bench Scale Experiment

The flowsheet of the bench scale experiment with a 50A cell was almost the same as that of the fullscale plant illustrated in Fig. 11, with some exceptions. The electrolytic solution was pumped to the anode and cathode compartments. The catholyte effluent was sent back to the reservoir. However, chlorine gas was separated from the anolyte before return to the electrolytic reservoir. A part of the electrolytic solution was circulated between the reservoir and the oxidation tower. The dilute gas was sent to the bottom of the tower, and its tail gas was brought to the wash tower to remove traces of acid mist and chlorine. The dilute gas was prepared with chlorine generated at the anode; hence, a very small amount of chlorine from the cylinder (an additional source) was required during the experiment.

The electrolytic cell made of Lucite resin was 50 mm wide and 515 mm high and had a flange 30 mm wide. The cell was equipped with a pair of graphite electrodes with a Nafion membrane between them. The cathode was sec-

tioned to determine the current distribution along the electrode. The anode was also sectioned for convenience of preparation and fabrication.

The catholyte oxidizer was a Lucite resin column of 10 cm diam and 100 cm height packed with Raschig rings of 1 cm diam and 1 cm height. The total height of the packings was about 60 cm. It was excessively large in capacity, compared with the cell capacity for convenience of experiment.

A beaker-shaped cell of 89 mm id and 145 mm height was used to investigate absorption of chlorine into the electrolytic solution (Fig. 3). The solution level was 80 mm. The solution and the gas in the test cell were agitated by their respective paddles. The mixed gas of N_2 and Cl_2 was sent to the cell at a given flow rate, and the tail gas was washed out by caustic liquor. The solution was pipetted out and titrated intermittently to obtain the absorption rate.

Results and Discussion

The chlorine evolution reaction is stimulated by Cu^{2+} , as described above (see Fig. 1). An example of the polarization curves of the graphite anode positioned in a vertical cell is shown in Fig. 4. The anode overvoltage is almost independent of the location along the vertical electrode. The Tafel slope of the anodic polarization curve is about 130 mV/decade in the range of 0.2-65.0 A/dm^2 , suggesting that the main reaction is Cl^- -to- Cl_2 oxidation controlled by charge transfer. (In reaction [2], it is accompanied with the chlorine evolution from cupric chloro-complex ions to some extent.)

Fig. 3. Setup for gas absorption

Fig. 4. Examples of the polarization curves of the graphite electrodes in 6M HCl + 1.5M CuCl₂ at 70°C. Flow rate: anolyte = 10 cm/sec; catholyte = 31 cm/sec.

The Tafel slope of the cathode process is about 120 mV/decade in the potential range of up to 0.3V vs. SCE and, hence, charge transfer of cupric ions to cuprous ions is assured. However, the diffusion limiting current density appears when the cathode potential becomes more negative than 0.3V. The limiting current density depends on its distance from the catholyte inlet or the location of the catholyte inlet, probably due to change in thickness of the diffusion layer along the vertical electrode.

The current density at a given potential is a linear function of the flow rate, as shown in Fig. 5. The results of previous work with a small electrode of 4 cm diam and 5 cm height are also illustrated; they represent very large current densities created by a rapid flow of catholyte in a small cell (4). A rotating-disk cathode enables the limiting current density to increase to more than 90 A/dm², as shown in Fig. 2. These results show that designing the cathode compartment so that it yields sufficient flow is

Fig. 5. Current density vs. flow rate curves in 6M HCl + 1.5M CuCl₂ at 70°C.

necessary in operating the cell, without trouble of copper deposition, in high ranges of current density.

Further experiments have been conducted to obtain design data such as limiting current density and solution conductivity. The summary of the results is as follows. First, the higher the solution temperature, the larger the current density at a given potential. For example, at -0.2V vs. SCE, the current density is 20 A/dm² at 51°C and 31 A/dm² at 70°C. Second, the current density increases with the increase of the Cu²⁺ concentration up to the solubility of CuCl₂ in HCl solution. The solubility of CuCl₂ in 6M HCl at room temperature is about 1.5M. Third, the HCl solution of about 6M in concentration shows the maximum conductivity, depending on the solution temperature. The electrical conductivity of the mixed solution of HCl and CuCl₂ decreases almost linearly with the increase of the CuCl₂ concentration (7, 8).

The voltage drop through the Nafion membrane in the mixed solution of HCl and CuCl₂ is low, compared with that in the solutions composed of alkali metal chloride, as shown in Fig. 6; this is due to a large permeability of H⁺ through the membrane. The Nafion membranes do not allow any anion to pass through. Accordingly, the current efficiencies for the anode and cathode processes are sufficiently high.

Figure 7 shows an example of the V-A curves. The voltage balances at both 20 and 40 A/dm² are as follows

	At 20 A/cm ²	At 40 A/dm ²
Decomposition voltage	0.60	0.60
Anode overvoltage	0.20	0.35
Cathode overvoltage	0.10	0.20
Solution IR-drop	0.10	0.20
Membrane IR-drop	0.15	0.30
Bubble effect	0.05	0.10

Terminal voltage 1.20V 1.75V

Along with the decomposition voltage, the membrane IR-drop and the anode overvoltage are major factors. The slope of the V-A curve becomes large when the current density exceeds 50 A/dm², due to delay of the cathode

Fig. 6. Voltage drop of Nafion 390 in various solutions at 70°C

Fig. 7. An example of the voltage breakdown of the chlorine recovery cell. Electrolyte = 6M HCl + 1.5M CuCl₂ at 70°C. Anode-to-cathode gap = 4 mm.

process. The chlorine current efficiency is in the range of 92-98%, with an average of 95%. Almost all the electrolytic current is carried by H⁺, and the remainder (about 1%) are covered by Cu²⁺. The water transport is 2 mol for 1F.

Experiments on the gas absorption are conducted with a Lucite cell having a paddle agitator (shown in Fig. 3). The area of the gas-solution interface is 62.2 cm², and the solution volume is 500 cm³. The size of the paddles located in the gas and solution phases is varied to estimate the absorption characteristics at the interface.

The chlorine absorption rate is unchanged during a 30 min period, as shown in Fig. 8, and is a function of the chlorine partial pressure and the paddle size in the solution. However, the paddle size in the gas phase is a small factor in the absorption rate. Consequently, the chlorine absorption in the mixture of HCl and CuCl₂ is controlled by mass transfer through the liquid-side boundary layer at the gas-solution interface. Absorption of chlorine into the solution containing cuprous ions is associated with chemical reaction [6], and its rate is large compared with the rate of physical absorption of chlorine in HCl single

Fig. 8. Chlorine concentration vs. time curves in 6M HCl with and without CuCl (0.1M). Rotating speed = 200 rpm.

solution. The Hatta number γ (see Eq. [19]) is 1.7 at 1 atm of chlorine partial pressure and is 5.6 at 0.2 atm.

Levenspiel *et al.* (9) classifies the processes of gas absorption with chemical reaction into eight types and describes the experimental method for evaluating the regime of the process.

The features of chlorine absorption into the mixture of HCl and CuCl are as follows: the process is fast because gas absorption is associated with chemical reaction [6]; the absorption rate is almost linear with chlorine partial pressure; the absorption rate is almost independent of the volume of liquid and the flow rate of gas; however, absorption of chlorine is stimulated by agitation of liquid. Consequently, it is assured that the reaction is instantaneous, occurring within the liquid-side boundary layer, and that the process is diffusion controlled (*i.e.*, Regime A of Levenspiel's classification).

Figure 9 illustrates the gas-solution interface under discussion. Assume that Henry's law

$$C = H p \tag{9}$$

is applicable in this case. The rate equation for the reaction

is thus represented as follows

$$v = \frac{D_G}{X_G} (p - p_i) \quad (\text{gas}) \tag{11}$$

$$= \frac{D_L}{\beta X_L} C_i \quad (\text{A in solution}) \tag{12}$$

$$= \frac{\alpha D_L}{(1 - \beta) X_L} \frac{C_B}{b} \quad (\text{B in solution}) \tag{13}$$

where

$$\alpha = \frac{D_L'}{D_L} \tag{14}$$

Substituting Eq. [9] into Eq. [11] and applying the addition theorem for fractional equations, we have

$$v = \frac{H p + \frac{\alpha C_B}{b}}{\frac{H X_G}{D_G} + \frac{X_L}{D_L}} \tag{15}$$

Since the first term of the denominator in Eq. [15] is negligible compared with the second term, the equation can be simplified

Fig. 9. Profile of the gas-solution interface

$$v = K_L C^* \left(1 + \frac{\alpha C_B}{b C^*} \right) \quad [16]$$

where

$$K_L = \frac{D_L}{X_L} \quad [17]$$

and

$$C^* = H p \quad [18]$$

The bracketed term on the right side of Eq. [16] is the Hatta number γ , which represents the acceleration of gas absorption with chemical reaction

$$\gamma = 1 + \frac{\alpha C_B}{b C^*} \quad [19]$$

The Hatta number can be obtained as a ratio of the slope of the absorption *vs.* time curve for the mixed solution to that for the single solution of HCl. From the data plotted in Fig. 8, γ is estimated to be 5.6 at 0.2 atm of chlorine partial pressure and 1.7 at 1 atm.

The experiment is conducted with a mixed solution of 6M HCl and 0.1M CuCl under various pressures of chlorine, and the results shown in Fig. 10 are obtained. The absorption rate is proportional to $(C^* + \alpha C_B/b)$ and, hence, Eq. [16] is valid.

A Pt rotating-disk cathode is operated to obtain the diffusion coefficient D_L of dissolved chlorine in HCl solution. The Levich equation (10)

$$i = 0.62 n F D_L^{2/3} \nu^{-1/6} \omega^{1/2} (C_o - C_s) \quad [20]$$

is used, where i is the current density, n is the number of charge transfer, and F is the Faraday constant. An estimated D_L is 1.9×10^{-5} cm²/s. With $\gamma = 5.6$ at $p_{Cl_2} = 0.2$ atm, $C_{CuCl} = 0.1$ M/l, and $H = 4.6 \times 10^{-5}$ mol/cm³ atm, the ratio of diffusion coefficients, α , is evaluated to be 0.85. Therefore, the diffusion coefficient of cuprous ion D_L' is 1.6×10^{-5} cm²/s. Since γ is significantly larger than unity under the conditions employed here, the chlorine partial pressure is a small factor in the absorption rate. Also, the absorption rate is almost independent of the CuCl₂ and HCl concentrations and the solution temperature. These experimental results are useful for designing the chlorine absorption tower.

Fig. 10. Absorption rate vs. concentration curve

Fig. 11. Flowsheet of the electrolytic chlorine recovery system

Figure 11 shows the flowsheet of the process. The electrolyzer consists of 22 bipolar cells of 1.5 kA in a series connection, and the capacity is 1 ton of chlorine per day. The nominal current density is low (15-20 A/dm²) to lower the cell voltage, *i.e.*, 1.1-1.3V for each cell or 25-30V terminal voltage. The system is composed of an adequate number of these stacks. For example, 3 stacks are installed as a 3 ton-Cl₂/day plant.

The electrolytic solution is pumped to the anode and cathode compartments. Chlorine gas generated at the anode is separated from the anolyte and cooled. The anolyte and the catholyte are sent back to the reservoir. A part of the electrolytic solution is pumped to the absorption tower, where cuprous chloride is oxidized to cupric chloride by chlorine in the waste gas. The inert gas leaving the chlorine absorption tower is washed with water prior to purge. The system has been designed to be operated in the temperature range of 50-70°C. However, the higher the temperature is, the lower the cell voltage is, and the water balance in the system varies with the operating temperature. The overall chlorine current efficiency is assumed to be an average of 95%. The dc electric power consumption is 890-950 kWh/ton-Cl₂, depending on the current density, the cell voltage, and the operating temperature. Also, additional ac power is required for pumping and gas blowing.

Because the system is small and the terminal voltage of the rectifier is low compared to a modern chlor-alkali cell plant, the conversion efficiency of the rectifier is somewhat low. Assuming that the overall efficiency of the power supply system, including rectifier, transformer, and auxiliaries, is 85-87%, the ac power consumption for electrolysis is estimated to be 1050-1120 kWh/ton-Cl₂.

Cost Estimation

The investment cost and the operating cost of the full-scale plant (shown in Fig. 11) in the range of 0.5-5.0 ton-Cl₂/day capacity have been evaluated on a Japanese money basis. The calculation for two plants, 1 ton/day and 3 ton/day, have been conducted in detail. The specifications employed are as follows

Plant capacity	0.5-5.0 ton-Cl ₂ /day
Flowsheet	shown in Fig. 11 with some exceptions
Electrolyzer	filterpress, bipolar type, plastic
Electrodes	graphite anode and cathode
Separators	Nafion 315
Number of cells	22 cells/stack
Capacity of each stack	1 ton-Cl ₂ /day
Amperage	1.5 kA
Terminal voltage	26.5V
Current efficiency	95%

An appropriate number of stacks are installed in a plant having a capacity of more than 1 ton/day. These stacks can be operated in parallel or in series, depending on the

Fig. 12. Investment cost as a function of the plant size

plant situation and other factors. For a small plant, such as 0.5 ton/day, a half-size electrolyzer composed of 11 cells is used. The capacity can also be controlled by changing the amperage in a range of 1-2 kA.

It is well known that the investment J for an electrochemical process plant of capacity P is represented as follows (11)

$$J = J_0 P^a i^b \quad [21]$$

where J_0 is the investment cost for a plant having unit capacity, i is the current density, a is the Williams coefficient, and b is also a coefficient. It is clear that the fixed charge in the manufacturing cost is decreased with increased current density because the coefficient b is negative, but the cell voltage and, hence, the electric power cost are increased. Consequently, there is an optimum current density which depends on investment, price of electricity, and other factors such as cell design and operating conditions other than current density. Under the present situation, an optimum current density is estimated to be about 20 A/dm².

The Williams coefficient for the cell room area including electrolyzers, rectifiers, and the busbar system is 0.83-0.84, which is significantly larger than the approximate 0.6 for the nonelectrochemical processes. In other words, the scale merit of an electrochemical process plant is relatively small (11). However, the coefficient for the total investment of the electrolytic chlorine recovery process under discussion is also small, 0.51-0.53, as shown in Fig. 12, because the installation, aside from the electrolyzers and the power supply, is large and is a weak function of the plant size.

The manufacturing cost of 1 ton of chlorine has been calculated with several assumptions in mind

Depreciation	On the fixed instalment method for 7 years
Life of membranes	2 years
Maintenance cost	10% of the fixed charge
Price of electricity	15 yen/kWh

The fixed charge and the manufacturing cost per unit ton of chlorine are shown in Fig. 13 as functions of the plant size in ton-Cl₂/day. Other costs such as overhead and laboratory must be added if required. Since replacement of the membranes is a large factor, extension of the service life must be considered to reduce the manufacturing cost of chlorine.

The estimated cost is 53,000 yen (\$214) and 43,000 yen (\$174) per ton of chlorine in the 1 ton/day and 3 ton/day

Fig. 13. Manufacturing cost and depreciation as functions of the plant size.

plants, respectively, which would be competitive with the brine electrolysis. A very small plant, such as 0.5 ton/day or less, is not economical and, hence, the waste gas should be washed out by caustic soda solution and the chlorine recovered as hypochlorite. Although the manufacturing cost decreases with increase in plant capacity, the cell configuration and the plant layout must be considered for further reduction of the fixed charge when the plant size is larger than 5 tons per day.

Electrochemical Evidence of a Possible Route for the Metabolism of Oltipraz 5-(2-Pyrazinyl)-4-Methyl-1,2-Dithiole-3-Thione

J. Moiroux and S. Deycard

Laboratoire Chimie Analytique, Faculté Pharmacie, Université René Descartes (Paris V) 75270 Paris Cedex 06, France

ABSTRACT

The presence of the 5-pyrazinyl substituent induces some noticeable changes in the reaction pathways accompanying the electrochemical reduction of oltipraz compared with the behavior of dithiole-thiones, which do not possess such a substituent and are not endowed with antischistosomal activity. First, electrochemical techniques ascertain the transient formation of the radical anion resulting from the reversible addition of one electron to oltipraz in aprotic media. Second, the electrochemical two-electron reduction, under anaerobic conditions, yields a mixture of dianionic isomers which can be protonated one, two, and even three times. In the protonated species which also exist in isomeric forms and are not starting materials for the regeneration of oltipraz through oxidation, both the dithiole-thione and pyrazinyl rings are reduced. In the presence of air or methylating reagent, the two-electron reduction products are transformed into pyrrolo [1,2-a] pyrazine derivatives, which are some of the major metabolites of oltipraz.

In a previous paper (1), we reported a detailed analysis of the electrochemical behavior of 1,2-dithiole-3-thiones (1,2-dithio-4-cyclopentene-3-thiones) variously substituted at positions 4 and 5

The polarographic behavior of those dithiole-thiones noted A in N,N-dimethyl-formamide (DMF) depends on the nature of substituent R_4 . When R_4 is a methyl group, a two-electron ($2e$) cathodic wave is observed. When R_4 is H, two, apparently $1e$, cathodic waves are observed. The first can be ascribed to a reversible monoelectronic reduction yielding an organomercurial. The second, in fact, corresponds to the occurrence of the same $2e$ cathodic process as observed when R_4 is a methyl group. The $2e$ process occurs at ca. -1050 mV vs. aqueous SCE¹, and this potential does not markedly depend on the nature of R_4 and/or R_5 . The $2e$ reduction product is either a cyclic dianion noted (A^{2-}) when R_4 is H and R_5 a phenyl group, or a mixture of (A^{2-}) and the open form of the dianion noted A^{2-} when R_4 and/or R_5 is a methyl group. The redox couple (A^{2-})/A exhibits reversible behavior at the mercury electrode.

The three dithiole-thiones, I, II, and III, mentioned above are of no remarkable pharmaceutical interest, but oltipraz [5-(2-pyrazinyl)-4-methyl-1,2-dithiole-3-thione, i.e., with $R_4 = \text{CH}_3$ and $R_5 = 2\text{-pyrazinyl}$] has a well-established antischistosomal activity (2-4). As an evaluation of a limited number of oltipraz analogs, including compound II, revealed among dithiole-thiones rather stringent structural requirements for antischistosomal activity (4), we examined the electrochemical behavior of oltipraz in order to see if changes in the electrochemical behavior could be related to structural changes and antischistosomal effects.

The present paper deals with the electrochemical reduction of oltipraz, 5-(2-pyrazinyl)-1,2-dithiole-3-thione, i.e., the oltipraz analog in which $R_4 = \text{H}$ instead of CH_3 and 5-(2-pyrazinyl)-4-methyl-1,2-dithiole-3-one, which is the ketone analog of oltipraz. The working electrode was a platinum electrode and the solvent was either DMF or acetonitrile (ACN). The excitation and measurement techniques used included electrochemical ones such as volt-

¹ In this paper, all potentials are referred to the potential of the aqueous saturated KCl calomel electrode (SCE).

ammetry at the rotating or stationary disk electrode (RDE or SDE, respectively) and potential step chronoamperometry and spectroscopic techniques such as UV-visible and IR absorption spectrophotometries and ¹H NMR spectrometry.

The analysis of the reduction pathways may be of pharmaceutical interest since the primary metabolite of oltipraz is a product resulting from the reduction of the drug (5).

Experimental

Materials.—Oltipraz and its two analogs were generously provided by Rhône-Poulenc-Santé and used without further purification. DMF, ACN, and deuterated solvents were obtained from Merck and used as received unless otherwise specified. Tetraethylammonium bromide (TEAB) from J. T. Baker was recrystallized twice from tert-butanol. A stock solution of 0.1M tetrabutylammonium hydroxide (TBAH) in isopropanol was obtained from Fluka and stored under nitrogen. For dehydration of solvents prior to electrochemical measurements we followed a procedure given in the literature (6) using neutral alumina (Merck 90, 0.063-0.200 mm). Thin layers or columns of Silicagel 60 from Merck have been used for chromatographic separations, the eluent being (v/v) toluene/acetone (95/5). Other reagent-grade chemicals were obtained from Prolabo.

Electrodes.—For voltammetry and potential step chronoamperometry, the working electrode was the platinum disk of a Tacussel EDI rotating electrode connected to a Tacussel CONTROVIT servocontrol electronic amplifier. For controlled potential electrolysis, the working electrode was a large platinum disk (8 cm diam).

For polarography, the working dropping mercury electrode was obtained with a Tacussel CMT 10/24 capillary. The drop-time was controlled by a Tacussel MPO 3 drop-knocker.

The counterelectrode was a platinum Tacussel Pt 33/88 electrode for voltammetry and chronoamperometry and a platinum foil for controlled-potential electrolysis.

The potentials were measured against an aqueous SCE using a two-part salt bridge.

Apparatus.—We used a three-compartment water-jacketed cell whose counter and reference electrode compartments were filled with the background solution (0.1M TEAB in DMF or ACN) and whose temperature was 25°C.

Electrochemical measurements were made with a Tacussel PRG 5 multipurpose polarograph, with a built-in iR drop compensation device, which was also used simply as a rapid-response potentiostat working under the control of a Tacussel GSTP function generator for cyclic voltammetry and potential step chronoamperometry. Current-potential curves were recorded on a Tacussel EPL 2 recorder or a Tektronix 5111 storage os-

cilloscope with voltage-amplifier 5 A 15 N and time-base 5 B 10 N (for current-time curves) plug-ins. A Tacussel PRT 30-01 potentiostat, a Tacussel IG 5 N electronic integrator, and a general purpose milliammeter were used for controlled potential electrolysis.

UV-visible and IR absorption spectra were obtained with a Varian DMS 90 (plus a Sefram TGM 164 X-Y recorder) UV-visible spectrophotometer and a Perkin Elmer 167 IR spectrophotometer.

In order to avoid the contact of electrolyzed solutions with air during spectrophotometric measurements, a cell for circulation (optical path length 0.1 cm) located in the spectrophotometer communicated with the electrochemical cell through a Teflon hose on the one side and with a vacuum pump on the other side, and the electrolyzed solution was sucked up into the spectrophotometric cell.

^1H NMR spectra were obtained with a Bruker Spectrospin 270 MHz spectrometer thanks to the skills of M. Belleney.

Results and Discussion

Voltammetry at the RDE.—A well-defined cathodic wave corresponding to the reduction of oltipraz appears in the voltammogram in the 0 to -1300 mV potential region, the solvent being either DMF or ACN and the rotation frequency N of the RDE being 10 Hz. A plot of E (potential) vs. $\log [i/(i_1 - i)]$, where i_1 is the limiting plateau current and i the current at potential E , is linear with a slope of -62 mV (DMF and ACN) almost as expected theoretically for a reversible $1e$ transfer. The value of i_1 compared with that of the first cathodic wave of 9-fluorenone under the same experimental conditions confirms the occurrence of a monoelectronic transfer. The value of the ratio $i_k/N^{1/2}$ does not depend on N as long as N is higher than 4 Hz in DMF or 7 rps in ACN, but increases with decreasing N when N becomes lower than 4(DMF) or 7(ACN) Hz.

Cyclic voltammetry at the SDE.—When oltipraz is dissolved in DMF the cyclic voltammogram is as expected theoretically for a reversible $1e$ transfer even when the potential sweep rate v is as low as 0.1 V s^{-1} . When the solvent is ACN, such a behavior is observed only when v is higher than 4 V s^{-1} . The ratio $i_{p,c}/v^{1/2}$ increases with decreasing v when v is lower than 4 V s^{-1} ($i_{p,c}$ being the peak height of the cathodic peak) and the chemical reversibility of the system diminishes accordingly.

Occurrence of ECE mechanism.—The observed increase in $i_{p,c}/v^{1/2}$ with decreasing v as well as the increase in $i_k/N^{1/2}$ with decreasing N mentioned above strongly suggests the occurrence of an ECE mechanism in which the radical anion resulting from the first electron addition can be involved in a chemical step yielding a species more reducible than oltipraz (7, 8). We also used potential step chronoamperometry at the SDE for the study of the kinetics of this process. In the following, i_k designs the measured value of the current and i_d the value of the current corresponding to the occurrence of a $1e$ reversible and diffusion-controlled transfer under the same experimental conditions whatever the technique is, i.e., the notation i_k is used in place of $i_{p,c}$ or i_1 .

Potential step chronoamperometry of a DMF solution of 9-fluorenone was used as a means of determination of the effective electrode area A , the estimation of the diffusion coefficient of 9-fluorenone in DMF being 6.9×10^{-6} $\text{cm}^2 \text{s}^{-1}$ (9). In the case of oltipraz, the plot of i_k vs. $t^{-1/2}$ is reproduced in Fig. 1a, t being the time elapsed since the potential was stepped from a value at which oltipraz is not reduced to a value corresponding to the plateau of the cathodic wave in the RDE voltammogram. i_k is proportional to $t^{-1/2}$ at short times, i.e., when the process is monoelectronic, and then the diffusion coefficient D of oltipraz can be determined with the help of the Cottrell equation. The knowledge of A and D enables us to compute i_d for SDE cyclic voltammetry and RDE voltammetry, the kinematic viscosities of DMF and ACN being taken as 0.84 and 0.44 cS, respectively (10).

Fig. 1. Reduction of oltipraz. Variations of i_k/i_d as observed by means of potential step chronoamperometry (a) and cyclic voltammetry (b) at the SDE, and RDE voltammetry (c). Oltipraz concentration $C = 1$ mM in either DMF (continuous lines) or ACN (discontinuous). For b, $i_d = 268 AD^{1/2}v^{1/2}C$ (13) and for c, i_d is given by the Levitch equation.

Besides the $i_k-t^{-1/2}$ plot, plots of i_k/i_d vs. $\log v$ or $\log N^{-1}$ are reproduced in Fig. 1 (b and c). All these plots can be readily compared to the working curves given in the literature (8, 11, 12) for each technique in the case of an ECE mechanism when the chemical step consists of a first- (or pseudo-first) order irreversible reaction. Assuming that the preceding condition is fulfilled, the rate constant k of the chemical reaction can be determined. We obtained data which are gathered in Table I. As can be seen, there is no significant dependence of k upon the oltipraz concentration C , a result which justifies the assumption concerning the order of the chemical reaction. It also appears that the three different techniques give comparable values for k .

Altogether, several results suggest that the intermediate chemical reaction is almost certainly the protonation of the radical anion. The proton donor is probably the residual water, the amount of which is roughly equivalent in commercial DMF and ACN, and it has already been reported that, under such conditions, ACN behaves as a more acidic medium than DMF (14). Addition of water up to 10% does not modify the kinetics of the reaction but cyclic voltammetric reversibility is obtained even at v as low as 0.1 V s^{-1} when the commercial ACN is dehydrated with neutral alumina prior to electrochemical measurement. Besides, addition of one electron to the oltipraz analog in which $R_a = \text{H}$ (see Appendix A) produces a radical anion which is less basic and then the rate of the intermediate chemical reaction is much slower. It has not been possible to check out that addition of protons actually increases the rate of the chemical reaction since such an addition causes the occurrence of catalytic hydrogen discharge giving rise to signals which superimpose upon the one due to the reduction of oltipraz thus hampering meaningful measurements. An ECE mechanism con-

sisting of the following steps, denoted [1], [2], and [3], seems likely

E_1^o can be determined by means of SDE cyclic voltammetry and RDE voltammetry when v and N , respectively, are large enough to overrun the protonation of the radical anion and numerical data are reported in Table I.

The radical anion can exist in many resonant forms since the delocalization of the negative charge and the unpaired electron can be extended to the pyrazine ring. That is probably the reason why such a radical anion is much more stable than the one resulting from the 1e reduction of a dithiole-thione bearing a 5-methyl or 5-phenyl substituent. In the latter case, direct 2e transfer was observed and we found no electrochemical evidence of transient formation of a radical anion (1).

The backward reaction of the above equilibrium is probably slow, since it implies the heterolytic cleavage of the N-H bond and it can account for the irreversible behavior appearing at low v in the cyclic voltammograms when the solvent is ACN.

Disproportionation of the protonated radical can actually occur instead of reaction [3] as long as such a disproportionation is faster than reaction [2], which must remain the rate-determining step since the overall process obeys first-order kinetics.

The 2e reduction product can exist in various resonant forms and tautomers. This point will be discussed later in the section assigned to the characterization of the 2e reduction products.

Controlled-potential electrolysis.—An exhaustive reduction of oltipraz by means of electrolysis at a controlled potential corresponding to the plateau of the cathodic wave appearing in the RDE voltammogram involves $n = 2.10 \pm 0.05$ e per molecule of oltipraz. Such a result confirms the effect of the time scale upon the nature of the electrochemical process, since the reduction proceeds according to a 2e process at the time scale of an exhaustive electrolysis, while only a 1e process is observed by means of RDE and SDE voltammetries, at least when N and v are not too small.

At the beginning of the electrolysis, the solution turns very dark due to the transient production of the radical anion. We have not been able to perform sufficiently fast

spectrophotometric measurements so as to record the UV-visible absorption spectrum of the radical anion whose half-life time is about 7s in DMF and 0.7s in ACN, according to the values of k given in Table I. We have only established that the spectrum of the radical anion in DMF exhibits an absorption maximum around 450 nm with a molar absorptivity greater than that of oltipraz at the same wavelength. However, the absorption spectrum of the radical anion of oltipraz probably does not differ markedly from that of the radical anion of 5-(2-pyrazinyl)-1,2-dithiole-3-thione, which is much less basic and can be prepared and characterized easily (see Appendix A). The UV-visible absorption spectrum of the latter is reproduced in Fig. 2.

Slightly different results were obtained in DMF and ACN. In the following, DMF solutions will be considered first, but before doing so it must be said that the results did not depend on the nature of the working electrode. For example, we checked out that exhaustive electrolysis at a mercury pool gave the same products as when the working electrode was a platinum disk. In the present paper, we do not report the results obtained at the dropping mercury electrode (polarography and cyclic voltammetry), because the signals were then very complex and poorly defined, owing to the occurrence of catalytic discharges related to surface reactions, which were strongly potential dependent.

Characterizations and reactivities of the 2e reduction products of oltipraz.—When the exhaustive electrolysis is carried out in DMF, the absorption spectrum of oltipraz

Fig. 2. UV-visible absorption spectra of oltipraz and its 2e reduction products in DMF. Curve a (—): oltipraz. Curve b (---): absorption spectrum of the exhaustively electrolyzed solution, 2e per molecule of oltipraz having been transferred. (— · —): Radical anion resulting from the 1e reduction of 5-(2-pyrazinyl)-1,2-dithiole-3-thione. Oltipraz concentration $C = 1$ mM, cell thickness: 0.1 cm; background: 0.1M TEAB in DMF.

(curve a in Fig. 2) is replaced by the absorption spectrum noted b in Fig. 2. Spectrum b is stable as long as the solution is not put in contact with air.

After injection of concentrated perchloric acid into the exhaustively electrolyzed solution, the absorption spectrum becomes analogous to spectrum c (Fig. 3) provided that the total concentration of added acid is $2C$ or more in the bulk, C being the initial concentration of oltipraz. When the concentration of added perchloric acid is lower than $2C$, the absorption spectrum is a mixture of spectra b and c, i.e., no spectrum is observable which could be ascribed to the formation of a monoprotated species. Once the solution has been acidified, it is not possible to reobtain spectrum b upon addition of an excess of a base as strong as TBAH. A spectrum similar to spectrum d (Fig. 3) is obtained instead. Moreover shifting from spectrum c to spectrum d, and vice versa, can easily be made by adding base or acid to the solution. Such a result ascertains that spectra c and d are the absorption spectra of an acid and its conjugated base, respectively. In that process, isosbestic points appear at 335, 380, and 470 nm (Fig. 3), and quantitative additions of strong acid and base show that the acid-base reaction involves the transfer of only one proton.

When the solutions corresponding to spectra c and d are left in contact with air, they undergo slow transformations, the half-reaction time being 100h for the acidic solution and 5h for the basic solution. In both cases, the ultimate products are identical. This common final product does not absorb appreciably at wavelengths greater than 420 nm but exhibits a flat absorption band around 350 nm (ϵ_{\max} being ca. $5500 M^{-1} cm^{-1}$) and a shoulder at 310 nm preceding a large increase in the absorbance at shorter wavelengths. In the following, the spectrum of this product will be called spectrum e (not shown in the figures). Besides, it is not possible to oxidize electrochemically the acidic and basic compounds whose absorption spectra are spectra c and d. However, the polarograms (dropping mercury electrode) of these solutions exhibit anodic waves which are typical of the oxidation of mercury in the presence of thiol or thiolate groups. The heights of such waves decrease markedly when the solutions are left in contact with air till their absorption spectra become like spectrum e.

When the solution corresponding to spectrum b is left in contact with air, the sharp absorption bands at 345 and 405-425 nm disappear as fast as oxygen diffuses through

the solution. In the end the absorption spectrum is a linear combination of spectra a (around 40%) and e (around 60%). Electrochemical reoxidation of the solution whose absorption spectrum is spectrum b can be performed at a controlled potential of -700 mV at the mercury pool electrode or at -100 mV (i.e., with an overpotential of ca. 900 mV) at the large platinum disk. Then the oxidation product is oltipraz.

Controlled-potential electrolysis carried out in ACN yields very similar results except for the following points: (i) spectrum d is obtained directly after exhaustive electrolysis, i.e., spectrum b is never recorded, at least when we operate under the same experimental conditions as when DMF is the solvent, particularly when the initial oltipraz concentration C is 1 mM. If C is greater than 5 mM, sharp absorption bands characteristic of spectrum b are superimposed on spectrum d in the spectrum of the exhaustively electrolyzed solution. (ii) When C is greater than 1 mM, the compound, whose absorption spectrum is c (Fig. 3), partially precipitates. Then, the crystalline red solid can be isolated by filtration, washed with ACN, dried and used for chemical analysis and 1H NMR spectroscopy after dissolution in deuterated solvents (DMF, DMSO, and pyridine). (iii) While spectrum c can be obtained as in the case of a DMF solution, a new species is formed in ACN when perchloric acid is added at a concentration higher than $2C$. Spectrum f (Fig. 3) is recorded when the bulk concentration of added perchloric acid is $3C$ or more. Shifting from spectrum c to spectrum f (either way) can be made easily by adding one equivalent of strong acid or base, isosbestic points appearing at 280, 365, and 430 nm (Fig. 3).

Methylation of the $2e$ reduction product of oltipraz can be achieved in DMF or ACN by adding pure methyl iodide (or dimethylsulfate) to the exhaustively electrolyzed solution. In both cases, the methylation is total when the concentration of methyl iodide introduced amounts to $2C$ or more. The UV-visible absorption spectrum of the methylated solution exhibits a band at $\lambda_{\max} = 350$ nm ($\epsilon_{\max} = 5500 M^{-1} cm^{-1}$) and two maxima of equal heights at 302 and 312 nm ($\epsilon = 5700 M^{-1} cm^{-1}$). This spectrum is similar to spectrum e, but most of all it is strikingly identical with that of the primary metabolite of oltipraz (5, 15). That the methylation of the $2e$ reduction product of oltipraz produces metabolites of the drug is confirmed by the isolation of the methylated products and 1H NMR and mass spectroscopy (see Appendix B).

Reaction pathways.—In order to justify the spectrophotometric changes which accompany the additions of strong acid or base to the exhaustively electrolyzed solution, it seems reasonable to assume that spectra b (Fig. 2) c, d, and f (Fig. 3) are the absorption spectra of dianionic, neutral (diprotonated), monoanionic (monoprotonated), and cationic (triprotonated) species, respectively.

As the structure of the diprotonated product (noted PH_2) can be established by means of 1H NMR spectroscopy (see Appendix B), the most probable structures of the monoprotonated (PH^-) and triprotonated (PH_3^+) products are as follows

The formation of the thione tautomeric form of PH_3^+ is likely since it can justify correctly the 100 nm hypsochromic shift which results from the protonation of PH_2 (Fig. 3). As PH_2 (see Appendix B), PH^- , and PH_3^+ can exist in isomeric (z, e) forms. TBAH is too weak a base, in either DMF or ACN, to deprotonate PH^- .

Therefore, we can consider that the electrochemical reduction of 1 mM oltipraz in ACN proceeds as follows

or

and depending on addition of perchloric acid

A solution of PH^- is obtained only when the amount of available protons is sufficient. It is not the case when the solvent is DMF, since DMF is less acidic than ACN as already noticed apropos of the kinetics of radical anion protonation, and it is no more the case when the initial concentration of oltipraz is higher than 5 mM in ACN. Under the latter circumstances, the basicity of the medium increases significantly as the electrolysis progresses towards completion and exhaustive electrolysis produces dianionic species. When the experiment is carried out in DMF, the dianionic species predominate markedly (spectrum b of Fig. 2).

The strong absorption band which appears at 345 nm in spectrum b is characteristic of the open form denoted P^{2-} of the dianion (1), while the twin bands at 405-425 nm are

probably due to the production of the cyclic form noted (P^{2-}) of the dianion.

The absorbance appearing at 500 nm and above in spectrum b of Fig. 2 can also be ascribed to the presence of P^{2-} (1). Similar equilibria between the cyclic and open forms of the dianionic $2e$ reduction products of 4,5-dimethyl-1,2-dithiole-3-thione and 4-methyl-5-phenyl-1,2-dithiole-3-thione have been described in a previous paper (1). We also showed that the dianionic $2e$ reduction products could be electrochemically oxidized at the mercury electrode at potentials no more positive than -700 mV, the oxidation yielding the original dithiole-thione, while the electrochemical oxidation is less easy at the platinum electrode, owing to large overpotential. However, when the dianionic $2e$ reduction products of oltipraz are left in contact with air, only a partial regeneration of oltipraz is obtained, its extent corresponds roughly to the amount of (P^{2-}) existing at the equilibrium before oxidation. In the cases of 4,5-dimethyl-1,2-dithiole-3-thione and 4-methyl-5-phenyl-1,2-dithiole-3-thione, the regeneration of the original dithiole-thiones through air oxidation were practically total. When left in contact with air, the open dianionic $2e$ reduction product of oltipraz yields the compound denoted ($\text{P}'\text{H}$)₂, whose absorption spectrum is spectrum e.

As mentioned in the previous section of this paper related to the reactivities of the $2e$ reduction products, (P^{2-}), P^{2-} , or PH^- can be methylated, and most of the methylated derivatives are metabolites of oltipraz denoted ($\text{P}'\text{CH}_3$)₂ (65%) and $\text{P}'(\text{CH}_3)_2$ (25%) (see also Appendix B).

Fig. 4. Reaction path for the electrochemical reduction of oltipraz and possible transformations of the $2e$ reduction products in the presence of protons, oxygen and/or methylating reagent. Most of the compounds can exist in resonant and/or isomeric forms. The structures of the pyrrolo(1,2-a)pyrazine derivatives denoted ($\text{P}'\text{H}$)₂, $\text{P}'(\text{CH}_3)_2$ and ($\text{P}'\text{CH}_3$)₂ are given in the text.

The following mechanism for the obtention of these derivatives is likely

The methylation is the driving force for such a process. A similar driving force is oxygen, since P^{2-} , (P^{2-}) , and PH^+ are ultimately transformed into $(\text{P}'\text{H})_2$ when left in contact with air.

As shown in Appendix B, $(\text{P}'\text{H})_2$ has the same pyrrolo[1,2-a]pyrazine structure as $(\text{P}'\text{CH}_3)_2$, thiol substituents replacing the methylthio groups at positions 8, 8'.

Conclusion

Figure 4, then, represents the state-of-the-art knowledge concerning the electrochemical reduction of oltipraz and the reactivity of its $2e$ reduction products in the presence of protons, oxygen, and/or methylating reagent.

In comparison with the electrochemical behavior of other dithiolethiones, which was reported in a previous paper (1), it appears that the influence of the pyrazinyl substituent is twofold.

1. The lifetime of the radical anion produced by the addition of one electron is considerably increased, a result which may be of biological interest if the antischistosomal activity is relevant to a radical mechanism.

2. The $2e$ reduction product can undergo complex transformations which involve the pyrazinyl ring and cannot occur when the latter is not present. It is particularly interesting to observe that these transformations yield the ultimate products noted $(\text{P}'\text{H})_2$, $\text{P}'(\text{CH}_3)_2$, or $(\text{P}'\text{CH}_3)_2$, which have been found among the metabolites of oltipraz isolated according to the procedures described in Ref. (5).

Before the electrochemical study was carried out, the latter result was far from evident, since the production of $\text{P}'(\text{CH}_3)_2$, for instance, could be considered at first glance as implying a $4e$ process like the following one

3. The presence of the methyl substituent at position 4 of the dithiole ring is not decisive since the reduction reaction pathway at the platinum electrode is not modified when it is replaced by a hydrogen, the only changes consisting in the lower basicity of the radical anion and the predominance of the cyclic form of the dianionic $2e$ reduction product (see Appendix B). However, 5-(2-pyrazinyl)-4-methyl-1,2-dithiole-3-one is reduced electrochemically according to a reaction pathway which differs markedly from that of oltipraz but is similar to those of dithiole-thiones (or one) having no pyrazinyl substituent (Appendix A). Besides, it is interesting to notice that

5-(2-pyrazinyl)-1,2-dithiole-3-one is not endowed with any antischistosomal activity, even though it is one of the metabolites of oltipraz (5).

APPENDIX A

Electrochemical Behavior of 5-(2-Pyrazinyl)-1,2-Dithiole-3-Thione

At the platinum electrode, the reduction of this oltipraz analog proceeds according to a pattern entirely similar to that of oltipraz. $2e$ reduction products having the same structures are obtained before and after addition of various amounts of perchloric acid to the exhaustively electrolyzed solution. Methylation or air-oxidation yield the compounds with pyrrolo [1,2-a] pyrazine skeletons analogous to $\text{P}'(\text{CH}_3)_2$ and $(\text{P}'\text{H})_2$. Since the electron donating effect of the methyl-4 substituent is missing, the radical anion produced upon $1e$ reduction is much less basic than in the case of oltipraz. As a result, its rate of protonation in DMF or ACN is so slow that preparing a solution of radical anion is possible when the controlled-potential electrolysis is stopped after transfer of a quantity of electricity amounting to $1e$ equivalent per molecule of the parent compound. The UV-visible absorption spectrum of the $1e$ reduced solution is reproduced in Fig. 2. Electrochemical or air oxidations of this radical anion regenerate the original oltipraz analog.

At the mercury electrode, the polarographic behavior of 5-(2-pyrazinyl)-1,2-dithiole-3-thione is identical to that of 5-phenyl-1,2-dithiole-3-thione, a dithiole-thione not substituted at the C-4 position of the dithiole ring. Such a behavior has been described and analyzed in a previous paper (1). The first monoelectronic cathodic wave occurring at -675 mV corresponds to the production of an organomercurial which can be prepared by means of controlled-potential electrolysis and has the same characteristics as the one obtained in the case of 5-phenyl-1,2-dithiole-3-thione (1). The second cathodic wave, at -1070 mV, corresponds to the $2e$ reduction, i.e., to the production of a mixture of the analogs of (P^{2-}) and P^{2-} . The suppression of the electron donating effect of the 4-methyl substituent renders the cyclic form markedly predominant (90%), as observed previously with other dithiole-thiones (1).

Electrochemical Behavior of

5-(2-Pyrazinyl)-4-Methyl-1,2-Dithiole-3-One

The electrochemical behavior of this oltipraz analog is identical with that of 5-phenyl-1,2-dithiole-3-one, which has been already reported (1). At the platinum electrode, only the $2e$ reduction is observable and it requires an overpotential of ca. -120 mV. The $2e$ reduction product prepared by means of controlled potential electrolysis is the following cyclic dithiole dianion

whose methylation results in ring opening. The methylated $2e$ reduction product has been isolated and its structure confirmed by means of ^1H NMR spectroscopy. No evolution yielding the formation of a pyrrolo[1,2-a]pyrazine skeleton can be obtained.

At the mercury electrode, the reversible $2e$ reduction occurs at -1080 mV. A $1e$ reduction producing an organomercurial is observable at -860 mV. However, the absence of the characteristic absorption band at ca. 400 nm in the UV-visible absorption spectrum (1) shows that it is not the carbon atom at position 5 of the dithiole ring which is bound to mercury, as occurred in the case

of 5-phenyl-1,2-dithiole-3-one. Thus, the structure of the organomercurial is probably

APPENDIX B

The derivatives resulting from the methylation of the 2e reduction products can be isolated as follows. After stoichiometric methylation of the exhaustively electrolyzed solution of oltipraz in ACN, ACN is evaporated under vacuum. The remaining solid is washed with acetone, in which the solubility of TEAB is very low. Acetone is removed under vacuum from the solution containing the methylated derivatives, and the remaining solid is recrystallized twice in water and dried under vacuum. The signals appearing in the ^1H NMR spectrum are identical with those given in the literature (5) for the metabolite of oltipraz which has the same structure and formula as $P'(\text{CH}_3)_2$, the solvent being deuterated DMSO, *i.e.*: 2.20 ppm [S, $-\text{SCH}_{3(8)}$]; 2.23 ppm [S, $-\text{SCH}_{3(6)}$]; 2.40 ppm [S, $-\text{CH}_{3(7)}$]; 7.75 ppm [D, $J = 5.2$ Hz, $-\text{H}_{(3)}$]; 8.37 ppm [D, $J = 1.5$ and $J = 5.2$ Hz, $-\text{H}_{(4)}$]; 8.92 ppm [D, $J = 1.5$ Hz, $-\text{H}_{(1)}$]; where S and D stand for singlet and doublet, respectively. However, the result of chemical analysis is: (experimentally found) C: 50.5%, N: 12.7%, S: 29.8%; (calculated) C: 53.5%, N: 12.5%, S: 28.6%. The disagreement between calculated and observed elemental analysis concerning particularly the carbon percentage suggests that the isolated solid is actually a mixture of compounds having similar spectral characteristics. This assumption can be confirmed by means of thin layer chromatography, and two major products can be separated by means of column chromatography. Then, chemical analysis gives for the first one (25%); C: 53.5%; N: 12.5%; S: 28.6%; and for the second one (65%); C: 51.7%; N: 13.4%; S: 30.6%. The preceding results indicate that the production of $P'(\text{CH}_3)_2$ amounts to only 25%. The elemental analysis of the second compound is in good agreement with the formula of $(P'\text{CH}_3)_2$, and its obtention is confirmed by the determination of a molecular weight of 418 by means of mass spectroscopy. The remaining products (10%), which have not been isolated, are probably unsymmetrical disulfides.

Isolation of PH_2 has been described in the text. There are many tautomers which can be considered as possible structures for PH_2 . However, all those containing a thione group are to be rejected for a number of reasons: a thione would be reducible at a not too negative potential, but no corresponding polarographic wave is observed, while the anodic wave characteristic of a thiol group appears in the polarogram, as already mentioned in the text. The band due to C=S vibration (16) cannot be found in the IR absorption spectrum. Besides, the persistency of a strong absorption band at ca. 500 nm (spectrum c, Fig. 3) indicates that the dithiole ring is not destroyed (1). When all the preceding arguments are taken into consideration, it is possible to make the following assignments concerning the ^1H NMR spectrum of PH_2 , which has been dissolved successively in deuterated ACN, DMF, DMSO and pyridine: [2.13 ppm S, $-\text{CH}_{3(4,z)}$]; 2.34 ppm [S, $-\text{CH}_{3(4,e)}$]; 7.23 ppm [D, $J = 5.2$ Hz, $-\text{H}_{(6,z)}$]; 7.29 ppm [D, $J = 5.5$ Hz, $-\text{H}_{(6,e)}$]; 7.48 ppm [S, $-\text{H}_{(3'e)}$]; 8.04 ppm [D, $J = 5.2$ Hz, $-\text{H}_{(5'z)}$ and/or e]; 8.3 ppm [S, $-\text{H}_{(3'e)}$]; where the subscripts z and e indicate the

type of isomeric z or e form concerned. According to the integration trace, the amount of z isomer is roughly twice that of e isomer. A broad peak which can be ascribed to the proton bound to a nitrogen atom appears at ca. 11.7 ppm. The result of chemical analysis is: (experimental) C: 41.8%; N: 11.8%; S: 35.8%; (calculated) C: 41.6%; N: 11.6%; S: 38.4%.

PH_2 , which has been isolated can be dissolved again in ACN, the PH_2 concentration being 1 mM or less, and acidified stoichiometrically with perchloric acid in order to produce PH_3^+ . The crystalline salt PH_3^+ , ClO_4^- can be gathered up after evaporation of the solvent under vacuum. The protonation (quaternarization) of a nitrogen atom, which causes the hypsochromic shift of the main visible absorption band from 475 to 400 nm (from spectrum d to spectrum f in Fig. 3), is corroborated by the IR absorption spectrum of the crystal dispersed into KBr since absorption bands appear in this spectrum at ca. 2800 and 1100 cm^{-1} , which are characteristic of $-\text{N}^+\text{H}_2$ (17) and ClO_4^- , respectively.

When the solution of PH_2 in deuterated DMF has been left in contact with air for one week, PH_2 is totally transformed into $(P'\text{H})_2$, which still bears thiol substituents according to its polarographic behavior. The structure proposed in the text for $(P'\text{H})_2$ is in agreement with the following assignments concerning its ^1H NMR spectrum: 1 ppm [S, $-\text{CH}_{3(8)}$]; 8.22 ppm [D, $J = 5.0$ Hz, $-\text{H}_{(3)}$]; 8.72 ppm [D, $J = 5.0$ Hz, $-\text{H}_{(4)}$]; 9.27 ppm [S, $-\text{H}_{(1)}$]. The decrease in the chemical shift of $-\text{CH}_{3(8)}$ of $(P'\text{H})_2$ compared with that of $-\text{CH}_{3(8)}$ of $P'(\text{CH}_3)_2$ results from the formation of the disulfide bond (5). The formation of a sulfoxide would provoke an increase in the chemical shift of $-\text{CH}_{3(8)}$ (5).

Fundamental Electrochemical Studies of Polyacetylene

J. H. Kaufman, T.-C. Chung, and A. J. Heeger

Institute for Polymers and Organic Solids, University of California at Santa Barbara, Santa Barbara, California 93106

ABSTRACT

We report an electrochemical and *in situ* optical study of doping processes in polyacetylene. Electrochemical voltage spectroscopy (EVS) is used to characterize the energies of charge injection and removal, as well as the kinetics of these processes. *In situ* optical spectroscopy provides complementary information on the energy of the electronic states where charge is stored (after injection). The EVS results provide a measurement of the energy gap; from these electrochemical data, we infer $E_g \cong 1.5$ eV, in good agreement with that obtained by other methods. The observation of hysteresis in the electrochemical cycle, and the associated increase in the midgap optical absorption upon doping, are both indicative of the formation of states in the bandgap. The resolution available with the EVS technique allows precise determination of both the energy and number of these states. The results demonstrate that the injected charge is stored in the form of charged solitons (chemical potential E_g/π , with respect to midgap) and not a random distribution of impurity states throughout the gap, nor polaron states near the bandedge. The observation of 300 ppm charge removal precisely at midgap provides a detailed verification of Kivelson's model of charge transport via intersoliton electron hopping. Kinetics studies performed both at low and high dopant levels reveal that ionic diffusion rates under load (current carrying conditions) are two orders of magnitude faster than free ionic-diffusion rates. This anomaly is explained in terms of electric field enhancement of the ionic diffusion in $(CH)_x$.

The discovery of rechargeable storage batteries (1,2) made from synthetic metals such as polyacetylene has stimulated detailed experimental studies of these materials using electrochemical techniques (3-8). The precise control of dopant levels available through electrochemistry and the ability to reversibly dope and undope the polymer offer unique advantages to fundamental scientific studies and to material characterization from a technological point of view.

Owing to the simplicity of its structure, polyacetylene is often considered the prototype conducting polymer (9). In electrochemical studies, experiments employing $(CH)_x$ as the active electrode demonstrated the utility of conducting polymers as an electroactive class of materials (1-8). By applying an external voltage to an electrochemical cell with $(CH)_x$ as one electrode, the chemical potential of the polymer can be shifted across the bandgap, and the polymer can be electrochemically oxidized or reduced (4). Microscopically, the $(CH)_x$ fibrils expand to admit the dopant ions between polymer chains, and charge transfer occurs without damage to the structure (10). Both oxidation and reduction are reversible even at fairly high concentrations (above 4%). Though the morphology (9) of $(CH)_x$ may differ in detail from that of other conducting polymers, the electrochemical techniques and concepts developed in studies of polyacetylene may be universally applied to this whole class of new materials.

In this paper, we report an electrochemical and *in situ* optical study of doping processes in polyacetylene. Electrochemical voltage spectroscopy (EVS) is used to characterize the energies of charge injection and removal, as well as the kinetics of these processes. At low doping levels, the results demonstrate a unique hysteresis in the cell voltage *vs.* charge relation, which we interpret as charge injection via polarons and charge removal via solitons. At higher doping levels, the voltage *vs.* charge shows a change in slope, and the hysteresis vanishes for rapid charge cycles. Kinetics studies performed at both low and high dopant levels reveal that ionic diffusion rates under load (current carrying conditions) are two orders of magnitude faster than free-diffusion rates. This anomaly is explained in terms of electric field enhancement of ionic diffusion in $(CH)_x$.

Experimental Techniques

Electrochemical voltage spectroscopy (EVS).—Computer-controlled electrochemical voltage spectroscopy is a convenient method for precise *V vs. Q* measurements of an electrochemical cell at quasiequilibrium (4) (see Fig. 1). The external power supply serves to vary the electrochemical potential difference between the $(CH)_x$ electrode and the lithium electrode. When carrying out an experiment, the cell first is allowed to equilibrate at some ini-

tial voltage V_0 , measured with respect to the lithium reference electrode. After stepping the voltage by an amount dV , the cell current (i_c) is monitored by the voltage drop across a series resistor (R) and decreases with time as the cell approaches equilibrium. When i_c falls below a preset minimum value, i_c^{\min} , (chosen to be small enough to insure quasiequilibrium conditions), the current is integrated, yielding the charge dQ that flowed on raising the cell voltage from V_0 to $(V_0 + dV)$. This procedure is repeated until a preset maximum voltage is reached. The sign of dV is then reversed, and the voltage is stepped back to V_0 . At each voltage, the differential charge that flowed (dQ_j) at the voltage $V_j = V_0 + jdV$ and the derivative dQ/dV are stored on disk. The derivative may be integrated to obtain a plot of *V vs. Q*, which in turn may be integrated to find the energy density of the cell. The derivative dQ/dV is the incremental charge capacitance of the battery.

The information obtained from EVS is very similar to that obtained from cyclic voltammetry (12). Both the derivative dQ/dV *vs.* *V* (from EVS) and *i vs. V* (from cyclic voltammetry) measure the number of charges transferred as a function of energy. There are, however, some important differences. The minimum current in the EVS method can be made arbitrarily small so that the entire system is in diffusion equilibrium. In cyclic voltammetry, the electrode reactants and products are considered to be in equilibrium if the kinetics of charge transfer are rapid compared to mass-transport rates (12). The method, therefore, probes the surface of the polymer where concentrations are related to cell voltage by the Nernst equation. Since the total charge accommodated on the surface [of a $(CH)_x$ fibril, for example] is orders of magnitude less than the charge capacity of the bulk, the resolution of the cyclic voltammetry method is orders of magnitude less than EVS. By sacrificing speed, features corresponding to parts per million of charge can routinely be resolved with EVS. The integrated EVS data, *V vs. Q*, is equivalent to a constant current charge discharge at $i_c = i_c^{\min}$. However, since $i_c^{\text{avg}} \gg i_c^{\min}$, data collection is much faster than the corresponding constant current method. In summary, (fast) cyclic voltammetry probes surface only, whereas (slow) EVS more truly reflects the response of the total polymer structure (interior plus surface). Thus, EVS represents a probe of the thermodynamics of the charge-discharge process.

Nonequilibrium effects such as I^2R loss and overpotentials do not contribute to the EVS data for conducting polymer electrodes. The unimportance of I^2R loss follows directly from the fact that all data are acquired at i_c^{\min} , which can be made arbitrarily small. The absence of overpotential effects in the EVS data of conducting polymers follows from an examination of the electrochemical

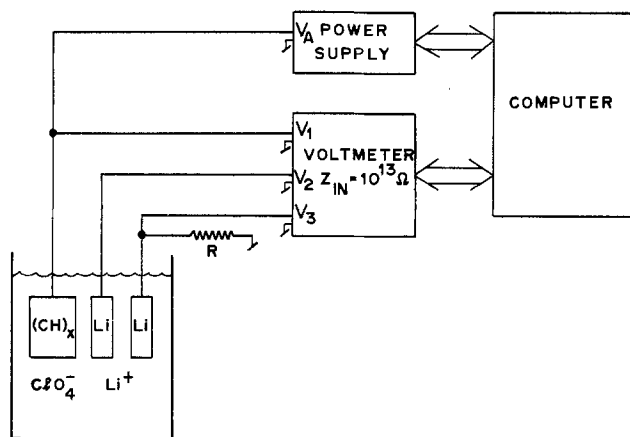

Fig. 1. Schematic diagram of computer-controlled instrumentation for electrochemical voltage spectroscopy (EVS); $V = V_1 - V_2$, $i = V_3/R$.

reactions. In a conventional electrochemical cell with two metal electrodes, the equilibrium cell voltage, V_e , is determined by the difference in chemical potentials of the metals. A double layer of ions at each electrode generates a potential barrier for each half-cell reaction. In equilibrium, at each electrode

and no current flows in the cell. When an overpotential $\Delta V = V_{app} - V_e$ is applied, the barrier heights at each electrode change and the half-cell reactions proceed at a rate determined by the activation energies at the barriers. The current through the cell as a function of applied overpotential is described by the Butler-Volmer equation (12). In such a cell (where the chemical potentials of the two metal electrodes do not change during charge or discharge), the current does not decay with time so EVS would not be a useful technique. In the case of a polymer electrode, however, the material dopes as current flows, and the chemical potential of the polymer changes until the equilibrium potential reaches the applied potential. At this point (where the EVS data are taken), the overpotential is rigorously zero. The double-layer barrier and all other contributions to the activation energy (e.g., ionic diffusion) determine the rate at which the polymer reaches equilibrium, but since all measurements are made arbitrarily close to equilibrium, they do not affect the EVS data.

Cell construction.—A battery cell is constructed by pressing $(CH)_x$ film (0.1 mm thick \times 1 cm²; 3 mg) onto platinum mesh to act as the working electrode. Lithium metal (surface scraped clean and then embedded in nickel mesh) acts as the counterelectrode and is separated from the $(CH)_x$ by a kiln-dried piece of glass filter paper. A second (identical) lithium electrode is used as the reference electrode. Basic activated alumina serves to scavenge impurities. One molar (1M) $LiClO_4$ -tetrahydrofuran is added as the electrolyte-solvent system for n-type doping, while 1M $LiClO_4$ -propylene carbonate is used for p-type doping. Prior to use, the $LiClO_4$ is melted under dynamic vacuum. Tetrahydrofuran (Fisher Scientific Company) is kept in sodium benzophenone, while propylene carbonate (Aldrich Chemical Company) is spin-band distilled and stored over lithium chips. The cell is encased in rectangular glass and sealed under vacuum across platinum wires, which are spot welded to the electrodes.

Although resolution at the ppm level is routinely available with the EVS technique, cell purity at this level is difficult to achieve. For example, impurities can lead to side reactions causing charge flow at cell voltages within the energy gap of *trans*- $(CH)_x$. In this case, the intrinsic charge-transfer processes might be masked.

When more rigorous cleaning procedures were required, a special three-armed apparatus was constructed

Fig. 2. Three-armed apparatus used for construction of rigorously clean electrochemical cells. This construction allowed extensive washing of the cell electrodes (and separators) while under vacuum.

(Fig. 2), which allowed washing of the cell electrodes (and separators) while under vacuum. The first arm, made of rectangular glass, contains the electrodes and leads. The second arm contains dried $LiClO_4$, and the third arm contains purified THF with $Li^+ Naph^-$ in solution. The apparatus was first evacuated, and then pure THF was vacuum distilled into the electrode arm. After washing, the THF was poured back into the arm containing the $Li^+ Naph^-$ solution (which serves to scavenge any impurities taken out in the washing step). This process was repeated a number of times. Pure THF was then vacuum distilled into the arm containing $LiClO_4$, and the electrolyte was transferred into the electrode arm. The rectangular glass was then twice sealed across the wire leads, and the sealed electrochemical cell removed from the apparatus.

Experimental Results: Charge Injection into the Electronic Band Structure

Figure 3 shows dQ/dV vs. V as obtained from EVS data. The derivative dQ/dV is plotted vs. V for injection of n- and p-type dopants. The integrated EVS data (i.e., V vs. Q) for charge injection and removal (p-type) is shown in Fig. 4. These data were obtained with 0.02V steps at $i_c^{min} = 1 \mu A/mg$. A threshold for n-type charge injection is observed at $1.75 \pm 0.05V$ (referenced to lithium). Hysteresis is evident; final charge removal occurs at $2.40 \pm 0.05V$. The threshold for p-type injection occurs at $3.05 \pm 0.05V$, and again final charge removal is at $2.40 \pm 0.05V$.

The thresholds for charge injection can be understood in terms of the band structure of *trans*- $(CH)_x$. Polyacetylene in its undoped state is a semiconductor

Fig. 3. dQ/dV vs. V as obtained from EVS data; injection n- (reducing) and p-type (oxidizing) dopants are shown.

with the electronic chemical potential at midgap. By applying an external potential between the $(\text{CH})_x$ working electrode and a Li counterelectrode in an electrochemical cell, it is possible to counterbalance the difference in chemical potential between $(\text{CH})_x$ and Li to allow injection into the available states of the polymer (see Fig. 5). If there are no localized states in the bandgap, no charge will flow until the chemical potential is at an energy equal to a bandedge of *trans*- $(\text{CH})_x$ where states are available. Thus, the band structure of $(\text{CH})_x$ determines the threshold for charge injection (n- or p-type). At an applied voltage V_p° , holes are injected into the $(\text{CH})_x$ electrode. Similarly, at a lower applied voltage V_n° , electrons are injected into the $(\text{CH})_x$ electrode. Structural relaxation around the injected charges will lead to polaron bound states (13, 14) below the bandedge and, thereby, an apparent energy gap (for charge injection) that is somewhat smaller than that determined by optical absorption (9, 15). The formation of a structural distortion is not a novel phenomenon in the context of charge injection into molecules. Structural relaxation after oxidation or reduction lowers the free energy of the molecule (or macromolecule) and is, therefore, thermodynamically favorable. Similarly, in semiconducting polymers, charge injection is expected to be followed by a localized structural distortion, *i.e.*, a polaron.

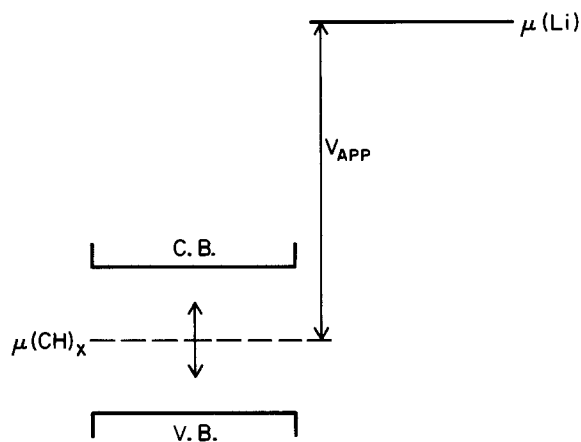

Fig. 5. Schematic band diagram relating injection threshold voltages to valence and conduction bandedges of *trans*- $(\text{CH})_x$.

The difference between injection energies for electron or hole creation is defined to be equal to the electronic energy gap $E_g = 2\Delta$, assuming a rigid band picture for the electronic structure. From optical absorption of the undoped polymer, one finds $E_g = 2\Delta \sim 1.5$ eV. Allowing for structural relaxation around the injected charge to form polarons, one would predict

$$V_p^\circ - V_n^\circ = 2E_p = (4\sqrt{2}/\pi)\Delta \cong 1.34 \text{ eV} \quad [1]$$

Experimentally, one finds (see Fig. 3)

$$(V_p^\circ - V_n^\circ) = 1.3 \text{ eV}$$

in good agreement with Eq. [1]. The implied value for the energy gap, $E_g \cong 1.5$ eV, is therefore consistent with that obtained from optical-absorption measurements.

Though injection occurs near the bandedge, charge removal occurs at lower energy. The observed hysteresis is independent of set voltage limits and step size (though smaller step size increases resolution). Figure 6 shows the EVS data for n-type charge injection (curve B) and charge removal (curve A). The small amount of charge injected in the shoulder between 2 and 1.75V is due to residual impurities or defects; curve C shows the injection data from a cell with an even cleaner injection edge for comparison. This same "impurity shoulder" is evident in the charge removal data as well.

In order to clearly observe the important features of Fig. 6, it is essential to have a cell construction which is rigorously clean. An example of the kind of data obtained under more routine conditions is shown in Fig. 7. In this case, the cell was constructed in a controlled atmosphere dry box, but the rigorous cleaning procedures were not carried out. In the initial cycle, charge flow begins even at midgap. On subsequent cycles, the injection curves clean up somewhat, with a more clearly defined edge appearing below 2V. The successive behavior (first cycle through fourteenth cycle) implies that impurities can be at least partially cleaned up in the cell through side reactions. However, after many cycles, both the injection edge and the midgap peak become broadened and more difficult to detect, suggesting that electrochemical cycling in-

Fig. 6. dQ/dV vs. V showing hysteresis in voltages for n-type charge removal (curve A) and charge injection (curve B). Curve C shows the injection data from a cell with an even cleaner edge for comparison. The data are plotted as dQ/dV , where y is the dopant concentration in the $(\text{CH})_x$ electrode.

Fig. 7. dQ/dV vs. V for an electrochemical cell showing the effect of impurities. The numbers (1, 4, 9, 14) refer to the number of cycles. Successive oxidation and reduction removes impurity effects (through side reactions) leading to a relatively clean injection below 2 eV (see text).

duces significant disorder in $trans-(CH)_x$. By extensive experimental studies on many cells, we have been able to sort out the impurity or imperfection related features (*i.e.*, extrinsic) such as the weak shoulder near 2.0V in Fig. 6.

Ignoring the impurity shoulder, we observe a single process for charge injection which occurs at about 1.75V. Note in particular that there is no detectable injection at midgap (2.4V). There are, however, two distinct modes for charge removal. Most of the charge is removed in the large peak which extends up to about 1.9V. A second peak at 2.4V (relative to Li) corresponds quantitatively to the removal of the final 300 ppm of charge at midgap.

The temperature dependence of the hysteresis has also been measured. Between $T = 21^\circ\text{C}$ and $T = 44^\circ\text{C}$, the hysteresis was found to be independent of temperature for $I^{\text{min}} \sim 2 \mu\text{A/mg}$ and below. Since Fickian diffusion rates are inversely proportional to temperature, the observed independence is a good indication of diffusion equilibrium below the metal-insulator transition (9). The ionic mobility is given by

$$\mu = e\tau/M = eD_0/k_B T \quad [2]$$

where M is the mass of the ion. Therefore

$$\tau = MD_0/kT \quad [3]$$

A 20°C change in temperature would result in a significant change in τ . Since the current is exponentially dependent on temperature, so is the concentration

$$c = \int j(t) dt \sim c_0 e^{-t/\tau}$$

If the system were diffusion limited, at each voltage step one would have $t \ll \tau$. Then $e^{-t/\tau} \sim 1 + t/\tau + \dots$. A 10% change in τ would, therefore, result in a 10% change in concentration at a given voltage. Alternatively, since the voltage *vs.* charge relation can be approximated by a power law (10)

$$V \sim A + Bc^\gamma \quad [4]$$

For $\gamma \sim 2/3$, a 10% change in τ (from ΔT of 20°C , ignoring any temperature dependence of D_0) would result in an 8% change in voltage or approximately 16% increase in hysteresis on lowering the temperature by 23 K. This is certainly a lower limit, since typically one expects D_0 to be

activated and thus strongly temperature dependent. The corresponding change in apparent concentration would certainly show up in the electrochemical-voltage spectrograph. Since no change of this magnitude is evident, it follows that $t > \tau$ and that the system is in diffusion equilibrium.

Discussion of Charge Injection and Removal Energies

Su *et al.* (16) demonstrated that the lowest energy-charge configuration for a polyacetylene chain is a collection of soliton-antisoliton pairs corresponding to bond-alternation domain walls in the $(CH)_x$ crystal lattice. Since in polyacetylene there is one π electron per carbon atom, each domain wall has associated with it a nonbonding localized state which by symmetry lies at the center of the energy gap (Fig. 8). Since this electronic state can hold zero, one, or two electrons, the soliton (electronic state plus structural distortion) can have charge 0 or $\pm 1e$, where e is the electron charge.

The soliton-antisoliton pairs that are created by doping store an energy equal to the soliton-creation energy (16-19), $E_s = (2/\pi)\Delta$, where $2\Delta = E_g$ is the energy gap. Thus upon adding a pair of electrons (reduction) the charge is accommodated in two negative solitons and the increase in free energy is $(2/\pi)\Delta$ per negative soliton. Consequently, in n-doped (reduced) $trans-(CH)_x$ at dilute concentrations, the chemical potential is at $\mu_n = +(2/\pi)\Delta$ with respect to midgap. Similarly, by a completely symmetrical argument, for p-doped (oxidized) $trans-(CH)_x$ the chemical potential is at $-(2/\pi)\Delta$ with respect to midgap. At higher concentrations, additional contributions arise from charge-charge interactions and from the change in electronic structure when the energy gap closes to form a true metal (~ 5 mole percent [m/o]) (10, 29). This analysis of the chemical potential in the dilute regime ignores a variety of additional contributions (see Appendix A) and it ignores the contribution from the configurational entropy; $S = k_B \ln W$, where W describes the number of independent ways in which N_s solitons can be arranged on a chain of N carbon atoms (see Appendix B). These additional contributions are small in magnitude (and independent of concentration), so that they are not important to the interpretation of the EVS data.

In addition to these "doping induced" soliton pairs, polyacetylene contains approximately ~ 300 ppm of permanent defects which originate during isomerization (9). These states can become charged; again, the associated defect levels would reside at midgap. Since the defect corresponding to the isomerization-induced neutral soliton is permanent, the charged soliton stores no energy. Consequently, the last ~ 300 ppm of charge should come out at a cell voltage corresponding to placing the chemical potential of the Li counter at the neutral point, *i.e.*, 2.4V (see next section).

These experiments establish the open-circuit voltage of neutral $trans-(CH)_x$ *vs.* Li to be 2.4V. This value is consistent with the measured difference in work functions. From photoemission studies (20) of $trans-(CH)_x$, the work function was found to be 4.5 eV, whereas the handbook value

Fig. 8. Schematic diagram of positive and negative bond alternation domain walls (solitons) in $trans-(CH)_x$. Each domain wall has associated with it a nonbonding state at the center of the energy gap. The soliton is positive if this state is empty, and negative if this state is doubly occupied. The diagram is schematic; the actual domain wall in $trans-(CH)_x$ is spread over about 12-15 carbon atoms.

for lithium metal is about 2.4 eV. Additional contributions are discussed in Appendix B.

Charge injection into the polymer is necessarily a non-equilibrium process since injection via the lower energy soliton state cannot take place. Injection directly into solitons is inhibited by a topological constraint: solitons must be made in pairs (16-19), whereas electrons (or holes) are injected at the electrode singly and in an uncorrelated manner. Moreover, even in the event of a fluctuation with simultaneous injection of a pair of electrons (or holes), the direct process is exponentially small since it requires a significant lattice distortion simultaneous with the electronic transition below the bandedge (21). Precisely the same features have been shown to dominate the photogeneration of solitons in polyacetylene (22). Thus, charge is injected into the band states (or associated polaron states) of the polymer, and the injection threshold should occur near the bandedge. After injection, the lattice distortions which lead to soliton formation take place through the reaction

where P denotes polaron and S and \bar{S} denote soliton and antisoliton, respectively. The injected charge is stored in the midgap soliton states. This has been proved experimentally through *in situ* optoelectrochemical spectroscopy (10) and through photoinduced absorption (23). Charge removal, on the other hand, takes place from the doped polymer in which the chemical potential is determined by the charged solitons, as defined above. The essential point is that once formed, the solitons can exist in any one of the three charged states (positive, neutral, or negative) (16-19), so that charge can be removed from the solitons one at a time. Thus, one expects charge injection (electrons) to occur at approximately the polaron energy (13, 14), $E_p = \sqrt{2}(2/\pi)\Delta$ (see Eq. [1]), charge removal to occur at the chemical potential, $\mu_n = E_s = (2/\pi)\Delta$. For hole injection and removal, the argument is the same: injection at $-\sqrt{2}(2/\pi)\Delta$ and removal at $\mu_p = -(2/\pi)\Delta$ (note that all energies are measured with respect to midgap). This hysteresis is evident in the data of Fig. 4 and 6. Moreover, the same hysteresis has been observed in the intensity of the midgap transition as a function of applied voltage during *in situ* optical studies (10). Thus, both the EVS data (4) and the optoelectrochemical data (10) indicate charge injection near the bandedge, but charge storage and removal from the states at midgap.

Integration of the data from Fig. 6 (curve A) yields the voltage as a function of charge (Fig. 9). The dashed lines in the figure represent idealized charge injection (via polarons at energy E_p) and charge removal (via solitons at energy $E_s = (2/\pi)\Delta$). From Fig. 6 and 9, we infer $E_p \cong 0.65$ eV (*i.e.*, the difference between midgap, 2.4V, and charge injection, 1.75V). From the observed hysteresis in the main charge injection-removal edge, ΔV on Fig. 6, we find $E_p - E_s \cong 0.1-0.15$ eV, implying $E_s \cong 0.5-0.55$ eV. $E_s = (2/\pi)\Delta$, this value leads to $2\Delta = 1.6-1.8$ eV, in close agreement with the 1d energy gap as obtained from studies of the pressure dependence of the optical absorption (15). Note that although most of the charge comes out at about 0.5-0.6V above (or below) midgap, the final ± 300 ppm of charge is removed precisely at midgap. This final charge removal is due to the neutral soliton defects and is discussed in detail in the next section.

The principal quantitative uncertainty in the above analysis is the role of three-dimensional effects resulting from interchain coupling (15, 24). Although relatively small, studies of the pressure dependence (15) of the interband absorption edge have shown that the energy gap is reduced from the 1d value by about 0.2-0.4 eV. Thus, although the soliton level remains rigorously at midgap in the presence of relatively weak interchain coupling, the injection threshold will be sensitive to interchain interaction. Consequently, the value inferred above for E_p (1d) may be too small by about 0.1 eV.

The interpretation of soliton states as the source of hysteresis in polyacetylene electrochemical cells requires an

Fig. 9. Q vs. V during charge removal (the integral of curve A in Fig. 6). The dashed lines represent idealized charge injection (at the polaron energy, E_p) and charge removal (at the soliton energy, E_s). The final 300 ppm will come out (from the soliton defects) at midgap, as predicted by the Kivelson mechanism. The inset shows a full cycle (n-type) to higher doping levels.

understanding (and dismissal) of other energy loss processes. Dissipation of energy through the cell internal resistance is eliminated through the use of a reference electrode (through which no current flows) and arbitrarily small minimum currents. Since the cell internal resistance is typically $\sim 100\Omega$, and since measurements were taken at $i_c^{\min} \sim 10^{-6}$ A, the voltage difference on charging and discharging would be $\Delta V \sim 10^{-4}$ V, truly negligible. The fact that data have been obtained with 100% coulombic efficiency rules out irreversible chemical reactions. Finally, factors limiting mass-transport rates were considered. Detailed measurements of ionic diffusion rates will be discussed in the "Optical Spectroscopy" section below. The results demonstrated electric field enhancement of ionic diffusion greater than 2 orders of magnitude. By insuring that the resting time at each voltage step was longer than the measured ion-transport rate, diffusion equilibrium was achieved. The hysteresis, therefore, can only be due to relaxation of the charged polymer state into a lower energy state after charge injection. The formation of soliton-antisoliton pairs seems to be the only relaxation mode with sufficient energy to account for the observed hysteresis in the main charge-removal peak (Fig. 6).

Charge Transport at Dilute Levels: the Kivelson Mechanism

The data of Fig. 6 show that ~ 300 ppm are removed in a narrow range about midgap (the charge removal peak in Fig. 6 has a full width of about 0.2V, centered at 2.4V). This demonstration of the removal of 300 ppm of charge precisely at midgap is important in understanding transport phenomena in lightly doped polyacetylene. Kivelson (25) proposed that, in lightly doped *trans*-(CH) $_x$, phonon-assisted electron hopping among soliton midgap states could be the dominant mechanism of charge transport. A key feature of the Kivelson mechanism (which distinguishes it from other hopping models that do not involve solitons) is that transport of charge occurs through energetically equivalent levels which are at gapcenter. This is to be contrasted, for example, with polaron hopping models, which involve excitation from localized states near the bandedge into band states. A critical test of the transport in *trans*-(CH) $_x$, therefore, is to establish the energy of the localized states that dominate the transport in the dilute regime (5). The EVS data (Fig. 6) give a direct measure of this energy and establish it to be precisely at midgap, as predicted by the Kivelson mechanism.

The EVS data, dQ/dV vs. V , may be thought of as an infinitely slow cyclic voltammogram (see the "Experimental Technique" section). Although the principal charge removal peak is observed in cyclic voltammetry experiments, the smaller midgap peak has never been reported. This is due to the small amount of charge removed at midgap and to the nonequilibrium effects inherent in cyclic voltammetry when ionic diffusion rates

become very slow. Since the EVS method has the resolution to detect parts per million of charge, and since the measurements can be made arbitrarily close to diffusion equilibrium, the data are not diffusion limited.

The removal of ~300 ppm of charge at midgap (see the previous section) follows directly from the Kivelson mechanism. We note, however, that charge injection directly into these neutral solitons is not observed, even though they exist in the neutral polymer. The Kivelson mechanism requires electron hopping between energetically equivalent states. Therefore, in the process of charge injection, the neutral soliton midgap states in the bulk of the $(\text{CH})_x$ electrode are not accessible since there are no Li^+ ions in the bulk material. As a result, electron hopping through the "midgap" states is inhibited by the inequivalence of the site energies. Thus, these levels will become charged at midgap only after initial charge injection (at the surface) into a band (or polaron) state with the charge subsequently migrating to and falling into the lower energy midgap state, as described in detail in the previous section. During charge removal, since the Li^+ ions are distributed into the polymer, electronic charge can hop between the equivalent midgap states, diffusing to the contact where it can be removed at midgap. The Li^+ ions will, of course, follow and return into the electrolyte. Therefore, the injection and transport of electronic charge into the neutral soliton defect states is inhibited by the site inequivalence, whereas the transport and subsequent removal of charge from these states proceeds via the Kivelson mechanism. The charge removal peak at 2.4V and the hysteresis are evident in Fig. 6.

Ionic Diffusion in *trans*-(CH)_x: Field Enhancement

A detailed study of mass transport in polyacetylene was conducted to determine its contribution (if any) to the observed hysteresis, as well as to study field-enhancement phenomena (26). By modifying the EVS experiment to store the current *vs.* time information (as opposed to just the integrated charge), the ionic diffusion rate can be measured as a function of energy and dopant concentration (under current carrying conditions). Alternatively, by measuring the recovery of the open-circuit voltage after a period of constant current charging (or discharging), the free diffusion rate can be measured (6, 27). In both experiments, the signal (after a short transient) is found to decay exponentially with time, indicating that the diffusion

obeys Fick's law. An example of the EVS current decay is shown in the inset to Fig. 10.

Figure 10 shows the diffusion time constant (τ) as a function of voltage for charging (removal of Li ions). The time constant is observed to rise from ~250s at 1V to ~1000s at the bandedge. In the bandgap, τ rapidly increases to ~3000s. These values are to be compared with the measured free diffusion rates of ~12h (40,000s). Assuming cylindrical geometry for the $(\text{CH})_x$ fibrils, the diffusion constant can be obtained from the exponential decay time (28)

$$D_0 = r_0^2 / [(2.405)^2 \tau_0] \quad [5]$$

where r_0 is the fibril radius ~100Å. From this expression, a time constant of 12h corresponds to a diffusion constant $D_0 \sim 4 \times 10^{-18} \text{ cm}^2/\text{s}$. A time constant ~400s corresponds to $D_0 \sim 4 \times 10^{-16} \text{ cm}^2/\text{s}$.

The apparent paradox between free-diffusion rates of 40,000s and rates ~400s under current carrying conditions was resolved in a publication by Kaufman *et al.* (26). The presence of a small driving potential (or a load) causes current to flow and generates a large electric field within the fibrils. This field dramatically increases the ion-transport rate when the electronic screening length is on the order of a fibril radius. Under current carrying conditions, this theory accounts for the observed enhancement of two orders of magnitude or more.

Since the minimum current in the EVS method can be made arbitrarily small, it is possible to wait at each voltage step a time much longer than the field-enhanced diffusion time. By measuring the diffusion rate, one can adjust the minimum current so that the cell is always in diffusion equilibrium when measurements are made. However, above some doping level (y_0), the polymer becomes sufficiently highly conducting that the electronic screening length may become much less than a fibril radius. At this point, field enhancement would cease to be effective, and the time required to achieve diffusion equilibrium would increase toward its unenhanced value. In this regime, a film uniformly doped to y_0 would exhibit "metallic" behavior; there would be no electric field in the fibril, and charge transfer would occur at the surface. The V *vs.* Q relation should resemble that of an electrolytic capacitor exhibiting linear behavior with no hysteresis. Since charge transfer above y_0 occurs primarily at the surface, diffusion times (as measured by the decay of the

Fig. 10. Diffusion time, τ vs. V , for charge removal (i.e., oxidation of *n*-doped material). Observed diffusion rates under load are two orders of magnitude faster than free diffusion. The inset shows the exponential decay of the cell current (over ~3 orders) after a 0.10V change in applied voltage.

cell current) would represent surface diffusion rates only and should decrease in the highly conducting regime. If the polymer were doped nonuniformly (by a "fast" cycle, for example), the surface of a fibril could become highly conducting before the bulk. It would, therefore, be possible to observe pseudometallic behavior at a concentration even less than y_0 .

A series of experiments were performed to investigate the effects of electronic screening length on diffusion as discussed above. Figures 11 and 12 show the time constant τ and the voltage V plotted together as a function of dopant concentration y (at $I_{\min} = 2\mu\text{A/mg}$). The voltage vs. charge relation in Fig. 11 shows a change in slope (kink) at $y \sim 2\%$. At the same concentration, the time constant decreases. Figure 12 shows a voltage kink at $y \sim 1\%$ and a corresponding decrease in τ . Though the voltage kink and decreases in τ occur at different doping concentrations in the two cycles, both features occur at the same voltage ($V \sim 1.25\text{V}$). Figure 13 shows an EVS cycle taken at voltages $V < 1.25\text{V}$ ($y > y_0$). This short (and comparatively fast) cycle demonstrates vanishingly small hysteresis and linear V vs. Q relation past the 1.25V kink. All these effects are consistent with retarding of ionic diffusion rates in the highly conducting regime. The absence of hysteresis for fast cycles and the decrease in τ indicate charge transfer at the fibril surface. Slow cycles, even in the highly conducting material, would involve free diffusion (without field enhancement) of the dopants into the polymer, driven by concentration gradients. We note that this interpretation of the change in kinetics is associated with the loss of electric-field enhancement (when the electrical conductivity becomes sufficiently high that the screening length is less than a typical fibril dimension). This appears to occur at a concentration somewhat below that required for the microscopic electronic structure transition, as evidenced by closure of the energy gap and the onset of Pauli susceptibility. The latter takes place at $y \approx 5\text{ m/o}$ (29, 30).

As is evident in Fig. 11 and 12, the concentration above which the change in kinetics occurs is sample dependent. However, the onset of this behavior occurs at the same voltage ($\sim 1.25\text{V}$). Since voltage is uniquely related to dopant concentration on the fibril surface (where contact is made to the polymer), the actual concentration at which the change in kinetics is observed appears to be unique for a uniformly doped film. There are a number of possible explanations for the sample dependence of the concentration. Different sample preparations may result in different characteristic fibril diameters, and different isomerization conditions may effect the conductivity of the doped polymer. Variations in cell construction result in different internal resistances, which, in turn, can effect doping kinetics. The primary effect, however, is probably polymer degradation after multiple cycling. As the electrochemical cell is repeatedly cycled to high dopant levels (which is necessary to "clean up" impurities

Fig. 11. Diffusion time, τ vs. y , for n-type injection. τ has a local maximum where V vs. y changes shape (see text).

Fig. 12. Diffusion time, τ vs. y , as in Fig. 11, but for a different cell (see text).

so 100% coulombic efficiency is achieved) disorder occurs in the $(\text{CH})_x$ chains. This results in a decrease in the effective mass of crystalline polymer in the cell. Initial cycles which sometimes exhibit $\sim 60\%$ charge loss may indicate polymer mass loss on the same order. If the calculated mass is twice the actual mass in a particular cell, doping levels computed from coulombs transferred would be reduced by a factor of two.

Optical Spectroscopy of Doped $(\text{CH})_x$: Charge Storage in Midgap States

As shown in the "Discussion of Charge Injection" section, charge is injected near the bandedge and stored in the midgap electronic states associated with the bond-alternation domain walls. *In situ* optoelectrochemical experiments have been previously reported (10), which demonstrated the charge storage in the midgap states through doping induced optical transitions between the midgap state and the bandedge (see Fig. 14). In these earlier *in situ* experiments, the doping was p-type, using ClO_4^- as the counterion. As doping proceeds, the midgap absorption appears, centered near 0.65-0.75 eV with an intensity which increases monotonically in proportion to the dopant concentration. We show here that these spectroscopic features are independent of dopant species and independent of whether the doping is p-type (oxidation) or n-type (reduction).

Figure 14 shows optical absorption spectra for polyacetylene doped with different species (Na, Li, Bu_4N , ClO_4^-) at $y \sim 1\%$. The Na samples were chemically doped, the others electrochemically (using *in situ* opto-EVS technique). The similarity between these data proves conclusively that the optical spectra of *trans*- $(\text{CH})_x$ depends only on the properties of the doped polymer, and not on the particular dopant species.

The midgap optical absorption provides direct evidence for charged soliton states in doped polyacetylene. Independent evidence has been obtained from the doping in-

Fig. 13. V vs. Q exhibits no hysteresis in highly conducting regime (see text).

Fig. 14. Near-IR absorption spectra showing the midgap transition for *trans*-(CH)_x doped with Na⁺ (○), Li⁺ (Δ), Bu₄N⁺ (•), and ClO₄⁻ (+). The inset is a schematic band diagram showing the midgap and interband transitions.

duced modes (31) which appear in the midinfrared associated with the local vibrational modes of the charged bond-alternation domain wall. Again, these mid-IR modes are independent of dopant (9) and show characteristic shifts after deuteration (32): (CD)_x compared to (CH)_x. That all of these spectroscopic features are associated with charged solitons has been unambiguously proven through a series of photoinduced absorption (22, 23, 33) and photoinduced ESR measurements (34).

The remarkable oscillator strength associated with these doping induced spectroscopic features arises directly from the spatial extent of the charge-storage state. Whereas one might anticipate that the ratio of oscillator strengths would be equal to the dopant concentration, a detailed theoretical analysis shows that for dilute concentrations the midgap transition is enhanced by a factor of about (2*l*), where (2*l*) is the full width of the bond-alternation domain wall and *a* is the carbon-carbon spacing along the (CH)_x chain (10). Since (2*l*) ≅ 14, this enhancement of the soliton transition makes it observable even at highly dilute dopant concentrations. A complete analysis of the strength of the midgap transition is included in the work of Feldblum *et al.* (10), who find the results to be in good quantitative agreement with theory.

Conclusion

The combined application of optical and electrochemical methods to the study of polyacetylene demonstrates an important technique for studying conducting polymers in general. By providing complementary information on the transition energies and joint density of states (from optical absorption) and the energies at which these (bandgap) states are created, transported, and destroyed (through EVS techniques), it is possible to study many properties not directly accessible by other methods. In the case of polyacetylene, we have been able to use the EVS technique to measure the energy gap. The resulting value, *E_g* ≅ 1.5eV, is in good agreement with that obtained by other methods. The subsequent observation of hysteresis in the electrochemical cycle, and an increase in the midgap optical absorption upon doping, are both indicative of the creation of bandgap states. The resolution available in the EVS technique allowed precise determination of both the energy and number of these states. The results demonstrated that the injected charge was stored in the form of charged solitons [chemical potential (2/π)Δ] and not some random distribution of impurity states throughout the gap or polaron states near the bandedge.

The demonstration that 300 ppm of charge is removed precisely at midgap provided a detailed verification of Kivelson's model of charge transport via intersoliton electron hopping.

Finally, kinetics studies (*τ vs. y*) were used to quantify the anomaly between slow free-diffusion rates and dramatically enhanced diffusion under conditions of current flow (*i.e.*, high current and power densities). With precise data available, a theory was developed to explain the observed enhancement quantitatively. The local maximum in *τ vs. y*, the change in slope of *V vs. y*, and the vanishing of the hysteresis — all occurring at a common concentration — provided insight into ionic transport in the highly conducting regime. All the above effects follow directly from a reduced screening length and vanishing electric field in the fibrils. Since this "metallic" behavior (and the slow free diffusion) allow greater dopant concentration near the surface, the large current levels obtainable from highly doped polyacetylene electrochemical cells is also understood.

APPENDIX A

Corrections to the Electronic Free Energies

In the discussion and analysis of the "Charge Transport" section, we assumed that the measured EVS injection and removal voltages are determined only by the differences in electrochemical potentials for electrons in Li and *trans*-(CH)_x. There are, however, many contributions to the free energy of charge injection and removal in an electrochemical cell. In particular, one must include the free-energy change associated with removing a Li atom from the metal electrode and taking it into solution, and the free-energy change between dopant ions in solution and in the oxidized or reduced polymer. The true chemical potential, *μ* = ∂*F*/∂*N*, must include all such solution energies.

Such contributions to the free energy can be accounted for by consideration of each half-cell reaction. The chemical potential of Li is the sum of the single electron contribution (*μ_{Li}^e*) and the solution energy for Li ions (*E_{Li⁺→Li}*).

$$\mu_{\text{Li}} = \mu_{\text{Li}}^e + E_{\text{Li}^+ \rightarrow \text{Li}} \quad [\text{A-1}]$$

Similarly, the chemical potential of (CH)_x is written as a sum of electronic and solvation contributions. For p-type doping

$$\mu_{(\text{CH})_x}^{\text{p,d}} = \mu_{\text{p,i}}^{\text{h}} + E_{\text{A}^- \text{sol-pol}} \quad [\text{A-2}]$$

where *μ_{p,i}^h* is the electronic energy for hole injection into the valence band and *E_{A⁻sol-pol}* is the energy change on taking the negative dopant ion A⁻ (in our case, ClO₄⁻) from the electrolyte into the polymer. For p-type undoping

$$\mu_{(\text{CH})_x}^{\text{p,u}} = \mu_{\text{p,r}}^{\text{h}} + E_{\text{A}^- \text{sol-pol}} \quad [\text{A-3}]$$

where *μ_{p,r}^h* is the electronic energy for the removal (electron injection) from the soliton levels in the gap. Similarly, for n-type doping and undoping

$$\mu_{(\text{CH})_x}^{\text{n,i}} = \mu_{\text{n,i}}^e + E_{\text{D}^+ \text{sol-pol}} \quad [\text{A-4}]$$

$$\mu_{(\text{CH})_x}^{\text{n,u}} = \mu_{\text{n,r}}^e + E_{\text{D}^+ \text{sol-pol}} \quad [\text{A-5}]$$

where *E_{D⁺sol-pol}* is the energy change on taking the positive dopant ion D⁺ (in our case, Li⁺) from the electrolyte into the polymer. The electronic contributions are defined as follows: *μ_{n,i}^e* is the electronic energy from electron injection into the conduction band, and *μ_{n,r}^e* is the electronic energy for electron removal from the soliton levels in the gap. The complexity of equations arises because the elec-

tronic chemical potential of *trans*-(CH)_s can be moved across the gap by doping. The various specific electronic energies are summarized in Table A-I.

The above equations can be combined to predict the voltage for charge injection and removal in the dilute regime (where dopant-dopant interactions are unimportant). For p-type doping oxidation occurs at (see Table A-I)

$$-eV_{(\text{ox})}^p = (E_{\text{VB}} + E_{\text{ClO}_4^{\text{sol-pol}}}) - (\mu_{\text{Li}}^e + E_{\text{Li}^+ \rightarrow \text{Li}}) \quad [\text{A-6}]$$

The voltage at which the p-doped material is reduced to neutral

$$-eV_{(\text{red})}^p = (\mu_{s_0} + E_{\text{ClO}_4^{\text{sol-pol}}}) - (\mu_{\text{Li}}^e + E_{\text{Li}^+ \rightarrow \text{Li}}) \quad [\text{A-7}]$$

For n-type doping, reduction occurs at

$$-eV_{(\text{red})}^n = (E_{\text{CB}} + E_{\text{Li}^{\text{sol-pol}}}) - (\mu_{\text{Li}}^e + E_{\text{Li}^+ \rightarrow \text{Li}}) \quad [\text{A-8}]$$

and final oxidation of n-doped material to neutral occurs at

$$-eV_{(\text{ox})}^n = (\mu_{s_0} + E_{\text{Li}^{\text{sol-pol}}}) - (\mu_{\text{Li}}^e + E_{\text{Li}^+ \rightarrow \text{Li}}) \quad [\text{A-9}]$$

Note that the relative sign of the solvation energies does not change on switching from oxidation to reduction because the process (solvation) is reversible and conserves energy.

In the "Experimental Techniques" section, we identified the difference between electron injection and hole injection energies with the energy gap. From Eq. [A-6] and [A-8], we find

$$-e(V_{(\text{red})}^n - V_{(\text{ox})}^p) = (E_{\text{CB}} - E_{\text{VB}}) + (E_{\text{Li}^{\text{sol-pol}}} - E_{\text{ClO}_4^{\text{sol-pol}}}) = E_g + (E_{\text{Li}^{\text{sol-pol}}} - E_{\text{ClO}_4^{\text{sol-pol}}}) \quad [\text{A-10}]$$

This difference gives the energy gap only if the difference in solvation energies, $(E_{\text{Li}^{\text{sol-pol}}} - E_{\text{ClO}_4^{\text{sol-pol}}})$, is negligible. This quantity can be obtained directly from experiment; using Eq. [A-7] and [A-9]

$$-e(V_{(\text{ox})}^n - V_{(\text{red})}^p) = E_{\text{Li}^{\text{sol-pol}}} - E_{\text{ClO}_4^{\text{sol-pol}}} \quad [\text{A-11}]$$

As shown in the "Experimental Techniques" section, final charge removal for both n- and p-type doping occurs at the same voltage (2.4V) to an accuracy of better than 0.05V. Thus, $(E_{\text{Li}^{\text{sol-pol}}} - E_{\text{ClO}_4^{\text{sol-pol}}}) \leq 0.05\text{V}$ and

$$-e(V_{(\text{red})}^n - V_{(\text{ox})}^p) \cong E_{\text{CB}} - E_{\text{VB}} \equiv E_g \quad [\text{A-12}]$$

The fact that the difference in solvation energies (Eq. [A-11]) is vanishingly small can be rationalized on very general grounds. The absolute energy difference between an ion screened in a conducting electrolyte and an ion screened in a conducting polymer depends on the dielectric constants of the polymer and electrolyte and on the charge distributions around the ion in the two environments. Since the dielectric constants are similar and since the screening charge distribution are similar, the energies, $E_{\text{Li}^{\text{sol-pol}}}$ and $E_{\text{ClO}_4^{\text{sol-pol}}}$ are both small and of the same magnitude. Thus the difference (Eq. [A-11]) is negligible.

Since in our experiments n- and p-doping experiments were carried out in different solvents (THF and PC, respectively) the value of the Li solvation energy $E_{\text{Li}^+ \rightarrow \text{Li}}$ would differ in the two cases. The difference equations should therefore include a term $(E_{\text{Li}^+ \rightarrow \text{Li}}^{\text{THF}} - E_{\text{Li}^+ \rightarrow \text{Li}}^{\text{PC}})$. This difference is also expected to be small for the same reasons outlined above. Since Eq. [A-12] is empirically zero (to within the resolution of the experiment), the inclusion of this and any other higher-order term does not affect the

Table A-I. Electronic chemical potentials of polyacetylene (taking midgap as the zero of energy)

$\mu_{n,i}^e = E_{\text{CB}} \equiv \Delta$.
$\mu_{n,r}^e = (2/\pi) \equiv \mu_{n,-}$ for soliton generated by charge transfer (reduction).
$\mu_{n,r}^e = 0 \equiv \mu_{s_0}$ for the 300 ppm soliton defects in the as-grown polymer.
$\mu_{n,i}^h = 0 \equiv \mu_{s_0}$ for the 300 ppm soliton defects in the as-grown polymer.
$\mu_{n,r}^h = -(2/\pi)\Delta \equiv \mu_{s,+}$ for solitons generated by charge transfer (oxidation).
$\mu_{n,i}^h = E_{\text{VB}} \equiv -\Delta$.

In the above, we have for simplicity ignored the polaron contribution to the electron and hole injection energies (see "Experimental Techniques" section).

final result. We therefore conclude that the difference in injection energies provides a direct measure of the energy gap (reduced by the polaron lattice-relaxation energy).

APPENDIX B

Contribution of the Configurational Entropy

The configurational entropy associated with placing N_s ion soliton pairs in polyacetylene may shift the chemical potential of the doped polymer as measured by EVS. The magnitude of this shift can be computed analytically.

The number of distinguishable ways to put N_s ions in a polymer with N available sites is

$$\Omega_{\text{ion}} = \binom{N}{N_s}$$

For a given configuration of ions, there is only one distinguishable way to place N_s solitons near N_s ions on a given chain: s s s --- with each s or s associated with one of the ions. Although there are two types of chains, the system is assumed to be either in the A phase or the B phase because of the broken symmetry. So, the total number of ways to place N_s soliton-ion pairs in the polymer is

$$\Omega_{\text{config}} = \binom{N}{N_s} \quad [\text{B-1}]$$

This contribution to the chemical potential (using Stirling's approximation) is

$$\mu_{\text{config}} = kT(d \ln \Omega / dN_s) = kT \ln (c/[1-c]) \quad [\text{B-2}]$$

where c is the concentration of ions (solitons) and $kT \sim 1/40$ eV at room temperature.

It is possible to modify Eq. [B-1] to include the finite width (l) of the N_s solitons. The correct combinatorial expression in the discrete limit [appropriate to a *trans*-(CH)_s chain] is

$$\Omega_{\text{config}} = l^{N_s} \binom{N/l}{N_s} \quad [\text{B-3}]$$

where $(N/l N_s)$ is the number of ways to place N_s rods (with fixed origin) of length la on a chain of length Na ; and l^{N_s} is the number of ways to fix an origin on N_s rods of length la . This expression for Ω_{config} also gives a contribution to the chemical potential of the form of Eq. [B-2].

This problem can also be solved in the continuum limit ($1 \ll N_s \ll N$) by considering the solitons to be solid beads on a ring (periodic boundary conditions). The total number of configurations for N_s beads of length la on a ring of circumference Na (where a is the lattice spacing) is the sum (or integral) of the possible configurations of each of the beads, i.e.

$$\Omega_{\text{config}} = \int_{\text{bead } N_s} \dots \int_{\text{bead } 1} \frac{dx_1}{a} \dots \frac{dx_{N_s}}{a}$$

where x_i is the position of the i^{th} bead. The first bead can be placed from the origin, 0, to the end of the second bead x_2 (less one bead length la). Then

$$\int_0^{x_2-la} \frac{dx_1}{a} = \left(\frac{x_2 - la}{a} \right) / 1!$$

$$\int_{la}^{x_3-la} \frac{x_2 - la}{a} \frac{dx_2}{2} = \frac{\left(\frac{x_3 - 2la}{a} \right)^2}{2!}$$

$$\int_{2la}^{x_4-la} \frac{\left(\frac{x_3 - 2la}{a} \right)^2}{2!} \frac{dx_3}{a} = \frac{\left(\frac{x_4 - 3la}{a} \right)^3}{3!}$$

etc. Therefore

$$\Omega_{\text{config}} = \int_{(N_s-1)a}^{Na-la} \frac{\left(\frac{x_{N_s-1} - (N_s-1)la}{a} \right)^{N_s-1}}{(N_s-1)!} \frac{dx_{N_s}}{a} \quad [\text{B-4}]$$

$$\Omega_{\text{config}} = \frac{(N_s - lN)^{N_s}}{N_s!}$$

Note that the results given in Eq. [3] and [4] are equivalent so long as $lN_s \ll N$, i.e., so long as the concentration is low enough to avoid significant overlap.

Conwell (35) deduced a slightly different expression for Ω_{config} ; she found

$$\Omega_{\text{config}} = \frac{1}{2^{N_s-1}} \frac{l^{N_s} \left(\frac{N}{2l} - 1 \right)^2}{\left(\frac{N}{2l} - \frac{N_s}{2} \right)^2 \left(\frac{N_s}{2} \right)^2} \quad [\text{B-5}]$$

which for $l = 1$ is identical to the expression found by Baughman and Moss (36)

$$\Omega_{\text{config}} = \frac{1}{2^{N_s-1}} \left(\frac{N/2}{N_s/2} \right)^2 \quad [\text{B-6}]$$

However, the factor 2^{N_s-1} is not correct. Since solitons (or antisolitons) can be centered on any site, even or odd (37), the correct counting procedure is given by Eq. [B-1] and [B-3].

To understand how the logarithmic dependence of μ_{config} (see Eq. [B-2]) affects the electrochemical potential as measured by EVS, we must first note that "neutral" $(\text{CH})_x$ has a charge carrier concentration (presumably charged solitons) on the order of 10^{18} cm^{-3} (i.e., $\sim 10^{-4}$ per carbon atom) due presumably to impurities which arise during synthesis. The most probable source of these carriers is from reaction of the $(\text{CH})_x$ chain with residual catalyst. With the inclusion of a concentration c_0 of such "ions," the configuration contribution to the chemical potential can be written

$$\mu_{\text{config}} = kT \ln \left\{ \frac{c + c_0}{1 - (c + c_0)} \right\} \\ \sim kT \ln \{c + c_0\}$$

where $c_0 \sim 10^{-4}$. This lifts the divergence at $c = 0$ (where Stirling's approximation is invalid anyway). The maximum value of μ_{config} occurs at $c = 0$, where the configurational contribution to the chemical potential is $\sim 0.25V$. However, since μ_{config} depends only on soliton number (or concentration) and is independent of sign, the shift of the electrochemical potential is in the same direction for n- and p-type dopants. The injection thresholds are

$$\mu_p^0 = \Delta_0 + \mu_{\text{config}} = \Delta_0 + kT \ln (c + c_0)$$

and

$$\mu_n^0 = -\Delta_0 + \mu_{\text{config}} = -\Delta_0 + kT \ln (c + c_0)$$

The difference in injection thresholds is still

$$\mu_p^0 - \mu_n^0 = 2\Delta_0$$

At low dopant concentrations, the logarithmic concentration dependence of μ_{config} may affect the shape of the V vs. Q curves (for n- and p-type dopants), but it in no way affects the injection thresholds as measured by EVS.

In the above discussion, changes in solvent concentration were neglected. For n-type doping, this is certainly valid, as the change in solvent concentration is rigorously zero. Then

$$\mu = dF/dN = 0 \quad (dN = 0)$$

For p doping there is a slight concentration dependence. One can estimate this by considering the chemical potential of N_i ions in a solvent with \bar{N} "available sites." The solution may be found in Landau and Lifschitz's "Statistical Physics." The result is

$$\mu_{\text{sol}} \sim kT[\ln(c_i) - c_i]$$

where c_i is the ion concentration in solution. On removing N_s of the N_i ions from the solution and transferring them to the polymer, the chemical potential of the solution changes by an amount

$$\delta\mu_{\text{sol}} = kT[1/c_i - 1] \delta c_i$$

where $\delta c_i = N_s/\bar{N}$. For a solution containing 10^{21} ions, removing 10^{19} ions to dope a 1 mg film to $\sim 10\%$ results in a change in chemical potential of the solution of 3×10^{-4} eV; truly a negligible effect.

Primary Current Distribution and Resistance of a Slotted-Electrode Cell

Mark E. Orazem^{*,1} and John Newman^{**}

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The primary current distribution and the resistance of a cell containing a slotted electrode were calculated using numerical methods coupled with the Schwarz-Christoffel transformation. Results are presented and compared to asymptotic solutions. An approximate analytic expression for the cell resistance is presented.

Primary current and potential distributions apply when the surface overpotential can be neglected and the solution adjacent to the electrode can be taken to be an equipotential surface. Calculation of a primary current distribution and resistance represents a first step toward analyzing and optimizing an electrochemical system. The cell resistance calculated can be coupled with calculations including mass-transfer and kinetic effects to optimize approximately a given cell configuration. The objective of this work is to calculate the primary current distribution and resistance of a cell containing a slotted electrode.

Calculation of the primary current and potential distributions involves solution of Laplace's equation, $\nabla^2\Phi = 0$, which is not trivial, even for relatively simple geometries. The method of images (1), separation of variables (2), and superposition (3, 4) have been used to solve Laplace's equation for a number of systems. A review of analytic solutions has been presented by Fleck (5).

The Schwarz-Christoffel transformation (6-8) is a powerful tool for the solution of Laplace's equation in systems with planar boundaries. This method was used by Moulton (9) to derive the current distribution for two electrodes placed arbitrarily on the boundary of a rectangle. Hine *et al.* (10) used this method to describe the primary current distribution for two plane electrodes of infinite length and finite width confined between two infinite insulating planes, perpendicular to but not touching the electrodes. Wagner (11) presented the primary and secondary current distribution for a two-dimensional slot in a planar electrode. Newman (12) has presented the primary current distribution for two plane electrodes opposite each other in the walls of a flow channel. These solutions made use of the Schwarz-Christoffel transformation.

Application of the Schwarz-Christoffel transformation is generally limited by the ability to generate solutions to the resulting integrals. Analytic solutions allow calculation of the primary current and potential distribution throughout the cell but are possible for a limited number of system geometries. Numerical evaluation of these integrals allows calculation of both the primary current distribution along the electrodes and the cell resistance.

Cell Geometry

A cell geometry is presented in Fig. 1 which may be well suited for photoelectrochemical applications. This cell contains a slotted semiconductor with the semiconductor-electrolyte interface open to illumination. A glass cover plate protects the cell. Sunlight passes through the cover plate and the electrolyte to illuminate the semiconductor surface. Electrical current flows from the semiconductor surface to the counterelectrode through the slots of the semiconductor. This configuration has the advantages that no shadows are cast upon the semiconductor, reaction products can be separated, absorption of light by the electrolyte can be minimized, and

¹Present address: Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia 22901.

an enhanced-surface-area counterelectrode (perhaps a porous electrode) can be used.

The slotted electrode cell can be sectioned and, under the assumption that the cell width W (in the direction perpendicular to the plane of the paper in Fig. 1b) is large as compared to the spacing between slots, has the electrochemical characteristics of the two-dimensional cell presented in Fig. 2a. Here, the cell has been turned from Fig. 1b so that illumination now comes from the right in Fig. 2a; the semiconductor electrode is represented by AB , the counterelectrode by EF , and all other boundaries of the cell are considered to be insulators. The lines DE and BC and FG represent two planes of symmetry in the cell in Fig. 1b; one plane bisects the semiconductor electrode, and the other bisects the slot.

The coordinate system of Fig. 2a is transformed through an intermediate half-plane t (see Fig. 2b) to a coordinate system (Fig. 2c) in which Laplace's equation can be solved easily.

Theoretical Development

The primary current distribution along the electrodes and the cell resistance can be calculated through application of the Schwarz-Christoffel transformation. Complex coordinate systems are used; thus

$$z = z_r + jz_i$$

The cell was assumed to be symmetric about $z_r = 0$. The approach presented below, however, could be easily extended to relax this assumption.

The z coordinate system is related to the t coordinate system of Fig. 2b by

$$z = \int_0^t \frac{(a2s - t^2)^{1/2}}{(b^2 - t^2)^{1/2}(c^2 - t^2)^{1/2}(d^2 - t^2)^{1/2}} dt \quad [1]$$

Fig. 1. Schematic diagram of the slotted-semiconductor photovoltaic cell

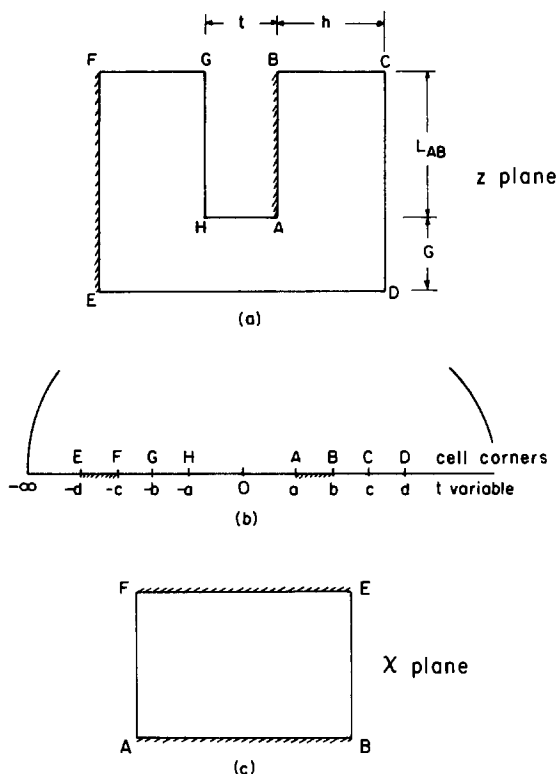

Fig. 2. Schematic diagram of the sectioned cell with coordinate systems: (a) $z = z_r + jz_i$, (b) $t = t_r + jt_i$, and (c) $\chi = \chi_r + j\chi_i$.

where a , b , c , and d are the values of t corresponding to z values of A , B , C , and D , respectively. Through the assumption of symmetry about $z_r = 0$, the values $-a$, $-b$, $-c$, and $-d$ correspond to z values of H , G , F , and E , respectively. The electrodes AB and EF correspond to ab and $-c-d$ in the t plane. Along the electrode AB (ab), this transformation can be expressed by

$$\left. \frac{dz_r}{dt_i} \right|_{ab} = jf(t_r) \quad [2a]$$

where

$$f(t_r) = \frac{(a^2 - t_r^2)^{1/2}}{(b^2 - t_r^2)^{1/2}(c^2 - t_r^2)^{1/2}(d^2 - t_r^2)^{1/2}} \quad [2b]$$

These equations will be used to calculate the derivative of the potential at the electrodes; z_r is the direction normal to the electrode in the z plane, and t_i is the direction normal to the electrode in the t plane.

The variable χ (see Fig. 2c) is related to the t plane by the Schwarz-Christoffel transformation

$$\chi = \int_a^t \frac{1}{(t-a)^{1/2}(b-t)^{1/2}(c-t)^{1/2}(d-t)^{1/2}} dt \quad [3]$$

Along the electrode ab , Eq. [3] can be expressed as

$$\left. \frac{d\chi_i}{dt_i} \right|_{ab} = g(t_r) \quad [4a]$$

where

$$g(t_r) = \frac{1}{(t_r - a)^{1/2}(b - t_r)^{1/2}(c + t_r)^{1/2}(d + t_r)^{1/2}} \quad [4b]$$

Equations [2] and [4] are also valid at the electrode EF ($-c-d$). The variable χ_i is normal to the electrode in χ space, and t_i is, as above, normal to the electrode in t space.

The potential in the χ system is

$$\Phi = \frac{\chi_i}{\chi_{i,\max}} V \quad [5]$$

where V is the cell potential difference and $\chi_{i,\max}$ is the separation between electrodes in χ space. The current density is related to the potential derivative at the electrodes. In the χ system, this derivative is given by

$$\left. \frac{\partial \Phi}{\partial \chi_i} \right|_{-c-d} = \left. \frac{\partial \Phi}{\partial \chi_i} \right|_{ab} = \frac{1}{\chi_{i,\max}} V \quad [6]$$

The potential derivative at the electrode ab in the t system is

$$\left. \frac{\partial \Phi}{\partial t_i} \right|_{ab} = \left. \frac{\partial \Phi}{\partial \chi_i} \right|_{ab} \left. \frac{\partial \chi_i}{\partial t_i} \right|_{ab} \quad [7]$$

and the potential derivative in the z system is given by

$$\left. \frac{\partial \Phi}{\partial z_r} \right|_{ab} = \left. \frac{\partial \Phi}{\partial t_i} \right|_{ab} \left. \frac{\partial t_i}{\partial z_r} \right|_{ab} \quad [8]$$

Substitution of Eq. [2a], [4a], [6], and [7] into Eq. [8] and similar manipulations for the $-c-d$ electrode yield the potential derivative along the electrodes ab and $-c-d$ in the original z coordinate system as functions of t_r

$$\left. \frac{\partial \Phi}{\partial z_r} \right|_{ab} = \frac{g(t_r)}{f(t_r)} \frac{V}{\chi_{i,\max}} \quad [9a]$$

and

$$\left. \frac{\partial \Phi}{\partial z_r} \right|_{-c-d} = \frac{g(t_r)}{f(t_r)} \frac{V}{\chi_{i,\max}} \quad [9b]$$

respectively.

The current distribution along the electrode AB is therefore given by

$$i(z_i) = \frac{g(t_r)}{f(t_r)} \int_a^B \frac{g(t_r)}{f(t_r)} dz_i \quad [10]$$

A similar expression results for the electrode EF . The dimensionless primary cell resistance is

$$W\kappa R = \frac{\chi_{i,\max}}{\int_a^B \frac{g(t_r)}{f(t_r)} dz_i} \quad [11]$$

where R is the actual cell resistance. The primary current distribution and the cell resistance for this system are functions of only three geometric ratios and were obtained numerically. Values of A , B , C , and D in the z plane corresponding to a , b , c , and d in the t plane were obtained through numerical integration of Eq. [1] (13). The value of $\chi_{i,\max}$ was obtained through numerical integration of Eq. [3] between the limits of a and $-d$. The values of t_r corresponding to given values of z were calculated through numerical integration of Eq. [1] and were used to calculate the values of $f(t_r)$ and $g(t_r)$.

Results

The calculated primary current distribution is presented below and compared to current distributions obtained from asymptotic solutions of Laplace's equation. The result most useful for cell design, however, is the cell resistance.

Primary current distribution.—The primary current distributions on the AB and EF electrodes are presented in Fig. 3. This distribution is characterized by three geometric ratios, chosen here to be $t/G = 0.25$, $h/G = 1$, and $L/h = 2.5$, where L is the length of the AB electrode and the insulating wall, t is the thickness of the protruding electrode assembly, G is the gap between the front edge of the AB electrode and the insulating wall, and h is the separation between the lines AB and CD (and, by symmetry, EF and GH) (see Fig. 2a). The current distributions of the two electrodes have been superimposed. The current density is infinite at A and is finite at B , E , and F .

Asymptotic forms of the current distribution can be derived and compared to the calculated current distribu-

Fig. 3. Current distribution along the AB and EF electrodes for $L/h = 2.5$, $t/G = 0.25$, and $h/G = 1$.

tion. The current distribution close to the edge of an electrode adjoining an insulator with an angle α is

$$\frac{i(z_i)}{i_{avg}} = \text{const.} \frac{\pi}{2\alpha} (Q - z_i)^{\pi/2\alpha - 1} \quad [12]$$

where Q is the point of intersection of the electrode and insulator. At A , where α is $3\pi/2$, the current density is proportional to $(A - z_i)^{-2/3}$, and at B , E , and F , the current density is independent of $(Q - z_i)$. The current density is seen in Fig. 3 to approach a constant value at both edges of the EF electrode and at the far edge of the AB electrode. The current distribution along the AB electrode is presented in a log-log format in Fig. 4. The behavior close to the edge is emphasized, and the expected $-2/3$ power dependence on $(A - z_i)$ is observed.

Far from the gap, the asymptotic form for the current distribution is

Fig. 4. Current distribution along the AB electrode compared to the asymptotic solution for $L/h = 2.5$, $t/G = 0.25$, and $h/G = 1$.

$$\frac{i(z_i)}{i_{avg}} = \text{const.} \nu \cosh [\nu (z_i - z_{i,max})] \quad [13]$$

where

$$\nu = \frac{\pi}{2h}$$

The calculated current distributions for the AB and the EF electrodes presented in Fig. 3 show agreement with this form for values of $E - z_i$ greater than about 7.5. The curves have the same shape in this region but are displaced vertically, attesting to the need for a different coefficient ("const.") for the two electrodes.

Primary cell resistance.—The primary cell resistance R can be expressed in terms of a dimensionless group $W\kappa R$. The dimensionless primary cell resistance for this system is a function of three geometric ratios, as described in the previous section. In the limit that the thickness t approaches zero, the resistance approaches a value that is independent of t/G . The cell resistance can therefore be expressed as the sum of the resistance for t/G equal to 0, $W\kappa R_0$, and a dimensionless correction term, Δ

$$W\kappa R = W\kappa R_0 + \Delta \quad [14]$$

The resistance $W\kappa R_0$ is presented in Fig. 5 as a function of L/h with h/G as a parameter. For all values of h/G , the dimensionless resistance in Fig. 5 approaches a constant value as L/h becomes greater than 2. The additional electrode length is relatively inaccessible and does not contribute much to current flow (see Fig. 3). For all values of h/G , the resistance approaches infinity with $[-1/\pi \ln(L/h)]$ as L/h approaches zero. The resistance increases with h at constant L and G because the distance between the electrodes AB and EF increases.

The resistance correction term, Δ , can be considered to be the additional resistance due to a finite (nonzero) electrode thickness t . Δ is presented in Fig. 6 as a function of t/G with L/h as a parameter. This term is independent of h/G and is only a very weak function of L/h . The correction term is given by the upper line in Fig. 6 for $L/h > 1$ and by the lower line in Fig. 6 for $L/h < 0.01$. The slope for $t/G > 0.5$ has the value 1, as anticipated from the asymptotic solutions for t/G approaching infinity.

The cell resistance for a given configuration can be obtained from Fig. 5 and 6 with Eq. [14]. The cell resistance is smallest when the gap (G) is large, the height (h) is small, and the electrode length (L) is large. An approximate analytic expression for the cell resistance can be obtained by interpolation of asymptotic solutions to Eq. [11]. The correction term for a finite electrode thickness can be expressed by

$$\Delta = t/G + \Delta_1 \quad [15]$$

The resistance of the cell with a zero electrode thickness is given by

Fig. 5. Dimensionless cell resistance with t/G equal to zero as a function of L/h with h/G as a parameter.

Fig. 6. Dimensionless correction to the cell resistance as a function of t/G with L/h as a parameter.

$$W\kappa R_0 = \frac{1}{\pi} \ln \left[\frac{16 \left(1 + \frac{c}{b}\right)}{\left(1 - \frac{c}{d}\right)} - (32 - e^\pi) \right] + \Delta_0 \quad [16]$$

where

$$\frac{b}{c} = \tanh \left\{ \frac{\pi}{2} \left[\frac{\left(\frac{L}{G}\right)^4}{\left(1 + 2\frac{L}{G}\right)^2} + \left(\frac{L}{h}\right)^4 \right]^{0.25} \right\} \quad [17]$$

$$\left(1 - \frac{c}{d}\right) = 2 \frac{\sinh^2\left(\frac{x}{2}\right)}{\cosh(x)} \quad [18a]$$

and

$$x = \frac{4 \cos\left(\frac{\pi}{2} \frac{L}{L+G}\right) e^{-\frac{\pi}{2} \frac{h}{L+G}}}{\cosh\left(0.3 \frac{\pi}{2} \frac{L}{h}\right)} + \frac{\frac{\pi}{2} \frac{G}{h}}{\cosh^2\left(1.2 \frac{\pi}{2} \frac{h}{L+G}\right)} \quad [18b]$$

Fig. 7. Dimensionless correction to Eq. [16] for a resistance of a cell with $t/G = 0$.

Fig. 8. Dimensionless correction to Eq. [15] for the contribution of t/G to the cell resistance.

The term Δ_0 in Eq. [16] is presented in Fig. 7 as a function of L/h . This term amounts to less than 5% and approaches a constant value as L/h approaches infinity and as L/h approaches zero. The term Δ_1 in Eq. [15] is presented in Fig. 8.

The effect of the cell resistance in the photoelectrochemical cell proposed, in the "Cell Geometry" section must be balanced with the need for a large semiconductor area open to illumination. Optimal design of this cell requires a large number of narrow slots (13, 14). The resistance of such a cell with $h/G = 10$, $L/h = 0.5$, and $t/G = 20$, can be expressed in terms of Eq. [14], [15], and [16] as

$$W\kappa R = W\kappa R_0 + \Delta_0 + t/G + \Delta_1 \quad [19]$$

$$W\kappa R = 2.9891 + 0.0148 + 20. + 0.2$$

The error in neglecting the correction terms, Δ_0 and Δ_1 , is 0.93%.

Conclusions

The primary resistance of a slotted-electrode cell was obtained by numerical integration coupled with the Schwarz-Christoffel transformation. An approximate analytic expression is also presented for the cell resistance. The slotted-electrode cell design may be well suited for photoelectrochemical devices for solar energy conversion. For optimal solar cell designs, the cell resistance can be expressed as the sum of $W\kappa R_0$ (given by Eq. [16]) and the simple parallel-plate term t/G .

Photodissolution Kinetics of n-GaAs in 1M KOH and Calculation of the Stabilization by Se^{2-}

Effect of the Ru^{3+} Surface Treatment

ABSTRACT

We present a method for obtaining the photodissolution kinetics of n-GaAs in 1M KOH. It is based upon the simultaneous measurement of photocurrent and impedance. It is shown that an accurate determination of the band bending is absolutely necessary to obtain the actual kinetic constants. In fact, the semiconductor bandedges shift toward positive potentials when illumination is increased. In addition, a potential-dependent surface charge variation is responsible for another voltage drop in the Helmholtz layer which modifies the band bending. This is shown by the surface-state capacitance C_{ss} (V), which presents sharp variations in applied potential. According to the current expression, $J_{\text{corr}} = k_{\text{corr}} p_s^2$, a value of $k_{\text{corr}} = 5.7 \times 10^{-27}$ mA cm⁴ is found to be independent of the photon flux, the surface orientation, and the ruthenium treatment. This value is used to estimate the stabilization coefficient s of the n-GaAs/1M ($\text{Se}^{2-}/\text{Se}_2^{2-}$) + 1M KOH junction. A value of s close to 100% is found. We then discuss the ruthenium treatment in selenide solution, where energetic conditions for charge transfer are changed through surface-charge modifications. Our calculations show an improvement of both cell performances and stability, as expected, when the electrode is Ru treated. Moreover, the effect of Ru^{3+} cations upon the impedance data suggests that the flatband potential shift is linked to chemical surface modifications, prior to corrosion. This is confirmed by the fact that k_{corr} is not photon-flux dependent. Finally, we examine whether the bonds (GaAs) with one electron might be responsible for the bandedge shift and the C_{ss} (V) behavior of the n-GaAs/1M KOH junction. The case of the Se^{2-} stabilized junction is also discussed.

For many years, the photocorrosion process at illuminated n-type III-V semiconductor electrodes in contact with aqueous electrolytes has been extensively studied in view of possible photoelectrochemical (PEC) application for solar energy conversion. A number of articles deal with the corrosion mechanism itself (1, 2) or with the competition between the photocorrosion of the semiconductor and the oxidation of a redox couple in solution (3-5). Until now, very little, to our knowledge, has been done to estimate the photocorrosion kinetic constants (6, 7).

At first, it was stated that for all n-type semiconductor electrodes, except Ge, holes are entirely responsible for the photocorrosion reaction (1). For example, for GaAs, six charges per molecule of GaAs are consumed. It is shown also for III-V semiconductors that the stabilization coefficient, defined as the fraction of the photocurrent associated with the oxidation of the redox couple over the total photocurrent, is light-intensity dependent (3, 4). This very important result led workers to study the different mechanisms for explaining the competition between the semiconductor and redox couple photo-oxidations (1-5). These studies show that the corrosion process can be de-

scribed by a two-step reaction, each one involving a hole. The first one is rate limiting while the second one is considered as very fast. Cardon *et al.* (3) developed a very general kinetic scheme assuming the first corrosion step can be reversible or not, the transfer upon the redox couple direct or indirect, and the intermediates mobile or motionless. These assumptions lead, for III-V semiconductors, to $s = f(y/j)$ or $s = f(y^2/j)$ relationships, where y is the redox concentration and j the total photocurrent. Unfortunately, it seems difficult to connect unambiguously experimental facts to these resulting equations. If a mechanism may be deduced from such equations, the number of parameters does not reasonably allow one to reach a kinetic constant for the corrosion. This quite extensive analysis was applied to n-GaP and n-InP electrodes (3). However, Frese and co-workers (4) and, more recently, Gerischer (5) presented very similar models for the corrosion-stabilization mechanism of n-GaAs and n-GaP, respectively.

In fact, all these models can be reduced to a mechanism that focuses on the breaking of a single surface bond, involving two electrons, as the one of Frese *et al.*, although it is known that six holes are consumed per mole-

cule of GaAs. It means that when a surface bond is completely broken, the corresponding atoms are more weakly linked to the semiconductor lattice and are attacked much faster than those having their three complete bonds. Thus, the breaking of the two last bonds is implicit and the first breaking is the rate-limiting mechanism of photocorrosion.

We retain the model of Frese *et al.*, which is appropriate to determine a kinetic constant, because parameters are very few and have a physical meaning. As it is necessary for the discussion, we briefly summarize the main points of this model and the signification of the involved rate constants. The photodissolution process is described by the two following reactions, where A and B denote the two compounds of the semiconductor

In Eq. [1], a photogenerated hole h^+ is captured by a two-electron surface bond (A : B) leading to the creation of a radical like (A · B). This step is supposed reversible. This means that the complete bond may be regenerated by the capture of an electron. The second reaction is assumed irreversible and fast because the bonding energy E_{SR} associated with the radical is very weak compared to the lattice bond energy. The first step is an activated hole capture between the top of the valence band E_V and the energy E_{SB} of a two-electron surface bond (Fig. 1). The rate constant k_1 is given by

$$k_1 = \langle q\sigma_1 v d \rangle (A : B) \exp\left(-\frac{(E_V - E_{SB})}{kT}\right) \quad [3]$$

where q is the electronic charge ($q > 0$), σ_1 the capture cross section for holes, v the thermal velocity for holes (1.7×10^7 cm/s), d a reaction length, and (A : B) the volume density of the two-electron surface bonds, which are likely to undergo corrosion. The reverse reaction is a hole exchange between the valence band and the energy level E_{SB} . If E_{SB} is close to E_V , one gets for the rate constant k_{-1}

$$k_{-1} = \langle q\sigma_1 v d \rangle N_V \quad [4]$$

where N_V is the valence-band-state density.

The second step is responsible for the corrosion current corresponding to the release of Ga^{3+} and As^{3+} ions to solution (2b). This is only indicative of the oxidation state of gallium and arsenic atoms, whereas the actual chemical entities may involve solvated ions or oxide or hydroxide compounds. This last step is a simple hole capture by the surface state connected with the radical (A · B). The corresponding energy of a one-electron bond is expected to be much weaker than a two-electron bond, which is why E_{SR} is higher in the bandgap than E_{SB} (Fig. 1). The capture rate constant k_2 is

$$k_2 = \langle q\sigma_2 v d \rangle \quad [5]$$

Under stationary conditions, $d(A \cdot B)/dt = 0$, and assuming first-order kinetics for all reactive species, one gets the corrosion current J_{corr} which arises from the transfer of Ga^{3+} and As^{3+} to solution

$$J_{corr} = k_1 p_s^2 / (k_{-1} k_2 + p_s) \quad [6]$$

where p_s is the hole concentration at the surface.

As mentioned above, kinetic constant investigations for photocorrosion has been neglected, while the stabilization coefficient was extensively studied, mainly by rotating ring-disk electrode. The aim of this paper is to estimate the photocorrosion rate constants for n-GaAs in 1M KOH. We intend to compare our results for photodissolution to the previous kinetics determination we made for n-GaAs in 1M KOH + 1M (Se²⁻/Se₂²⁻) (8). Through stabilization coefficient calculations, we show that our experimental method, based upon simultaneous impedance

Fig. 1. Energy diagram of an n-type III-V semiconductor/electrolyte PEC junction. The energy levels E_{SR} and E_{SB} associated with (A · B) and (A : B) bonds are reported. The currents associated with Eq. [1] and [2] are represented.

and current measurements in order to determine the actual band bending at any bias, is self-consistent. Furthermore, the effect of the ruthenium treatment is studied and discussed in terms of surface modifications. At last we try to see if the model of Frese *et al.* can be used to interpret impedance results for corrosion and for the stabilized junction.

Experimental and Analysis Procedure

Undoped n-type (2.3×10^{16} cm⁻³; <100> orientation) and (1.4×10^{16} cm⁻³; <111> orientation) GaAs single crystals are purchased from MCP Limited and RTC, respectively. After polishing, semiconductor electrodes are etched with a (H₂SO₄; H₂O₂; H₂O) (2V; 1V; 1V) mixture. All measurements are made in a classical three-electrode electrochemical cell. All potentials refer to the saturated calomel reference (SCE). Ruthenium treatment is performed as follows: the freshly etched electrode is dipped in 1M KOH + 1M (Se²⁻/Se₂²⁻) electrolyte for a few minutes, rinsed with water, then dipped in an acidic 0.1M HCl + 10⁻²M RuCl₃ solution for a few minutes, and water rinsed before being employed for photoelectrochemical experiments (9). A 100W quartz-halogen lamp is used for illumination and light intensity is changed with neutral filters and measured with a MACAM TR 3010 radiometer. The given light intensities, in the following, are measured before the light flux comes into the PEC cell. Stationary I-V curves and impedance measurements are performed under potentiostatic conditions. Impedance analysis has been presented elsewhere (8), but as it is important for kinetics studies, we emphasize the band bending determination in the next paragraph.

We will not describe once again the way impedances are analyzed; one should refer to our previous paper for the significance of C_{ss} (V) and C_{sc} (8); C_{sc} is the space-charge capacitance, and C_{ss} (V) is associated with surface-charge variations. The main point is that these capacitances are C_H dependent, C_H being the Helmholtz capacitance. According to the equivalent electrical scheme we use (8), two cases may exist: (i) when $C_{ss} \ll C_{sc}$, as it is the case in the linear part of the Mott-Schottky plot, the series combination of C_{sc} and C_H is measured. (ii) When C_{ss} is much greater than C_{sc} , the series combination of C_{ss} and C_H is measured. This happens under illumination for potentials close to -1.25 V/SCE (see Fig. 5).

Consequently, the slope β of the experimental Mott-Schottky plot ($C_{sc}^{-2} = \beta V_b$) and the C_{ss} (V) curve are C_H dependent. The aim is to determine the real band bending V_b of the semiconductor at each potential V , for a given C_H .

From capacitance measurements, the band bending V_b can be derived from the following differential equation (10)

$$dV_b/dV = C_H/(C_{sc} + C_{ss} + C_H) \quad [7]$$

If we integrate this equation between two potentials close to each other, one gets the variation δV_b^i of the band bending when V varies from V^i to $V^i + \delta V^i$. δV_b^i and δV^i are no longer infinitesimal, but are now finite variations, and the following relation holds

$$\delta V_b^i = \delta V^i \cdot C_H/(C_H + C_{sc}^i + C_{ss}^i) \quad [8]$$

where C_{sc}^i and C_{ss}^i are the space-charge and the surface-state capacitances, respectively, at the potential V^i . If we repeat this procedure for each potential V^i , one may reach the total variation of V_b for any variation of the applied potential. Thus V_b^i is known with respect to an additive constant V_b^0

$$V_b^i = V_b^0 + \sum_{j=1}^i \delta V_b^j \quad [9]$$

where V_b^i is the effective band bending of the semiconductor at the potential V^i , and V_b^0 the additive constant corresponding to the band bending at $V = V^0$.

We then compare, for a given V_b^0 , at each potential, the experimental C_{sc}^{-2} value and the quantity $\beta V_b(V)$, β being the experimental slope of the Mott-Schottky plot, and V_b defined by Eq. [7]. Doing this, we may: (i) check that Eq. [7] is valid, and (ii) determine V_b^0 and then $V_b(V)$ at each potential.

Using this procedure for I-V curve analysis of n-GaAs/selenide junctions, we found that C_H should take a value close to $2.8 \mu\text{F}/\text{cm}^2$ to obtain the best fit between experimental and calculated I-V characteristics (11). In the case of the n-GaAs/1M KOH interface, C_H represents the series combination of the Helmholtz and the oxide overlayer capacitances. In fact, in 1M KOH electrolyte, the surface is covered by a very thin As_2O_3 layer that does not exist when K_2Se is put in solution (Fig. 2) (12). Moreover, direct observation of nuclear reactions allowed us to estimate the O_2 quantity at the surface (13). It appears that the As_2O_3 thickness is about 10-20Å (12). Taking $\epsilon \sim 10$ and a thickness of 10Å, one gets $C_{ox} = 8.8 \mu\text{F}/\text{cm}^2$, C_{ox} being the surface-oxide capacitance.

For calculations, we take $C_H = 2 \mu\text{F}/\text{cm}^2$. This value is obtained by the same procedure as for n-GaAs/selenide junctions. Note that this value is close to the series combination of $C_{ox} = 8.8 \mu\text{F}/\text{cm}^2$ and $C_H = 2.8 \mu\text{F}/\text{cm}^2$.

Results

Figure 3 presents $C_{sc}^{-2}V$ Mott-Schottky plots for an n-GaAs(100)/1M KOH PEC junction in the dark and under various illuminations. As for n-GaAs/selenide junctions (8, 11), these curves are straight lines, almost parallel, and shifted toward positive potentials as light intensity is in-

Fig. 3. Mott-Schottky plots for the n-GaAs/1M KOH junction in the dark and under the various illuminations. Curve (a): in dark. Curve (b): in dark, after a photocorrosion current flowing through the junction ($I = 1 \text{ mA}/\text{cm}^2$ for 1h). Curves (c), (d), and (e); under 1, 5, 20 mW/cm^2 illumination.

creased. In the dark, the flatband potential $V_{FB} = -1.85 \text{ V/SCE}$, is independent of the surface orientation. This result is in good agreement with other publications (14). For potentials anodic of -1.2 V/SCE , the semiconductor bands are pinned and a pseudo-flatband potential V_{FB}^* under illumination can be defined as the intercept of the $C_{sc}^{-2}V$ straight line with the V axis. Moreover, this shift is reversible. The bandedges return to their initial positions when light is cut off, although the slope of the Mott-Schottky plot is slightly changed (Fig. 3, curve b). This latter point may be the consequence of a change of the geometrical surface due to surface corrosion. Under illumination and for potentials cathodic of -1.2 V/SCE , all the curves slightly deviate from their linear part; the same behavior is observed in the dark around -1.5 V/SCE . The variations of the flatband potential shift $\Delta V_{FB} = V_{FB}^* - V_{FB}$ as a function of the saturation current density is reported in Fig. 4. It can be seen that ΔV_{FB} presents a step for very low illumination and then a regular variation with light intensity. Furthermore, ΔV_{FB} tends to an asymptotic value of $\sim 0.380 \text{ V}$, similar to the one found for n-GaAs/selenide junctions (11).

Surface charge variations are evidenced by the surface-state capacitance $C_{ss}(V)$ curves under illumination (Fig. 5). These data are characterized by a sharp peak located around -1.25 V/SCE , and its height increases with increasing light intensity. In the dark, the peak disappears. This behavior recalls the one of n-GaAs/selenide junctions. Note that measurements are not performed for potentials cathodic of -1.35 V/SCE to avoid any chemical modification of the surface: our surface observations show that the As_2O_3 oxide layer, which results from the

photocorrosion process, can be reduced by hydrogen evolution (12).

In Fig. 4, the flatband potential shift ΔV_{FB} for an n(111) GaAs electrode is also reported. This value is almost on the curve corresponding to the (100) electrode, showing no particular effect of the orientation. In addition, this parameter is not crucial for the photocorrosion process of n-GaAs. This fact is confirmed by Fig. 6, which presents very similar I-V curves for n(100) (curve a) and n(111) (curve d) GaAs in the same pure photocorrosion conditions in 1M KOH under 20 mW/cm².

The ruthenium treatment is only sensitive over the flatband potential in the dark, which is now $V_{FB} = -1.78$ V/SCE. This value is slightly more positive than that of the untreated electrode, indicating that the surface has gained positive charges as Ru^{3+} . However, the I-V curves and the V_{FB}^* are independent of this treatment (Fig. 6, curves e and f). On the contrary, this treatment is quite important for n(100) GaAs/selenide junctions, as is revealed by our preliminary results. The I-V characteristics, Mott-Schottky plots and surface-state capacitance are modified. As reported by Parkinson *et al.* (9), it is confirmed that the fill factor is greater for treated electrodes (Fig. 7), while the open-circuit voltage remains little changed. This is to be connected to capacitance measurements. In the dark, the flatband potential is $V_{FB} = -1.91$ V/SCE, while under 22 mW/cm² the pseudo-flatband potential becomes $V_{FB}^* = -1.85$ V/SCE (Fig. 8). As a result, the bandedge shift $\Delta V_{FB} = 0.06$ V is much smaller for treated electrodes. For untreated ones the values are, respectively: $V_{FB} = -2.06$ V/SCE, $V_{FB}^* = -1.79$ V/SCE, and $\Delta V_{FB} = 0.270$ V. Correlatively, the peak in C_{ss} (V) keeps almost the same location but it is lowered (Fig. 9).

Discussion

In a previous paper, we dealt with the detailed analysis of the photoresponse of a n-type semiconductor/electrolyte liquid junction, assuming a direct hole transfer upon the reduced species in solution (8). The transfer rate constant being defined, we calculated the surface hole concentration through the balance between photogenerated holes and holes which disappear because of recombination (at the surface and in the space-charge region) or because they cross the interface towards solution. In this paper, the same method is used. We only have to change the hole-transfer current upon the redox couple J_p (8) by the expression of the photocorrosion current J_{corr} (Eq. [6]) in Eq. [24] of Ref. (8). The other currents only concern the

Fig. 9. Surface-state capacitance C_{ss} (V) curves for n-GaAs/(Se²⁻/Se²²⁻) liquid junctions under ~ 30 mW/cm² illumination. Curve (a): ruthenium-treated electrode. Curve (b): untreated electrode.

semiconductor itself and thus have not to be modified, except the surface recombination current. For this latter, the complete analogy of the surface-state capacitance C_{ss} (V) results between the two systems, stabilized or not, allows one to think that this current is negligible. In the following, we do not take it into account.

Kinetic rate constant determination.—As before, all parameters (V_{FB} , V_b (V), . . .) are predetermined by impedance and current measurements (8), except for the ratio $k_1 k_2 / k_{-1}$, which is the only adjustable parameter in the present analysis of the photocorrosion I-V curves. In fact, according to the model of Frese *et al.*, it appears that $k_{-1} k_2 = N_V \sigma_1 / \sigma_2 \gg p_s$ at any bias for the illumination range we use. Thus J_{corr} reduces to Eq. [10]

$$J_{corr} = \frac{k_1 k_2}{k_{-1}} p_s^2 = k_{corr} p_s^2 \quad [10]$$

In the following, we will attempt to discuss the different constants that are included in k_{corr} within the framework of our impedance results. For the moment, we assume that Eq. [10] is valid and that k_{corr} is an adjustable parameter.

Under various illuminations, we try to fit, in the best way, the calculated I-V curve to the experimental one. Of course, in this analysis, we take into account the band-edge shift (Fig. 3) to estimate the band bending V_b of the semiconductor. Taking the pseudo-flatband potential V_{FB}^* as the reference for V_b , e.g., $V_b = V - V_{FB}^*$, where V is the applied potential, we obtain a good match (Fig. 10, curve a). But under illumination, for potentials close to -1.25 V/SCE, the Mott-Schottky plots present a slight deviation with respect to their linear part (Fig. 3). This experimental fact can be interpreted by a slower variation of V_b with respect to the applied potential V , owing to surface-charge variations (Eq. [7]). Calculating V_b with all the capacitances of the equivalent circuit, we find a better fit between calculated and experimental I-V curves, and we are also able to represent the Mott-Schottky plots. The calculated photocurrent rise is less abrupt and more representative of the observed behavior (Fig. 10, curve b). Moreover, the value of k_{corr} is found to be much smaller than in the case of the simple analysis (Fig. 10). In the following, the complete analysis is performed to determine the actual V_b at each potential.

Fig. 10. Comparison between calculated and experimental I-V curves for the n-GaAs/1M KOH junction under 20 mW/cm² illumination. (●): Experimental data. (—): Calculated curves according to the model of Frese *et al.* Different methods to calculate V_b are considered. Parameters are: $\alpha = 26,000$ cm⁻¹; $L = 0.2$ μ m; $\tau = 1.45 \times 10^{-10}$ s; $V_{FB} = -1.85$ V/SCE; Curve (a): $V_{FB}^* = -1.50$ V/SCE. V_b is taken as: $V_b = V - V_{FB}^*$. $k_{corr} = 1.1 \times 10^{-25}$ mA cm⁴. Curve (b): The complete calculation of the band bending V_b is performed at every potential. $k_{corr} = 5.7 \times 10^{-27}$ mA cm⁴.

For an n-type GaAs (100) electrode, we obtain $k_{\text{corr}} = 5.7 \times 10^{-27}$ mA cm⁴ under any illumination (Fig. 6, curves a, b, c). In fact, during the photodissolution process, charges are transferred to atoms of the semiconductor itself. Thus the relative bandedge position with respect to a reference in solution does not play any role upon the kinetic constant k_{corr} . This point is well verified experimentally. The corrosion model, its quadratic dependence in p_s , and our band bending analysis are then found to be justified. Consequently, all studies based only upon capacitance data in the dark are erroneous. The latter would lead to a light intensity-dependent constant k_{corr} , and the resulting values would be much smaller than ours. The stabilization coefficient calculation further reinforces our analysis.

Physically, the potential for the onset of the photocorrosion hole current is the potential where a critical surface hole concentration is reached. For a given p_s , the required V_b becomes smaller when the illumination increases. Thus, the flatband potential shift with illumination makes k_{corr} independent of the photon flux. This remark leads us to believe that the bandedge shift could be linked to steps that precede corrosion itself. The last step (corrosion) does not occur if the hole transfer upon the redox species is more favorable, as it is the case with Se²⁻ electrolytes (8, 11). These intermediate steps should be then understood as chemical modifications at the surface through interactions between holes trapped in surface bonds and the solvent (11, 15).

In the case of n(111) GaAs electrodes, we found $k_{\text{corr}} = 8.0 \times 10^{-27}$ mA cm⁴. This value is very similar to the one obtained for n(100) electrodes and confirms that photocorrosion process in 1M KOH is not strongly affected by surface orientation. However, the surface morphology of a photocorroded n-GaAs (100) electrode in 1M KOH shows a slight variation in corrosion rate for different crystallographic planes (Fig. 11) (12, 16). A difference of a few percent is sufficient to produce such a pattern.

Last, the case of n(100) ruthenium-treated electrodes has been examined. We find $k_{\text{corr}} = 1.14 \times 10^{-27}$ mA cm⁴ and 0.8×10^{-27} mA cm⁴ for the treated and untreated electrodes (Fig. 6, curves e and f). These latter values are close to each other and confirm the previous determination of k_{corr} . In fact, if we consider the extreme sensitivity of k_{corr} with respect to the band bending estimate, it can be concluded that the ruthenium treatment and the surface orientation have no significant influence upon the photodissolution rate of GaAs in 1M KOH. It is worth noting that a 10 mV change in the determination of V_b may modify k_{corr} by a factor 2. In the dark, flatband potential measurements give $V_{\text{FB}} = -1.85$ and -1.78 V/SCE for the untreated and the treated electrodes, respectively. These

values indicate the surface has gained Ru³⁺ chemisorbed ions. It is well known that Ru³⁺ ions are incorporated at the surface defects (9). In spite of this remark, our analysis shows that the ruthenium treatment has no influence upon the photocorrosion kinetics of GaAs. This may be explained by the observed generalized attack (4, 12) (Fig. 11). The initial Ru³⁺ defect passivation is not sufficient to prevent corrosion because the defects are not preferred sites for corrosion. Under heavy photocorrosion conditions, Ru³⁺ ions are removed from the electrode. This is confirmed by the identical values of V_{FB}^* found for treated and untreated electrodes (Fig. 6, curves e and f).

Stabilization coefficient (case of untreated electrodes).—Evaluation of the rates of the reactions of photodissolution of the semiconductor and photo-oxidation of the redox couple allows one to estimate the stabilization coefficient of the n-GaAs/(Se²⁻/Se₂²⁻) junction. The parameters we use in our calculations are those of the stabilized junction (particularly bandedge positions). As above, the current J_p of Ref. (8) is replaced by $J_p + J_{\text{corr}}$ in Eq. [24] of Ref. (8). The stabilization coefficient is then $s = J_p/(J_p + J_{\text{corr}})$. When arriving at the surface, a hole may be transferred to solution either directly to be reduced species (Se²⁻) or through Ga³⁺ and As³⁺ ions as these leave the surface upon photocorrosion. In the second case, the hole current crosses the surface state E_{SR} .

Calculations have been performed with the data of the n-GaAs/(Se²⁻/Se₂²⁻) cell given in Ref. (11) for various levels of illumination. With $k_{\text{corr}} = 5.7 \times 10^{-27}$ mA cm⁴, our largest and least favorable value, we obtain a stabilization coefficient $s > 95\%$ (see Table I). This means that less than 5% of the total photocurrent is a corrosion current. Moreover, it is found that s increases when the light intensity is lowered or when the current is reduced through the applied potential at a given illumination (Fig. 12), as expected from theory (3): s varies between 95% and better than 97% when the illumination decreases from 50 to 1.5 mW/cm² (see Table I). It is worth noting that with a value of k_{corr} deduced from curves e and f (Fig. 6), s would be about 99%. In spite of the extreme sensitivity of k_{corr} to V_b , our finding of s is close to being 100% and is a very positive result that supports our current- and impedance-based analysis. This result also agrees with the one of Chang *et al.*, who performed weight loss experiments for the same cell (17): they found $s = 99.9\%$ for the n-GaAs/(Se²⁻/Se₂²⁻) junction under 70 mW/cm² solar illumination. The slight difference between the two results may come from the surface preparation (4) or from the Se²⁻ concentration (17). When the regeneration of the (A · B) bond by the redox species (3) is considered, the calculated stabilization is only improved of a few tenths of a percent. Figure 13 shows the electrode surface after

Fig. 11. SEM picture of the surface of the electrode of Fig. 2b. The entire surface is attacked, but the rate of attack depends slightly on the crystallographic planes.

Table I. Stabilization coefficient s calculated for various electrodes in contact with (Se²⁻/Se₂²⁻) under various illuminations ($V_{\text{redox}} = -0.96$ V/SCE)

Light intensity ^e (mW/cm ²)	I^b (mA/cm ²)	$k_{\text{corr}} = 5.7 \times 10^{-27}$ mA cm ⁴	s^a $k_{\text{corr}} = 10^{-27}$ mA cm ⁴
50 ^c	4.310	0.940	0.987
22 ^c	1.845	0.950	0.989
9 ^c	0.723	0.968	0.993
1.5 ^c	0.113	0.970	0.994
30 ^d	2.458	0.975	0.994

^a $s = J_p/(J_p + J_{\text{corr}})$ is calculated under short-circuit conditions (i.e., $V = V_{\text{redox}}$). Calculations have been performed for two values of k_{corr} corresponding to the extreme values obtained for all the studied samples.

^b I is the current density crossing the junction n-GaAs/(Se²⁻/Se₂²⁻) at $V = V_{\text{redox}}$.

^c Untreated electrode [parameters are those of Fig. 2a, curves a, b, c, and d of Ref. (11)].

^d Ruthenium-treated electrode (parameters are those of Fig. 7, curve a).

^e Light intensity is measured before the flux enters into the PEC cell.

Fig. 12. Evolution of the calculated stabilization coefficients with potential for an n-GaAs/(Se²⁻/Se₂²⁻) junction under 22 mW/cm² ($k_{\text{corr}} = 5.7 \times 10^{-27}$ mA cm⁴ is used in calculation).

passage of photocurrent through the n-GaAs/(Se²⁻/Se₂²⁻) interface. The surface remains smooth, showing again that Se²⁻ is very efficient in stabilizing the GaAs in 1M KOH.

Ruthenium-treated electrodes in contact with K₂Se.—Heller *et al.* showed that there is an improvement of the solar energy conversion efficiency of the n-GaAs/(Se²⁻/Se₂²⁻) PEC cell when the electrode is ruthenium treated. Figure 7 confirms this fact: the fill factor is increased and the I-V characteristics are improved. A reduction of the surface recombination velocity by Ru treatment has been stated by Nelson *et al.* (18). The fact that C_{ss} (V) capacitances are lowered for treated electrodes might be further evidence for this phenomenon (Fig. 9). However, we do not think that this result explains all of the improvement in cell performance.

Our calculations, for untreated electrodes as well as for treated ones, show that the recombination current at the very surface is much smaller than the photocurrent as soon as the potential is positive of -1.55 V/SCE. Thus it appears that surface recombinations have little influence upon the I-V characteristics of our PEC cell. According to our model for the photocurrent, the Ru treatment mainly increases the exchange current $J_{p,0}^{**}$ [see Ref. (8)] through modifications of the energetic conditions of the charge transfer: $V_{\text{FB}}^* = -1.85$ V/SCE is found instead of -1.78 V/SCE for untreated electrodes (Fig. 8). One may then think that ruthenium has two effects; a newly discovered catalytic effect upon the hole transfer kinetics, and the reported reduction of the surface recombination (9, 18). Thus, the stabilization is better than for untreated electrodes under a given illumination (see Table I). This

Fig. 13. SEM picture of the surface of an n(100) electrode after passing a 3 mA/cm² photocurrent for 2h through the n-GaAs/1M (Se²⁻/Se₂²⁻) junction. $V_{\text{redox}} = -0.95$ V/SCE.

agrees with experiment (19). The fact that the Ru-treatment is persistent (9) requires, however, explanation. We also observe that the I-V curves and the Mott-Schottky plots (V_{FB}^*) remain stable for hours, *i.e.*, that the surface concentration in Ru³⁺ ions is constant with time. This means that Ru³⁺ ions are either able to form quickly new bonds with the lattice atoms to saturate their own reactive bonds (formed by corrosion) or that they chemisorb again as soon as they are removed from the surface. In both cases, the main idea is the ability of Ru³⁺ ions to move laterally on the surface if the corrosion rate is sufficiently reduced (this is not possible under rapid photocorrosion).

Our impedance results show that the Ru chemisorption reduces both fast and slow surface-state densities at the n-GaAs/(Se²⁻/Se₂²⁻) interface: the surface-state capacitances C_{ss} (V) (fast states) are lower, and ΔV_{FB} (slow states) is smaller than for untreated electrodes (Fig. 9 and 8, respectively) (11). These states may originate in chemical interactions between the solvent and the semiconductor, as is the case between GaAs and a metal in Schottky barriers (20-22). The pH dependence of V_{FB} for GaAs (23) suggests that OH groups in solution are involved in such interactions. Surface atoms which are likely to form these chemical bonds with OH groups are "isolated" from solution by the Ru treatment, because the reactive bonds are saturated. Thus, the state densities are smaller. Finally, the correlation between the experimental improvement of the stabilization by Ru and the smaller observed ΔV_{FB} seems to confirm that ΔV_{FB} is linked to the formation of corrosion intermediates (see the above discussion about corrosion).

The model.—According to the model of Frese *et al.*, we obtained $k_{\text{corr}} = 5.7 \times 10^{-27}$ mA cm⁴, thus $k_1 = 5 \times 10^{-8}$ mA cm with $\sigma_1 = \sigma_2 = 10^{-15}$ cm² ($N_V = 8.7 \times 10^{18}$ cm⁻³ for GaAs). Knowing that corrosion is generalized, *i.e.*, (A : B) $\sim 10^{15}$ cm⁻², one gets $E_{\text{SB}} = E_V + 0.075$ eV (Eq. [3]). This value is very close to the top of the valence band at the surface and is in good agreement with the fact that intrinsic surface states which are moved out of the bandgap then move back when surface agents are present (20, 21).

We have tried to see if this model is able to interpret our impedance results [ΔV_{FB} and C_{ss} (V)]. As reaction [1] is a surface hole trapping, it is interesting to examine if the one-electron (A · B) surface bond formation could give rise to the C_{ss} (V) peak and ΔV_{FB} .

Kinetic analysis only gives information about k_{corr} . But, k_{corr} may be written (Eq. [4], [5], and [10])

$$k_{\text{corr}} = \frac{k_1}{N_V} \frac{\sigma_2}{\sigma_1} \quad [8]$$

Moreover, at stationary conditions, one gets

$$(A \cdot B) = \frac{k_1}{N_V} p_s \quad [9]$$

Without changing k_{corr} and thus p_s , it is possible to modify the calculated (A · B) concentration, by multiplying k_1 by a given factor and dividing σ_2/σ_1 by the same one. Figure 14 presents our results when $k_1 = 5 \times 10^{-6}$ mA cm and $\sigma_2/\sigma_1 = 10^{-2}$ ($\sigma_1 = 10^{-15}$ cm²; $\sigma_2 = 10^{-17}$ cm²). The C_{ss} (V) curve in 1M KOH is well accounted for by this calculation, and E_{SB} is slightly changed. However, as for n-GaAs/(Se²⁻/Se₂²⁻) cells, the entire surface charge variation is insufficient to promote the whole ΔV_{FB} .

If now we take these values of σ_1 , σ_2 , and k_1 to estimate the stabilization coefficient on the n-GaAs/(Se²⁻/Se₂²⁻) junction, we find that: (i) s is unchanged because k_{corr} remains equal to 5.7×10^{-27} mA cm⁴; (ii) under these conditions, calculations show that (A · B) is divided by about 10. Correspondingly, the surface-charge relaxation, owing to the variations of the concentration (A · B) gives too small a contribution to represent the experimental C_{ss} (V) curve. This mechanism does not explain either ΔV_{FB} or

Fig. 14. Calculated surface-state capacitance C_{ss} (V) curve, assuming that the variations of the surface bonds ($A \cdot B$) are responsible for the surface charge relaxation at the n-GaAs/1M KOH interface. (—○—): Experimental data. (---): Calculated curve. Parameters are those of Fig. 5, curve a, except: $k_1 = 5 \times 10^{-6}$ mA cm; $\sigma_1 = 10^{-15}$ cm²; $\sigma_2 = 10^{-17}$ cm² (k_{corr} remains unchanged at 5.7×10^{-27} mA cm²).

the C_{ss} (V) peak in the case of the selenide-stabilized junction. The origin of these states remains to be found.

Conclusion

The present study shows the following points.

1. Self-consistent results are obtained for the photocorrosion and the stabilization of the studied junction. Our band bending calculations appear to be sufficiently precise and realistic to yield the real rate constants, as well as the stabilization coefficient.

2. The results on the Ru-treated electrodes confirm that reaction intermediates are responsible for the flatband potential shift under illumination. These intermediates are not formed when Ru^{3+} is chemisorbed, i.e., after the reactive semiconductor bonds are saturated with Ru^{3+} .

3. The model for the photocorrosion allows one to obtain the right stabilization coefficient of the n-GaAs/selenide junction, but does not account for all our impedance data. Under rapid photodissolution conditions, the unsaturated surface bond concentration ($A \cdot B$) may account for the C_{ss} (V) peak. This latter hypothesis does not apply for the stabilized junction, where we invoke other states (11).

Our study describes, for the first time, that Ru^{3+} ions have a double role: they improve the photoresponse and stability of the n-GaAs/(Se^{2-}/Se_2^{2-}) PEC cell, not only by reducing the surface-state density, but also by improving the transfer kinetics upon the redox species in solution. The latter point appears to be the most important.

Annealed Single-Crystal Cadmium Selenide Electrodes in Liquid Junction Solar Cells

S. Wessel, A. Mackintosh, and K. Colbow

Department of Physics, Simon Fraser University, Burnaby, British Columbia, Canada V5A 1S6

ABSTRACT

I-V characteristics, voltage dependence of the quantum efficiency, and spectral response were compared for annealed single-crystal CdSe photoanodes. Annealing in cadmium atmosphere improved the overall solar response considerably, while annealing under vacuum revealed a poor response for photon energies larger than 1.8 eV and a high quantum efficiency for near-bandgap energies. This behavior may be attributed to electron-hole pair generation from interbandgap states and a large density of minority carrier recombination centers near the crystal surface, owing to a high nonstoichiometry and a selenium layer at the surface. Annealing in selenium atmosphere resulted in very poor solar response caused by compensation. Simultaneous illumination of the electrodes with a He-Ne laser strongly enhanced the quantum efficiency for vacuum-annealed crystals for near-bandgap photons. We attribute this to electron trapping in the selenium-rich surface, with a resulting increase in depletion-layer width in the cadmium selenide.

The quantum efficiency spectral response of an ideal semiconductor photoelectrochemical solar cell will exhibit a flat behavior for photon energies moderately larger than the bandgap, independent of illumination intensity. Recombination centers within the bulk of the semiconductor and at its surface can substantially reduce the photocurrent and thus the quantum efficiency in a nonlinear fashion, while photogenerated carrier losses in the depletion region are usually small (1, 2). For highly doped semiconductors ($> 10^{18} \text{ cm}^{-3}$), the space-charge region becomes smaller than the absorption length for near-bandgap photon energies, which will thus lead to generation of minority carriers (holes for n-CdSe) in the bulk of the semiconductor with increased probability of loss by recombination (3). Carriers photogenerated by high energy photons will originate near the surface, where large losses of photocurrent may arise from a high density of surface recombination centers. In a two-beam experiment using a He-Ne laser (6328Å) as a dc pumping source, it was found that the spectral dependence of the quantum efficiency obtained with a weak, modulated measuring beam was very sensitive to the presence of carrier recombination centers (1).

We analyzed and compared various annealed crystals by single- and double-beam photocurrent spectroscopy. In this paper, we present data for vacuum-, cadmium-, and selenium-annealed single-crystal CdSe and give a possible explanation for the large change in spectral response of the vacuum-annealed crystals.

Experimental

Precut and polished C-plate single-crystal CdSe (batch A) and a raw ingot of CdSe (batch B) were obtained from Cleveland Crystals, Cleveland, Ohio. The conductivities of batch A and B were $0.3 \Omega \text{ cm}$ and $2 \text{ M}\Omega \text{ cm}$, respectively. The ingot was cut and polished into C-plates. The crystals were annealed for 6h at 600°C under vacuum, or in sealed evacuated quartz tubes in the presence of selenium or cadmium. The crystals were then mounted on a copper disk with an In-Ga (25:75) eutectic and silver dag for ohmic contact and sealed in a plexiglass disk with Devcon epoxy.

Prior to testing, all samples were etched for 1 min in a 50% H_2O_2 and glacial acetic acid solution in the ratio of 1:3. Light entered the test cell through a quartz bottom window, allowing $\sim 3 \text{ mm}$ of electrolyte between the window and the CdSe electrode, which was faced by a large Pt counterelectrode ring (25 cm^2). In all cases, the sulfide/polysulfide redox electrolyte was unstirred and consisted of 1M NaOH , $2\text{M Na}_2\text{S}$, 1M S , and 0.01M Se . N_2 gas continuously flushed the system since the electrolyte is sensitive to oxygen. The spectral response of the electrodes was obtained under short-circuit conditions using a 100W tungsten halogen lamp, the output of which was chopped at 20 Hz, followed by a Jarrel-Ash grating

monochromator with 8 nm resolution, and a Princeton Applied Research lock-in amplifier (Model HR-8). The illumination intensities were corrected for electrolyte absorption and at the crystal surface they were measured to be $20\text{-}40 \mu\text{W cm}^{-2}$. In the two-beam experiment, a He-Ne laser (Spectra Physics Model 133) served as an intense pumping source, with a weak, modulated probing beam obtained from the monochromator. The irradiance on CdSe from the laser was 1 mW cm^{-2} .

The current-voltage (I-V) characteristics of the electrodes were determined in the dark and under 100 mW cm^{-2} white light illumination from a 100W tungsten halogen lamp by adjusting the bias voltage. The change in quantum efficiency (η) with forward bias voltage was measured using the lock-in amplifier and a Spectra-Physics Model 125 He-Ne laser source (14 mW cm^{-2}).

Anodization of the electrodes was achieved in saturated KCl by 30 min white light illumination (100 mW cm^{-2}), while connected through a 100Ω load.

Results and Discussion

It is known that annealing of polycrystalline CdSe under vacuum liberates selenium from the surface, leaving a cadmium-rich sample behind (4, 5). While in polycrystalline samples selenium would escape via grain boundaries, it is plausible that in single crystals the selenium diffuses through the crystal surface, resulting in a selenium-rich surface layer over a nonstoichiometric CdSe crystal, which is indicated by a reddish color. This gives rise to bulk defects and a surface barrier associated with a high density of surface states. The polysulfide redox electrolyte would readily dissolve the Se° surface layer; however, the rate of dissolution is strongly reduced by the addition of 0.01M Se° to our electrolyte.

Figure 1 presents the current-voltage characteristics of cadmium and vacuum-annealed single-crystal CdSe. While the total current of the two different samples are similar, the dark currents (Fig. 1b) show very different behavior: the dark current increases rapidly at approximately 1500 mV forward bias for vacuum-annealed single crystals and between 500 and 600 mV for cadmium-annealed samples. This may be accounted for by the presence of a surface barrier to electron flow arising from the selenium-rich surface which breaks down at high forward bias. This is in agreement with a model proposed by Frese (6-8) for anodized single-crystal surfaces.

It can be seen in Fig. 1a that the decrease in current density of the cadmium-annealed crystals is primarily determined by its dark current, while the vacuum-annealed samples do not depend on dark current. For both samples, the decrease in current density for low forward bias indicates a blocking barrier for holes at the surface (9).

El Guibaly *et al.* (9) associated this behavior with surface states acting as hole trapping sites and becoming ion-

Fig. 1. *i*-*V* characteristics for 100 mW cm^{-2} white light irradiation (a) and in the dark (b) for annealed single-crystal CdSe in Cd-atmosphere (—) and under vacuum (---).

ized with illumination, thus reducing the amount of band bending. As seen from Fig. 1a, the vacuum-annealed single crystals show a larger open-circuit voltage than the

Fig. 2. Voltage dependence of the quantum efficiency at 632.8 nm (14 mW cm^{-2} He-Ne laser) for single-crystal CdSe annealed (a) in Cd atmosphere and (b) under vacuum.

Fig. 3. Spectral response of single-crystal CdSe (batch A) for Cd-annealed (—) and vacuum-annealed electrodes without (---) laser pumping and the vacuum-annealed electrode under laser pumping (···). Actual efficiencies of the dashed and dotted curve is one-half as shown.

Cd-annealed samples, which may result from larger band bending or a different shift of the bandedges, consistent with electron-hole pair generation within the Se-rich surface and immobilization of electrons in the selenium layer (6-8).

Figure 2 shows the behavior of the quantum efficiency at 632.8 nm with applied forward bias. The current direction of the vacuum-annealed single crystal (Fig. 2b) reverses for voltages larger than the open-circuit voltage. A possible explanation is that as the bands of the CdSe flatten at large forward bias, additional photogenerated holes in the selenium may accumulate at the CdSe/Se interface and are injected into the CdSe crystal, where they recombine with electrons; thus, more e-h pairs recombine than were photogenerated in CdSe.

The cadmium-annealed sample gave the same "normal" spectral response (Fig. 3) as an untreated single crystal (3) (not shown), but with a six-fold increase in quantum efficiency (see Table I), with and without laser pumping. However, vacuum annealing of the CdSe crystals did not improve the overall solar response; in fact, it

Fig. 4. Short-circuit current wavelength response of vacuum-annealed CdSe (batch A) with simultaneous laser pumping for different laser intensities as shown in milliwatts per square centimeter.

showed a rather unusual spectral behavior, which became more pronounced with laser pumping: a double peak in the photocurrent spectrum at 1.66 and 1.71 eV near the bandedge of CdSe, and a lower, nearly constant response for photon energies larger than 1.8 eV. With laser pumping, the efficiencies near the bandgap increase substantially, while the efficiency decreases and reaches a low value for high energy photons. Heller *et al.* (2) observed similar, but much less pronounced, behavior for

single-crystal CdSe with peaks at 1.64 and 1.69 eV. They ascribed these peaks to states within the bandgap owing to imperfections near the semiconductor surface acting as carrier traps and recombination centers, which would lead to changes in the photoresponse, particularly for light absorbed near the semiconductor surface. It seems plausible that the observed peaks arise from photon absorption and electron-hole generation involving inter-bandgap states. Photons of energy larger than 1.8 eV are strongly absorbed near the surface, resulting in a reduced quantum efficiency due to recombination via the large density of surface states. Laser pumping would result in the filling of traps near the CdSe/selenium interface and an increased quantum efficiency. Amorphous selenium has a bandgap of 2.05 eV (10) just above the laser energy of 1.96 eV. Amorphous selenium at the surface with a large concentration of cadmium will likely show strong absorption at the laser energy. If electrons are trapped in the selenium-rich surface layer, while the light generated holes diffuse away (6-8), a larger band bending will be produced in the CdSe and thus a larger depletion width. The increased number of electrons near the surface will decrease the quantum efficiency for electron-hole pairs generated by high energy photons, owing to increased recombination probability, and the increased depletion width will give an increased quantum efficiency for holes generated by near-bandgap photons, which create hole-electron pairs deeper into the crystal. This would then also explain why carrier generation from the 1.66 eV impurity levels becomes more efficient with increasing laser intensity (Fig. 4). At a laser intensity of $\sim 0.7 \text{ mW cm}^{-2}$ the photocurrent saturates, giving rise to the same response as for 1 mW cm^{-2} laser pumping, consistent with a slow transfer velocity of holes to the electrolyte (9, 11) with resulting photocorrosion.

Figure 5 shows the spectral response of anodized, Cd- and vacuum-annealed CdSe. The grown Se layer was found to be $\sim 0.27 \mu\text{m}$ thick for both samples as calculated from integrated photocurrent measurements (6-8). While the Cd-annealed samples again reveal the same behavior with and without laser pumping (Fig. 5a), the

Fig. 5. Spectral response of single-crystal CdSe (batch A) for etched electrodes (—), and anodized electrodes after 1/2 h (---) and 24h (· · ·) in redox electrolyte. All curves in graph b show twice and the dotted line in graph c one-third the actual efficiencies.

Fig. 6. Spectral response of single-crystal CdSe (batch B). Graph a shows the behavior of untreated (—) and Cd-annealed (---) electrodes; graphs b and c vacuum- and selenium-annealed CdSe, respectively, with (---) and without (—) laser pumping. The solid line in graph b shows ten times and both curves in graph c 500 times the actual efficiencies.

vacuum-annealed anodized crystals (Fig. 5b, 5c) show a similar response as etched vacuum-annealed crystals. The overall increase in quantum efficiency of anodized samples is most likely caused by improved surface condition due to photoetching. Similar results were obtained by Frese (8), showing an increased quantum efficiency near the bandedge for anodized CdSe electrodes. For selenium thicknesses of 0.24 and 0.36 μm , the response substantially decreased for wavelengths smaller than 630 nm (1.96 eV) and was associated with photon absorption in the selenium layer. Our results show a smaller decrease in quantum efficiency for the high energy photons, indicating that our selenium layer may in fact be thinner than calculated, or porous (12).

Leaving the anodized samples for 24h in redox electrolyte under short-circuit conditions improves the quantum efficiency, which indicates that the selenium layer dissolves, thus leaving a photoetched CdSe surface behind. The double-peak feature of the vacuum-annealed sample (Fig. 5b) disappears upon anodizing, and only the 1.71 eV peak remains visible. Upon laser pumping (Fig. 5c), the quantum efficiency peak shifts again to 1.66 eV. This would indicate that the 1.66 eV peak is due to a deep interband state which is essentially not affected by photoetching.

Figure 6 presents various heat-treatments for batch B single-crystal CdSe. Again, the spectral response of the quantum efficiency is considerably improved for Cd-annealed samples compared to untreated single crystals (Fig. 6a). They show a "normal" spectral response and reveal identical results with and without laser pumping. The untreated crystals show some band tailing, which seems to disappear upon Cd annealing. The vacuum-annealed single crystals (Fig. 6b) show one peak only at 1.71 eV with very low quantum efficiency. Photons with energy larger than ~ 1.8 eV do not show any measurable photoresponse, indicating a strong absorption in the selenium-rich surface layer of the crystal and/or a larger density of hole trapping sites at and near the surface. Upon laser pumping, again only one peak is observed which shows strong band tailing and a large 50-fold increased quantum efficiency at 1.66 eV. Figure 6c presents

selenium-annealed CdSe crystals. While the quantum efficiency is extremely small, the crystals show a "normal" behavior, with a bandgap of 1.74 eV. With laser pumping, the bandedge shifts towards lower energies, giving rise to a small peak at 1.74 eV. Annealing in selenium atmosphere may compensate the semiconductor, since selenium would act as an electron acceptor, resulting in a low effective donor density and a large number of carrier traps.

Table I summarizes and compares the observed quantum efficiencies for highly energetic photons (2.0 eV) and the observed peak efficiency at 1.71 eV (without laser pumping) and 1.66 eV (with laser pumping) for the untreated and annealed CdSe single crystals.

Conclusions

A satisfactory model to account for our data as well as previous work suggests that vacuum annealing of CdSe single crystals produces a selenium-rich surface and a large density of bulk defect states, probably due to selenium interstitials. This results in an unusual spectral response: namely, high quantum efficiency in two distinct bands below the CdSe absorption edge (1.74 eV) and decreased efficiency for highly absorbed light due to large recombination near the semiconductor surface. Simultaneous pumping with a strong He-Ne laser enhances these unusual spectral characteristics, which may be accounted for by assuming that the laser light is strongly absorbed in the larger bandgap selenium surface, where electron trapping leads to a larger band bending and thus increase of the depletion layer in the CdSe. This, as well as hole injection from the CdSe/selenium interface, would lead to an improved quantum efficiency for below bandgap photon energies.

One may be tempted to attribute the laser enhancement to a photoconductivity effect, that is, a lowering of the series resistance by penetrating light (≈ 745 nm), which does indeed occur for the high resistance vacuum-annealed samples. However, the observed photoconductivity reduced the series resistance by $\approx 40\%$; this is not sufficient to account for our data.

ABSTRACT

Semiconductor/liquid junctions derived from 0.5 μm thick films of amorphous hydrogenated silicon, a-Si:H, have been investigated in CH_3OH solvent. The a-Si:H films consist of a weakly doped n-type layer over a 200 \AA n⁻-a-Si:H layer on a stainless-steel substrate. The low series resistance and high ratio of minority carrier collection length to film thickness in this arrangement allows a study of the properties of semiconductor/liquid interfaces with minimal interference from bulk resistance losses. We find that a-Si:H anodes in 0.02M ferrocene, $\text{FeCp}_2/0.5 \text{ mM FeCp}_2^+/1.5\text{M LiClO}_4/\text{CH}_3\text{OH}$ solutions exhibit poor short-circuit quantum yields and low fill factors with 632.8 nm irradiation, but that these junctions display internal quantum yields of close to unity and high fill factors with short wavelength ($\lambda < 450 \text{ nm}$) irradiation. Photons absorbed within a distance comparable to the minority carrier collection length are efficiently collected, and the fill factors and quantum yields under such conditions are insensitive to increases in photocurrent density over a range of 0.1-2 mA/cm². Solar-simulated irradiation (88 mW/cm²) from a ELH-type tungsten-halogen lamp in the a-Si:H/0.02M $\text{FeCp}_2/0.5 \text{ mM FeCp}_2^+/1.5\text{M LiClO}_4/\text{CH}_3\text{OH}$ system yields open-circuit photovoltages of 0.75-0.85V, short-circuit photocurrents of 6-7 mA/cm², and photoelectrode efficiencies for conversion of light to electricity of 2.7%-3.3%. Photovoltages with the acetylferrocene⁺⁰ redox system are among the highest reported for any a-Si:H surface barrier system, and can exceed 0.85V under AM1 illumination conditions. Variation in the redox potential of the solution leads to changes in open-circuit photovoltage in accord with theory, and does not yield evidence for pinning of the a-Si:H Fermi level by interface states or by surface oxides over the potential range investigated. The observed photoelectrochemical behavior of these a-Si:H films is consistent with documented bulk transport and carrier collection properties of a-Si:H, and does not show evidence for series resistance losses, unusual spectral response characteristics, or recombination sites at the semiconductor/liquid junction. Manipulation of the electronic properties of the a-Si:H films can thus lead to improved energy conversion parameters and a clearer picture of the chemistry at the a-Si:H/liquid interface.

To elucidate the fundamental chemistry at the semiconductor/liquid interface, we have studied photoelectrodes having liquid contacts derived from nonaqueous solvents. Nonaqueous solvents largely circumvent the photocorrosion and photopassivation processes prevalent in aqueous solution (1-4), and thus provide media which are suitable for reproducible, controlled investigations of the semiconductor/liquid interface. Unfortunately, most semiconductor/liquid combinations in nonaqueous solvents have been reported to exhibit low solar energy conversion efficiencies and generally rather poor interface properties (3-9). The major cause of this behavior has been assigned to interface states at the semiconductor/liquid junction (10-14). These

states can act as recombination sites, and thereby lead to low quantum efficiencies and fill factors. Also, these states may serve to pin the surface Fermi level and lead to less than ideal photovoltages at the semiconductor/liquid interface (13, 14).

Of major concern, however, must be the correct assignment of properties to the semiconductor/liquid interface as distinguished from those that are simply electronic properties of the semiconductor itself or artifacts of the method of measurement of current-voltage characteristics. Recent investigations on common semiconductor substrates, such as n-type Si (15) and n-type GaAs (16), have demonstrated that proper attention to bulk electrode properties and control of interfacial chemistry can lead to efficient nonaqueous semiconductor/liquid junctions.

* Electrochemical Society Active Member.

tion systems. We have thus turned our attention to thin film materials, such as amorphous hydrogenated silicon (a-Si:H), in an attempt to extend these principles to a wider class of semiconductor materials.

We report herein new data on the photoelectrochemistry of a-Si:H/liquid junctions in nonaqueous solvents. Notably, our results demonstrate that such interfaces exhibit little evidence of recombination sites at the semiconductor/liquid interface which would act to decrease the short-circuit quantum efficiency or to produce unusual wavelength response characteristics. We find that inefficiencies can be ascribed primarily to transport properties in the semiconductor material itself. Control of these parameters can thus lead to improvements in the properties of a-Si:H/liquid junctions. We observe that properly designed semiconductor/liquid combinations with a-Si:H can exhibit internal quantum yields for electron flow which are close to unity over a substantial portion of the solar spectrum. In addition, we observe open-circuit photovoltages and photoelectrode efficiencies for conversion of visible light to electricity which are comparable to the best reported values for any surface barrier device fabricated with similar a-Si:H material. An important conclusion of our study is that substantial progress in improving the photocurrent response of a-Si:H/liquid junctions will require improvements in electronic properties of the bulk material itself rather than improvements in the properties of the semiconductor/liquid interface.

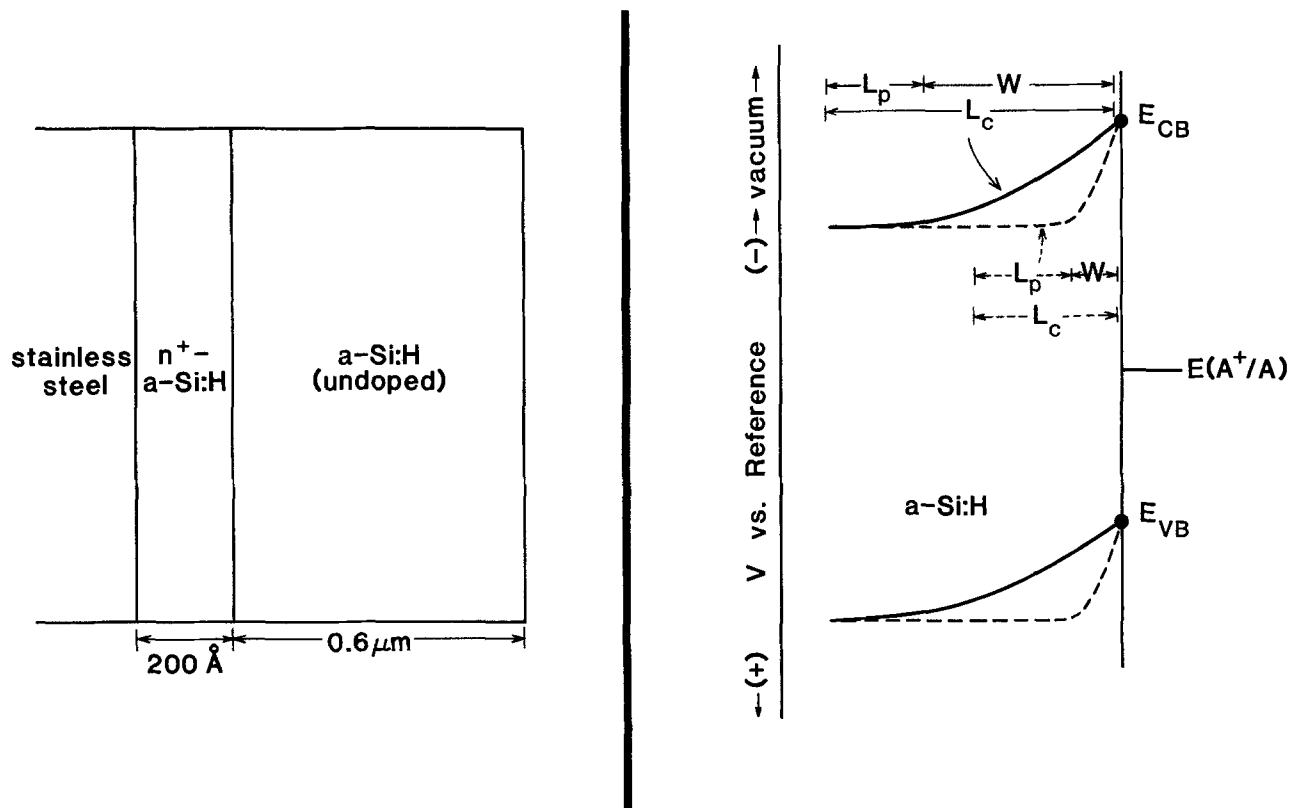

Electronic Properties of a-Si:H

Amorphous hydrogenated silicon, a-Si:H, has been the subject of intense study for application in terrestrial photovoltaic and photoelectrochemical devices (17-20). This material can be produced by a number of methods (21-23) which yield thin films which are either p-type, "intrinsic," or n-type. In contrast to single-crystal silicon, a-Si:H

films possess a strong optical absorption resembling that of a direct gap semiconductor having a bandgap at 1.7 eV (25). The overlap of the absorption spectrum of a-Si:H with the solar spectrum, as well as the ease of deposition of the material itself, are attractive features of these films. An especially critical property in a-Si:H is the relatively short hole-diffusion length. Doping of the film has generally been found to decrease the hole-diffusion length substantially (25-26); thus the preferred structure for photoanode applications consists of a relatively thin, heavily doped n-type layer followed by a thicker "intrinsic" layer (usually weakly n-type), as shown in Scheme I.

Another important property of a-Si:H is that over $2 \mu\text{m}$ of the material is required to absorb essentially all visible light with energy greater than 1.7 eV. However, film thicknesses significantly below this value are employed in practical solar cells at present. This is because of the low value of the hole-diffusion length, which is typically $0.2\text{-}0.7 \mu\text{m}$ in intrinsic a-Si:H films of the highest quality currently available (27). Thicker films would absorb more light, but electron-hole pairs created at depths large compared to the collection length (at most the sum of the diffusion length and the depletion width) would not be collected and would recombine in the bulk material. Also, the increased series resistance of relatively thick a-Si:H films could produce poor fill factors. Thus, use of relatively thick films would require a detailed analysis of bulk-transport properties in order to isolate those features originating from the semiconductor/liquid interface.

In this study, we have employed $0.5\text{-}0.6 \mu\text{m}$ thick a-Si:H films which have been plasma deposited on a reflecting substrate, stainless steel. The film thickness is on the order of the minority-carrier collection length, L_c , and the reflection of light by the substrate provides an additional pass for light of long wavelengths, effecting increased carrier creation within a distance L_c of the interface. Series resistance losses due to excess bulk thickness have been

Scheme I. Left: Representation of the thin film a-Si:H photoelectrode structure. The contact to the stainless steel substrate is provided by a 200\AA thick n⁺-a-Si:H film, followed by a $0.5\text{-}0.6 \mu\text{m}$ thick layer doped weakly n-type. The situation will result in photoanode behavior qualitatively similar to conventional single-crystal photoanodes. Right: Interface energetics for two different light intensities at a-Si:H/liquid interfaces. The collection length, L_c , is the sum of the minority carrier diffusion length, L_p , plus the depletion region thickness, W . Contraction of the depletion width in a-Si:H with increasing light intensity (---) leads to a decrease in L_c at a fixed voltage bias, and yields poor charge collection for light which penetrates deeply into the a-Si:H film. The fill factor and short-circuit quantum yield of these interfaces is thus sensitive to both the intensity and wavelength of light incident on the a-Si:H film.

minimized without sacrifice of light absorption within a distance L_c of the surface. Our films provide an opportunity for detailed examination of the properties of the semiconductor/liquid junction. Information concerning the significance of recombination sites at the semiconductor/liquid interface has been obtained from suitable variations in incident light wavelength and intensity, as well as from photocurrent-voltage properties.

Experimental

Experimental techniques and procedures have been described previously (15). CH_3OH was distilled from Mg prior to use; no other precautions concerning exclusion of air or water were found necessary to obtain reproducible photocurrent-voltage characteristics. All current-voltage curves were obtained under potentiostatic control of the working electrode vs. a Pt reference electrode, and thus represent photoelectrode efficiencies which measure the properties of the a-Si:H photoanode. These values cannot be compared directly with two electrode solar cell efficiencies without actual fabrication of such devices.

The a-Si:H films were prepared by RF decomposition of silane, and were all prepared at HT Products by H. Wiesmann. The stainless-steel substrate was maintained at 220°C , with a deposition rate of 1.5 \AA/s . A 200 \AA thick n-doped layer was deposited from silane with 1% phosphine, and was then followed by a nominally intrinsic $0.5\text{--}0.6 \text{ \mu m}$ layer of a-Si:H. Infrared absorption measurements indicate that film deposition under these conditions yields a-Si:H with 15% hydrogen content; thus the stoichiometry of our material does not differ substantially from samples used in previous liquid junction studies (9). Slight compositional differences between these samples and previous results (9) do not affect an interpretation of our results, because we obtained excellent agreement with previous data when our a-Si:H samples were tested under experimental conditions identical to those described in other studies.

Photoanodes were fabricated by bonding the stainless-steel substrate to a coil of Cu wire with Ag paint. Insulation from the liquid was obtained with ordinary epoxy resin. Typical photoelectrode areas exposed to the elec-

trolyte were $0.1\text{--}0.4 \text{ cm}^2$. All electrodes were etched for 10s in 5% aqueous HF and washed with CH_3OH immediately before use. Reflectance spectra were obtained by use of spectral response apparatus previously described (15), with reflected light determined by a calibrated Si detector from United Detector Technologies, Incorporated. Spectral response and Schottky barrier measurements were performed using apparatus at SERA Solar, and all other data was collected at Stanford using techniques described previously (15, 16).

Open-Circuit Photovoltage Measurements to Probe Interface Kinetics

We have performed cyclic voltammetry and steady-state current-voltage experiments with outer-sphere redox couples in order to establish trends in photovoltages for the a-Si:H/ CH_3OH interface. The data are summarized in Fig. 1, which indicates the photovoltages, V_{oc} , obtained for a-Si:H films in contact with various redox couples, A^+/A . At sufficiently negative potentials, as in the cyclic voltammetry for (N,N'-dimethyl-4,4'-bipyridinium) $^{2+/+}$ (Fig. 1a), we observe dark oxidations and dark reductions near the formal potential of the redox couple, indicating no appreciable photovoltage for this system (10). The (N,N'-dimethyl-4,4'-bipyridinium) $^{2+/+}$ redox system does exhibit anodic photocurrent, and the photovoltage [as determined by the difference in anodic peak potential between an a-Si:H photoanode and a Pt electrode (3, 10)] is 0.2V under 100 mW/cm^2 of tungsten-halogen irradiation. The dark reductions at a-Si:H films have not been reported in other nonaqueous solvents, and indicate substantial room temperature dark conductivity in this particular sample of a-Si:H material (likely owing to tailing of phosphorus dopant into the intrinsic layer). Accurate values of the conduction band edge position would require measurement of the barrier height, not the photovoltage (28, 29); however, the data do allow us to conclude that E_{CB} is more negative than -0.7V vs. SCE in CH_3OH solvent.

We have also employed steady-state photocurrent-voltage techniques to complement the cyclic voltammetry V_{oc} measurements. All experiments were per-

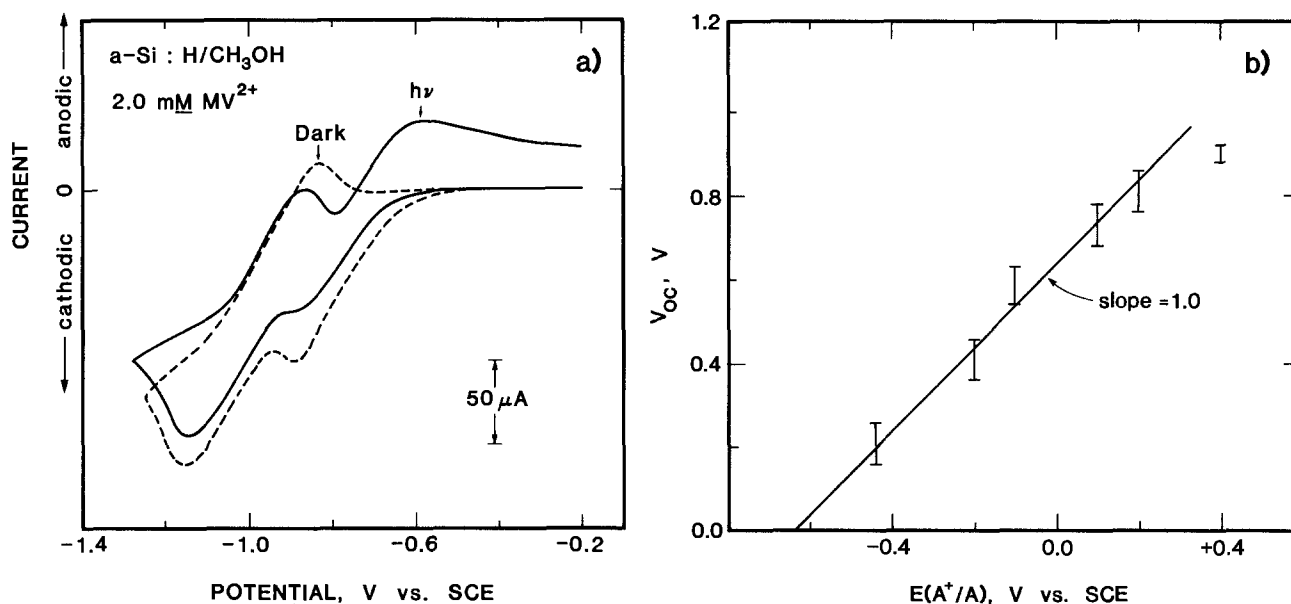

Fig. 1. (a) Cyclic voltammetry (100 mV/s) of a-Si:H films in 1.0M KCl/ CH_3OH with 2.0 mM N,N'-dimethyl-4,4'-bipyridinium (MV^{2+}) dichloride added. Irradiation is 100 mW/cm^2 provided from a tungsten-halogen lamp, and is expanded uniformly over the entire electrode surface. The $\text{MV}^{2+/+}$ couple exhibits enhanced oxidation currents in the light, while $\text{MV}^{+/0}$ shows both oxidation and reduction currents in the dark. Cathodic peaks at a Pt foil electrode under the same conditions are at -0.50V vs. SCE for $\text{MV}^{2+/+}$ and -1.00V vs. SCE for $\text{MV}^{+/0}$. Substantial room temperature conduction in a-Si:H can be obtained due to tailing of phosphorus dopant from the n^+ layer into the undoped region of the film. (b) Open-circuit photovoltage for the a-Si:H/ CH_3OH interface as a function of solution redox potential. Cell potentials, including redox couples, with $E(\text{A}^+/\text{A})$ in V vs. SCE, are as follows: N,N'-dimethyl-4,4'-bipyridinium $^{+/0}$ (-0.95V); N,N'-dimethyl-4,4'-bipyridinium $^{2+/+}$ (-0.45V); $[\eta^5\text{-C}_5(\text{CH}_3)_5]_2\text{Fe}^{+/0}$ (-0.21V); N,N,N',N'-tetramethylphenylenediamine $^{+/0}$ (-0.11V); 1,1'-dimethylferrocene $^{+/0}$ ($+0.10\text{V}$); ferrocene $^{+/0}$ ($+0.20\text{V}$); acetylferrocene $^{+/0}$ ($+0.39\text{V}$). All determinations were in 1.0M LiClO₄ except for the N,N'-dimethyl-4,4'-bipyridinium system, which required 1.0M KCl for solubility. Measurements are the result of several independent determinations for a number of anodes.

formed with irradiation from a tungsten-halogen lamp, and the solutions contained sufficiently high concentrations of electroactive material to preclude significant photodecomposition processes on the time scale of the measurement. In each cell, the light intensity was adjusted to yield typical AM1 short-circuit photocurrent densities for this a-Si:H of 6-7 mA/cm². V_{oc} values obtained through a high impedance voltmeter or from the onset of anodic photocurrent in a steady-state current-voltage scan were in excellent agreement. We observe a linear dependence of V_{oc} vs. $E(A^+/A)$ over a wide (1.0V) potential range, with a slope of V_{oc} vs. $E(A^+/A)$ of 1.0 ± 0.2 (Fig. 1b). The data are thus in accord with the ideal model for the semiconductor/liquid interface (30), and do not yield evidence for gap states which pin the surface Fermi level to yield a relatively low photovoltage. While the V_{oc} values do seem to level off at very positive potentials, photoanodic decomposition processes prevented further variation in the solution potential. For A-acetyl ferrocene, the V_{oc} of 0.88-0.91V at light levels equivalent to 6-7 mA/cm² photocurrent densities for A = acetylferrocene are among the highest values of V_{oc} reported for any a-Si:H surface barrier device (17, 19, 31).

Cyclic voltammetry measurements of a-Si:H anodes in C₂H₅OH solvent are reported to yield nonideal behavior of V_{oc} vs. $E(A^+/A)$ (9). Photoanodic decomposition processes at low concentrations of redox couples and relatively high water content can lead to low values of V_{oc} in cyclic voltammetric experiments, and this is responsible for the discrepancy between our new dependence of V_{oc} vs. $E(A^+/A)$ and a previous study of a-Si:H in C₂H₅OH solvent. Cyclic voltammetric scans with our a-Si:H samples yield excellent agreement with previously reported data (9) in C₂H₅OH and yield similar data in CH₃OH solvent. However, a direct interpretation of these experiments is hindered by concurrent decomposition processes, as is evidenced by the disparity between cyclic voltammetric V_{oc} (0.57V) and steady-state V_{oc} photocurrent-voltage data (0.75V) for the ferrocene⁺⁰ system in previous studies (9). The high concentrations of electroactive reagents and minimal faradaic currents in the direct open-circuit photovoltage determinations (Fig. 1) minimize these complications, and yield an internally consistent set of data which indicate a substantially different dependence of V_{oc} vs. $E(A^+/A)$.

Our new data also modify the basic interpretation of the causes of junction nonideality in the a-Si:H system. We note that a slope of only 0.42 for V_{oc} vs. $E(A^+/A)$ has been found by cyclic voltammetry for p-i a-Si:H cathodes in aqueous solution (32). In addition, metal/semiconductor Schottky barriers with a-Si:H have been reported to yield a slope of V_{oc} vs. metal work function of 0.52 (33). This slope in Schottky systems has been attributed to the presence of interface states with a density of 10^{13} cm⁻²eV⁻¹

(33). Within this framework, it has been proposed (32) that the native a-Si:H surface oxide is the source of interface states, and that this oxide results in nonideal behavior at all of these a-Si:H interfaces. Our data (Fig. 1b) indicate ideal behavior [slope of V_{oc} vs. $E(A^+/A) = 1.0 \pm 0.2$] for a-Si:H/CH₃OH interfaces, and demonstrate that systems with surface oxides present can indeed exhibit ideal junction behavior in the proper system.

Our a-Si:H/liquid junction ideality data can be easily rationalized within the framework of past direct comparisons of liquid interfaces to Schottky systems. We have previously demonstrated that the chemistry of the semiconductor/contact junction can play a large role in determining interface kinetics, and that under identical illumination conditions, semiconductor/liquid interfaces with n-Si, n-GaAs_{1-x}P_x ($0 < x < 1$), and n-GaAs exhibit higher values of V_{oc} than do direct Schottky contacts with metals such as Pt or Au (15, 16, 34). Surfaces which exhibit a high density of gap states at metal contacts may not possess similar interface states at liquid junctions. For example, surface pinning in Si Schottky systems can be related to metal-silicide formation (35), and pinning in n-GaAs systems can be assigned to formation of Ga/metal alloys or formation of surface defects upon deposition of the metal barrier (36). There would appear to be few documented examples where the behavior of Schottky contacts successfully correlates with the behavior of liquid junctions. Consistently, immersion of a-Si:H in liquid systems (Fig. 1b) can yield ideal V_{oc} vs. $E(A^+/A)$ behavior and large photovoltages with no direct relation to Schottky barrier data.

Photocurrent-Voltage Characteristics of a-Si:H/CH₃OH Interfaces

We observe several novel effects in the photocurrent-voltage behavior of our a-Si:H films. These effects should be general for low L_c material, and have been observed for metal/semiconductor barriers with a-Si:H (37), but have not been previously noted for a-Si:H in contact with a liquid electrolyte. Previous work (9) on the a-Si:H/liquid interface has suggested that a source of inefficiency may be the use of relatively thick a-Si:H layers, and concurrently suggests that thinner samples may yield improved quantum efficiencies and fill factors since the field could extend across the entire material. Within the framework of Scheme I, it is apparent that if bulk collection difficulties are indeed the sole source of inefficiency, the use of shorter wavelength irradiation should yield improved cell behavior for any thickness of sample. However, substantial wavelength effects on the fill factor and short-circuit quantum efficiency, which would confirm the proposed suggestion, were not observed (9). In fact, exactly the opposite behavior was found, and 454.4 or 514.5 nm light gives lower observed quantum yields than does 632.8 nm light. Furthermore, no improvements in fill factor were observed with white light irradiation as compared to 632.8 nm irradiation, and little or no improvement in efficiency was observed with shorter wavelength excitation sources.

In contrast, we observe here substantial improvements in the photocurrent-voltage characteristics of the semiconductor/liquid interface with decreases in the wavelength of the excitation light source. Our data indicate that measurements of the photocurrent-voltage properties of a-Si:H at a single wavelength of light, especially light with energy near the absorption edge, are insufficient to identify the nature of the kinetics at the a-Si:H/liquid interface. We assign the previous declines in fill factor and quantum efficiency with decreasing photon wavelength not to a fundamental property of the a-Si:H/liquid interface, but rather to a combination of series resistance losses and to solution absorption of light. If these losses are minimized, the behavior of a-Si:H/alcohol interfaces can be consistently understood within the framework of the known bulk properties of a-Si:H.

Figure 2 displays the photocurrent-voltage characteristics as a function of the excitation wavelength of a-Si:H

Table I. Photocurrent-voltage parameters vs. photon wavelength for the a-Si:H/CH₃OH interface

λ (nm) ^a	Input (mW/cm ²)	Φ_{sc} ^b	V_{oc}	V_{pmax} ^c	η (%) ^d
632.8	5.46	0.18	0.69	0.54	3.4
632.8	11.9	0.16	0.73	0.56	3.2
632.8	25.1	0.16	0.77	0.54	3.2
514.5	1.86	0.46	0.64	0.50	6.8
514.5	3.27	0.47	0.66	0.52	7.6
514.5	5.30	0.44	0.68	0.52	7.1

^a Input at 632.8 nm is from a beam expanded He/Ne laser; input at 514.5 is from a beam expanded Ar ion laser.

^b Quantum yield for electron flow at short circuit.

^c Voltage at the maximum power point.

^d Maximum energy conversion efficiency for monochromatic light to electricity, uncorrected for cell reflection losses or solution absorption. Data are for one particular a-Si:H sample, and were obtained in a stirred 5.0 mM FeCp₂/0.5 mM FeCp₂⁺/1.0M LiClO₄/CH₃OH solution. The potential of the cell was measured as +0.20V vs. SCE. Efficiencies at other wavelengths are a compromise between variations in quantum yield and fill factor, as depicted in Fig. 2 and 3.

Fig. 2. Photocurrent-voltage properties of a-Si:H films (0.35 cm^2) in contact with stirred $10 \text{ mM FeCp}_2/0.5 \text{ mM FeCp}_2^+/1.0 \text{ M LiClO}_4/\text{CH}_3\text{OH}$ solution. The optical path length through the solution is 2 mm . The photocurrent-voltage curves are scanned at 50 mV/s , and potentials were measured vs. a Pt reference electrode poised at the cell potential through a 0.2 mm od Luggin capillary. (a) Photocurrent-voltage properties with irradiation of $\lambda < 450 \text{ nm}$ obtained from a 200 W Hg lamp equipped with a short pass filter. Curves b and c were obtained with neutral density filters transmitting 50% and 25% of the light intensity available in curve a. (b) Photocurrent-voltage properties under identical cell conditions as in Fig. 2a, but irradiation is far $\lambda > 600 \text{ nm}$ from a ELH-type tungsten halogen lamp equipped with a 600 nm long pass colored-glass filter. Curves c and d were obtained with 50% and 25% transmittance neutral density filters from the irradiation level in curve b; curve a has the light intensity adjusted to provide similar photocurrent density to curve a in Fig. 2a. Note the pronounced decline in fill factor in Fig. 2b relative to the collection properties displayed in Fig. 2a.

films in contact with a $1.0 \text{ M LiClO}_4/10.0 \text{ mM ferrocene (FeCp}_2)/0.5 \text{ mM FeCp}_2^+/\text{CH}_3\text{OH}$ solution. With excitation of $\lambda > 600 \text{ nm}$ (Fig. 2b, Table I), we observe low short-circuit quantum yields which decline with increasing light intensity. In addition, the fill factor is 0.50 at very low current density and shows a decline with increasing light intensity. Higher values of photocurrent density than displayed in Fig. 2b, as obtained with $\lambda > 600 \text{ nm}$ from a filtered tungsten-halogen lamp, yield even poorer fill factors and quantum efficiencies. These photocurrent-voltage characteristics generally resemble those reported previously for a-Si:H films in $\text{C}_2\text{H}_5\text{OH}$ solution with 632.8 nm excitation (9), except that the lower series resistance of the $\text{CH}_3\text{OH}/1.0 \text{ M LiClO}_4$ electrolyte (15) and the lower bulk resistance in the $0.5 \mu\text{m}$ film leads to better fill factors in our system.

In contrast, Fig. 2a displays the photocurrent-voltage behavior of the a-Si:H/ $10.0 \text{ mM FeCp}_2/0.5 \text{ mM FeCp}_2^+/\text{CH}_3\text{OH}$ interface when irradiated with light of $\lambda < 450 \text{ nm}$ (obtained from a 200 W Hg lamp equipped with a 450 nm short pass filter). We observe significantly higher fill factors, which do not degrade even at photocurrent densities threefold higher than the onset of decline with the $\lambda > 600 \text{ nm}$ light. In addition, with minimal solution absorption, the quantum efficiency for carrier collection with 450 nm light is over twice the value obtained at 632.8 nm (*vide infra*). Thus, both the short-circuit quantum yield and fill factor of these a-Si:H/liquid junctions are dependent upon incident photon energy.

Previous studies have speculated that a decline in fill factor with increasing photocurrent density observed with 632.8 nm irradiation might be due to surface recombination sites at the a-Si:H/liquid interface, or perhaps due to series resistance losses associated with the photoconductivity property of the a-Si:H films (9, 32).

The improvements in our photocurrent-voltage responses with excitation by higher energy photons rule out both of these possibilities in our system. We find that our observations are consistent with the transport and absorption properties of a-Si:H, and we conclude that the behavior of a-Si:H/liquid junctions is dominated by these processes.

In a-Si:H films irradiated with sufficiently short wavelengths, such that the penetration depth $\alpha(\lambda)^{-1}$ is on the order of 100 nm or less (24), essentially all of the photogenerated holes will be collected at the junction, resulting in high short-circuit quantum efficiencies. In addition, fill factors should be high, provided that series resistance losses from the use of excessively thick a-Si:H films and highly resistive electrolytes are minimal. As depicted in Fig. 2a, these expectations are in excellent agreement with the photocurrent-voltage characteristics for irradiation of the a-Si:H/ $\text{CH}_3\text{OH}/\text{FeCp}_2^+/\text{FeCp}_2$ interface with light of wavelength less than 450 nm .

The situation for 632.8 nm excitation is substantially different. The $\alpha(\lambda)^{-1}$ in a-Si:H of 632.8 nm light is typically $1\text{--}2 \mu\text{m}$ (24); thus, low quantum efficiencies should be expected, since only a fraction of the carriers will be created within a collection length of the interface. Use of material with thicknesses greater than L_c may lead to increased light absorption, but will not necessarily produce substantial increases in photocurrent flow. Quantum yields with 632.8 nm light are rather modest even with our film geometry (Table I), and we conclude that increases in quantum efficiency at this wavelength will require fabrication of material with larger collection lengths, rather than passivation of surface states.

We have noted above that the fill factor at a specific photocurrent density is dependent on the wavelength of the incident photons (31). This can be understood by considering the factors which determine the fill factor of a semiconductor/liquid junction, with emphasis upon the particular electronic properties of a-Si:H. The hole-collection length usually is the depletion width, W , plus the diffusion length, L_p ; thus, only holes produced at depths comparable to $L_p + W$ will diffuse to the depletion region where the built-in field can sweep them to the junction.¹ a-Si:H differs from its crystalline counterparts in that L_p is on the order of, and sometimes less than, W (25-29). Application of an external potential to bias the cell from open circuit towards short circuit will serve to increase the field-assisted drift, and thus will lead to collection lengths, and hence photocurrents, which are a strong function of applied voltage. Additionally, in a-Si:H, L_c is known to decrease with increasing light intensity, due to a contraction of the depletion region under illumination (38). Thus, the fill factor should be dependent upon both the light intensity and the penetration depth of the light as compared to $L_p + W$, with shorter wavelengths of light yielding improved photocurrent-voltage characteristics (Fig. 2, 3; Table I).

Clearly, a complete description of the a-Si:H/liquid interface must take these bulk effects into account in order to interpret the photocurrent-voltage data. Quantitative descriptions of the light intensity and potential dependence of the fill factors are being developed, and should yield information concerning carrier transport in a-Si:H similar to that produced by the established surface photovoltage technique. The stability of a-Si:H films in the nonaqueous $\text{FeCp}_2^+/\text{FeCp}_2/\text{CH}_3\text{OH}$ solvent should provide a distinct advantage over the aqueous redox system presently used for these surface photovoltage measurements (38). In this regard, the study of liquid junctions may aid in developing improved techniques for characterizing a-Si:H films, as well as a-Si:H interface properties.

¹ In our discussion of collection lengths, we have implicitly assumed that the hole mobility is sufficiently large that all carriers created in the depletion region are collected. Under this condition, $L_c = L_p + W$. However, if the hole mobility is sufficiently small, drift alone will dictate the collection length, and L_c may then only be a fraction of W . Our data can be accommodated within the framework of either of these two conditions.

Fig. 3. (a) Short-circuit quantum yield vs. photon wavelength for the a-Si:H/5.0 mM FeCp₂/0.5 mM FeCp₂⁺/1.0M LiClO₄/CH₃OH interface. Optical path length through the solution is 1 mm, and the light intensity is approximately 1 mW/cm². (b) Reflectivity spectrum at an air interface of an a-Si:H film on a Pd-coated n-Si substrate. The interference fringes for $\lambda > 600$ nm arise from the 0.5 μ m film thickness.

Spectral Response Characteristics of a-Si:H/Liquid Junctions

The spectral response of short-circuit photocurrent *vs.* photon wavelength lends further credence to the notion that the electronic properties of a-Si:H dominate the photoelectrochemical behavior. The spectral response data for a-Si:H/CH₃OH/5.0 mM FeCp₂/0.5 mM FeCp₂⁺ are depicted in Fig. 3. In addition, a reflectivity spectrum of a similar a-Si:H film on a substrate of Pd-coated single-crystal silicon is displayed for reference in Fig. 3b. The spectral response data have been obtained at short-circuit conditions (1 mm optical path length through the solution), with an average light intensity of 1 mW/cm². As discussed above, the quantum yields obtained for long wavelength excitation at these light intensities will be somewhat higher than differential quantum yields under solar photon fluxes. The measurement in Fig. 3a is based upon light incident upon the photoelectrochemical cell, and is not corrected for solution absorption or optical reflection losses. For excitation with short-wavelength photons, we observe high quantum yields for electron flow, >0.55 . Reference to the reflectivity spectrum at the a-Si:H/air interface (Fig. 3b) indicates that the effective index of refraction of this a-Si:H film at 450 nm is 4.8 (39). Using a value for the index of refraction of 1.0M LiClO₄/CH₃OH of 1.35 (40), we calculate that reflective losses from the air/glass/solvent/a-Si:H interfaces will amount to approximately 30% of the incident light. Thus, quantum yields corrected for reflection are greater than 0.8, and would approach unity if corrections for solution absorption were also included.

The effect of small carrier collection lengths in a-Si:H is demonstrated by a comparison of the spectral response curves in the 600-700 nm region to the reflectivity data. In this wavelength region, the absence of interference fringes and the known increase in absorption coefficient with wavelength indicate increasing absorption by the

a-Si:H film; however, in the same wavelength region, the short-circuit quantum yield declines noticeably. Long wavelength photons penetrate too deeply into the film to be efficiently collected because of the modest collection lengths of these particular samples of a-Si:H. Thus, low short-circuit quantum yields and low fill factors for excitation of a-Si:H with 632.8 nm light do not necessarily result from recombination sites at the semiconductor/liquid interface, but can be assigned to carrier transport and optical-absorption properties of the material itself.

We note that typical p-i-n solid-state devices show a decline in short-circuit quantum efficiency with short-wavelength excitation because of high recombination rates in the doped layers near the surface (25). However, liquid junctions should benefit from the efficient collection of carriers generated near the interface, and need not possess the surface dead layer present in p-i-n-type systems. In addition, a liquid junction may not exhibit metal/semiconductor interfacial stress, which can induce recombination sites and cause declines in the spectral response for short-wavelength excitation. Ideal semiconductor/liquid junctions should not show a decline in short-circuit quantum efficiency with high energy excitation unless bulk resistivity effects influence majority-carrier collection. Previous investigations of n⁺-i-a-Si:H films in C₂H₅OH/FeCp₂ liquid junctions indicate that the short-circuit quantum yield decreases when the excitation wavelength is changed from 632.8 nm to 514 or 454 nm (9). Recent work on p-i type a-Si:H films in liquid junctions also reveals this effect, and the assumption of low series resistance in these films has led to the suggestion that a decline in short-wavelength response is an intrinsic property of the a-Si:H/liquid interface (32). Different preparations of a-Si:H films could produce different interface properties; however, reference to the spectral response characteristics in Fig. 3 demonstrates that a-Si:H/liquid junctions can exhibit internal quantum yields near unity, and that a decline in spectral response characteristics at short wavelengths is not apparent with our a-Si:H samples under these conditions.

Excessive series resistance losses, especially for majority carriers in p-i a-Si:H films, can lead to decreases in short-circuit quantum yield at short-excitation wavelengths. With excitation of $\lambda < 500$ nm, we can assign reduced quantum efficiencies in our low resistance n⁺-i a-Si:H/liquid junctions to solution absorption of light, and not to recombination at the semiconductor/liquid interface or to the a-Si:H material itself. Figure 4 depicts the spectral response parameters of a-Si:H films as a function of the concentration of FeCp₂ in CH₃OH solvent. We observe that the quantum yield declines severely at short wavelengths, owing to excessive solution absorption, even at relatively modest levels of FeCp₂ and with relatively short optical path lengths through the solution (0.5-1.0 mm). Addition of small amounts of the highly absorbing FeCp₂⁺ makes the effect more pronounced. Absorption spectra indicate that 0.070M FeCp₂ in C₂H₅OH in a 2.0 mm thickness absorbs 43% of the light at 514 nm and 97% at 454 nm, and that accurate quantum yields based on photons incident on the a-Si:H electrode surface in these solutions would require extremely short path lengths. Minimization of these losses does not yield evidence for low quantum efficiencies, and yields improved behavior for the a-Si:H/liquid junctions.

Efficiency Parameters for the a-Si:H/FeCp₂/FeCp₂⁺/CH₃OH System

The photocurrent-voltage characteristics under simulated solar illumination of a-Si:H films in 20.0 mM FeCp₂/0.5 mM FeCp₂⁺/1.5M LiClO₄/CH₃OH are depicted in Fig. 5. Even with the relatively poor long wavelength response of our particular a-Si:H samples and substantial solution absorption for $\lambda < 500$ nm, at 88 mW/cm² of ELH-type tungsten-halogen irradiation, we observe a short-circuit photocurrent density of 7-8 mA/cm². Under these

Fig. 4. Short-circuit quantum yield vs. photon wavelength for a-Si:H/CH₃OH junctions at varying concentrations of FeCp₂. The optical path length through the solution is 1.5 mm, and the electrode is maintained at short circuit vs. a Pt counterelectrode. Initial FeCp₂⁺ concentration is 0.5 mM; curve (a) has 5.0 mM FeCp₂. In curve (b), 13.3 mM FeCp₂ is present, in (c) 25.4 mM FeCp₂, in (d) 43.4 mM FeCp₂, and (e) contains 40.0 mM FeCp₂ with 2.0 mM FeCp₂⁺ in solution.

conditions, we observe open-circuit photovoltages of 0.75-0.85V and fill factors of 0.5-0.6, with typical photoelectrode efficiencies for conversion of optical energy to electricity of 2.7%-3.3%. On identical samples of a-Si:H, Schottky barriers fabricated with nominally 50Å thick Pt films yield short-circuit currents of 5-7 mA/cm² and efficiencies of 1%-2%. We attribute the variation in short-circuit current to differences in transmittance of Schottky barriers and liquid junctions, while the lower efficiency of the Schottky contacts arises from a lower V_{oc} . Open-circuit photovoltages on the best surface barrier devices with high quality a-Si:H can be 0.85V (31) at AM1 irradiation levels, which is comparable to the value we observe with the acetylferrocene^{+/0} redox system in our unoptimized liquid junctions. We note that an improve-

Fig. 5. Photocurrent-voltage characteristics of (50 mV/s) of an a-Si:H film in 20.0 mM FeCp₂/0.5 mM FeCp₂⁺/1.5M LiClO₄/CH₃OH solution. The solution is stirred, and potentials are measured vs. a Pt reference electrode at the cell potential (+0.18V vs. SCE). Irradiation is 88 mW/cm² from an ELH-type tungsten-halogen source, and optical path length through the solution is minimized in order to avoid substantial light absorption losses (Fig. 4).

ment in material quality of our a-Si:H samples would yield substantial increases in photocurrent owing to improved quantum efficiencies in the 600-700 nm region of the spectrum. In addition, the fill factor under ELH irradiation is a combination of the relatively poor long-wavelength response and the good short-wavelength parameters, and is also expected to improve with better electronic transport properties in the a-Si:H. With a collection length of 1.0 μm and fill factors similar to those depicted in Fig. 2a, we calculate that a-Si:H/liquid junction cells would yield photoelectrode efficiencies for conversion of sunlight to electricity of over 5% without further optimization of the system. These values are comparable to efficiencies obtained with a-Si:H surface-barrier-type systems, and would compare favorably to the highest efficiencies obtained for single-crystal silicon semiconductor/liquid junctions under solar conditions (15). It would thus appear that the a-Si:H/liquid interface is not the limiting factor in development of efficient a-Si:H/liquid junctions, but that control and improvement of the electronic properties of the a-Si:H films are the dominant factors at present.

The high quality of the a-Si:H/liquid interface observed in this study is consistent with other recent descriptions of photoelectrodes in nonaqueous solvents (15, 16, 34), and implies that systematic design and study of efficient photoelectrochemical systems in nonaqueous solvents may be possible with a variety of materials. We have demonstrated that a-Si:H/CH₃OH/FeCp₂/FeCp₂⁺ junctions can exhibit high quantum efficiencies for electron flow, large photovoltages, and excellent photocurrent-voltage characteristics under the proper conditions. Successes with properly prepared single-crystal photoelectrode substrates strongly suggest that future challenges in the area will arise from the chemistry of grain boundaries and recombination sites in polycrystalline materials at liquid junctions, where the unique chemistry at semiconductor/liquid interfaces should allow manipulation of recombination sites through simple chemical processes.

Blockage of the Active Sites of a Platinum Electrode

Influence of Dissolved Molecular Oxygen on the Time Dependence of Blockage in the Methanol/Electrolyte/Rotating Disk Electrode System

Albert Marie de Ficquelmont and May Marie de Ficquelmont-Loïzos¹

Institut de Topologie et de Dynamique des Systèmes, Université Paris VII, associé au CNRS, 75005 Paris, France

ABSTRACT

The MeOH/0.1M NaClO₄/Pt system is investigated in aerated and deaerated medium, by analyzing the $I(t)$ output signals for a single gating input potential signal $[SII(t)]$ and for a sequence of two isochronic gating input signals $[DII(t)]$ separated by a varying time $\Delta\tau$ in open circuit, under the same conditions ($U = +750$ mV/SCE; $\omega = 12.5$ rps; $\theta = 25^\circ\text{C}$; electrode pretreatment = polishing plus sonication). Analysis (in $\ln I - \ln t$ coordinates) of the $I(t)$ signals resulting from an $SII(t)$ of 600s shows that the current decays to $I = 0$ as a function of time through three nearly linear sections, much more slowly in aerated medium. For $DII(t)$, the current increases as a function of $\Delta\tau$ up to a plateau. These results are interpreted in terms of two types of adsorption: a hard one (species strongly bound to the substrate), and a soft one (weakly bound species). Dissolved O₂ is shown to act as a blockage inhibitor through a mechanism based on the following hypotheses: (i) competition between MeOH and O₂ adsorptions leading to sites occupied by oxygen admolecules, (ii) dissociative chemisorption of MeOH, on bare Pt sites and on Pt(Ad-O₂) sites without segregation, with the same stepwise dehydrogenation mechanism. With these hypotheses, the blocking adsorbates, whatever their nature, are more labile on Pt(Ad-O₂) sites, due to a higher oxidation state of the carbon atom therein, thus explaining the two types of adsorption observed.

The interest of methanol as a solvent (in organic chemistry, chemical kinetics, or electro-organic synthesis) and as a fuel in fuel cells is no longer to be demonstrated. From this last point of view, methanol electro-oxidation in acidic or alkaline aqueous media, *i.e.*, the water/methanol + electrolyte/electrode system, has been widely investigated. However, only few studies deal directly with the methanol/electrolyte/electrode system (1-3) and the role of the blockage of the electrode active sites therein. The latter is known to exist in methanol oxidation in acidic medium (4), in contrast with alkaline medium (5), and constitutes a very important obstacle to the development of methanol-air fuel cells (6). It is important to specify that blockage means, in general, any decrease in the number and the reactivity of the active sites.

We present here a study on the blockage of the active sites for the simple system MeOH/NaClO₄/Pt. We shall also show the role of dissolved molecular oxygen, which has a marked influence on the interface topography

(number and nonrandom distribution, at the atomic level, of the active sites), as was shown for metal systems (titanium or iron) in sulfuric acid (7, 8). To our knowledge, the role of dissolved oxygen on the behavior of the electrode in methanol has not previously been investigated; only deaerated media have been considered.

We study here the response of a rotating disk electrode to a potential pulse input. This response depends on the interface topography, *i.e.*, (i) on parameters inherent in the electrode itself (nature, structure, shape, pretreatment etc.), (ii) on parameters inherent in the medium (concentration, temperature, viscosity, hydrodynamic conditions, diffusion phenomena, etc.), and (iii) on the type of reaction mechanisms taking place at the interface (8, 9).

Experimental

The supporting electrolyte (0.1M) was sodium perchlorate (Merck proanalysis), dried at 150°C under vacuum. Methanol (Baker Absolute) was distilled over Prolabo 99.8% magnesium turnings in order to eliminate water and metallic impurities. Measurements performed with undistilled solvent have indeed shown blockage occur-

¹Present address: CNRS, E.R. 248, "Instrumentation et Dynamique Cardiovasculaire," Hôpital Broussais, 75674 Paris Cedex 14, France.

ring more rapidly. The solutions were aerated by dry atmospheric air in thermodynamic equilibrium with methanol without bubbling. Deaeration was performed by argon bubbling (Air-Liquide N55) saturated with methanol of cell composition. During the measurements, in order to avoid a perturbation of the fluid flow and bubbles at the electrode surface, bubbling was stopped, but an overpressure of methanol-saturated argon was maintained over the solution. Under these conditions, solvent evaporation was negligible. Between two measurements, argon bubbling was maintained. The efficiency of deaeration was regularly verified through the current variation of oxygen reduction from aerated to deaerated medium (e.g., at -0.6V , from $300\ \mu\text{A}$ to less than $3\ \mu\text{A}$ on the average at a rotation speed $\omega = 0$). The currents depend of course on the atmospheric pressure. Note that oxygen is far more soluble in methanol than in water, leading to more important currents (current densities ten times higher).

Measurements were performed, at $+25^\circ\text{C} \pm 0.1^\circ\text{C}$, using a classical three-electrode system and a hemispherical one-compartment and double-wall cell (solution volume = 125 ml). The working electrode was the cross section of a platinum cylinder (0.5 cm diam) inserted in a Teflon thermoshrinkable sheath (overall diameter of the electrode = 1 cm). The counterelectrode was a large, hemispherical iridium-coated platinum grid. The reference electrode was a removable double-compartment calomel electrode in saturated $\text{KCl}(\text{MeOH})$. $I(t)$ curves were recorded potentiostatically (home-built potentiostat, solid or mercury contactor according to the range of ω), and $I(U)$ curves under potential sweep conditions. The electrode rotation speed was measured to $\pm 1\%$ photoelectrically (home-built frequency meter). The rotating disk electrode (RDE) was mirror polished with $3\ \mu\text{m}$ diamond paste for 150s then sonicated for 450s in methanol of cell composition. The RDE and the glassware were rinsed with the distilled methanol.

Results

The RDE behavior has been examined through the current-time $I(t)$ curves recorded, in laminar flow (10), at different values of the potential U and of the rotation speed ω (ranging from 6.25 to 100 rps), both in aerated and in deaerated medium. This behavior is exemplified here by the results relative to $U = +750\ \text{mV/SCE}$ and $\omega = 12.5\ \text{rps}$. Since any change in the initial and boundary conditions is liable to lead to a different mathematical expression of the output signal, we have always operated as follows: after pretreatment (polishing and sonication), the RDE was rotated in the solution before the counterelectrode circuit was closed.

The potential of $+750\ \text{mV/SCE}$ corresponds (Fig. 1) to a range between oxygen reduction and an oxidation step (prewave at an average value of $1.2\ \text{V/SCE}$). The initial forward trace is very reproducible with a polished RDE, but is affected by blockage during consecutive sweeps, as is the case in sulfuric acid (4). On the contrary, the backward trace markedly varies with the experimental conditions. The prewave at 1.2V is to be compared with the one observed for $\text{NaClO}_4\text{-MeOH}$ under other experimental conditions, which was attributed to the oxidation of the solvent and not to that of the supporting electrolyte (3). The cathodic processes correspond to the reduction of dissolved O_2 and Na^+ [solvated in MeOH (11)].

The $I(t)$ output signal corresponds to the following conditions: on circuit closure, the potential is held at a fixed value over a time interval T and is zero before and after T (open circuit). Further information on the RDE behavior was provided by the $I(t)$ curves recorded after open-circuit exposure. To this end, two isochronic $I(t)$ signals recorded at a given U and separated by a time $\Delta\tau$ on open circuit ($U = 0$) were compared (Fig. 2). The RDE was pretreated for the first signal only; the hydrodynamic conditions were held all over (RDE immersed and rotated at the same ω); $\Delta\tau$ was varied from some fractions of a second to 1 or 2h. The input signals are obviously of the

Fig. 1. Linear sweep voltammogram for 0.1M NaClO_4 in aerated methanol. [$\omega = 0$; sweep rate = $600\ \text{mV/min}$; RDE treatment: $3\ \mu\text{m}$ diamond paste polishing (150s) + sonication (450s); $\tau = 25^\circ\text{C}$; ϕ RDE = $0.5\ \text{cm}$]. Scale: 1 unity = $200\ \mu\text{A}$ or $200\ \text{mV}$.

gating pulse type, and will be denoted hereafter, for the sake of convenience, as $S_{II}(t)$ for the single and $D_{II}(t)$ for the double gating pulse.

Experimental $I(t)$ curves for an $S_{II}(t)$ input signal.—The experimental $I(t)$ curves exhibit (Fig. 2) in both media a very important impulse (D_1) followed by a rapid and continuous decrease down to a zero or at least a very low current value, when $t \rightarrow \infty$ (fall of 99% even at U 's at which I is important on the $I(U)$ curve). The shape of the signal is different from the one given, for example, by the oxidation of the methanol residue on platinized platinum in sulfuric acid (12). The fact that no stationary current is reached and the very fast decay of I are indicative of blocking phenomena taking place very rapidly at the RDE surface.

The part of the signal at very short times is the consequence of the circuit closure, the charge of the double-layer capacitance, the transfer function of the device, and the mass transfer of species arriving at the electrode under the influence of the electric field (although the hydrodynamic steady state was attained before circuit closure, since the RDE was rotated before U was applied).

Fig. 2. Experimental $I(t)$ output signal recorded after RDE treatment [$S_{II}(t)$ input signal] and after open-circuit exposure during a time $\Delta\tau$ [$D_{II}(t)$ input signal] for 0.1M NaClO_4 in aerated methanol. [$U = +750\ \text{mV/SCE}$; $\omega = 12.5\ \text{rps}$; $\theta = 25^\circ\text{C}$; ϕ RDE = $0.5\ \text{cm}$; $T = 600\text{s}$].

Scheme I

The ascending part of the impulse reaches a maximum value at 0.18–0.20s after circuit closure and is therefore located within the time range for mass transfer.

The descending part of $I(t)$ is not a simple exponential over the duration T of the input signal, since the $\ln t$ vs. t curve is similar to $I(t)$, i.e., $\ln I$ nonlinear vs. t . Its analysis in $\ln I - \ln t$ coordinates reveals the existence of three nearly linear sections, both in aerated and deaerated medium (Fig. 3, curves A and B), as was observed in the case of the formation of oxide layers on iridium from sulfuric acid (13). The number of sections (three) is relative to a time T of 600s, but another number may be revealed when the observation time is varied. In deaerated medium, the second section is less extended, the instant value of I is lower, the slopes are higher, and the transition times (defined at the intersections of the tangents) are shorter. In Fig. 3, the ratios of the slopes are 2.5 for the first and 1.1 for the second and third sections; the ratios of the transition times are 1.2 for the first to the second section and 1.5 for the second to the third section.

Experimental $I(t)$ curves for a $DII(t)$ signal.—By increasing $\Delta\tau$ (Fig. 2), a sharp increase of I followed by a plateau is observed, as shown by the values D_2 of the maximum in the second $I(t)$ signal (Fig. 4). This behavior is revealed in both media, whatever the value of ω , but the height of the plateau is markedly lower in the absence of dissolved molecular oxygen (5% instead of 30% in aerated medium). Owing to our procedure, the values of D_1 and D_2 are obviously coupled, and therefore the ratio D_2/D_1 has been plotted in order to take account of this coupling.

In aerated medium, analysis of the second $I(t)$ curve leads to two linear sections only at low $\Delta\tau$ values (Fig. 5, curve 1 for $\Delta\tau = 1.95$ s). When $\Delta\tau$ is increased, the shape of the curves becomes more and more similar to that of the initial curve (three sections), i.e., the one with the pretreated RDE (curve 0). In deaerated medium, the behavior

Fig. 3. Comparison between aerated (A) and deaerated (B) medium on the $I(t)$ curves, expressed in $\ln I - \ln t$ coordinates, recorded for an $s\Pi(t)$ input signal, for 0.1M NaClO_4 in methanol. [$U = +750$ mV/SCE; $\omega = 12.5$ rps; $\theta = 25^\circ\text{C}$; ϕ RDE = 0.5 cm; $T = 600$ s.]

observed shows similarities but also differences, since low $\Delta\tau$ values do lead to two sections only (Fig. 6, curve 1) whereas the third section starts to appear at higher values, but not as clearly as in aerated medium. In addition, the gap between curve 0 and the other curves is far more important in deaerated medium for a given $\Delta\tau$, as shown by curve 4 in Fig. 5, curve 2 in Fig. 6 ($\Delta\tau = \text{ca. } 30$ s in both cases), and Fig. 7 ($\Delta\tau = \text{ca. } 60$ s).

Influence of the RDE pretreatment.—The results presented here are relative to average current values, because of a scattering over a Gaussian curve (shown up on the values of D_1). This scattering can be due partly to the pretreatment of the RDE. It is indeed known that a change in the pretreatment of the electrode (chemical, thermal, physical, electrochemical methods, or combinations of these) gives rise to different results on adsorption phenomena (14). Moreover, a simple change in the grade of the abrasive paper used in mechanical polishing also leads to marked differences in the blockage (8). More expectedly, a change in the potential sequence during an electrochemical treatment leads to significant modifications of the adsorption process and the oxidation of the resulting adsorbates in $\text{MeOH-H}_2\text{SO}_4$ medium (15, 16).

In the present case, using always the same type of pretreatment and the same grade of diamond paste, we have shown that certain parameters characterizing our technique play an important part in the current measured, even if the overall shape of the curves remains unchanged. Thus, the polishing time t_p of the RDE has a marked influence, as shown by D_2 values (Fig. 8), and a correlation can be established between D_1 , D_2 , and t_p ac-

according to the working time of the RDE (Fig. 9). This may be due to the fact that successive polishings can assign different weights, during time, to the planes (100), (110), and (111) of the polycrystalline surface constituting the

RDE, and to the fact that methanol adsorption may depend on this weight. The latter indeed takes place differently in H_2SO_4 (4) but similarly in NaOH medium (5). But this interpretation is to be ruled out, since, not only the medium is neutral here, but also the size of the grains of the Pt employed is such that the distribution of the crystal orientations remains unchanged whatever the polishing plane. Therefore, this combined influence of t_p and the working time can be explained by the existence of adsorbates strongly bound to the substrate which cannot be entirely eliminated after a certain working time by successive polishings with the same t_p (e.g., 150s).

Discussion

In the literature, methanol electro-oxidation on platinum has been investigated over two directions mainly (separate study of MeOH electroadsorption and electro-oxidation of the residue or simultaneous study of the adsorption-oxidation). In general, unstirred and deaerated media were investigated, and different types of working electrodes were used (poly- or monocrystalline, wire, plate, and, more seldomly, rotating disk), as well as various electrochemical conditions and different electrode pretreatments. The nature of the intermediates in water has been shown to depend on the experimental conditions, i.e., the pH, the MeOH concentration, the structure of Pt, and, more particularly, the potential (15, 17-20). The adsorbed intermediates acceptedly formed up in aqueous methanol through stepwise dehydrogenation can be: $^*\text{CH}_2\text{OH}$; $^*\text{CHOH}$; $^*\text{COH}$; $^*\text{C} = \text{O}$, $^*\text{C} = \text{O}$ (16, 18, 19, 21), in addition to OH_{ads} (22). The species which admittedly poisons the electrode is $^*\text{COH}$ [see, e.g., Ref. (6, 18, 23)] bound to three Pt sites through carbon

(6, 24) or *CHO bound to a single Pt (25). However, an *in situ* IR investigation has shown, under certain conditions, the presence of *C=O and *C≡O to the exclusion of *COH (21). In addition, multimolecular layers have been assumed to form (12, 16, 26), and the existence of a weakly bound species has long been subject to discussion (12, 27, 28).

The MeOH/NaClO₄/Pt stirred medium: existence of two types of adsorption.—In the present work, the hydrodynamic conditions established by the RDE ensure (i) a continuous contact of the solid-liquid interface with the bulk of the fluid, (ii) a constant renewal of the fluid adjacent to the RDE surface, and (iii) shearing stresses and a flux density more important than in unstirred medium. Taking account of the recirculations that can exist even in laminar flow (29), the organization of the fluid within the Levich layer is higher at the interface than in the solution bulk or in unstirred medium. The increased flux density (and, hence, shorter intermolecular distances) enhances the possibility of physical adsorption. Adsorption phenomena will be more organized, especially as the fluid can penetrate into the stagnant viscous layer of Lewis (30) as organized aggregates coming from the bulk of the flow (31, 32). Subsequently, when the potential is applied, electroadsorption and/or electro-oxidation will be generated, possibly in several steps as is the case in water, leading to the blockage of active sites.

In addition, owing to the continuous mass supply (and departure) maintained by stirring, various types of bondings, more or less strong, between the substrate and the adsorbates can be expected. This is supported by our results on the behavior in open circuit of a previously blocked RDE, *i.e.*, the fact that the current (D_2) increases but only up to a limit which always remains lower than the value (D_1) measured with a pretreated RDE (Fig. 4). This is indicative of the existence of two types of adsorption: a "hard" one (species strongly bound to the substrate) and a "soft" one (weakly bound species). In that case, one (or several) of the blocking species seems to be removed, partly or totally, by circuit opening, and the other (or the others) remains adsorbed, even if the RDE is withdrawn from the solution after blockage. The current decrease at very high $\Delta\tau$'s can be explained by a further adsorption in open circuit (Fig. 4, at 480-1800s). The dual character of the adsorption is also confirmed (Fig. 5 and 6) by the $\ln I$ vs. $\ln t$ curves for the second $I(t)$ signal in $DI(t)$. At low $\Delta\tau$ values, the curves exhibit two linear sections only; now, considering our procedure, they still correspond to a nearly total blockage of the active sites. When $\Delta\tau$ is more and more increased, the weakly bound species are eliminated under open circuit, thus liberating active sites on which the phenomenon relative to curve 0 (presence of three sections) can again take place, at least partly, since the RDE is not entirely regenerated (curves always under curve 0).

The MeOH/NaClO₄/Pt stirred medium: influence of dissolved molecular oxygen.—In pure methanol, the species liable to adsorb and lead to blockage phenomena are the entities initially present in the medium (and species derived from them subsequently): (i) CH₃OH (neutral medium here); (ii) ClO₄⁻ [analogy with anion adsorption during methanol oxidation in aqueous medium (33)]; Na⁺ should not interfere at the anodic potential used; (iii) residual H₂O [its initial concentration is low (less than 1%) with respect to the critical threshold determined for the influence of water (or at least its detection) as a function of the supporting electrolyte (1, 2)]; (iv) dissolved O₂ in aerated or residual O₂ in deaerated medium. In what follows, we shall consider CH₃OH and O₂ only, given the significant differences observed between the two media, and shall not take account of the possible influence of the other entities (ClO₄⁻ and H₂O), since their initial concentrations are the same in both media.

The existence of three sections in the $\ln I$ vs. $\ln t$ curves traduces changes in the regime of the system, each of them being related to a different adsorption regime tak-

ing place with a different kinetic law. It is, however, difficult to establish a direct relationship between the number of species involved and the presence of three nearly linear sections. As a matter of fact, the complexity of the $I(t)$ curve in various coordinates (no linear part in $\ln I$ vs. t among others) is indicative of a complex adsorption process (of order other than 0 or 1), in which would intervene several species in each section, for instance, and/or isotherms other than the Langmuir isotherm. In addition, an interaction between adsorption kinetics and mass transfer was shown here, since the slopes and the transition times for the three sections depend on ω (see Table I).

Deaerated medium.—Since the amount of residual O₂ is very low (residual current at -600 mV/SCE about 100 times lower than in aerated medium), the results observed are mainly due to MeOH. We can assume that the latter forms (i) first, weak bondings (of the physical adsorption type) with the substrate, which are favored by stirring, thus leading to a structure we denote by (MeOH)_{ads}, and (ii) then stronger bondings (of the strong chemisorption type), thus leading to irreversible (17) dehydrogenation and/or electro-oxidation steps. As in water, we can assume a stepwise mechanism through the formation of several adsorbates or groups of adsorbates (I)_{ads} (Eq. [1])

In Eq. [1], three possible structures, (I), (II), or (III), can be considered for (MeOH)_{ads}. These will undergo dissociative chemisorption depending on the energies involved, *i.e.*, on the bond energies and the energies of formation of adsorbate-substrate bondings relatively to the value of the potential. For instance, at certain U values, (II) and (III) can be more favored than (I), since the O—H bond is more difficult to break than C—H or C—O, assuming that the bond energies in Pt—H and Pt—C are similar.

In reaction [1], the number, nature, and subsequent evolution of the adsorbates will depend on the experimental conditions as is the case in water. Therefore, various species can arise from side-reactions and adsorb and/or react according to their environment, *i.e.*, to the neighboring species adsorbed at the RDE surface or the bulk species. For example, depending on the starting structure of (MeOH)_{ads}, (I)_{ads} can be

Table I. Influence of mass transfer on the slopes and the transition times from one section to another for an $SII(t)$ input signal in 0.1M NaClO₄ in aerated methanol.
 $U = +750$ mV/SCE; $\theta = 25^\circ\text{C}$; ϕ RDE = 0.5 cm

ω (rps)	Slopes in the $\ln I$ - $\ln t$ curves			Transition time (s)	
	First section	Second section	Third section	First → second section	Second → third section
16	-0.45	-1.07	-0.75	2.72	21.3
25	—	-1.06	-0.67	—	27.1
49	-0.25	-0.82	-0.55	1.43	40.0
81	-0.28	-0.89	-0.65	1.16	50.4
100	-0.22	-0.77	-0.59	0.70	60.3

Another example is given by adsorbed hydrogen, which can be more or less strongly bound to the substrate as in the case of Fe or Ti in acidic aqueous medium (7, 34) and react with other entities adsorbed at the surface or coming from the solution bulk on account of the conditions for constant renewal of the interface. In this last case, Pt—H would react with CH_3OH or with CH_3O^- , solvated by five solvent molecules (11), arising from the autoprotolytic equilibrium of methanol in neutral medium. Therefore, the current observed can result from one (or all) of the possible reactions for the elimination of adsorbed hydrogen atoms, *i.e.*

Reaction [5] is invoked in aqueous medium where atomic hydrogen can adsorb at coverage fractions almost as important as those of methanol (35-38). Side reactions can take place between Pt—H and adsorbed species, *e.g.*, Pt— CH_3 , Pt—OH, Pt— CH_2OH , Pt—H, $(\text{CH}_3\text{OH})_{\text{ads}}$, etc., thus liberating platinum sites without current production.

Starting from $(\text{I}_1)_{\text{ads}}$, dissociative chemisorption (steps 2, 3, 4, ...) will proceed provided the various energies involved be at the adequate level. In $(\text{I}_1)_{\text{ads}}$ mainly will be implied the carbon containing species Pt— OCH_3 , Pt— CH_3 , and Pt— CH_2OH . Thus, among the $(\text{I}_2)_{\text{ads}}$'s, may exist: $(\text{Pt})_2\text{—CHOH}$; among $(\text{I}_3)_{\text{ads}}$: $(\text{Pt})_3\text{—COH}$; among $(\text{I}_4)_{\text{ads}}$: $(\text{Pt})_3\text{—CO—Pt}$, which can evolve to give $(\text{Pt})_2\text{—C} \equiv \text{O}$, then $\text{Pt—C} \equiv \text{O}$.

The foregoing shows that it is very difficult to determine which species are formed up under our conditions and block the RDE, but it can be accepted that they are directly bound to the substrate (Pt), in contrast to the aerated medium.

Aerated medium.—Since the same experimental conditions are used, the blockage inhibition, the RDE regeneration, and the differences in the $\ln I$ vs. $\ln t$ curves must be caused by the presence of dissolved molecular oxygen. It is known that oxygen can bring modifications to the bulk solvent and to the interface. The presence of a gas can indeed modify the order and hence the structure of methanol with respect to degassed medium (39). Rigorously speaking, the deaerated medium here is not degassed (due to argon bubbling), but it is probable that methanol is modified differently by two gases of different natures (air and argon). Such a difference is also observed in the case of the effect of supporting electrolytes on methanol structure (40). At the level of the interface, adsorption of oxygen (molecular or atomic) is expected to bring changes in: (i) the platinum surface as was shown for solid-gas (41) and for solid-liquid interfaces (42-45); (ii) the interface topography (8, 9); and (iii) the adsorption-desorption kinetics of other species without changing the overall mechanism (46).

The structure of adsorbed (molecular or atomic) oxygen is influenced by the experimental conditions. Several types of platinum oxide arising from water dissociation have been considered in aqueous medium (47), particularly during the dynamic aging of oxygen containing electrosorbed layers in acidic (48, 49) or alkaline (50) medium. In the case of O_2 adsorption at the solid-gas interface, the existence of two types of surface oxygen on Pt(100) has been shown: chemisorbed oxygen and a platinum oxide (41, 51). In addition, the structure of the oxygen adlayer depends on the method of formation of the substrate (41).

Considering our results, we shall assume that dissolved molecular oxygen does adsorb at the anodic potential used. Taking account of the electron structure of oxygen and platinum, O_2 adsorption would take place on two neighboring platinum atoms through the unpaired electrons in the π^* antibonding molecular orbitals of oxygen and the unpaired electron in the 5d orbital of platinum, thus leading to (IV) and (V). Such a bonding requires a

lower energy than does the complete dissociation of the O_2 molecule.

Structure (V), denoted hereafter by Ad—O_2 , corresponds stoichiometrically to a Pt_2O_2 platinum oxide in which the O/Pt ratio is the same as in PtO (one of the possible forms of adsorbed oxygen from water) or Pt—O (adsorbed oxygen atoms). We shall make no assumptions on the thickness of the oxygen adlayer which can exceed one monolayer (50, 52), the possible diffusion of O_2 into the metal lattice, the anisotropy of the crystal planes of platinum towards the adsorption of simple molecules (53), or the mobility of surface platinum atoms under the influence of oxygen (54, 55).

Accepting oxygen adsorption under our conditions, we can reasonably consider that there is a competition between O_2 and MeOH adsorptions. At this stage, arises the question on methanol adsorption at a surface partaken between bare substrate [Pt (subs)] and Ad—O_2 sites. Two cases can be distinguished: (i) methanol adsorbs both on Pt(subs) and Ad—O_2 , and (ii) methanol adsorbs on Pt(subs) only.

First case: no segregation between Pt(subs) and Ad—O_2 sites.—In this case, the dissociative chemisorption of CH_3OH also proceeds on Ad—O_2 , hence on a partially modified RDE, according to a stepwise mechanism, *i.e.*, through a sequence of dehydrogenation steps similar to reaction [1] proposed for the deaerated medium or for aqueous media in the literature. For example, starting from (III), the first step is

Since other Ad—O_2 sites are liable to be present in the vicinity of Pt— $\text{O—CH}_2\text{OH}$ [at the solid-gas interface, oxygen adsorbs on Pt(111) in islands (56)], the following steps can be considered

As in deaerated medium, the $(\text{I}_1)_{\text{ads}}$'s can undergo several side reactions with neighboring groups such as Pt—OH, Pt—H [resulting from the adsorption of MeOH on Pt(subs)], etc., thus liberating active sites. It is to be noted that decarboxylation can occur at any stage of the various steps, *e.g.*

In that way, the mechanism is to be compared with the one proposed for formaldehyde electro-oxidation on oxygen adsorbing adatoms on Pt in aqueous medium through a parallel path without obstruction by the COH poison (57).

In reaction [8], $\ast\text{COH}$ is fixed on three PtO sites, but other possibilities can be considered according to the environment [presence of Pt(subs) or Ad—O₂ sites] in the steps leading to $\ast\text{COH}$

From the foregoing, it may be concluded that the higher currents observed in aerated medium result from several concomitant facts, listed below.

1. In all adsorbates on PtO (from Ad—O₂), the carbon atom is in an oxidation state, as defined in Ref. (58), higher than in the corresponding adsorbates on Pt(subs) and is hence more labile. For example, taking a value -1 for each bond to H and Pt, and +1 for each bond to O, as for C atoms covalently bonded in organic molecules, the carbon atom in PtO—CH₂OH is in an oxidation state two units higher than in Pt—CH₂OH. In the various structures for $\ast\text{COH}$, the oxidation state varies from -2 to +4; therefore, the same adsorbate (e.g., $\ast\text{COH}$, $\ast\text{C} \equiv \text{O}$), or $\ast\text{C} \equiv \text{O}$) can undergo different subsequent reactions, depending on its environment and the experimental conditions. Similarly, a higher oxidation state is reached more rapidly in aerated medium.

2. The Pt—OH adsorbate, which is thought to be indispensable for the electro-oxidation in aqueous medium [e.g., Ref. (6)], is formed simultaneously to (PtO)₃—COH, whereas in deaerated methanol it can only be formed through the dissociative chemisorption of (II), hence less easily.

3. The oxidizing effect of Pt—OH is more readily performed on species such as (PtO)₃—COH than on (Pt)₃—COH, owing to the oxidation states of C in such entities. Consequently, Pt and PtO sites will be liberated more easily in aerated medium.

As for the dual character of the adsorption, whether the poison is the same or not on Pt(subs) and on PtO and whatever its nature, it becomes a hard adsorbate when fixed on Pt(subs) and a soft one when fixed on PtO (via Ad—O₂), owing to the difference of the oxidation states. In the stepwise mechanism, a part of the Ad—O₂ sites would be recovered, and, therefore, O₂ can be considered as playing a double role, i.e., as a catalyst and as an oxidizer. However, this does not prevent the RDE from being blocked, since the sites liberated are in turn subjected to the MeOH/O₂ competition, and their number continues thereby to decrease with time. This interpretation also holds for the deaerated medium, owing to the presence of residual O₂ and of air-oxygen adsorbed during the pre-treatment of the RDE.

Second case: segregation between Pt(subs) and Ad—O₂ sites.—If such a segregation is assumed, i.e., MeOH adsorption on Pt(subs) only, then the mechanism on Pt(subs) would be reaction [1], but with the possibility of oxidation by oxygen at any step. For example, considering an island-type topography (56), the (Pt)₃—COH poison could be oxidized at the island boundaries by oxygen adsorbed on neighboring Pt(subs) sites as follows

This process is to be compared with the mechanism proposed in the case of oxygen adsorbing adatoms on Pt which enhance methanol or formaldehyde electro-oxidation (38, 57). Such a mechanism would, of course, account for the higher current values in aerated medium, but would explain less readily the existence of two types of adsorption, and should, therefore, be ruled out in the present case.

ABSTRACT

Mixtures of 1-methyl-3-ethylimidazolium chloride (MEICl) and aluminum chloride are molten salts at room temperature and below. Acidic melts, which contain AlCl_3 mole fraction (N) greater than 0.5, can be used as catholytes, with basic melts ($N < 0.5$) as anolytes, in a concentration cell using Al plate electrodes and a microporous polypropylene separator. Gravimetric analysis of electrodes indicates that the anode reaction is

and the cathode reaction is

The open-circuit potential for the cell

is 1.38V, and the voltage remains above 1.0V at constant current discharge of 1-3 mA for 6 cm² Al electrodes. Coulometry is combined with gravimetric and compositional analysis (using NMR spectroscopy) of the electrolytes to estimate transport numbers.

Researchers at the Frank J. Seiler Research Laboratory have discovered a chloroaluminate salt which is liquid at room temperature and below (1). This salt is formed by mixing 1-methyl-3-ethylimidazolium chloride (MEICl) with AlCl_3 , with both solids at room temperature, as shown by

When AlCl_3 is added to MEICl in less than stoichiometric amount (*i.e.*, N in the melt is less than 0.5), the anions in the melt are AlCl_4^- and Cl^- . Such mixtures are basic because Cl^- acts as a Lewis base in these melts. When $N > 0.5$, the process

occurs, and the anions are AlCl_4^- and Al_2Cl_7^- . Such melts are acidic because Al_2Cl_7^- acts as a Lewis acid. K_1 and K_2 have not been measured yet for these melts. However, the values of K_1 and K_2 for the analogous system, $\text{NaCl}/\text{AlCl}_3$, have been determined to be 3.2×10^{-11} and 3×10^4 , respectively, at 175°C (2). Because preliminary studies in our laboratory show that the MEICl/ AlCl_3 melts have

*Electrochemical Society Active Member.

significantly lower vapor pressure (due to AlCl_3) than $\text{NaCl}/\text{AlCl}_3$ melts at the same temperatures, it can be assumed that K_1 and K_2 for the MEICl/ AlCl_3 melts are even larger than for the $\text{NaCl}/\text{AlCl}_3$ melts. The anion mole fraction of each ion as a function of N is shown in Fig. 1.

These curves are calculated from the stoichiometry of Eq. [1] and [2]. These dependencies are similar to those for *n*-butyl pyridinium chloride/aluminum chloride (3) and to a lesser extent to those for alkali metal chloride/aluminum chloride melts at elevated temperature (2).

The acid-base properties of chloroaluminate melts are best understood in terms of the equilibrium

Since K for this reaction is large, about 10^{16} (4), acid melts and basic melts can be combined as catholytes and anolytes in concentration cells with relatively high potentials, using aluminum electrodes and an appropriate separator. A schematic of such a cell, in which the electrolytes are $N = 0.33$ and $N = 0.60$ melts, is shown in Fig. 2. The

Fig. 1. Mole fractions of anions in melts vs. mole fraction of AlCl_3 in melt.

species in the dashed boxes are shown with coefficients that indicate their relative amounts in these melts. These coefficients represent the stoichiometric amounts required to generate three equivalents of electrons if the cell discharges according to the anode and cathode reactions shown in Eq. [4] and [5]

Directions of transport of charge by MEI^+ , AlCl_4^- , and Al_2Cl_7^- are indicated by the dashed arrows in Fig. 2.

Three aspects of concentration cell performance are investigated to determine if the picture of the basic cell electrochemistry shown in Fig. 2 is valid. Gravimetric analysis of the electrodes is correlated to measured charge passed, cell open-circuit potential is compared to the predicted potentials based on previous obtained cyclic voltammograms (5), and measured specific energies are compared to values obtained from calculations based on the Fig. 2 model (6). Knowledge of the quantities of MEI^+ in the anolyte before and after discharge of a measured number of coulombs also allows us to estimate the external (relative to the separator) transport numbers for MEI^+ , AlCl_4^- , and Al_2Cl_7^- .

Experimental

All melts were prepared as reported previously (1). All operations described below were done in an Ar-atmosphere dry box. The concentration cells were constructed by sandwiching each component — anode, separator, and cathode — between Teflon gasket/spacers and clamping the package together. Electrodes (0.25 mm-thick 99.999%

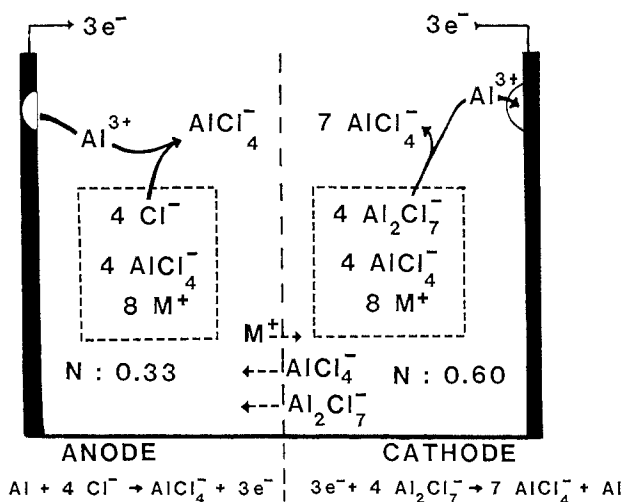

Fig. 2. Schematic diagram of concentration cell

Al [Alfa Products] with about 6 cm^2 active area) were abraded with carborundum paper to remove oxides, rinsed with acetonitrile, dried, and weighed before cell assembly. The separator, Celgard® 4510 microporous polypropylene film, was also preweighed. The electrodes were 1.0 cm apart in the assembled cell, which was weighed before and after each electrolyte was added (about 2.5g [$\sim 2.0 \text{ ml}$] anolyte, $N = 0.37$, and 3.5g [$\sim 2.8 \text{ ml}$] catholyte, $N = 0.60$). A Mettler AE163 electronic balance in the dry box was used for all weighing. Within a few minutes of assembly, the cell was connected to a PAR 173 Potentiostat/Galvanostat with a PAR 179 Coulometer. The cells were discharged at controlled current, and the voltage was recorded on a chart recorder connected to the PAR 173 summing amplifier output. At various times during discharge, voltage/current behavior was recorded by varying the constant current. Following discharge, which is usually to about 0.5V from a load voltage of over 1.0V, the electrolytes were removed (this included wiping parts of the cell in contact with them) to determine final anolyte and catholyte masses. The final mole fractions of the anolyte samples were determined using an NMR technique (7). Final electrode masses were obtained after they were rinsed with acetonitrile and blotted dry. The final separator mass was also recorded. Because we observed that acidic melts wetted the separator much more effectively than basic melts, the gain in separator mass was added to the final catholyte mass. To insure this was the case, the separator was positioned so that its rougher, more porous surface faced the catholyte; the smoother side faced the anolyte.

Results

Cell discharges.—Cyclic voltammograms of Al in acid melts and in basic melts are shown in Fig. 3. The difference in potential between reduction to Al in $N = 0.60$ melt [a reversible process (8)] and oxidation of Al in $N = 0.40$ melt (an irreversible process) lies between 1.2 – 1.5V. The open and circuit potentials of our cells fall in this range, as indicated by the discharge curves in Fig. 4. Thus, reduction and oxidation of Al appear to be the dominant electrode processes in the concentration cell, as expected.

The fairly long time (about 10-15h) required for the cell to achieve maximum voltage under load is due to the slow rate at which a dry separator is wetted by the melt. This process can be accelerated by discharging at low currents during the first several minutes after the cell is connected. When a separator wetted with melt (from use in an earlier run) is used in the cell, the maximum load voltage is achieved in about 30 min. The slopes of V vs. I plots at various times during discharge are plotted against the charge, Q , in Fig. 5 for some representative cells. Comparison of the plots for the discharges using dry and

Fig. 3. Cyclic voltammograms of Al in acid melts and in basic melts [reproduced from Ref. (5)].

Fig. 4. Sample discharge curves for concentration cells

prewetted separators demonstrates the effect of the separator resistance on the load voltage.

Electrode analysis.—That Al oxidation and deposition are the electrode reactions is confirmed by the gravimetric analysis of the cell electrodes shown in Table I. Values for the predicted charge, Q_{calc} , based on Eq. [4] and [5] are calculated from the mass changes in the anode and cathode. The averages of the two calculated values, $Avg Q_{calc}$, are in reasonably good agreement with the measured values, Q_{meas} . In each cell, the reason for the lack of exact agreement is that the loss in mass of each of the electrodes is slightly more than can be attributed to the electrode reactions shown in Eq. [4] and [5]. If we assume that a certain amount of corrosion of both anode and cathode occurs during discharge, we can obtain Q_{calc} values that equal Q_{meas} . These deduced corrosion losses are listed in Table I. This is probably a good assumption, in view of the results of a separate gravimetric analysis of Al corro-

Fig. 5. Slopes of V vs. I plots for various cells as a function of charge passed.

sion in $N = 0.37$ melts and in $N = 0.60$ melts, as shown in Fig. 6. Several strips of Al with areas equal to our electrode areas (in contact with electrolyte) are either abraded or etched with 15% HF in 5% HNO_3 . These are submersed in melts for various times and then rinsed with acetonitrile, blotted dry, and reweighed. Each point in Fig. 6, except for the first in each run, is the average of weightings of more than one strip (up to 10 for the last points); hence, the initial increase in mass observed in some runs is real, if unexplained at this point. While this indicates that further studies are required to understand the effect of impurities and other initial reactions on the Al surface, it is clear that the deduced corrosion losses of the concentration cells are similar to the corrosion losses measured for the Al strips which are simply submersed in the melts. Molten chloroaluminate salts are very sensitive to moisture (9), so the initial high corrosion rate in these submersed strips is probably due to impurities caused by water contamination. The much slower steady-state corrosion rate of aluminum in acidic melts and in basic melts is equivalent to $0.2 \mu A/cm^2$. These steady-state rates are obtained from the averages of slopes of linear fits of points after 200h (the solid lines in Fig. 6). Thus, it appears that virtually all of the corrosion loss in the concentration cells is due to reactions of Al with impurities in the melts.

Scanning electron micrographs of the aluminum anode and cathode surface are shown in Fig. 7. It appears that aluminum is etched uniformly and with minimal pitting. The deposited aluminum is crystalline and uniform, with no evidence of dendritic growths, and it adheres strongly to the electrode surface. This strong adherence of Al de-

posited from acidic melts has also been observed to occur on Al, C, W, Fe, and Pt at rates of up to 20 mA/cm² (8).

Specific energies.—Specific energies of the cells are calculated from the following equation

SP EN (W-h/kg) =

$$\frac{(V)(Q, eq)(26.8 \text{ A-h/eq})}{[\text{mass anolyte} + \text{mass catholyte} + \Delta \text{mass anode}]} \quad [6]$$

where V is the average load voltage and Q is the total measured charge in equivalents. The results from the 10 cells which are analyzed are presented in Table II, along with the calculated specific energies. Five cells with capacities (in terms of total charge passed per grams anolyte, Q/M-ALY, in Table II) less than 85 C/g were discarded, generally because electrolyte had leaked through the Teflon seals. The average load voltage in the discharge of these cells is 1.1V, and the average ratio of mass catholyte to mass anolyte is 1.5. Theoretical specific energies (based on the Fig. 2 model) are calculated (6) for the case of cells with $N = 0.37$ melts and $N = 0.60$ melts, 1.1V load voltages, and 1.5 electrolyte mass ratios for various transport numbers. The results of these calculations are compared in Fig. 8 to the experimental results for the ten cells.

Transport numbers.—Transport numbers are calculated from the measured charge and measured changes in anolyte mass and N . The number of moles of MEI⁺ in the anolyte can be calculated from both N and the mass of the anolyte, which are measured before and after the discharge.

Fig. 7. Scanning electron micrographs of aluminum anodes and cathodes from concentration cells

Fig. 8. Experimental values, +, of specific energies and transport numbers, t_+ , of concentration cells (from Table II); calculated values for cell with $N = 0.37$ and $N = 0.60$ melts and load voltage of 1.1V.

The change in moles of MEI^+ in the anolyte can thus be calculated, then divided by the equivalents of charge passed, to give an estimate of t_+ . Since $t_+ + t_{-4} + t_{-7} = 1$, where t_{-4} and t_{-7} are the transport numbers for AlCl_4^- and Al_2Cl_7^- , respectively, we can get t_{-4} from the change in mass of the anolyte as follows

$$\Delta m (\text{anolyte}) = \frac{Q (\text{meas})}{96,487} [-t_+ MW(\text{MEI}^+) + t_{-4} MW(\text{AlCl}_4^-) + (1 - t_+ - t_{-4}) MW(\text{Al}_2\text{Cl}_7^-)] \quad [7]$$

where the MW's are the molecular weights of the species designated in parentheses. Then t_{-7} is obtained as $(1 - t_+ - t_{-4})$. The transport numbers calculated in this way are listed in Table III.

We can also calculate transport numbers from the change in Cl^- content in the anolyte, a value which is also determined from both the initial and final mass and N of the anolyte. In each discharge, the loss of Cl^- is larger than that calculated from the measured charge using the assumed anode reaction (Eq. [4]). The excess loss in Cl^- is assumed to be due to the reaction shown in Eq. [3], where the Al_2Cl_7^- is transported into the anolyte. Thus, the Δ mol Cl^- (excess) is equated to mol Al_2Cl_7^- transporting charge. This is divided by the measured charge, giving t_{-7} . Then t_{-4} can be obtained from

$$\Delta m (\text{anolyte}) = \frac{Q (\text{meas})}{96,487} [-(1 - t_{-7} - t_{-4}) MW (\text{MEI}^+) + t_{-4} MW (\text{AlCl}_4^-) + t_{-7} MW (\text{Al}_2\text{Cl}_7^-)] \quad [8]$$

The transport numbers obtained in this way are virtually identical to those obtained from Δ mol MEI^+ and Eq. [7].

Discussion

The acid-base cell described here appears to behave according to the simple model shown in Fig. 2. The reversible deposition of aluminum from acidic (AlCl_3 rich) catholyte proceeds by a $3e^-$ Al process that is coulometrically balanced by irreversible dissolution of the aluminum negative electrode in basic (MEI^+ rich) anolyte. Delivered specific energies are close to those calculated (based on the model) for complete discharge to neutral melt.

Minor deviations in electrode mass changes are adequately explained by small corrosion losses. Long term corrosion rates, after removal of impurities, appear to be slow and about equal in acid melts and in basic melts. Further studies are required to determine if the steady-state corrosion rates obtained in the submerged strip experiments may be influenced by formation of passivating surfaces on the aluminum. Variability of corrosion rates in acid melts may be due to variations in contamination by trace amounts of water. Corrosion in basic melts may be related to irreversible reduction of the imidazolium cation by aluminum metal (8).

The majority of ionic conduction in the melt is accomplished by the organic cation, MEI^+ . The transport number for the acidic anionic species, Al_2Cl_7^- , appears to be larger than the number for the neutral anionic species, AlCl_4^- . The transport number for MEI^+ of 0.80 ± 0.09 calculated from electrode and electrolyte compositional changes in the concentration cells, is in reasonable agreement with the values of 0.72 ± 0.03 obtained by Hussey and Øye (10). Hussey and Øye also find that the transport numbers for the anions depend on the acidity of the melts, with Al_2Cl_7^- dominating in more acidic melts and AlCl_4^- dominating at near-neutral melts in approximately direct relation to their concentrations. Further work has shown that t_+ (MEI^+) is 0.70 ± 0.03 , in basic and neutral melts, with Cl^- and AlCl_4^- sharing in the transport of the remaining charge (11).

Acidic melts react slowly with the microporous polypropylene separator used in these experiments. The extent and nature of melt diffusion through the separator is unknown. However, based on the relative consistency of our results and on agreement with the expected model, it is probably a minor effect. Reactivity of polypropylene with acidic melts may be dependent on impurities such as water in the melt or separator. This may account in part for the large standard deviations observed for anion transport numbers, as small errors in the electrolyte weighing give rise to fairly large errors in the anion transport numbers. It must also be noted that we have calculated these transport numbers as if they were independent of concentration. While this appears to be valid for the MEI^+ based on other studies (10, 11), it is probably not true for the anionic species. Lacking the strict control of concentrations required in traditional methods for determining transport numbers, the data from the concentration cells give, at best, rough estimates of "average" transport numbers for the anions in the concentration range spanned during cell discharge.

Variable amounts of impurities (especially those derived from reactions with H_2O) in the melts probably account for the scatter in the observed aluminum electrode weight changes. This is indicated by the fact that the deduced corrosion losses (Table I) are variable and not correlated with the charge passed.

Conclusions

Low-specific-energy, aluminum acid-base concentration cells using ambient-temperature chloroaluminate ionic liquids have been discharged close to their theoretical limits. Relatively flat constant-current discharge curves at current densities of up to 0.5 mA/cm^2 have been obtained at 1.0-1.3V. Analysis of electrode mass changes and electrolyte compositional changes accompanying discharge show that aluminum is reduced from acidic melts and oxidized in basic melts, by a $3e^-$ process. Transport

numbers determined by these experiments show that the MEI^+ cation is the principal charge carrying species.

The Electrochemistry of Colloidal Semiconductor Particles

Theory

W. John Albery,* Philip N. Bartlett, and John D. Porter*¹

Department of Chemistry, Imperial College, London, England SW7 2AY

ABSTRACT

The distribution of majority carriers in a collection of colloidal semiconductor particles is calculated. The kinetics of electron transfer from such particles to a macroscopic electrode are considered. Although each particle may have hundreds of electrons, the kinetics are shown to obey the simple equations of classical electrochemistry, such as the Tafel relation. The effect of illuminating the particles and photogenerating majority carriers is also considered. Again, the classical results for the photoelectrochemistry on a transparent rotating disk electrode are obtained, providing that account is taken of the much slower diffusion of the particles.

Colloidal semiconductors have attracted considerable attention (1, 2) as possible systems for utilizing solar energy. Their advantages include good adsorption of the solar energy and a large surface area for carrying out chemical reactions. To trap the energy, electron-transfer reactions have to take place on the surface of the particle for both the minority and majority carriers. An understanding, therefore, of electron-transfer processes at the surface of these particles is important for the design, characterization, and optimization of these systems. In this paper, we first discuss the distribution of electrons among a system of colloidal particles. Unlike a simple ionic reactant, where the charge is the same on each ion, a collection of colloidal particles will contain different numbers of electrons. It is interesting to explore this distribution function and to find out the dispersion about the mean number of electrons per particle. Second, we report theoretical results for electron transfer from colloidal particles to a macroscopic electrode. A new theoretical description is necessary because when the colloidal particle reaches the surface of the electrode, several hundred electrons may be transferred. We prove that, although these particles, containing large numbers of reactant electrons, are very different from normal one-electron species, nevertheless, many of the results of classical electrode kinetics, such as the Tafel relation, are found to hold. Having described the kinetics at the electrode surface, we next combine these results with the convective diffusion equation for mass transfer to derive

expressions for the current at a rotating disk electrode. We show that the classical Koutecky-Levich equation applies to the system. Experimentally, the system has been investigated using the optical rotating disk electrode (ORDE), and again we show that the rotation speed dependence of the photocurrent is similar to that for classical systems. In the subsequent paper (3), the theoretical model and results will be tested using results from n-type colloidal TiO_2 and CdS . Throughout this paper, therefore, we will consider n-type particles.

Distribution of the Number of Majority Carriers Between the Particles

In the subsequent paper (3), we will show that the number of majority carriers (electrons in our case) per particle may vary from three or four up to several hundred. With these small numbers, the number of electrons per particle will not be the same for every particle; there will be a distribution about some mean number. We start by calculating that distribution. We assume first that majority carriers are generated by thermal and/or photonic processes with a rate constant k_g/s^{-1} and, second, that the loss of majority carriers, described by the rate constant k , is first order in the number of majority carriers per particle. This second assumption is particularly appropriate for small particles ($\sim 50\text{\AA}$) where field effects are small; for larger particles, complications may arise from the space charge. In the steady state, the flux generating a particle with, say, m electrons in it from a particle with $m - 1$ electrons must balance the loss of an electron from the particle with m electrons to form a particle with $m - 1$ electrons. Writing the concentration of particles with m electrons as

*Electrochemical Society Active Member.

¹Present address: AT&T Bell Laboratories, Murray Hill, New Jersey 07974.

c_m and similarly c_{m-1} for the particle with $m - 1$ electrons, we have

$$k_g c_{m-1} = k m c_m$$

Applying this recurrence relation successively, we obtain

$$c_m = \frac{c_0 (k_g/k)^m}{m!} \quad [1]$$

The concentration c_0 is fixed by summing all the c_m to give the total concentration of particles in the system, c_p

$$c_p = \sum_0^{\infty} c_m = c_0 \exp(k_g/k) \quad [2]$$

We can also find the average number of electrons per particle, \bar{n}

$$\bar{n} = c_p^{-1} \sum_0^{\infty} m c_m = (k_g/k) \exp(-k_g/k)$$

$$\sum_{m=1}^{\infty} (k_g/k)^{m-1} / (m-1)! = (k_g/k) \quad [3]$$

Substitution of Eq. [2] and [3] in Eq. [1] gives

$$\frac{c_m}{c_p} = \frac{(\bar{n})^m \exp(-\bar{n})}{m!} \quad [4]$$

which is the Poisson distribution (4). Inspection shows that c_m is at a maximum when $m = \bar{n}$. For values of \bar{n} greater than 10, we can use the fuller form of Stirling's approximation

$$\ln(m!) \approx m \ln m - m + 1/2 \ln(2\pi m)$$

to give

$$\frac{c_m}{c_p} \approx \frac{\exp[-\bar{n}(\chi \ln \chi + 1 - \chi)]}{(2\pi \bar{n} \chi)^{1/2}} \quad [5]$$

where

$$\chi = m/\bar{n} \quad [6]$$

Comparison of the results from Eq. [4] and [5] shows that the approximation holds to within 1% for $\bar{n} \geq 10$. As in Eq. [4], c_m/c_p has a maximum value when $m = \bar{n}$ or $\chi = 1$

$$(c_m/c_p)_{\max} = (2\pi \bar{n})^{-1/2} \quad [7]$$

For \bar{n} greater than 500, Eq. [5] reduces to a Gaussian distribution. It is interesting to calculate the width of the distribution in terms of m or its normalized counterpart χ (Eq. [6]) at half-height. For the range $10 \leq \bar{n} \leq 1000$, we find that to within 1%

$$(\Delta m)_{1/2} = 2.36 (\bar{n})^{1/2} \quad [8]$$

and

$$(\Delta \chi)_{1/2} = 2.36 (\bar{n})^{-1/2} \quad [9]$$

In view of Eq. [7], these results are not surprising; in fact, the product $(\Delta m)_{1/2} (c_m/c_p)_{\max} = 0.94$, which is close to unity. Figure 1 shows plots of $(\Delta m)_{1/2}$ and $(\Delta \chi)_{1/2}$ as a function of \bar{n} . The distribution function (c_m/c_p) is also shown for $\bar{n} = 10, 100$, and 1000. It can be seen that as \bar{n} increases the absolute width of the distribution, $(\Delta m)_{1/2}$, increases but that the normalized parameter $(\Delta \chi)_{1/2}$ decreases, giving a sharper peak.

These results hold for both the dark and when the particles are illuminated. We are always dealing with a distribution of particles with different numbers of majority carriers.

Electrode Kinetics

Turning next to the electrode kinetics, the crucial difference between the electrochemistry of a colloidal particle and an ordinary species is that the number of elec-

[8] and [9] in the lower half of the diagram.

trons transferred from each particle to the electrode may be large and will depend upon the potential of the electrode. In Fig. 2, we depict the model for an encounter of a particle with an electrode. We describe the transport of the particle to the electrode with the mass-transfer coefficient k_D' (5) where

$$k_D' = D_p/X_D$$

D_p is the diffusion coefficient of the particle, and X_D is the diffusion layer thickness of the electrode. For a rotating disk electrode, the Levich equation gives (6, 7)

$$X_D = 0.643 D_p^{1/3} \nu^{1/6} W^{-1/2} \quad [10]$$

where ν is the kinematic viscosity and W is the rotation speed in Hz. Hence, the flux of particles arriving at the electrode is given by

$$j_0 = k_D' c_p$$

For the moment, we assume that each particle has n electrons (majority carriers) in the conduction band; we will return to the effects of the distribution function below. We further assume that the rate constant for the transfer of an electron from the particle to the electrode is proportional to the number of electrons in the conduction band

$$k_m' = k_1' (n - m + 1)$$

where k_1' describes the transfer of the last electron from the conduction band of the particle at this particular electrode potential. We further assume that the potential distribution between the particle and the electrode and within the particle is not effected by the successive electron transfers. Our previous work showed (8) that, in many cases, particles are so small that field effects are small and, often, a constant potential distribution is found within the particle.

Fig. 2. Kinetic scheme for the successive transfer of electrons from a colloidal particle to a macroscopic electrode.

With these assumptions, we consider the cascade process depicted in Fig. 2. Summing the transfer of electrons for each partition, we obtain for the total flux of electrons

$$\frac{j_e}{j_0} = \sum_{m=1}^{m=n} \prod_{i=0}^{i=m-1} \frac{1}{1 + \lambda(n-i)} = S_n \quad [11]$$

where $\lambda = k'_D/k'_i$. The successive terms $\lambda/(n-i)$ describe the partition between leaving the surface and transferring another electron.

The series may be summed up by the method of induction. We assume that the sum S_n is given by

$$S_n = n/(1 + \lambda) \quad [12]$$

Then

$$S_{n+1} = \left(1 + \frac{\lambda}{n+1}\right)^{-1} (1 + S_n) \quad [13]$$

Substitution of Eq. [12] in Eq. [13] gives

$$S_{n+1} = (n+1)/(1 + \lambda)$$

For $n = 1$

$$S_1 = 1/(1 + \lambda)$$

and hence Eq. [12] holds for all values of n . We therefore obtain the gratifyingly simple result that

$$j_e/j_0 = n/(1 + k'_D/k'_i) \quad [14]$$

This equation has exactly the same form as the current voltage curve for a single-electron transfer. This is because in our model each electron has the chance $k'_i/(k'_i + k'_D)$ of being transferred at the electrode. As long as k'_i is independent of the number of electrons in the conduction band, it makes no difference whether the electrons all

come together in one big particle or each comes separately on its own little ion. Hence, although the electrons will be distributed among the particles as shown in Fig. 1, there will be no complications in the observed kinetics arising from this effect. We can also conclude that for this model the Tafel relation and the Koutecky-Levich equation should hold. The limiting current i_L , for large values of k'_i is given by

$$i_L = nFAk'_Dc_p \quad [15]$$

Under these conditions all the electrons in the conduction band are removed, and the current is limited by the arrival of the particles at the electrode surface.

Although the electrode kinetics of the particles give similar equations to those for simple ions, it is interesting to use Eq. [11] to explore the details of the cascade process depicted in Fig. 2. For this purpose, we use the variables y and χ , which describe the flux of electrons compared to the limiting flux and the number of electrons compared to the total number in the conduction band

$$y = j_e/j_0n$$

and

$$\chi = m/n$$

Then from Eq. [11] considering the contribution, δy , from each successive transfer, we have

$$\delta y_m = \delta y_{m-1} [1 + \lambda(n-m+1)]^{-1} \quad [16]$$

Next we assume that n is a reasonably large number, so that

$$\delta\chi = n^{-1} \ll 1$$

Then, providing m is not too close to n , we can write from Eq. [16]

$$\begin{aligned} \delta y_{m-1}/\delta y_m &\approx 1 + \lambda(n-m) \approx [1 + (n-m)^{-1}]^\lambda \\ &= \left[\frac{n-(m-1)}{n-m} \right]^\lambda \end{aligned} \quad [17]$$

when $m \rightarrow 1$, $\delta y_0 \rightarrow 1/n$, corresponding to the transfer of a single electron at the first encounter.

Hence, we find that to satisfy Eq. [17]

$$\begin{aligned} \delta y_m &\approx n^{-1} (1 - m/n)^\lambda \\ &= \delta\chi (1 - \chi)^\lambda \end{aligned}$$

or

$$dy/d\chi \approx (1 - \chi)^\lambda \quad [18]$$

It is satisfactory that integration of this equation with respect to χ from $\chi = 0$ (no electrons transferred) to $\chi = 1$ (all the electrons transferred) gives, for the total flux of electrons described by y

$$y = (1 + \lambda)^{-1} = S_n/n$$

This result agrees with Eq. [14] and justifies the approximation used in deriving Eq. [17]. (It is interesting that there is no error in the approximation for the particular case of $\lambda = 1$.) Figure 3 shows plots of Eq. [18] for different values of λ . The curves describe the fraction of particles that survive to deliver the m th electron in the cascade process. Thus for low values of λ , corresponding to fast electrode kinetics, most particles survive to the bitter end and lose all their electrons. However, for large values of λ , few electrons are transferred before the particles diffuse back into the solution.

Differentiation of Eq. [18] gives a distribution function, f , for the number of electrons delivered by the particles

$$f = -d^2y/d\chi^2 = \lambda(1 - \chi)^{\lambda-1} \quad [19]$$

Again, it is satisfactory that integration by parts of this equation shows that the total flux of electrons is given by

$$\int_0^1 \chi f d\chi = (1 + \lambda)^{-1} = S_n/n$$

Fig. 3. Curves calculated from Eq. [18] showing the fraction of particles that remain at the electrode to deliver the m th electron where $\chi = m/n$. Each curve is labeled with its value of λ , which in Eq. [11] compares the transport and electrode kinetics.

Curves for the function, f , given by Eq. [19] for different values of λ are shown in Fig. 4. For large values of λ (slow electrode kinetics), the particles transfer few electrons, while for small values of λ (fast electrode kinetics), many particles lose all their conduction-band electrons. It is interesting that for $\lambda = 1$ a completely flat distribution is found, so that some particles lose no electrons, while an equal number lose all their electrons. This distribution

Fig. 4. Distribution curves, calculated from Eq. [19], showing the fraction of the electrons in the conduction band delivered by the particles to the electrode. Each curve is labeled with its value of λ .

imposed by the irreversible reaction is very different from the peaked distribution of the unperturbed system (Fig. 1).

The Convective Diffusion Equation

While the section above considers the electrode reaction, we now consider the convective diffusion equation for the system of particles as they diffuse towards a rotating disk electrode.

We can write a convective diffusion equation for a particle containing m electrons in the conduction band of concentration c_m

$$\text{Tr}(c_m) + k_g c_{m-1} - k m c_m + k(m+1)c_{m+1} - k_g c_m = 0 \quad [20]$$

In this equation the operator Tr describes the diffusion and convection terms for a rotating disk electrode

$$\text{Tr} = D_p \frac{\partial^2}{\partial x^2} + C x^2 \frac{\partial}{\partial x} \quad [21]$$

where x is the distance normal to the electrode and (9)

$$C = 8.0W^{2/3}\nu^{-1/2} \quad [22]$$

As described above, the first-order rate constant k_g describes electron promotion either by thermal or by photonic processes, and the rate constant k describes the loss of electrons from the conduction band by a process which is first order in the electron concentration. There will be an equation similar to Eq. [20] for each value of m . We now multiply each equation by its value of m and sum the set of equations to obtain the simple result that

$$\text{Tr}(c_e) + k_g c_p - k c_e = 0 \quad [23]$$

where c_e , the total concentration of electrons in the conduction band, is given by

$$c_e = \sum_{m=0}^{\infty} m c_m$$

and where, as in Eq. [2], c_p is the concentration of particles.

This result shows that the transport of the whole system of particles may be treated by the usual convective diffusion equation using c_e as the variable. For an irreversible reaction, the boundary condition at the electrode surface is given by

$$j_e = D_p \left[\frac{\partial c_e}{\partial x} \right]_0 = k' c_e$$

where k' is an electrochemical rate constant. This result again confirms the analysis from the cascade model; the simple Tafel and Levich relations will apply to the system of particles.

In Eq. [20], when one uses the ORDE, the generating rate constant k_g can be made up of a thermal contribution, k_T , and a photonic contribution

$$k_g = k_T + (I_0/\epsilon_p) \exp(-x/X_e) \quad [24]$$

where I_0 is the irradiance at the electrode surface

$$X_e = (\epsilon_p c_p)^{-1}$$

and ϵ_p is the molar extinction coefficient (in natural logarithms) of the particles treated as a species in solution of concentration c_p .

In terms of bulk properties

$$X_e \approx (\epsilon_B c_{FU} V)^{-1}$$

where ϵ_B is the extinction coefficient of the bulk material, c_{FU} is the concentration of formula units, and V is the molar volume. Just as k_g is split in Eq. [24] into two contributions, so c can be split into the thermal contribution $(c_e)_T$, giving rise to the dark current and the photogenerated contribution $(c_e)_{hv}$ giving rise to the photocurrent. The variable $(c_e)_{hv}$ obeys the same differential equation as a photogenerated product, such as leucothionine, and so all

of the results we have previously deduced for the ORDE can be applied to the colloidal system (10-12).

In particular, when the absorption length, X_c , is much longer than the thickness of the diffusion layer, so that the diffusion layer is uniformly illuminated, and when the photogenerated electrons are stable with respect to their passage across the diffusion layer, we obtain (10) the following result for the limiting photocurrent

$$(i_{hv})_L = \phi A F I_0 (X_D/X_c) \quad [25]$$

Finally, we summarize our conclusions below.

1. The distribution of majority carriers in a system of colloidal particles obeys the Poisson distribution (see Fig. 1).

2. A collection of particles, each with n electrons, will transfer electrons to an electrode as shown in Fig. 2, giving distribution functions shown in Fig. 3 and 4.

3. Despite the complex behavior in conclusions (1) and (2), providing that the electrochemical rate constant is independent of the number of electrons in the conduction band, the Tafel relation will be obeyed.

4. The rotating disk convective diffusion equation for a system of particles can be solved and the Koutecky-Levich relation will be obeyed.

5. Similarly, a system of illuminated particles obeys the simple equations for the optical rotating disk electrode.

In the subsequent paper, these theoretical results will be tested using experimental results from n-type TiO_2 and CdS.

The Electrochemistry of Colloidal Semiconductor Particles

Experiments on CdS and TiO_2

W. John Albery,* Philip N. Bartlett, and John D. Porter*¹

Department of Chemistry, Imperial College, London, England SW7 2AY

ABSTRACT

Results are presented for the dark electrochemistry and photoelectrochemistry of CdS and TiO_2 colloidal particles studied with the optical rotating disk electrode (ORDE). The electron-transfer reactions between the particles and the electrode are found to be irreversible. However, in agreement with theoretical predictions, the kinetics obey both the Tafel and Levich relations. Several hundred electrons may be transferred on each encounter between a particle and the ORDE. Added halide ions are shown to be good scavengers for photogenerated holes. Results for the quantum efficiencies for the photogeneration of majority carriers are reported.

In the previous paper (1), we derived various theoretical relations for the electrochemistry and photoelectrochemistry of colloidal particles of semiconductors such as TiO_2 and CdS. In this paper, we report experimental results designed to test the model presented and the relations derived. These results were obtained using the optical rotating disk electrode (ORDE) (2-4). This electrode consists of a quartz rod, the end of which is coated with tin oxide to form a transparent electrode. Light is shone down the rod through the electrode and then into the solution. The rotation of the electrode imposes known transport by convection and diffusion on the species reacting on the electrode. In this case, the species are the colloidal semiconductor particles. We report results on the dark electrochemistry of the particles and on the photocurrents observed when the particles are illuminated. Experiments have also been carried out in the presence of different halide ions, which scavenge the photogenerated holes. The kinetics of this process are shown to obey the Stern-Volmer quenching law.

Experimental

The apparatus and ORDE have been described previously (5). The radius of the electrode used in this work was 2.03 mm. The light source was a Thorn 250W quartz halogen slide projector lamp. Because of the small currents involved (\sim nA), a special potentiostat was constructed, which used commutating operational amplifiers, and which was powered by dry cells.

All chemicals were of analytical reagent grade. The TiO_2 colloids were made by the method of Henglein (6), which involves the hydrolysis of titanium tetraisopropoxide. We made two modifications to the method. First, we carried out the hydrolysis in $0.05 \text{ mol dm}^{-3} \text{ HClO}_4$ under nitrogen, rather than in HCl under air; this was to avoid the incorporation of Cl^- or oxygen into the particles. Second, the isopropanol, formed by the hydrolysis, was removed as an aqueous azeotrope by a three-stage rotary evaporation. The particles were used without the addition of any support material, such as polyvinylalcohol. The CdS colloids were made by the method of Grätzel (7), which involves the reaction of $\text{Cd}(\text{NO}_3)_2$ with H_2S . For the same reasons as discussed above, in our

method, we dissolved CdO in HClO_4 and performed the reaction with H_2S under nitrogen. For both colloids the size of the particles was determined by light scattering using a Cary 14 spectrophotometer. The diameters of the TiO_2 and CdS particles were 2.5 and 8.0 nm, respectively. In addition, transmission electron microscopy was performed on the TiO_2 particles, and a mean diameter of less than 6 nm was found.

All potentials were measured and are reported with respect to the saturated calomel electrode (SCE). All experiments were carried out at 25°C. Experiments with TiO_2 particles were carried out in 0.05M dm^{-3} HClO_4 ; the concentration of TiO_2 was 10 mM dm^{-3} . Experiments with CdS particles were carried out in a solution containing 10 mM dm^{-3} KClO_4 and 10 mM dm^{-3} sodium hexametaphosphate; the concentration of CdS was 5 mM dm^{-3} .

Results and Discussion

Dark electrochemistry.—Typical current voltage curves for the transfer of electrons from the conduction band of TiO_2 and of CdS to a macroscopic electrode in the dark are shown in Fig. 1. Because the currents were so small, the voltammograms were obtained point by point. It is clear that the electron-transfer reactions are very irreversible. The flatband potentials for TiO_2 and CdS may be estimated from their bulk values (8) to be approximately -0.6 and -0.8V, respectively. Hence, overvoltages of some 800-1000 mV are required to drive the electron-transfer reaction to the macroscopic electrode.

Next, we consider the variation of the limiting current, i_L , from the particles with the rotation speed of the electrode. Equation [15] of our previous paper (1) shows that these currents should obey the Levich equation

$$i_L = nFAD_p W^{1/2} c_p / X_{D,W=1} \quad [1]$$

where n is the number of electrons in the conduction band, A is the area of the electrode, D_p is the diffusion coefficient of the particles, W is the rotation speed (Hz), c_p is the concentration of the particles, and $X_{D,W=1}$ is the thickness of the diffusion layer for $W = 1$ Hz. From the Levich equation (9)

$$X_{D,W=1} = 0.643\nu^{1/6} D_p^{1/3} \quad [2]$$

Figure 2 shows typical results for CdS, and it can be seen that the limiting currents vary linearly with the square root of the rotation speed. The intercept probably arises

Fig. 1. Typical current voltage curves in the dark for CdS (o) and TiO_2 (●) colloids

Fig. 2. Limiting dark currents for CdS plotted according to Eq. [1] against the square root of rotation speed ($W^{1/2}$).

from background currents or offset currents from the amplifiers. From the Stokes-Einstein equation (10), and the radius of the particles, we estimate that

$$D_p/\text{cm}^2\text{s}^{-1} = 4 \times 10^{-7} \quad [3]$$

From the bulk density (11) and the radius, we find that each particle contains about 5×10^8 atoms of Cd; hence, in our solution

$$c_p/\mu\text{M dm}^{-3} = 0.9$$

Using this value, the value of D in Eq. [3], the gradient of the plot in Fig. 2, and Eq. [1], we find that the number of electrons in the conduction band of a single particle is

$$n = 4$$

This corresponds to a doping density of $1.6 \times 10^{19} \text{ cm}^{-3}$, which seems reasonable, considering that the particles were prepared in the absence of halide and oxygen. Similar results were found for the TiO_2 particles.

Next, we turn to the irreversible electrode kinetics on the rising part of the current voltage curve in Fig. 1. Equation [14] or our previous paper (1) shows that

$$i_L/i = 1 + k_D'/k_1' \quad [4]$$

where

$$k_D' = D_p W^{1/2} / X_{D,W=1}$$

and k_1' is the electrochemical rate constant for the transfer of a single electron from the conduction band of a particle to the macroscopic electrode. Equation [4] can be rearranged to give

$$\ln(i_L/i - 1) = \ln(k_D'/k_{1,E=0}') - \alpha E \quad [5]$$

where E is the potential of the macroscopic electrode.

Figure 3 shows a typical plot of Eq. [5] for CdS in the dark. A reasonably straight line is obtained, showing that the electrode kinetics of the colloidal particles obey the Tafel relation. Similar results are found for TiO_2 . However, the values of the transfer coefficient, α , are somewhat smaller than usual, being 0.40 and 0.34 for TiO_2 and CdS, respectively. It might be thought that these results, coupled with the irreversibility of the reaction, are those

Fig. 3. Corrected Tafel plots (Eq. [5]) for CdS in the dark (o) and under illumination (o).

that would be expected for such a reaction being driven hard by the electrode potential (12). However, solvent reorganization will not be relevant to this type of transfer between two massive entities, and the traditional Marcus picture (13) is not applicable. With negligible solvent reorganization, one might have expected instead that the electron-transfer reactions would have been very rapid. The observed irreversibility may arise from the mutual repulsion of the double layers, so that the transfer of the electron resembles that in a metal insulator semiconductor junction.

Photoelectrochemistry.—Having characterized the dark electrochemistry, we now report what happens when the ORDE is illuminated. Figure 4 shows typical results obtained with CdS. It can be seen that the photocurrent voltage curve has a similar shape to the dark current voltage curve. This is in agreement with the theoretical model, where all the conduction band electrons have the same electrode kinetics. The rising part of the photocurrent

Fig. 4. Typical current voltage curves for a CdS colloid in the dark (o) and under illumination (o).

voltage curve can be plotted according to the Tafel relation given in Eq. [5]; the results are shown in Fig. 3. Similar values of the electrochemical rate constant and of α are found.

Turning to the limiting photocurrent, we find that these currents decrease with increasing rotation speed. This behavior is to be expected if the photogenerated electrons are kinetically stable in their passage across the diffusion layer (1). Under these conditions, the photogenerated electrons are either transferred to the electrode or are lost to the bulk of the solution as the particles are swept on their way by the radial convection. Equation [25] of our previous paper (1) states that

$$(i_{hv})_L = FA\phi I_0(X_{D,w=1}/X_e) W^{-1/2} \quad [6]$$

where ϕ is the quantum efficiency for the photogeneration of holes that leave the particle giving stable conduction band electrons, I_0 is the irradiance at the electrode surface, and X_e is the absorbance length (3), describing the Beer-Lambert profile of the incoming light (1)

$$X_e = (\epsilon_p c_p)^{-1} \quad [7]$$

Figure 5 shows typical results for the limiting photocurrents for CdS plotted, according to Eq. [6] against $W^{-1/2}$. A good straight line is obtained. The small intercept is caused by photocurrents generated at the electrode surface. Thus, these results again confirm the theoretical results of our previous paper.

From the gradient, we find that the value of ϕ , the quantum efficiency, is 2×10^{-3} . Hence, we may conclude that under these conditions, where there is no scavenger for photogenerated holes in the solution, the main process is recombination of the holes and electrons inside the particle. The photogenerated electrons that survive to reach the electrode do so because the holes have been removed, and then they are safe in their tiny particle. We cannot identify the reaction that removes the holes; it may be corrosion or it may be reaction with trace electron donors. However, it is clear that this value of ϕ sets an upper limit on the corrosion rate.

Comparing the size of the photocurrent to that of the dark current, we can estimate a typical number of conduction band electrons which are transferred per particle in the light. For a rotation speed of 1 Hz, the number is 20. Under these conditions the particles take about a second to cross the diffusion layer, where they are in the light.

Fig. 5. Limiting photocurrents for CdS plotted according to Eq. [6] against $W^{-1/2}$.

Fig. 6. Stern-Volmer analysis according to Eq. [8] of the scavenging of photogenerated holes in CdS by Br^- . Note the scale on the y axis, which means that an intercept of unity is indistinguishable from zero.

During this passage they are hit by a photon every 0.1 ms, which with ϕ equal to 2×10^{-3} , generates the 20 photoelectrons that finally reach the macroscopic electrode.

We have also measured the action spectrum of the photocurrent and have found it to be identical to the absorption spectrum of bulk CdS.

For TiO_2 , the photocurrents were smaller by an order of magnitude, and so less time was spent on this system. However, the limiting photocurrents did decrease with increasing rotation speed, and the general behavior was similar to CdS.

Effect of added halide ions.—We found that the photocurrents for CdS could be dramatically increased by adding Br^- . The rotation speed dependence was similar to that in Fig. 5. We therefore conclude that the action of the Br^- is to increase ϕ by scavenging the photogenerated holes out of the particles, before they recombine with the electrons. If this is the case, then the usual Stern-Volmer equation should apply, and we can write, as shown in the Appendix

$$(\phi - \phi_0)^{-1} = 1 + k_R/k_S[\text{Br}^-] \quad [8]$$

where ϕ_0 is the quantum efficiency in the absence of Br^- , k_S describes the scavenging of a hole by Br^- , and k_R de-

scribes the recombination of a hole inside the particle. Figure 6 shows that this modified Stern-Volmer relation is indeed obeyed. Similar plots were found for Cl^- and I^- . Results for the ratios of rate constants are collected in Table I. It can be seen that Br^- is a much more efficient scavenger than either Cl^- or I^- . These results suggest that Br^- systems are to be preferred for solar energy conversion. At the largest concentration of Br^- used in this work (4.5 mM dm^{-3}), ϕ was 0.022, and 270 electrons were being transferred on each encounter of a particle with the macroscopic electrode.

The study of the electrochemistry of colloidal particles with the ORDE can therefore determine the number of electrons in the conduction band, the quantum efficiency of their generation, and their lifetime. All of these parameters are fundamental to an understanding of the behavior of such systems and their possible application to solar energy conversion.

APPENDIX

In this Appendix, we derive the modified Stern-Volmer relation in Eq. [8]. We assume that a photogenerated hole may recombine with a rate constant, k_R , or it may be

Table I. Scavenging of holes from CdS particles

Halide ion	$(k_S/k_R)/\text{dm}^3 \text{ mol}^{-1}$
Cl^-	0.074 ± 0.011
Br^-	5.2 ± 0.1
I^-	0.093 ± 0.009

lost from the particle with a rate constant $k_0 + k_s [\text{Br}^-]$, where k_0 describes the processes in the absence of Br^- and k_s describes the scavenging by Br^- . We then find that

$$\phi = \frac{k_0 + k_s [\text{Br}^-]}{k_R + k_0 + k_s [\text{Br}^-]}$$

$$\phi_0 = k_0 / (k_R + k_0)$$

and

$$\frac{1}{\phi - \phi_0} = \frac{k_0 + k_R}{k_R} \left[1 + \frac{k_0 + k_R}{k_s [\text{Br}^-]} \right] \quad [9]$$

Now $\phi_0 \ll 1$ and so $k_0 \ll k_R$. With this assumption, Eq. [9] simplifies to give Eq. [8].

Breakdown Phenomena During the Growth of Anodic Oxide Films on Zirconium Metal

Influence of Experimental Parameters on Electrical and Mechanical Breakdown

Francesco Di Quarto, Salvatore Piazza, and Carmelo Sunseri

Istituto di Ingegneria Chimica, Università di Palermo, 90128 Palermo, Italy

ABSTRACT

Different aspects of the breakdown phenomena observed during the growth of anodic films on zirconium metal in aqueous solutions have been investigated. Two different mechanisms of breakdown are suggested as a result of the experimental observations. A mechanical breakdown, which is dependent upon the logarithm of the anodizing current density, has been observed in carbonate and sulfate solutions at low concentrations of salt or acid and/or low anodizing current densities. The appearance of small fissures in the ZrO_2 films is related to this type of breakdown. An electrical breakdown was observed in sulfamic acid solutions as well as in sulfate and carbonate solutions at high salt or acid concentrations and/or high current densities. In the case of electrical breakdown, the first spark voltage showed a significant dependence upon the value of current density only in carbonate and sulfate anion containing solutions. A possible explanation for this dependence is suggested in agreement with Christov's model, taking into account also the incorporation of anions into the films. The different influences of the electrolytic solutions upon both types of breakdown are presented and discussed.

Breakdown phenomena in solids have been the subject of research for many years (1, 2) because of the practical importance of solid dielectrics (2). In the case of dry systems, a reasonable agreement exists on the possible explanations of the breakdown phenomena (1-4). In wet systems, and particularly in MOE (metal-oxide-electrolyte) systems, further complications arise from the electrolyte interface. In this case, besides the influence of the dielectric thickness and magnitude of electric field, it is necessary to take into account other variables such as: (i) nature of the solutions and their resistivity; (ii) anodizing current density; (iii) incorporation of electrolytic species into the oxide films; (iv) parasitic side reactions at the oxide/electrolyte interface; and (v) existence of mechanical stresses during the growth of the films.

Owing to the possible influence of all these parameters in determining the breakdown phenomena in a MOE system, it has been very difficult to develop a theoretical model which could explain the general behavior of the breakdown for different MOE systems. In the case of the growth of anodic films on valve metals two different types of breakdown can be envisaged, according to the different experimental findings and the interpretative models proposed by different authors (5-16).

A mechanical breakdown has been suggested in those cases where a mechanical failure due to stress is the cause of the arrest of growth of the films. In this case, although the existence of stresses during the growth of the films is widely accepted (5-13), the agreement about the source of these stresses is less general. It has been attributed to: (i) hydration and dehydration of the films (5-6); (ii) presence of impurities (7) and flaws (8-10); (iii) a Pilling-Bedworth ratio (molar volume of the oxide/molar volume of the metal) higher than unity, or, more generally, changes in volume due to the conversion of metal to oxide (11-12); and (iv) electrostrictive effects (13). The influence of the electrolytic solution on this last type of breakdown has been predicted theoretically by Sato (13).

An electrical breakdown has been proposed in those cases where the arrest of growth process seems related to

the onset of phenomena of electronic conduction in the films with consequent light emission phenomena and/or gas evolution at the oxide/electrolyte interface.

Previous studies (14, 15) have excluded for breakdown possible mechanisms such as crystallization and thermal heating due to the Joule effect. On the contrary, it has been suggested that crystallization is a result of the breakdown. The hypothesis (16) that only solid-state properties of the oxide films control the breakdown phenomena has been definitely discarded, while it has been suggested that the main source of electrons is the oxide/electrolyte interface (14, 17, 18, 22).

In this work, we present some experimental results on the breakdown phenomena observed during the growth of ZrO_2 anodic films in different solutions and at various current densities.

In particular, we will show how the different kinds of breakdown observed on ZrO_2 films follow different phenomenological relationships. The influence of the anodizing parameters on both types of breakdown will be discussed on the basis of the available theories of breakdown in MOE systems.

Experimental

Zirconium of purity 99.8%+ (Goodfellow Metals, Cambridge, England) was used. Rods were sealed to Teflon cylinders with epoxy resin (TorrSeal, Varian Associates) or forced into heated Teflon cylinders (4.5 mm id). The area exposed to the electrolytic solution was 0.196 cm². The surface exposed to the solution was mechanically polished before each experiment with very fine abrasive papers, ultrasonically cleaned in distilled water, and then chemically etched. The chemical etching was in $HF:H_2O:HNO_3$ mixture (1:4:2 in volume) (8). During the etching, the electrode was rotated at constant rotation speed so that a better finish of the electrode surface was obtained.

The electrodes were anodized galvanostatically by using a Keithley Model 227 constant current generator. The cell voltages were measured by a digital multimeter and

the V_{cell} vs. time curves (V - t curves) were recorded on a X, Y, t recorder. Surface inspection, before and after the anodization, was made with a scanning electron microscope.

The counterelectrode was a Pt wire or a Zr foil. Solutions were prepared from analytical-grade reagents. All experiments were carried out at room temperature.

Experimental Results

The different types of breakdown phenomena were classified on the basis of the galvanostatic growth curves as well as of the morphological analysis performed by electron microscopy. In Fig. 1, we show three typical anodic growth curves, which display the different behavior observed during the anodization of zirconium electrodes in various electrolytes and in a range of current densities between 2 and 32 mA cm⁻². The slope of the growth curves changed with the c.d., with the electrolytic solutions, and with the film thickness, as reported in previous work (19). Curves 1a and 1b were typical of anodization processes performed, respectively, in NH₂SO₃H (0.1-1.5M) and in 1N H₂SO₄ solutions at any current density of anodization.

By decreasing the concentration of the anion and the anodizing current density in sulfate containing solutions the shapes of the growth curves became similar to that of curve 1c. The behavior depicted in Fig. 1c was typical of films grown in 0.1M Na₂CO₃ solution at any c.d. In 0.5M carbonate solution, the growth curves showed a behavior similar to that depicted in Fig. 1b at high anodizing current densities ($i \geq 8$ mA cm⁻²), while the behavior displayed in Fig. 1c was observed at low c.d.

The main difference between curves a, b, and c of Fig. 1 is the appearance in the last one of a shoulder well below the onset of sparking phenomena. The appearance of the shoulder also marked the beginning of a second straight-line behavior in the growth curve having a lower slope. It must be mentioned that the slope of the growth curves after the shoulder was related to the anodizing current

Fig. 1. Growth curves for films grown on zirconium metal at $i = 8$ mA cm⁻² in different solutions: (a) 1M NH₂SO₃H; (b) 1N H₂SO₄; (c) 0.1N H₂SO₄. The arrows mark the first spark occurrence.

density. In particular, the second slope was about one-half of the initial one in both solutions.

Using electron microscopy it was possible to associate the appearance of the shoulder in the V - t curves with the presence in the anodic films of very small fissures as shown in Fig. 2 (see also Fig. 5).

The presence of these fissures did not stop the growth of the films. The subsequent decrease of slope in the growth curves is interpreted in terms of the onset of a mechanical breakdown in the films well before the start of the sparking phenomenon. The cell voltage at which this phenomenon appears is defined as "mechanical breakdown voltage" (V_{mb}). The V_{mb} values were found to follow a relationship

$$V_{\text{mb}} = A_{\text{mb}} + B_{\text{mb}} \log i \quad [1]$$

where A_{mb} and B_{mb} are constants which depend on the electrolytic solution. As reported in Fig. 3, the coefficients A_{mb} and B_{mb} depend mainly upon the kind of anion in the solution, while the pH of electrolytic solution seems to have a negligible effect on both coefficients. A deviation from the behavior depicted in Eq. [1] was observed at high current densities in 0.1N H₂SO₄ solution.

In order to get more information on different aspects of the mechanical breakdown some experiments were focused on the dependence of V_{mb} upon the film thickness in various solutions.

For carbonate solutions, a nearly constant film thickness was calculated at the breakdown voltages both from the interference colors and by using the kinetic parameters of Fromhold's theory previously obtained for 0.5M Na₂CO₃ solutions (19).

In the range of c.d. reported in Fig. 3a, the film thickness at the different V_{mb} values was equal to about 4000Å. In the case of sulfate anion containing solutions the film thickness at the breakdown voltages generally increases with c.d., as reported in Table I.

An exception to this was the films formed in 0.1N H₂SO₄ solution for $i \geq 8$ mA cm⁻². For these films, a nearly constant critical thickness of about 3500Å was estimated on the basis of the interference colors of the films.

In Fig. 4, we show an electron micrograph typical of films with anodic growth curves similar to curves 1a and 1b in Fig. 1. Anodizing processes producing these curves showed all the features typical of the sparking phenomena (light emission, cell-voltage oscillations, noise) already described in the literature for different MOE systems [Ref. (17) and references therein]. As shown in Fig. 4, the surfaces of the electrodes are free of fracture, but in some areas a certain texture can be observed. Anodic films grown in similar conditions did not show such textured regions if the anodization process was stopped be-

Fig. 2. SEM micrograph of a film grown in 0.1N Na₂CO₃ at $i = 16$ mA cm⁻² after the appearance of shoulder in the growth curve.

Fig. 3. Voltage of mechanical breakdown vs. anodizing current density for films grown in various solutions: (a) 0.1M Na_2CO_3 ; (b) H_2SO_4 (circles: 0.05N; triangles: 0.1N; squares: 0.5N); (c) K_2SO_4 (circles: 0.05N; triangles: 0.1N; squares: 0.5N).

fore the onset of sparking. X-ray analysis, performed on foils not chemically etched but anodized in the same solutions, showed clear evidence of crystallization only after prolonged sparking. We think the texture identifies thicker crystalline areas. These results must be taken with caution, because it is known from the literature that the crystallization of ZrO_2 films is strongly affected by the nature of the solution, the anodization technique, the thickness of the film, and the initial surface treatment (12, 20).

Fig. 4. SEM micrograph of a film grown in 1M $\text{NH}_2\text{SO}_3\text{H}$ at $i = 16 \text{ mA cm}^{-2}$ above the first spark voltage.

Table I. Film thickness values at the breakdown voltage calculated by means of Fromhold theory (26) (L_c^{calc}), and estimated on the basis of the interference colors (L_c^{exp}), for films grown in different solutions at various c.d.'s. A mean refractive index equal to 2.2 was assumed for the estimation of L_c^{exp}

i (mA cm^{-2})	H_2SO_4 0.05N		K_2SO_4 0.1N	
	L_c^{exp} (\AA)	L_c^{calc} (\AA)	L_c^{exp} (\AA)	L_c^{calc} (\AA)
24	4000	3970	3900	4000
16	3750	3820	3700	3800
12	3600	3630	—	—
8	3250	3380	3300	3420
6	3150	3210	—	—
4	2800	2830	2700	2760

* The kinetic parameters are assumed equal to those already published for 0.1N H_2SO_4 solution (19).

The sparking phenomenon could be observed also in the case of fractured films as shown in Fig. 5. In this case, the sparking seems to occur preferentially along the edges of the fissures.

The values of the cell voltage at which sparking began (V_{FS}) were identified either by visual inspection or from the first oscillation recorded in the galvanostatic $V-t$ curves (see Fig. 1). This V_{FS} value was reproducible, and the V_{FS} values used here are the average for different experiments performed under similar conditions (a very small influence of the surface finish was observed).

In Fig. 6, we report the dependence of V_{FS} on the value of current density for different electrolytic solutions. A constancy in the V_{FS} value is observed in sulfamic acid solutions, while a linear dependence on c.d. value is observed for carbonate and sulfate solutions. Moreover, the linear dependence is valid, regardless of the kind of anodic growth curves obtained, that is, types a, b, c in Fig. 1.

In Fig. 7, is reported the dependence of V_{FS} on the resistivity of the electrolytic solutions. As reported for other MOE systems (21-24) the experimental values (at a fixed i) follow a relationship

$$V_{\text{FS}} = a + b \log \rho \quad [2]$$

where a and b are constants and ρ is the resistivity of the electrolytic solution. For films grown in $\text{NH}_2\text{SO}_3\text{H}$ solutions, the a and b values are independent of the anodizing current density values according to the results of Fig. 6. In the case of sulfate containing solutions, the a and b constants are dependent on the anodizing current as reported in Table II.

In Table III, we report the estimated film thicknesses and the average electric fields at the first spark voltages for different sulfamic acid solutions at various c.d.'s.

Discussion

The experimental results outlined here for the Zr/ZrO₂/electrolyte system provide new information on the breakdown of anodic oxide films grown in various electrolytic solutions. We stress the fact that two different kinds of phenomena are involved in the breakdown of the system. They are not mutually exclusive, but these two phenomena are governed by experimental parameters in different ways.

In the solutions where mechanical breakdown occurs, the most important parameter in determining the V_{mb} value seems to be the anodizing current density. This influence can be explained by assuming that mechanical failure of the films occurs when a critical thickness, L_c , is reached at which the internal stresses exceed the

1M NH ₂ SO ₃ H	32	2910	5.97
1M NH ₂ SO ₃ H	16	3000	5.79
1M NH ₂ SO ₃ H	8	3120	5.58

mechanical strength of the film. The critical thickness is related to the breakdown voltage by

$$V_{mb} = \bar{E} \cdot L_c \quad [3]$$

where \bar{E} is the average anodizing electric field strength.

According to this hypothesis, the internal stresses must increase with the film thickness. This appears in conflict with the results of Leach and co-workers (8, 12), which show nearly constant stresses in ZrO₂ films formed on chemically etched Zr anodized above 80V in ammonium borate as well as in carbonate solutions. Moreover, they have shown that the stresses measured at different c.d.'s decrease with increasing c.d. in a range of current densities analogous to that exploited in our measurements. It must be stressed, however, that in our experimental conditions bending was biaxial rather than uniaxial (8, 12).

If the results obtained by Leach and co-workers are representative of the behavior of ZrO₂ films grown in our conditions, an explanation is needed for the mechanical breakdown of ZrO₂ films in the presence of a constant compressive stress. We suggest that the stress distribution normal to the surface of the film is not uniform, but rather changes with thickness in such a way that the average value remains constant.

In this frame, the results obtained in sulfate solutions are quite well explained by saying that, according to Leach *et al.*, greater mean stresses and anodizing ratios ($\Delta D/\Delta V$) combine to lower the V_{mb} values at low c.d.'s.

In the case of breakdown at constant film thickness (0.1N H₂SO₄ solution at $i \geq 8 \text{ mA cm}^{-2}$ and carbonate solution), the interpretation of the mechanical breakdown requires further hypothesis about the effect of anion incorporation on the mechanical properties of ZrO₂ films grown in these solutions. We suggest that the level of impurity content into the films lowers the mechanical strength of these films. This suggestion is based on the following findings: (i) in sulfamic acid solutions, where the incorporation phenomenon has been supposed to be absent (19), higher film thicknesses were reached without appearance of mechanical breakdown (compare Tables I and III), (ii) according to Leach and Pearson [see

Fig. 5 and 6 of Ref. (12)], lower compressive stresses are observed in carbonate solution in a range of c.d. where higher anion incorporation occurs (27); as reported in Fig. 5 of Ref. (12), the compressive stress measured in carbonate solution at the critical thickness is halved by increasing c.d. from 6 to 10 mA cm⁻², and (iii) according to our results, the mechanical breakdown occurs in carbonate solution at constant thickness ($L_c \cong 4000\text{\AA}$) for films grown at $i \geq 6$ mA cm⁻², which is the range of c.d. where a steep increase of carbonate incorporation has been observed (27).

The same interpretative hypothesis could explain the experimental findings in 0.1N H₂SO₄ solution at $i \geq 8$ mA cm⁻², if the dependence of internal stresses upon c.d. is supposed to be analogous to that observed in ammonium borate and carbonate solutions. Further investigations on these aspects are necessary before reaching a firm conclusion.

The different values of A_{mb} and B_{mb} obtained for films grown in different electrolytic solutions should reflect the complex role played by the electrolyte in the kinetics of growth as well as in the mechanical properties of the films due to the incorporation of anions. A more quantitative analysis of the experimental data should need a knowledge of the laws of variation of internal stresses with oxide thickness in each solution at each current density.

At this point, it is important to note that the observed absence of any influence of the resistivity of the electrolytic solution on V_{mb} values suggests that no direct effect should be assigned to the solution in determining the mechanical breakdown of ZrO₂ anodic films, although an indirect effect can arise through the anion incorporation phenomenon (27, 28). By taking into account all of these findings, it would appear that the most likely source of stresses during the growth of these films at the metal/oxide interface is the volume change accompanying oxide formation. A Pilling-Bedworth ratio higher than unity [$V_{molar}^{ZrO_2}/V_{molar}^{Zr} = 1.56$ (29)] and a very low transport number of cation (30) suggest the existence of compressive stresses inside the films. The increase, with increasing film thickness, of local stresses to a critical value which should be dependent only on the bulk properties of ZrO₂ films, then causes the mechanical failure of the films. In fact, the above-mentioned absence of influence of the solution resistivity seems to exclude any effect of the interfacial tension on the mechanical breakdown of the investigated systems.

For the sparking phenomena, the experimental results fall into one of two groups, according to the nature of the electrolytic solution: (i) nonincorporating solutions [sulfamic acid solutions (19, 31)] in which there is no influence of the anodizing current density on the V_{FS} values, and (ii) incorporating solutions [sulfate and carbonate containing solutions (27)] which show a clear influence of the anodizing current density on V_{FS} values.

A linear dependence of V_{FS} on the logarithm of the solution resistivity was found experimentally for both kinds of solutions.

According to the electron ionization avalanche mechanism, an increase of the internal electric field and/or the dielectric film thickness enhances the multiplication of electrons which are injected at the cathode (in MOE systems, the oxide/electrolyte interface). This is in qualitative agreement with the results in sulfamic acid solutions, where sparking occurred with thinner films in the presence of a higher anodizing electric field (see Table III).

The strong influence on the V_{FS} values of the electrolytic solution, which is reflected in the V_{FS} vs. $\log \rho$ relationship, suggests that the electron injection levels at the oxide/electrolyte interface affect the sparking phenomenon. A quantitative analysis of sparking phenomena requires a knowledge of the laws governing electronic injection at this interface for each MOE system. However, a preliminary analysis on the basis of Ikonopisov's model (17) of electrical breakdown for MOE systems shows that

present experimental results are in agreement with the essential features of this model. In fact, both the nearly constant values of V_{FS} with the ionic current density and the V_{FS} vs. $\log \rho$ relationship agree with the theoretical predictions of the model. However, the discrepancies between the model and the experimental results obtained in sulfate and carbonate containing solutions (chiefly the strong dependency of V_{FS} on the anodizing current) could be associated with the incorporation of sulfate and carbonate anions (27, 28) which could modify the solid-state properties of the anodic films.

It has been reported that: (i) the amount of anion incorporation in ZrO₂ anodic films is strongly dependent on the c.d. and the local pH of solution (12, 27); (ii) the value of dielectric constant decreases with increasing anion incorporation (19, 33, 34).

These facts help explain the results in Fig. 6 for carbonate and sulfate solutions if we recall that according to Ikonopisov's model (17) the electron injection level at the oxide/electrolyte interface controls the V_{FS} value. Moreover, in the model recently proposed by Christov (18) the electronic current injected at this interface can be written

$$i_{el} = i_0 \exp \alpha \left(\frac{\bar{E}}{\epsilon_i} \right)^{1/2} \quad [4]$$

where i_0 and α are constants which depend only on the temperature and on the oxide/electrolyte interface and ϵ_i is the dielectric constant of the film.

Perhaps the main effect of anion incorporation is to decrease ϵ_i and hence increase the electron injection level at the oxide/electrolyte interface in such a way as to make the dependence of V_{FS} on the applied current density more pronounced. According to this, the results of Fig. 6 suggest that the influence of c.d. on anion incorporation should be stronger in more dilute acidic solutions (0.1N H₂SO₄) as well as in concentrated neutral solutions of carbonate. In this last case, a very strong influence of the c.d. on the incorporation phenomenon has been reported (27).

Conclusions

The results of this work illustrate the complex nature of the breakdown processes in MOE systems. It has been shown that both "mechanical" and "electrical" breakdown can occur during the anodization process. Each type of breakdown occurs in a different way and depends on the anodizing parameters in a different way. In the case of ZrO₂/electrolyte systems, it has been shown that the conditions favoring electrical breakdown are high c.d. and/or low electrolytic resistivity. The appearance of electrical breakdown is always associated with a rapid end to film growth. In the case of mechanical breakdown, although the rate of film growth is decreased, a second linear but slower dV/dt relationship is observed, until sparking eventually puts an end to film growth.

The phenomenon of mechanical breakdown suggest fracture brought about by critically large internal stresses, associated with the volume increase when metal is converted to oxide.

The incorporation of anion, which affects mechanical breakdown through a mechanism of relaxation of internal stresses (11) and by changing the mechanical strength of the films, is thought to influence the electrical breakdown of the films in such a manner as to increase the electronic injection current at the oxide/electrolyte interface.

A better knowledge of the electron injection process at this interface during the film growth seems necessary for improving the quantitative agreement between experimental data and theoretical analysis of the sparking phenomena.

Plasma Etching of Oxygen Containing Titanium Silicide Films

F.Y. Robb*

Motorola, Incorporated, Process Technology Laboratory, SRDL, Phoenix, Arizona 85008

ABSTRACT

Anisotropic etching of titanium silicide is essential if its low resistivity gate properties are to be utilized on scaled MOS devices. CCl_4 and CF_4 plasmas, as well as ion milling, were used to etch composite titanium silicide/polysilicon films, with each displaying definite drawbacks. CCl_4 plasmas yielded rough etching and etch residue, presumably due to the high oxygen content of the silicide film and the relatively high selectivity (low oxide etch rate) of the etch. CF_4 reactive ion etching and ion milling produced smooth etching but lacked the selectivity to stop on thin underlying gate oxides. A combination of these processes, however, provided successful anisotropic patterning of such structures. A nonselective, smooth etching CF_4 reactive ion etch was used to etch through the silicide layer, followed by a higher selectivity Cl_2 plasma etch through the underlying polysilicon down to the thin gate oxide.

Anisotropic etching of titanium silicide is essential if its low resistivity is to be utilized on scaled MOS devices.

Increases in packing density and complexity of MOS devices have increased the importance of the interconnect technology (1, 2). With the sheet resistance of even the most heavily doped polysilicon greater than $15 \Omega/\square$, the advantages of further scaling will soon be offset by the interconnect resistance at the gate level. The selection of a lower resistivity gate material, together with the shortening of interconnect lengths by circuit designers, is essential in order to take advantage of the higher switching speeds of scaled down devices.

The low resistivity refractory metal silicides, with sheet resistances over an order of magnitude lower than polysilicon (3, 4), offer an attractive alternative. Replacing polysilicon entirely with the silicide, however, entails major changes in device design and processing and, perhaps most importantly, introduces an interface at the gate oxide of questionable stability. Thus, the more conservative approach has been to replace enough of the doped polysilicon with the silicide to achieve the desired resistance goal, but not so much as to cause a change in the ef-

fective metal-semiconductor work function (and thereby gate threshold voltage).

Since titanium silicide (TiSi_2) has one of the lowest resistivities of the refractory metal silicides, very low resistivity titanium polycide gates can be achieved. In fact, a titanium polycide structure of 1500\AA of silicide over 1500\AA of polysilicon has a composite resistance of 1 to $2 \Omega/\square$ (5), more than an order of magnitude lower than straight doped polysilicon.

The etchability of titanium silicide is, of course, one of the prime processing considerations. Anisotropic etching is essential in order to produce the fine patterns required for scaled MOS devices.

Little information is available on the etching of titanium silicide. Wang *et al.* (6) have reported the successful use of chlorine plasma etching for the patterning of composite TiSi_2 /polysilicon gate structures, but found an extreme sensitivity to contamination in the film and required that the oxygen level in the film be less than 0.5%. In practice, obtaining such a low oxygen content in titanium silicide films is difficult and perhaps unnecessary, as resistances as low as $1 \Omega/\square$ have been obtained on films containing 5% oxygen (5).

The plasma-etch characteristics of oxygen containing titanium silicide films is the subject of the present study. CCl_4 and CF_4 reactive ion etching, as well as ion milling, will be detailed and contrasted. Successful anisotropic etching could not be accomplished in any one-step etch; it required two etch steps. The first step used a low silicon-to-oxide etch-rate ratio to etch smoothly through the oxygen containing silicide. The second step, in contrast, utilized a high silicon-to-oxide etch-rate ratio to pattern the underlying polysilicon and stop on the thin gate oxide.

Experimental

Etch systems.—Several different etch systems were used in this study.

CCl_4 plasma etching was studied in a single-wafer planar reactor. The top electrode was powered (13.56 MHz), while the etching wafer was placed on the lower grounded electrode. An upper-to-lower electrode-area ratio of 2 to 1 was utilized. All surfaces exposed to the plasma were passivated with an anodized aluminum coating. Wafer cooling was provided by a cold (10°C) plate physically affixed to the lower electrode. A gas mixture of 8 sccm CCl_4 , 7 sccm Ar, 8 sccm N_2 , and 3 sccm H_2 , at $300\ \mu\text{m}$ with $1\ \text{W}/\text{cm}^2$ was used. This process was developed for anisotropic etching of N^+ polysilicon.

CF_4 etching was performed in two reactors.

Initial CF_4 studies utilized a laboratory-scale diode configured reactor. The wafers were positioned on the smaller powered (13.56 MHz) electrode, while the outer chamber walls acted as the grounded anode. The chilled (10°C) cathode, which held nine 3 in. substrates, was covered with a thin silicon plate to minimize metallic contamination. A flow rate of 7 sccm CF_4 , with a $100\ \mu\text{m}$ pressure, and $0.55\ \text{W}/\text{cm}^2$ was used.

The temperature dependence of CF_4 etching was measured in a Perkin-Elmer Omni-Etch Cornerstone single-wafer etcher, where the wafers were physically clamped to a temperature-controlled lower electrode. The system had a powered (200 kHz) porous graphite top electrode. A flow rate of 50 sccm CF_4 , with a $800\ \mu\text{m}$ pressure, and $1.5\ \text{W}/\text{cm}^2$ was used.

The Cornerstone was also used for low frequency Cl_2 plasma etching of polysilicon in the second step of the two-step polycide etch process. Process conditions used were 100 sccm Cl_2 , $800\ \mu\text{m}$ pressure, $0.7\ \text{W}/\text{cm}^2$, and a 5°C lower electrode. No undercutting of even highly doped N^+ polysilicon was observed.

All plasma-etch systems used standard rotary pumps and maintained base pressures of between 20 and $40\ \mu\text{m}$. Mass flowmeters were used to monitor gas flow and pressure was measured with capacitance manometers.

Ion milling was performed in the Veeco Microetch system, which utilized a 10 in. diffusion pump and a Kaufman-type ion gun. Typical milling conditions were $0.4\ \text{mA}/\text{cm}^2$, 600V, and 9.0×10^{-4} torr argon pressure. Milling angles between 0° and 15° were studied.

Sample preparation and analysis.—Titanium silicide films were cosputtered in a Sputtered Films, Incorporated, Research System with a Ti:Si ratio of 1:2.2. At this composition, the resistivity after anneal was about $17\ \mu\Omega \cdot \text{cm}$.

Auger electron spectroscopy (AES), in conjunction with sputter profiling, was used to analyze the samples as a function of depth. As shown in Fig. 1, deposited films were uniform, incorporated an atomic oxygen concentration of about 5%, and had a native oxide thickness of between 50 and $100\ \text{\AA}$. After anneal, the bulk oxygen content decreased slightly, as apparently some of the oxygen diffused to the surface to react with Ti or Si. The surface oxide thickness after anneal was about twice that of the nonannealed films.

Unannealed pure titanium films, sputter-deposited in the same system, were etched for comparison. AES profiling showed a similar oxygen content and native oxide as for the unannealed silicide.

Fig. 1. Auger depth profile of an as-deposited $\text{TiSi}_{2.2}$ film. This film was deposited directly on thermal oxide.

The TiSi_2 film was typically $1500\text{--}2000\ \text{\AA}$ thick and deposited directly on a $2000\ \text{\AA}$ thick polysilicon film. Underlying the polysilicon was gate oxide. The polysilicon was phosphorus doped via either standard ion-implantation techniques or by 950°C PH_3 diffusions. In most cases, no annealing of the $\text{TiSi}_2/\text{poly}$ was done prior to etch, although where specified a 950°C , 30 min N_2/H_2 anneal was utilized. On these samples, a $1000\ \text{\AA}$ CVD oxide cap was deposited on top of the silicide to stop out-diffusion of phosphorus from the underlying polysilicon. The cap was removed via CHF_3 reactive ion etching after photoresist masking but before subsequent polycide etching.

KTI II and AZ-1350J positive photoresists, as well as trilevel (7, 8) plasma oxide/HPR-204 masks, were used to produce patterned samples.

Analytical techniques.—Silicide and resist rates were calculated from etch depth measurements made on the Tencor 10-0020 Alpha Step. Polysilicon and oxide rates were calculated from thickness measurements made on an IBM 7840 Film Thickness Analyzer.

The surface roughness as a function of the etch technique was quantified with reflectance data from the IBM 7840. The reflectance of each sample was measured and plotted as a function of wavelength from 4300 to $7000\ \text{\AA}$. In order to simplify data reporting, an "average" reflectivity was calculated from the maximum and minimum reflectances, as shown below

$$R = \frac{R_{\text{max}} + R_{\text{min}}}{2}$$

All reflectivities are reported as a percentage of an evaporated aluminum standard measured at the same time.

Cross-sectional scanning electron micrographs (SEM's) of patterned samples were utilized to determine etch anisotropy.

AES was used to analyze the cleanliness of etched surfaces.

Results and Discussion

CCl_4 etching.—Table I summarizes the etch data from the single-wafer etcher. The unannealed silicide etched at about the same rate as polysilicon, whereas the annealed silicide etched about 20% more slowly. In addition, the pure titanium etch rate was considerably higher than that of either polysilicon or the silicide. The fast titanium rate was unexpected, considering the reported volatilities of the expected etch products. SiCl_4 , the more volatile product, has a vapor pressure of 1 torr at -63.4°C , while TiCl_4 has a similar vapor pressure at -13.9°C (9).

A simple evaporation model allows an estimate of the maximum TiSi_2 etch rate achievable from evaporation only. The model assumes thermal equilibrium, so that the number of molecules condensing must equal the number evaporating. From simple kinetic theory, the number condensing is assumed to be $1/4 n\bar{v}$, where n is the num-

Table I. CCl_4 plasma etch data from the single-wafer etcher with 8 sccm CCl_4 , 7 sccm argon, 8 sccm N_2 , and 3 sccm H_2 , a 300 μm pressure and 1 W/cm^2

Film	Etch rate ($\text{\AA}/\text{min}$)	Etch residue	Anisotropy* (with resist mask)
Titanium silicide			
Unannealed	2300	Dense	Good
Annealed	1800	Moderate	Good
Polysilicon	2200	None	Excellent (undoped) Good (N^+ poly)
Titanium	3400	Dense	Good

Positive resist	800	—	—

* "Excellent" means zero undercut with 50% overetch. "Good" means zero undercut with 10% overetch and slight notching with 50% overetch. "Fair" means very slight undercut with 10% overetch.

ber of molecules per cubic centimeter and \bar{v} is the average molecular speed. Using this model and the above vapor-pressure data, a maximum TiSi_2 etch rate of $10^7 \text{\AA}/\text{min}$ is calculated. The poor agreement with the measured etch rate of 2300 $\text{\AA}/\text{min}$ indicates that evaporation is not the rate-limiting step of the etch mechanism.

Figure 2 shows composite titanium silicide/polysilicon films etched in the CCl_4 process. The anisotropy of the CCl_4 etch was good, with no undercutting observed for a 10% overetch and only very slight notching with a 50% overetch. Etch residue, however, plagued the etch. The

Fig. 2. Composite 2 k\AA titanium silicide/2 k\AA polysilicon films etched in the CCl_4 process. The bottom film was annealed and etched in CHF_3 to remove its CVD oxide cap, before the CCl_4 etch. Both samples were given a 10% overetch. The resist mask remains to demonstrate anisotropy.

residue was presumed to be simply unetched polysilicon, since Auger analysis of etched surfaces found only silicon, oxygen, and carbon. Because N^+ poly was used for the polycide gate, the residue provided conductive paths and was therefore unacceptable. Although longer overetches somewhat reduced the residue height and density, the thin underlying gate oxide prohibited this.

The etch residue was attributed to rough etching of the TiSi_2 layer. Reflectivity, which provides a quantitative measure of the roughness is plotted as a function of etch depth in Fig. 3. Within experimental error, no differences can be seen between the unannealed silicide and pure titanium films. Both became extremely rough as etching proceeded. This roughness, which was then replicated into the underlying polysilicon layer, resulted in the etch residue. The annealed silicide, surprisingly, etched much more smoothly. In addition, the reflectivity of virgin polysilicon as a function of depth is also plotted for comparison and shows that polysilicon films by themselves etched quite smoothly.

The rough etching was attributed to both the presence of a native oxide and to the relatively high oxygen content of titanium containing films. Auger analysis revealed that all the titanium containing films had more than an order of magnitude more oxygen than polysilicon. In addition, although the thickness of the native oxide on both polysilicon and unannealed TiSi_2 films was comparable (50 \AA), the oxide on the silicide contained titanium. The "toughness" of titanium oxide is well known to ion millers (10), as it is reported to have one of the lowest known milling rates.

The relatively low oxide etch rate of the CCl_4 process meant submicron sized "oxide" inclusions in/on the film would act as micromasks, blocking etching of the underlying material. Rough etching, and ultimately etch residue, would result.

The role of the bulk vs. surface oxide was separated by comparing the two samples shown in Fig. 2. The annealed sample, which was given a CHF_3 pre-etch to remove its CVD oxide cap (and would also remove any native oxide), showed a much cleaner etched surface than the unannealed sample. A similar CHF_3 pre-etch of unannealed films also produced cleaner etching. Since both films still yielded etch residues even after native ox-

Fig. 3. Reflectivity as a function of etch depth for the CCl_4 plasma etch. The silicide films were 2 k\AA titanium silicide/2 k\AA polysilicon. The polysilicon and pure titanium films were 4 k\AA and deposited directly on 1 k\AA gate oxide.

ide removal, however, bulk oxides as well as surface oxides contribute.

The use of lower selectivity etches (those with higher oxide etch rates) to eliminate the rough etching and etch residues is expanded below. Both ion milling, with silicon-to-oxide selectivities on the order of 1/1, and CF_4 reactive ion etching, where the selectivity was even less than 1/1, are considered.

Ion milling.—Argon ion milling was investigated as a function of the incidence angle as it was varied from 0° to 15° . Within experimental error, the etch rates of titanium silicide, silicon dioxide, and positive resist did not vary with angle in this range and were 170, 200, and $125 \text{ \AA}/\text{min}$, respectively. In addition, the silicide rate did not depend on whether the film was annealed prior to etch.

The low selectivity ion milling produced much smoother etching than with CCl_4 , as evidenced by a comparison of Fig. 3 and 4. Unlike the CCl_4 etch, however, annealed silicides etched more roughly than unannealed silicides. This rougher etching was attributed to the already rougher surface of the annealed silicide before etch. The well-known milling rate dependence on angle (10) would cause a rough surface to further roughen as etching proceeds.

Trenching and shadowing during the milling of actual titanium silicide features prohibited its successful use, despite its much smoother etching in open areas. A 0° incidence angle produced severe trenching along etched features. As the angle was raised from 0° to 15° , the severity of the trenching decreased, with trenching only present around isolated features at 15° . Shadowing, or slower etching between closely spaced features, however, appeared with increasing intensity as the angle was increased from 5° to 15° . Thus samples milled at 15° showed both shadowing and trenching depending on the geometry/pitch of the etching features. In short, an optimum set of conditions, one where neither trenching nor shadowing occurred, could not be found.

CF_4 etching.—Reactive ion etching with fluorine containing gases was also studied as a means of reducing the silicon-to-oxide selectivity in order to produce smooth etching of titanium containing films. Both CHF_3 and CF_4 plasmas were characterized, but since the trends/results of each were similar, only the CF_4 data will be discussed here.

Table II lists the etch rates, surface smoothness during etch, and the anisotropy obtained when utilizing a CF_4 reactant in the diode-configured reactor. The silicide etched at the same rate as polysilicon but faster than pure titanium. In addition, both thermal oxide and positive photoresist etched faster than titanium silicide and polysilicon, limiting any practical application.

Fig. 4. Reflectivity as a function of etch depth for argon ion milling of 2 k\AA titanium silicide/ 2 k\AA polysilicon. The reflectivity was independent of milling angle, within the 0° - 15° range studied.

Table II. CF_4 etch data from the laboratory-scale diode reactor with 7 sccm CF_4 , $100 \text{ }\mu\text{m}$ pressure and $0.55 \text{ W}/\text{cm}^2$

Film	Etch rate ($\text{\AA}/\text{min}$)	Etch texture	Anisotropy* (with resist mask)

Polysilicon	125	Smooth	Good-Fair
Titanium	60	Smooth	Excellent
Thermal SiO_2	445	—	—
Positive resist	250	—	—

* See Table I for anisotropy definitions.

The anisotropy of titanium containing films etched in CF_4 was excellent. No undercutting was ever seen for titanium silicide, while polysilicon films were undercut somewhat during extended overetches. This lower reactivity of titanium films in CF_4 is attributed to the low volatility of the expected product, TiF_4 . No vapor pressure data is available on TiF_4 , as it is reported in the literature simply as a white solid having a density of $2.8 \text{ g}/\text{ml}$ which sublimates at 284°C (11).

This low volatility is, however, evidenced by the strong temperature dependence of the CF_4 etch rate of titanium silicide. Figure 5 shows data collected in the single-wafer CF_4 plasma etch. No measurable etching occurred with the wafer clamped to a 5°C electrode, while the etch rate increased from 950 to $1350 \text{ \AA}/\text{min}$ as the temperature was increased from 25° to 60°C .

The reflectivity as a function of etch depth for CF_4 etching in the diode-configured reactor is shown in Fig. 6. The unannealed silicide and pure titanium films etched very smoothly, as evidenced by the flat reflectivity. The annealed silicide, however, etched quite roughly. This trend is similar to, although more dramatic than, that observed for ion milling (see Fig. 4). The reason for the rough etching after annealing is not clear, but may be simply that, as for ion milling, the rougher surface on annealed films "facets" during etching due to an angle dependence of the etch rate.

Figure 7 compares the surface roughness of partially etched annealed and unannealed polycide samples. In addition to the obvious differences in surface texture, the SEM inspection showed no undercutting of the silicide or any problems such as trenching or shadowing.

The reverse selectivity of the fluorine-based processes makes them unsuitable for complete etching of a polycide structure. Calculations show that polysilicon-to-oxide selectivities of at least 10/1 are needed for successful etching over thin (150\AA) gate oxide. Etches with selectivities that high, however, produced rough etching of oxygen containing $TiSi_2$. The solution is a two-step etch. The first step requires a low selectivity to oxide to etch

Fig. 5. The titanium silicide and polysilicon etch rates as a function of temperature in the Perkin-Elmer Cornerstone CF_4 etch process.

Fig. 6. Reflectivity as a function of etch depth for CF_4 reactive ion etching. The silicide films were $2 \text{ k}\text{\AA}$ titanium silicide/ $2 \text{ k}\text{\AA}$ polysilicon. The titanium film was $4 \text{ k}\text{\AA}$ and deposited directly on gate oxide.

smoothly through the silicide, the second a high selectivity to oxide to stop at the thin underlying gate oxide.

Fig. 7. Composite $2 \text{ k}\text{\AA}$ titanium silicide/ $2 \text{ k}\text{\AA}$ polysilicon films partially etched (stopped in the poly layer) in CF_4 in the laboratory scale diode reactor. The bottom film was annealed before etch. The photoresist remains on both samples.

Fig. 8. Unannealed $2 \text{ k}\text{\AA}$ titanium silicide/ $2 \text{ k}\text{\AA}$ polysilicon film etched via a two-step process. Step one utilized a CF_4 reactive ion etch through the silicide. Step two was a Cl_2 plasma polysilicon etch. The photoresist remains to demonstrate anisotropy.

Two-step etching.—This section details a specific two-step etch of unannealed titanium polycides. The first step was a CF_4 reactive ion etch through the silicide, stopping in the polysilicon. The second step was a low frequency Cl_2 plasma etch of the underlying polysilicon. Figure 8 shows a sample etched via this process. Anisotropic etching with very little etch residue resulted.

The two-step etch, however, also had drawbacks. The first was simply that it was a two-step two-reactor process. A successful one-step process would certainly be more desirable. The second was that the etch selectivity with respect to photoresist was extremely poor, owing to the CF_4 etch, where resist was removed at more than twice the rate of the silicide. Trilevel resist processing (7, 8) was utilized, however, to produce the very thick sub-micron-sized resist patterns needed to mask this two-step process. In this manner, titanium polycide gates as small as $0.5 \mu\text{m}$ have been produced.

Certainly other two-step etch processes should work equally well. Chlorine-based plasmas produced smooth etching of oxygen containing TiSi_2 , when the silicon-to-oxide selectivity was reduced to less than 2/1. Higher power densities, lower pressures, and hydrogen addition were combined to produce the low selectivity needed for the first step in a two-step, one-reactor etch. In addition, the resist-removal rate in the "all-chlorine" etch was substantially less than with CF_4 .

Conclusions

Successful anisotropic etching of oxygen containing titanium silicide/polysilicon films could not be achieved in conventional one-step plasma etches. Selective, anisotropic chlorine-based plasmas produced unacceptably rough etching of the titanium silicide, presumably because "oxide" micromasks in/on the silicide block etching of the underlying material. Although the low selectivity of either CF_4 reactive ion etching or ion milling enabled smooth etching of unannealed silicide, the inability to stop on underlying gate oxide limited any practical application. A two-step etch, utilizing a low selectivity etch to smoothly "mill" through the silicide, followed by a high selectivity etch of the polysilicon down to the thin gate oxide, produced residue-free anisotropic etching of oxygen containing titanium polycide films.

Acknowledgments

The author wishes to thank Dr. Clarence Tracy for his helpful comments and suggestions during the etch evaluations, and for his review of this paper. Also, the film deposition and analysis performed by Carl Aspin and

Jerry Adams, and Auger analysis by Mike Kottke were greatly appreciated.

Thermal Diffusion Effects in Chemical Vapor Deposition Reactors

Joel P. Jenkinson and Richard Pollard*

Department of Chemical Engineering, University of Houston, Houston, Texas 77004

ABSTRACT

A mathematical model that describes the behavior of chemical vapor deposition reactors with well-defined hydrodynamics has been extended to include the effects of multicomponent thermal diffusion. The influence of thermal diffusion on the deposition rate is dependent on the deposition system and on the operating conditions of the reactor. For production of silicon by reduction of silicon tetrachloride in excess hydrogen, deposition rates are typically lowered by 15-20%. However, for deposition of boron from boron trichloride and hydrogen, thermal diffusion can raise growth rates by approximately 7% when concentrated inlet gas mixtures are used.

Chemical vapor deposition (CVD) processes are widely used in the manufacture of electronic materials and in the formation of surface coatings. Several theoretical descriptions of CVD systems have been proposed (1-15). However, the complex nature of the coupled multicomponent transport phenomena and reaction kinetics has necessitated the incorporation of many assumptions into these models. As a result, the physical factors that control the behavior of CVD reactors are only partially understood. In particular, the role and relative importance of thermal diffusion in CVD processes is a subject of controversy. Some workers feel that it can be neglected (12), whereas others state that it needs to be considered because temperature gradients are large and because there are substantial differences in the molecular weights of the reactants (13). An approximate model based on constant binary thermal diffusion ratios indicates that deposition rates could be altered significantly (15, 16). However, an order of magnitude analysis suggests that the opposite is true (12). A detailed investigation is needed to clarify the specific effects of thermal diffusion on the behavior of CVD processes.

In this paper, a previous analysis (10, 15) of CVD reactors is extended to include multicomponent thermal diffusion. Comparisons of simulations with and without thermal diffusion terms in the heat and mass transport equations are used to illustrate the effects of thermal diffusion on the performance of CVD reactors. Quantitative results are obtained for two representative CVD systems: deposition of silicon at a rotating disk, using SiCl_4 in excess hydrogen (17); and deposition of boron from BCl_3 and hydrogen, using an impinging jet apparatus (18).

Analysis

A steady-state model for CVD systems with an arbitrary number of chemical species has been developed previously (10, 15). The analysis includes multicomponent transport phenomena, variable physical properties, finite interfacial velocity, and simultaneous homogeneous and heterogeneous reactions. The governing equations are summarized in Table I. For laminar flow in geometries

such as the rotating disk or impinging jet, Eq. [5] and [6] can be transformed into a set of ordinary differential equations, and the problem becomes one-dimensional. Also, at atmospheric pressure, it is reasonable to neglect pressure variations across the diffusion layer (10) and, hence, to use only two Navier-Stokes relations (Eq. [5]). Boundary conditions for the velocity components v_r and v_θ are dependent on the flow system (10, 15). However, the axial velocity v_z at the substrate surface is determined by the heterogeneous reaction rates, as indicated by Eq. [11]. Surface compositions are obtained with Eq. [1] and [3]. Far from the substrate, the inlet gas is assumed to be at equilibrium at the inlet gas temperature.

When thermal diffusion is included in the analysis, the multicomponent diffusion equation for an isobaric system becomes (19)

$$c_i \nabla \mu_i = RT \sum_{k \neq i} \frac{c_i c_k}{c_T \mathfrak{D}_{ik}} \left[v_k - v_i + \left(\frac{D_k^T}{\rho_k} - \frac{D_i^T}{\rho_i} \right) \nabla \ln T \right] \quad [12]$$

The last term on the right-hand side of Eq. [12] represents the contribution of the temperature gradient to mass transport. The method for calculating values of the multicomponent thermal diffusion coefficients D_i^T is given in the Appendix. If gas behavior is ideal, Eq. [12] may be rewritten in dimensionless form as

$$\nabla x_i - k_i^T \nabla \ln T = \sum_{k \neq i} \frac{(x_i J_k - x_k J_i)}{D_{ik}} \quad [13]$$

where D_{ik} is a dimensionless diffusion coefficient for binary interactions defined by

$$D_{ik} = c_T \mathfrak{D}_{ik} / c_{\infty} v_z \quad [14]$$

and k_i^T is a dimensionless multicomponent thermal diffusion ratio given by

$$k_i^T = \sum_{k \neq i} \frac{(x_i M_i D_k^T - x_k M_k D_i^T)}{M_i M_k c_{\infty} v_z D_{ik}} \quad [15]$$

Table I. Governing equations for CVD processes (10, 15). Description of steady-state equations for system with n species in gas phase: [1] multicomponent diffusion equation; [2] material balance; [5] Navier-Stokes equation of motion for Newtonian fluid; [6] continuity equation; [7] ideal gas equation of state; [9] thermal energy equation; [10] law of mass action to predict homogeneous production rates (equation used to eliminate R_i in Eq. [2] and [9]); [11] boundary condition for axial velocity at surface due to heterogeneous reactions.

Variable	Equation	Number of equations	Equation number
\underline{J}_i	$x_i \left(\nabla \mu_i - \frac{M_i \nabla p}{\rho} \right) = \sum_{k \neq i} \frac{x_i \underline{J}_k - x_k \underline{J}_i}{c_T \mathcal{D}_{ik}}$	$n - 1$	[1]
x_i	$\nabla \cdot \underline{J}_i = R_i - c_T \underline{v} \cdot \nabla x_i + c_i \underline{v} \cdot \nabla \ln \bar{M}$	$n - 1$	[2]
—	$\sum_i x_i = 1$	1	[3]
—	$\sum_i M_i \underline{J}_i = 0$	1	[4]
v_r, v_θ, v_z	$\rho \underline{v} \cdot \nabla \underline{v} = -\nabla p + \rho \underline{g} + \nabla \cdot \left[\mu \nabla \underline{v} + \mu (\nabla \underline{v})^T - \frac{2}{3} \mu \underline{I} \nabla \cdot \underline{v} \right]$	3	[5]
p	$\nabla \cdot (\rho \underline{v}) = 0$	1	[6]
c	$p = c_T R T$	1	[7]
ρ	$\rho = \bar{M} c_T$	1	[8]
T	$c_T \bar{C}_p \underline{v} \cdot \nabla T = \nabla \cdot (k \nabla T) + \underline{v} \cdot \nabla p - \sum_i (\underline{J}_i \cdot \nabla \bar{H}_i + \bar{H}_i R_i)$	1	[9]
R_i	$R_i = -\sum_{l=1}^{l_h} \nu_{il} \left(k_{lf} \prod_i x_i^{\nu_{il}} - k_{lb} \prod_i x_i^{-\nu_{il}} \right)$ $\nu_{il} > 0 \quad \nu_{il} < 0$	n	[10]
$(v_z)_s$	$(v_z)_s = -\sum_i \sum_{l=1}^{l_s} M_l s_{il} \left(k_{lf} \prod_i x_i^{\nu_{il}} - k_{lb} \prod_i x_i^{-\nu_{il}} \right) \theta_{vl}^{\nu_{il}}$ $s_{il} > 0 \quad s_{il} < 0$	1	[11]

For a two-component system, Eq. [15] reduces to the binary thermal diffusion ratio (20), $k^T = (\rho/c_T^2 M_1 M_2) (D_1^T / \mathcal{D}_{12})$. The sum of k_i^T or D_i^T over all the species is zero, i.e.

$$\sum_i D_i^T = \sum_i k_i^T = 0 \quad [16]$$

Consequently, for a system with n species, there are $n - 1$ independent values of D_i^T or k_i^T .

The steady-state thermal energy equation also needs to be modified to account for the temperature changes induced by thermal diffusion of the species. For an ideal gas mixture in which viscous energy dissipation can be neglected, Eq. [9] becomes

$$c_T \bar{C}_p \underline{v} \cdot \nabla T = \nabla \cdot (k \nabla T) - \sum_i (\underline{J}_i \cdot \nabla \bar{H}_i^* + \bar{H}_i^* R_i) - \nabla \cdot q^{(x)} \quad [17]$$

for an isobaric system. The Dufour energy flux $q^{(x)}$ is given by

$$q^{(x)} = -\sum_i \frac{D_i^T}{\rho_i} c_i \nabla \mu_i = -RT \sum_i \frac{D_i^T}{\rho_i} \nabla x_i \quad [18]$$

For the examples of CVD of silicon and boron considered here, the chemical reactions are taken to be

Reaction III:

where A represents either silicon ($y = 4$) or boron ($y = 3$). Reactions I and II can occur in the gas phase as well as at the substrate surface. In each example, five gas-phase species are present: H_2 , HCl , ACl_y , AHCl_{y-1} , and ACl_{y-2} . Thermal diffusion is accounted for by replacing Eq. [1]

and [9] in Table I with Eq. [13] and [17], respectively. The governing equations are solved numerically by a finite difference technique (19).

Results and Discussion

In general, thermal diffusion effects are directly related to the temperature gradient and to the relative magnitudes of the molecular weights of the species in the system. Motion toward the hot substrate surface is enhanced for smaller molecules and retarded for larger molecules. Consequently, local compositions and reaction rates are altered. The influence of thermal diffusion on the behavior of two CVD systems is described below. In both cases, the Dufour term in Eq. [17] is always several orders of magnitude smaller than the other terms in the equation and has a negligible effect on the results.

Silicon deposition at a rotating disk.—The production of silicon from silicon halides and hydrogen is an example of a CVD process that generally uses excess reducing agent. The results presented here are for an inlet gas mixture with 1 mole percent (m/o) SiCl_4 .

Figure 1 illustrates the predicted effects of thermal diffusion on steady-state composition variations across the mass-transfer boundary layer adjacent to the substrate surface. If thermal diffusion is included in the analysis, silicon compounds reach the surface less easily and transport of HCl from the surface is facilitated. As a result, the surface compositions of these species are reduced. Away from the substrate, these compositions are increased and the diffusion layer thickness becomes slightly larger. The maxima for the intermediates SiHCl_3 and SiCl_2 are shifted to larger values of ζ . Also, a small maximum for x_{SiCl_4} is shown near $\zeta = 12$. In this region, movement of SiCl_4 toward the disk is restricted by thermal diffusion, but the local temperature is too low for homogeneous decomposition of SiCl_4 to occur.

Equation [16] indicates that thermal diffusion cannot move all molecules in the same direction. Therefore, the effects on the chloride compounds are balanced by the effects on the hydrogen, which moves to the disk more easily. Composition profiles for hydrogen are not shown in

Fig. 1. Composition profiles, with and without thermal diffusion effects (solid lines and broken lines, respectively), in diffusion layer adjacent to substrate surface for CVD of silicon at a rotating disk. $T_s = 1473$ K, $T_\infty = 298$ K, $p_\infty = 1.013 \times 10^5$ N/m², $x_{SiCl_4}^\infty = 0.01$, $\Omega = 12.57$ rad/s, $\theta_{v1} = 1$. Kinetic parameters are as in Fig. 1 of Ref. (10).

Fig. 1 because it is present in excess and mole fraction variations are small. However, the surface composition x_{H_2} is raised by thermal diffusion and, in order to satisfy Eq. [3], it slightly exceeds the inlet value of 0.99. Also, the hydrogen profile shows a small minimum near $\zeta = 12$, where the compositions of the other species are larger.

For the operating conditions used in Fig. 1, the variations of some physical properties are shown in Fig. 2. Small but noticeable changes occur when thermal diffusion is included in the analysis. These changes can be attributed to the modifications in the composition profiles because the temperature profile is essentially unchanged by thermal diffusion. Figure 3 indicates that the changes

Fig. 2. Dependence of viscosity and density on distance from surface, in rotating disk system for silicon CVD with and without thermal diffusion effects (solid lines and broken lines, respectively). Parameter values are as in Fig. 1. $\mu_\infty = 9.602 \times 10^{-5}$ g/cm s; $\rho_\infty = 1.536 \times 10^{-3}$ g/cm³.

in the local density and viscosity of the fluid reduce the minimum in the dimensionless axial velocity H but do not alter the radial or angular velocity profiles.

The effects of thermal diffusion on the dimensionless silicon deposition rate S are illustrated in Fig. 4. The kinetic parameters used in the simulations are chosen to match the shape of the experimentally observed temperature dependence of the deposition rate (10, 17). The model predicts that, for the range of surface temperatures considered, thermal diffusion does not alter the shape of the curve significantly, but S is lowered by approximately

Fig. 4. Temperature dependence of dimensionless deposition rates for deposition of silicon at a rotating disk with and without thermal diffusion effects (solid lines and broken lines, respectively). Parameter values are as in Fig. 1. Curves marked L are thermodynamic-mass-transfer limits.

15%-20%. The lower HCl mole fraction near the surface (see Fig. 1) favors a higher deposition rate. However, this is overshadowed by the lower surface compositions of the silicon halides which reduce the forward rates of the reactions.

Dimensionless surface fluxes N_i' are related to local dimensionless reaction rates r_i' by

$$N_i' = - \sum_1 s_{i1} r_1' \quad [22]$$

For the reaction mechanism considered here (Eq. [19]-[21]), the dimensionless deposition rate S is given by $-\sum_k N_k'$, where the sum k is over the silicon compounds.

In this example, the rate of heterogeneous reaction II (Eq. [20]) is negligible (10) and, hence, the deposition rate simplifies to $-N_5'$, where the subscript 5 represents SiCl_2 . For an inlet gas mixture with 1 m/o SiCl_4 , the use of binary transport equations gives results that are typically within 7% of those obtained with the multicomponent diffusion relations (21). Therefore, the deposition rate can be approximated by

$$S = D_{5,H_2} x_5 (\nabla \ln x_5 + \alpha^T \nabla \ln T)_s - \frac{x_5 c_T H_s}{c_\infty} \quad [23]$$

where α^T is a binary thermodiffusion factor (22) and H_s is the axial velocity at the substrate surface

$$H_s = \frac{c_\infty \sum_1 M_1 N_1'}{\rho} \quad [24]$$

With a substrate temperature of 1473 K, the surface value of α^T is 1.2, and inclusion of the second term on the right-hand side of Eq. [23] reduces S by approximately 8%. The deposition rate changes by a larger percentage (see Fig. 4) because the SiCl_2 composition gradient at the surface becomes slightly less positive when thermal diffusion is incorporated into the analysis (see Fig. 1).

Also shown in Fig. 4 are two curves representing the thermodynamic-mass-transfer limits (10) with and without the inclusion of thermal diffusion effects. These limits represent maximum dimensionless deposition rates obtained as the reaction rate constants approach infinity and the local gas compositions approach their equilibrium values. The effects of thermal diffusion under these conditions are similar to those obtained with finite kinetic parameters: motion of reactants to the substrate is retarded and the deposition rate is reduced. The change is greater at higher surface temperatures because the temperature gradient is larger.

Simulations were repeated with different values of the bulk gas temperature T_∞ in the range of 20°-400°C. As T_∞ is increased, the thermal boundary layer thickness decreases; but the temperature gradient near the surface and the role of thermal diffusion, do not change appreciably.

Boron deposition via an impinging jet.—Chemical vapor deposition of boron represents an example where relatively concentrated mixtures of the gaseous reactants are used. The mole fraction of BCl_3 in the BCl_3/H_2 inlet gas is usually between 0.1 and 0.6 (18). As a result, the mole fractions of the intermediate species are higher than in CVD of silicon and the multicomponent nature of the system is more evident.

Composition profiles for typical reaction conditions are shown in Fig. 5. With thermal diffusion terms included in the model, mole fractions of the chlorides are lower at the surface. Further from the substrate, compositions are predicted to be higher and, hence, species diffusion layers are thicker. With $x_{\text{BCl}_3}^0 = 0.4$, values of k_i^T are positive for all species except hydrogen. However, thermal diffusion coefficients D_i^T for the lighter chlorides, HCl and BCl, are

Fig. 5. Composition profiles, with and without thermal diffusion effects (solid lines and broken lines, respectively), in diffusion layer adjacent to reaction surface for boron deposition in the impinging jet system. $T_s = 1373$ K, $T_\infty = 298$ K, $p_\infty = 1.013 \times 10^5$ N/m², $x_{\text{BCl}_3}^0 = 0.40$, $a = 417$ s⁻¹. Kinetic parameters are as in Fig. 2 of Ref. (15).

negative (see Fig. A-2). This is in contrast to the silicon deposition example, where k_i^T and D_i^T have the same sign. This difference in the effect of thermal diffusion on the motion of intermediate size molecules can be associated with the relative numbers of large and small species in the gas phase and the balancing constraint of Eq. [16].

Physical property variations across the boundary layer are modified by thermal diffusion, and the temperature gradient near the surface is slightly reduced. Also, the axial velocity at a given location in the impinging jet system is lower, but the radial velocity component is not changed noticeably.

The influence of thermal diffusion on dimensionless boron deposition rate is illustrated in Fig. 6 and 7. Figure 6 indicates that, with $x_{\text{BCl}_3}^0 = 0.4$, the deposition rate is generally raised by thermal diffusion. With the sequence of reactions given by Eq. [19]-[21], each value for $-S$ can be equated to the sum of the dimensionless surface fluxes N_i' of the boron compounds. The absolute magnitude of the BHCl_2 flux is largest because the composition of BCl is very low near the substrate and because significant homogeneous decomposition of BCl_3 takes place (15). Inversion of the Stefan-Maxwell equations shows that, for a concentrated gas mixture, the flux of BHCl_2 cannot be determined from the composition gradient of BHCl_2 alone. However, the increase in deposition rate with thermal diffusion is consistent with the less negative surface mole fraction gradient for BHCl_2 shown in Fig. 5. At high jet mass flow rates (large values of a) and high surface temperatures, thermal diffusion increases the deposition rate less and, in extreme cases, lower values for S are predicted.

Figure 7 shows the influence of inlet gas composition on S for a specific jet mass flow rate. With large values of $x_{\text{BCl}_3}^0$, thermal diffusion raises the dimensionless deposition rate by 6%-8%. As the inlet composition of BCl_3 is reduced, the direction of the thermally induced motion of HCl and BCl is altered. The signs of D_i^T for HCl and BCl change at $x_{\text{BCl}_3}^0$ values of approximately 0.28 and 0.33, re-

Fig. 6. Dependence of dimensionless boron deposition rate on substrate temperature, with and without thermal diffusion effects (solid lines and broken lines, respectively). Experimental data (18): $\bullet \sim a = 310 \text{ s}^{-1}$, $\blacktriangle \sim a = 417 \text{ s}^{-1}$, $\blacksquare \sim a = 626 \text{ s}^{-1}$, with other parameters as in Fig. 5. Curves marked L are thermodynamic-mass-transfer limits.

spectively. At lower inlet compositions, the deposition process is more closely analogous to CVD of silicon: thermal diffusion retards the motion of all boron com-

Fig. 7. Dependence of dimensionless boron deposition rate on inlet gas composition, with and without thermal diffusion effects (solid lines and broken lines, respectively). Parameter values are as in Fig. 5. Experimental data (18): $\blacktriangle \sim a = 102 \text{ s}^{-1}$ at $x^0_{\text{BCl}_3} = 0.4$. Curves marked L are thermodynamic-mass-transfer limits.

pounds toward the heated substrate, and it is predicted that thermal diffusion will lower the deposition rate.

The match of the data given by the lower dashed curve in Fig. 7 uses a Langmuir-Hinshelwood model with adsorption of BCl_3 to represent the heterogeneous kinetics (15). With thermal diffusion, local compositions are modified; this can affect the fraction of vacant adsorption sites available, as well as the forward and backward terms in the rate expression. However, the change in shape of the curve for the thermodynamic-mass-transport limit is similar to the change predicted for the case with finite kinetic parameters. This suggests that the influence of thermal diffusion is dictated primarily by the transport processes, rather than by effects associated with the reaction kinetics.

The changes in the shapes of the theoretical curves caused by incorporation of thermal diffusion into the analysis have implications concerning the identification of rate-limiting steps in the process. In Fig. 6 and 7, modified kinetic parameters or rate equations would be needed to provide a satisfactory match between the experimental data and the theoretical predictions that include thermal diffusion effects. For the boron deposition example, it is anticipated that adsorption terms in the rate expressions may be modified but that the relative importance of homogeneous and heterogeneous reactions will not be changed significantly.

Conclusions

A one-dimensional model that describes the coupled transport phenomena and reaction kinetics of CVD reactors has been extended to include the effects of multicomponent thermal diffusion. The role of thermal diffusion in CVD processes has been elucidated by studies of two systems: silicon deposition at a rotating disk and boron deposition using an impinging jet apparatus. The model predicts that numerical changes in the deposition rate associated with thermal diffusion are different in the two cases. For growth of silicon from a dilute mixture of 1 m/o SiCl_4 in hydrogen, deposition rates are lowered by 15%-20%. In contrast, thermal diffusion can raise the boron deposition rate by approximately 7% if high inlet compositions of BCl_3 are used. However, with larger quantities of hydrogen in the feed stream, the boron deposition rate is lowered and the system behavior becomes more analogous to the silicon deposition example. The analysis also shows that the Dufour energy flux in the thermal energy equation is not important in CVD reactors.

APPENDIX

Calculation of Thermal Diffusion Coefficients

Multicomponent thermal diffusion coefficients may be calculated using the Chapman-Enskog kinetic theory of gases. The method presented here, based on the Lennard-Jones potential function, is adapted from the book by Hirschfelder *et al.* (23).

The second-order approximation¹ for the multicomponent thermal diffusion coefficient for species *i* is given by

¹The first-order approximation, which uses only the first term in the Sonine polynomial expansion, results in zero-valued thermal diffusion coefficients. For this reason, thermal diffusion is often referred to as a second-order effect.

$$D_i^T = x_i \sqrt{\frac{M_i k T}{2}} \begin{vmatrix} Q_{11}^{00} & Q_{12}^{00} & \dots & Q_{1n}^{00} & Q_{11}^{01} & Q_{12}^{01} & \dots & Q_{1n}^{01} & 0 \\ Q_{21}^{00} & Q_{22}^{00} & \dots & Q_{2n}^{00} & Q_{21}^{01} & Q_{22}^{01} & \dots & Q_{2n}^{01} & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ Q_{n1}^{00} & Q_{n2}^{00} & \dots & Q_{nn}^{00} & Q_{n1}^{01} & Q_{n2}^{01} & \dots & Q_{nn}^{01} & 0 \\ Q_{11}^{10} & Q_{12}^{10} & \dots & Q_{1n}^{10} & Q_{11}^{11} & Q_{12}^{11} & \dots & Q_{1n}^{11} & R_{11} \\ Q_{21}^{10} & Q_{22}^{10} & \dots & Q_{2n}^{10} & Q_{21}^{11} & Q_{22}^{11} & \dots & Q_{2n}^{11} & R_{21} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ Q_{n1}^{10} & Q_{n2}^{10} & \dots & Q_{nn}^{10} & Q_{n1}^{11} & Q_{n2}^{11} & \dots & Q_{nn}^{11} & R_{n1} \\ \delta_{11} & \delta_{12} & \dots & \delta_{1n} & 0 & 0 & \dots & 0 & 0 \end{vmatrix} \begin{vmatrix} Q_{11}^{00} & \dots & Q_{1n}^{00} & Q_{11}^{01} & \dots & Q_{1n}^{01} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ Q_{n1}^{00} & \dots & Q_{nn}^{00} & Q_{n1}^{01} & \dots & Q_{nn}^{01} \\ Q_{11}^{10} & \dots & Q_{1n}^{10} & Q_{11}^{11} & \dots & Q_{1n}^{11} \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ Q_{n1}^{10} & \dots & Q_{nn}^{10} & Q_{n1}^{11} & \dots & Q_{nn}^{11} \end{vmatrix} \quad [A-1]$$

where n is the number of species in the system. The elements of the determinants are given by

$$Q_{ij}^{00} = 8 \sum_{k=1}^n \frac{x_k M_k}{\sqrt{M_i M_j} (M_i + M_j)} [x_i M_i (\delta_{ij} - \delta_{jk}) - x_j M_j (1 - \delta_{ik})] \Omega_{ik}^{(1,1)} \quad [A-2]$$

$$Q_{ij}^{10} = \left(\frac{M_i}{M_j}\right) Q_{ij}^{01} \quad [A-4]$$

$$Q_{ij}^{11} = 8 \left(\frac{M_i}{M_j}\right)^{3/2} \sum_{k=1}^n \frac{x_i x_k M_k}{(M_i + M_k)^3} \left\{ (\delta_{ij} - \delta_{kj}) \left[\frac{5}{4} (6M_j^2 + 5M_k^2) \Omega_{ik}^{(1,1)} - 5M_k^2 \Omega_{ik}^{(1,2)} \right] + M_k^2 \Omega_{ik}^{(1,3)} + (\delta_{ij} + \delta_{jk}) 2M_j M_k \Omega_{ik}^{(2,2)} \right\} \quad [A-5]$$

$$R_{im} = \delta_{m1} \frac{15}{4} x_1 \sqrt{2kT/M_i} \quad [A-6]$$

$$\delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases} \quad [A-7]$$

The collision integrals $\Omega_{ik}^{(l,s)}$ for the Lennard-Jones (6-12) potential function are related to dimensionless integrals $\Omega_{ik}^{(l,s)*}$ by (20-24)

$$\Omega_{ik}^{(l,s)*} = \frac{\Omega_{ik}^{(l,s)} \sqrt{2\pi m_{ik} N_A / kT}}{\frac{1}{2} (s+1)! \left[1 - \frac{1}{2} \left(\frac{1+(-1)^s}{1+1} \right) \right] \pi \sigma_{ik}^2} \quad [A-8]$$

where σ_{ik} is the collision diameter and m_{ik} is the reduced mass, given by

$$m_{ik} = \frac{M_i M_k}{M_i + M_k} \quad [A-9]$$

Values for $\Omega_{ik}^{(l,s)*}$ have been tabulated as a function of kT/ϵ_{ik} (20, 23, 25, 26).

The equations above indicate that the thermal diffusion coefficients are dependent on the compositions and molecular weights of the species and on the temperature. Figures A-1 and A-2 show typical values of local thermal diffusion coefficients for CVD of silicon and boron, respectively. Comparison of these figures with the corresponding composition profiles (Fig. 1 and 5) illustrates the strong composition dependence of the thermal diffusion coefficients. It should be noted that for a dilute system (i.e., silicon deposition) values of D_i^T/ρ_i for the minor species are approximately equal, and the function $D_i^T/\rho_i T$ varies by less than an order of magnitude across the diffusion layer.

Fig. A-1. Typical absolute values of thermal diffusion coefficients in the diffusion layer adjacent to the reaction surface for silicon deposition in the rotating disk system. Minus sign denotes negative thermal diffusion coefficient for that species. Parameter values are as in Fig. 1.

Fig. A-2. Typical absolute values of thermal diffusion coefficients in the diffusion layer adjacent to the reaction surface for boron deposition in the impinging jet system. Minus signs denote negative thermal diffusion coefficients for those species. Parameter values are as in Fig. 5.

LIST OF SYMBOLS

- a hydrodynamic constant in impinging jet system (proportional to mass flow rate of jet stream) (s^{-1})
- c_i concentration of species i (mol/cm^3)
- c_T total concentration (mol/cm^3)
- c_∞ bulk total concentration (mol/cm^3)

\tilde{C}_p = $\sum_i x_i \tilde{C}_{pi}$, molar heat capacity of mixture (J/mol K)
 \tilde{C}_{pi} molar heat capacity of species i (J/mol K)
 \mathcal{D}_{ik} diffusion coefficient for binary interactions (cm²/s)
 D_{ik} dimensionless diffusion coefficient for binary interactions
 D_i^T thermal diffusion coefficient for species i (g/cm s)
 F dimensionless radial velocity
 G dimensionless angular velocity
 H dimensionless axial velocity
 \bar{H}_i partial molar enthalpy of species i (J/mol)
 \bar{H}_i^* molar enthalpy of ideal gas (J/mol)
 I unit matrix
 \bar{J}_i flux of species i relative to mass average velocity (mol/cm² s)

J_i = $J_i/c_x \sqrt{\nu_x \lambda}$, dimensionless flux
 k Boltzmann constant (used in Appendix) (1.3806×10^{-23} J/K)

k thermal conductivity (W/cm K)
 k_i thermal conductivity of species i (W/cm K)
 k_{1f} forward rate constant for reaction 1
 k_{1b} backward rate constant for reaction 1
 k^T dimensionless binary thermal diffusion ratio
 k_i^T dimensionless multicomponent thermal diffusion ratio for species i , defined by Eq. [15]

l_h number of homogeneous reactions
 l_s number of surface reactions
 m_{ik} reduced mass as defined by Eq. [A-9]
 M_i molecular weight of species i
 \bar{M} = $\sum_i M_i x_i$, average molecular weight
 n number of species in gas phase
 n_l exponent for θ_{vl} in surface reaction 1
 N_i flux of species i (mol/cm² s)

N_i' $N_i/c_x \sqrt{\nu_x \lambda}$, dimensionless flux of species i
 N_A Avogadro's number (6.023×10^{23} per g mol)
 p gas pressure (N/m²)
 Pr Prandtl number

$q^{(x)}$ Dufour energy flux, defined by Eq. [18] (J/cm² s)
 $Q_{ij}^{mm'}$ parameters defined by Eq. [A-2]-[A-5]
 r radial distance (cm)
 r_1' dimensionless rate of reaction 1
 R universal gas constant (8.3143 J/mol K)
 R_{im} parameters defined by Eq. [A-6]
 R_i rate of homogeneous production of species i (mol/cm³ s)

s_{il} stoichiometric coefficient for species i in heterogeneous reaction 1 (positive for reactants, negative for products)
 S = actual deposition rate/ $c_x \sqrt{\nu_x \lambda}$, dimensionless deposition rate

T temperature (K)
 v mass average velocity (cm/s)
 \bar{v}_r radial velocity (cm/s)
 v_θ angular velocity (cm/s)
 v_z axial velocity (cm/s)
 $(v_z)_s$ axial velocity at surface given by Eq. [11] (cm/s)
 x_i mole fraction of species i
 z axial distance from surface

Greek Symbols

δ_{ij} Kronecker delta defined by Eq. [A-7]
 ϵ_{ij} maximum energy of attraction between molecules i and j (J)
 ζ = $z \sqrt{N/\nu_x}$, dimensionless axial distance

Prediction of Spatial Patterns of Oxygen Precipitation in Silicon

G. Markovits, E. E. Hearn, M. V. Kulkarni,* and B. J. Elliott¹

IBM Corporation, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

This work demonstrates a correlation between the initial resistivity pattern and the final precipitation pattern in silicon wafers. The correlation allows prediction of the final precipitation pattern by measuring of the initial resistivity pattern prior to any thermal donor annihilation by thermal processing. By using a simple change in the form of the thermal cycle, this precipitation pattern can be forced into a positive or negative image of the initial resistivity pattern. Time domain reflectometry and cathodic hydrogen generation ("bubble test") are two nondestructive methods used to characterize the state of the electrically active donor complexes; both methods are described here.

Oxygen precipitation in silicon wafers during device fabrication is an important factor in final product yields. The role of oxygen begins during crystal growth and plays a key part through all phases of processing. It can act as a getterer of heavy metal ions, thereby increasing product yield, or it can cause device killing defects. Usually oxygen effects are measured after one or more heat cycles. However, oxygen effects can be monitored, predicted, and therefore controlled before being exposed to any heat cycles.

This paper describes how to predict the oxygen precipitation pattern found after thermally processing silicon wafers. Prediction is made by measuring the wafer resistivity before any heat-treatment and by comparing the resistivity pattern to the infrared absorbance pattern after heat-treatment. Also, the nondestructive detection schemes and heat-treatment conditions are described; we show how they reinforce each other's being able to predict where oxygen will precipitate in wafers after heat-treatment.

Materials and Equipment

100 mm diam wafers are processed from boron-doped crystals of 11-24 Ω -cm resistivity. The wafers have an orientation of [100], are 675 μ m thick, and are chem-mech polished on both sides. These samples are taken from ingots grown in Czochralski-type crystal pullers.

Thermal Donor Determination

Kaiser and Keck (1) have shown that oxygen can be introduced into p-type silicon during growth. This oxygen can be incorporated in two forms during growth: one is the solid solution interstitial oxygen; the other is the electrically active formed donor complex. In p-type silicon, the latter form tends to compensate the intended boron dopant. It is possible to convert large areas of the silicon to n-type, depending on the relative concentrations of boron and oxygen thermal donors (2). The net effect of the electrical activity of these interactions can be measured by resistivity techniques (3). Two nondestructive methods are used to obtain this information. Most of the available techniques require some contact with the sample and are likely to damage the sample.

The first technique is time domain reflectometry [TDR] (4). Essentially, this method uses a miniature radarlike set, with the wafer surface acting as a reflecting target. By analyzing the magnitude, shape, and duration of the reflected 2.3 GHz signal, the impedance of the target can be determined. Through a novel modification of capacitively coupling the signal source to the wafer, this device becomes a contactless tool suitable for point-to-point measurements on a wafer. This technique is called capacitively coupled time domain reflectometry [CCTDR] (5) and is schematically shown in Fig. 1. CCTDR has its limitations. In this experiment, the equipment was reasonably accurate over a limited range of 5-500 Ω -cm. This limitation is acceptable. A comparison of

a CCTDR scan and a stepped four-point probe scan on the same sample reveals that the CCTDR captures all of the salient features (see Fig. 2).

It should be emphasized that this study is strictly phenomenological. Thus, the CCTDR is adequate, and, most importantly, it avoids introducing damage which, in subsequent processing, might propagate and influence oxygen precipitation.

The second method is the cathodic generation of hydrogen, referred to as "the bubble test." First reported by Markovits (6), this technique is described here. A silicon wafer is reverse-biased at 5V in a cell that allows the back side of the wafer to be the cathode and the front side to be the anode. Figure 3 shows that the wafer's front side contacts the anode through an electrolyte of 2% H₂SO₄. The wafer back side is vacuum sealed, and it contacts the cathode by carbon impregnated wool.

The silicon (wafer) acts as a catalyst while the water molecule and its associated hydrogen ion reduce and provide the extra electron to free the hydrogen gas, as in

At any place there is a higher probability of electron

transfer from the semiconductor to the electrolyte, hydrogen is formed at a proportionately higher rate. This can occur as a result of p-n junctions, damage, dirt, excessive light.

An ohmic contact exists between the dilute sulfuric acid and the n-type regions of the wafer. In contrast, the p-type regions produce a condition like that of a reverse-biased junction. The resulting current variation across the sample reflects the change in conductivity from p to n. This variation in current density is reflected by variations in hydrogen production at the silicon surface. Hydrogen bubbles adhere to the silicon surface by surface

tension. When illuminated obliquely, they can be photographed to provide a record of the conductivity changes

Fig. 3. Apparatus used for wafer "bubble test"

Fig. 4. Hydrogen bubble pattern (top) and CCTDR pattern for crystal seed end (bottom).

across the wafer. For a totally p-type wafer, visible hydrogen bubbles are absent.

The conductivity-type changes revealed by the cathodically generated hydrogen pattern are checked in two ways: the first is with a hot probe (7), which confirms that it is only the n-type regions that generate the visible amounts of hydrogen; the second check is made with a copper stain, which preferentially plates out on n-type regions. This essentially confirms the results of the other two methods. It also is applied to a beveled sample to confirm that the surface conductivity-type pattern is continuous through the bulk.

Interstitial oxygen concentration measurement.—The interstitial oxygen concentration is determined by the infrared absorption method. Absorption due to an 1107 cm^{-1} interstitial oxygen wave number peak is measured, at the sample location, on the double-side polished wafers, using a Fourier transform spectrometer with a beam spot size of less than 6 mm in diameter. The silicon lattice contribution is removed by using an oxygen-free floating-zone wafer reference. The concentration of oxygen is calculated from these measurements using a calibration plot generated from three similar wafers that are accurately measured for oxygen content by the ASTM method (8). Because oxygen precipitates also generate absorption peaks quite close to the 1107 cm^{-1} interstitial oxygen peaks (9), we use a point-to-point subtraction method to determine the contribution of interstitial oxygen to the composite spectrum. The resolution used for most of the measurements is 8 cm^{-1} . The time of measurement is

chosen so that the standard deviation for the precision of the measurement is about 0.5 ppma of oxygen. The decrease in interstitial oxygen is solely attributed to its precipitating to form SiO_x complexes of various kinds. As precipitation progresses, absorption traces of the different spectra are made so that it is possible to monitor development of different oxygen precipitate forms (9).

Thermal treatment of our samples occurs in a Thermco Brute American furnace equipped with a Tylan GP481 flow controller. A quartz liner and polysilicon boats are used. Experimental samples are sandwiched in the center of a group of 20 dummy wafers. This is done to further ensure that the thermal environment of all experimental samples will be identical, even during heat-up and cool-down phases of the cycle. The ambient for our thermal cycles is nitrogen.

Fig. 6. Oxygen concentration profile at seed end of crystal

Fig. 7. Schematic summary of raw wafer characteristics

Experiment and Results

Initial characterization.—Two broad classes of wafers exist, according to their initial resistivity and conductivity-type patterns. The group exhibiting conductivity-type patterns is referred to as the character group; the remainder is referred to as the characterless group. There is also a correlation between the character/characterless conductivity groups before heat-treatment and the character/characterless precipitation groups after heat-treatment. Examples of the character and characterless patterns are shown in Fig. 4 and 5. Simple patterns, as in Fig. 4, are typical for the first 20-30% of most crystals. This is the seed end of the crystal, and it usually contains the greatest oxygen concentration. However, it is not oxygen concentration alone that determines whether or not the conductivity-type patterns will exist. For the last 70-80% of the crystal, we find no conductivity-type patterns. The thermal donor concentration is always less than the intended boron dopant; it is not invariant across the sample. Figure 5 shows the result of the cathodic genera-

(a) Isothermal Anneal Cycle

(b) Totally Ramped Cycle

Fig. 8. (a) Isothermal anneal cycle, and (b) totally ramped cycle

tion test for such wafers. The CCTDR traces corresponding to the bubble test are also shown in Fig. 4 and 5.

In contrast to the initial resistivity patterns, the initial interstitial oxygen concentration is uniform. In most samples, the concentration varies by only one or two parts per million until within approximately 6 mm from the edge, at which point it decreases more drastically in some of the seed end samples. An example of typical initial oxygen concentration profiles is given in Fig. 6.

The overall oxygen range, as determined by center readings on each sample, is 24-43 ppm. The group of samples with initial resistivity character span a range of 34-43 ppm, while the characterless group has a range of 24-38 ppm. This overlap of oxygen concentration demonstrates that the initial resistivity character is a function of more than the oxygen concentration. This is further supported in later experiments where lower oxygen content crystals are found to extend the range of the character

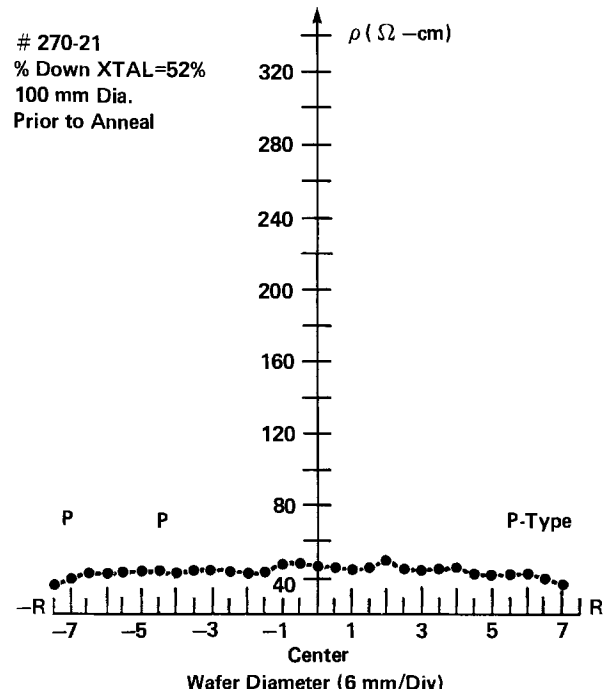

Fig. 9. Initial resistivity, prior to thermal donor anneal, vs. wafer diameter. Measurement made by time domain reflectometry.

Fig. 10. Oxygen precipitation vs. radius for two samples

group down to 27 ppm. It appears that the dominant factor is the axial position within a crystal and, therefore, the thermal history during crystal growth, rather than absolute oxygen level.

A schematic summary of the raw wafer characteristics is presented in Fig. 7. In the as-grown material, the thermal donor concentration varies from seed to tail. This results in producing annular conductivity-type patterns in the first third or less of the crystal.

Post Thermal Processing

Isothermal anneals.—Samples are divided into groups and subjected to two different thermal cycles. The first cycle is isothermally annealed to 1000°C in nitrogen for a period of 15h. Insertion and withdrawal times are done within 20s for each cycle. The second cycle form is ramped up and down from an end cap temperature to a

peak of 950°C. The peak temperature is maintained for a period of 90 min. Details of the two cycles are shown in Fig. 8. Each thermal cycle form is populated with wafers from both the character and characterless groups, as de-

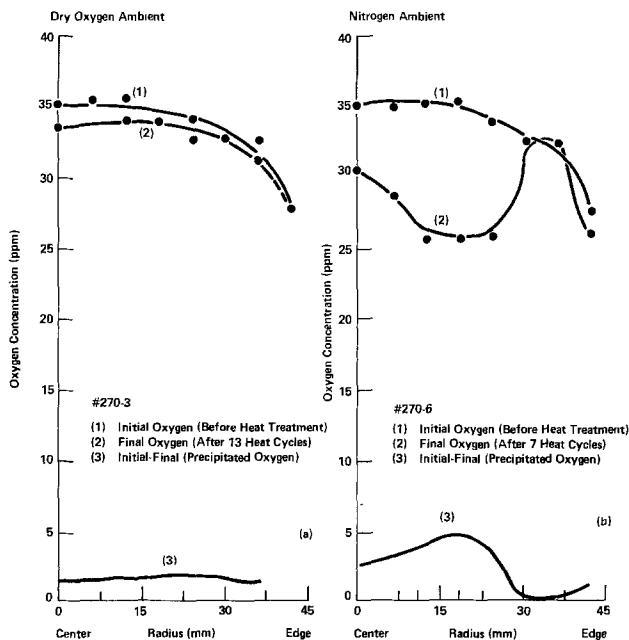

Fig. 11. Interstitial oxygen precipitation vs. crystal radius for characterless and character samples after ramped thermal cycles.

Fig. 12. Pattern obtained by cathodic generation of hydrogen on a seed-end wafer. Areas (bottom) covered by hydrogen bubbles are of n-type conductivity.

Fig. 13. Examples of complex nonsymmetric patterns before heat-treatment.

terminated by initial resistivity patterns. The ambient in all cases is nitrogen.

Sample numbers 270-5 and 270-21 in Fig. 9 come from the character and characterless groups, respectively. Figure 9 contains the respective CCTDR traces before the isothermal heat-treatment. Sample 270-5 displays the simple annular pattern, *i.e.*, an n-type central disk surrounded by an intrinsic ring which is surrounded by a p-type ring.

Figure 10 is a plot of the amount of precipitated oxygen *vs.* radius. It is obtained by subtracting the post thermal processing measurements from the initial raw wafer measurements. A ring of precipitation occurs in sample 270-5. The little precipitation that occurs in sample 270-21 is quite uniform.

Ramped heat cycles.—Results for samples subjected to ramped thermal cycling are consistent, yet quite different. They are similar, in that the group with initial resistivity character also has character in its final precipitation pattern, whereas the initially characterless group does not. The results are quite different from those of the isothermal experiment because the “sign” of the correlation has inverted. Where earlier we find that the maxi-

mum precipitation occurs in the intrinsic ring, with relatively less in the central disk, we now find the central disk to be the more heavily precipitated region.

Samples 270-6 and 270-3 are subjected to seven thermal cycles of the ramped form; they represent a character and a characterless sample, respectively. The hydrogen bubble pattern and CCTDR trace of sample 270-6 before heat-treatment appear the same as shown in Fig. 4. The initial and final oxygen concentrations *vs.* radius are plotted in Fig. 11. Both thermal cycle types are populated with samples from the same crystals. What we discover is that a wafer with initial resistivity character can be forced to precipitate in either the disk or the ring by proper selection of the thermal cycle form.

These experiments are repeated with similar results on material from five other crystals. In all cases, a correlation exists in form between the initial resistivity pattern and the final precipitation pattern. The causes and effects of these heat cycles are the subject of Hearn *et al.* (10) and are omitted here.

Other examples of variation of the theme of simple patterns (Fig. 4) are shown in Fig. 12 and 13. Multiple rings spaced by alternating intrinsic regions (n-i-p-i-n) result in a typical swirl pattern, as seen by the bubble test before heat-treatment (Fig. 12). Noncentrosymmetric rings are also seen in the bubble test before heat-treatment. Again, these same patterns remain after heat-treatment, as detected by x-ray topography, etching, and infrared absorbance measurements.

The measured initial oxygen concentration in some of these complex samples lacks a corresponding variation in oxygen concentration, which is sometimes used to explain the patterns. However, the initial oxygen concentration is always uniform within a few parts per million until it is within a few millimeters of the sample edge.

Summary

This work demonstrates a correlation between the initial resistivity pattern and the final oxygen precipitation pattern in silicon wafers. This correlation enables one to predict the final oxygen precipitation pattern by simply measuring the initial resistivity pattern prior to any thermal donor annihilation by thermal processing.

A complex relationship between oxygen thermal donors, the intended acceptors, and the final precipitation sites is suggested. This is demonstrated by using a simple change in the thermal cycle form to force an oxygen precipitation pattern into either a positive or negative image of the initial resistivity pattern.

Interaction of H₂O with Si(111) and (100)

Critical Conditions for the Growth of SiO₂

G. Ghidini¹ and F. W. Smith

Department of Physics, City College of New York, New York, New York 10031

ABSTRACT

The reactions of H₂O with the clean Si(111) and (100) surfaces have been studied at high temperatures (890°-1350°C) for H₂O pressures between 7×10^{-5} and 4×10^{-1} torr. The critical conditions involving H₂O pressure and substrate temperature which are necessary for the growth of SiO₂ have been determined, and are consistent with a thermodynamic model modified to include effects due to H₂O dissociation and SiO desorption. In addition to clean (active) and SiO₂-covered (passive) surface regions, an intermediate region is observed and is proposed to be related to a thin, nonpassivating Si_xO_yH_z film on the Si surface.

Passivating films of SiO₂ can be grown on Si via the reaction of H₂O with the clean Si surface at high temperature (1-3). The SiO₂ layers grown via the H₂O + Si reaction are more protective and can be grown more rapidly than those prepared via the comparable O₂ + Si reaction (3). Information concerning the critical conditions for growth of SiO₂ via the reaction of H₂O with Si is thus of considerable technological interest, as well as being important for aiding in our understanding of gas-surface interactions and thin film growth processes.

Our previous study (4) of the O₂ + Si reaction has indicated that the processes of O₂ dissociation on and SiO desorption from the Si surface are crucial for determining the critical conditions for the growth of SiO₂. Analogous processes will influence the H₂O reaction, with the additional factor of the presence of hydrogen on the surface to be considered.

We report here on a study of the reactions of H₂O with the clean Si(111) and (100) surfaces, which has been undertaken to determine the critical conditions for growth of SiO₂. We will first summarize some previous studies both of the growth of thick SiO₂ films via the H₂O + Si reaction and of the adsorption and dissociation of H₂O on Si. Experimental details are then presented, followed by the results of this study for the critical growth conditions, SiO₂ growth features, and parameters characterizing the dissociation of H₂O and desorption of SiO. These results will be discussed in terms of a thermodynamic model modified to take into account H₂O dissociation and SiO desorption. Finally, the presence of a thin, nonpassivating Si_xO_yH_z layer on the Si surface under certain experimental conditions is proposed.

Background

Growth rates of films of SiO₂ produced via the reaction of Si with H₂O have been analyzed in terms of the linear-parabolic model (5), with rate constants for both the linear and parabolic regimes observed to be at least an order of magnitude larger than those observed for the corresponding O₂ + Si reaction. The linear rate constant k_{LIN} reflects the reaction occurring between the oxidizing species and Si at the Si-SiO₂ interface. In the case of H₂O (and H₂O + O₂) oxidation, the enhancement of k_{LIN} has been proposed to be due to the "catalytic" effect of hydrogen on the oxidation reaction (1, 6). One possible mechanism for this "catalytic" effect is the weakening of Si-Si bonds at the interface for those Si atoms bonded to H, thus facilitating oxygen atom insertion. Hydrogen may play an analogous role in the initial stages of the interaction of H₂O with the clean Si surface, which would then be an important factor for determining the critical conditions for the growth of SiO₂.

The initial adsorption of H₂O on Si at room temperature has been the topic of several recent experimental investigations (7-10). It seems clear that the H₂O molecule is adsorbed on Si with the oxygen atom bonding to the surface Si (7, 8). The removal of gap states (associated with the

dangling bonds at the surface) is readily achieved via H₂O adsorption on Si, indicating a strong interaction. Whether the adsorption is initially molecular or dissociative at room temperature appears to depend critically on the structure of the Si surface (8-10). It has been found (9) that the sticking coefficient at room temperature for adsorption and decomposition of H₂O is unity on Si(100) and about 10^{-2} on Si(111)-(7 × 7). In the same work, evidence has been seen for SiH and SiOH groups on the Si surface at room temperature, with further dissociation leading to the reaction SiOH → Si-O-Si + SiH by 150°C, and finally H₂ desorption by 330°C. Other workers claim that H₂O adsorbs molecularly at room temperature if the surface is smooth, but dissociates if the surface is disordered (8). Dissociative adsorption of H₂O on Si at room temperature has recently been predicted theoretically (11).

A study of the critical conditions for the oxidation of Si via the H₂O + Si(111) reaction has been carried out by Maguire and Augustus (12) for $P(\text{H}_2\text{O}) < 8 \times 10^{-4}$ torr and $T_s < 1000^\circ\text{C}$. They used Auger electron spectroscopy to detect the presence of oxygen bound to the Si surface at room temperature following the high temperature H₂O + Si reaction. Their results will be discussed in more detail below.

Experimental

These reactions of H₂O with Si(111) and (100) have been carried out in the UHV system described previously (4), using the same experimental procedures for determining the critical growth conditions. Briefly, the Si substrates studied were supported in Mo clamps in the UHV chamber and cleaned thermally *in situ* via treatment at 1350°C. The H₂O used was distilled, deionized, and further purified via repeated freezing in liquid nitrogen and subsequent evacuation in order to remove volatile impurity gases. The H₂O was stored in a glass cylinder and admitted to the UHV chamber via a bakeable leak valve. $P(\text{H}_2\text{O})$ was measured above 10^{-3} torr via a Pirani gauge, while below 10^{-3} torr an ionization gauge was used.

By varying both $P(\text{H}_2\text{O})$ and the substrate temperature T_s , different regions of etching via SiO production (active surface) and SiO₂ growth (passive surface) on the Si surface were observed using an optical pyrometer. The pyrometer also served to measure T_s at the boundaries between the different regions which are present at the same time on the Si surface due to the temperature gradient along the sample. It was determined that in addition to regions of clean surface (region I, etching) and SiO₂ growth (region III), there existed on the Si surface an intermediate region II which was still active but which had a different emissivity and "grainier" appearance than the clean Si surface of region I. Details of these three regions are presented below.

Following the reactions, the samples were examined using optical and scanning electron microscopy. The boundary on the Si surface between regions II and III was quite sharp and showed growth features similar to those observed for the O₂ + Si reaction. The boundary be-

¹Present address: SGS, Agrate Brianza, Milano, Italy.

tween regions I and II was much less distinct and showed no distinctive growth or etching features. Nevertheless, it was observed reproducibly *in situ* for several different samples via the optical pyrometer.

Results

In Fig. 1 are presented our results for the critical conditions for growth of SiO₂ via the reaction of H₂O with both the Si(111) and (100) surfaces. At the highest values of $P(\text{H}_2\text{O})$ and lowest values of T_s , the surface is covered with SiO₂ (region III in Fig. 1), while at the lowest $P(\text{H}_2\text{O})$ and highest T_s , the surface remains clean via the production of SiO and H₂ (region I). Unlike the case of the O₂ + Si reaction, where only regions analogous to I and III were observed, for H₂O + Si we observe an intermediate region with surface structure and emissivity differing from the other regions. In this intermediate region, etching continues as SiO and H₂ are still produced via the reaction of H₂O with the Si surface. We will discuss this intermediate region in more detail below. The dashed line in Fig. 1 labeled $P_c(\text{O}_2)$ represents our previous results (4) for O₂ + Si, where only a single boundary was observed.

In Fig. 2 are shown SiO₂ growth features in the shape of pyramids whose square bases are rotated by 45° with respect to the [100] axes of the Si(100) substrate. This type of growth feature has previously been observed (4) for the O₂ + Si(100) reaction, and has been proposed to be the result of the epitaxial growth of the high temperature cubic form of SiO₂, β -cristobalite, specifically on Si(100), where there is only a 7% lattice constant mismatch when the two lattices are rotated by 45°, as observed in Fig. 2. We note that the growth features shown in Fig. 2 consist of only a thin [estimated (4) thickness of about 100Å], passivating layer of SiO₂ protecting the Si core of the pyramid. One

Fig. 2. SEM micrograph of SiO₂ growth features formed via the reaction of H₂O with Si(100) at $P(\text{H}_2\text{O}) = 0.15$ torr and $T_s = 1085^\circ\text{C}$. The growth features, pyramids whose square bases are rotated by 45° with respect to the Si [100] axes, sit in depressions whose sides are parallel to the [100] axes.

new result observed for H₂O + Si(100), and also illustrated in Fig. 2, is the association of the pyramidal growth features with square depressions whose sides are parallel to the Si[100] axes. No such depressions were observed for the O₂ + Si(100) case.

As for O₂ + Si and several other reactions previously studied [e.g., C₂H₄ + Si (13), C₂H₂ + Si (14), NH₃ + Si (14)], the observed boundaries between different surface regions indicated in Fig. 1 can be expressed in terms of a critical pressure via

$$P_c(\text{H}_2\text{O}, T_s) = P_0 \exp(-\Delta E/k_B T_s) \quad [1]$$

For the H₂O + Si(100) reaction, we find $P_0 = 2.3 \times 10^{13}$ torr and $\Delta E = 3.9$ eV from the straight line drawn for the upper boundary in Fig. 1, while for the lower boundary we find $P_0 = 5.6 \times 10^7$ torr and $\Delta E = 3.0$ eV. Our results for H₂O + Si(111) are consistent with the above Si(100) results, but are not as complete and are somewhat more scattered. For $P(\text{H}_2\text{O}) < 1 \times 10^{-3}$ torr (or $T_s < 950^\circ\text{C}$), we note that the boundary between regions II and III falls below the straight line drawn in Fig. 1. This result will be discussed below.

The reaction of H₂O in regions I and II of Fig. 1 leads to rapid etching of the Si surface via the production of volatile SiO molecules. An important parameter influencing the critical growth conditions is $S(\text{H}_2\text{O} \rightarrow \text{SiO})$, which gives the probability that an incident H₂O molecule adsorbs on the Si surface, dissociates, and reacts to form an SiO molecule, which eventually desorbs. The incoming flux of H₂O is determined from the H₂O pressure via the kinetic theory expression

$$R(\text{H}_2\text{O}) = P(\text{H}_2\text{O})N_0/(2\pi M(\text{H}_2\text{O})RT_g)^{1/2} \quad [2]$$

where N_0 is Avogadro's number, $M(\text{H}_2\text{O}) = 18$, R is the gas constant, and $T_g = 300$ K. The outgoing flux of SiO molecules is given by $R(\text{SiO}) = v_e \rho(\text{Si})$, where v_e is the experimentally measured etching velocity and $\rho(\text{Si})$ is the atomic density of Si. Values of $S(\text{H}_2\text{O} \rightarrow \text{SiO}) = R(\text{SiO})/R(\text{H}_2\text{O})$ determined from $P(\text{H}_2\text{O})$ and v_e are given in Table I for three groups of samples: samples at the upper boundary between regions II and III; samples near the lower boundary; and samples in region II. We note that the highest values of $S(\text{H}_2\text{O} \rightarrow \text{SiO})$, 0.016-0.029, are observed in region II.

Further evidence for the dramatic effects of etching via SiO production can be seen when the oxidant pressure falls below the critical value for the growth of SiO₂. The etching process then dominates and the pyramidal SiO₂-covered growth features can be undercut (see Fig. 3).

Fig. 1. The critical conditions for the growth of SiO₂ via the reaction of H₂O with Si(111) and (100). $P(\text{H}_2\text{O})$, water vapor pressure; T_s , substrate temperature. Previous results obtained for the O₂ + Si reaction are indicated by $P_c(\text{O}_2)$.

Discussion

In order to understand the upper boundary of Fig. 1, separating the intermediate region II from region III of SiO₂ growth at higher values of P(H₂O), we will first consider the thermodynamics of the reactions involved. The

Fig. 3. SEM micrograph of a pyramidal SiO₂ growth feature formed via the reaction of O₂ with Si(100) at P(O₂) = 1.8 × 10⁻² torr and T_s = 1090°C. The pyramid is undercut at its base via the etching reaction producing SiO.

net reactions which are important for the interaction of H₂O with Si under our experimental conditions are

Reactions [3] and [4] proceed to the right under our experimental conditions, with free energy changes ΔG₃ and ΔG₄ both less than zero. Reaction [3] dominates in regions I and II, while reaction [4] dominates in region III of Fig. 1.

Noting that 2ΔG₃ - ΔG₄ = ΔG₅, we find that reactions [3] and [4] will proceed at the same rate, per incident H₂O molecule, when reaction [5] is in equilibrium, i.e., when ΔG₅ = 0. The equilibrium SiO vapor pressure P_{eq}(SiO, T_s) for reaction [5], measured for ΔG₅ = 0, also determines the maximum rate at which SiO can be produced by reaction [3]. This maximum rate is given by

$$R_{\text{max}}(\text{SiO}, T_s) = S_{\text{SiO}} P_{\text{eq}}(\text{SiO}, T_s) N_A / (2\pi M(\text{SiO}) RT_s)^{1/2} \quad [6]$$

Here S_{SiO} is the vaporization coefficient for SiO on Si at temperature T_s (15). The critical conditions for growth of SiO₂ via the H₂O + Si reaction are attained when S(H₂O → SiO)R(H₂O), the rate at which H₂O molecules react to form SiO, is equal to R_{max}(SiO, T_s). The critical value for P(H₂O) is thus given, using Eq. [2] and [6], by

$$P_c(\text{H}_2\text{O}, T_s) = \left(\frac{S_{\text{SiO}}}{S(\text{H}_2\text{O} \rightarrow \text{SiO})} \right) \left(\frac{M(\text{H}_2\text{O})T_s}{M(\text{SiO})T_s} \right)^{1/2} P_{\text{eq}}(\text{SiO}, T_s) \quad [7]$$

Apart from a factor of 1/2, this is equivalent to the expression previously derived (4) for the O₂ + Si case. Using P_{eq}(SiO, T_s) = (3.08 × 10¹¹ torr) exp(-3.54 eV/k_BT_s) measured experimentally (16) and our measured values of S(H₂O → SiO) given in Table I, we assume Eq. [7] to be correct and thus obtain the values of S_{SiO} also listed in Table I from our measured results for P_c(H₂O, T_s). Once again, as for the case of O₂ + Si, we find S_{SiO} < 1, indicating that the vaporization of SiO from the Si surface is somewhat retarded.

The curvature, or bending down, of the boundary between regions II and III, which is evident in Fig. 1 for P(H₂O) < 1 × 10⁻³ torr and T_s < 950°C, can be seen from the results presented in Table I to be consistent with both an increase in S(H₂O → SiO) and a decrease in S_{SiO} in this region. This bending down of the boundary corresponds to an enhancement of region III of SiO₂ production and likely results from an increased coverage of the surface with adsorbed SiO molecules which would cause reaction [5] to tend to proceed in the reverse direction, i.e., 2SiO(ads) → SiO₂(s) + Si(s). Alternatively, a lower value of S_{SiO} implies that the SiO molecules remain on the surface longer before desorption, thus increasing the probability of their being further oxidized by incoming H₂O molecules via the reaction H₂O(g) + SiO(ads) → SiO₂(s) + H₂(g). The increased coverage by adsorbed SiO molecules results both from the increased rate of H₂O reaction (i.e., higher S(H₂O → SiO) and from the decreased vaporization of SiO from the surface (i.e., lower S_{SiO}). It is not clear why SiO molecules remain on the Si surface longer for T_s < 950°C, but it may be related to an increased coverage of the surface by hydrogen. The reaction 2H(ads) → H₂(g) is an activated one and if it goes more slowly for T < 950°C, then preferred sites for SiO desorption may be blocked by adsorbed hydrogen.

Thus we conclude that the thermodynamic model for P_c(H₂O, T_s), Eq. [7], as modified to include effects due to H₂O dissociation and SiO desorption, adequately represents the critical conditions for growth of SiO₂ via the H₂O + Si reaction with the parameters S(H₂O → SiO) and S_{SiO} listed in Table I. That this statement also holds for the case of the O₂ + Si reaction was not so clear previously (4), when average values of S(O₂ → SiO) and S_{SiO} were used instead of the observed pressure- and temperature-dependent ones. The kinetic growth etching model presented previously (4) to describe the development of

the SiO₂ growth features is still valid, but should not be considered to be an improvement on the thermodynamic model.

As mentioned previously, Maguire and Augustus (12) have also studied the initial interaction of H₂O with Si at high T_s (up to 1000°C) and low P(H₂O), up to 8 × 10⁻⁴ torr. Our results for P_c(H₂O, T_s) agree qualitatively with theirs, although they did not observe three regions of interaction, such as we have indicated in Fig. 1. Their results for P_c(H₂O, T_s) show more scatter than ours and lie between our lower and upper boundaries, with a slope, or activation energy, of 2.5 eV, as compared with our result of 3.9 eV for the upper boundary. For P(H₂O) approaching 1 × 10⁻⁴ torr, our results merge with those of Maguire and Augustus. From a study of pumping speed, they determined the initial sticking probability of H₂O on Si to be about 10⁻³, somewhat lower than our result, S(H₂O → SiO) = 0.0034-0.029.

We note from Fig. 1, which includes our previous results for P_c(O₂, T_s) for the O₂ + Si reaction, that for a given oxidant pressure, SiO₂ is stable on the Si surface for higher values of T_s for the O₂ + Si reaction than for the H₂O + Si reaction. In other words, P_c(O₂, T_s) is less than P_c(H₂O, T_s) for T_s > 950°C. It is apparent that this results from the fact that S(O₂ → SiO) is greater than S(H₂O → SiO), (0.027-0.061) for O₂ as compared with (0.0034-0.029) for H₂O. We note that S_{SiO} values are comparable for the two reactions, (0.059-0.19) for O₂ and (0.048-0.13) for H₂O. Thus, per incident molecule, more SiO is produced on the Si surface for the O₂ + Si case, increasing the likelihood of further oxidation to SiO₂. The lower value of S(H₂O → SiO) as compared to S(O₂ → SiO) may result from the fact that two bonds in the case of the H₂O molecule must be broken before an oxygen atom is available to form an Si-O-Si bridging bond, where in the case of O₂ the breaking of a single bond generates two reactive oxygen atoms. We note that O=O and H-OH bonds are of essentially equal strength (17), 5.0 eV.

From Table I, it can be seen that S(H₂O → SiO) is generally a decreasing function of P(H₂O), an effect which may be related to the increasing coverage of the Si surface by SiOH and SiH groups, which could block further adsorption of incident H₂O molecules.

Our results indicate that the Si surface is more reactive to O₂ than to H₂O as far as the production of SiO and the initial growth of SiO₂ are concerned, in contrast to the observed more rapid growth of thick SiO₂ films in H₂O. The existence of region II, extending down to the lower boundary in Fig. 1, apparently does signal a type of enhanced reactivity of H₂O with Si. The existence of three surface regions for H₂O + Si, as compared with only two for O₂ + Si seems likely to be due to the presence of hydrogen on the surface in SiOH and SiH groups in the former case. We will now discuss the possibility of a thin, nonpassivating Si_xO_yH_z layer on the Si surface in region II.

In region I, when incident H₂O molecules dissociate on the Si surface, SiOH and SiH groups are formed initially. If P(H₂O) is low enough and T_s high enough, the SiOH groups will be unstable and the following reaction

will proceed readily, leading to rapid etching and the maintenance of a clean Si surface. As P(H₂O) increases or T_s decreases, the coverage of the Si surface by SiOH and SiH groups will increase. A "catalytic" effect of hydrogen in this situation could be the weakening of Si-Si back bonds to the extent that an Si_xO_yH_z layer, with O atoms in both bridging and nonbridging configurations, could form on the Si surface well before the generation of SiO has reached its maximum value given by Eq. [6]. Also, it has been stated (18) previously that an SiOH group on the Si surface can stabilize a neighboring Si-O-Si bond. This effect may also aid in the formation of an Si_xO_yH_z layer. Thus, a thin, nonpassivating Si_xO_yH_z layer could exist for values of P(H₂O) lower than those which would lead to the formation of a passivating SiO₂ layer.

The continuing (nonuniform) etching of the underlying Si through this Si_xO_yH_z layer via the production of SiO could lead to the rougher, "grainier" surface observed in region II. The possible existence of this Si_xO_yH_z layer has been inferred from the fact that the emissivity observed in region II differs from that of the SiO₂ layer and of the clean Si surface. An analogous situation has recently been reported (19) for the case of an amorphous Si_xH_z layer observed using similar procedures on the surface of Si during SiH₄ CVD. A semipassive surface layer has also previously been inferred (20) to exist on the surface of SiC during reaction with oxygen atoms and molecules.

The Si_xO_yH_z layer proposed here for region II is not expected to be stable, but rather to exist on the Si surface only in semiequilibrium both with the underlying Si and the incoming flux of H₂O. For lower P(H₂O) or higher T_s (i.e., region I), the layer would disappear via a reduction reaction

while for higher P(H₂O) or lower T_s, approaching region III, oxidation to SiO₂ would occur

Unfortunately, thermochemical data for such an Si_xO_yH_z layer are not available, and the kinetics of its formation are not clear, so that a model for the critical P(H₂O) for the lower boundary, separating regions I and II, does not seem possible at this time.

The square depressions in which the pyramidal SiO₂ growth features are found (see Fig. 2) are likely to be caused by enhanced etching of the Si substrate in this region. The mechanism for this enhanced etching is not clear, although one possibility may be that H₂O molecules incident on the SiO₂-covered pyramid which stick and dissociate cannot all be consumed by the reaction producing SiO₂ (typical SiO₂ film growth rates are only on the order of 0.1 Å/s (1), compared to etching velocities v_e, which are typically (10-1000) Å/s, see Table I). Thus, there may be a considerable flux of OH groups (or even H₂O molecules) diffusing down the sides of the pyramids to the Si substrate. Such a flux should result in an enhancement of the etching via SiO production, thus explaining the presence of the square depressions surrounding the pyramids. This effect could be negligible for the O₂(g) + Si(s) reaction because of the smaller diffusion velocity of O₂ (or O) on the SiO₂ layer and the lower sticking coefficient on SiO₂ (21). Enhanced etching due to SiH_x (x = 1-4) production is very unlikely on thermodynamic grounds.

Conclusions

We have determined experimentally the critical conditions for growth of SiO₂ on the clean Si(111) and (100) surfaces for values of T_s between 890° and 1350°C and P(H₂O) between 7 × 10⁻⁵ and 4 × 10⁻¹ torr. These results are consistent with a thermodynamic model for SiO₂ growth, which has been modified to account for the dissociation of H₂O on and desorption of SiO from the Si surface. The presence on the Si surface for certain values of P(H₂O) and T_s of a thin, nonpassivating Si_xO_yH_z film has been inferred. Further experiments are required to confirm the presence of this Si_xO_yH_z film.

Acknowledgments

We wish to thank Dr. J. Osinchak and Mr. J. Downey for taking the SEM micrographs. Thanks also to Dr. E. A. Irene for many helpful discussions. The support of the U.S. Department of Energy under Contract no. DE-AC02-79ER10438 is greatly appreciated.

Properties of Magnetron-Sputtered Silicon Nitride Films

T. Serikawa and A. Okamoto

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Midoricho, Musashino-shi, Tokyo, 180 Japan

ABSTRACT

Films 100-200 nm thick have been deposited at 200°C by reactive sputtering of a silicon target in nitrogen-argon mixtures using an RF planar magnetron system. Film properties were examined in reference to nitrogen partial pressure and sputtering gas pressure. At nitrogen partial pressure higher than a certain pressure, silicon nitride films are deposited. Properties of silicon nitride films are remarkably dependent on sputtering gas pressure. By controlling the pressure, silicon nitride films have been synthesized with 1.7-200 nm/min etching rate in buffered HF, 2.97-2.28 g/cm³ density, 1.97-1.82 refractive index, 5×10^9 - 1×10^9 dyne/cm² compressive intrinsic stress and 5.5×10^6 - 3.5×10^6 V/cm breakdown voltage. High density, low etching rate films deposited under optimized sputter conditions act as an efficient barrier to oxygen diffusion in oxygen atmospheres at high temperature. In addition, it was demonstrated from MOS device characteristics that the silicon nitride films are free from contaminants and can be successfully applied to device fabrication.

Silicon nitride films are very important in semiconductor device fabrication because they afford a good moisture and contamination barrier (1, 2). Great effort has been made to investigate the formation and characterization of the film (2). For formation of silicon nitride films, chemical vapor deposition (CVD) has most widely been in use (2, 3). The method, however, has a disadvantage in regard to its high substrate temperature. Certain process schemes in device fabrication require that silicon nitride films be deposited at low substrate temperature. To meet this requirement, a plasma-assisted CVD has been recently developed (3-5). This method uses mixtures of SiH₄ and NH₃ in the same manner as the CVD method. As a result, the silicon nitride films are contaminated with hydrogen, which degrades device characteristics (6, 7). However, in sputtering, films are deposited at low substrate temperature and are free from hydrogen contamination. These advantages make sputtering a potentially attractive method to deposit silicon nitride films.

Sputtered silicon nitride films have commonly been deposited in nitrogen mixed gases using a diode-type system (8-11). This system has the disadvantage of small deposition rate and substrate heating due to plasma exposure. However, in the recently developed magnetron system, lower substrate temperatures are still obtainable, even when deposition rates are significantly higher (3). This combination of higher rates and lower temperature can improve sputter deposition economics. However, there have been only a few reports on silicon nitride film deposition by magnetron sputtering. Moreover, the magnetron system is different from the diode-type system in some respects (12).

This paper describes the preparation and properties of silicon nitride films made by reactive sputtering, using

an RF planar magnetron apparatus in reference to sputter conditions. Also, it was demonstrated that the film deposited under optimized conditions is applicable as an oxidization mask in a wet oxygen atmosphere at high temperature for MOS device fabrication.

Experimental

Sputtering apparatus and film deposition.—Film depositions were carried out with a 13.56 MHz RF magnetron sputtering apparatus, shown in Fig. 1 (13). An RF electrode is mounted in a bell jar so that the target materials are sputtered onto a barrel-type rotatable substrate holder. The 5 × 15 in. silicon target (99.999% pure), 0.25 in. thick was mechanically clamped to a water-cooled RF electrode. The minimum spacing between the target and the substrate holder was 50 mm. The target could be covered with a movable shutter mounted approximately 25 mm in front of the target. The bell jar was made of stainless steel, but the holder and shutter were made of titanium.

The sputtering system was evacuated to less than 2×10^{-4} Pa before a baffle valve above the diffusion pump was throttled. Nitrogen-argon mixtures were admitted to the system. After presputtering was carried out for 10 min, the shutter was removed to deposit films ranging in thickness from 100 to 200 nm on 3 in. diam silicon and aluminum substrates. The main deposition parameters were nitrogen partial pressure and sputtering gas pressure. The sputtering conditions are listed in Table I.

Measurements.—Films were evaluated on the basis of infrared absorption spectra, film composition, etching rate, film density, surface texture, refractive index, resistivity, breakdown voltage, and film stress. In addition,

Fig. 1. The RF planar magnetron sputtering apparatus

thermally oxidized films were analyzed by Auger electron spectroscopy (AES) to determine depth profiles.

Film compositions were measured using x-ray microanalysis and the Lorentz-Lorenz relationship. Film densities were measured by a gravimetric technique. Etching rates were calculated from etching depth in 30°C buffered hydrofluoric acid [100 ml (50% HF) + 860 ml (40% NH_4F)] and etching time. The etched depths were measured by a roughness tester (TalystepTM). Surface textures of as-deposited and slightly etched in 30°C buffered hydrofluoric acid for 5s were observed by transmission electron microscopy of a carbon replica. Resistivities and breakdown voltages were measured using an MIS capacitor, which had a 500 μm diam aluminum electrode-silicon nitride film-silicon substrate structure. Film stresses were calculated from silicon substrate curvature measured by the Newton-ring method (14).

MOS device fabrication.—MOS transistors and capacitors were fabricated using the reactively sputtered silicon nitride films as a local oxidation (LOCOS) mask on silicon substrates (15). The silicon substrates used were boron-doped p-types with a (100) orientation and 4 $\Omega\text{-cm}$ resistivity. SiO_2 films 60 nm thick were thermally grown on the substrates. Next, 150 nm thick silicon nitride films were deposited on SiO_2 films. After patterning silicon nitride films and SiO_2 films, thick SiO_2 films were formed for field isolation by thermal oxidation for 370 min in wet oxygen atmosphere at 1000°C. After removing the silicon nitride film patterns and underlying SiO_2 films, gate SiO_2 films were thermally grown to 60 nm thick. MOS devices were completed through additional fabrication steps: gate electrodes for poly-Si film, source/drain electrodes, intermediate SiO_2 films, and aluminum interconnections. Finally, all devices were annealed in forming gas for 20 min at 450°C.

Results and Discussions

Preparation and properties.—**Nitrogen partial pressure effect.**—Figure 2 shows changes in deposition rate and film composition as a function of nitrogen partial pressure. In the pressure range lower than 0.12 Pa, decrease in deposition rate is small, but deposition rate decreases abruptly near 0.15 Pa. Nitrogen concentration saturates at a pressure higher than 0.1 Pa. The infrared absorption spectrum for film deposited at 0.28 Pa nitrogen partial pressure is shown in Fig. 3. Absorptions at 840 and 460 cm^{-1} are peculiar to silicon nitride (2, 6), and are representative

of all films deposited at higher than 0.1 Pa partial pressures. No additional peaks were observed between 400 and 2000 cm^{-1} .

In reactive sputtering of targets like silicon, three possible nitrogen reaction sites can be considered: (i) at the target surface, (ii) on the substrate, and (iii) during transfer from target to substrate (16). The last can be neglected because silicon nitride films are deposited even at 0.12 Pa nitrogen partial pressure at which collision with nitrogen is unity. In the magnetron system, the discharge intensity is localized close to the target so that the substrates are located in a less chemically reactive environment (17). At low nitrogen partial pressure, insufficient nitrogen is available to form a silicon nitride on the target surface.

Fig. 3. Infrared absorption spectrum for film deposited at 0.28 Pa nitrogen partial pressure, where sputtering gas pressure was 0.56 Pa.

Fig. 4. Change in etching rate as a function of sputtering gas pressure. Sputtering gas composition was 50% nitrogen-50% argon.

Only when nitrogen partial pressure reaches a value near 0.15 Pa is sufficient nitrogen available to form silicon nitride on the target (17, 18). This formation on the target reduces deposition rate, since the sputtering rate for silicon nitride is less than that for silicon. Moreover, silicon nitride films are obtained, as shown in Fig. 2 and 3.

Sputtering gas pressure effect.—Etching rate in buffered HF showed a marked dependence on sputtering gas pressure, as seen in Fig. 4. Etching rate is smallest near 0.6 Pa and increases drastically at 1.2 Pa. Figure 5 shows changes in film density, refractive index, and film composition at different sputtering gas pressures. Film compositions were calculated from measured film density and refractive index using Lorentz-Lorenz correlation (19). At 0.56 Pa, film density and refractive index reach maximums of 2.97 g/cm³ and 1.97, respectively. Film composition N/Si changes from 1.42 to 1.15 as a result of increasing sputtering gas pressure. Figure 6 shows surface textures of as-deposited and slightly etched films at 0.3, 0.56, and 6.7 Pa sputtering gas pressure. In the 6.7 Pa as-deposited films, 100 nm diam irregularities are observed and many microvoids a few nanometers in diameter are observed. In contrast to the relatively smooth surfaces of as-deposited films, the slightly etched film surfaces are markedly different. The film at 0.56 Pa is the smoothest. In the film at 6.7 Pa, the surface becomes very irregular.

Figure 7 illustrates typical current-voltage characteristics for films deposited at 0.3, 0.56, and 6.7 Pa. Films at 0.3 and 0.56 Pa exhibit linear $\ln I$ vs. $V^{1/2}$ plots indicative of a Poole-Frenkel conduction mechanism, whereas $\ln I - V^{1/2}$ data for the films at 6.7 Pa invariably exhibit curvature when plotted in the same manner. Arrows in the figure indicate breakdowns of the films. High density films at 0.56 Pa show high breakdown voltage. Films at 0.3 Pa have low breakdown voltage, in spite of a linear $\ln I$ vs. $V^{1/2}$ relationship.

Silicon nitrides formed on target are sputtered with an energy spectrum having a strong peak at a few electron

Fig. 5. Changes in film density, refractive index, and film composition by sputtering gas pressure. Sputtering gas composition was 50% nitrogen-50% argon.

volts (20). Sputtered materials lose their energies and directions through collisions with argon and nitrogen, and are finally thermalized to the average gas energy (21). Before thermalization, the materials travel normal to the target surface. However, after thermalization, oblique and horizontal incident components are mixed in an incident angular distribution of sputtered materials (22). As shown in Fig. 4, etching rates change drastically at 1.2 Pa. At 1.2 Pa, the thermalization distances, which the sputtered materials travel before thermalization, are 40 and 65 mm at initial energies of 5 and 1000 eV, respectively (21). Therefore, thermalized materials are in the majority on a substrate 50 mm from the target.

Reducing sputtered material energy results in the attenuation of (i) surface mobility of deposited atoms and (ii) re-emission of weakly bound atoms, which are in unfavorable positions for achieving optimum density (3, 11). Also, after thermalization, oblique and horizontal components increase in incident angular distribution (21, 22). Sputtered materials with oblique and horizontal components are shadowed by irregularities on substrate and growing film (22, 23). Because surface mobility and re-emission are attenuated, the areas shadowed by the components remain, resulting in microvoid formation, as shown in Fig. 6. Consequently, at a sputtering gas pressure higher than 1.2 Pa, silicon nitride films with microvoids are deposited, resulting in abnormal etching rates, low resistivity, and low breakdown voltage.

By decreasing sputtering gas pressure from 0.56 Pa, etching rate increases and film surface texture becomes irregular again, as seen in Fig. 4 and 6. Substrate surfaces are negatively self-biased against plasma in RF sputtering (3). The self-biased potential increases with decreasing pressure (3). In the magnetron sputtering system used in this study, the potential was nearly constant at -8V for pressures higher than 1 Pa, but increased markedly for low pressure and reached -20V at 0.4 Pa. Consequently, at lower pressures, growing film surfaces are bombarded by argon and nitrogen positive ions with higher energies. These energetic ion bombardments enhance re-emission and surface diffusion of depositing atoms. However, the bombardments lead to surface irregularities. The irregularities on growing film promotes the self-shadowing ef-

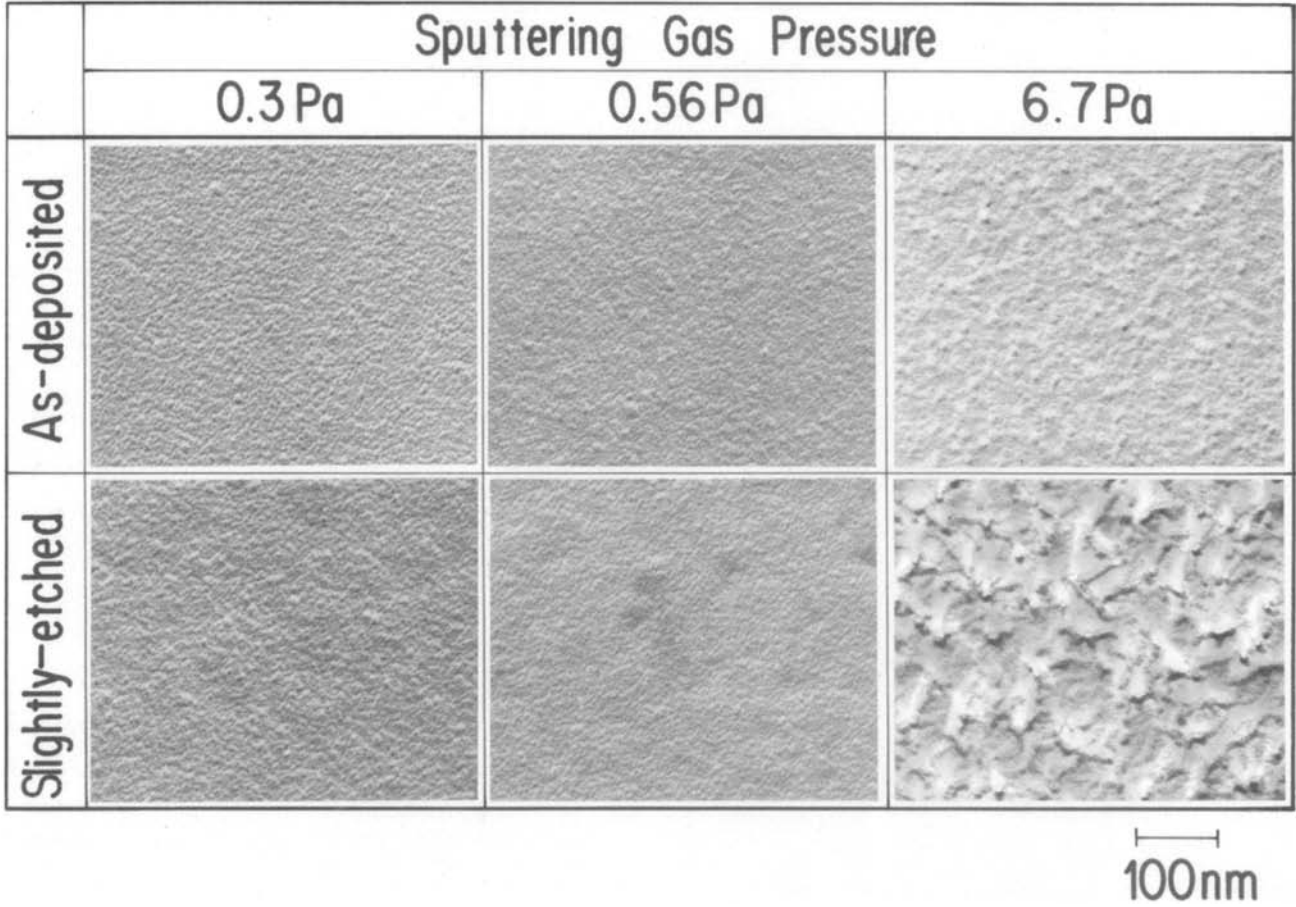

Fig. 6. Transmission electron micrographs of as-deposited and slightly etched films deposited at 0.3, 0.56, and 6.7 Pa sputtering gas pressures.

fect. The self-shadowing effect overshadows enhanced re-emission and surface diffusion. Consequently, silicon nitride films are deposited with high etching rates and

low refractive index. Degradation for film property deposited at low pressure results from energetic argon and nitrogen ion bombardments. This fact is clarified further by application of RF biases to the substrate through a capacitor. The dc self-biased potential was adjusted to -20V. In the entire sputtering gas pressure range, the etching rate for films deposited under RF bias is greater than that for films deposited in the absence of applied bias. For example, silicon nitride films deposited at 0.56

Fig. 7. Current-voltage characteristics for silicon nitride films deposited at 0.3, 0.56, and 6.7 Pa.

Fig. 9. Change in mask efficiency as a function of sputtering gas pressure.

Pa under an RF bias show 5.0 nm/min, which is greater than 1.7 nm/min in films without bias. In addition, as shown in Fig. 8, the electron micrograph reveals that biased sputtered films are more irregular than film without bias. Growing films are bombarded by argon and nitrogen ions accelerated due to dc self-biased potential, resulting in film property degradation. It was anticipated, on the basis of surface irregularities and the self-shadowing effect, that films deposited at low pressure and biased sputtered films exhibit poor film properties. For surface irregularization by energetic ion bombardments, the mechanisms assumed to be responsible are either nonuniform re-emission or etching by the bombardments. More work is needed to clarify this.

Intrinsic stresses are indicated as compressive for all silicon nitride films. The stress decreases with increasing sputtering gas pressure.

Properties of silicon nitride films deposited at 0.56 and 6.7 Pa are summarized in Table II.

Application to MOS device fabrication.—Figure 9 indicates mask efficiency for silicon nitride films deposited at various sputtering gas pressures. The mask efficiency was defined as D/d , as shown in the inset in the figure, where d and D are thermally oxidized thicknesses on silicon nitride and (100) oriented silicon substrate, respec-

Table II. Silicon nitride film properties

	0.56 Pa	6.7 Pa

tively. Thermal oxidation was carried out for 370 min in a wet oxygen atmosphere at 1000°C, where D was about 1 μm . Mask efficiency markedly depends on sputtering gas pressure in the same manner, as shown in Fig. 4 and 5. Moreover, mask efficiency reaches a maximum at 0.56 Pa, where high density and low etching rate films are deposited. Figure 10 shows Auger depth profile after film oxidation, when film was deposited at 0.56 Pa. An oxygen peak is observed only at less than 25 min etching time.

Owing to high density in film deposited at 0.56 Pa, the film acts as an effective barrier against oxygen, as seen in Fig. 10. Moreover, mask efficiency is as great as 35. However, low density films are easily oxidized, showing low mask efficiency (Fig. 9).

Figure 11 shows breakdown voltage characteristics for gate SiO_2 films 60 nm thick. The characteristic distribution has a peak at 7.8 MV/cm and high breakdown voltage. In Fig. 12, change in threshold voltage in a MOS transistor is shown as a function of substrate voltage. The calculated curve uses 3.5×10^{15} 1/cm³ acceptor-type boron concentration and -0.9 V as work function difference between the poly-Si electrode and the silicon substrate (24, 25). Threshold voltages agree with calculations. Also, field effect mobility in the transistor in Fig. 12 is greater than 700 cm²/V·s. The MOS transistor characteristics mean that neither oxide charge in gate SiO_2 films nor surface state at Si-SiO₂ interface are generated when magnetron-sputtered silicon nitride films are used. Figures 9, 11, and 12 show that silicon nitride film deposited under optimized condition is successfully applicable to MOS device fabrication without contamination and degradation in MOS device.

Conclusions

Silicon nitride films were deposited at 200°C by reactive sputtering of a silicon target in a nitrogen-argon mixture using an RF planar magnetron system. Films properties, composition, etching rate, film density, stress, and breakdown voltage, were measured. Experiments demon-

Fig. 11. Breakdown voltage characteristics for gate SiO_2 film 60 nm thick

strated that film properties displayed remarkable dependence on sputtering gas pressure. Under proper sputtering conditions, good quality silicon nitride films with high density and low etching rate can be deposited. Moreover, it was demonstrated that the silicon nitride films act as an efficient barrier to oxygen diffusion and are successfully applicable to MOS device fabrication. However, by adjusting sputtering conditions, films with microvoids are deposited. The film formation mechanism was discussed on the basis of self-shadowing of deposited atoms owing to irregularities on growing film surfaces.

Interaction Between Ti and SiO₂

C. Y. Ting, M. Wittmer,* S. S. Iyer,* and S. B. Brodsky

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

We have investigated the interaction between Ti and SiO₂ in the temperature range of 400° to about 1000°C. The reaction proceeds in a layer-by-layer fashion and consists of SiO₂ reduction followed by the formation of a Ti-rich silicide at the interface. At higher temperatures, a Ti-rich oxide is formed near the surface. The reaction starts at approximately 400°C, and the loss of SiO₂ becomes significant above 500°C. A strong interaction between Ti and SiO₂ takes place at 700°C and above. The thicker the SiO₂, the higher resistance it has to degradation due to elevated temperature effects.

The performance and density of today's MOS integrated circuits are further improved by scaling down the physical dimensions of the individual circuit elements. It follows from the MOS scaling laws that the miniaturization process reduces the length of interconnect lines by the scaling factor and their cross-sectional area by the square of that factor. Consequently, the resistance of polycrystalline silicon lines increases with the scaling factor. However, the area of ohmic contacts is reduced by the square of the scaling factor, which results in an increase of the contact resistance by the square of that factor. The above resistance increases give rise to excessive RC time constants and IR voltage drops which may offset the speed advantages gained by scaling the MOS technology to smaller feature sizes.

Recently, refractory metals and their silicides have found an increased interest as means to reduce both the contact resistance and the high resistance of poly-Si lines and diffusion layers. Specifically, VLSI technology makes use of Ti in contact structures (1, 2) and self-aligned TiSi₂ in both source/drain and gate areas (3, 4). If Ti is employed in oxide windows for ohmic contacts and Schottky diodes, it is likely to be in connection with the field oxide as well. However, any reaction between Ti and SiO₂ during postmetal annealing at 400°-450°C could degrade the device performance. However, self-aligned TiSi₂ over poly-Si lines and diffusion layers is formed at higher temperatures, around 600°-700°C. The unreacted Ti over the field oxide is removed in a subsequent step. Any residue on the oxide as a result of the interaction of Ti with SiO₂ during self-aligned TiSi₂ formation presents a potential hazard to the performance of the device. Therefore, the Ti/SiO₂ interaction has to be minimized. For this purpose, it is imperative to study the interaction between Ti and SiO₂.

The reactions of thin films of Ti, V, and Nb with SiO₂ substrates was first investigated by Kräutle *et al.* (5). They found that, upon annealing a Ti film on SiO₂ at 800°C for 2h in vacuum, a bilayer structure is formed, consisting of a surface layer of Ti with about 50% oxygen and a layer beneath of mostly Si and Ti in the ratio Si:Ti = 0.62. They were unable to identify the compounds formed. Our goal was to study in detail the interaction between Ti and SiO₂ in order to determine its implications on device performance. For that purpose, we carried out both thin film analysis and electrical measurements on MOS capacitors. The results of this paper extend very well those of two recent photoelectron spectroscopy studies on low coverages of Ti and SiO₂ to the case of thin films, as they are used in integrated circuits.

Experimental

The Si substrates used in this work were <100> oriented and p-type doped. A 1000Å thick SiO₂ layer was grown on 10 Ω cm Si substrates in a dry-wet-dry oxidation sequence at 1000°C with HCl addition to the oxygen gas. Thinner SiO₂ layers up to 350Å were grown on 2 Ω cm material in dry oxygen with HCl addition. Blanket layers of 1000Å Ti were evaporated in a diffusion-pumped system from a resistively heated source. The base pressure

Electrochemical Society Active Member.

prior to evaporation was better than 2×10^{-7} torr, and the evaporation rate was 10 Å/s. During evaporation, the substrates were maintained at a temperature of 150°C. Titanium MOS capacitors were prepared by evaporating circular Ti dots of 0.8 mm diam through a metal mask.

Samples of the blanket-deposited wafer as well as of the MOS capacitors were subsequently annealed for various times at temperatures ranging from 400° to about 1000°C in Ar. The Ar gas was purified in a hot Ti sponge filter prior to purging of the annealing furnace. The thin films were analyzed with Rutherford backscattering spectrometry (RBS) (6) and glancing angle x-ray diffractometry. Both leakage current and C-V measurements were used in the investigation of the Ti-MOS capacitors.

Other samples of the blanket-deposited wafer were first annealed at temperatures between 500° and 800°C and then stripped of the unreacted Ti in an etching solution which attacks neither titanium silicide nor SiO₂ (3). The thickness of the remaining SiO₂ layer was then measured with optical interferometry. Finally, SIMS analysis was used to determine a possible Ti diffusion into the SiO₂.

Results

Thin film analysis.—A set of samples with 1000Å Ti on 1000Å SiO₂ was annealed for 30 min in 100°C steps from 400° to about 1000°C. The RBS spectra of these samples are summarized in Fig. 1. From this figure, it is clearly seen that the Ti signal is well separated from the Si signal, whereas the oxygen signal is superimposed on the Si signal. This is due to the difference in atomic mass of these elements. The energies for scattering of the ⁴He⁺ particles from surface positions of the elements are indicated by the vertical arrows marked Ti, Si, and O.

The spectra for the as-deposited sample and the samples annealed up to 600°C are practically identical and

Fig. 1. 2.3 MeV ⁴He⁺ spectra of 1000Å thick Ti layers on 1000Å thick SiO₂ annealed under various conditions. The vertical arrows mark the surface position of the corresponding elements.

represented by the solid line in Fig. 1. The oxygen and silicon signals of the SiO₂ layer are displaced to energies below their corresponding surface position because of the energy loss of the ⁴He⁺ particles in the overlying Ti film. Diffusion of Ti into the SiO₂ is not observed under these annealing conditions. Upon annealing at 700°C, two changes in the RBS spectrum (open circles) can be discerned. First, the height of the Ti signal has dropped and a second oxygen peak near the surface position of oxygen has appeared. This indicates that a significant amount of oxygen has dissolved in the Ti film. Second, the width of the Ti signal has increased and the Si signal extends now to higher energies. This signifies that Ti and Si at the original Ti/SiO₂ interface have reacted with each other and formed a mixed layer. Heat-treatments at 800°C and higher yield RBS spectra typical of the one represented by the filled triangles in Fig. 1. It is clearly seen that most of the oxygen from the SiO₂ layer is now distributed in the Ti layer and that the Ti and the Si have mixed extensively. Finally, we find from Fig. 1 that within the accuracy of RBS the area under the oxygen peaks is preserved, indicating that the oxygen in the Ti layer originates mainly from the decomposed SiO₂ layer.

Strong interactions occur between the Ti and the SiO₂ at high temperatures. This is demonstrated in Fig. 2, which shows the RBS spectrum of a sample annealed at 900°C for 30 min. It is apparent from the step in the Ti signal at 1.7 MeV in Fig. 2 that the original SiO₂/Ti structure has been transformed into a different bilayer structure. The uppermost layer contains Ti and O₂ in the ratio Ti:O = 2:3. This can be inferred from the heights of the Ti and O₂ signals near their surface positions. In a similar fashion, we can determine the composition of the layer beneath. It consists mostly of Ti and Si in the ratio of Ti:Si = 5:3. A thin interfacial layer of the original SiO₂ remains between the Ti-Si mixed layer and the Si substrate, as indicated in Fig. 2. The drop of the oxygen signal between the surface position "s" and interface position "i" indicates that the Ti-Si mixed layer contains only a small amount of oxygen.

We used glancing angle x-ray diffraction to identify the compounds formed in the interaction between Ti and SiO₂. Figure 3 shows the diffraction spectrum of a sample which has been annealed at 800°C for 30 min. Most of the diffraction lines can be ascribed to two compounds, Ti₅Si₃ or Ti₅Si₄, with the exception of one line which can only be identified as the (121) diffraction of Ti₅Si₃. Thus, we conclude from the x-ray analysis that the compound formed is the metal-rich silicide Ti₅Si₃. This result is in excellent agreement with the composition of the compound determined by RBS. The result is also in good agreement with the atomic ratio of Si and Ti reported by Kräutle *et al.* (5).

Fig. 2. 2.3 MeV ⁴He⁺ RBS spectrum of a Si/1000Å SiO₂/1000Å Ti sample following a heat-treatment for 30 min at 900°C. The contributions of the various compounds to the overall spectrum is indicated by the dashed lines, and the vertical arrows mark the surface positions of the corresponding elements.

Fig. 3. Glancing angle x-ray diffraction pattern obtained with Cu K α radiation from a Si/1000Å SiO₂/1000Å Ti sample after annealing for 30 min at 800°C, identifying the compound Ti₅Si₃. The broad diffraction peaks are artifacts of the x-ray equipment.

The broad diffraction peaks in Fig. 3 are artifacts of the x-ray equipment.

We cannot identify the Ti-oxide phase from the x-ray spectra of Fig. 3. The number of diffraction lines we obtained from this as well as other samples is insufficient to determine which of the many possible Ti-oxide compounds are formed. From RBS analysis alone one would speculate that Ti₂O₃ is the compound in question. However, we believe that in this temperature range rutile TiO₂ is formed in the presence of some unreacted Ti.

MOS capacitor measurements.—The breakdown voltage of the Ti-MOS capacitors prepared with a 1000Å thick Ti layer was measured before and after various heat-treatments. We defined the breakdown voltage as the voltage at which the leakage current surpassed 50 μ A. The histograms of the capacitors as a function of breakdown voltage for oxide thicknesses of 100, 200, and 350Å are shown in Fig. 4. Histograms are shown before any heat-treatment of the capacitors and after a maximum permissible time-temperature cycle that the capacitors were able

Fig. 4. Distribution of Ti-MOS capacitors as a function of breakdown voltage for oxide thicknesses of 100, 200, and 350Å. Distributions are shown before and after a heat-treatment at 400° and 500°C, respectively.

to withstand: namely, 10 min at 400°C for 100Å SiO₂, 4h at 400°C for 200Å SiO₂, and 30 min at 500°C for 350Å SiO₂. Two features are apparent from Fig. 4. First, the width of the distributions is small and is not altered in a marked way by the annealing process. This indicates that the integrity of the MOS structure is maintained. Second, the breakdown voltage is shifted to lower voltages after the annealing process. This points to either a thinning of the SiO₂ layer and/or increase of the dielectric constant of SiO₂. We could not measure the breakdown voltage for thicker oxide layers because the voltage was too high for our instrumentation. In this case, we measured only the leakage current.

The leakage current of Ti-MOS capacitors with 1000Å thick oxide layer is stable for heat-treatments of 30 min up to 600°C. This is shown in Fig. 5, which illustrates the dependence of the leakage current of a typical capacitor on applied bias. The small peak at 0 V is due to charging of the capacitor. After a heat-treatment of 30 min at 700°C, a pronounced increase in leakage current is observed on some of the capacitors. The I-V characteristic differed strongly from one capacitor to another upon annealing at 700°C. An example is shown in Fig. 5. It seems that the capacitor is about to fail at that temperature. However, after annealing the capacitors for 30 min at 800°C and above the I-V characteristics turned out to be consistent among the capacitors investigated. A typical example is shown in Fig. 5. The asymmetry of the leakage current on the polarity of the applied bias is remarkable and is indicative of a rectifying behavior. We believe that in this temperature range the Ti has completely decomposed the oxide layer, thereby destroying the MOS capacitor and forming a low barrier Schottky diode with the Si substrate. Titanium-MOS capacitors prepared on 350Å thick oxide layers were destroyed after a heat-treatment at 600°C for 30 min.

We have also investigated the Ti-MOS capacitors with C-V measurements. The high frequency (1 MHz) C-V characteristics of capacitors with a 350Å thick oxide layer are shown in Fig. 6. The C-V characteristics are well behaved for as-deposited capacitors and capacitors which have been annealed for 30 min up to 500°C. However, it is obvious from Fig. 6 that the capacitance in accumulation increases with increasing annealing temperature. In addition, a reduction in flatband voltage is noticeable in Fig. 6 upon annealing of the capacitors, in accordance with the increase in accumulation capacitance. Both effects can be explained by a thinning of the oxide layer due to Ti-SiO₂ interaction and/or an increase of the dielectric constant of the SiO₂. Diffusion of Ti into the SiO₂ is not expected to increase the dielectric constant because Ti in SiO₂ will be bound to oxygen, forming a semiconducting titanium oxide. Therefore, the above effects are likely to be due to a thinning of the oxide layer. Finally, Fig. 6 indicates that heat-treatments of 600°C and higher essentially

short the MOS capacitors prepared with a 350Å thick oxide layer. For MOS capacitors prepared with a 1000Å thick SiO₂, shorting occurred during heat-treatments at 700°C.

Investigations of the oxide layer.—So far, it seems that the electrical properties of the oxide layer beneath the titanium silicide are not altered by the Ti-SiO₂ interaction. The steep trailing edges of the Ti signals in the RBS spectra of Fig. 1 and 2 indicate that the silicide-oxide interface is sharp. In addition, a noticeable Ti diffusion into the SiO₂ has not been observed with RBS. To further substantiate these facts, we have investigated the properties of the oxide layer beneath the reaction interface in detail.

First, we measured the thickness of the SiO₂ layer after the interaction between Ti and SiO₂. For that purpose, we annealed Ti films on SiO₂ at temperatures between 500° and 800°C. The unreacted Ti was then etched away (3), and the thickness of the remaining oxide was measured with optical interferometry. Table I lists the amount of oxide consumed by the Ti-SiO₂ interaction for various annealing conditions. It is clear from Table I that the amount of SiO₂ lost depends on both annealing temperature and time. The amount of SiO₂ lost during the 500°C heat-treatment corresponds to the increase of the accumulation capacitance at 500°C, as shown in Fig. 6. For annealing temperatures of 700°C and above, the SiO₂ surface acquires a metallic luster and the measurement of the loss of SiO₂ with optical interferometry became difficult. We tried to analyze the nature of the metallic luster with ESCA, but were unable to detect foreign elements within its resolution limit. However, a SEM investigation revealed tiny residues on the surface of the SiO₂, as shown in the micrograph of Fig. 7. The spherically shaped residues are about 300Å diam and cover only about 0.5% of the SiO₂ surface. Therefore, ESCA could not detect them. We were not able to determine the composition of the res-

Fig. 7. SEM micrograph of a Si/1000Å SiO₂/300Å Ti sample following a heat-treatment for 30 min at 800°C and stripping of the Ti-silicide on unreacted Ti. A thin Au layer has been evaporated to prevent charging up of the SiO₂ Layer.

ides. It is possible that they consist of a metal-rich titanium silicide such as Ti₅Si₃ because they were not removed by the selective etching solution.

The loss of SiO₂ during interaction between Ti and SiO₂ is consistent with the RBS profiles of oxygen shown in Fig. 1 and the increase of the accumulation capacitance observed in Fig. 6. These facts rule out Ti diffusion into the SiO₂. We also performed SIMS analysis of the SiO₂ layer after stripping of the Ti-silicide to further support the absence of Ti diffusion. The analysis revealed that a possible Ti concentration in the SiO₂ must be below the sensitivity of SIMS for Ti ($< 10^{15} \text{ cm}^{-3}$).

Finally, we have prepared Al-MOS capacitors on 1000Å thick SiO₂ layers which had been reacted with the Ti at 700°C for 30 min and subsequently stripped of the silicide and any unreacted Ti. For comparison, we have also prepared Al-MOS capacitors on unreacted SiO₂ layers. The thickness of the Al dots was 7000Å. The high frequency (1 MHz) C-V characteristics of the capacitors, which are shown in Fig. 8, are well behaved in both cases, irrespective of the 700°C heat-treatment. The accumulation capacitance for the capacitors on reacted SiO₂ is 50 pF higher than for those on unreacted SiO₂. This corresponds to a reduction of the oxide thickness of about 200Å, which is in good agreement with the observed oxide loss given in Table I. Thus, we are confident to rule out Ti diffusion into the SiO₂ during the heat-treatments.

Discussion

It is observed in general that the interactions between thin films of refractory metals and plain Si substrates yield silicon-rich silicides. In the case of Ti films on Si, the formation of the monosilicide TiSi is observed around 500°C and the disilicide TiSi₂ is formed at 600°C or higher temperatures (7). This is in contrast to the present results of the interaction between Ti and SiO₂. Here, a metal-rich silicide, Ti₅Si₃, is formed at the Ti-SiO₂ interface. The silicon needed for the silicide formation originates from SiO₂, which is decomposed by the Ti-SiO₂ interaction. The oxygen which is freed by this interaction is dissolved in the Ti and at higher temperatures reacts with the Ti to form an oxide layer near the surface. The oxide layer is metal rich and consists presumably of TiO₂ and unreacted Ti.

These conclusions are in basic agreement with those presented by Krättele *et al.* (5). However, our investigation of Ti-MOS capacitors revealed the onset of the Ti-SiO₂ interaction at 400°C, which is below the temperature for conventional Ti-silicide formation. Krättele *et al.* (5) claimed that refractory metals react with SiO₂ at temperatures which are about 200°C higher than the temperature to form the corresponding silicide with Si. This discrep-

Fig. 8. High-frequency (1 MHz) C-V characteristics of Al-MOS capacitors fabricated on etched Si/SiO₂/Ti substrates. Two cases are shown, one for substrates with Ti stripped after evaporation and one for substrates with Ti stripped after reaction with SiO₂ at 700°C for 30 min.

ancy is not surprising because their methods of analysis were restricted to RBS and x-ray diffraction. As shown in Fig. 1, RBS does not detect any interaction between Ti and SiO₂ below 600°C. There is also a remarkable analogy between the interaction of Ti and SiO₂ and that of Ti and Si₃N₄. Borisov *et al.* (18) reported that mixtures of Ti and Si₃N₄ powders reacted at temperatures below 1330°C to form Ti₅Si₃ and TiN compounds.

It seems that the Ti-SiO₂ interface is a very reactive one. Titanium atoms at the interface have a strong tendency to reduce neighboring Si-O bonds and to form new Ti-O and Ti-Si bonds. At this point, it is instructive to compare our results with the findings of two recent photoelectron spectroscopy investigations of the Ti/SiO₂ interface (9, 10). It is reported that the presence of SiO₂ at the Si surface has a significant effect on the reaction of Ti and Si, and, more important, that the thickness of the SiO₂ determines the end products of the reaction. The evaporation of Ti onto thin layers ($< 20\text{Å}$) of SiO₂ at room temperature was found to break Si-O bonds and to rebond the free oxygen atoms to Ti atoms (10). This reactivity of the Ti is reflected in its excellent adhesion to insulators, in particular SiO₂ and Si₃N₄. The formation of silicides is not observed during evaporation of Ti onto SiO₂. Annealing at moderate temperatures (300°-400°C) changes the bonding of the Ti from Ti-O to Ti-Si and produces a stable silicide phase. For thin oxide layers, the silicide is similar to that formed with a clean Si substrate (9, 10).

It is the combination of both processes, the reduction of SiO₂ and the low temperature interfacial reaction with Si, which mark the reliability of Schottky barriers and the low resistivity of ohmic contacts prepared with Ti. However, the reactivity of the Ti/SiO₂ interface is a disadvantage when the preservation of thin SiO₂ layers is important. This is specially the case for gate oxides and regions of thinner field oxide around device oxide windows. Heat-treatments above 400°C cause a noticeable reduction of the oxide thickness, owing to the Ti-SiO₂ interaction. The excess oxygen probably forms a solid solution with the unreacted Ti. As the Ti-SiO₂ reaction proceeds during extended or higher temperature heat-treatments, the oxygen concentration in the Ti increases. When it exceeds the solid solubility limit, a Ti-rich oxide forms, in agreement with the photoelectron spectroscopy results of Ti on thick SiO₂ layers (9).

We have not found any indication of Ti diffusion into the SiO₂ during heat-treatments up to 800°-900°C. The

photoelectron spectroscopy studies of the Ti/SiO₂ interface (9, 10) were also unable to detect diffusion of Ti beyond the mixed interfacial layer amounting to a few monolayers. Thus, we conclude that the diffusivity of Ti in SiO₂ is very low. This is also expected from the fact that Ti is very reactive and reduces quickly many oxide compounds. As a consequence, the interface between evaporated Ti and SiO₂ is very sharp and stays relatively sharp during subsequent heat-treatments up to 700°C. This is beneficial to the application of Ti in the manufacture of integrated-circuit elements.

Conclusions

We have studied the interaction between Ti and SiO₂ during thermal annealing in the temperature range of 400° to about 1000°C. The results show that Ti reacts in a limited fashion with SiO₂ at temperatures of 700°C and below, but strong interactions take place at higher temperatures. At high temperatures, the reaction mechanisms consist of the decomposition of SiO₂ by the Ti metal and the formation of a Ti-rich silicide, Ti₅Si₃, at the interface and a Ti-rich oxide, presumably a mixture of Ti and TiO₂, near the surface. Below 700°C, the reaction results in a net loss of the SiO₂ and exhibits a sharp interface, characteristic of a layer-by-layer growth process. However, we have not observed diffusion of Ti into the SiO₂ during the interaction.

The application of a Ti-based metallurgy to silicon devices requires special attention. The use of Ti or Ti silicides in contact structures and interconnects should be of no concern as long as the oxide thickness is greater than 350Å and the post-metal heat-treatment is performed at a temperature not exceeding 400°-450°C. However, in the case of self-aligned TiSi₂, the formation temperature of the silicide should be kept below 700°C in order to prevent excessive Ti-SiO₂ interactions. Also, the field oxide should have a thickness of at least 1000Å. Besides these

restrictions, which are not severe at all, there is no reason why the full advantage of the application of Ti or Ti-silicide metallurgies to device manufacturing cannot be taken.

Low Energy Proton Beam Lithography with a Thin Oxygen-Etch Barrier Layer

H. Hiraoka*

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

Low energy protons in the several keV energy range have very limited penetration depths into polymer films. This limitation necessitates the use of very thin oxygen-etch barrier layers and of dry image development by oxygen reactive ion etching. For negative tone images, the etch-barrier layers were deposited patternwise by proton-beam-induced polymerizations of organo-metallic compounds, followed with dry image development by oxygen reactive ion etching. For positive tone images, the etch-barrier layers were deposited (prior to patternwise exposure to proton beams) on top of polymer films by plasma polymerizations of organo-metallic compounds, or by evaporation or sputtering of certain metals. Hydrogen atoms and/or protons react with metal atoms in the etch barrier layers to yield volatile metal hydrides, making the exposed areas more vulnerable to oxygen reactive ion etching, and providing positive tone images after image development. Sub-keV electrons can replace low energy protons for fabrications of positive-tone polymer images. In these processes, almost any kind of carbonaceous polymer film can be used as the imaged material. With a bright ion gun available, the exposure times could be less than a second, yielding high aspect ratio and high resolution polymer patterns.

Ion beam lithography does not suffer from the proximity effect, which is one of the most serious problem of electron beam lithography with electron energy of 20-30 keV (1). The very limited penetration depths of ions, however, require high acceleration energies of ions (for example, 150 keV proton beams), to be useful for lithographic applications (2). Associated with high energy ion beams, there are many problems to be considered. With the use of very thin oxygen etch barrier layers deposited from the vapor phase, as in plasma polymerization or by sputtering

or evaporation, a few keV proton beams can be utilized successfully to delineate high resolution positive-tone polymer images, as described later.

Shallow ion implantation [gallium ion (3), indium ion (4), silicon ion (5)] into resist films has been reported to fabricate negative-tone polymer images. An organic semiconductor film was used to avoid charge buildup with scanning indium ion (4). In all these shallow ion implantations for reducing oxygen plasma etch rates, high doses of ion beams (1×10^{15} Si ion/cm²) are required to obtain reasonably thick polymer images. In a similar way as in ion implantations, thin oxygen-etch barrier layers can be

*Electrochemical Society Active Member.

deposited patternwise in ion-beam-induced polymerization onto the exposed surfaces of polymer films during proton-beam exposures. As opposed to the ion-implantation method, no charge build-up problem appears and high sensitivity is possible.

Experimental

Proton-beam exposures.—Proton-beam exposures were carried out through a stencil mask with a cold cathode ion source, a 2-30 Magmiller ion gun from Commonwealth Scientific Company. At a typical hydrogen pressure of 4×10^{-5} torr, the proton-beam current density was 1.5×10^{-7} A/cm² at 4 keV, resulting in a dose of 5×10^{-4} C/cm² for a 60 min exposure period. The stencil masks used are the same ones reported for electron-beam proximity printing (6). The spacings between the mask and resist layers are about 200 μ m.

Electron-beam exposures.—Sub-keV electron-beam exposures were carried out through a stencil mask with a Varian scanning Auger electron gun operating in a raster scan mode. With a beam current of 25 μ A, the electron dose was about 1×10^{-4} C/cm² for an exposure period of 60 min.

Dry image development.—Polymer images were developed by oxygen reactive ion etching. After proton- or electron-beam exposures, wafers with polymer films were placed in a reactive ion etching system, which was a parallel-plate diode system with a cathode of 12 in. diam. Under typical experimental conditions, images were developed at an oxygen pressure of 0.12 torr with a power density of 0.34 W/cm² at a bias potential of -300V. Image development times varied from 15 to 60 min, depending upon a film thickness and a kind of polymer films; PMMA films without oxygen etch barrier layers have an etch rate of 1 μ m/10 min.

Negative-Tone Polymer Patterns

For fabrication of negative-tone images, thin oxygen-etch barrier layers were deposited through a stencil mask in ion-beam-induced polymerizations during proton-beam exposures on top of polymer films; images are developed afterwards by oxygen reactive ion etching. Figure 1 shows the process. The thickness of the deposited oxygen-etch barrier layers is not so critical as in the case for positive-tone polymer images; the thickness could be as thick as 1000 Å , but there is a lower limit of about 150 Å , as discussed below for the fabrication of positive-tone images.

Many organo-silicon compounds and organo-tin compounds can be used as the etch-barrier forming materials as long as they have sufficient vapor pressure; for example, tetravinylsilane, hexamethyldisiloxane, hexamethyl-

disilazane, tetramethyltin. Halogenated aromatic compounds like hexafluorobenzene can also be deposited as an etch-barrier layer on top of PMMA films. The etch-barrier layers made of hexafluorobenzene deposited in proton-beam-induced polymerization has a graphitic polymer structure, based on its ESCA data, which explains the relatively high etch resistance under our RIE conditions.

The monomer vapor inlet tube was located 12 in. away from the ion source, about 2 in. above the mask and resist/wafer assembly. Because polymer deposition on top of the stencil mask cannot be avoided, it is essential to remove deposited polymer films from the mask surface after certain times of deposition; this cleaning has been carried out in a CF₄/oxygen plasma without any deterioration of the mask.

A typical example of the results obtained by this method is shown in Fig. 2. Polyamic acid films were deposited on a silicon wafer from vapors of 1,2,4,5-benzene-tetracarboxylic anhydride (PMDA) and of 4-aminophenyl ether (ODA) (7). After curing the polyamic acid films at 250°C for 30 min in air, the polyimide films formed were subjected to patternwise exposures of proton beams through the mask, as described earlier. During the proton-beam exposure, tetravinylsilane vapor was introduced through the inlet tube located above the mask-polyimide film assembly; the partial pressure of the silane was 2×10^{-5} torr as measured at a distant location, and the hydrogen pressure was 3×10^{-5} torr. The exposure period was 60 min, corresponding to 5.4×10^{-4} C/cm² with 1.5×10^{-7} A/cm² ion density. After patternwise deposition of the etch-barrier layer, the mask was removed from the mask-polyimide film assembly. Polymer images were developed by oxygen reactive ion etching: development time was 15 min at an oxygen pressure of 0.12 torr, with power density of 0.34 W/cm² and a bias potential of -300V. SEM pictures of the polyimide patterns are shown in Fig. 2 together with a partial image of the mask used. The thickness of the oxygen etch barrier layer deposited was 0.1 μ m. Figure 3 shows the thermal stability of the polyimide patterns; (a) polymer images prior to heating, and (b) and (c) polyimide patterns after heat-treatment at 450°C for 30 min in vacuum, revealing no thermal flow of a half- or a quarter-micron-sized polyimide images. In a similar way as described for polyimide images, we have been successful in obtaining negative tone high resolution and high aspect ratio polymer patterns made of PMMA, cresol-formaldehyde novolac resins, and poly(p-hydroxystyrene).

Positive-Tone Polymer Images

The positive tone polymer pattern fabrications consist of three processes: first, deposition of very thin oxygen etch barrier layers on top of polymer films; second,

Fig. 2. Negative-tone polyimide (PMDA-ODA) made by the process outlined in Fig. 1. (a): A part of a stencil mask. (b) and (c): The polyimide patterns obtained.

Fig. 3. Thermal stability of dry processed-polyimide patterns. (a): Prior to heat-treatment. (b) and (c): After heat-treatment at 450°C for 30 min in vacuum after dry development.

patternwise exposure of polymer films with thin etch barrier layers to proton beams; and third, image developments in oxygen reactive ion etching, as shown in Fig. 4.

Thin oxygen-etch barrier layers were deposited from the vapor phase on top of polymer films in plasma polymerizations of organo-metallic compounds. Another method used was evaporation or sputtering of certain metals. In either case, the control of the thickness of the etch barrier is extremely important. This control was realized with a quartz crystal microbalance (8). Assuming unit density of the etch barrier layers, the thickness must be in the range of 150-250Å. With thinner barrier layers, the thinning of unexposed areas appears, yielding poor quality polymer patterns. With thicker etch barriers, the images cannot be developed, even after prolonged oxygen reactive ion etching.

Plasma polymerized organo-metal films.—The same kind of organo-silicon and organo-tin compounds described in the preceding section have been used in plasma polymerization to form oxygen etch barrier layers: tetra vinylsilane, hexamethyldisilazane, hexamethyldisiloxane, and tetramethyltin. A monomer vapor was introduced into the tail end of an argon or helium glow discharge, and thin plasma polymerized organo-metal films were deposited onto polymer surfaces on silicon substrates located about 5 in. away from the monomer inlet. The deposition was usually completed within 30-60s at about 0.5 torr total pressure, while the amount of deposited films was carefully monitored with a microbalance to a film thickness of 150-250Å.

Polymer films with thin oxygen-etch barrier layers were then exposed to 3-5 keV proton beams through a stencil mask with a beam dose ranging from 2×10^{-4} to 1×10^{-3} C/cm². With the present Magmiller ion gun, these doses corresponded to 20-80 min exposure periods. With a

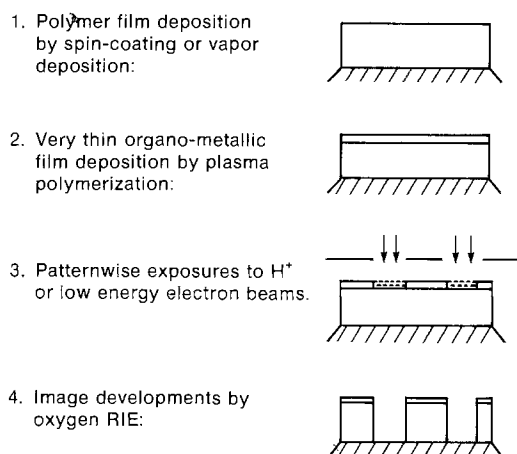

Fig. 4. Positive-tone polymer patterns fabricated by low energy proton beams with the use of thin oxygen-etch barrier layers made of organo-metallic films.

brighter ion source which is now commonly available, this exposure time should be less than 1s. During proton exposures, protons and/or hydrogen atoms reacted with silicon or tin to yield volatile metal hydrides, as discussed later.

After proton-beam exposures, faint color changes appeared in the exposed areas, but the thickness loss never exceeded a few hundred angstroms. Polymer images were then developed by oxygen reactive ion etching; RIE conditions were as already described.

Typical examples of the polymer patterns obtained are shown in Fig. 5. Figure 5a consists of positive-tone polyimide patterns with plasma-polymerized thin tetra vinylsilane layers as the oxygen-etch barrier. These polyimide films were made from vapor-deposited polyamic acid, as previously described. A narrow line (1.5 μm) was delineated completely with vertical wall profiles on 1.3 μm thick polyimide film. The present technique successfully provides fine lines narrower than 1.5 μm, with high resolution in an all dry process.

A charge buildup trouble appeared, however, in the delineation of larger-sized patterns. It was difficult to develop the inner areas of larger images completely, and sometimes the images were developed in the form of a ring like a doughnut, as shown in Fig. 5b and 5c. Figure 5b is a PMMA pattern with plasma-polymerized tetra vinylsilane film as an oxygen etch barrier; 4 keV proton beams impinged onto the silane film through the stencil mask used for images shown in Fig. 2a. As opposed to the other cases, however, island bars with vertical wall profiles were formed inside the developed areas. A 3 μm

Fig. 5. Positive-tone images of polyimides (a) and (c), or PMMA (b) imaged by 5 keV proton-beam exposures onto polymer films with thin oxygen-etch barrier layers made of plasma polymerized tetra vinylsilane, and subsequently developed by oxygen reactive ion etching.

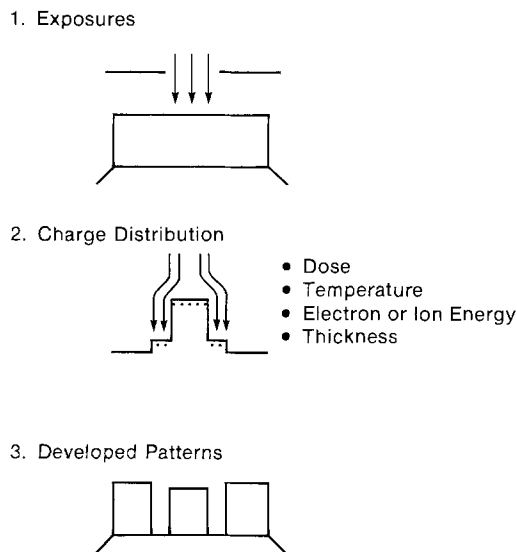

Fig. 6. Trapped charge mechanism for doughnut-shaped pattern formation.

wide mask image appeared as a $5\ \mu\text{m}$ wide rectangular hole with a $2.3\ \mu\text{m}$ wide island bar. Figure 5c shows positive-tone polyimide images of a circular hole, which was made by impinging 4 keV proton beams onto plasma-polymerized tetravinylsilane film and subsequent oxygen reactive ion etching for image developments. The inside island should not appear if there were no charge buildup. The height of the inside island depends upon the degree of charge buildup, which was in turn determined by proton-beam dose, proton energy, substrate temperature, and film thickness. The $1.5\ \mu\text{m}$ wide channel delineated by polymer films was completely developed by oxygen reactive ion etching with surrounding vertical walls. Figure 6 illustrates schematically how these doughnut-shaped patterns were formed by proton charge trapped in the films. Although the polarity should be opposite, low energy electron beams of 800-1000 eV energy generated similar patterns from trapped electrons, as described below.

Fig. 7. Images of trapped low energy electrons in PMMA. (a): 25 keV SEM picture of trapped electrons. (b): Optical picture of the exact same areas of (a).

Sub-keV electron beam exposures.—Low energy electron beam lithography has been reported with focused scanning electron beams with an electron energy below 5 keV (9). Either thin polymer films like PMMA or inorganic resist films have been used; troubles associated with trapped low energy electrons have never been reported. In low energy scanning electron microscopy, no metal coatings are required because of the rapid dissipation of impinging electrons via surfaces. However, as shown in Fig. 7, electrons with 5 keV energy were trapped more efficiently in polymer films than those of 15 or 25 keV energies. In Fig. 7, electrons were scanned on polymer surfaces with equal doses ($\sim 5 \times 10^{-4}\ \text{C/cm}^2$) at 5, 15, and 25 keV. Although there were no images seen optically as shown in Fig. 7b, traces of scanned electrons were seen in SEM pictures of Fig. 7a taken with 25 keV scanning electrons for the same area, particularly the clear traces of 5 keV electrons because of their trapped charge. These images disappeared in heating, or on standing for long times in air, by charge leakage via surfaces and/or through media.

After PMMA films bearing thin oxygen etch barriers were exposed to 5 keV scanning electron beams, attempts were made to develop images by oxygen reactive ion etching. Hollow images were formed, however, in these conditions, as shown in Fig. 8b and 8c, indicating that the electron energy was deposited inside the film, but not very much in the etch barrier layers. With electrons of lower energies of 800-1000 eV, images were developed "from top to bottom" by oxygen reactive ion etching, as shown in Fig. 8a. With such a low energy as 800 eV, however, the doughnut-shaped patterns reported in the preceding section on proton beam exposures were obtained, as

Fig. 8. Positive-tone images of PMMA by 800 eV electron beams (a) or by 5 keV scanning electron beams (b) and (c).

shown in Fig. 9 for large area delineation. The charge buildup is again responsible to these images. In these electron-beam exposures of PMMA films, considerable amounts of hydrogen atoms were formed (10), and these hydrogen atoms are expected to react with silicon atoms to make the exposed areas more vulnerable to oxygen reactive ion etching.

Thin metal films.—The charge buildup problem encountered in the delineation of large patterns in polymer films with insulating plasma polymerized organo-metal films could be avoided in several ways. One way is the use of neutralizing thermal electrons flooding polymer surfaces during proton-beam exposures; most ion sources available have a built-in neutralizer. Another way is to use conducting oxygen etch barrier layers, as reported here. High energy proton beams do not cause this charge buildup problem. Certain metal hydrides are well known for their volatility; for example, SiH_4 , SnH_4 , AlH_3 , Ga_2H_6 , and Ge_2H_6 . When low energy proton beams impinged onto thin metal films, metal films were removed by formation of metal hydrides such as SiH_4 or SnH_4 . Preferential removal of Si atoms or Sn atoms from organo-metal films have been demonstrated with ESCA, as discussed later.

Thin metal films, such as aluminum, bismuth, tin, or other volatile hydride forming metals, were deposited by evaporation or by sputtering onto polymer surfaces; the thickness is critical and must be in the range described above. Subsequent processes are exactly the same as the ones in the preceding section. During image development by oxygen reactive ion etching, the metal films in unexposed areas were converted to metal oxides, which were readily removed in a mild acidic solution.

Fig. 9. Positive-tone images of PMMA generated by 800 eV electron-beam exposures. The polymer films have thin oxygen-etch barrier layers made of plasma-deposited tetravinylsilane.

Fig. 10. Thin bismuth films on top of PMMA were exposed to 4 keV proton beams through a stencil mask, followed by oxygen reactive ion etching for positive-tone image development.

Figure 10 shows 5 μm thick positive tone PMMA patterns. The images were made with thin bismuth films deposited on top of the polymer films, exposed to 4 keV proton beams through a stencil mask, then developed by oxygen reactive ion etching. The bismuth oxide was dissolved in a mild hydrochloric acid. Even the presence of thin bismuth metal films could not prevent a small amount of degradation of PMMA during the oxygen reactive ion etching, resulting in somewhat rough surfaces of PMMA patterns after development. The roughness extended about a few thousand angstroms into 5 μm thick polymer films. With other polymer films, such as polyimide or novolac resin films, this kind of surface degradation never took place during image development. The polymer patterns with 0.5 μm wide and 5 μm high vertical-wall profiles are obtained in this way without any charge buildup, as shown in Fig. 10.

Hydrogen reactive ion etching lithography.—In the preceding sections, proton beams with 3-5 keV energy have been used to delineate polymer images by impinging onto thin oxygen-etch barrier layers and making the impinged areas vulnerable to oxygen reactive ion etching. We do not know exactly how deep these protons penetrate through to the polymer films, although a Monte Carlo calculation predicted about 1000 \AA with 4 keV proton. However, our result that the etch barrier has to be less than 250 \AA to obtain developable images indicates the proton-penetration depth could be less than the calculated extent (11). We also do not know that the active species is a proton or a neutral hydrogen atom, or both. We learned, however, that the etch resistance of the oxygen-etch barrier layers was markedly diminished once the barrier layers were exposed to hydrogen reactive ion etching even for a short period. In our RIE conditions of 0.15 torr and -300V bias potential, neutral hydrogen may play a significant role. PMMA films bearing plasma polymerized tetravinylsilane layers were exposed to hydrogen reactive ion etching for a short period (1 min) through a stencil mask, as had been done with proton beams, followed by image development by oxygen reactive ion etching. The resulting polymer patterns are shown in Fig. 11. In contrast to the images shown in Fig. 5, no doughnut-shaped patterns are obtained in this case, although the same oxygen-etch barrier layer was employed. The difference may have originated from the contribution of neutral hydrogen atoms (hydrogen pressure: 5×10^{-5} torr vs. 0.1 torr in RIE), or because of the different proton energies (4 keV vs. 0.3 keV in RIE). The very shallow penetration of 300 eV protons may help charge leakage via surfaces. The polymer patterns obtained have vertical wall profiles with 6 μm high, but fine images could not be fabricated, probably because of the poor directionality of the proton beams under our RIE conditions.

Discussion

The results described in the preceding sections clearly demonstrate feasibility of thick submicron polymer pattern fabrications with high aspect ratios using low energy proton beams. The present processes depend upon the

Fig. 11. Positive-tone images of PMMA generated by hydrogen reactive ion etching.

use of thin oxygen-etch barrier layers; the images were made in this thin oxygen-etch barrier layer, and oxygen reactive ion etching extended the thickness of patterned images. This mechanism for micropattern generations is different from the "top down" development mode for nitrocellulose resist films, which is a sensitive, self-developing resist under low energy argon ions beams or pulsed UV laser radiations (12). Our technique for micropattern generation does not depend upon the nature of the imaged films, as shown in the examples of PMMA and polyimide, but the role of thin oxygen etch barrier layers is very important. The thickness of the barrier layers is related with the penetration depth of low energy proton beams. The reactivity of a proton and/or a hydrogen atom with a metal atom of the etch-barrier layers determines a proton dose required for image development.

The selective removal of metal atoms from plasma polymerized organo-metal films by proton beams or by hydrogen reactive ion etching is shown in Fig. 12. The ESCA data of the plasma polymerized tetramethyltin films has the core level signals of $\text{Sn}_{3\text{D}3/2}$ and $\text{Sn}_{3\text{D}5/2}$ at 494 and 495 eV, respectively, and the $\text{C}_{1\text{S}}$ core level signal at 284 eV. After 20 min exposure of the plasma polymerized films to hydrogen RIE, the $\text{Sn}_{3\text{D}}$ signals diminished to 10% of their original intensities, whereas the $\text{C}_{1\text{S}}$ core level signal intensity did not change at all, indicating the initial preferential removal of tin atoms. Further exposure to the hydrogen reactive ion etching removed the carbon signal along with the Sn signals; the immediate increase of the oxygen signal after the hydrogen RIE was caused by oxygen attachment to the exposed polymer surfaces, and a signal at 308 eV may arise from an inorganic substrate material. Similarly, silicon and other metal atoms were removed from thin oxygen-etch barrier layers by proton beams, leaving the exposed areas vulnerable to oxygen RIE.

The penetration depth of low energy proton beams is limited from a few hundred angstroms to 1000Å. An extension of the Monte Carlo calculation indicates about 1000Å as the projected range of 4 keV proton beams in PMMA. Although the range of proton beams inside organo-metal films is not known, our experimental requirement that the etch barrier thickness must be within

Fig. 12. Removal of Sn from plasma polymerized tetramethyltin films by hydrogen reactive ion etching.

250Å to get developable images indicates that the penetration depth of the proton beams must be far shallower in the etch-barrier layers than expected from the projected range in PMMA.

After the proton-beam exposures, there are only faint color changes in the exposed areas, but the thinning in the exposed areas was so shallow that the measurement was very difficult, probably within 100Å. The only way to develop images after patternwise removal of the etch-barrier layer by proton beams is oxygen reactive ion etching, which does not erode unexposed areas of the oxygen-etch barrier.

Summary

Low energy proton beams in several keV energy ranges, which are readily available for ion milling and other processes, have been used successfully for the fabrication of high resolution polymer patterns in both negative and positive tones. The proton exposures were carried out through a stencil mask used for the proximity electron printing process. Very thin oxygen etch barrier layers are required because of the limited penetration depths of proton beams. For negative-tone images, etch barriers are deposited in H^+ -beam-induced polymerization of organo-metal compounds. For positive-tone images, etch barriers are deposited by plasma polymerization or by sputtering or evaporation of certain metals prior to patternwise exposures. Charge buildup, which appeared in large pattern delineation, can be avoided by the use of thin metal films as etch barriers, or possibly by flooding the polymer surfaces with thermal electrons. Images are developed by oxygen reactive ion etching, and almost any kind of carbonaceous polymer films can be used as the imaged materials.

Internal Gettering in Bipolar Process

Effect on Circuit Performance and Relationship to Oxygen Precipitation Kinetics

L. Jastrzebski,* R. Soydan, B. Goldsmith,¹ and J. T. McGinn

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

The effect of internal gettering on circuit performance has been studied for I^2L and linear logic bipolar circuits. The gettering has been introduced by controlled precipitation of oxygen in silicon wafers during processing, and its effect has been measured as reduction of circuit leakage current, which has been reflected in yield improvement. The efficiency of internal gettering has been found to be a strong function of the amount of precipitated oxygen and precipitate's morphology. It has also been found that the same factors affect the mechanical strength (warpage) of silicon wafers. The best gettering and yield improvement was obtained for relatively low amounts of precipitated oxygen (about 10 ppm), which resulted in the desired precipitate's morphology. An increase in the amount of precipitated oxygen decreased the gettering efficiency and also reduced the mechanical strength of the silicon wafers. The present work showed that, in addition to well-known factors, such as the interstitial oxygen concentration in virgin wafers, oxygen-precipitation kinetics during bipolar processing is strongly affected by other factors, such as concentration of nucleation centers for oxygen precipitation. They control the rate of oxygen precipitation and precipitate's morphology. Since the concentration of these centers is related to the crystal-growth conditions, differences in precipitation kinetics are found in the wafers provided by various commercial suppliers. This can lead to unusual results. For instance, lower amounts of precipitated oxygen have been found in wafers with an initial oxygen concentration of 40 ppm than in wafers with 28 or 31 ppm coming from different suppliers. We believe that our results clearly demonstrate that internal gettering after optimization can be used to improve circuit yield in bipolar processing lines.

The one most important material problem associated with the use of silicon wafers in LSI and VLSI circuits is control of crystallographic defects formation, which is closely related to the oxygen-precipitation kinetics during processing (1-3). Defects present in the device active area, especially those decorated by heavy metals (4, 5), would give dark current generation sites, which could cause functionality failure or excessive leakage in integrated circuits (1). However, defects present in the bulk of a silicon wafer would have a beneficial effect on circuit performance by acting as a gettering site for contamination, which otherwise would precipitate in the active area of the circuit leading to defect formation and/or decoration (1-3, 6-8).

Oxygen present in silicon affects the formation of oxygen precipitates, stacking faults, dislocations, and thermal donors (1, 2). During the defect-generation process, oxygen can play a positive (dislocation pinning and internal gettering) or a negative (thermal donor generation, poorer mechanical strength, and precipitates in the device active area) role (1). Even in the same state and at the same point in processing, oxygen can be both an asset and a liability, as in the case of SiO_2 precipitates that introduce sites for internal gettering but also lower the mechanical strength, resistance to warpage, of silicon wafers (9).

In order to be able to use internal gettering successfully on production lines, it is essential to balance the amount of oxygen in different states during the circuit-fabrication process in such a way that will simultaneously result in efficient internal gettering and good mechanical strength of the silicon wafers. This can be achieved by controlling the oxygen-precipitation process.

¹Present address: RCA Solid State Division, Findlay, Ohio 45840.

In addition to the amount of precipitated oxygen, the morphology of the precipitates has the strong influence on the efficiency of internal gettering. Conditions exist under which an efficient gettering action and an excellent mechanical strength, resistance to warpage, of silicon wafers in the presence of a relatively low density of oxygen precipitates can be achieved (6). To obtain the desired density and morphology of oxygen precipitates in processed wafers, control of the oxygen-precipitation kinetics during bipolar processing and the relationship of kinetics to the as-grown wafer characteristics become important issues.

It has been well documented that the oxygen-precipitation kinetics are controlled by the interstitial oxygen concentration in the as-grown wafers (10). Two models of nucleation and growth, homogeneous and heterogeneous (1), for oxygen precipitation have been proposed. The homogeneous precipitation model (11, 12) assumes that the driving force for oxygen precipitation is oxygen supersaturation in the crystal during processing, which is a function of the interstitial oxygen concentration. The homogeneous precipitation process is spontaneous. If precipitation is homogeneous, it should be similar in different crystals with different contents of impurities or point defects but the same oxygen content and thermal history. It has been shown that the presence of carbon at high levels (10^{17} cm^{-3}) (13), and variations in the cooling schedule of the crystal after the crystal growth (14), affect oxygen precipitation kinetics during subsequent processing. These data indicate that the oxygen precipitation process can also be heterogeneous (*i.e.*, precipitation of oxygen driven by oxygen supersaturation; nucleation occurs not spontaneously but around nucleation sites already present in the crystals). Heterogeneous nucleation occurs during the growth of the silicon crystal or during the postgrowth process. In addition to foreign impurities,

nucleation sites can be formed by complexes of point defects (15). The formation of these sites during the crystal-growth process is not well understood and is controlled, usually, on a semi-empirical basis. It would appear that the extent to which oxygen-precipitation kinetics will be homogeneous or heterogeneous in nature during processing depends on the concentration of the nucleation sites for oxygen precipitates in the silicon crystal (1).

Because of the differences in equipment and growth procedures used, one can expect that the concentration of nucleation sites in silicon wafers can significantly differ in material obtained from various, commercial, silicon wafer suppliers. Therefore, large differences in the oxygen-precipitation kinetics could be expected in wafers with similar oxygen and carbon concentration coming from different suppliers. This work has been aimed towards providing a link between oxygen-precipitation kinetics, which has been observed during bipolar device processing, and characteristics of virgin wafers. In addition, the goal of this work is to present the relationships which exist between the density and morphology of precipitated oxygen, and (i) the efficiency of internal gettering and (ii) the mechanical strength of the silicon wafer during bipolar processing.

Experimental Procedure

(100) silicon wafers (3 in. diam) were bought from five commercial suppliers. The wafers were p-type (boron-doped) 4-11 Ω cm and 500 $\mu\text{m} \pm 50 \mu\text{m}$ thick. They have been divided into nine categories, according to supplier, interstitial oxygen concentration, degree of back-side damage (group 5), and the density of nucleation centers (group 1). Parameters of different groups of wafers are compared in Table I. Wafers from each group covered approximately 5 ppm range of oxygen concentration. In most instances, two groups of wafers with similar oxygen concentrations, but coming from different suppliers, were available. In addition to interstitial oxygen concentration in virgin wafers, carbon concentration and the concentration of noninterstitial oxygen have also been determined (16). To study the effect of carbon on the oxygen-precipitation process, the wafers from group 3 have been divided into two subgroups containing different carbon concentrations, less than 0.5 ppm and between 1 and 2 ppm. Some wafers from each group have been exposed to preannealing at 800°C for 16h in N_2 prior to processing to enhance the precipitation process. Subsequently, wafers have been introduced into two bipolar fabrication processes used to make linear bipolar logic circuits and I^2L circuits. The time/temperature schedules are presented in Fig. 1. In the initial stage, the processes differ for the I^2L and linear bipolar circuits in the duration of the pocket deposition (a ½h vs. 1h at 1250°C, respectively). The next significant difference between these two pro-

Fig. 1. Temperature/time of I^2L and analog processes

cesses takes place after about 10h of high temperature processing during base diffusion. At this time, the linear bipolar circuits are exposed to a higher temperature than the I^2L circuits. Also, the I^2L process is about 5h longer than the linear bipolar.

The interstitial oxygen and carbon concentration for each group of wafers have been measured after each high temperature step. The amount of oxygen precipitated during processing in each group of wafers has been determined by comparing the interstitial oxygen concentration in the processed blank wafers (which did not receive diffusions) to the amount of interstitial oxygen in the virgin wafers. The morphology of the oxygen precipitates has been studied by Nomarski microscopy after Wright etching of cleaved wafers. It has been verified that the blank wafers and the wafers with circuits had similar defect morphology. Bulk defects in some of the wafers were also examined using TEM.

The mechanical strength of the wafers has been determined by measuring their bow during and after completion of processing. Statistically, wafers from different groups have been exposed to identical stress forces during processing; therefore, one can assume that their bow will be a good qualitative indication of resistance to deformation/mechanical strength of silicon. About 3000 wafers have been processed.

Results

Circuit performance.—To easily separate the effect of internal gettering on circuit performance, the circuit types chosen for this study were such that printing of critical photolithographic dimensions have not been limited by wafer warpage. Usually slip has been localized to the regions at the edge of the silicon wafer which did not contain working circuits. It was thus felt that the circuit yield was not affected by the slip.

Table I. Parameters of as-grown wafers

Group ^a	Interstitial oxygen (ppm)			Noninterstitial oxygen in as-grown (ppm)	Carbon concentration (ppm)
	20	30	40		
1-1 ^b		—		None	1-3.5
1-2		—		≈1.5	1-3.5
2-1	—			None	None
2-2		—		None	0.3-0.6
3-1	—			≈2	0.6-1.0
3-2		—		≈3	< 2 ^c
4			—	None	0.3-0.8
5-1 ^d		—		None	None
5-2		—		None	None

^a First number corresponds to supplier.

^b According to supplier 1, group 1-2 had higher precipitation rate than 1-1.

^c Two subgroups: (i) carbon less than 0.5 ppm, and (ii) carbon 1-2 ppm.

^d Group 5-1 had 3 μm back-side damage, group 5-2 had 10 μm back-side damage.

The effectiveness of internal gettering has been measured directly by its impact on circuit yield. The observed yield increase caused by internal gettering has been traced directly to the improvement of leakage current distribution (soft junction leakage) in the analog bipolar circuits. This is shown in Fig. 2, where the leakage current distribution for two types of wafers, internally gettered wafers (group 1-2 and 1-1) and wafers without intentional internal gettering (standard), are compared. Owing to gettering action of the oxygen precipitates in the wafer interior, impurities are removed from the device active area, which decreases the probability of defect formation (*e.g.*, iron needles which cause emitter collector pipes) and the decoration of already present crystallographic defects (*e.g.*, edge dislocation). As a result of the reduction of the density of electrically active defects, the statistical distribution of leakage current is improved. Excessive leakage current in the analog circuits is the major mechanism limiting yield, and, therefore, internal gettering resulted in yield improvement. As a result of the improved statistical distribution of leakage current, variations of the yield from wafer to wafer in the lots of processed wafers has been also improved. In the I^2L circuit, a relationship between leakage current and yield is not as straightforward as for the analog circuit, and had to be established on a statistical basis. In this case, the most likely cause of circuit performance degradation is functionality failure caused by excessive leakage current of individual small transistors. This is probably related to the presence of collector-emitter pipes. Figure 3 presents a relationship between yield (arbitrary units) and the percentage of devices in which total leakage exceeds 3.0 mA level. Although a one-to-one correlation does not exist as for the analog circuits, a trend can be clearly observed.

The yield improvement observed for various groups of wafers in the I^2L circuits and the analog circuits has been measured through extended periods of time, during which the contamination level in the processing line showed significant fluctuations. The yield improvement, which is presented in Table II, is measured by two factors: (i) a ratio of yield loss due to an excessive leakage in the internally gettered *vs.* standard wafers (CZ wafers with oxygen concentration between 25-40 ppm which did not have any intentional internal gettering) which were processed at the same time (the lowest values correspond

Fig. 2. Leakage distribution for analog circuits made on standard and internally gettered wafers (1-1-I, 1-2).

to the best improvement), which measures the improvement caused by gettering for a given contamination level in the line, and (ii) normalized yield loss, which is the ratio between observed yield loss for a given group of wafers to the lowest yield loss observed in gettered silicon during the time of the experiment, and which gives a certain base line to which the efficiency of internal gettering can be referred (the most efficient gettering for group 4 has the normalized yield of one). The normalized yield should be used essentially as a measure of gettering efficiency, while the ratio of yield loss shows how much yield improvement can be expected over the wafers which do not have any intentional internal gettering. This ratio is also a good measurement of contamination level in the line. For high level of contamination this ratio will be small; for a clean line, this ratio will be close to one. In order to estimate the effect of internal gettering on the yield of bipolar circuits, the normalized yield and the ratio of yield losses should both be considered since the impact of internal gettering on circuit performance can depend on the contamination level present in the processing line. For instance, for low levels of contamination (lot 1-1-II) internal gettering in wafers 1-1 have been sufficient to remove defects from the active area, achieving a normalized

Fig. 3. I^2L circuit yield vs. percentage of highly leaky circuits (exceeding 3 mA).

yield loss of 1.15, which is close to the best values obtained, although the improvement over standards was relatively low (ratio of yield loss 0.93). When the contamination level increased, the gettering action was not strong enough to remove the majority of contamination from the circuit area, and, therefore, the significant yield reduction took place (normalized yield loss 2.7): A large improvement over standard product has, however, been observed in this case (ratio of yield loss: 0.46). An enhancement of gettering action in these wafers due to preannealing (group 1-1) resulted in a significant increase in the yield (normalized yield loss: 1.8) and the larger difference *vs.* the standard wafers (ratio of yield loss: 0.31 *vs.* 0.46). For group 4, the best results were obtained for all contamination levels. The value 0.54 given for the yield loss is an average of the values obtained over an extended period of time when contamination level showed significant fluctuations, ranging from low (time at which 1-1-I was being processed) to high (1-1-II being processed). For I^2L circuits which have been processed through shorter periods of time, with all wafers encountering similar levels of contamination, only the normalized yield loss has been given in Table II.

It is apparent that large differences in the efficiency of internal gettering have been observed between the different groups. The similar trends in the efficiency of internal gettering for the different groups of wafers are visible for I^2L as well as for analog circuits. The effect of preannealing on the efficiency of internal gettering is not straightforward: for group 1-1 and 3-2, a beneficial effect was observed, while for group 4, a detrimental effect occurred. It has to be pointed out that carbon for group 3-2 does not influence gettering efficiency. Two subgroups of wafers, one with carbon concentration between 1-2 ppm and other less than 0.5 ppm, showed similar gettering efficiency. Also, the effect of back-side damage is not clear. Wafers with 10 μm back-side damage (group 5-2) showed slightly less efficient gettering than the same wafers with 3 μm back-side damage (group 5-1). As will be discussed later, these differences are most likely attributed to differences in the oxygen-precipitation kinetics observed in these wafers, and not to differences in gettering caused by the back-side damage.

For a given circuit type, the efficiency of internal gettering is related to the density of precipitated oxygen and the precipitate morphology. The amount of precipitated oxygen during the two processes, together with the interstitial oxygen concentration in the as-grown wafers for different groups of wafers, is also presented in Table II. The gettering efficiency for analog circuits (normalized

Fig. 4. Normalized yield loss (see test) as a function of amount of precipitated oxygen after completion of the analog process (wafers without preannealing) ●: Group 1. ×: Group 2. ▲: Group 3. ■: Group 4. △: Group 5.

yield) is plotted in Fig. 4 as a function of the amount of precipitated oxygen present after processing. The most efficient gettering takes place around 10 ppm of precipitated oxygen (group 4). When the amount of the precipitated oxygen increases beyond this point, the efficiency of gettering decreases. As it will be discussed later, this phenomena is most likely related to the effect of precipitate's morphology on gettering action. It has to be pointed out that the denuded-zone depth is very similar for all groups of wafers. As shown on Table III, it seems that preannealing does not significantly alter the depth of denuded zone. The effect of preannealing on the efficiency of internal gettering is not straightforward. It seems that, for the groups 3-2 and 1-1, preannealing improves yield in the analog circuits, while it deteriorates yield in the wafers from group 1-2 during the analog process and groups 3-1 and 3-2 during the I^2L process. The deterioration of the yield after the preannealing was attributed to an increase of the number of defects in the denuded zone, which propagated through the epilayers to device active regions, causing functionality failures.

The two typical types of bulk defects observed in the wafer's interior after completion of the analog circuits are shown in Fig. 5. It is quite apparent that the morphology of oxygen precipitates is different for these two groups. The wafers in which the amount of precipitated oxygen after processing does not exceed 11 ppm (groups 2, 4, 5) usually have a low density of large, bulk stacking faults (see Fig. 5c). The wafers with the higher amount of precipitated oxygen (groups 1 and 3) have a high density of small stacking faults and precipitates (see Fig. 5a). It has been observed that if the preannealing does not significantly change the concentration of precipitated oxygen in a wafer (groups 1 and 3-2), no change in the precipitate morphology will occur during preannealing (Fig. 5a and 5b). In the wafers in which preannealing significantly increases the concentration of precipitated oxygen (all other groups), a significant change in precipitate morphology is apparent (Fig. 5c and 5d). Preannealing causes the formation of a high density of the small bulk precipi-

tates (Fig. 5d) which are not present in the nonpreannealed wafers with low amounts of precipitated oxygen (Fig. 5c) and are similar to those observed in pre- (Fig. 5a) and nonpreannealed (Fig. 5b) wafers with the higher amounts of precipitated oxygen. An increase of the amount of precipitates and a change of their morphology in the preannealed wafers has detrimental effects upon the efficiency of internal gettering. An example is seen in group 4, where the preannealing deteriorated the normalized yield loss from 1 to 2.2 while the amount of precipitated oxygen increased from 10 to 20 ppm. The increase in the efficiency of internal gettering in the case of preannealing for groups 1-1 and 3-2 analog process should probably be attributed to the stronger gettering action (higher concentration of precipitated oxygen) during the initial processing steps (see below). Although the amount of precipitated oxygen differs slightly for the I^2L and the analog process, the morphology of precipitates for each group, subjected to these two processes, is similar.

Warp/mechanical strength.—The histogram of the warpage distribution in the wafers from group 1-1, 4, 3-1, and 3-2 after the completion of the analog processing is presented in Fig. 6. The best mechanical properties have been observed in wafers from group 4, which have the highest interstitial oxygen concentration in both the as-grown states (40 ppm) and after completion of processing (29 ppm). Preannealing of these wafers significantly increases the amount of precipitated oxygen, changes the precipitate morphology, and catastrophically decreases resistance to warpage (see dashed line).

It seems that mechanical properties are different for the two different ranges of precipitated oxygen. When the amount of precipitated oxygen is relatively low (below 10-12 ppm), the observed variations in the mechanical strength between the different groups of wafers could be explained by the larger relative changes in the interstitial oxygen concentration. For about 10 ppm of precipitated oxygen, wafers with 29 ppm of interstitial oxygen warped less than wafers with 13 ppm of interstitial oxygen (compare group 4 and 3-1). It seems that for low concentrations of precipitated oxygen (not exceeding 10-12 ppm), a small change in the amount of precipitated oxygen does not significantly affect the mechanical strength of the silicon wafer. In the group 3-1, a change of oxygen concentration due to preannealing by about 5 ppm was not reflected in a noticeable change of warpage.

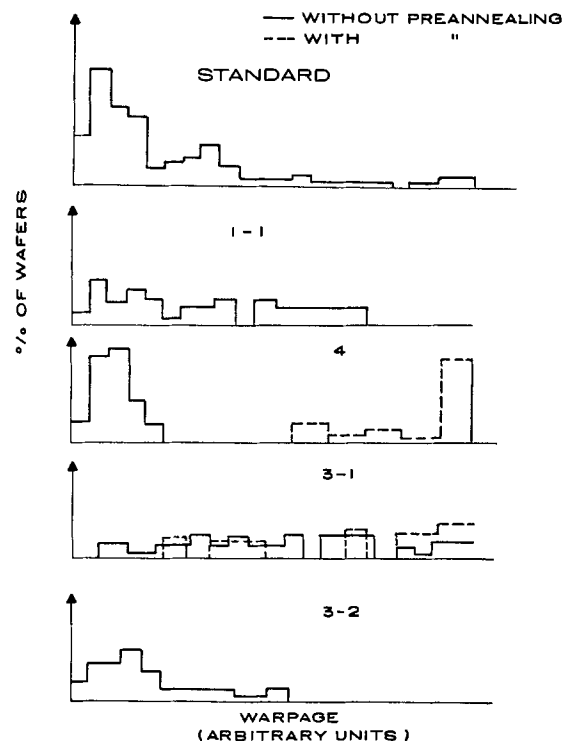

Fig. 6. Histogram of warpage in the wafers from different groups after completion of analog process.

For the high range, when the amount of precipitated oxygen exceeds 10 ppm, a small change in the amount of precipitated oxygen does affect the mechanical strength. For wafers with 12-13 ppm of interstitial oxygen, mechanical strength is reduced when the amount of precipitated oxygen increases from 15 to 20 ppm (compare 3-2 and 1-1). At the present stage, it is not clear why the small change in the high concentration of precipitated oxygen has such a dramatic effect upon warpage while the same change for a low concentration of precipitated oxygen has far less noticeable effect. It seems that for the case of the high amount of precipitated oxygen, change in the interstitial oxygen concentration has less effect on mechanical properties than do changes in the amount of precipitated oxygen. A comparison of mechanical properties of group 1-1 (12 ppm of interstitial oxygen, 20 ppm of precipitated oxygen) to group 4 after preannealing (17 ppm of interstitial and 23 precipitated oxygen) shows that an improvement in the mechanical strength due to 5 ppm increase in the interstitial oxygen concentration can be totally offset by 3 ppm increase in the amount of precipitated oxygen. These data clearly indicate that the mechanical strength of silicon wafers is related to the amount of precipitated and interstitial oxygen, although the observed relation is not straightforward.

It seems that there are two ranges of precipitated oxygen which influence mechanical strength differently during bipolar process. In the low range (up to 10-12 ppm of precipitated oxygen), changes in the amount of precipitated oxygen do not significantly influence wafer warpage. For the high range, a slight increase in the amount of precipitated oxygen significantly decreases the mechanical strength. This effect is probably related to the change of the oxygen-precipitated morphology. For the low range, a significant amount of the defects are long stacking faults often reaching 10 μm in length, which do not seem to have a strong effect upon mechanical strength. In the high range, in addition to small stacking faults, a much higher density of oxygen precipitates resulting in small etch pits is also present. These defects seem to significantly deteriorate mechanical properties.

The beneficial effect of oxygen on mechanical strength of silicon has been attributed usually to dislocation pinning by oxygen in the form of complexes (17, 18) or at in-

terstitial positions (19). However, oxygen precipitates which act as sources of dislocation loops were shown to deteriorate the mechanical strength of silicon (1). It seems that, for high concentrations of precipitated oxygen (above 11 ppm), the deteriorating mechanical properties correlate well with the amount of precipitated oxygen. It also would appear that the extent of dislocation pinning is well characterized by the measure of interstitial oxygen. It has to be pointed out that the present analysis is simplified since it discusses only the effects of two variables, the concentration of precipitated and interstitial oxygen, and is not able to distinguish between the effects which oxygen in complexes or different forms of precipitates would have on the mechanical properties.

Precipitation kinetics.—One can expect that the differences in the internal gettering observed for different groups of wafers are related to the differences in the oxygen-precipitation kinetics which took place during processing. Figures 7-11 present the interstitial oxygen concentration measured in the processed wafers after each high temperature step during I^2L bipolar process. The reduction in the interstitial oxygen concentration is plotted as a function of processing steps.

Micrographs of typical defects observed in the wafer interior after initial oxidation and completion of the process are also included in Fig. 7-11. The samples have been classified by the supplier, and each plot includes wafers which also received preheat-treatment prior to processing. Figures 7-11 show two types of trends: (i) a gradual decrease in the concentration of the interstitial oxygen through practically all processing steps (groups 2, 4, 5) or (ii) a sharp decrease in the interstitial oxygen concentration during the few initial processing steps (prior to isolation deposition and drive). This was observed in all the preannealed wafers and the wafers from groups 1 and 3. It has to be pointed out that the initial interstitial concentration of oxygen in silicon wafers will not determine which type of precipitation kinetics will be observed during processing and, therefore, will not determine the total amount of precipitated oxygen after completion of the process. The slow kinetics has been observed for all inter-

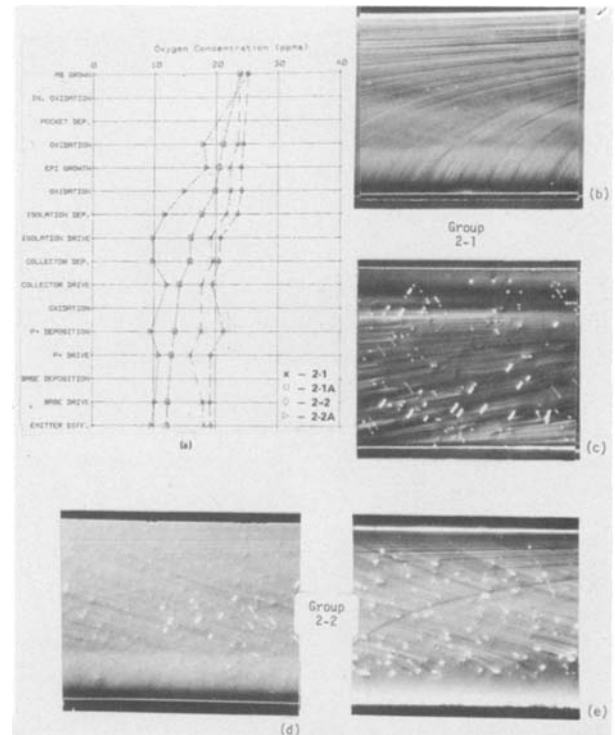

Fig. 8: a: Change in the interstitial oxygen concentration during I^2L processing observed in the wafers from groups 2-1 and 2-2 (2-1, 2-2, no preannealing; 2-1A, 2-2A, after preannealing). b, d: Precipitate morphology after initial oxidation in groups 2-1 (b) and 2-2 (d). c, e: Precipitate morphology after completion of process in groups 2-1 (c) and 2-2 (e).

stitial oxygen concentrations [i.e., in the wafers with the highest (group 4) as well as the lowest (group 2-1) concentration of the interstitial oxygen], while the rapid precipi-

tation has been observed mostly in the wafers which initially had certain trace amounts of the oxygen in a noninterstitial form (see Table I).

The amount of oxygen precipitation which takes place during the analog and I^2L processes for different groups of wafers is compared in Table II. The amount of precipitated oxygen during these two processes is very similar, although the amount of oxygen precipitated during I^2L process is slightly higher (about 2 ppm). For the wafers with the lowest oxygen content (groups 2-1 and 3-1), the difference in the amount of precipitated oxygen during these two processes is the largest.

The morphology of oxygen precipitates after the initial steps and completion of the process is quite different for different groups of wafers (Fig. 7-11). The observed differences in morphology correspond to the differences in the rate of oxygen precipitation for the various groups of wafers. It seems that the slower precipitation kinetics results in a relatively low density of large oxygen precipitates and stacking faults, while the rapid precipitation process gives a high density of small precipitates and stacking faults. As has been discussed before, preannealing changes the oxygen precipitation kinetics from slow to rapid; the amount and morphology of bulk precipitates will also change (see groups 2, 4, 5). For wafers with rapid precipitation kinetics, preannealing does not have a pronounced effect on the amount and morphology of bulk precipitates. The morphology of the precipitates after completion of the process was usually similar to the morphology observed after the initial processing steps. Only wafers with the highest oxygen concentration (group 4) were an exception; their defect morphology at the beginning of the process was similar to that of groups 1 and 3, and to groups 2 and 5 after completion of the process.

The amount of precipitated oxygen and precipitate morphology have been affected by the degree of mechanical damage present on the back of the wafers. The wafers with 10 μm damage had more precipitated oxygen during analog process than 3 μm damaged wafers. This indicates that mechanical damages accelerate the precipitation process in group 5.

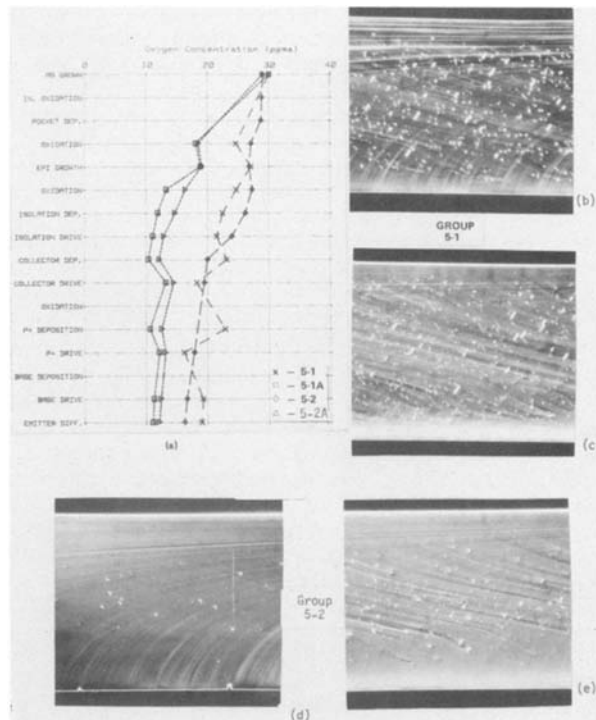

Fig. 11. a: Change in the interstitial oxygen concentration during I^2L processing observed in the wafers from groups 5-1 and 5-2 (5-1, 5-2, no preannealing; 5-1A and 5-2A, with preanneal). b, d: Precipitate morphology after initial oxidation in groups 5-1 (b) and 5-2 (d). c, e: Precipitate morphology after completion of process in groups 5-1 (c) and 5-2 (e).

A comparison of the precipitates in the wafers from group 3 with various carbon levels did not show any substantial differences. From this, it appears that, for the rapid kinetics (group 3), carbon at the level up to 2 ppm does not influence the oxygen-precipitation process.

Some variations in the amount of precipitated oxygen and precipitate morphology have been observed in the wafers belonging to the same group as well as across individual wafers. In the latter case, the most noticeable differences were in precipitation density and morphology between the edges and center of the wafer or a striation-type distribution of precipitates in the wafer. In most instances, these differences in precipitate's density were not related to the differences in the oxygen or carbon concentrations across the wafer. Because oxygen and carbon concentration did not show any appreciable variations, it was assumed that the observed changes in the precipitate's density were caused by nonuniform distribution of nucleation centers for oxygen precipitation (1) in the wafers.

Microcharacterization of defects.—The etching study provides quantitative information about the defect density and their distribution in the wafers, but does not evaluate the microscopic defect structure. To investigate differences in the microdefect structure in the wafers with slow and rapid precipitation kinetics, samples from group 4 and group 3-2 were examined using TEM. The preliminary results showed large differences in the microscopic nature of stacking faults in these two groups of wafers (Fig. 12). As is shown in Fig. 12a, stacking faults in the wafers from group 3-2 are usually not decorated with precipitates, while those from group 4 showed more complex structures (Fig. 12b). The stacking faults from group 4 has several distinguishing characteristics: (i) the stacking faults appear in segmented form, (ii) dislocations are observed at numerous locations along the fault, and (iii) numerous precipitates decorate the fault.

The segmentation of the stacking fault, shown in Fig. 12b, is a result of the formation of additional stacking faults along slip planes parallel to the original fault. As

Fig. 12. Comparison of typical defects observed by TEM in groups 3-2 (a) and group 4 (b)

the electron beam passes through successive, closely spaced faults, it undergoes a phase shift of $\pm 2\pi/3$ at each fault (20). If the electron beam passes through $3n$ stacking faults each resulting in the same sign of the phase shift, the characteristic fringe structure of the fault will be absent. Stacking faults are bounded by partial dislocations. In overlapping faults, a partial dislocation will then delineate the boundary across which a phase shift will occur. A total phase shift of zero will occur every two dislocations if the signs of the shifts at the dislocations are opposite or every third dislocation, if the signs are the same. Both of these occur in Fig. 12b.

A total of seven precipitates may be seen along the various segments of the stacking fault in Fig. 12b, while the bulk of the silicon is relatively free of such defects. The high density of precipitates along the fault clearly indicates that their nucleation occurred preferentially after the formation of the initial stacking fault. What is not clear is whether or not the formation of the additional overlapping faults and associated dislocations (those other than initial fault and bounding dislocation) preceded or followed the nucleation of precipitates. The presence of numerous precipitates situated along the stacking fault indicates that the precipitation process took place after the stacking fault was formed. It is not clear at the present stage why the microstructure of the stacking faults in Fig. 12 differs. These differences can be caused by fundamental differences in the stacking faults' nucleation process in the two groups of wafers or be related to the time during processing when stacking faults have been generated in these two groups of wafers. According to data on the oxygen precipitation, it seems that the stacking faults' formation process in group 4 was

gradual, while in group 3-2 it took place abruptly during a few initial processing steps.

In addition to precipitates which have formed on stacking faults, larger faceted precipitates (see Fig. 13) have been observed away from stacking faults. Microdiffraction from the regions containing the faceted precipitates shows only silicon matrix spots. This suggests that the precipitates are either amorphous or coherent with the silicon matrix. Ponce *et al.* (21) have examined similar precipitates using high resolution lattice imaging techniques. Their results indicate that these precipitates are amorphous and the faceting is a consequence of matrix effects within the silicon crystal.

Energy dispersive x-ray spectroscopy performed with a windowless detector showed that the precipitates formed outside the stacking faults contained only oxygen and silicon, when precipitates formed at the stacking faults often have heavy metals (see Fig. 14) associated with them. This result indicates that the gettering of contaminations during internal gettering is carried out by stacking faults; other defects play a secondary role in the gettering process.

Discussion

Oxygen precipitation kinetics and gettering.—Surprising differences have been observed when the oxygen precipitation kinetics between various groups of wafers have been compared. Two types of precipitation kinetics have been observed during the bipolar processes: a slow, gradual decrease in the interstitial oxygen concentration through all processing steps (groups 2, 4, and 5), and a sharp, fast change during the few initial processing steps (prior to the isolation drive) (groups 1, 3, and all the preannealed wafers).

Fig. 13. Large-faced precipitates found away from stacking faults

Oxygen supersaturation during processing is not the main factor controlling precipitation kinetics in various groups of wafers. For instance, group 4 with the initial oxygen concentration of 40 ppm exhibits slow precipitation kinetics, giving about 10 ppm of precipitated oxygen, while for the same process for a lower oxygen concentrations, of 28 ppm group 3-2, a faster precipitation kinetics resulted in 18 ppm of precipitated oxygen. Therefore, the specification of the oxygen content in as-grown wafers is not sufficient to predict the wafer behavior during processing. The differences for the two types of precipitation kinetics have been reflected in the character of the oxygen precipitate's morphology, and the amount of precipitated oxygen; (e.g., compare wafers from group 5 and 1 with apparently identical initial characteristics in terms of interstitial oxygen concentration but visible differences in precipitates' morphology). These differences are visible after the initial processing steps and are preserved through the entire process.

It seems that one of the factors affecting the mechanism of oxygen precipitation is the amount of oxygen in noninterstitial state in the virgin wafers. The rapid kinetic occurs if oxygen is present in noninterstitial sites in the as-grown wafers, while slower kinetic is typical for wafers with interstitial oxygen. Group 3-1 and 2-1 had similar initial oxygen concentration (24 ppm), but the amounts of precipitated oxygen after completion of the P^2L process were 11 and 6 ppm, respectively. Initially, the wafers from group 3-1 had about 2 ppm of oxygen in noninterstitial sites, while the wafers from group 2-1 had none. These data indicate that silicon crystals which have the same grown-in interstitial oxygen concentration can behave differently during processing if different growth procedures, giving different levels of noninterstitial oxygen, were used during the crystal-growth process.

Preannealing seems to convert a slow precipitation mechanism into a rapid mechanism, by introducing oxygen into noninterstitial state. However, preannealing does not significantly influence the precipitation character in wafers in which precipitation would have otherwise undergone the rapid process. Nucleation centers in these wafers are already provided by noninterstitial oxygen introduced during the crystal-growth process. In the case when the oxygen-precipitation process occurs rapidly, a carbon concentration of up to 2 ppm does not affect the precipitation kinetics (group 3 wafers).

Mechanical damage on the back side of the wafers can influence the precipitation process, as demonstrated for group 5. For the slow precipitation process, mechanical damages slightly accelerate oxygen precipitation.

Noticeable differences in precipitation kinetics have been observed for two bipolar processes which differ slightly in temperature but significantly in the time duration of high temperature steps (see Fig. 1). The differences were largest for the wafers with the lowest oxygen

(a)

(b)

Fig. 14. Energy dispersive spectra (EDS) taken from (a) faceted precipitate—notice only oxygen and silicon signal—and (b) precipitate found on a stacking fault. Heavy metal is clearly associated with precipitate.

concentration (lowest supersaturation). The higher amounts of precipitates usually observed during the P^2L process than during the analog process can be explained by the longer processing time during the P^2L process. At these longer times, more oxygen was able to diffuse to the precipitates, thus contributing to their growth.

Differences in the precipitation kinetics observed in the wafers belonging to the same group are most likely related to the differences in the concentration of nucleation centers for oxygen precipitation, which were introduced by point defect complexes (15) during the crystal-growth process.

The bulk oxygen precipitates and stacking faults generated during the bipolar process have been used successfully to reduce defect density which results in a reduction of leakage current and, therefore, a yield improvement of bipolar circuits. The efficiency of internal gettering is not only dependent on the total amount of precipitated oxygen during processing, but is also strongly affected by the precipitate morphology. The most efficient gettering for various contamination levels in the processing line has been achieved by about 10 ppm of postprocessing, precipitated oxygen, which formed large stacking faults. Any attempt to increase the amount of precipitated oxygen above this value results in the reduction of the gettering efficiency. It seems that the increase in the amount of precipitated oxygen results always in change of defect morphology from low density, large, bulk stacking faults

and precipitates to high density, small stacking faults and precipitates. The preliminary TEM data indicate that the microstructures of these bulk defects are also quite different, with large stacking faults acting as good gettering sink for heavy metals. In addition to the adverse effect on the gettering efficiency, the increase in the amount of precipitated oxygen seems to adversely effect the mechanical strength of silicon wafers.

It is remarkable that the best efficiency of internal gettering and resistance to warpage has been observed for the same wafers (group 4). These wafers had the highest initial interstitial oxygen concentration and exhibit the slow oxygen-precipitation kinetics during the bipolar process. This resulted in about 10 ppm of the precipitated oxygen forming large, precipitate decorated stacking faults. It seems that this morphology and density of precipitated oxygen is small enough not to cause serious degradation of the wafer strength but sufficiently large to provide efficient gettering.

Summary

We believe that our results clearly demonstrate that internal gettering can be used to improve circuit yield in bipolar processing lines. The oxygen-precipitation process has to be carefully adjusted to obtain the desirable morphology and the optimum density of precipitates to provide an efficient gettering action. Simultaneously, the amount of oxygen in a state which results in dislocation pinning and ensures good mechanical strength and resistance to warpage of silicon wafers must be achieved. These results can only be accomplished with a well-controlled oxygen-precipitation process.

The present work shows that, in addition to the well-known factors, such as the interstitial oxygen concentration in virgin wafers, oxygen-precipitation kinetics during bipolar processing is also strongly affected by an additional factor which could be related to the concentration of nucleation centers. These centers are generated by the oxygen in noninterstitial sites or point-defect complexes present in virgin wafers. The concentration of these centers is related to the crystal-growth conditions, and is different in silicon from various commercial suppliers. It should be pointed out that the nature and formation of these centers is not well understood. The development of the more complete understanding will require an extensive basic study of the relationship between formation of nucleation centers and the phenomena taking place during crystal growth. For practical application, a reproducible and controllable precipitation rate is required, which implies that in addition to oxygen content the concentration and the nature of the nucleation centers must be precisely controlled. In most instances, only the concentration of interstitial oxygen, and sometimes carbon, is specified in commercial silicon wafers. Therefore, one has to realize that to achieve controllable precipitation kinetics during bipolar processing the density of nucleation sites in silicon also has to be controlled on a reproducible basis by the crystal growers. Only then will processing

engineers be able to take full advantage of the benefits of internal gettering in production lines.

Analysis and Thermodynamics of the Vapor Phase over Liquid InTe at 1106 ± 2 K

Raman S. Srinivasa* and Jimmie G. Edwards**

Department of Chemistry, University of Toledo, Toledo, Ohio 43606

ABSTRACT

The vapor phase over InTe(l) at 1106 ± 2 K was analyzed by an isothermal total exhaustion experiment with a Knudsen-cell mass spectrometer. In^+ , In_2^+ , Te^+ , Te_2^+ , InTe^+ , In_2Te^+ , InTe_2^+ , and In_2Te_2^+ were observed. The appearance potentials of In^+ , In_2^+ , Te^+ , InTe^+ , In_2Te^+ , InTe_2^+ , and In_2Te_2^+ were 7.7, 9.6, 9.9, 8.6, 8.3, 8.2, and 7.6V, respectively, with an uncertainty of 0.3V. The fragment ions and their precursors were identified in three ways: (i) their appearance potentials were compared with those in the literature; (ii) the slopes of the plots of ionic intensities vs. time were compared; and (iii) all ions were assumed to be parents; hypothetical equilibrium constants for several vapor-phase reactions involving the hypothesized gaseous precursors were checked for time-dependent trends and, where possible, compared with literature data. From these three tests, we found that almost all of In^+ , In_2^+ , Te^+ , InTe^+ , and In_2Te^+ came from $\text{In}_2\text{Te}(\text{g})$, almost all of Te_2^+ came from $\text{Te}_2(\text{g})$, and almost all of InTe_2^+ and In_2Te_2^+ came from $\text{In}_2\text{Te}_2(\text{g})$. Thus, it was found that the vapor phase was composed of $\text{Te}_2(\text{g})$, $\text{In}_2\text{Te}(\text{g})$, and $\text{In}_2\text{Te}_2(\text{g})$. The mass spectrometer was calibrated with integrated ion intensities and the analysis of the fragmentation processes. Partial pressures of the vapor species were derived from ionic intensities. The equilibrium constant for the reaction

was found to be $(1.81 \pm 0.10) \times 10^{-3} \text{ Pa}^{-1}$. The standard enthalpy of the above reaction at 298 K was $-310.9 \pm 0.5 \text{ kJ}$.

The study of indium telluride is of interest because of its application in solid-state devices: nuclear radiation detectors (1), photoconductors (2), and heterojunction devices (3-4). Knowledge of the chemistry and thermodynamics of the gas phase over indium tellurides will be useful in the preparation of such devices by vapor-phase growth. In this paper, we report our analysis of the vapor phase over InTe(l) at 1106 ± 2 K and thermodynamics of the reaction

Colin and Drowart (5) studied the gas-phase equilibria among indium tellurides by mass spectrometry in the temperature range 1093-1234 K with a single Knudsen cell and in the range 1198-1557 K with a double cell in a double oven. They observed Te^+ , Te_2^+ , In^+ , InTe^+ , In_2Te^+ , InTe_2^+ , and In_2Te_2^+ . They measured the appearance potentials of these ions. On the basis of the appearance potentials, they concluded that in their single-cell experiments In^+ and Te^+ were composed of both parent and fragment ions. All other ions were parent ions. They took the vapor phase over liquid In_2Te_3 to be composed of $\text{In}(\text{g})$, $\text{Te}(\text{g})$, $\text{Te}_2(\text{g})$, $\text{InTe}(\text{g})$, $\text{In}_2\text{Te}(\text{g})$, $\text{InTe}_2(\text{g})$, and $\text{In}_2\text{Te}_2(\text{g})$ and calculated partial pressures from the ion intensities.

We carried out an isothermal total exhaustion experiment on InTe(l). From the relationships between ion intensities as functions of time and from the appearance potentials, we could identify the fragment ions and their parent ions. On the basis of our understanding of the fragmentation processes in this system, we found that the vapor phase over InTe(l) consists of $\text{Te}_2(\text{g})$, $\text{In}_2\text{Te}(\text{g})$, and $\text{In}_2\text{Te}_2(\text{g})$ and analyzed the thermodynamics of the gas-phase reaction [1].

Experimental

InTe(s) was prepared by heating the high-purity elements in vacuum-sealed Vycor tubes. A Nuclide 12-90 HT Knudsen-cell mass spectrometer was used to analyze the vapor from the Knudsen cell. A movable shutter was used to focus the molecular beam from the Knudsen cell into the ionization chamber of the mass spectrometer and to discriminate against background gases. The Knudsen cell was heated by radiation from electrically heated tungsten filaments. The cell and the filaments were surrounded by tantalum radiation shields. The temperature of the sample was measured with a Leeds and Northrup, disapp-

earing filament, optical pyrometer focused on a black-body hole in the bottom of the Knudsen cell.

A sample of $9.39 \pm 0.05 \text{ mg}$ of InTe(s) was evaporated completely at 1106 ± 2 K, while the intensities of the ions were measured as functions of time. The sample was contained in a graphite Knudsen cell whose effective orifice area was $1.08 \pm 0.03 \text{ mm}^2$. Intensity measurements were made at m/e values of 115 (In^+), 130 (Te^+), 230 (In_2^+), 241 (InTe^+), 256 (Te_2^+), 360 (In_2Te^+), 371 (InTe_2^+), and 486 (In_2Te_2^+). The electron multiplier gain at m/e of 202 (Hg^+) was measured at room temperature before the evaporation of the sample.

In separate experiments with samples of InTe(s) from the same preparation batch, ionization efficiency curves were obtained for all ions whose precursors originated from the Knudsen cell and for Hg^+ , CO_2^+ , and H_2O^+ , which were background ions. The appearance potentials of the background ions above and that of Te_2^+ were used to calibrate the voltage axis. Weighted least squares analysis was carried out to obtain the calibration curves. During the same experiments, the electron multiplier gains of all ions, including $^{202}\text{Hg}^+$, were measured.

Partial pressures in the Knudsen cell were related to ion intensities with the equation

$$p_i = kT \sum_j \frac{I_{ij}^+}{\sigma_i \gamma_j f_j} \quad [2]$$

in which p_i is the partial pressure of i th precursor, I_{ij}^+ is the ion intensity of j th fragment of i th precursor, σ_i is the ionization cross section of i th precursor leading to j th fragment, γ_j is the electron multiplier gain of j th ion, f_j is the isotopic fraction of the observed ion, T is the temperature, and k is the instrument transmission factor

$$k = g \left[\frac{2\pi R}{T} \right]^{1/2} \left[AW \sum_i M_i^{1/2} \sum_j \frac{\int_0^t I_{ij}^+ dt}{\sigma_i \gamma_j f_j} \right]^{-1} \quad [3]$$

where g is the mass of the sample, M_i is the molecular weight of i th precursor, t is the time, t' is the time at which the sample was completely vaporized, A is the area of the orifice, and W is its transmission probability.

The atomic ionization cross sections are those of Mann (6). Ionization cross sections of In_2 , Te_2 , InTe , In_2Te , and InTe_2 were taken to be 0.8 times the sum of the ionization cross sections of the atoms. Ionization cross section of In_2Te_2 was taken to be 0.8 times that of InTe . Lacking dependable values of ionization cross sections for the

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

various fragmentation processes, we assumed the ionization cross section of the precursor to be independent of the subsequent fragmentation events. This assumption had the effect of removing the subscript j from σ_{ij} in Eq. [2] and [3].

The fragmentation processes in this system were analyzed in three ways. In the first method, ionic intensities were plotted as functions of time, and their slopes were compared to identify those ions with a common precursor. In the second method, the appearance potentials of the ions were analyzed to find the fragment ions and the parent ions. In the third method, we assumed that all ions were parents and ion intensities were used to calculate partial pressures of the hypothetical gaseous precursors with Eq. [2] and [3]. This assumption had the effect of removing summations over j , there being but one ion from each precursor. With these hypothetical partial pressures, equilibrium constants were calculated for the following hypothetical reactions

and for reaction [1]. The reaction quotients were checked for their trends with time and, where possible, compared with equilibrium constants from the literature.

The standard enthalpy of the vapor-phase reaction [1] was calculated from partial pressures, temperature, and Gibbs energy functions $\phi^\circ(T)$ with the equation (8)

$$\Delta H^\circ(298 \text{ K}) = RT [\Delta \phi^\circ(T)/R + \ln(K_1 \times \text{Pa}) + 11.526] \quad [9]$$

where K_1 is the equilibrium constant, in units of Pa^{-1} , for reaction [1], and the last term accounts for the fact that the standard pressure is 1 atm. Gibbs energy functions of $\text{In}_2\text{Te}_2\text{(g)}$ and $\text{In}_2\text{Te(g)}$ were those of Colin and Drowart (5), and that of $\text{Te}_2\text{(g)}$ was taken from Hultgren *et al.* (10).

Results

In^+ , In_2^+ , Te^+ , Te_2^+ , InTe^+ , In_2Te^+ , InTe_2^+ , and In_2Te_2^+ were observed. Their intensities measured as electron currents at the electron multiplier output, and corrected for the isotopic fraction, during the total exhaustion experiment are shown in Fig. 1. In this figure, region I corresponds to a period during which the temperature of the Knudsen cell was raised sharply to a steady-state value of $1106 \pm 2 \text{ K}$. Regions II and III correspond to a period during which the Knudsen cell was at constant temperature. In region II, the ion intensities varied continuously with time till a point of discontinuity occurred at $75.5 \pm 0.5 \text{ min}$ from the beginning of heating. At this point of discontinuity, In^+ intensity dropped by a factor of ~ 15 , Te^+ intensity by a factor of ~ 60 , In_2Te^+ intensity by a factor of ~ 100 , and In_2^+ intensity by a factor of ~ 15 . The intensities of Te_2^+ , InTe_2^+ , and In_2Te_2^+ dropped below the sensitivity of the instrument. The variation of ion intensities in region II fell into three distinct groups. The curves which represented the variation of In^+ , In_2^+ , Te^+ , InTe^+ , and In_2Te^+ were parallel, and those of InTe_2^+ and In_2Te_2^+ were parallel. The curve which represented the variation of Te_2^+ with time was unique. In region III, In^+ and Te^+ continuously decreased to a value of about a thousandth of their maximum intensities. At this stage, the variation of ion intensities with the shutter position suggested that the gaseous precursors were originating from the radiation shields and not from the Knudsen cell.

Table I gives the appearance potentials, electron multiplier gains, and cross sections of the ions. Column 1 gives the list of ions observed, column 2 the appearance potentials from this work, and column 3 the appearance potentials of these ions from the literature. The literature values are those reported for parent ions. Column 4 gives

rium constant for reaction [8]. Column 7 gives the equilibrium constant for reaction [1]. The bottom two rows give the equilibrium constants from the literature and their source. The literature values of the equilibrium constants of reactions [4] and [6] are the vapor pressures of pure indium and pure tellurium because the solution laws and concentrations of the system are unknown.

The instrument transmission factor, k , calculated with the hypotheses that all In⁺, Te⁺, In₂⁺, InTe⁺, and In₂Te⁺ came from In₂Te(g), all In₂Te₂⁺ and InTe₂⁺ came from In₂Te₂(g), and all Te₂⁺ came from Te₂(g), was 1.27×10^{-10} Pa m² A⁻¹ K⁻¹. Thermodynamics of reaction [1] derived on the basis of the above hypotheses are in Table IV. Column 1 gives the time, and columns 2 to 4 give the partial pressures of Te₂(g), In₂Te(g), and In₂Te₂(g), respectively. Column 5 gives the equilibrium constant of reaction [1], and column 6 gives the ΔH° (298 K) for this reaction derived by the third-law method. The average ΔH° (298 K) was -310.9 ± 0.5 kJ.

Discussion

We reached five conclusions: (i) the chemical system we studied can be thought of as a solution of tellurium in an indium-rich liquid; (ii) the vaporization of this liquid is incongruent; (iii) almost all of In⁺, In₂⁺, Te⁺, InTe⁺, and In₂Te⁺ came from a single precursor, In₂Te(g); (iv) almost all of Te₂⁺ came from Te₂(g); and (v) almost all of In₂Te₂⁺ and InTe₂⁺ came from a common precursor, In₂Te₂(g).

The standard enthalpy of reaction [1] at 298 K from this work is -310.9 ± 0.5 kJ. The uncertainty in our data is the standard deviation of the mean. The overall uncertainty is estimated to be less than 10 kJ. From the results of Colin and Drowart, we calculated -298 ± 33 kJ for the same reaction.

The variation of ionic intensities with time in Fig. 1 for the three groups of ions were different and indicated that the vapor-phase composition was changing during evaporation. Hence, the vaporization was incongruent. In a two-component system with a changing vapor composition, there should be but one condensed phase. We took this phase to be a solution of tellurium in an indium-rich liquid. During the vaporization of such a liquid, the activity of tellurium should be decreasing, while the activity of indium should be increasing. We observed that the intensity of Te₂⁺ was falling more rapidly than those of the indium containing ions and of Te⁺. The slow decrease in the intensities of indium containing ions was attributed to the decreasing surface area of the sample.

The three groups of curves in the plots of ionic intensity vs. time indicated that there were three molecular precursors in this system. Each precursor gives rise to one group of ions. The curves for In⁺, In₂⁺, Te⁺, InTe⁺, and In₂Te⁺ were parallel and indicated that these ions had a common precursor. This common precursor can be thought of as a species present in the gaseous phase or the condensed phase. If the precursor were to be present in the gaseous phase, and if we assume that we observed all parent ions, then In₂Te(g) would be the common precursor of In⁺, In₂⁺, Te⁺, InTe⁺, and In₂Te⁺. If the precursor were to be present in the condensed phase, then this precursor during vaporization should produce In(g), In₂(g), Te(g), InTe(g), and In₂Te(g), and these, in turn, should produce the corresponding ions. We ruled out this possibility by tests described later in this section.

The curves for In₂Te₂⁺ and InTe₂⁺ were parallel and indicated that In₂Te₂(g) would be the common precursor. The curve for Te₂⁺ was unique and indicated that Te₂(g) would be its precursor.

Appearance potentials provided additional support to the hypothesis of three gaseous precursors over InTe(l). The appearance potential of In₂Te₂⁺ agreed with that in the literature for the parent ion, within the uncertainty limits. The appearance potential of InTe₂⁺ was lower than that in the literature, but higher than the appearance potential of In₂Te₂⁺. The appearance potential of In⁺, In₂⁺, Te⁺, InTe⁺, and In₂Te⁺ were higher than the ones in the literature for parent ions. The appearance potentials of In₂⁺,

Te⁺, and InTe⁺ were higher than that of In₂Te⁺ and indicated that these three ions could be the fragments of In₂Te⁺. The appearance potential of In⁺ was lower than that of In₂Te⁺ and indicated that a part of In⁺ came from a different source.

The various gaseous species inside the Knudsen cell should be at equilibrium. The equilibrium constants for vapor-phase reactions should be independent of the time at which the partial pressures were measured, and the values should be comparable to literature data. The reaction quotients of reactions [5], [7], and [8] failed these tests. The reaction quotients for the incongruent vaporization of indium and tellurium from the homogenous condensed phase showed variations with time because of variations in their activities and sample surface area. The partial pressure of In(g) over liquid InTe was about seven times that over pure indium and showed that the major source of In⁺ was fragmentation processes. The partial pressure of Te₂⁺ at its maximum value was lower than that over pure tellurium, as expected. The equilibrium constant for the dimerization of indium showed variations with time, and its value was higher than the literature value by four orders of magnitude. The dimerization constant for Te(g) showed large variations with time. Large variations in the equilibrium constant for reaction [8] showed that such an equilibrium did not exist in the Knudsen cell. The hypothetical equilibrium constant for reaction [1] remained constant. These tests with reaction quotients provided additional support in the identification of fragment ions and the ruling out of the possibility that all ions are parents and the precursor is the condensed phase. The fact that the reaction quotient of reaction [1] remained constant, $(1.81 \pm 0.10) \times 10^{-3} \text{ Pa}^{-1}$, in spite of large variations in the partial pressures of Te₂(g), In₂Te(g), and In₂Te₂(g) confirmed conclusions (iii)-(v) above.

Process Modeling of n-Type Doping in Gallium Arsenide

J. K. Dhiman and K. L. Wang*

Department of Electrical Engineering, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Empirical models have been developed for predicting the carrier distributions after ion implantation and annealing process steps used in GaAs device fabrication. The present models predict the carrier distributions for n-type GaAs using Si and Se as the dopants. The simulation is done by using the atomic profile and activation efficiency models developed in this study. These models are based on SIMS and measured carrier concentration profile studies reported in the literature. The model for atomic distribution provides a gaussian profile for Si and a joined half-gaussian one for Se using the projected range and standard deviation parameters obtained from SIMS studies. The effect of radiation enhanced diffusion is taken into account. Impurity diffusion during annealing for temperatures up to 920°C for Si and 1000°C for Se is neglected. Volumetric concentration has been properly chosen as a canonical parameter for obtaining activation efficiency. The universal activation efficiency plots for each dopant species give percentage activation efficiency as a function of atomic concentration (cm^{-3}) at different annealing temperatures.

GaAs is rapidly emerging as an important alternative material in high speed digital and microwave monolithic integrated-circuit applications (1, 2). The rapidly improving technology of GaAs FET's is making a major impact on a wide range of microwave power and digital circuits. Direct ion implantation into bulk-grown semi-insulating GaAs with or without an epitaxially grown buffer layer has become a mainstream technology for GaAs FET fabrication. The characteristics of GaAs devices strongly depend on the carrier concentration profile which results from ion implantation and subsequent annealing. Therefore, a model for predicting carrier concentration profiles is needed to facilitate the processing of GaAs devices. Most of the experimental work using Cr-doped HB mate-

rial reported so far does not give consistent results in the low doping range. This is because of the strong dependence of the doping on the initial Cr content in the substrate material (3). Moreover, the experimental data available in the literature are not systematic enough for the purpose of constructing a theoretical model. The decision was, therefore, made to develop empirical models based on the available experimental data. These models will give a first-order estimate of the carrier concentration profile and will serve the needs for all practical purposes.

In GaAs device processing, ion implantation is normally used to dope the channel, and the source and drain regions of MESFET's where n-type dopants such as silicon (group IV) and selenium (group VI) have been most extensively used. Owing to the limited availability of ex-

*Electrochemical Society Active Member.

perimental data for other species, this study models Si and Se impurities only.

Approach

The basic approach taken for modeling the ion implantation and annealing steps of GaAs device processing for obtaining the carrier distribution is to generate the impurity atomic profile first. Then the activation efficiency plots as a function of atomic concentration (N) are constructed, as it has been widely found that activation efficiency is a function of N , the volumetric concentration (cm^{-3}), rather than the integrated quantity, fluence. Other important process variables that will be considered are categorized as follows: (i) ion-implantation variables: energy (E), fluence (ϕ), and implantation temperature (T_i); (ii) thermal annealing variables: capped or controlled atmospheric technique (CAT), annealing temperature (T_E); type of substrate materials used: Cr-doped HB, VPE, LEC, LPE.

It has been assumed that the electrical activation efficiency (η) is a function of impurity atomic concentration (cm^{-3}) and not of any other implantation variables such as ion energy and fluence separately. The volumetric concentration thus becomes a canonical parameter for computing η . Activation efficiency (η) is defined as the fraction of implanted impurity atoms, which shows electrical activation, *i.e.*, the ratio of carrier concentration n (cm^{-3}) to atomic concentration N (cm^{-3}).

Development of Basic Empirical Models

Model for atomic profile.—According to the LSS theory, the atomic impurity profile for an amorphous GaAs substrate is gaussian (49). Its parameters, *i.e.*, projected range (R_p) and standard deviation (ΔR_p), are only a function of energy of the implanted impurity. However, in practice, these parameters can be a function of other implantation variables such as implantation temperature. Owing to the complicated functional dependence of these parameters on the implantation conditions, the experimental data from secondary ion mass spectrometry (SIMS) studies rather than theoretical values were used to obtain the distribution parameters for calculating atomic distributions of Si and Se impurities.

Silicon atomic profile.—The dependence of R_p and ΔR_p on implant energy (E) for Si obtained from SIMS studies (4-8) has been found to be independent of substrate material, implant temperature up to 400°C, and annealing procedures with temperatures up to 920°C for 20 min. These parameters are tabulated in Tables I and II and plotted as a function of implant energy in Fig. 1. The relationships between R_p , ΔR_p , and E are fitted with empirical mathematical formulas, which in turn are used to generate atomic profiles. The least squares spline fit of cubic polynomials obtained in different ranges of energy gives the relationships of R_p and ΔR_p with E . The atomic profile

is assumed to be gaussian for $E < 700$ keV and a joined half-gaussian or Pearson's distribution for $E > 700$ keV based on the results of SIMS study (7).

Selenium atomic profile.—After reviewing the SIMS results for Se implants, the following conclusions were arrived at: (i) atomic profile is independent of substrate material type, annealing methods used, and annealing temperature up to 1000°C for a period of 15 min (9-11), (ii) diffusion length (\sqrt{Dt}) during implantation is a complex function of implant energy, fluence, and temperature due to radiation-enhanced diffusion (9-13), and (iii) use of a joined half-gaussian distribution rather than a normal gaussian better approximates the deeper side of the as-implanted profile (14).

Based on the above-mentioned facts, the following procedure has been adopted for modeling the atomic distribution. A two-dimensional diffusion equation can be solved using a finite element method. By knowing the implant time (t) and using a half-gaussian distribution (49) as the initial condition, the diffusion coefficient (D) can be obtained. However, if the product Dt is small, the resulting profile due to radiation-enhanced diffusion can be approximated simply by another joined half-gaussian

Fig. 1. Projected range (R_p) and standard deviation (ΔR_p) as a function of energy from LSS theory and the empirical fit of experimental (SIMS) data from Ref. (5-7).

having a lower peak as given by Eq. [1]. Therefore, the diffusion length (\sqrt{Dt}) may be calculated from the peak of the as-implanted profile (N_{\max}) by using Eq. [2].

$$N(x) = \frac{\phi}{[2\pi(\Delta R_p^2 + 2Dt)]^{1/2}} \exp - \frac{(x - R_p)^2}{2(\Delta R_p^2 + 2Dt)} \quad [1]$$

and

$$Dt = \frac{1}{2} \left[\frac{1}{2\pi} \left(\frac{\phi}{N_{\max}} \right)^2 - (\Delta R_p)^2 \right] \quad [2]$$

In Eq. [2], the description of the broadening of the distribution function using diffusion length \sqrt{Dt} (cm) is valid because it is found to be almost independent of implant time with a given fluence (10).

In addition to the available SIMS data, published carrier concentration profile results (28, 34, 35, 37, 53) were used to obtain Dt for the range of implant energy in which SIMS data are lacking. In the latter case, only carrier profiles having peak carrier concentration between $2E17$ and $3E17$ cm^{-3} obtained from high purity epitaxial samples were utilized. In this doping range, the effect of thermal conversion, if any, is very small. Furthermore, the activation efficiency in this doping range is independent of the annealing temperature and is known to be approximately 94%-97%. Thus, the atomic distributions can be obtained directly from the measured carrier profiles. This approach appears to provide correct Dt as a function of energy for those cases in which the corresponding SIMS data are not available.

The data from the SIMS and carrier concentration studies done at $T_i \geq 150^\circ\text{C}$ are used to evaluate Dt data and the results are plotted in Fig. 2. Based on our procedure of using the peak of the diffused profile, Dt is found to be independent of fluence but increases as E increases. The atomic profile can then be generated from the factor $(\Delta R_p^2 + 2Dt)^{1/2}$, knowing the peak value and assuming that the profile remains half-gaussian after diffusion. This procedure has led to a program step for obtaining the as-implanted Se atomic profile.

Model for electrical activation efficiency.—Activation efficiency (η) can be obtained if both the carrier and atomic concentration profiles are available. Most of the work published to date provides only the carrier profiles. However, in such cases the atomic profile of Si and Se can be generated for the work that reported only carrier profiles using the procedure to be described in the subsequent section. The carrier concentration data used in this study were taken from the results of either C(V) measurements or a series of etching and Hall measurements:

Fig. 2. Plot of diffusion length square (Dt) vs. fluence (ϕ) of Se in GaAs as a function of implant energy obtained from atomic and carrier profile studies. Numbers within parentheses are the implant energy (keV).

In principle, η should be obtained as a function of N for the entire range of the distribution. Owing to the steep nature of the gaussian profile, an accurate alignment of the peaks of atomic and carrier profiles is essential for correctly obtaining η in the tail portion of the distribution, where a small shift of the gaussian peak position can result in a large difference in η . It is difficult to determine the actual peak position of the carrier profile accurately because its apparent peak position may not be the true one. This difficulty in determining the peak position may be due to the thermal conversion of the substrate, error in measurements, or smearing of the peak that can be caused by decreasing activation near the peak concentration regions. Additionally, the thermal conversion can affect the carrier concentration profile markedly in the lower concentration regions. In order to avoid any significant error caused by the above-mentioned sources, only one data point per carrier profile corresponding to the maximum carrier concentration (n_{\max}) was used and the η was calculated as the ratio of n_{\max} to N_{\max} .

Some experimental studies which reported only the conductivity measurements of the implanted samples were also utilized in our study. In such cases, sheet carrier concentration (N_s) cm^{-2} was obtained from the measured conductivity (σ_s) and sheet mobility (μ_s) of the implanted samples from ($\sigma_s = q\mu_s N_s$). The effective electrical activation efficiency (η_s) obtained as the ratio of N_s to the implant fluence has been plotted against the peak atomic concentration (N_{\max}). However, η_s obtained this way is lower than the true η because of the steep nature of the gaussian profile (15). The problem of evaluating the appropriate correction for each η_s data point is nontrivial. These uncorrected data points were, therefore, used for providing some simple guidelines in the regions where volumetric activation data are not available. These data points have been shown moved up with arrows in Fig. 3 and 4.

In order to obtain the activation efficiency, only reproducible data were used. These data were obtained from the work including the use of various substrate materials (VPE, LEC, Cr-doped HB). No distinction was made for using different annealing methods, *i.e.*, Si_3N_4 or AlN capping, or controlled atmospheric technique.

Silicon activation efficiency.—The activation efficiency of Si impurity was found to be independent of implant temperature (12, 17) and therefore the data for low and high implant temperatures were both used together. Similarly, annealing time and annealing method (capped or CAT) for Si implantation (43, 54) were not considered as variables. The resulting activation data were compiled and plotted in Fig. 3, on which the points with an up-arrow distinguish the values of η_s from η according to the

Fig. 3. Universal activation plots for Si impurity in GaAs annealing at $T_A = 800^\circ, 850^\circ, 900^\circ, 950^\circ\text{C}$. Data points having letters represent the references: A, b = (5); B, C, Z, R, T, e, k, m, y = (12); D, u = (8); E, P, W = (27); F, O, d = (43); G = (44); H = (46); I = (50, 7); J = (47); K = (48); L = (50); M, P, k = (7); N = (45); Q = (49); S, X, a, f, i, q, t, u = (42); U, Y = (49); V = (52); g = (17); h, j, r = (51); n, Z = (52).

Data points having letters represent the references: such as A = (29); B, F, = (32); C, S, = (32); D, N = (30); B, E = (31); F = (32); G, Q = (36); H, J, R, P, U, X, Z = (12); I = (21, 41); K, O, Y = (38); M = (26); T = (53); V = (11); i = (34); e = (35); g = (39); h = (17). Low activation for K, Y, O is due to low annealing time used.

different calculating procedures described in the previous section. A 100% activation in the low doping concentration region is not obtained from Cr-doped HB material. The scattering of the data in the low doping region ($N < 3 \times 10^{17} \text{ cm}^{-3}$) is indicative of possible doping compensation or thermal conversion arising from the redistribution of Cr or Mn. For high purity VPE material, another study (5) shows an actual 100% activation in the low doping concentration. As the doping level increases beyond $1E17 \text{ cm}^{-3}$, η decreases, probably because of the combined effect of defects generated, amphoteric property of doping, and the solid solubility limitations.

The activation efficiency, η , of Si, in general, appears to be independent of annealing temperature, T_A , in the low doping region ($N \approx 3 \times 10^{17} \text{ cm}^{-3}$). However, η becomes increasingly dependent on annealing temperature and time as the implant dose increases, *i.e.*, as the implanted region approaches the amorphous phase. Analytical expression was used to fit these empirical data between η and N for different T_A used.

Selenium activation efficiency.—The η of Se was found to depend markedly on implant temperature (12, 13, 16-22). The data for all implant temperature greater than 150°C were used together because of insufficient number of data points available for each temperature and because of the small dependence of η on T_i in the temperature region. The annealing method and time (19) were not considered as variables. The activation data were plotted in Fig. 4 similar to the Si case. Again, some scattering of data for $N < 3 \times 10^{17} \text{ cm}^{-3}$ is indicative of thermal conversion of the Cr-doped material used. In this doping level, η decreases for similar reasons as for the Si case (22). The η of Se is again independent of T_A in the low doping region ($N \approx 3 \times 10^{17} \text{ cm}^{-3}$). However, η becomes increasingly dependent on T_A as N increases. A higher activation efficiency is generally observed for Se as compared to the Si case for the same doping level. This increase in η for Se may be attributed to the lack of amphoteric behavior of Se impurity. Solid solubility at different temperatures is used to limit the maximum value of the calculated carrier concentration when exceeded. The data of solid solubility used are the average from the two studies (24, 36), being $7.75E18$ and $1.64E19 \text{ cm}^{-3}$ for 900° and 950°C , respectively. For 850°C annealing, the value is $2.56E18 \text{ cm}^{-3}$ from another study (24).

The least squares spline fit of cubic polynomials was used as for the Si case to represent the relationship of η and N for different T_A .

Generation of Carrier Distribution

A computer program was developed for generating the carrier profiles resulting from Si or Se impurity implantation. The details follow.

Silicon carrier distribution.—The program generates an atomic profile using Eq. [1] when an implant energy (E) and a fluence (ϕ) are given. In Eq. [1], $D = 0$ is assumed, while R_p and ΔR_p are calculated for a given E from the empirical equation discussed in the "Silicon atomic profile" section. By using the activation efficiency *vs.* N relationship described in the "Silicon activation efficiency" section, the carrier concentration n (cm^{-3}) as a function of depth (μm) can be computed. An example is illustrated in Fig. 5.

Selenium carrier distribution.—The as-implanted atomic profile is assumed half-gaussian (see the "Selenium atomic profile" section) and its maximum value calculated by knowing the factor $(\Delta R_p^2 + 2Dt)^{0.5}$. The Dt can be obtained from Fig. 2, in which a linear interpolation between the available experimental data point is applied. The R_p and ΔR_p are obtained from the LSS theory (49). Since the diffusion of Se impurity during annealing is negligible, the as-implanted profile is identical to the final impurity profile. By knowing η as a function of N (see the "Selenium activation efficiency" section), the resulting carrier distribution can be calculated as a function of depth.

Applicability of the Present Models

In order to achieve a good activation and reproducibility of the doping process, the substrate material used in the direct ion-implantation step should meet certain requirements. Different qualification criteria of the substrate material have been employed from time to time (26, 27).

The present process model should only be applied to the qualified substrate material in the following range of the process variables: (i) annealing method: cap (Si_3N_4 , AlN), CA, ACCA having $P_{\text{AsH}_3} \approx 3$ torr; (ii) annealing temperature used: $< 920^\circ\text{C}$ for Si and $< 1000^\circ\text{C}$ for Se; (iii) annealing time: 10-30 min; (iv) implant temperature: $\approx 150^\circ\text{C}$ for Se impurity.

The model is a simplified one, owing to the complex nature of the problem and lack of enough data for the large number of process variables. If the above conditions

Fig. 5. Atomic and carrier profiles of Si in the high doping level for the process variables given above using the empirical models developed in the present study.

are not met by the process variables, the present model has to be modified.

Conclusion

Empirical models have been developed for simulating the implantation and annealing steps used for doping GaAs with Si and Se. The modeling efforts in the present research has led to the recognition of important process variables which affect the atomic distribution and the activation efficiency of the implanted impurities. The first-order effect of radiation-enhanced diffusion for Se has been modeled. The diffusion effect due to high annealing temperatures normally employed can be neglected. The compilation of the activation data has led to the establishment of universal plots for each dopant which are different for each annealing temperature.

The empirical models can be updated from time to time with the availability of more experimental data. The deeper side of the profile will be better approximated by using Pearson's distribution as more experimental SIMS data become available. Other more exact formulation of radiation-enhanced diffusion and the diffusion of impurity during annealing can be incorporated in the future. The effect of other process variables, *i.e.*, annealing time, detailed effect of the ambient used for annealing can be modeled in future.

In essence, the present study will serve as a foundation for future development of more realistic and comprehensive process models.

Boltzmann-Matano Analysis of Boron Profiles in Silicon

C. Kim,* Z-Y. Zhu,¹ R-I. Kang, and K. Shono*

Faculty of Science and Technology, Sophia University, Kioicho-7, Chiyoda-ku, Tokyo 102, Japan

ABSTRACT

Boltzmann-Matano analysis of the boron profiles in silicon diffused from the boron-excess BN film was carried out, and the boron diffusivity was obtained as a function of the local concentration. Boron diffusivity in silicon can be described by the diffusion model, which considers both effects of the charged monovacancy-impurity interaction and the internal electric field. The prefactors in the simplified expressions of x , Q , and R_s as a function of the surface concentration normalized to the intrinsic carrier concentration at the diffusion temperature were obtained by the numerical analysis of the diffusion equation, including the concentration-dependent diffusivity.

A general theory of impurity diffusion in silicon was proposed by Hu and Schmidt (1). They formulated the concentration dependent diffusivity involving both effects of the impurity-vacancy interaction and the internal electric field. The arsenic diffusivity reported by Fair and Tsai (2) is in good agreement with the theoretical prediction, and the arsenic profiles are coincident with the approximate solution of diffusion equation with the concentration-dependent diffusivity.

For the case of boron, Fair summarized the diffusivity data obtained from BN disk and B₂O₃ box source diffusions and concluded that the boron diffusion was dominated only by the interaction of charged monovacancy and boron ion, without the electric field effect (3). However, the effect of internal electric field is clearly apparent in the diffusivity data by Matsumoto *et al.*, who employed boron-doped oxide as the diffusion source (4). It seems that the diffusivity data reported are not yet sufficient to discuss the mechanism of boron diffusion in silicon.

Boron-excess BN film deposited on a silicon surface and encapsulated with thin Si₃N₄ film acts as a boron-diffusion source. The surface concentration is kept constant during the diffusion heat-treatment and can be controlled in the high concentration from 2×10^{18} cm⁻³ to the solid solubility as a function of deposition temperature of the BN film (5). It has also been confirmed that silicon boride is not formed at the interface of silicon and BN film (6). By using the boron-excess BN film as a diffusion source, Boltzmann-Matano technique (7) can be employed for the analysis of boron profile over a wide range of the surface concentration.

This paper describes the boron diffusivity as a function of the boron concentration. The prefactors in the simplified expressions of x , Q , and R_s of boron-diffused layer in silicon will be discussed.

Experimental

Substrates used in the experiment were mirror-finished n-type silicon having a resistivity of 4-5 Ω-cm and (100) orientation. The boron-excess BN films as the boron source were deposited on the silicon wafers by use of the experimental apparatus schematically described in Ref. (8) and a quartz tube with the internal width 35 mm, height 25 mm, and length 400 mm. The gaseous flow conditions were 50 cm³/min of 1% B₂H₆ in N₂, 70 cm³/min of NH₃, and 2000 cm³/min of N₂, and the deposition temperature was in the range of 440°-720°C. The Si₃N₄ film was successively deposited on the BN film, under the gaseous flow conditions of 20 cm³/min of 5% SiH₄ in N₂, 70 cm³/min of NH₃, and 2000 cm³/min of N₂ at 720°C. Resultant thicknesses of the BN and the Si₃N₄ films were 50 and 30 nm, respectively. Heat-treatment for boron diffusion was carried out at the temperature range of 990°-1200°C in a nitrogen atmosphere. After the heat-

treatment, the Si₃N₄ and the BN films were removed by etching in HF and in H₃PO₄, respectively.

An analyzed spreading resistance profile is in good agreement with the incremental sheet resistivity profile except near the surface, and the difference between the junction depth obtained from spreading resistance profiles and that determined with drilling and staining technique is within the range of $\pm 5\%$ (9). In this investigation, we have mainly employed spreading resistance method in order to determine the boron profiles in terms of the carrier concentrations. In addition, incremental sheet resistance technique was used to correct the profiles near the surface. The four-point probe method and the spherical drilling and staining technique were used for measurements of the sheet resistance and the depth of diffused layers.

Results and Discussion

Profiles and diffusivity.—By using a concentration factor α introduced by Hu and Schmidt (1), the diffusion equation can be written as, in one-dimensional form

$$\frac{\partial \alpha}{\partial t} = \frac{\partial}{\partial x} \left\{ D(\alpha) \frac{\partial \alpha}{\partial x} \right\} \quad [1]$$

where $\alpha = C/2n_i$, C is the local concentration of boron, and n_i is the intrinsic carrier concentration at the diffusion temperature, given in Ref. (10) as

$$n_i^2 = 1.5 \times 10^{33} T^3 \exp \left(- \frac{1.21}{kT} \right) \quad [2]$$

$D(\alpha)$ in Eq. [1] is the concentration-dependent diffusivity expressed as

$$D(\alpha) = D_i \frac{1 + \beta (\alpha + \sqrt{\alpha^2 + 1})}{1 + \beta} (1 + \alpha/\sqrt{\alpha^2 + 1}) \quad [3]$$

where β is the phenomenological coefficient in the value of 19 for boron (11), and D_i is the intrinsic diffusivity at the diffusion temperature.

Figure 1 shows the boron profiles in silicon. The local concentration C is normalized by the surface concentration C_s , and the distance from surface is by $(4D_i t)^{1/2}$. The solid lines correspond to the numerical solutions of Eq. [1], with the normalized surface concentration by the intrinsic carrier concentration C_s/n_i , ranging from 0.4 to 12.0. The boron profile with the normalized surface concentration C_s/n_i of 0.4 fits on the theoretical curve for $C/C_s > 0.01$, but the profile at the diffusion front is retarded from the theory. The retardation of boron diffusion is observed only when the surface concentration C_s is lower than the intrinsic carrier concentration n_i (9). For $C_s/n_i > 1$, the boron profiles agree well with the theoretical curves, and the shape becomes steeper with increasing C_s/n_i .

The boron diffusivity obtained as the results of Boltzmann-Matano analysis on the profiles is described in Fig. 2 and 3 as a function of the local concentration. The surface concentration C_s is in the range of $4 \times 10^{19} - 2.4 \times 10^{20}$

Fig. 1. Normalized boron profiles in silicon. The normalized surface concentration C_s/n_i is (a) 0.4, (b) 2.8, (c) 4.4, (d) 8.2, and (e) 12.0.

Fig. 2. Boron diffusivity at 1200°C as a function of the local concentration.

cm^{-3} . The relationship of the boron diffusivity and the local concentration agrees very closely with the theoretical relation of Eq. [3], shown as the solid curves in the figure, and is independent of the surface concentration in the given range. The diffusivity is coincident with the intrinsic value D_i at $C \ll n_i$ and is proportional to $2CD_i/n_i$ for $C > n_i$. The boron diffusivity at the temperature range of 990°-1200°C is shown as a function of the local boron concentration in Fig. 3. An excellent agreement of the experimental values on the theoretical curves is found at the given temperature range.

Fig. 3. Boron diffusivity in temperature range of 990°-1200°C as a function of the local concentration.

From the experimental results shown in Fig. 1-3, it can be concluded that the boron diffusion in silicon is clearly described with the diffusion theory proposed by Hu and Schmidt, except the diffusion front with the surface concentration C_s is lower than the intrinsic carrier concentration n_i .

Prefactors of x_i , Q , and R_s .—Approximate solutions of Eq. [1] have been driven in polynomial form by Guo (12) and Wang and Lo (13), and a fitting function of the experimental boron profiles has been proposed by Fair (3). Their works are commonly based upon the assumption that the boron profiles would be independent of the surface concentration and could be uniquely described as a function of the distance from surface normalized by the diffusion depth taken at $C(x_i) = 0.01C_s$. By use of the approximate profiles, they gave also simplified expressions of the diffusion depth x_i , the total diffused boron Q , and the sheet resistance R_s in the following form

$$x_i = K_j \sqrt{D_s t} \quad [4]$$

$$Q = K_q C_s x_i \quad [5]$$

and

$$R_s = K_r / (C_s x_i) \quad [6]$$

where the surface diffusivity $D_s = 2D_i C_s/n_i$ for $C_s > n_i$, and the hole mobility in diffused layer was approximated as $55 \text{ cm}^2/\text{Vs}$ in derivation of Eq. [6]. The prefactors K_j , K_q , and K_r are given as the constant in their reports, where K_j and K_q are dimensionless.

Figure 4 shows the numerical solutions of Eq. [1] in terms of the normalized profile. The diffusion depth was taken at $C(x_i) = 10^{-4} C_s$, because the range of background concentration is 10^{15} - 10^{16} cm^{-3} in the conventional CMOS and bipolar IC fabrication. The normalized profiles are clearly dependent on the normalized surface concentration C_s/n_i for the values less than 10, even though they are almost independent of C_s/n_i for larger than 10. In order to obtain x_i , Q , and R_s in the whole range of the surface concentration between the intrinsic carrier concentration and the solid-solubility, their prefactors must be described as a function of the normalized surface concentration.

The prefactors obtained as the results of numerical analysis of Eq. [1] are shown as the solid curves in Fig. 5. In the calculation of K_r , the hole mobility was fixed as a constant of $55 \text{ cm}^2/\text{Vs}$. For $C_s/n_i < 10$, the prefactors depend strongly on the normalized surface concentration

Fig. 4. Numerical solutions of diffusion equation with concentration-dependent diffusivity. The normalized surface concentration C_s/n_i is (a) 0, (b) 1.6, (c) 3.8, (d) 5.6, (e) 11.1, and (f) 16.6.

Fig. 5. Prefactors K_j , K_q , and K_r as a function of normalized surface concentration C_s/n_i .

C_s/n_i , where K_r and K_j decrease and K_q increases with the increase of C_s/n_i . For $C_s/n_i > 10$, all prefactors depend linearly and weakly on the normalized surface concentration. Experimentally obtained values of K_j , K_q , and K_r are also plotted in the same figure and fit well with the solid curves.

In Fig. 5, the values of prefactors reported in the previous papers are also indicated on the scales. The prefactors reported by Guo and also by Wang and Lo are comparable with those of the work only for $C_s/n_i \approx 20$. This means that their expression of the profile and the prefactors are in good approximation only for the solid-solubility boron diffusion. In order to determine the prefactors, Fair has used the experimental data where the surface concentration distributed in a wide range, and attempted to express the data with a universal relationship. Therefore, the prefactors by Fair might be considered as a mean value for the adopted data.

Conclusions

Boltzmann-Matano analysis was carried out on the boron profiles in silicon diffused from the boron-excess BN film, and the boron diffusivity was obtained as a function of the local concentration. For the boron diffusion with the surface concentration higher than the intrinsic carrier concentration at the diffusion temperature, the diffusivity can be described by the diffusion model which considers both effects of the charged vacancy-impurity interaction and the internal electric field. The prefactors in the simplified expressions of x_j , Q , and R_s were given by the numerical analysis of the diffusion equation including the concentration-dependent diffusivity and described as a function of the surface concentration normalized by the intrinsic carrier concentration.

Metal Impurities near the SiO₂-Si Interface

Akira Ohsawa,* Kouichirou Honda, and Nobuo Toyokura

Fujitsu Laboratories Limited, Nakahara-ku, Kawasaki, Japan

ABSTRACT

The behavior of metal impurities (Cu, Fe, Cr, and Ni) near the SiO₂-Si interface during dry O₂ and O₂/HCl oxidation was studied by means of defect etching and secondary ion mass spectroscopy methods using intentionally metal-contaminated silicon wafers. Redistribution of metal impurities resulting from a thermal oxidation is different for each metal. Copper diffused into the silicon, showing concentration peaks 0.3-1.2 μm from the interface, and tended to be rejected by the silicon dioxide. Iron accumulated at the interface, while chromium tended to accumulate in the oxide having a lower concentration in silicon. Gettering ability using O₂/HCl oxidations was excellent for copper, but poor for iron and chromium impurities. Copper and iron impurities precipitate in the silicon near the interface, but chromium and nickel impurities do not.

The dielectric-breakdown strength of silicon dioxide is directly related to the reliability of MOS LSI devices because of the thin oxide layers they use. Breakdown strength was reported to be reduced by metal-decorated stacking faults in the silicon substrate at the SiO₂-Si interface (1). The authors reported that stacking faults did not reduce the breakdown strength, but metal precipitates in the silicon substrate did (2, 3). Gettering of metals (Cu, Fe, and Au) in the silicon substrate by annealing in ambients with HCl was studied by Green *et al.* (4). Gettering of met-

als (Cu, Fe, Cr, Co, and Ni) through silicon dioxide was also performed by annealing in dry oxygen with 1% HCl using a 950°-1250°C ramp cycle (5). The redistribution of gold during the growth of an oxide was reported on contaminated silicon wafers (6). However, it is necessary to understand the behavior of metals near the SiO₂-Si interface during thermal oxidation to fabricate highly reliable devices. In this study, we intentionally contaminated silicon wafers by ion implantation of Cu, Fe, Cr, and Ni. The behavior of these metals near the SiO₂-Si interface during oxidation was studied on the wafers by defect etching and secondary-ion mass spectroscopy (SIMS) methods.

Fig. 2. SIMS depth profiles of Cu in the samples of (a) 10¹⁴ cm⁻² and (b) 10¹⁵ cm⁻² Cu⁺ implanted, then oxidized in dry O₂ (Dry) and in O₂/HCl (HCl). The profile of a control (Nondosed) sample is shown for reference.

Experimental

Boron-doped, 10 Ω-cm (100), Czochralski-grown silicon wafers, 500 μm thick, were used for this experiment. Cu⁺, Fe⁺, Cr⁺, and Ni⁺ ions were implanted in the wafers using 100 keV through 50 nm dry oxide films. The doses were 10¹³, 10¹⁴, and 10¹⁵ cm⁻² for Cu⁺ and Fe⁺ ions, and 10¹³ and 10¹⁴ cm⁻² for Cr⁺ and Ni⁺ ions. After removing the filter oxide films, gate oxides were grown in dry O₂ (24 nm thick) and in O₂/HCl (30 nm thick) at 1050°C, then annealed in N₂ at 1100°C for 20 min. Portions of the sample were Secco etched (7) for 1 min to observe any crystal defects in the silicon at the SiO₂-Si interface. Other portions were etched with HF-HNO₃ (1-20), then Secco etched to observe the depth profile of crystal defects.

The primary ion ¹⁶O₂⁺ was used for secondary ion mass spectroscopy (SIMS) measurements. Profiling was initiated from the oxide surface and continued across the interface into the silicon. The secondary ⁶³Cu⁺, ⁵⁶Fe⁺, ⁵²Cr⁺, or ⁵⁸Ni⁺ ions were monitored at the slow Si sputter rate of 0.115-0.225 nm/s. ¹⁸O⁻ and ¹¹B⁺ were monitored at the same time. The depth resolution was about 20 nm. The metal data were reduced to concentration by comparison with doped standards (metal ion-implanted silicon). The redistribution of metal impurities near the SiO₂-Si interface was determined. The secondary ⁶³Cu⁺ ions were also monitored at a fast Si sputter rate of 2.84 nm/s into the silicon to a depth of 5 μm. The redistribution of Cu impurities in the silicon was determined.

Results and Discussion

Cu impurities.—Figure 1 shows the depth profiles of etch pits in silicon substrate. The samples are for Cu⁺ doses of 10¹⁴ and 10¹⁵ cm⁻², which were oxidized in dry O₂ (Dry) and in O₂/HCl (HCl). No defects were observed in the samples of 10¹³ cm⁻² dose, and the samples are not shown in the figure. No pits or only traces of pits were

Fig. 4. Depth profiles of etch pits in silicon from the SiO₂/Si interface. The samples are Fe⁺ doses of 10¹⁴ and 10¹⁵ cm⁻², and are oxidized in dry O₂ (Dry) and in O₂/HCl (HCl).

Fig. 5. SIMS depth profiles of Fe in the samples oxidized in dry O₂ (a) Dry and in O₂/HCl (b)HCl for Fe⁺ doses of 10¹⁴ and 10¹⁵ cm⁻².

observed at the depth of 13 μm, but black-line and S pits (8, 9) on a rough background were observed near the SiO₂-Si interface. The rough background was due to stacking faults generated by implantation damage and oxidation (2). The black-line pit is a Cu precipitate colony and is along <110> directions (2). The line pits are 3-8 μm long and 8 × 10⁵ cm⁻² in density for samples (g) and (h), and are shorter than the 2 μm 3 × 10⁶ cm⁻² pits in samples (a) and (j). S pit densities are 10⁶ cm⁻² in sample (b), 8 × 10⁵ cm⁻² for sample (e), 2 × 10⁵ cm⁻² for sample (h), and 2 × 10⁶ cm⁻² for sample (k). The difference caused by the oxidation methods is clear: there are larger Cu precipitates in the dry samples, but smaller ones or S pits in the HCl samples. This suggests getting of Cu due to HCl oxidation.

Figures 2(a) and 2(b) shows SIMS depth profiles of Cu for samples (a) 10¹⁴ cm⁻² and (b) 10¹⁵ cm⁻² Cu⁺-implanted and followed by dry O₂ (Dry) and O₂/HCl (HCl) oxidations. The profile of control sample is shown for reference in Fig. 2(b). The level indicated by a chain line is the solid solubility at 1100°C (10), which is the last and highest annealing temperature. The depth profile of Cu in the implanted state shows a sharp peak just left of 0.1 μm, indicated by an arrow in the figure. The sharp distribution is redistributed by oxidation at 1050°C, and subsequent annealing at 1100°C to yield the depth profiles seen in Fig. 2(a) and 2(b). The profiles of Fig. 2 are very different: (a) between dry and HCl oxidation, and (b) between 10¹⁴ and 10¹⁵ cm⁻² dose. The HCl oxidation redistributes Cu shallower in silicon than the dry oxidation. HCl oxidation lowers the Cu concentration, as shown in Fig. 2(a). The higher dose distributes Cu wider and deeper in silicon. The first result clearly shows a getting of Cu from the

Fig. 6. Depth profiles of etch pits in silicon from the SiO₂-Si interface. The samples are Cr⁺ or Ni⁺ dose of 10¹⁴ cm⁻², and oxidized in dry O₂ (Dry), and in O₂/HCl (HCl).

surface due to HCl oxidation. The second result shows re-distribution of Cu is not caused by simple diffusion during the oxidation and subsequent annealing. We must take into account the effects of copper impurities: (i) outdiffusion through the oxide layer, (ii) segregation at the SiO₂-Si interface resulting from thermal oxidation, and (iii) interaction with the crystal defects.

Figure 3 shows SIMS depth profiles of (a) copper, (b) oxygen, and (c) boron near the SiO₂-Si interface. The sample had 10¹⁵ cm⁻² Cu⁺ implanted followed by dry O₂ oxidation. The profile for copper in the control sample is also shown for reference in (d). The position SiO₂-Si interface was estimated relative to an oxide thickness of 24 nm, and is indicated as a chain line in the figure. A segregation of copper impurities at the interface is shown in Fig. 3(a), and the one for boron is shown in Fig. 3(c). Copper is rejected from the oxide and accumulates near the interface about 30 nm in the silicon. Using segregation coefficient *m*, the ratio of equilibrium concentration in the silicon to that of silicon dioxide (11), *m* for copper is larger than 1. Boron migrates into the oxide as shown in Fig. 3(c). This tendency is consistent with other reports (12, 13).

Fe impurities.—The depth profiles of etch pits in silicon substrate are shown in Fig. 4. The samples are for Fe⁺ doses of 10¹⁴ and 10¹⁵ cm⁻², which were oxidized in dry O₂ and in O₂/HCl. No defects were observed for samples of 10¹³ cm⁻² dose. As shown in the figure, no pits were observed at the depth of 6 μm. Black pits on rough backgrounds were observed near the SiO₂-Si interface in Fig. 4(g), 4(h), and 4(j) for 10¹⁵ cm⁻² dose. In Fig. 4(h) of 10¹⁵

cm⁻² and the Dry sample, faint line pits along <110> directions were also observed. These black and line pits were confirmed to be Fe precipitates by transmission electron microscopy and energy dispersive x-ray spectroscopy (14). S pits are seen in Fig. 4(g), 4(h), 4(j), and 4(k) of 10¹⁵ cm⁻² implanted samples, but less than those in Fig. 4(a), 4(b), 4(d), and 4(e) of 10¹⁴ cm⁻² implanted samples. The defect generation is different between 10¹⁴ and 10¹⁵ cm⁻² dose, but the difference due to oxidation methods Dry and HCl is small. This suggests that iron impurities are not getterd by HCl oxidation.

Figures 5(a) and 5(b) show SIMS depth profiles for Fe impurities near the SiO₂-Si interface. Figure 5(a) is the sample oxidized in dry O₂ (Dry), and Fig. 5(b) that oxidized in O₂/HCl (HCl) for Fe⁺ doses of 10¹⁴ and 10¹⁵ cm⁻². The interfaces were estimated from the oxide thickness of 24 nm (Dry) and 30 nm (HCl), and are indicated by the chain line in the figure. The characteristics of Fe profiles are as follows: (i) the peak concentration increases from 1-2 × 10¹⁹ to 1-2 × 10²⁰ cm⁻³ proportionally to doses of 10¹⁴-10¹⁵ cm⁻²; (ii) the iron impurities do not diffuse into silicon, but accumulate up at the interface. The peak position is at the interface for Dry [Fig. 5(a)] samples, and at 10-15 nm deep into SiO₂ from the interface for HCl samples [Fig. 5(b)]; (iii) oxidation in O₂/HCl apparently does not lower peak concentration, rather, it sharpens the profile. Iron impurities could have a harmful effect on device reliability, because they tend to accumulate in the active region of the devices (15).

Cr and Ni impurities.—The depth profiles of etch-pits in silicon substrate are shown in Fig. 6 for samples of Cr⁺

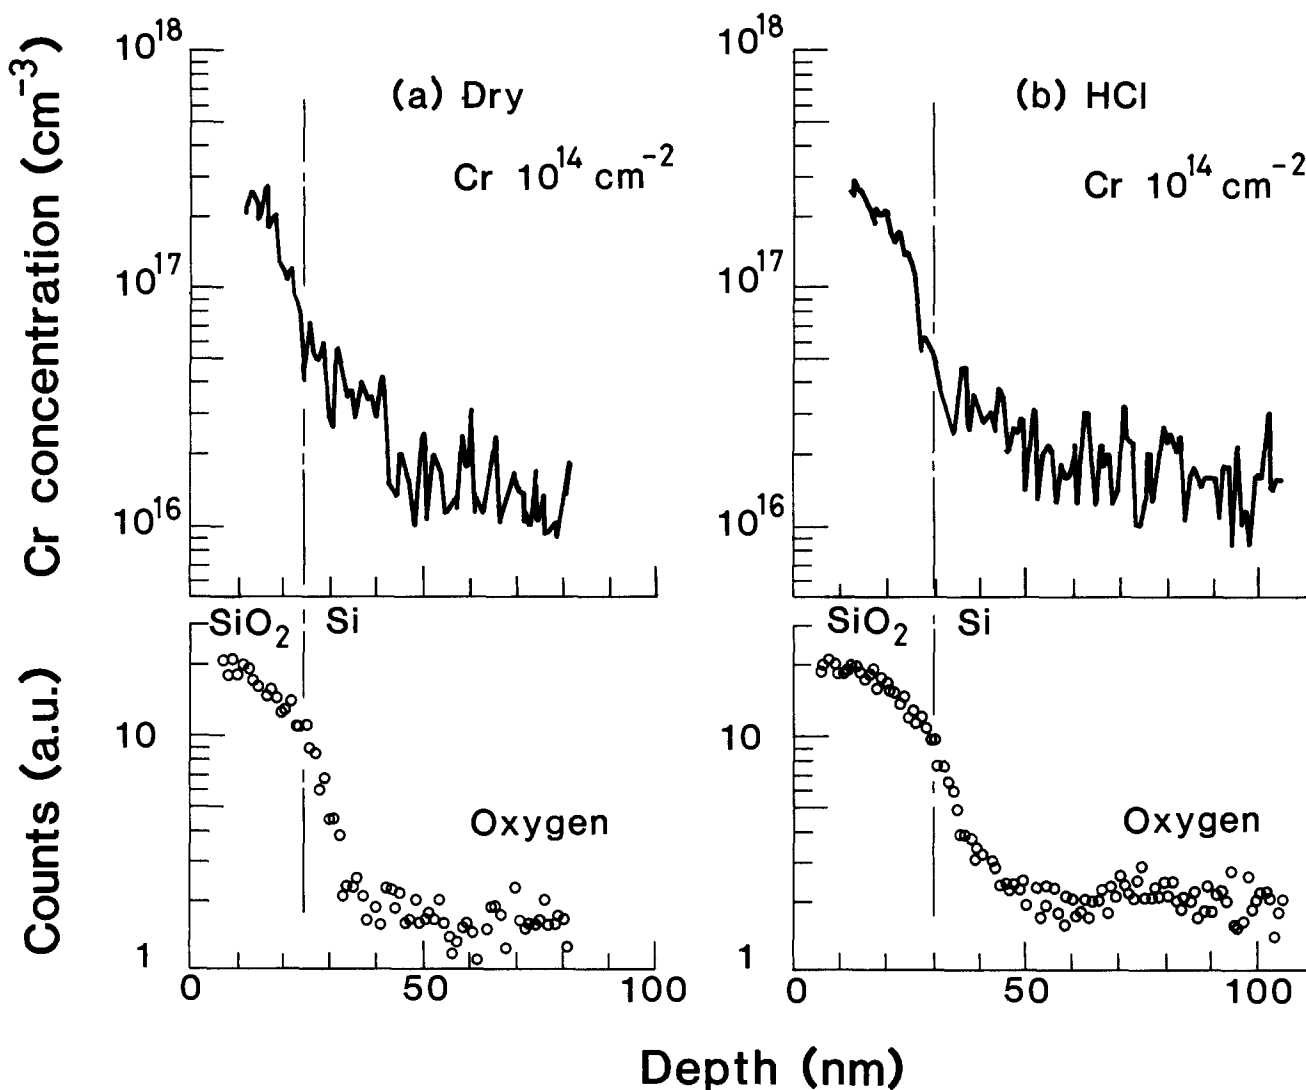

Fig. 7. SIMS depth profiles of chromium and oxygen for the samples oxidized in dry O₂ (a) Dry and in O₂/HCl (b) HCl for Cr⁺ dose of 10¹⁴ cm⁻².

and Ni⁺ doses of 10¹⁴ cm⁻² oxidized in dry O₂ (Dry) or O₂/HCl (HCl). No defects were observed for the 10¹³ cm⁻² dose samples. The depth profiles for Cr⁺- and Ni⁺-implanted samples resemble each other, but are very different from those for the Cu⁺- and Fe⁺-implanted samples (Fig. 1 and 4). Metal precipitates and S pits were not observed in the Cr⁺- and Ni⁺-implanted samples in Fig. 6. The stacking faults were observed only near the SiO₂-Si interface. The stacking faults are about 2 μm long and 2 × 10⁷ cm⁻² in density in Fig. 6(a) Cr Dry, smaller than 0.5 μm and 6 × 10⁷ cm⁻² in Fig. 6(d) Cr HCl, 1-2 μm long and 9 × 10⁶ cm⁻² in Fig. 6(g) Ni Dry, and smaller than 1 μm and 10⁷ cm⁻² in Fig. 6(j) Ni HCl. The rough backgrounds observed in Fig. 1 and 4 were not observed in Fig. 6 because of the low stacking fault density. The stacking fault is smaller and higher in the HCl, than in the Dry. Because of metal (Cr or Ni) decoration, the stacking faults are thick at the interface in Fig. 6(a) and 6(g).

Figures 7(a) and 7(b) show SIMS depth profiles of Cr impurities and oxygen near the SiO₂-Si interface. Figure 7(a) shows the samples oxidized in dry O₂ (Dry), and Fig. 7(b) those oxidized in O₂/HCl (HCl) for Cr⁺ doses of 10¹⁴ cm⁻². The interface was estimated from the oxide thickness, and is indicated as a chain line. The characteristics of Cr profiles are as follows: (i) chromium segregates out of the silicon and accumulates in the silicon dioxide; this suggests that the segregation coefficient resulting from thermal oxidation is larger than 1; (ii) the difference between Dry [Fig. 7(a)] and HCl [Fig. 7(b)] oxidation is very small. This suggests that the HCl oxidation cannot getter Cr impurities.

Summary

The behavior of metal impurities (Cu, Fe, Cr, and Ni) near the SiO₂-Si interface during dry O₂ and O₂/HCl oxidations was studied by means of etching and SIMS methods using intentionally metal-contaminated wafers. Copper and iron impurities precipitate in the silicon near the interface, but chromium and nickel impurities do not. Redistribution of the metal impurities resulting from the thermal oxidation is different for each metal. Copper diffuses deep into the silicon and shows concentration peaks

at a depth of 0.3-1.2 μm from the interface, and tends to be rejected by the silicon dioxide. Iron accumulates up at the interface. Chromium tends to accumulate in the oxide and has a low concentration in silicon. Gettering ability due to O₂/HCl oxidation is very different for each metal. The ability is excellent for copper, but poor for iron and chromium impurities.

X-Ray Investigation of Boron- and Germanium-Doped Silicon Epitaxial Layers

H.-J. Herzog

AEG-Telefunken, Forschungsinstitut, D-7900 Ulm, Germany

L. Csepregi and H. Seidel

Fraunhofer-Institut für Festkörpertechnologie, D-8000 München 60, Germany

ABSTRACT

The lattice strain in highly boron-doped, highly germanium-doped, and simultaneously boron-and-germanium-doped epitaxial layers was investigated by means of x-ray techniques. The lattice-contraction coefficient was determined for both impurities, and was found to be 5 × 10⁻²⁴ cm³/atom for boron and -6.2 × 10⁻²⁵ cm³/atom for germanium doping. A simple linear superposition of calculated or experimentally determined lattice-contraction coefficients obtained for layers doped with boron vs. those doped with germanium does not yield satisfactory results in estimating the germanium concentration necessary for strain compensation in highly boron-doped layers. Strain-compensated dislocation-free epitaxial layers were fabricated with a boron concentration of 1 × 10²⁰ atom/cm³, using a germanium concentration of 1 × 10²¹ atom/cm³.

Highly boron-doped layers are becoming increasingly important in the fabrication of three-dimensional structures in silicon, such as micromechanical devices, sensors, or masks for x-ray as well as ion-beam lithography (1-3). Since silicon layers with boron concentrations

higher than 1 × 10²⁰ atom/cm³ have extremely low etch rates with certain anisotropic selective etchants, these layers are very useful for accurate control of the etching process, taking advantage of their etch stopping properties (4). The most widely used etchants providing these

features are solutions of KOH and water or ethylenediamine, pyrocatechol, and water.

The incorporation of boron at such concentration levels causes a significant lattice mismatch between the doped layer and the undoped substrate, resulting from the smaller covalent radius of boron compared to that of silicon. This lattice mismatch induces high strain and, in thicker layers, misfit dislocations as well (5). In some applications, such as for lithography masks, a certain tensile strain is often desired to avoid out-of-plane distortions due to thermal effects (3); however, strain is disadvantageous in structures such as pressure sensors, owing to the significantly reduced sensitivity (6). In both cases, films with well-defined strain levels are desirable, while crystal defects such as dislocations are generally undesirable.

In order to eliminate strain as well as dislocation generation in highly boron-doped silicon films, codoping with a strain counterbalancing element of a larger covalent radius has been proposed (7, 8). Germanium was found to be a suitable element, owing to its advantageous properties, such as high solubility and electrical inactivity. However, quantitative experimental data concerning the degree of strain compensation when using germanium as a codopant have not been available up to now.

In this work, the concentration dependence of the strain in silicon layers doped with boron, germanium, or both simultaneously, has been investigated. The goal was to fabricate highly boron-doped, strain-compensated, dislocation-free layers with the help of these data.

Lattice Mismatch and Lattice-Contraction Coefficient

The incorporation of dopants in a silicon epitaxial layer contracts or expands the lattice of the layer relative to that of the undoped silicon substrate. This lattice mismatch is expressed as

$$\eta = \frac{\Delta a}{a_{\text{Si}}}$$

where a_{Si} is the lattice constant of silicon and Δa is the change in lattice constant induced by the dopant. It has been determined that thin films, or layers with small mismatch, are strained in a purely elastic manner to match the substrate lattice. With increasing lattice registry, the film strain ϵ_f increases until a "critical mismatch" is reached, the value of which depends on the film thickness. Beyond this value, the film strain ϵ_f decreases, since the generation of misfit dislocations becomes the dominant process in the accommodation of the lattice mismatch (9, 10). This means that in the subcritical range, the film strain ϵ_f is equal to the mismatch value η , whereas beyond the critical value, the film strain is lower than the mismatch value.

In the range of purely elastic accommodation, the film strain ϵ_f depends linearly on the dopant concentration C (11)

$$\epsilon_f = \beta C \quad [1]$$

where β is the lattice-contraction coefficient. Obviously, when misfit dislocations participate in mismatch accommodation, Eq. [1] is no longer valid. Two different equations for calculating β exist, based on a linear model and a volumetric model, (12, 13)

$$\beta_1 = \left[1 - \frac{r_{\text{dop}}}{r_{\text{Si}}} \right] N^{-1} \quad [2]$$

$$\beta_v = \frac{1}{3} \left[1 - \left(\frac{r_{\text{dop}}}{r_{\text{Si}}} \right)^3 \right] N^{-1} \quad [3]$$

where r_{dop} and r_{Si} are the covalent radii of the dopant and silicon atoms, respectively, and N is the density of lattice sites in silicon.

Substitution of Pauling's covalent radii (14) ($r_{\text{Si}} = 1.17\text{\AA}$, $r_{\text{B}} = 0.88\text{\AA}$, and $r_{\text{Ge}} = 1.22\text{\AA}$) yields the following results for β_1 and β_v

	Boron	Germanium
β_1 [cm^3/atom]	4.96×10^{-24}	-8.55×10^{-25}
β_v [cm^3/atom]	3.83×10^{-24}	-8.92×10^{-25}

These values can be inserted into Eq. [1] in order to calculate the germanium-to-boron concentration ratio necessary to match the lattices of the epitaxial layer and the undoped substrate. One obtains 5.8:1 or 4.4:1 for this ratio, depending on whether Eq. [2] or Eq. [3] is used.

Experimental Techniques

Silicon wafers with (100) orientation, a diameter of 3 in, and 1-10 Ω cm resistivity were used for the experiments. Their nominal thickness was 380 μm ; however, the precise thickness of each wafer was measured prior to deposition. The epitaxial layers were deposited in a barrel-type vertical reactor (AMC-7000, made by Applied Materials), employing the $\text{SiH}_2\text{Cl}_2\text{-B}_2\text{H}_6\text{-GeH}_4\text{-H}_2$ chemical system. The growth temperature and the growth rate were 1080°C and 0.9 $\mu\text{m}/\text{min}$, respectively. The final thickness of the epitaxial layers was $5 \pm 0.2 \mu\text{m}$.

The boron concentration of the deposited layers was measured by determining the wavelength of the plasma-resonance minimum in the infrared spectrum (15). The composition of the germanium-doped layers was determined by the methods of backscattering and channeling with helium ions (16).

Measurement Techniques

X-ray topography and curvature measurement.—A strained film on a substrate causes bending of the wafer. The strain-induced curvature of a silicon wafer can be measured with high accuracy using x-ray diffraction (17). We employed a Lang transmission camera with Mo-K α radiation, as described in Ref. (10).

The relationship between the measured curvature k , the lattice film strain ϵ_f , the thickness of the epitaxial layer t_f , and that of the substrate t_s , is given by the equation

$$k = 6\epsilon_f \frac{t_f}{t_s^2} \quad [4]$$

assuming thin layer ($t_f \ll t_s$) and equal elastic constants of film and substrate (18, 19). Using Eq. [4], the film strain ϵ_f can be obtained from the curvature k as a function of the dopant concentration.

As mentioned above, Eq. [1] is only valid when misfit dislocations do not contribute to the accommodation of lattice mismatch. X-ray transmission topography measurements were carried out (with the same Lang camera as for the curvature measurements) on all wafers to determine the presence of misfit dislocations.

Rocking curves.—Small differences between the lattice constants of the epitaxial layers and the substrate can be measured with high accuracy by means of x-ray rocking-curve analysis, where two reflections at different Bragg angles are obtained, one from the substrate, the other from the layer. In order to verify and supplement the results of the curvature measurements, rocking curves were taken from samples where plastic relaxation through misfit dislocations had not occurred. As a consequence, the mismatch value η is expected to be equal to the elastic film strain. For this analysis, a double-crystal diffractometer in the (+, -) mode with Cu-K α radiation was employed. As the monochromator, a (100)-oriented silicon crystal in the (422)^R setting was used (20), and rocking curves from the specimen crystals were taken using different (hkl) reflecting planes. However, in order to determine the lattice constant of the layer in the relaxed state, the tetragonal distortion of the epitaxial lattice has to be taken into account (21-23). Because of this tetragonal distortion, two Bragg-angle splittings $\Delta\theta_1$ and $\Delta\theta_2$ can be recorded when x-rays are diffracted on one set of inclined (hkl) planes under two specimen positions relative to the x-ray path. In order to determine the lattice mismatch as a function of angle difference in the rocking curves, the calculation procedure given in detail by Halliwell (23) was used.

Fig. 1. Results of x-ray measurements on an epitaxial silicon layer with a boron concentration of 5×10^{19} atom/cm³. Diagram a (left) yields a curvature radius of 19.1m. Rocking curves for the two reflections on the same (115) crystal plane for the same sample are shown in diagram b (right).

Results and Discussion

Boron-doped layers.—The investigated epitaxial layers had a boron concentration between 2×10^{19} and 1.5×10^{20} atom/cm³. As a typical result, a curvature measurement (Fig. 1a) and a set of rocking curves (Fig. 1b) are shown for a wafer covered with a 5×10^{19} atom/cm³ boron-doped epitaxial layer. As expected, the wafer is under tensile stress, and exhibits spherical curvature. The calculated elastic film strains ϵ_f obtained by both methods are in excellent agreement, and indicate a value of 2.5×10^{-4} . The film strain ϵ_f as a function of the boron concentration is shown in Fig. 2. Up to the "critical strain" value, the film strain increases linearly with increasing boron concentration. For epitaxial layers with a thickness of $5 \mu\text{m}$, the critical strain amounts to 5.5×10^{-4} , corresponding to a boron concentration of 1.1×10^{20} atom/cm³. Above this critical value, a rapid increase in the density of misfit dislocations occurs, and ϵ_f drops considerably. This is confirmed by x-ray topographs, as shown in Fig. 3. Below the critical strain, no, or only a few, misfit dislocations are found (Fig. 3a and 3b); however, a dense net of

Fig. 2. Film strain ϵ_f as a function of the boron concentration C_B , obtained by curvature measurements and rocking-curve analysis.

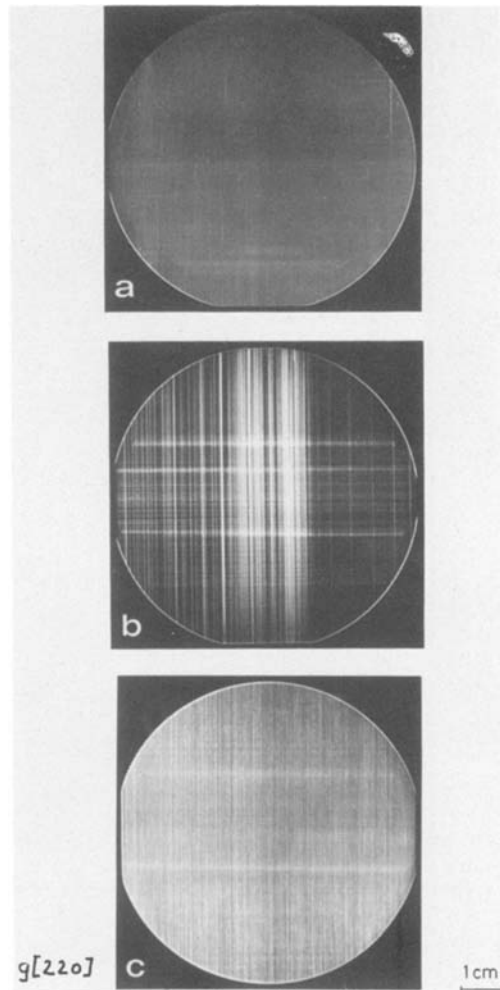

Fig. 3. X-ray transmission topographs of epitaxial layers with boron concentrations of 5×10^{19} atom/cm³ (a), 8×10^{19} atom/cm³ (b), and 1.5×10^{20} atom/cm³ (c).

misfit dislocations is observed in the region above the critical strain (Fig. 3c). The blurred horizontal lines are artifacts of the measurement technique, and do not represent actual crystal defects. The slope of the straight line in Fig. 2, where the strain is only elastically accommodated, corresponds to a lattice-contraction coefficient of $\beta_B = 5 \times 10^{-24}$ cm³/atom. This value agrees well with the results reported by McQuhae and Brown (5.2×10^{-24} cm³/atom) (12) and by Horn (5.6×10^{-24} cm³/atom) (24), but is higher than that reported by Pearson and Bardeen (2.5×10^{-24} cm³/atom) (25) or by Cohen (2.3×10^{-24} cm³/atom) (11).

Germanium-doped layers.—The x-ray analysis of the germanium-doped layers was carried out the same as that for boron. The germanium concentration was determined in all samples by means of the Rutherford backscattering and channeling techniques. Lattice-location experiments such as that shown in Fig. 4 indicated that the germanium atoms are situated on substitutional sites, even at concentrations around 1×10^{21} atom/cm³. In Fig. 5, the result of a curvature measurement and a set of rocking curves are shown for a wafer with a germanium concentration of 4×10^{20} atom/cm³. The dependence of the film strain ϵ_f on the germanium content for a layer thickness of $5 \mu\text{m}$ is shown in Fig. 6. As expected, the films are under compression. In this case too, there is an initial region of linearly increasing film strain with increasing germanium concentration, followed by predominant relaxation of lattice mismatch through misfit dislocations. This behavior is also confirmed by the x-ray topographs, which appear very similar to those obtained for boron-doped wafers. For the $5 \mu\text{m}$ thick layers, the critical strain amounts to -5×10^{-4} ,

Fig. 4. Backscattering spectra for 2.2 MeV ⁴He ions incident on a highly germanium-doped sample in the random and channeling directions, with a detector angle of 135°.

corresponding to a germanium concentration of 8×10^{20} atom/cm³. The slope of the straight portion of the curve in Fig. 6 yields a contraction coefficient of $\beta_{Ge} = -6.2 \times 10^{-25}$ cm³/atom. This experimentally determined value is considerably smaller than the lattice-contraction coefficient

calculated by means of Eq. [2] and [3]. This behavior may be partly explainable in terms of a deviation from Vegard's law in germanium-silicon solid solutions, as reported by Dismukes *et al.* (26).

Boron/germanium codoped layers.—For the investigation of the strain-compensation effect, the boron-

Fig. 5. Results of x-ray measurements on an epitaxial silicon layer with a germanium concentration of 4×10^{20} atom/cm³. Diagram a (left) yields a curvature radius of -20.2 m. Rocking curves for the two reflections on the same (115) crystal plane for the same sample are shown in diagram b (right).

Fig. 6. Film strain ϵ_f as a function of the germanium concentration C_{Ge} , obtained by curvature measurements and rock curving analysis.

concentration level in the $5\ \mu\text{m}$ thick layers was held constant at $C_B = 1 \times 10^{20}\ \text{atom/cm}^3$. The film strain ϵ_f was measured for several germanium concentrations ranging from 2 to $10 \times 10^{20}\ \text{atom/cm}^3$. The solid line in Fig. 7 shows the film strain, obtained by curvature measurements and rocking-curve analysis, as a function of the germanium concentration. As expected, the film strain decreases with increasing germanium codoping, indicating that strain compensation takes place. From the experimental curve in Fig. 7, the germanium concentration for a strain-free layer containing $1 \times 10^{20}\ \text{atom/cm}^3$ boron is found to be $\sim 1.1 \times 10^{21}\ \text{atom/cm}^3$. For the above boron concentration, Eq. [2] and [3] predict complete strain compensation at germanium doping levels of $4.4 \times 10^{20}\ \text{atom/cm}^3$ or $5.8 \times 10^{20}\ \text{atom/cm}^3$, respectively, as indicated by the dashed lines a and b in Fig. 7. A linear superposition of the experimental lattice-contraction coefficients β_B and β_{Ge} obtained for layers doped with only one element predicts a required germanium concentration of $8 \times 10^{20}\ \text{atom/cm}^3$ for a strain-free layer (line c in Fig. 7), which is slightly above the value used by Black *et al.* (6). This deviation from the experimentally obtained value for codoped layers ($1.1 \times 10^{20}\ \text{atom/cm}^3$) indicates that changes in lattice constant induced by simultaneous doping with the two elements are not independent of each other, and that a linear superposition is not allowable.

X-ray topographs taken from wafers with different levels of germanium codoping are shown in Fig. 8. Some misfit dislocations are still observable in Fig. 8a and 8b, with a decrease in density correlated with increasing germanium concentration. The epitaxial layers in Fig. 8a and 8b have germanium concentrations of $2 \times 10^{20}\ \text{atom/cm}^3$ and $6 \times 10^{20}\ \text{atom/cm}^3$, respectively. Above a germanium codoping level of $7 \times 10^{20}\ \text{atom/cm}^3$, the wafers are completely free of misfit dislocations. Figure 8c shows a topograph of a wafer close to the point of complete strain compensation, with a germanium concentration of $9.8 \times 10^{20}\ \text{atom/cm}^3$.

Conclusions

Measurements of doping induced lattice strain and misfit dislocations by means of x-ray diffraction, for highly boron-doped and highly germanium-doped epitaxial silicon layers, yielded the following results.

The lattice-contraction coefficient β was found to be $5 \times 10^{-24}\ \text{cm}^3/\text{atom}$ for boron and $-6.2 \times 10^{-25}\ \text{cm}^3/\text{atom}$ for germanium single-doped layers. The experimental result for boron doping shows a very good agreement with previously reported values (12, 23), as well as with the linear calculation model. The germanium coefficient, however,

Fig. 7. Film strain ϵ_f of boron-and-germanium-codoped epitaxial layers as a function of the germanium concentration. The boron concentration is kept constant at $1 \times 10^{20}\ \text{atom/cm}^3$. The solid line shows the experimental results. The broken lines indicate the strain compensation, calculated by a linear superposition of experimental (line c) and theoretical (lines a and b) lattice-contraction coefficients for single-doped layers.

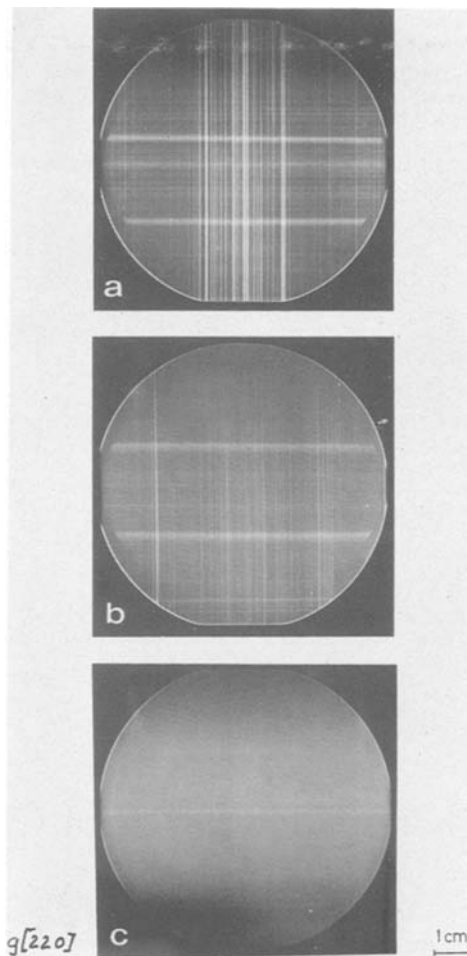

Fig. 8. X-ray topographs of epitaxial layers doped simultaneously with boron and germanium. The boron concentration is kept constant at a level of $1 \times 10^{20}\ \text{atom/cm}^3$. The germanium concentration varies from $2 \times 10^{20}\ \text{atom/cm}^3$ (a), over $6 \times 10^{20}\ \text{atom/cm}^3$ (b), to $1 \times 10^{21}\ \text{atom/cm}^3$ (c).

deviates from the values calculated by the linear and volumetric models.

The value of critical mismatch in epitaxial layers $5\ \mu\text{m}$ thick is 5.5×10^{-4} in the case of boron and 5×10^{-4} in the case of germanium doping, corresponding to concentration levels of 1.1×10^{20} and $8 \times 10^{20}\ \text{atom/cm}^3$, respectively. When the dopant concentration is increased to a level above the critical mismatch, the film strain decreases and the actual lattice mismatch is accommodated mainly by misfit dislocations. Below this critical mismatch, there are no, or only a few, misfit dislocations.

The boron-induced film strain can be reduced by codoping with germanium. Surprisingly enough, however, it was found that strain compensation in codoped layers is not obtained at the concentration predicted by linear superposition of the results for boron and germanium single-doped layers.

Using the experimental data given in this paper, it is not only possible to compensate the strain in highly boron-doped epitaxial layers, but also to adjust it to a certain desired level.

Two problems remain to be clarified. First, the experimental lattice-contraction coefficient of germanium in silicon is considerably lower than the calculated value. Second, the strain predicted by linear superposition of the experimentally determined lattice-contraction coefficients for single-doped epitaxial layers does not agree with the results for codoped layers.

Photoluminescence of Chemical Bath Deposited CdS Films

M. Gracia-Jiménez, G. Martínez,¹ J. L. Martínez, E. Gómez, and A. Zehe²

Departamento de Física, Instituto de Ciencias de la Universidad de Puebla, Apdo. Postal J-48, Puebla, Pue., Mexico

ABSTRACT

Photoluminescence spectra of chemical bath deposited CdS films have been taken. It is shown that the emission line reaching from 0.8 to 2.4 eV depends on the stoichiometry of the films. The stoichiometry is controlled either by changing the pH of the working solution during the deposition process or by carrying out a thermal annealing in air on the films. The most stoichiometric CdS films present a green edge emission line which persists even at room temperature. This line is identified as a radiative transition between a Cd complex and an S vacancy.

Current interest in direct energy conversion devices has led to renewed research on different fabrication techniques in order to elaborate a simple, low cost, low energy consumption technology for fabricating such devices. Recently, there has been a great deal of interest in studying the optical properties of spray-pyrolyzed CdS (1). However, the chemical bath deposition technique, which has many of the advantages claimed for the better known spray deposition technique (2), should offer the prospect of better control over the preparation process because of the slower rate of formation of the film (3). It is the aim of this work to report that this material has a photoluminescence spectrum which depends strongly on the fabrication parameters in the chemical bath and that the most stoichiometric films display photoluminescence spectra reported in single crystal CdS material (4).

Experimental

The CdS films were fabricated by the chemical bath deposition technique (CBD) suggested by Kaur *et al.* (3). Briefly, it consisted of preparing thin CdS films by decomposing thiourea [(NH₂)₂CS] in an alkaline solution of salt of the corresponding cation. This process, which involves a controllable chemical reaction at a low rate by adjusting the pH and the temperature of the working so-

lution, allows maintaining the stoichiometry constant for any ratio of anions and cations. The working solution consisted of preparing three aqueous solutions, thiourea (1M), Cd sulfide (1M), and ammonium hydroxide (0.7-15.0M), in deionized water (DI). We prepared several thin film CdS samples on Corning glass substrates; each was prepared with different molar concentrations of ammonium hydroxide. In Table I, we show the amounts of NH₄OH employed in the solutions and the resulting pH measured for each prepared sample. Half a slice of each sample was subjected to thermal annealing in air at 350°C for 20-60s. Spectra of the photoluminescence of the "as-prepared" and annealed samples were taken by mounting them on a cold finger of a Displex system and were held at temperatures ranging from 10 to 300 K. These samples were photoexcited by the 488 nm line of a Spectra Physics cw Ar ion laser. Luminescence spectra were analyzed by a Zeiss SPZ monochromator and recorded by a lock-in technique in a HP X-Y plotter.

Results

The stability plots of ion concentration *vs.* pH of the depositing reactants in the working solution are obtained by the method reported by Martínez (5). These results are shown in Fig. 1. From this, we can distinguish two regions: one in which the amount of S⁻² ions exceeds the amount of Cd⁺² ions in the prepared films (region I) and in which the corresponding pH values are <11.5; and another in which films are prepared with pH values of

Table I. pH of working solution as function of the molarity (M) of $(\text{NH}_4)\text{OH}$ in H_2O

Sample no.	Molarity of $(\text{NH}_4)\text{OH}$	pH measured
1	0.5	9.4
2	1.0	10.1
3	1.5	10.4
4	3.0	11.3
5	4.5	11.5
6	6.0	11.5
7	7.5	11.7
8	9.0	11.5
9	10.5	11.9
10	12.0	11.9
11	13.5	11.9
12	15.0	11.9

>11.5 (region II). The excess of Cd^{2+} ions is easily seen from Fig. 1. In films whose pH is approximately the calculated value of pH 11.5, one could expect to get the most stoichiometric films. The measured values of pH for the samples prepared with the method mentioned above are shown in Table I.

The luminescence spectra of three different samples held at 10 K are shown in Fig. 2. The samples prepared with characteristics shown in region I of Fig. 1 (pH < 11.5, sample 1) show a characteristic spectrum consisting of a broad line (640 meV, half-width) centered around 1.68 eV (curve A, Fig. 2). A similar broad spectrum is recorded for those CdS films displaying the characteristics of region 2 (pH > 11.5, sample 11). This Fig. 1 spectrum is centered around 1.70 eV and is a little broader than that in Fig. 2 (720 meV, curve C). However, films whose preparation method was at pH = 11.5 show distinct spectra, compared to those mentioned above (sample 4). These spectra consist of a similar featureless broad line ("red"), centered also at 1.68 eV, with a half-width of 620 meV and an addi-

Fig. 2. Luminescence spectra for samples 1 (A), 4 (B), and 11 (C) under Ar laser excitation (488 nm), held at 10 K.

tional "green" edge line centered at 2.255 eV with a narrow half-width of 180 meV (curve B, Fig. 2).

In Fig. 3a and 3b, the temperature dependence and the characteristic green luminescence line intensity are shown. The green line intensity is reduced by a factor of 10, but it does not vanish at 300 K. The peak position, on the other hand, shows a clear maximum at about 80 K (2.265 eV at 80 K, compared to 2.255 eV at 10 K and 150 K). In Fig. 4, we show $\log(\text{intensity})$ vs. $1/T$ dependence of the green radiative transition. Two somewhat clear regions of different inclination are apparent, the one in the high tem-

perature region resulting in an activation energy of 6.19 meV and the other resulting in an activation energy of 0.103 meV. We have assumed that this calculation contains an $\exp(E/KT)$ dependence of the green luminescence peak with temperature.

For comparison, we display in Fig. 5a and 5b the temperature behavior of the red luminescence band intensity and the peak position of sample 4 for the same region of temperature. We also include samples 1 and 11, which do not present the green line. A similar run is found for all samples below 200 K, but whereas the peak energy de-

creases continuously for samples 1 and 11 with increasing temperature, the peak energy position of sample 4 increases above 200 K. Also, in Fig. 6 we show the spectra lines of sample 2 "as-prepared" with a 30s annealing in air at 400°C. Both show the red broad line, but a green small line tends to appear for the annealed sample.

Discussion

Broad photoluminescence at 1.65 eV has been reported in surface-damaged and electron-irradiated single-crystal CdS and identified with a complex sulfur interstitial (4). In our CBD CdS samples, one would expect to find similar defects and luminescence sites in dislocations and stacking faults of polycrystalline films. It is found that CBD generates films with numerous stacking faults (6). We believe that this situation helps cause radiative recombination channels in our CBD films whose method of preparation has almost no influence over the broad red emission line. Samples prepared with pH around 11.5, on the other hand, show characteristic green edge emission lines (the most stoichiometric films); the behavior of the red line is modified only for the case of this type of sample, e.g., sample 4. A high energetic recombination channel underlying the broad red emission line starts gaining efficiency at 200 K, causing a blue shifting of the overall peak position of the line (see Fig. 5a). A similar argument holds for the abrupt decrease of the peak energy position of sample 11 at 300 K.

For the case of "as-prepared" and annealed samples, we detect a modification in the spectra of the films. Samples whose preparation was at pH < 11.5 are able to show an increase in a green emission band after thermal annealing. The opposite is true for samples whose pH is > 11.5; they do not show any modification of the overall intensity line and the peak energy position. It is known that thermal annealing of CBD films in air evaporates the excess sulfur ions in the films because of their high vapor pressure (compared with the Cd ions). Thus, samples with concentrations of S-ions greater than that of Cd ions during preparation are thermally "annealed," and they present a modification of the spectra emission line. The samples whose Cd ion concentration is greater than S ion concentration during preparation are thermally annealed and do not show any change in the spectral emission line. There seems to exist two ways of achieving films which present a green emission line: selecting a pH whose Cd ion and S ion concentrations are equal; or selecting thermally annealed samples whose S ion concentration exceeds the Cd ion concentration. Only for these cases have we found the green emission line which has been related to a complex transition between cadmium and sulfur vacancies present in dislocated single CdS crystals (7).

The overall room temperature photoluminescence of the CBD CdS films grown with pH 11.5 is higher than that of single crystal CdS. The same behavior has been reported by Feldman and Dusiman (1) for spray pyrolyzed CdS, with no explanation for it. From our point of view, such behavior might be possible when taking into ac-

Fig. 6. Luminescence spectra for sample 2, held at 80 K for as-prepared (A) and annealed-in-air at 400°C for 30s (B).

count existing electric fields between microcrystallites of optically excited films, which cause an acceleration of the radiative recombination process, as compared with the nonradiative processes always present in single and polycrystalline material. A detailed experimental study of this behavior is still in progress, and electroluminescence excitation seems the appropriate means. At the same time, it should be possible to make clear whether the large room temperature green photoluminescence is a sufficient indication of a high efficient electroluminescence device.

Summary

In this work, we have shown that CBD CdS films prepared with approximately equal amounts of Cd and S ions give films whose green emission persists up to room temperature. There are two ways to achieve this situation: by preparing films whose pH value of the working solution corresponds to equal amounts of Cd and S ion concentrations; or by thermally annealing samples whose S ion concentration exceeds the Cd ion concentration. The mechanism for red luminescence is not affected by these processes. The green emission line is strongly influenced

by this situation. We have tried to identify the green emission line with a complex transition between Cd and S ion vacancies present in dislocated films.

Photoelectric Properties of ITO/CdS/Surfactant Aluminum Phthalocyanine/Au Solar Cells

M. F. Lawrence, J. P. Dodelet,* and L. H. Dao*

Institut National de la Recherche Scientifique-Energie, Varennes, Quebec, Canada J0L 2P0

ABSTRACT

A heterojunction solar cell made by sequential electrodeposition of CdS and a surfactant aluminum phthalocyanine, (SAIPc), onto ITO (Nesatron) conductive glass, has been analyzed. Barrier formation occurs upon light absorption and is related to "doping" of the organic pigment by trapped electrons. When the cell is illuminated with white light, all the band bending occurs in the phthalocyanine, and two mechanisms are at work in relation to current production. The optimum thickness for the CdS and SAIPc layers was found to be 4000 and 2500Å, respectively. The photovoltaic characteristics of the optimized cell, under an illumination of 50 mW cm⁻², were: $J_{sc} = 0.33 \text{ mA cm}^{-2}$, $V_{oc} = 0.46\text{V}$, $ff = 0.3$, and $\eta = 0.09\%$. From capacitance measurements a density of $N \sim 3 \times 10^{17}$ charge carriers/cm³ was calculated, and the barrier parameters were: $w_0 \sim 300\text{Å}$ and $V_0 \sim 0.5\text{V}$. To illustrate how the junction changes with "doping" of the organic layer by photogenerated electrons, an energy level diagram of the proposed model is presented.

For years now, solar cell research has been primarily concerned with finding efficient devices that are easily fabricated, utilizing low cost durable materials. This task has led to the consideration of, among other things, the possibility of employing organic semiconductors as a substitute for some of the more expensive inorganic materials. With this in mind, determining the electrical and photoelectrical characteristics of the most promising organic molecules (phthalocyanines, merocyanines, porphyrines, squaryliums, etc.), became a major priority in the hope of discovering one with all the right qualities.

These organic pigments exhibit p-type conductivity (1-4), and the first devices fabricated with them were of the Schottky barrier type, using metals such as aluminum, indium, or chromium to establish a blocking contact. Lately, cells incorporating an organic-inorganic heterojunction have attracted attention in regard to their potential for eventual use in energy conversion. Phthalocyanine-type molecules, because of their environmental stability, their high absorption in the visible region, and their relatively good photoconductive properties, have emerged as one of the main organic substances to be used conjointly with inorganic n-type semiconductors like CdS and ZnO (5) to form heterojunctions.

Hor *et al.* (6) have developed a CdS/trivalent metal-phthalocyanine device with a conversion efficiency of 0.22% under AM2 illumination of 75 mW cm⁻², which is

*Electrochemical Society Active Member.

one of the largest values obtained for devices using organic photoconductors at high light intensity. A conversion efficiency of 0.5% has also been attained with a CdS/polyacetylene photovoltaic cell under AM1 irradiation (7). These results are quite modest compared to the > 9% conversion efficiency obtained with the CdS/Cu₂S cell (8), but, nevertheless, many aspects of organic-inorganic systems remain to be clarified; they deserve further investigation.

In our own effort, we have undertaken the fabrication and analysis of a heterojunction cell built up by sequential electrodeposition of CdS and a surfactant aluminum phthalocyanine (SAIPc) onto Nesatron conductive glass. This metal-phthalocyanine, unlike those commonly used (MgPc, CuPc, ZnPc, H₂Pc, etc.) and usually deposited by vacuum sublimation, has the interesting property of forming a positively charged colloid when put in an iso-octane + n-butanol mixture, permitting its electrodeposition on top of the CdS layer. This practical deposition technique of organic compounds was first performed by Tang and Albrecht (9) using microcrystalline Chl *a*, which forms a positively charged colloid in 3-methylpentane or iso-octane. Dodelet *et al.* (10) have subsequently applied the method to SAIPc in making an Al/SAIPc/Ag photovoltaic cell, where stability and conversion efficiency were found to be seriously hampered by the accumulation of electrons trapped in Al₂O₃ at the Al/SAIPc interface. Besides providing a simple and rapid way of film deposi-

tion, this technique allows the coverage of large surfaces, making it particularly well suited for an eventual practical application.

The main goal of this article is to describe our cell's behavior and to report on its characteristics and its optimization through variation of the semiconductor layer thicknesses. The experiments show that, when the cell is illuminated with white light, all the band bending occurs in the phthalocyanine and two mechanisms are at work in relation to current production. The information gained sheds more light on the organic and inorganic semiconductors separate functions, on how they combine to produce power, and provides a deeper understanding of the model proposed for organic-inorganic heterojunction devices (11).

Experimental

The CdS was deposited electrochemically onto Nesatron conductive glass of 82% transparency (indium-tin-oxide coating, P.P.G. Industries), according to the method described by Baranski and Fawcett (12). The cadmium chloride, elemental sulfur, and dimethylsulfoxide were reagent grade and used without further purification. The procedures by which the surfactant aluminum phthalocyanine (SAIPc) shown in Fig. 1 was synthesized and electrodeposited have been described previously (10). The SAIPc film thickness was varied from ~ 400 to 3700\AA , depending on the amount of SAIPc in the iso-octane + n-butanol mixture, and the CdS layer was varied from ~ 1000 to 5500\AA , depending on the electrodeposition time. Figure 2A shows a picture of a 2000\AA thick CdS film and Fig. 2B is a 2500\AA SAIPc film taken with an ETEC Autoscan scanning electron microscope. The CdS films have surfaces that are quite smooth up to thicknesses of about 6000\AA , above which the layer becomes cracked by the appearance of numerous crevices. The SAIPc films are less smooth and gradually become rougher as they get thinner. Nevertheless, reasonable films are obtainable down to about 400\AA (13). Film thicknesses were measured with a Dek-Tak surface profile measuring system (Sloan). The heterojunction cells were completed by the evaporation under vacuum ($\leq 5 \times 10^{-7}$ torr, Varian Cryostack 8) of a gold collecting (0.5 cm^2) and guard electrode (99.9% pure from Alfa).

The cells are installed in a Faraday cage, where they could be irradiated through the Nesatron with monochromatic light from a 650W tungsten-halogen lamp (Schoeffel) passing through a Kratos monochromator (Schoeffel), or/and with white light from a Kodak Ektagraphic slide projector (300W tungsten-halogen lamp). Because of the detrimental effect oxygen has on cell performance (see "Results and Discussion" section), the cells were analyzed while under N_2 atmosphere. The light intensity was

varied by interposing neutral density filters (Oriol Corporation) and measured with a United Detector Technology 21A power meter equipped with a Radiometric filter. The intensities reported correspond to light incident on CdS. Filters (Oriol Corporation) having different cut-on and cut-off wavelengths were used in order to illuminate the cells with isolated parts (blue light or red light only) of the visible spectrum emanating from the slide projector. Currents and voltages generated by the cells were measured with a Keithley Model 616 electrometer. Capacitance measurements were performed according to the discharge method using a setup similar to the one described by Popovic (14). The absorption spectra were obtained with a Hitachi Model 100-60 spectrophotometer.

Results and Discussion

J-V characteristics.—Figure 3 shows the J-V curves of a typical CdS/SAIPc cell, corresponding to three important stages of measurement in which cell behavior is found to be different. The first curve is obtained by measuring the dark J-V characteristics of a freshly prepared cell, not yet exposed to light. At this stage, all of the cells exhibit very little rectification and their behavior is mostly resistive. The second stage (curve 2), involving the J-V measurement under white light illumination, clearly demonstrates that the rectifying properties appear as a result of light absorption. In the third stage, the J-V curve is taken in the dark, immediately after illumination, and the rectifying qualities of the cell are still present but have al-

Fig. 3. J-V characteristics of CdS-SAlPc cell. Curve 1: first stage, in the dark. Curve 2: second stage, under white light illumination (50 mW cm⁻²). Curve 3: third stage, in the dark, after illumination.

ready begun to decay. Now, if after illumination, the cells are kept in the dark long enough (from 8h to 5 days, depending on the SAlPc film thickness), they gradually regain their initial resistive behavior. From that point, putting them again through the same three respective steps yields the same result. Wagner and Loutfy (11) obtained an identical result with a NESACdS/MgPc/Au cell before and during illumination, but the behavior of the device, in the dark after illumination, was not mentioned.

Figure 4A shows the semilogarithmic plots of the forward dark current *vs.* applied voltage (curves 1 and 3 of Fig. 3) and provides additional information concerning the state of the cell before and after illumination. The J-V data of a cell in the first stage (before illumination and very little rectification) cannot be fitted to the modified Schottky equation (15)

$$J = J_0 [\exp e(V - JR_s)/nkT - 1] + (V - JR_s)/R_{sh} \quad [1]$$

where J_0 , n , R_s , R_{sh} , and e are the reverse saturation current, the diode quality factor, the series resistance, the shunt resistance, and the electronic charge, respectively. J is the measured dark current, and V the forward applied voltage (positive potential on gold electrode). Rectification's being practically absent implies that the device at this point is not a diode, or that, at most, it is a very poor one and therefore Eq. [1] is not suited for its description. The data, however, fit reasonably well to an ohmic relation

$$J = \frac{V}{R} \quad [2]$$

which is more appropriate for the description of an essentially resistive device. Curve 1 of Fig. 4A (left axis) was calculated with Eq. [2] taking $R = 0.16 \text{ M}\Omega$. The J-V data of the same cell in the third stage (immediately after illumination, with rectification) can be fitted quite well to Eq. [1] using values of $J_0 = 8.2 \times 10^{-8} \text{ A cm}^{-2}$, $n = 2.85$, R_s

$= 415 \Omega$, and $R_{sh} = 1 \text{ M}\Omega$ (curve 3 of Fig. 4A, right axis). $R_{sh} = 1 \text{ M}\Omega$ was calculated from the slope of the reverse bias characteristics. Figure 4B illustrates how the open-circuit

Fig. 4. A: J-V forward bias characteristics in the dark corresponding to curves 1 and 3 of Fig. 3. B: J_{sc} vs. V_{oc} for light intensities ranging from 0.7 to 18 mW cm⁻² (second stage).

voltage V_{oc} and the short-circuit current J_{sc} at light intensities ranging from 0.7 to 18 mW cm^{-2} (second stage) follow the relation

$$V_{oc} = \frac{nkT}{e} \ln \left(\frac{J_{sc}}{J_0} + 1 \right) \quad [3]$$

From the plot of $\log J_{sc}$ vs. V_{oc} , we find $n = 2.2$ and $J_0 = 2.7 \times 10^{-7} \text{ A cm}^{-2}$. Comparing these parameters with those obtained for the same cell immediately after illumination (curve 3, Fig. 4A) shows that the diode is at its best in the presence of light.

The J-V characteristics indicate the following: when the CdS and SAIPc are first brought together to form a heterojunction, the amount of free carriers in SAIPc is too little at this stage, and the result is a diode with poor rectification. Light absorption in SAIPc causes the formation of excitons that dissociate into electron-hole pairs. Because some of the electrons are rapidly trapped in SAIPc, mobile holes are left for conduction. Consequently, the pigment takes on a p-type semiconducting behavior, which permits, in the presence of nearly degenerate electrodeposited CdS (16), the formation of a nonideal Schottky barrier diode. The voltage developed at the barrier, therefore, corresponds to the difference between the Fermi levels of CdS and SAIPc when the system is illuminated and not to the difference between their respective Fermi levels when both materials are at equilibrium in the dark. Immediately after illumination (third stage), the captured electrons start escaping from their traps only to recombine with the holes present at that point in the SAIPc layer. This has the effect of transforming the organic pigment from its light-induced semiconducting character back to its initial, more insulating state, and causes the gradual decrease of the diode's rectifying capability. This mechanism, involving "doping" of the pigment by trapped electrons has also been mentioned in the case of chlorophyll α (17, 18). At the end of this article, an energy band diagram is presented to give a more detailed description of the barrier formation upon illumination.

Action and absorption spectra.—Figure 5A presents the absorption spectra of CdS (broken line) and SAIPc (solid line). Figure 5B shows the action spectra of three cells having different thicknesses of CdS for which the SAIPc film thickness has been kept constant at 2000Å. In the red part of the action spectrum (520 to 800 nm), where the absorption is due to SAIPc, the action spectra for all three cells are identical and correspond to the absorption spectrum of SAIPc. In the blue region, however (400 to 520 nm), the absorption by CdS has a marked effect on the resulting action spectrum. We have also noticed that when the cells are illuminated with red light only (≥ 600 nm), the photocurrent decreases quite rapidly and continues to do so unless a certain amount of blue light (430 nm) is added. This noteworthy observation, and what occurs in the blue region of Fig. 5B, can be explained by assuming the existence of two mechanisms responsible for current production.

Under white light illumination, electron-hole pairs are formed simultaneously in both semiconductors. The major mechanism at work for current production involves the recombination, at the junction, of electrons from the SAIPc conduction band with holes from the CdS valence band, leaving extra electrons in the CdS and extra holes in SAIPc to be recuperated. Blue light is essential, because the holes it generates in CdS are needed to balance the photocurrent. When the photocurrent produced with red light only (≥ 600 nm) is balanced with just the right amount of added blue light (430 nm), we find

$$\frac{N_{(e)}}{N_{(ph)}} = 0.7 \pm 0.1 \quad [4]$$

where $N_{(e)}$ is the total number of electrons collected per second and $N_{(ph)}$ is the total number of blue photons absorbed in the CdS within a distance from the phthalocyanine not exceeding the diffusion length of holes in CdS

Fig. 5. A: Absorption spectra of SAIPc (full line) and CdS (broken line). B: Normalized action spectra of three cells having different CdS thicknesses. Curve 1: 1100Å. Curve 2: 2300Å. Curve 3: 4400Å. SAIPc thickness is 2000Å.

(*vide infra*). $N_{(e)}/N_{(ph)}$ represents an efficiency for the conversion of minority carriers from SAIPc to majority carriers in CdS.

In Fig. 5B, the effect CdS thickness has on the photocurrent generated in the blue part of the action spectra provides us with evidence for a second mechanism in relation to current production. It is important here to note that the action spectra are given as a percentage normalized at the maximum in the red (634 nm). If we assume that the CdS acts only as a filter for blue light, it is possible to calculate for each CdS thickness (taking into consideration the absorption coefficients of both semiconductors) what the action spectra would be from 400 to 520 nm, if the phthalocyanine was the only one to contribute currentwise. Subtracting these calculated action spectra from their corresponding spectra in Fig. 5B, we find that the CdS layer is responsible for $70\% \pm 10\%$ (independent of its thickness) of the overall photocurrent measured in the region where it absorbs. This would imply another mechanism of current production, however secondary, involving a direct injection of holes from the CdS valence band into the SAIPc valence band.

In an additional experiment, we have measured the cell V_{oc} when irradiated with red light only (≥ 600 nm), therefore, giving the voltage developed uniquely in the SAIPc. If the cell is illuminated with a red light intensity at which the maximum V_{oc} is obtained from SAIPc, the subsequent addition of blue or white light does not increase the measured potential, indicating that the band bending is entirely located on the phthalocyanine side of the junction. These results agree with findings already reported in the literature (11, 19), and they are expected since the

electrodeposited CdS is a nearly degenerate semiconductor.

The information gained by probing the heterojunction with isolated parts of the visible spectrum (blue or red light) permits us to determine how both semiconductors participate in this cell. Unlike completely inorganic devices (20), heterojunctions of this type behave rather like Schottky barrier cells where the organic layer acts as absorber-generator and simultaneously contains the built-in voltage region which allows the generated minority carriers to be collected and converted to majority carriers in the inorganic layer. The CdS, in this case, serves as a blocking contact and also contributes directly to the photocurrent.

The action spectra in Fig. 5B were obtained for a constant photon flux, with a maximum energy of 0.2 mW cm⁻² incident on the CdS layer at 634 nm. Quantum efficiencies at the maximum in the red (634 nm) vary between 6% and 11%, calculated according to

$$\phi(\%) = \frac{100 J_{sc} h\nu}{eI} \quad [5]$$

where $h\nu$ is the photon energy at 634 nm and I is the 634 nm light intensity incident on the CdS layer. Considering only the major mechanism for current production described previously, the requirement of balanced electron-hole pair production in both halves of the junction means, in fact, that the maximum quantum efficiency of this system is 50%.

Cell optimization.—In an attempt towards cell optimization, the semiconductor layers were varied in thickness starting with CdS. Figure 6 shows the variation of current density as a function of CdS thickness under white light illumination (8 mW cm⁻²). The optimum thickness, which corresponds to the diffusion length of holes in the electrodeposited CdS, was found experimentally to be ~ 4000Å. The full line in Fig. 6 (right axis) is the fraction of light, F , absorbed in CdS within a distance from the SAlPc not exceeding the hole diffusion length. F is calculated taking into account the absorption of light in CdS at a specific wavelength (400 nm) and using 4000Å as the diffusion length of holes in the inorganic semiconductor. For CdS thicknesses $\leq 4000\text{\AA}$, we have

$$F = [1 - \exp(-\alpha d)] \quad [6]$$

and for thicknesses $> 4000\text{\AA}$

$$F = [1 - \exp(-\alpha d)] - [1 - \exp\{-\alpha(d - \Lambda_h)\}] \\ = \exp(-\alpha d) \times [\exp(\alpha \Lambda_h) - 1] \quad [7]$$

Fig. 6. Short-circuit current density, J_{sc} , vs. CdS thickness (left axis). Fraction of light, F , absorbed in CdS within a distance from SAlPc not exceeding the hole diffusion length ($\Lambda_h = 4000\text{\AA}$) vs. CdS thickness (right axis). Also indicated are the maximum and minimum experimental values obtained.

where α is the absorption coefficient for CdS at 400 nm (see Fig. 5A), which we have found to be $9.7 \times 10^4 \text{ cm}^{-1}$ ($2.30259 \times 4.2 \times 10^4 \text{ cm}^{-1}$), d is the total CdS layer thickness, and $\Lambda_h = 4000\text{\AA}$, the hole diffusion length in the CdS. Wagner and Loutfy (11), taking $\alpha \sim 10^5 \text{ cm}^{-1}$, at 520 nm (which seems large for CdS at that wavelength), estimated a Λ_h of 1000Å. The fit of the calculated curve to the experimental points using $\Lambda_h = 4000\text{\AA}$ is reasonably good.

Figure 7 illustrates the variation of cell efficiency, η , vs. the organic layer thickness measured under white light illumination of 20 mW cm⁻². The CdS layer of these cells was kept at the optimum thickness of ~ 4000Å. Cell efficiency is calculated with the expression

$$\eta(\%) = \frac{100 J_{sc} V_{oc} ff}{I_T} \quad [8]$$

where ff is the cell fill factor and I_T is the white light intensity incident on CdS. Typical values of ff were found to be ~ 0.3. A maximum efficiency of ~ 0.1% was attained at a SAlPc thickness of ~ 2500Å.

The absorption of visible light by the organic pigment results in exciton formation. The excitons are capable of diffusing a certain length (Λ) across the SAlPc layer before they decay or dissociate into charge carriers which can be collected readily, if they are formed in the space-charge region, or if the excitons form outside at a distance $\leq \Lambda$ and diffuse into the space-charge region. The width of the depletion region at zero applied bias being w_0 , the active region extends over a distance of $w_0 + \Lambda$. In photoelectrochemical cells using SAlPc (13), a maximum value of ~ 250Å was found for Λ , which agrees with $\Lambda \sim 300\text{-}500\text{\AA}$ obtained for $x\text{-H}_2\text{Pc}$ (21, 22).

Figure 8 shows the efficiency variation (right axis), open-circuit voltage and short-circuit current density variation (left axis) with I_T for an optimized cell. The light exponent, γ , appearing in the expression

$$J_{sc} \propto I_T^\gamma \quad [9]$$

has a value of ~ 0.9. The sublinear dependence of J_{sc} on I_T is related to the distribution of traps for holes in the phthalocyanine (23). This effect, combined with the fact that V_{oc} reaches a constant value at ~ 20 mW cm⁻², causes the efficiency to decrease at greater intensities. An efficiency of ~ 0.09% at a 50 mW cm⁻² white light illumination compares well to $\eta = 0.10\%$ obtained with ITO/CdS/ZnPc/Au and $\eta = 0.066\%$ for ITO/CdS/MgPc/Au at the same light intensity (24). The best result for heterojunction devices of this type, however, was reached with an ITO/CdS/ClAlPc/Au cell having a conversion efficiency of 0.22% at an AM2 illumination of 75 mW cm⁻² (6).

Capacitance measurements.—The capacitor discharge technique consists in measuring the total accumulated charge, Q_i , after the cell has been biased with a voltage V . The result is

$$C_i = Q_i/V \quad [10]$$

where C_i is the integral capacitance. The accumulated charge, when external voltage V is applied to an ideal or MIS Schottky barrier, can be expressed by (14)

$$Q_i = \left(1 + \frac{V}{V_0}\right)^{1/2} Q_0 - Q_0 \quad [11]$$

where $Q_0 = AeNw_0 = A(2e\epsilon\epsilon_0NV_0)^{1/2}$ is the amount of charge accumulated in the barrier at zero bias, A the sample area, e the electronic charge, ϵ the SAIPc dielectric constant, ϵ_0 the vacuum permittivity, N the density of majority carriers, and V_0 and w_0 are the built-in voltage and barrier width at zero applied bias. Since the CdS/SAIPc heterojunction behaves like a Schottky barrier (while under illumination or immediately after), we assume the application of the present theory to be justified. Equation [11] can be rewritten in the more convenient form

$$\frac{1}{C_i} = \frac{1}{C_0Q_0} Q_i + \frac{2}{C_0} \quad [12]$$

where $C_0 = Q_0/V_0$. From the slope, $1/C_0Q_0$, and the intercept, $2/C_0$, obtained by plotting $1/C_i$ vs. Q_i , the different barrier parameters V_0 , w_0 , and N can be estimated. Substituting Eq. [11] in the definition of the integral capacitance (Eq. [10]), we obtain

$$\frac{C_i}{C_0} = \left(\frac{V_0}{V}\right) \left[\left(1 + \frac{V}{V_0}\right)^{1/2} - 1\right] \quad [13]$$

For small applied biases ($V \ll V_0$), Eq. [13] becomes

$$C_i = 1/2 C_0 \quad [14]$$

and under this condition, determining Q_i permits (when

V_0 and N are known) the direct evaluation of w_0 , the barrier width at zero applied bias.

As was the case in the J-V experiments, capacitance measurements performed before and after illumination provide valuable results. For a freshly prepared device, not yet exposed to light (or a cell kept in the dark long enough after illumination), the capacitance dependence on applied voltage does not resemble the typical dependence of depletion layer capacitance on applied voltage for p-n junctions and Schottky barriers (25). At this stage, the values found for w_0 when Q_i is measured at $V \ll V_0$ (0.01V), correspond quite closely to the thickness of the SAIPc layer of the cell, if $\epsilon = 4.3$ is assumed for SAIPc. A dielectric constant of 4.25 has been reported for α -H₂Pc (26). This indicates that, before illumination, the density of mobile charge carriers in the organic layer must be quite low and, because of the high resistivity of phthalocyanines compared to CdS, the cell behaves like a simple capacitor with the SAIPc as dielectric. A similar behavior was observed by Skotheim *et al.* (19) for an Au/merocyanine/TiO₂ sandwich cell in the dark.

Furthermore, to obtain a suitable plot of $1/C_i$ vs. Q_i (Fig. 9), it was necessary to illuminate the cells before each measurement of Q_i in the dark at a specific reverse applied V . This is consistent with the behavior indicated by the J-V results. The significant band bending at the p-n junction appears with the onset of light, and measuring Q_i at $V \ll V_0$ immediately after illuminating the cell with white light, yields the barrier width at zero applied bias, w_0 . By determining C_i at $V = 0.01V$, we found w_0 to be independent of the CdS thickness and to vary only with SAIPc thickness. This helps in confirming a model with virtual absence of band bending in CdS, and where all of the built-in potential develops across the phthalocyanine film. From the $1/C_i$ vs. Q_i plots (as described by Eq. [12]), typical values of $N \sim 3 \times 10^{17} \text{ cm}^{-3}$, $w_0 \sim 300\text{\AA}$, and $V_0 \sim 0.5V$ were obtained for the optimized cells (CdS $\sim 4000\text{\AA}$ and SAIPc $\sim 2500\text{\AA}$). These results are in accordance with $N \sim 10^{18} \text{ cm}^{-3}$, $w_0 \sim 200\text{-}250\text{\AA}$, and $V_0 \sim 0.6V$ found by Ghosh *et al.* for an Al/MgPc/Ag Schottky barrier cell (1).

Fig. 9. Reciprocal integral capacitance, C_i^{-1} , vs. total accumulated charge, Q_i , at different applied reverse biases.

If the collected charges are the result of excitons dissociating in w_0 only, the active region of the cell would therefore correspond to $w_0 + \Lambda \sim 550\text{\AA}$. Figure 7 shows, however, that the efficiency increases up to a SAIPc thickness of at least 2000\AA , leaving $\sim 1500\text{\AA}$ in excess of $w_0 + \Lambda$ unaccounted for, which also contributes to the total efficiency. A possible explanation would be that the minority carriers created in the bulk of SAIPc might be capable of migrating towards the space-charge region over a distance of $\sim 1500\text{\AA}$, or a participation by triplet excitons may be involved.

ITO/CdS/SAIPc/Au cells are much more stable than the Al/Al₂O₃/SAIPc/Ag cells already investigated (10), but their photovoltaic properties still decrease slowly during illumination. Under 90 mW cm^{-2} white light, J_{sc} typically drops to $\geq 70\%$ of its initial value after 10h of irradiation. A smaller drop is observed if the irradiation power is reduced.

Water vapor and atmospheric gases also have an influence on the cell characteristics. J_{sc} (and V_{oc}) decreases when atmospheric air is replaced by dry air, but increases when atmospheric air or dry air is replaced by dry N₂. J_{sc} decreases also by wetting N₂. This indicates, first of all, that water vapor has a positive influence on J_{sc} only in the presence of O₂ and, second, that O₂ by itself has a negative effect on J_{sc} .

The conjugated effect of water vapor and O₂ on J_{sc} has already been mentioned for Al/Al₂O₃/chlorophyll *a*/Ag cells (27), but the dry N₂ effect is quite puzzling. O₂ is known to reversibly adsorb on phthalocyanines (28). The decrease of J_{sc} when O₂ is present could be explained by the formation of surface states on SAIPc, through which the photogenerated electrons and holes could recombine. This reaction would be in competition with the main mechanism for current production in the cell. The effect of O₂ could also be explained by again assuming the participation of triplet excitons in photocurrent generation. These excitons would be quenched by O₂, therefore reducing the overall photoactivity of the cells.

The influence of water vapor and gases was not investigated further, and, as indicated in the experimental section, all the measurements were performed in dry N₂ environment.

Energy band diagram for barrier formation.—Figure 10 shows the energy band diagram of the optimum ITO/CdS/SAIPc/Au cell in the dark, before (or in the dark long enough to be at equilibrium) and immediately after illumination. For CdS, the value of E_c is at 4.50 eV below the vacuum level and $E_g = 2.42\text{ eV}$ (29). Being a nearly degenerate semiconductor with $N = 10^{18}\text{ cm}^{-3}$ (16), electrodeposited CdS has a Fermi level located at $\sim 0.06\text{ eV}$ below E_c (4.56 eV below vacuum). With experiments described elsewhere (13), using photoelectrochemical cells having a SAIPc/Fe(CN)₆^{3/4-} electrolyte junction, a value of $E_{FB} = 5.05\text{ eV}$ vs. vacuum was found for the flatband energy of SAIPc, which corresponds to the Fermi level's location immediately after "doping by illumination. The

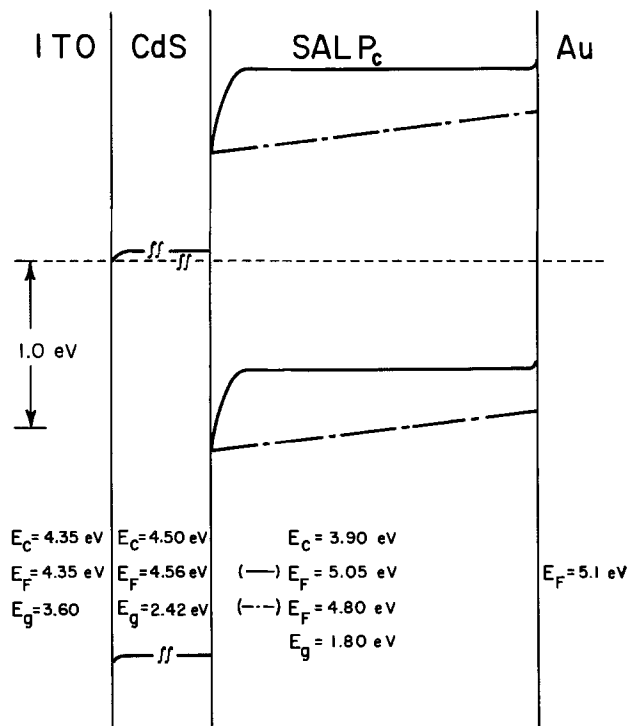

Fig. 10. Energy band diagram of the optimum ITO/CdS/SAIPc/Au cell in the dark. The solid line represents SAIPc band bending immediately after illumination; the dash-dotted line represents SAIPc band bending before the first illumination or in the dark long enough after illumination to be at equilibrium.

equalization of the CdS and SAIPc Fermi levels, therefore, results in a built-in potential of $5.05 - 4.56 = 0.49\text{V}$. This is in good agreement with $V_0 = 0.50$ obtained from the capacitance-voltage measurements. In order to position the SAIPc valence band relative to its Fermi level, we have used a value reported by Loutfy (30) for metal-free phthalocyanine. With studies of current-voltage variations, Loutfy found that the H₂Pc Fermi level lies at 0.65 eV above the valence band. For the bandgap of SAIPc, the value of 1.8 eV reported for AlPc⁺ (31) is employed. The ITO and Au energy level positions appearing in Fig. 10 were obtained from Ref. (32) and (33), respectively. The energy diagram, of course, is only accurate to the extent of how well the physical quantities borrowed from the literature for H₂Pc and AlPc⁺ apply to SAIPc.

When the cell is left long enough in the dark after illumination, the depletion width increases from its minimum length of 300\AA until it eventually attains the SAIPc film thickness (2500\AA in optimum cells). This increase results from the recombination of electrons with mobile holes, which causes N in SAIPc to diminish. N_t , the majority charge-carrier density when the system has returned to equilibrium, can be estimated in the following manner. In the dark, immediately after light-induced doping, SAIPc contains $N_i = 3 \times 10^{17}\text{ cm}^{-3}$ majority carriers and the cell at this stage has a series resistance $R_{si} = 415\Omega$. After having been in the dark for a few days, the cell's series resistance increases to $R_{sf} = 160\text{ k}\Omega$. If it is assumed that SAIPc is mostly responsible for R_s and that the mobility of majority carriers stays constant, we may write

$$\frac{\rho_i}{\rho_f} = \frac{e\mu N_f}{e\mu N_i} = \frac{R_{si}}{R_{sf}} \quad [15]$$

where ρ is the resistivity of the sample, μ is the mobility and N is the density of majority charge carriers, R_s is the series resistance, and the index *i* and *f* refer, respectively, to the initial (immediately after illumination) and final (at equilibrium) stage in the dark. From Eq. [15], we obtain $N_f \approx 8 \times 10^{14}\text{ cm}^{-3}$. This decrease of N implies that the Fermi level moves from its position at $\sim 0.65\text{ eV}$ above the valence band towards the middle of the forbid-

den bandgap. At most, the Fermi level of SAIPc can move from 5.05 eV to $1/2 (E_c + E_v) = 4.80$ eV below vacuum, which yields a V_0 of $|4.80 - 4.56| = 0.24$ V. This change is represented in the diagram of Fig. 10.

Conclusion

We have presented evidence that, for this CdS/SAIPc heterojunction solar cell, the mechanism related to barrier formation is initiated by light absorption in the organic layer. Subsequently, the trapping of electrons dopes the organic pigment and transforms it into a p-type semiconductor, which, in the presence of CdS, permits the formation of a Schottky barrier. Even though all of the band bending occurs in the phthalocyanine, the CdS, nevertheless, contributes directly to the overall photocurrent. The presence of these electron traps in SAIPc is of primary importance. Without them, the pigment could not behave as a semiconductor. This is also the case with other organic materials, such as chlorophylls, for example.

Future work on this subject will be directed towards the determination of the energy levels associated with the "doping" electron traps in SAIPc and the description of their nature. Future work will also be concerned with the enhancement of power conversion efficiency by selectively doping each of the materials with appropriate electron donors (for CdS) and acceptors (for SAIPc). The technique of film deposition presently in use seems well suited for the accomplishment of this task because it permits the simultaneous electrodeposition of the semiconductor and the dopant.

Chemical Reactions Involved in the Initiation of Hot Corrosion of IN-738¹

G. C. Fryburg, F. J. Kohl, and C. A. Stearns

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

Sodium-sulfate-induced hot corrosion of preoxidized IN-738 was studied at 975°C, with emphasis on processes occurring during the long induction period. Thermogravimetric tests were run for predetermined periods of time, after which one set of specimens was washed with water to give information about water-soluble metal salts and residual sulfate. A second set of samples was cross-sectioned dry and polished in a nonaqueous medium. Element distributions within the oxide scale were obtained from electron microprobe x-ray micrographs. Evolution of SO₂ was monitored throughout the thermogravimetric tests. Kinetic studies were performed for several pertinent processes, and rate constants were obtained for the following chemical reactions

Recently, we reported on the chemical reactions involved in the initiation of Na₂SO₄-induced hot corrosion of the nickel-base alloys B-1900 and NASA-TRW VIA (1), which derive their oxidation resistance from the formation of a thin continuous oxide layer composed largely of α-Al₂O₃. It was shown that, after an induction period, hot corrosion was initiated by basic fluxing of the protective Al₂O₃ layer by the liquid Na₂SO₄ deposit. This was followed by a catastrophic attack resulting from acidic fluxing of the remaining oxide layer by a Na₂MoO₄·MoO₃ molten phase that had formed underneath the oxide layer.

Unlike B-1900 and VIA, the alloy IN-738 derives its oxidation resistance from a protective layer composed largely of Cr₂O₃. This superalloy is of special interest because of its widespread use, both coated and uncoated, in gas turbine engines (2, 3). This position of prominence is due not only to its good mechanical properties, but also to its superior hot corrosion resistance.

The Na₂SO₄-induced hot corrosion of IN-738 between 825° and 1000°C had been studied by several investigators (3-13). Depending on test conditions, either the alloy had not displayed hot corrosion, or hot corrosion had been preceded by a long induction period, during which the corrosion rate was similar to that in simple oxidation. Most of these studies had emphasized hot corrosion kinetics or the morphology of the corrosion scale. Less effort had been devoted to the important processes occurring during the long induction period. These processes were emphasized in this study. We used the same techniques employed in our studies of B-1900 and VIA and, in addition, performed rate studies on several of the simple processes thought to be important in the hot corrosion of IN-738. This work complemented recent research on the effects of temperature and oxide scale thickness on the hot corrosion of IN-738 (13).

Experimental

Specimens of alloy IN-738 were obtained from commercial sources and given conventional heat-treatments. The composition was nominal for IN-738 (weight percent (w/o): Cr, 16.0; Al, 3.4; Ti, 3.4; Co, 8.5; Mo, 1.7; W, 2.6; Ta, 1.7; Nb, 0.9; Zr, 0.1; C, 0.17; Ni, balance) (7). Test samples' dimensions were 0.3 × 1.0 × 2.5 cm. All surfaces were glass-bead blasted to give a uniform matte finish and were scrupulously cleaned.

All samples were preoxidized at 975°C in 1 atm of slowly flowing oxygen for 24h. Hot corrosion was induced by coating the preoxidized samples with about 3 mg cm⁻² of Na₂SO₄; this was followed by isothermal oxidation at 975°C in a vertical tube furnace. Oxygen flowed downward at 126 cm min⁻¹ (620 ml min⁻¹) in the 2.5 cm

diam quartz furnace tube. Continuous weight change measurements were made with a Cahn R-100 microbalance and corrected for flow and buoyancy effects. The concentration of product SO₂ was measured continuously with a Thermoelectron-Pulsed Fluorescent Analyzer specific to SO₂, whose detection capability extended from 0.01 to 50.0 ppm.

One set of reacted samples was cross-sectioned for morphological examination of the corrosion scale by light microscopy and electron microprobe techniques. Reaction products were identified from elemental x-ray micrographs and x-ray diffraction analyses, as reported previously (7). A second set of samples was washed with hot water to extract soluble species, and the wash solutions were analyzed for metal cations and/or anions by atomic absorption techniques. Residual sulfate was determined by ion chromatography.

Results and Discussion

A typical weight gain curve for IN-738 during preoxidation at 975°C, showing typical parabolic kinetics, is presented in Fig. 1. Elemental x-ray micrographs of a typical oxidized sample (Fig. 2), preoxidized for 24h, show that the compact oxide is about 10 μm thick and is composed primarily of Cr₂O₃, with considerable amounts of TiO₂. Tentacle-like internal oxides of Al₂O₃ are observed below the Cr₂O₃ layer, extending 30 μm into the substrate. Tantalum and, possibly, niobium oxides are found beneath the Cr₂O₃-TiO₂ layer. Titanium and chromium have depletion zones about 30 μm thick. Little or no nickel or molybdenum appear in the oxide layer. *In situ* high temperature x-ray diffraction (15) was performed to identify the

Fig. 1. Typical specific weight gain for isothermal oxidation of IN-738 at 975°C in flowing oxygen and for mol fraction of Cr₂O₃ and TiO₂ in scale, as a function of time.

¹A more detailed account of this work can be found in NASA TP-2319 (1984).

Fig. 2. Secondary electron and x-ray micrographs of IN-738 specimen preoxidized at 975°C for 24h in flowing oxygen

oxides formed during isothermal oxidation and to roughly calculate their relative amounts. The results for Cr_2O_3 and TiO_2 presented in Fig. 1 show that the oxide layer formed in 24h is about 75 mole percent (m/o) Cr_2O_3 and 25 m/o TiO_2 .

Thermogravimetric analysis.—A typical hot corrosion curve for preoxidized IN-738 is shown in Fig. 3a. The hot corrosion process for this alloy is characterized by a rather long induction period. The duration of this period is a function of alloy composition, preoxidation treatment, test temperature, and amount of Na_2SO_4 applied (7). An examination of Fig. 3a indicates that the induction period is about 55h and that the corresponding specific weight gain is 5 mg cm^{-2} . If the specific weight gain during the latter part of the induction period is plotted on an expanded scale, it is seen that the specimen corrodes at a linear rate from 15 to 55h, an indication that the oxide formed is not protective in the usual sense. The linear corrosion rate is $0.14 \text{ mg cm}^{-2} \text{ h}^{-1}$, about four times the oxidation rate at 24h during preoxidation.

The induction period is followed by a period of rapidly accelerating corrosion until, at about 60h, attack becomes catastrophic and rapid linear weight gain which continues until about 75h is displayed. By this time, most of the specimen is consumed and is covered with a voluminous, porous, greenish-black oxide (Fig. 4). Most of the attack occurs on the bottom half of the specimen, owing to "slumping" of the liquid Na_2SO_4 .

Sulfur dioxide evolution.—Sulfur dioxide evolution results are shown in Fig. 3b for a typical specimen. The SO_2 product concentration rises rapidly when beginning a run to about $3.4 \pm 0.25 \text{ ppm cm}^{-2}$ (25 ppm), generally within the first 5-10 min of reaction, then it decreases to about 0.27 ppm cm^{-2} (2 ppm) at 4h and to $<0.0027 \text{ ppm cm}^{-2}$ (<0.02 ppm) at 20h. No further SO_2 is detected until the specimen starts corroding catastrophically. Then, the SO_2

level rises slowly to about $0.014 \text{ ppm cm}^{-2}$ (0.1 ppm) at 80h and decreases to 0.02 ppm at 110h.

Analysis of water soluble elements.—Water-soluble compounds are extracted from reacted specimens for chemical analysis. Tests times ranging from 5 min to 100h are normalized to the weight-gain time scale by matching each individual weight gain with the curve given in Fig. 3a. The quantities of various species, reported in Fig. 3c, are normalized to the initial quantity of Na_2SO_4 of 0.168 mmol. The S^{-2} concentrations in the specimens are also shown in Fig. 3c as a function of time.

The amount of SO_4^{-2} recovered drops rapidly to 10% of its original value in 12.5h and to ~ 0 after 25h. The applied sodium ($1/2 \text{ Na}^+$) is completely recovered for times of up to about 5h, after which it rapidly decreases to $\sim 30\%$ of its original value at 30h, persists to $\sim 40\text{h}$, rises to 0.07 mmol at 75h, then falls sharply and levels out at ~ 0.01 mmol. A large quantity (0.11 mmol) of soluble chromium (CrO_4^{-2}) is formed. The soluble chromium rises rapidly to a peak at $\sim 10\text{h}$, then falls in a nearly linear manner until about 30h, subsequently decreasing slowly to a small value after about 60h. Soluble molybdenum (MoO_4^{-2}), which is assumed to come from Na_2MoO_4 , appears at $\sim 10\text{h}$ and increases linearly through the induction period to >0.02 mmol at 55h. It increases more rapidly during catastrophic corrosion, peaks at 0.06 mmol at 75h, and decreases rapidly to 0.01 mol at 90h. Soluble tungsten (WO_4^{-2}) is detected at about the same time as the soluble molybdenum, but increases more slowly than molybdenum and peaks at 40h.

The solutions are also analyzed for soluble aluminum, titanium, tantalum, niobium, and nickel. Soluble aluminum, an important feature in the hot corrosion of B-1900 and VIA, is not detected here. Only soluble nickel is found, at levels less than 0.01 mmol, during the period of catastrophic corrosion. Sulfur is found in the 5 and 10h

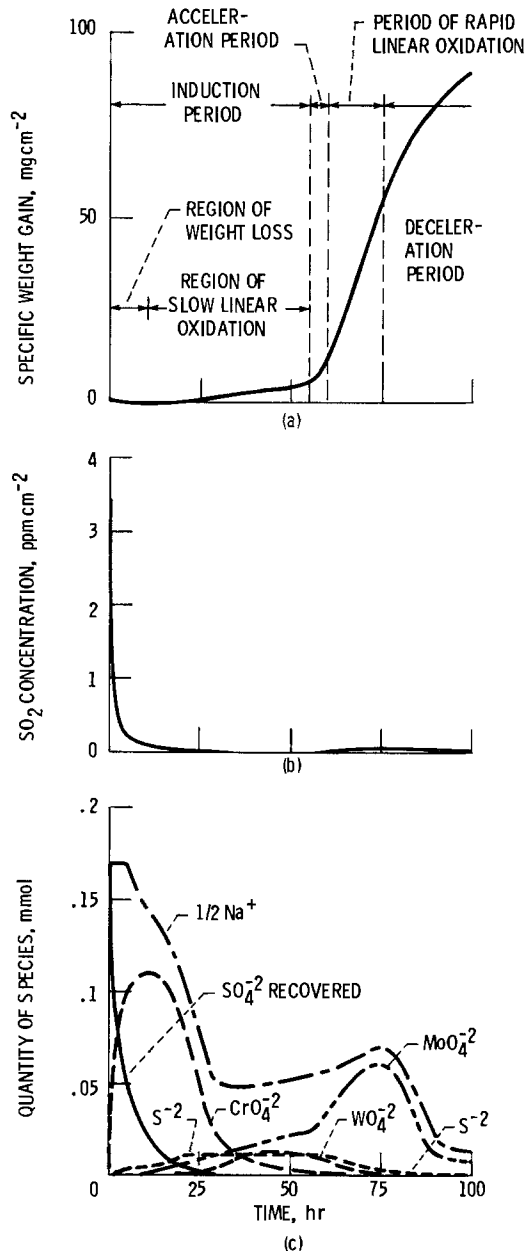

Fig. 3. Preoxidized IN-738 corroded with $3 \text{ mg cm}^{-2} \text{ Na}_2\text{SO}_4$ at 975°C in slowly flowing oxygen: (a) typical specific weight change; (b) concentration of SO_2 evolved as a function of time; and (c) quantity of water soluble species found remaining.

specimens at 0.004 mmol . The value rises to 0.01 mmol at 20h , remains constant until after 60h , and decreases to 0 at 100h .

If the loss of sulfate is due to reaction with Cr_2O_3 and TiO_2 in the scale, there should be a direct proportionality between the SO_2 evolved and the sulfate reacted, as shown by the reactions

Cumulatively evolved SO_2 quantities are obtained by numerically integrating the concentrations over time. These values are compared with the sulfate reacted in Fig. 5. A direct relationship does exist between the two quantities, but the quantity of SO_2 evolved is only about 35% of the quantity of sulfate reacted. This discrepancy arises because some SO_2 is converted to SO_3 in and below the reaction zone. Since the SO_3/SO_2 ratio is characteristic of a temperature lower than that in the reaction zone, accurate theoretical correction for its presence is precluded. The

Fig. 4. Typical IN-738 specimen after corrosion with $3 \text{ mg cm}^{-2} \text{ Na}_2\text{SO}_4$ for 100h at 975°C in slowly flowing oxygen (edge view with oxide scale intact).

direct relationship between evolved SO_2 and the reacted sulfate lends credence to the occurrence of reactions [1] and/or [2] in the early part of the hot corrosion process.

Microprobe analysis.—Samples from specimens tested for 5 min – 90h are prepared for microprobe examination. All of the samples are examined carefully in several different areas, and only the most pertinent micrographs will be discussed.

The appearance of the 5 min sample is similar to that of the preoxidized sample (Fig. 2), but radical changes occur in 5h (Fig. 6). Most of the original continuous Cr_2O_3 - TiO_2 layer is removed, and islands of the alloy, with most of the Cr , Al , and Ti leached out, protrude along the surface. The outer oxide layer is still primarily Cr_2O_3 and TiO_2 , but is no longer continuous, and depletion of chromium in the alloy is more pronounced. Sodium seems to be associated with the chromium and/or the titanium. X-ray micrographic observations in 5 and 10h samples are complicated by formation of a void that encircles most of the sample cross section between the oxide layer and the copper coating. It is believed that the void develops during polishing by removal of a large drop of Na_2CrO_4 which is observed visually on the specimens after testing. The chromium micrograph in Fig. 6 indicates the presence of chromium in the void and an almost continuous Cr_2O_3

Fig. 5. Relationship between cumulative quantity of SO_2 evolved and quantity of sulfate reacted during hot corrosion of IN-738 at 975°C .

Fig. 6. Secondary electron and x-ray micrographs of preoxidized IN-738 specimen corroded at 975°C with 3 mg cm⁻² Na₂SO₄ for 5h

layer on the sample, though the secondary electron micrograph clearly shows a noncontinuous Cr₂O₃ layer. Light micrographs are not affected by the presence of the void, and they show the discontinuous Cr₂O₃-TiO₂ layer unambiguously (Fig. 7). Micrographs of the 10h sample resemble those of the 5h sample.

For the 20h sample, the micrographs (Fig. 8) show reforming of a 20-30 μm thick oxide scale. The oxide advances into the region of Al₂O₃ tentacles and is primarily Cr₂O₃ and TiO₂, with scattered NiO and engulfed Al₂O₃. The depletion zones for Cr and Ti are wider and more depleted. Chromium sulfides appear near the bottom of the depletion zone and probably in the upper portion, as well. Sodium remains associated with Cr and Ti along the outer edge of the sample. Some areas of sodium within the scale are associated with tantalum and/or niobium and are probably either NaTaO₃ or NaNbO₃, formed from the original Ta and Nb carbides. Sodium is also associated with tantalum and niobium oxides found along the bottom edge of the scale. Molybdenum and tungsten are associated with the isolated Ni-Co islands between the Al₂O₃ tentacles in the scale.

The micrographs of the 30h sample (Fig. 9) show continued growth of the Cr₂O₃-TiO₂-Al₂O₃-NiO scale. "Ghosts" of the Al₂O₃ tentacles appear near the bottom of the scale. Nickel oxide becomes more prominent along the outer edge of the oxide layer. Sodium is still distributed in the scale and associated with tantalum and niobium. Sulfur is at the bottom of the depletion zone and on grain boundaries; it is associated primarily with titanium. An area of MoO₃-WO₃ appears at the bottom of the scale near the left side.

In the 40h sample, the oxide is about 30-35 μm thick, with some areas up to 60 μm thick (Fig. 10). It appears that the leached Ni-Co islands oxidize. At the lower edge of the oxidized islands are isolated areas of MoO₃-WO₃, which must have originated from the Mo and W in solution in the Ni-Co islands. The composition of the scale is similar to that of the 30h sample, but the sodium seems to

be tied up as NaTaO₃/NaNbO₃, and little or no sulfur is in evidence.

In the 48h sample, a large fraction of the oxide is 60 μm thick (Fig. 11) and has a morphology similar to that of the thick area of the 40h sample. The MoO₃-WO₃ areas on the bottom edge of the scale are still discrete, but so numerous as to be virtually continuous. Although some sodium is combined with the Ta and Nb, some is also associated with the MoO₃-WO₃ areas, probably as Na₂MoO₄ and/or Na₂WO₄. Sulfur occurs in small concentrations in the MoO₃-WO₃ areas. NiO is observed in the oxidized islands and along the outer edge of the scale.

Most of the oxide layer in the 56h sample is similar to the 48h sample presented in Fig. 11. In two locations, MoO₃-WO₃ areas merge to form a molten phase, probably composed of MoO₃-WO₃ and Na₂MoO₄-Na₂WO₄ (Fig. 12). The sulfides are engulfed by the molten phase, and sodium is distributed throughout the entire oxide layer and the molten phase. The oxide scale is 80-90 μm thick and is composed of all the metallic components of the alloy, except molybdenum and tungsten. The striated or layered structure is characteristic of that found when acidic fluxing occurs (reaction [1]; Fig. 14). The 62, 68, and 77h samples all show an increasing occurrence of areas similar to those in the 56h sample.

In the 90h sample, the molten phase under the scale decreases in prominence. In some areas, the molten MoO₃-WO₃/Na₂MoO₄-Na₂WO₄ is converted to solid NiMoO₄-NiWO₄, as identified by x-ray diffraction (Fig. 13). Most of the thick oxide scale peels off the sample, revealing the NiMoO₄-NiWO₄ layer. This layer exhibits a great deal of cracking because of the NiMoO₄ phase transformation or cooling. Sodium is no longer observed with the molybdate; it diffuses deep into the alloy where it combines with tantalum and niobium located in internal carbides.

Rate determinations of pertinent processes.—To interpret the above results, measurements of the rates of several pertinent physical and chemical processes are re-

Fig. 7. Light micrographs of IN-738 specimens: (a) preoxidized for 24h at 975°C; and (b) preoxidized for 24h and corroded at 975°C with 3 mg cm⁻² Na₂SO₄ for 5h.

quired. Some of these processes have been investigated, and they allow reasonable conclusions to be drawn regarding the hot corrosion of IN-738.

Evaporation of Na₂SO₄ and Na₂CrO₄.—3 mg cm⁻² deposits of Na₂SO₄ or Na₂CrO₄ are air brushed onto coupons the same size as the oxidation specimens. Gold coupons are used for Na₂SO₄ (16), and platinum is used for Na₂CrO₄. The weight loss at 975°C is determined under the same experimental conditions as in the hot corrosion tests. Weight losses are monitored for periods of up to 100h and are linear in time. After the tests, the cooled coupons are water-washed, and the resulting solutions are analyzed for sodium and either SO₄⁻² or CrO₄⁻². The analyses agree well with the measured weight losses. In addition, the pH's of the wash solutions are measured and are found to agree well with pH values of prepared solutions of the respective salts. This agreement of pH values

indicates that no dissociative vaporization occurs. The bare coupons have no weight loss, showing that no reactions occur between them and the salts. The rates of evaporation are given in Table I, where it is seen that Na₂CrO₄ evaporates about 1.5 times more rapidly than Na₂SO₄.

Rate of reaction of Na₂SO₄ with the pure oxides Cr₂O₃ and TiO₂.—To measure the individual rates of reactions [1] and [2], pure Cr₂O₃ and TiO₂ layers are reacted using the same experimental conditions as for hot corrosion of IN-738. The Cr₂O₃ sample is made by preoxidizing a coupon of pure chromium at 975°C. The TiO₂ sample is made by plasma spraying high purity TiO₂ onto a platinum coupon and annealing in oxygen at 975°C for 2h. The amounts of TiO₂ and Cr₂O₃ are more than are required for complete reaction with Na₂SO₄.

Results for a Cr₂O₃ specimen, tested for 2.5h, are shown in Fig. 14. The specific weight increases initially, followed by a loss during the period when SO₂ and SO₃ are being evolved rapidly. Finally, a slow increase occurs because of further oxidation of the Cr coupon. The concentration of evolved SO₂ rises rapidly to 4.3 ppm cm⁻² and then falls at a fast, though decreasing rate. Based on the results of Fig. 5, the low value for the concentration of SO₂ at the end of the experiment indicates that the reaction between Cr₂O₃ and Na₂SO₄ is mostly completed. This conclusion is supported by the chemical analyses of the water-wash solutions (Table II), which show that 94% of the SO₄⁻² reacts during the experiment. The quantity of CrO₄⁻² formed equals the quantity of SO₄⁻² reacted, as expected (Table II, column 7). The ratio of SO₂ evolved to SO₄⁻² reacted is 0.40, similar to (but slightly larger than) that obtained in the hot corrosion experiments (Fig. 5).

To calculate a rate constant for reaction [1] from the data shown in Fig. 14, we have assumed that the reaction is first order with respect to the concentration of SO₄⁻². Therefore, the kinetics should be described by the equation

$$\log(C_0/C) = k_1 t / 2.303 \quad [3]$$

where k_1 is the first-order rate constant, C is the concentration of SO₄⁻² at time t , and C_0 is the initial concentration of SO₄⁻². The concentration of SO₄⁻² can be obtained from the cumulative SO₂ at any time using the relationship shown in Fig. 5. From the values of residual SO₄⁻² so obtained, a plot of $\log C$ vs. t is constructed (Fig. 15). The data follow a straightline relationship reasonably well for the first 2h, during which 95% of the sulfate is reacted. The first-order rate constant is $k_1 = 1.55\text{h}^{-1}$ (Table I).

The specific weight of the TiO₂ sample falls at a constant rate throughout the experiment after an initial 4h period (Fig. 16) and levels off at 24h, at which time virtually all of the Na₂SO₄ has reacted. The concentration of SO₂ evolved is approximately constant throughout the experiment, with an average value of 0.145 ppm cm⁻². The observed weight loss can be correlated with the expected evolution of SO₂ during the experiment, as indicated by reaction [2]. There should also be a weight gain of the TiO₂-Pt coupon resulting from the formation of Na₂O(TiO₂)_n. The results presented in the last line of Table II correlate well with the behavior predicted by reaction [2]. Analysis of the water-wash solution indicates that all of the SO₄⁻² applied has reacted (Table II, columns 3, 4, and 6). The ratio of SO₂ evolved to SO₄⁻² re-

Table I. Rates of pertinent processes

System	Evaporation rate (mmol cm ⁻² h ⁻¹)	First-order rate constant, k_1 (h ⁻¹)	Zero-order rate constant, k_0 (mmol cm ⁻² h ⁻¹)
Na ₂ SO ₄ (l) → Na ₂ SO ₄ (g)	1.0 × 10 ⁻⁴		
Na ₂ CrO ₄ (l) → Na ₂ CrO ₄ (g)	1.5 × 10 ⁻⁴		
Cr ₂ O ₃ + 2Na ₂ SO ₄ (l) + 3/2 O ₂ → 2Na ₂ CrO ₄ (l) + 2SO ₃ (g)		1.55	
n TiO ₂ + Na ₂ SO ₄ (l) → Na ₂ O(TiO ₂) _n + SO ₃ (g)			1.25 × 10 ⁻³
n TiO ₂ + Na ₂ CrO ₄ (l) → Na ₂ O(TiO ₂) _n + CrO ₃ (g)			5.9 × 10 ⁻⁴

Fig. 8. Secondary electron and x-ray micrographs of preoxidized IN-738 specimen corroded at 975°C with 3 mg cm⁻² Na₂SO₄ for 20h

acted is 0.335 (Table II, column 9). The total weight loss expected from SO₂ + SO₃ evolution during the experiment agrees with the experimental value given in column 11. The expected overall weight gain of the coupon after the experiment, resulting from Na₂O(TiO₂)_n formation

(column 12), agrees well with the experimental value given in column 13. After the experiment, the coupon is examined by x-ray diffraction. Unreacted TiO₂ and the compound Na₂Ti₃O₁₁, the most stable form of sodium titanate, are identified.

Fig. 9. Back-scattered electron and x-ray micrographs of preoxidized IN-738 specimen corroded at 975°C with 3 mg cm⁻² Na₂SO₄ for 30h

Fig. 10. Back-scattered electron and x-ray micrographs of preoxidized IN-738 specimen corroded at 975°C with 3 mg cm⁻² Na₂SO₄ for 40h

The kinetics of reaction [2] are characteristic of a zero-order reaction, for which

$$C_0 - C = k_0 t \quad [4]$$

where k_0 is the zero-order rate constant, C is the concentration of sulfate at time t , and C_0 is the initial concentra-

tion of sulfate. Because the weight loss of the sample is equivalent to the SO₄⁻² reacted, Fig. 16 is a plot of C vs. t , and the slope of the straight line gives $k_0 = 5.9 \times 10^{-4}$ mmol cm⁻² h⁻¹ (Table I).

The rate constants in Table I can be used to calculate the relative rates of Na₂SO₄ reactions with Cr₂O₃ and TiO₂

Fig. 11. Back-scattered electron and x-ray micrographs of preoxidized IN-738 specimen corroded at 975°C with 3 mg cm⁻² Na₂SO₄ for 48h

Fig. 12. Back-scattered electron and x-ray micrographs of preoxidized IN-738 specimen corroded at 975°C with $3 \text{ mg cm}^{-2} \text{ Na}_2\text{SO}_4$ for 56h

during hot corrosion. The rate of reaction [1] can be determined using the SO_4^{-2} curve in Fig. 3c. The zero-order rate constant for reaction [4] is multiplied by 7.5 cm^2 , a typical area for the IN-738 specimens.

Results of these calculations in Table III show that the Na_2SO_4 should react much more rapidly with Cr_2O_3 than with TiO_2 on IN-738. The Cr_2O_3 reaction rate is initially 30 times faster than the TiO_2 rate, and when the SO_4^{-2} is half

^a Calculated for a specimen area of 7.5 cm².

gone after 2.5h, the factor is still 15. The rates do not become comparable until virtually all of the SO₄⁻² has reacted. Thus, most of the Na₂SO₄ applied to the IN-738 specimens should react primarily with the Cr₂O₃ in the preoxidized scale.

Rate of reaction of Na₂CrO₄ with TiO₂.—Considerable Na₂CrO₄ is formed in the initial stage of hot corrosion, which can evaporate and/or react with other oxides present on the preoxidized IN-738 specimens. The rate of the reaction

is studied.

The oxide CrO₃ should volatilize rapidly at 975°C (17). However, because of boundary layer considerations, some fraction may back-reflect to the hot specimen (18), decomposing on contact and resulting in redeposition of Cr₂O₃. For these molecules, the net reaction is

The specimens used are made by plasma spraying TiO₂ onto Pt coupons and annealing in oxygen for 2h at 975°C. The Na₂CrO₄ at 3 mg/cm² is air-brushed onto the speci-

mens. Experimental methods similar to those used in the hot corrosion experiment are used.

Samples tested up to 14h exhibit a steady, constant decrease in specific weight, similar to that exhibited in Fig. 16 for the reaction of TiO₂ with Na₂SO₄. The rate of weight loss is calculated to be 4.1 × 10⁻² mg/cm² h⁻¹, corrected for Na₂CrO₄ evaporation. The constant rate of weight loss indicates that the reaction of TiO₂ with Na₂CrO₄ is of zero order.

The overall rate constant of reaction of Na₂CrO₄ with TiO₂ can be calculated from the results of the chromium analyses of the water-wash solutions. These data give a value for the rate constant k₀ of 9.55 × 10⁻² mg cm⁻² h⁻¹ or 5.9 × 10⁻⁴ mmol cm⁻² h⁻¹, both corrected for Na₂CrO₄ evaporation. This value is given in Table I for comparison with the rate constant from reaction [4]. Using the value of 9.55 × 10⁻² mg Na₂CrO₄ cm⁻² h⁻¹ for the reaction and using the experimental value for the rate of weight loss, 4.1 × 10⁻² mg cm⁻² h⁻¹, we deduce that 60% of the Na₂CrO₄ reacts by reaction [5] and that 40% reacts by reaction [6]. The overall weight gain of the coupon resulting from Na₂O(TiO₂)_n formation corroborates these percentages. As in the reaction with TiO₂ and Na₂SO₄, x-ray diffraction analysis shows the presence of Na₂Ti₅O₁₁ on the coupons after the experiment, and the water-wash solutions yield soluble sodium equivalent to the unreacted Na₂CrO₄.

Chemical Mechanisms

The results obtained in the present studies of Na_2SO_4 -induced hot corrosion of IN-738 can be explained in terms of the sequence of reactions presented in Table IV. The time periods listed in this table are defined in Fig. 3a.

The initial oxide fluxing reactions are generally discussed with reference to thermodynamic stability diagrams such as those for the Cr-O-S, Ti-O-S, Mo-O-S, and W-O-S systems shown superimposed on a diagram for the Na-O-S system at a temperature of 975°C (Fig. 17a, b, c, and d). The diagrams are constructed by using the FACT computer program (19), and they show the phases that are in equilibrium with gas mixtures having specified pressures of O_2 and SO_3 . The dashed vertical line in the diagrams is the boundary where $\log a_{\text{Na}_2\text{O}} = \log P_{\text{SO}_3}$ in Na_2SO_4 , and it is representative of "neutral" Na_2SO_4 at 975°C .

Examination of Fig. 17 shows that the oxides of all four elements should be converted to the appropriate sodium salts in neutral Na_2SO_4 under 1 atm of oxygen and that the most stable sodium salts under high SO_3 pressure (or low oxide ion activities) are Na_2MoO_4 and Na_2WO_4 .

Although these diagrams have been used extensively to interpret hot corrosion behavior in terms of the chemical reactions involved, their usefulness is limited because

they give no kinetic information. The interpretation of our results will be based largely on the results of the kinetic studies described in a previous section.

Induction period, region of weight loss (0-10h).—Immediately upon bringing the test specimens to temperature, the Na_2SO_4 melts and reacts with the Cr_2O_3 to form Na_2CrO_4 and SO_3 ([a], Table IV). The early occurrence of this reaction is substantiated by the evolution of SO_2 (Fig. 3b), the appearance of water-soluble chromium (Fig. 3c), and the rapid drop in residual SO_4^{2-} (Fig. 3c). This behavior is predicted by the stability diagram for chromium (Fig. 17a), and kinetic studies of [a], Table IV, indicate that Cr_2O_3 and Na_2SO_4 should react rapidly until all Na_2SO_4 is consumed. The 0.11 mmol of Na_2SO_4 that reacted with the Cr_2O_3 in the first 10h of hot corrosion is equivalent to removal of all of the Cr_2O_3 from the bottom 2/5 of the specimen; this agrees with observations of "slumping" of the liquid reactants.

After an incubation period of about 5h, the TiO_2 on the specimen begins to react with the Na_2SO_4 and forms water-insoluble $\text{Na}_2\text{O}(\text{TiO}_2)_n$, ([b], Table IV), as evidenced by the drop in soluble sodium beginning at this time (Fig. 3c). This behavior is also predicted by the stability diagram for titanium (Fig. 17b). Our kinetic studies also demonstrate that [b], Table IV, should occur, though at a much slower rate than the Na_2SO_4 - Cr_2O_3 reaction.

Comparison of the SO_2 concentrations in Fig. 3b for IN-738 and in Fig. 14 for Cr_2O_3 indicates that the reaction with the alloy continues for 20-25h; the reaction with Cr_2O_3 is effectively completed in 2.5h. The lowered activity of the Cr_2O_3 in the oxide mixture relative to that of pure Cr_2O_3 may account for the difference. This difference precludes quantitative interpretation of the IN-738 kinetic data, and it appears that kinetic data for reactions of Na_2SO_4 with known mixtures of Cr_2O_3 and TiO_2 are required.

In the first 10h of corrosion of IN-738, Na_2SO_4 is mostly consumed by reaction with the protective oxide scale on the alloy. The Cr_2O_3 - TiO_2 scale is removed from the bottom half of the specimen by this basic fluxing (Fig. 6). The weight loss observed during this period results from evolution of SO_3 + SO_2 from the sample as a result of the reactions.

Induction period, region of slow linear oxidation (10-55h).—A result of the reaction between Cr_2O_3 and Na_2SO_4 during the first 10h of corrosion is the formation of Na_2CrO_4 (Fig. 3c). The Na_2CrO_4 is liquid at 975°C , and it covers the surface of the specimen. Examination of Fig.

Table IV. Corrosion mechanism

Deceleration period (75h to end)

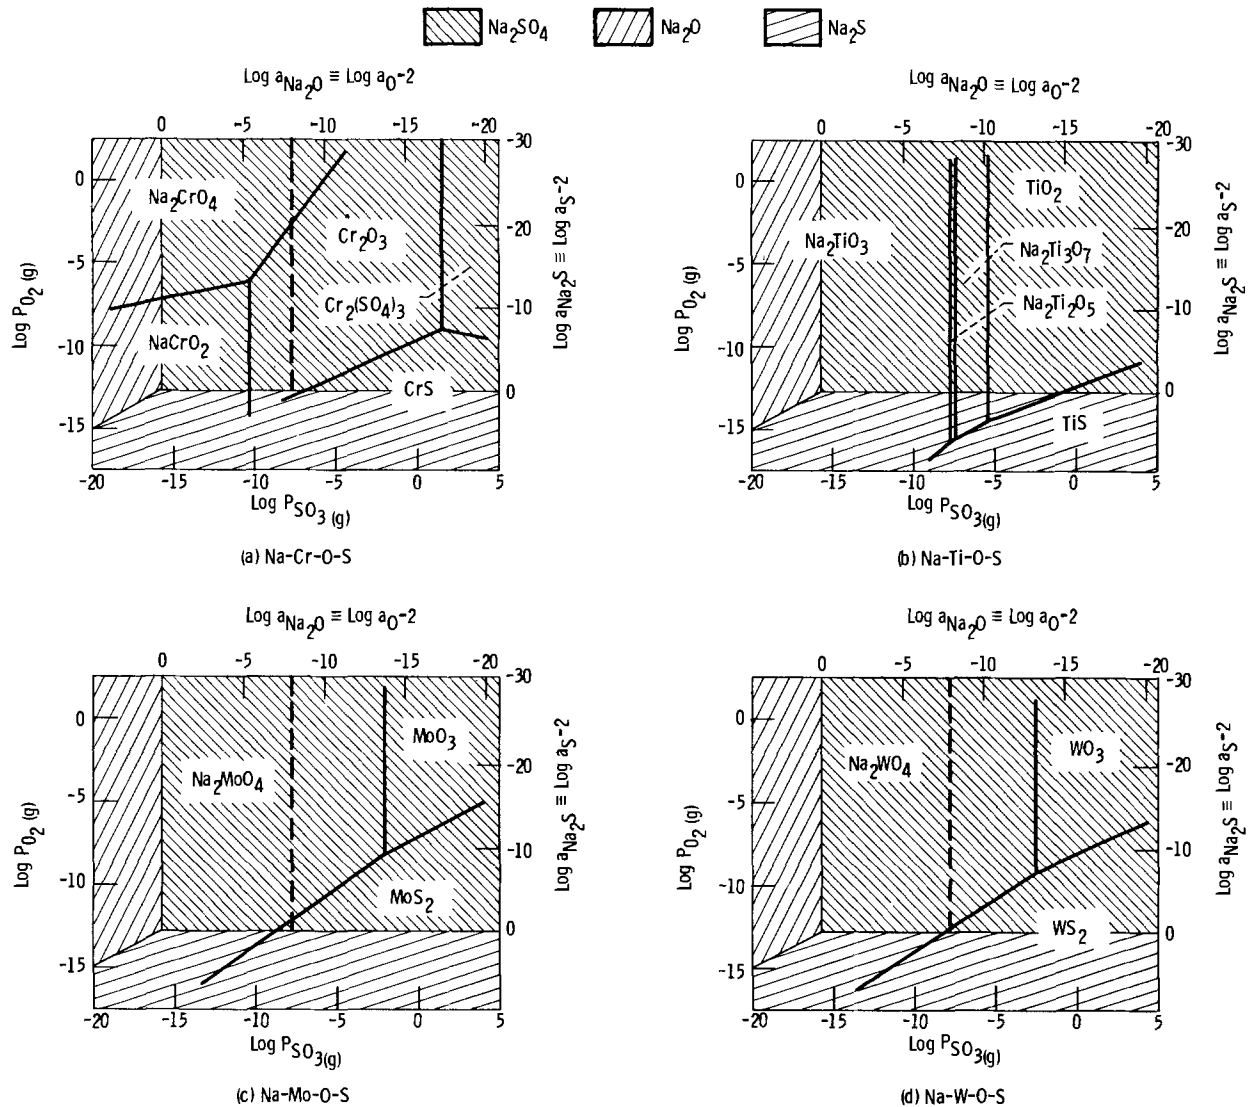

Fig. 17. Thermodynamic phase stability diagrams at 975°C. The Cr-, Ti-, Mo-, and W-O-S diagrams are superimposed on the Na-O-S diagram. The dashed line is drawn where $\log a_{\text{Na}_2\text{O}} = \log P_{\text{SO}_3(\text{g})}$.

3c shows that soluble chromium and soluble sodium disappear rather rapidly between 15 and 30h. We can calculate a linear disappearance rate for these species of 7.7×10^{-4} mmol $\text{cm}^{-2} \text{h}^{-1}$.

The soluble sodium and chromium can be lost by evaporation of Na_2CrO_4 and/or reaction with TiO_2 ([d], Table IV). The sum of the rates of these two processes (Table I) is 7.4×10^{-4} mmol $\text{cm}^{-2} \text{h}^{-1}$, which agrees with the rates of disappearance of soluble sodium and chromium. We may conclude that the loss of Na_2CrO_4 depicted in Fig. 3c can mostly be accounted for, 20% by vaporization and 80% by reaction with TiO_2 .

The rapid reaction between Cr_2O_3 and Na_2SO_4 during the first 10h of corrosion results in the removal of most of the protective oxide scale. The alloy then begins a slow reoxidation that lasts until the end of the induction period ([e1]-[e5], Table IV). This is verified by the nearly linear weight gain displayed in Fig. 3a for this time period and by the growth of the oxide layer observed in Fig. 8-12. The reformed oxide is not protective in the usual sense, though the rate of oxidation is relatively slow; this is indicated by the fact that the weight increase is linear rather than parabolic. The inability of the alloy to produce a protective oxide scale probably results from the large depletion of chromium resulting from preoxidation, reoxidation, and sulfide formation near the bottom of the depletion zone (20).

The most important development during the reoxidation period is the gradual growth of areas of MoO_3 - WO_3 along the lower edge of the oxide layer. Soluble Mo and

W arise from reaction between MoO_3 - WO_3 and Na_2CrO_4 ([f], Table IV). As the Na_2CrO_4 is converted to $\text{Na}_2\text{O}(\text{TiO}_2)_n$ by [d], Table IV, soluble Mo and W arise from reaction of the oxides with $\text{Na}_2\text{O}(\text{TiO}_2)_n$ ([g1], Table IV). Some of the recovery of soluble sodium after 40h is probably due to this reaction. The micrographs of Fig. 10 and 11 show how the MoO_3 - WO_3 areas develop. After the reformed oxide layer reaches a thickness of about 30 μm , the underlying isolated Ni-Co islands are leached of all active elements, except molybdenum and tungsten. Further oxidation of the specimen oxidizes these islands. The molybdenum and tungsten dissolved in the islands also oxidize and are found on the interface between the oxidized islands and the alloy. The presence of sodium, often found in the MO_3 - WO_3 areas, effects a lowering of the melting point of MoO_3 - WO_3 by formation of Na_2MoO_4 - Na_2WO_4 and also reduces the effective vapor pressure (1). Toward the latter part of this period, the soluble tungsten starts to decrease, probably by [i], Table IV, as a result of the slightly greater thermodynamic stability of Na_2MoO_4 , as compared with Na_2WO_4 (Fig. 17c and d).

The period from 10h to the end of the induction period, 55h, is a time in which the alloy slowly reoxidizes to form an oxide scale about 60 μm thick. This oxide is nonprotective, and numerous discrete areas of MoO_3 - WO_3 / Na_2MoO_4 - Na_2WO_4 are formed along the lower edge.

Acceleration period (55-60h).—The corrosion process begins to accelerate at about 55h (Fig. 3a), and the amount of soluble molybdenum increases markedly (Fig. 3c). This

results from an increase in the rate of formation of Na_2MoO_4 by [g2] and [i], Table IV, probably because of the considerable quantity of MoO_3 that accumulates along the oxide scale. This amount of Na_2MoO_4 effects melting of some discrete $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4\text{-Na}_2\text{WO}_4$ areas into a large molten phase (21). In Fig. 12, the molten oxide phase can be seen migrating across the sample, disrupting and fluxing the scale above it. The oxide above the $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4\text{-Na}_2\text{WO}_4$ is striated and layered, typical of acidic fluxing. Most of the oxide layer is still similar to that shown in Fig. 11, with discrete areas of $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4\text{-Na}_2\text{WO}_4$.

Period of rapid linear oxidation (60-75h).—Beyond 60h, the quantity of Na_2MoO_4 increases rapidly (Fig. 3c) as more of the discrete oxide areas merge into large molten masses below the oxide scale. Finally, in the 77h sample, the large molten phase of $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4$ has become the major feature of the scale. This development promotes acidic fluxing of the oxide scale by [j1] and [j2], Table IV. Bornstein *et al.* (22) have shown that Al_2O_3 exhibits an extremely rapid rate of dissolution in molten MoO_3 at 900°C. A major breakup of large areas of the oxide scale occurs and exposes the alloy surface. Rapid oxidation of the alloy ensues and produces a large porous oxide scale, as shown in Fig. 4. The rate of oxidation is nearly $3 \text{ mg cm}^{-2} \text{ h}^{-1}$, about 20 times larger than the rate observed in the induction period. The molten oxide phase appears to attack the alloy itself, possibly by [k] and [m], Table IV, which have been calculated to be thermodynamically favored. Reactions such as these have first been suggested by Leslie and Fontana (23) and have been discussed more recently by Peters, Whittle, and Stringer (24).

The acidic fluxing is self-sustaining, and it accounts for the linear nature of the attack. The self-sustaining feature may have resulted from the cyclic operation of [j1] and [j2], Table IV, and their reverse reactions. After solution of the oxides in the molten $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4$ phase, the metal cations diffuse to the outer zone of the melt, where they reoxidize by the higher oxygen potential. The cycle repeats as the alloy is consumed. The cyclic behavior of acidic fluxing can be explained more quantitatively by the Rapp-Goto model (25), in which attack is explained in terms of a negative solubility gradient of the corrosion product across the molten phase. The striated appearance of the oxide (Fig. 12) is a result of the cyclic nature of the attack. Table IV, [k] and [m], are also capable of exhibiting cyclic behavior through reoxidation of MoO_2 at the outer zone of the melt ([n], Table IV).

The small amount of SO_2 observed during this period must have resulted from oxidation of the sulfur in the molten oxide phase. This conclusion is supported by the observation that the sulfur content of the test specimens drops from the 50h sample to the 75h sample.

Deceleration period (75h to end).—At ~75h, a deceleration of the corrosion rate is observed (Fig. 3a); it results from conversion of the molten $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4$ to solid $\text{NiMoO}_4\text{-NiWO}_4$ by [p] and [q], Table IV, and is accompanied by a rapid decrease in both the soluble molybdenum and sodium (Fig. 3c). The formation of these stable nickel compounds eliminates the molten oxide phase that causes acid fluxing. Figure 3c shows that the Na_2MoO_4 is reduced at 90h to a value below the one at which the catastrophic attack begins at 55h. An area where the transformation to $\text{NiMoO}_4\text{-NiWO}_4$ occurs is shown in Fig. 13. Here, $\text{NiMoO}_4\text{-NiWO}_4$ is found along the oxide alloy interface, and no evidence of a molten phase is present.

Other aspects.—The formation of sulfides has not been included in Table IV, though sulfides certainly form early in the corrosion process (Fig. 3c and 8). Although this sulfide formation leads to degradation of the alloy, it is considered to be of secondary importance in the overall mechanism. It does contribute to the depletion of chromium and to the resulting inability of the alloy to form a

protective oxide scale during the induction period. Finally, the formation of NaTaO_3 and NaNbO_3 ([r], Table IV) has not been discussed. This is an important reaction in some alloys, as discussed previously (26), because NaTaO_3 seems to act as a sink for Na_2O and, thus, it inhibits the formation of Na_2MoO_4 . However, it has not been effective in IN-738 because of the low concentration of tantalum and niobium.

Concluding Remarks

We have shown that the induced hot corrosion of IN-738 is initiated by basic fluxing of the protective $\text{Cr}_2\text{O}_3\text{-TiO}_2$ scale and that the fluxing reaction continues as long as Na_2SO_4 is available. Reoxidation of the alloy is not able to produce a protective scale because chromium is depleted from the exterior surfaces. A slow linear oxidation ensues, during which $\text{MoO}_3\text{-WO}_3$ builds up along the oxide-alloy interface. Gradually, MoO_3 reacts with Na_2CrO_4 and $\text{Na}_2\text{O}(\text{TiO}_2)_n$ to form Na_2MoO_4 , which lowers the melting point of the $\text{MoO}_3\text{-WO}_3$ areas. Large areas of the molten phase $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4$ are formed, and these areas effect acidic fluxing of the oxide scale and result in catastrophic attack of the alloy. The attack eventually slows down as Na_2MoO_4 and $\text{MoO}_3\text{-WO}_3$ are converted to their corresponding nickel salts, but the alloy specimen is largely destroyed by this time.

The Na_2SO_4 has two main effects in this mechanism of hot corrosion: it removes the protective $\text{Cr}_2\text{O}_3\text{-TiO}_2$ scale; and it supplies sodium that eventually forms Na_2MoO_4 , which initiates melting of the $\text{MoO}_3\text{-WO}_3$ areas. Therefore, any method of removing the scale should cause hot corrosion if sodium is available. In contrast, if sodium is extracted after scale removal, no hot corrosion should occur. With reference to the first effect, Bourhis and St. John (6) find that, in Na_2SO_4 -induced hot corrosion tests at 900°C, alloys forming a protective Cr_2O_3 layer are not susceptible to accelerated attack. However, if the oxide scale is removed by abrasion, heavy corrosion occurs. We have performed tests in which the preoxidation scale is removed by water quenching and the specimen is coated with 2 mg cm^{-2} of Na_2CrO_4 to supply a source of sodium. The specimen is oxidized at 975°C, and catastrophic hot corrosion occurs in 60h, a time not much different from our normal induction period. With reference to the second effect, a normal hot corrosion test is stopped after 10h, by which time the protective oxide scale has been largely fluxed. The specimen is cooled and water-washed. This removes the Na_2CrO_4 that has formed and any Na_2SO_4 that has not reacted. The oxidation is then reinitiated and continued for times of up to 200h. Although a long period of reoxidation ensues, no catastrophic hot corrosion occurs.

The corrosion mechanism postulated here includes several new ideas and new processes. We have demonstrated that the Na_2SO_4 fluxes the $\text{Cr}_2\text{O}_3\text{-TiO}_2$ scale until all of the Na_2SO_4 is consumed. Generally, it has been believed that reaction [1] results in the Na_2SO_4 becoming so "acidic" that the Cr_2O_3 becomes stable in the Na_2SO_4 and the reaction ceases (27). We have shown that Na_2CrO_4 reacts with TiO_2 to form $\text{Na}_2\text{Ti}_2\text{O}_{11}$, and that both of these compounds react with $\text{MoO}_3\text{-WO}_3$ to form the low-melting-point compounds Na_2MoO_4 and Na_2WO_4 . We have also shown that acidic fluxing is caused by a molten $\text{MoO}_3\text{-WO}_3$ oxide phase containing Na_2MoO_4 , instead of a molten Na_2SO_4 phase "acidified" by dissolved $\text{MoO}_3\text{-WO}_3$ (28). In addition, we have suggested that the molten $\text{MoO}_3\text{-WO}_3/\text{Na}_2\text{MoO}_4$ phase can attack the components of the alloy itself by a form of basic fluxing involving MoO_3 and MoO_2 .

Two methods of preventing hot corrosion of the alloys which principally form Cr_2O_3 protective scales are suggested by this research: increasing the chromium content of the alloy; and replacing the molybdenum and, possibly, the tungsten with tantalum or niobium. This latter suggestion has been made previously (1, 26). It appears that in IN-738, in which there is a small initial amount of

molybdenum, catastrophic corrosion can be eliminated by this replacement.

Application of the corrosion mechanism postulated here to the problem of hot corrosion of IN-738 in gas turbine engines is complicated by the widely different environmental conditions encountered in service. Although the mechanism is based on laboratory results, we feel the same processes are involved in practice, but the relative importance of the various processes may be quite different. The rate of evaporation of Na_2CrO_4 will be considerably higher in the high-velocity flow environment of a gas turbine. As compared with our tests, this should decrease the formation of Na_2MoO_4 and lengthen the induction period for catastrophic corrosion. However, repeated engine cycling and attendant spallation would accelerate chromium depletion and probably shorten the induction period. Possibly, the overriding factor is that in an operating gas turbine, the Na_2SO_4 is deposited more or less continuously. If the salt level is high, as in a marine environment, the Na_2SO_4 will probably effect catastrophic hot corrosion. But if the salt level is low, as in a power generating turbine, the high rate of vaporization of Na_2CrO_4 and MoO_3 may prevent catastrophic hot corrosion entirely. A quantitative evaluation of these many complex processes is not possible at this time.

It is necessary to stress the importance of using kinetic data when interpreting hot corrosion processes. Until now, interpretation has been based on thermochemical Pourbaix diagrams. Such diagrams have been invaluable, but their usefulness is limited because they give no kinetic information. In addition, the environment in a gas turbine is hardly an equilibrium system. Even if the SO_3 pressure is maintained at some constant value, SO_3 is only one of the products being evolved in the reaction between Na_2SO_4 and Cr_2O_3 . The Na_2CrO_4 also evaporates, as we have shown, at the rate of $1.5 \times 10^{-4} \text{ mmol cm}^{-2} \text{ h}^{-1}$. In the high-velocity environment of a gas turbine, this rate would be increased markedly.

Unfortunately, little kinetic data are available for reactions of the type involved in hot corrosion. We have studied three such reactions ([a], [b], and [d], Table IV), but our investigation has been limited. The need for more extensive information of this type is imperative in the proper interpretation of hot corrosion phenomena.

Acknowledgments

The authors would like to thank Frank M. Terepka for obtaining the electron microprobe data. Warren F. Davis and Constance S. Buchar are thanked for performing the chemical analyses. We would also like to thank Dr. Reza Haque and Dr. Ajay K. Misra for running some of the later hot corrosion tests.

Gaseous Sulfidation of Pure Molybdenum at 700°-950°C

Bom Soon Lee¹ and Robert A. Rapp*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The kinetics and mechanism of sulfide scale growth on pure molybdenum have been investigated in an elemental sulfur (S_2) atmosphere and in an H_2S/H_2 gas mixture over the temperature range of 700°-950°C. Below about 800°C, linear kinetics were observed, and at higher temperatures the kinetics were parabolic. The surface orientation of the metal affected the sulfidation mode and rate, and the MoS_2 scale showed a strong epitaxial relationship with the metal at all temperatures. For the low temperature linear kinetics, a sulfide crystal nucleation step is believed to be rate limiting. In the high temperature parabolic regime, the diffusion of sulfur ions through the scale is the rate-limiting step. After the scale reaches some critical thickness, Mo_2S_3 crystals form beneath the MoS_2 scale, which slows the reaction somewhat. The parabolic rate constants for sulfidation in H_2S/H_2 gas mixtures at high temperatures were about one order of magnitude higher than those in elemental sulfur at the same sulfur activity.

The practical importance of the sulfidation of metals and alloys has become apparent because of the increasing utilization of metals at high temperatures in industrial atmospheres containing sulfur and its compounds. The increased use and conversion of low-grade fossil fuels and the introduction of sodium-sulfur batteries, etc., have made high temperature sulfidation problems even more frequent.

Many investigators have studied the sulfidation resistance of the metals iron, nickel, cobalt, and copper, as well as their alloys with chromium. In each case, the high concentrations and mobilities of point defects in the sulfide scales yield relatively high scaling rates. However, some previous studies of molybdenum sulfidation which reported slow scaling rates (1-3) in either S_2 or H_2S have been limited to narrow ranges of temperatures and sulfur activity or H_2S/H_2 gas ratios, and a comprehensive mechanistic study is not available.

Dutrizac (1) investigated the thermogravimetric kinetics of the sulfidation of Mo in pure sulfur vapor for sulfur pressures ranging from 0.03 to 300 torr. Dutrizac obtained linear kinetic curves for the temperature range 415°-550°C for $P_{S_2} > 20$ torr. At lower P_{S_2} , parabolic kinetics were obtained for approximately half the experiments. Dutrizac concluded that the linear sulfidation kinetics of Mo are controlled by some reaction step occurring at either the MoS_2 /gas or the Mo/MoS_2 interface. The kinetic rate was insensitive to changes in sulfur pressures in excess of 20 torr, but the sulfidation rate decreased at lower sulfur pressures. The mechanism of scale growth was not detailed, and hexagonal MoS_2 was reported as the only reaction product formed under all conditions.

Gerlach and Hamel (2) obtained parabolic sulfidation curves for reactions in H_2S/H_2 gas mixtures at 900°-1050°C. Curve markers were used, and it was concluded that the inward diffusion rate of the sulfur ion is higher than the outward diffusion rate of the Mo ion in MoS_2 , which was the only corrosion product reported. To calculate the activation energy for sulfidation, they used a constant H_2S/H_2 ratio for each temperature rather than a constant sulfur activity (P_{S_2}). Slope changes were observed in parabolic plots of weight change vs. time, but the authors did not elaborate.

Fueki *et al.* (3) studied the sulfidation of Mo in H_2/H_2S gas mixtures at 800°-950°C. They obtained parabolic kinetic curves, but the rate constants differed from those of Gerlach and Hamel (2). Again, a constant H_2S/H_2 gas ratio (1:1) was used for each temperature to calculate the activation energy for sulfidation.

The objectives of this research were to determine kinetic information for the sulfidation of pure Mo over a wide range of sulfur activities and temperatures and to clarify the mechanisms of sulfidation. The experiments were conducted in elemental sulfur vapor and in H_2S/H_2

gas mixtures. Kinetic results from these two environments were compared for the same sulfur activity (P_{S_2}).

Thermodynamics of Mo-S system.—Several sets of thermodynamic data are available for the Mo-S system. The data of Larson and Elliott (4) for ΔG_f° (MoS_2) in combination with those of Hager and Elliott (5) for ΔG_f° (Mo_2S_3) would indicate that Mo_2S_3 is not stable at temperatures below 1400°C. However, Young *et al.* (6) reported the formation of Mo_2S_3 on a Ni-Mo alloy at 700°C. The data of Stubbles and Richardson (7) show the existence of Mo_2S_3 in the phase stability diagram of Fig. 1. Suzuki *et al.* (8) also confirmed a narrow band of Mo_2S_3 stability.

Experimental Apparatus, Materials, and Procedure

A quartz-spring² TGA balance system shown in Fig. 2 was used for kinetic measurements of molybdenum sulfidation. The total length of the reaction tube was about 150 cm; the lower part of the tube was connected to an isothermal reservoir of pure liquid sulfur, which was heated to generate the desired sulfur vapor pressure. The silicone-greased standard taper joint connection was heated about 30°C higher than the sulfur reservoir to avoid sulfur condensation. A cathetometer outside the reaction chamber was used to monitor the weight gain of the specimen by measuring the elongation of the quartz

spring. A Pyrex rod was used to lower or raise the specimen.

For initial experiments in H_2S/H_2 gas mixtures, convection caused severe fluctuations in the spring because of the large temperature gradient between the spring column ($200^\circ C$) and the main furnace ($800^\circ-950^\circ C$). This noise problem was reduced significantly by inserting several quartz cylinders inside the reaction chamber (not shown in Fig. 2) to induce downward flow of gas around the specimen and to increase the resistance to the gas flow.

Sublimed sulfur (Mallinckrodt) was used to generate sulfur vapor. Prepurified H_2 gas (NCG Industrial Gas) and H_2S gas (Matheson) were used. Thin (0.25 mm) cold-rolled sheet of 99.97% Mo with $3\text{ }\mu\text{m}$ average grain size from Alfa Chemical Company was cut into $2 \times 3\text{ cm}$ specimens for elemental sulfur experiments and $1 \times 5\text{ cm}$ for H_2S/H_2 gas experiments. Molybdenum sheet with equiaxed grains, $5\text{ }\mu\text{m}$ average grain size, was received from Climax Molybdenum Company. The purity of this annealed molybdenum sheet was about 99.97%, with impurities of about 70 ppm C, 80 ppm O, 48 ppm Si, and 23 ppm Al.

For some experiments, the shiny as-received (as-rolled) surface was degreased with a detergent and warm water; for other experiments, specimens were ground to 600 grit paper, polished with $3\text{ }\mu\text{m}$ alumina, and washed with detergent and warm water. To investigate the effects of surface finish and grain size on the reaction kinetics, four different surfaces were studied: as-rolled coupons (Alfa Products) and annealed specimens (Climax) were used in the as-received condition or with a ground and polished surface.

During kinetic runs, the thermally insulated tube surrounding the spring was heated to a constant temperature above the dew point for the sulfur vapor. The spring constant was calibrated to be $39.9\text{ }\mu\text{g}/0.01\text{ mm}$ for a tube temperature of $25^\circ C$, and $42\text{ }\mu\text{g}/0.01\text{ mm}$ for a tube temperature of $200^\circ C$. To avoid oxide formation on the specimen during its residence in the tube prior to the experiment, the system was evacuated to about 10^{-5} torr while the sulfur reservoir was brought to temperature. Then the specimen was lowered into the hot zone. A quartz specimen submitted to the same procedure did not indicate any weight gain in 2h.

In the elemental sulfur experiments, gaseous sulfur consisted mainly of S_2 species at the experimental tem-

peratures ($700^\circ-950^\circ C$). These experiments were conducted in the viscous pressure regime so that the pressure inside the chamber was uniform throughout. The total vapor pressure above the liquid sulfur was calculated using the equation obtained by Meisen and Bennet (9). For the experiments in H_2S/H_2 gas mixtures, the gas ratio was adjusted to provide an equivalent P_{S_2} of 1 torr at each temperature.

Results and Discussion

Elemental sulfur experiments at $700^\circ-800^\circ C$.—Figure 3 is a plot of the sulfidation kinetics for the annealed Climax Mo specimen at $750^\circ C$, $P_{S_2} = 0.03$ torr, which shows representative kinetic behavior for the lower temperatures. The most important characteristic of the kinetics is that the sulfidation rate of Mo is low, $< 0.3\text{ mg}/\text{cm}^2$ over many hours reaction time. The curve is initially linear, but after about $0.15\text{ mg}/\text{cm}^2$ weight gain (scale thickness: $\sim 0.6\text{ }\mu\text{m}$), much slower approximately parabolic period II kinetics are initiated. Period III is comprised of repeated parabolic weight gains and interruptions. During period III, a vibration of the spring was detected occasionally, which may indicate sudden release of stress by scale fracture. This kinetic behavior was common for studies in the temperature range $700^\circ-800^\circ C$, as shown also in Fig. 4 and 5.

Figure 6 is an Arrhenius plot of the initial linear sulfidation rate constants for four different specimens. The as-rolled Alfa specimen exhibited apparent parabolic behavior at $800^\circ C$, and the linear rate constant was calculated from the first five data points; the resulting point on Fig. 6 falls between the two lines. The activation energy for linear sulfidation calculated from this plot is $103 \pm 21\text{ kJ}/\text{mol}$, which is identical with the $103 \pm 13\text{ kJ}/\text{mol}$ obtained by Dutrizac (1), who established linear scaling rates for S_2 reactions at $415^\circ-550^\circ C$. As seen in Fig. 6, the as-received Alfa specimens have the highest linear kinetic rates, and the other specimens react more slowly.

X-ray diffraction patterns were made from unreacted Mo surfaces to identify any differences which might re-

late grain orientation to the observed kinetics. For the as-rolled Alfa specimen, the $\{110\}$ peak which is expected to exhibit the highest intensity was very weak, and the $\{200\}$ and $\{211\}$ peaks were very strong. Thus, the surface of this specimen exhibited a strong rolled texture with $\{100\}$ and $\{211\}$ planes predominantly normal to the surface. The as-received surface of the Climax specimens showed a strong $\{110\}$ peak, and indicated a lesser degree of preferred orientation. A ground and polished Alfa specimen showed the strongest peak from $\{110\}$ planes, so that this surface preparation removed the outermost oriented grains. This information and the kinetic results in Fig. 6 show that the orientation of the Mo surface grains affects the sulfidation rate. This will be discussed in detail later.

As shown in Fig. 6, polished Alfa and Climax specimens of different grain sizes exhibited the same sulfidation rate. Figure 7 shows a cross section of a specimen sulfidized at 800°C. The thickness of the fine-grained columnar scale is uniform, and the grain boundaries of the metal do not show any preferential attack, which is consistent with the independence of rate on grain size.

Scale morphology.—According to the x-ray diffraction patterns, MoS_2 was the only product phase formed at lower temperatures. The scale morphology changed as the reaction temperature was increased, but the scale al-

ways exhibited a uniform thickness with small columnar aggregate grains, as shown in Fig. 8, where the scale was fractured intentionally to show its cross section. The MoS_2 scale was always tightly adherent, and no spalling occurred.

Scratches on the initial metal surface remained evident at the surface of the scale after sulfidation. This feature represents evidence that sulfur is the mobile species in the scale (inward diffusion), so that new scale forms at the metal/scale interface. Further evidence for inward diffusion of sulfur is shown in Fig. 9, where the eccentric corner morphology shown is characteristic of inward diffusion for the oxidant and scale formation at the metal/scale interface. For example, this morphology is commonly observed in the high temperature oxidation of the refractory metals niobium and tantalum.

A marker experiment was also conducted by evaporating gold onto the surface of a molybdenum specimen before reaction. After the sulfidation, the particulate gold markers remained at the scale/gas interface, providing further evidence for the inward diffusion of sulfur.

Orientation of sulfide crystals.—An x-ray diffractometer pattern was made from a specimen after sulfidation at 800°C in $P_{S_2} = 0.03$ torr for 66h. The MoS_2 pattern should exhibit the highest peak for $\{001\}$ at $14.75^\circ (2\theta)$, but this peak was absent. Instead, the $\{101\}$ and $\{100\}$ MoS_2 planes from the pyramidal and prism planes, respectively,

Fig. 8. MoS_2 scale on as-rolled Mo specimen sulfidized at $T = 800^\circ C$ and $P_{S_2} = 0.03$ torr.

Fig. 9. Edge of the sulfidized Alfa Mo specimen, $T = 800^\circ\text{C}$ and $P_{\text{S}_2} = 0.03$ torr 14h.

showed strong peaks. The absence of the $\{001\}$ peak in the diffraction pattern is caused by the preferred orientation of MoS_2 crystals; in this case, the basal $\{001\}_{\text{MoS}_2}$ planes are preferentially oriented normal to the Mo grains with $\{100\}$ preferred texture as drawn schematically in Fig. 10. This epitaxial relation is described by $\{100\}_{\text{MoS}_2} \parallel \{100\}_{\text{Mo}}$ and $\langle 001 \rangle_{\text{MoS}_2} \perp \langle 100 \rangle_{\text{Mo}}$. This arrangement is favored, because the lattice parameter "a" of MoS_2 is an excellent match with that for Mo, and the lattice parameter "c" of MoS_2 is almost exactly four times that of "a" for Mo. Clearly, there are two equivalent, but incompatible, epitaxial MoS_2 orientations on Mo.

Another x-ray diffraction pattern was made from the back side of the scale (metal/scale interface) by removing the scale using adhesive tape, and again the peak from the basal planes for MoS_2 , $\{001\}_{\text{MoS}_2}$, was absent. A sample of the scale was scraped from a reacted specimen and powdered; in this case, the expected $\{001\}_{\text{MoS}_2}$ peak appeared.

The size of the individual sulfide crystallites of the low temperature MoS_2 scale ranged from 0.1 to 0.2 μm as shown in Fig. 11a. Thus, the columnar scale observed in surface and cross-sectional views does not represent individual grains, but rather the columns are comprised of thousands of small crystallites, as shown in the schematic diagram of Fig. 11b.

Dependence of scaling kinetics on P_{S_2} .—For 750°C , the plot of $\log k_1$ vs. $\log P_{\text{S}_2}$ showed a slope of 0.06, so that the sulfidation rate is essentially independent of the sulfur activity within the range of P_{S_2} studied (0.03 ~ 0.06 torr). At 750°C , for $P_{\text{S}_2} = 1$ torr, the kinetics were not linear, but approximately parabolic. As will be explained later, the kinetics at 750°C , in $P_{\text{S}_2} = 1$ torr fit the high temperature mechanism.

Proposed mechanism.—From the kinetic studies and the epitaxial microcrystalline nature of the MoS_2 sulfide scale, a mechanism for low temperature molybdenum sul-

Fig. 10. Schematic diagram of the MoS_2 growing epitaxially on the $\{100\}$ surface of Mo.

Fig. 11. a (top): MoS_2 scale formed on as-rolled Alfa Mo specimen reacted at $T = 800^\circ\text{C}$ and $P_{\text{S}_2} = 0.03$ torr for 14h. b (bottom): Schematic diagram of the columnar MoS_2 scale.

fidation can be suggested. As demonstrated by the Au markers and the retention of surface markings, sulfur is transported through the MoS_2 scale to form new crystals at the Mo/ MoS_2 interface.

When one $\{100\}$ grain of Mo reacts with sulfur at the Mo/ MoS_2 interface, MoS_2 grains of two equivalent, but incompatible, epitaxial orientations can be formed, as shown in Fig. 10. Because of the impossibility of intergrowth between adjoining MoS_2 crystals of equivalent but incompatible epitaxial orientations on the same Mo grain, MoS_2 grain growth is very restricted as basal planes of some grains impinge on prism planes of others. This grain impingement results in a very fine MoS_2 grain size and the requirement for continuous nucleation at the metal/scale interface. The MoS_2 nucleation rate, \dot{N} , can be calculated in terms of the linear gravimetric rate constants k_1 , plotted in Fig. 6. Let us assume that the scale is comprised of cubic MoS_2 grains with a side length equal to δ . Then the nucleation rate is given by

$$\dot{N} = k_1 \bar{V}_{\text{MoS}_2} / 64 \delta^3 \quad [1]$$

where \bar{V}_{MoS_2} is the molar volume of MoS_2 . For a k_1 value of 3×10^{-8} ($\text{g}/\text{cm}^2\text{s}$), δ equal to 10^{-5} cm, and $\bar{V}_{\text{MoS}_2} = 33.3$ cm^3/mol ; \dot{N} equals 1.6×10^7 $\#/\text{cm}^2\text{s}$.

With emphasis on the importance of sulfide nucleation at the metal/scale interface, the rate-limiting step(s) for each of the three periods in Fig. 3 will be discussed.

Period I, initial linear kinetics.—The Pilling-Bedworth ratio ($\bar{V}_{\text{MoS}_2}/\bar{V}_{\text{Mo}}$) in Mo sulfidation is about 3.5. Thus, for a MoS_2 crystal to form, or for an existing crystal to grow at the metal/scale interface, the previously formed sulfide crystallites must be pushed out or extruded toward the surface, a deformation which should introduce micro-

cracks in the scale. These microcracks are presumably generated almost continuously, so that even the innermost scale can be considered faulted. The mismatch between two adjoining crystallites of equivalent epitaxy but differing orientation maintains a microcrystalline grain size.

To form new crystallites at the Mo/MoS₂ interface, or to grow existing sulfide crystals, the steps illustrated in Fig. 12 should be involved. It is assumed that the MoS₂ scale contains microcracks everywhere. Because the arrival flux of S₂ molecules in the gas phase is adequate to support the observed kinetics, one of the steps 1 to 5 in Fig. 12 should be the rate-limiting step: (1) the transport of sulfur molecules along the microcracks of the scale, (2) the dissociation of diatomic sulfur molecules to form adsorbed atomic sulfur, (3) the reduction of internally adsorbed atomic sulfur, (4) the diffusion of S²⁻ through one or several MoS₂ crystals near the metal/scale interface, and (5) the nucleation of new crystallites after crystalline impingement has locally halted crystallite growth.

If the rate-limiting step were step 1, the dissociation of the molecular gas (S₂), the sulfidation rate should increase with the square root of the gas pressure. But the linear kinetic rate constant was virtually independent of P_{S₂}. In the much more rapid sulfidation of other transition metals (Fe, Ni, Co, Cr, etc.) at the same temperatures, the dissociation of molecular sulfur and the reduction step offer trivial hindrance to the rapid scaling kinetics, so the steps 2 and 3 should not be limiting here. The linear rate extends to the start of the reaction when the initially formed scale is quite thin and easily fractured; then the diffusion of S²⁻ should not be rate limiting either. Thus, sulfide nucleation at the metal/scale interface, as affected by the two epitaxial orientations of the sulfide to the substrate, must be the rate-limiting step for the initial linear sulfidation kinetics. This difficult nucleation step can be envisioned as requiring a significant local rearrangement of the metal/scale interface with a resultant large strain energy requirement for a relatively small Gibbs energy driving force.

Period II.—After a weight gain of 0.13-0.16 mg/cm² (scale thickness: 0.5-0.7 μm), the sulfidation kinetics are no longer linear, but change to slower parabolic kinetics. As a scale increases in thickness, its mechanical strength should increase, at least by the sintering of adjacent MoS₂ crystallites. Thus, after some critical thickness of the scale is reached, it becomes more difficult to fracture the scale, so that the diffusion of sulfur ions through the compact inner scale becomes important in limiting the sulfidation rate.

However, sometimes period II also exhibits linear kinetics with a rate which is lower than that for period I.

Fig. 12. Illustration of series reaction steps for the MoS₂ scale growth

With the realization that very small weight changes are being measured, and with the presence of gross edge and corner heterogeneities (Fig. 9), a precise explanation may not be justified. However, the period II is a transition period from linear I to parabolic III kinetics.

Period III.—Period II is concluded by a cracking of the scale, which is followed by clearly parabolic kinetic behavior. In period III, a compact inner scale forms at the interface of Mo and MoS₂, and the diffusion of sulfur ions through the inner scale becomes the rate-limiting step. As a result, period III shows parabolic behavior until the increased thickness and the decreased plasticity of the MoS₂ scale prevents further plastic deformation, so that scale fracturing occurs again and the cycle repeats. Such a mechanism is also observed in the oxidation of niobium, *i.e.*, at steady state, parabolic kinetic segments have been correlated to the repeated cracking of a compact inner scale (10). Because of the hexagonal layered structure of MoS₂, sulfide ion diffusion can only occur between {001} layers, not normal to them. But for the low temperatures and fine grain sizes of this study, grain boundary diffusion may be more important than lattice diffusion anyway.

Elemental sulfur experiments at higher temperatures (850°-950°C).—**Kinetics.**—At temperatures higher than 850°C, and at 750°C for P_{S₂} = 1 torr, the scaling behavior was clearly parabolic with time. Initially, the plots of Δm/A vs. t^{1/2} showed straight lines; then, after the scales reached some thickness, the slope changed to lower values. After that stage, the scaling behavior was described by sequences of weight gains and interruptions, as was the case for period III of the low temperature curves.

Figures 13-15 show representative kinetic results for different temperatures and values of P_{S₂}. Figure 16 is an Arrhenius plot for the parabolic sulfidation of Alfa as-rolled Mo specimens. The activation energy for sulfidation was 147 kJ/mol (35.2 kcal/mol). The results from H₂S/H₂ gas mixture experiments noted in Fig. 16 will be discussed later.

Morphology and scale composition.—The scale morphology at the scale/gas interface at higher temperatures differs significantly from that observed at lower temperature. As shown in Fig. 17, the scale appears to be compact and not fractured. When scales formed with linear kinetics at temperatures lower than 800°C were spalled by bending the specimens, bare metal with metallic color was revealed. However, when the scales formed at higher temperatures were similarly detached, the underlying metal was not bare, but showed a very thin layer of gray color with a slight gold tone. Upon bending the sulfidized specimen, the outermost layer (MoS₂) cracked eas-

ily and could be removed. However, the innermost layer was tightly adherent to the metal.

Figure 18 shows the fractured cross section of a scale formed at 950°C in $P_{S_2} = 0.05$ torr. The outer scale exhibits a laminated or layered structure, while the inner scale ex-

Fig. 17. MoS_2 scale of Alfa Mo specimen reacted at 900°C in $P_{S_2} = 0.11$ torr.

hibits a blocky equiaxed structure. Adhesive tape was applied to the surface of the MoS_2 scale, and the specimen was bent several times; the MoS_2 scale was successfully removed, leaving only the inner scale adherent to the metal, as shown in Fig. 19. An x-ray diffraction pattern was made from the inner layer using $Cu K\alpha$ radiation and a Ni filter, and this phase was identified as Mo_2S_3 . Refer to Ref. (11) for more details.

Previous investigators have not reported the existence of an Mo_2S_3 inner scale beneath the MoS_2 scale in sulfidation, but the formation of Mo_2S_3 is not surprising. As shown in the phase stability diagram in Fig. 1, for all temperatures, there exists a narrow regime of $\log P_{S_2}$ where Mo_2S_3 is stable. At 945°C and a sulfur pressure of 0.0076 torr, only Mo_2S_3 was formed. For these conditions, a marker experiment was conducted with the Au evaporation technique previously described, and the gold markers remained on the surface of Mo_2S_3 , indicating inward diffusion of sulfur in this phase.

The dependence of the parabolic rate constant on P_{S_2} .—As shown in Fig. 13-15, high temperature sulfidation in S_2 vapor obeyed parabolic kinetics. Figure 20 is a plot of k_p vs. $\ln P_{S_2}$ for three different temperatures, 850°, 900°, and 950°C. The parabolic rate shows a small dependence on P_{S_2} at low sulfur activities, but becomes independent of P_{S_2} above $P_{S_2} = 1$ torr.

Mechanism of high temperature sulfidation of Mo in S_2 vapor.—The slope of the plot of $\Delta m/A$ vs. $t^{1/2}$ decreases

Fig. 18. Cross section of a scale formed on as-rolled Mo specimen reacted at 950°C in $P_{S_2} = 0.05$ torr for 21h.

Fig. 19. Inner scale formed at 950°C in $P_{S_2} = 0.05$ torr

somewhat after some scale has formed, as shown in Fig. 13-15. This phenomenon was also observed by Gerlach and Hamel (2) and Fueki *et al.* (3), but was not explained. From the results of the current study, it seems this slope change is caused by the formation of Mo_2S_3 . The growth rate of Mo_2S_3 was found to be slower than that for MoS_2 (11), so that the formation of an Mo_2S_3 inner layer should reduce the overall sulfidation rate.

At the beginning of a high temperature sulfidation experiment, *e.g.*, at $P_{S_2} = 0.03$ torr, MoS_2 forms initially. As the parabolic sulfidation progresses, the Mo/MoS_2 interface should maintain a local metastable equilibrium with a P_{S_2} value higher than the equilibrium P_{S_2} for Mo/MoS_2 coexistence. But after the MoS_2 scale grows to some critical thickness, Mo_2S_3 is nucleated at the Mo/MoS_2 interface.

Gerlach and Hamel's results (2) showed a reduction in parabolic kinetics after ~30 min at 951°C in 0.10 $H_2S/0.90 H_2$, while the slope did not change up to ~90 min in 0.50 $H_2S/0.50 H_2$ at 953°C. In terms of the present hypothesis, the critical MoS_2 scale thickness for the formation of Mo_2S_3 must be larger for a higher P_{S_2} , *i.e.*, for a higher MoS_2 growth rate.

The parabolic kinetics for sulfidation of pure molybdenum at temperatures above 850°C indicate that the diffusion of sulfur ions through a compact sulfide scale is the rate-limiting step. Indeed, parabolic kinetics are also expected for the diffusion-limited growth of a layered scale comprised of two phases (12). The question remains whether bulk diffusion or grain boundary diffusion (for pure or doped compounds) through the inner compact scale is rate limiting.

Suzuki *et al.* (8) have recently reported on the compositions of $MoS_{2.6}$ equilibrated in H_2S/H_2 mixtures at 750° and 950°C. Each sulfide is sulfur deficient; point defects are associated with the nonstoichiometry in Mo_2S_3 , but no defect was proposed for MoS_2 . Especially for the layered hexagonal MoS_2 lattice, the intercalation (doping) for hydrogen ions between the layers must be considered. Frivaz and Mooser (13) reported that MoS_2 is an n-type semiconductor, but the temperature range of experimentation only reached 700 K and the specimens were not equilibrated to any sulfur activity. The exact modes of sulfur ion diffusion and electrical conduction remain uncertain.

In the oxidation of metals to form a pure, compact n-type semiconducting oxide scale whose growth is limited by volume diffusion, the ideal Wagnerian parabolic scale growth rate is predicted to be nearly independent of the oxidant gas pressure. This theoretical expectation results because the equilibrium concentration of anion vacancies in the scale at the metal/scale interface is many orders of magnitude higher than that in equilibrium with

Fig. 20. P_{S_2} dependence of the parabolic rate constant

the gas phase when a large Gibbs energy change is involved for forming a highly stable oxide. Then in that case, *e.g.*, for ideal parabolic oxidation of refractory metals, the change in defect concentration gradient resulting from a change in the oxidant activity is negligible, and thus k_p is predicted to be virtually independent of imposed P_{O_2} .

This independence of the parabolic rate on oxidant pressure is valid only when the ambient oxidant pressure is several orders of magnitude higher than the equilibrium oxidant activity at the metal/scale interface. As shown in Fig. 1, for the sulfidation of pure Mo, a gaseous S_2 pressure of 0.03 torr is only about two orders of magnitude higher than the MoS_2/Mo_2S_3 equilibrium sulfur activity at 950°C, so the change in the point defect concentration gradient caused by a change in P_{S_2} should not be negligible here.

Let us assume a simple and ideal point defect model³ applicable for both MoS_2 and Mo_2S_3

$$K = [V_s^{\cdot\cdot}] (P_{S_2})^{1/2} [e']^2 / [S_s^x] \quad [3]$$

where, for electrical neutrality

$$[e'] = 2[V_s^{\cdot\cdot}] \quad [4]$$

The incorporation of the constant $[S_s^x]$ into K provides

$$K = 4[V_s^{\cdot\cdot}]^3 (P_{S_2})^{1/2} \quad [5]$$

so that

$$[V_s^{\cdot\cdot}] = K' (P_{S_2})^{-1/6} \quad [6]$$

For low concentrations of $V_s^{\cdot\cdot}$, the ionic conductivity, σ_{ion} , or the diffusivity, D_s , should be proportional to $[V_s^{\cdot\cdot}]$. Then

$$\sigma_{ion} \propto D_s \propto K' P_{S_2}^{-1/6} \quad [7]$$

Wagner's rational rate constant becomes

$$k \propto k_p \propto K' \{ (P_{S_2}^i)^{-1/6} - (P_{S_2}^o)^{-1/6} \} \quad [8]$$

where $P_{S_2}^i$ and $P_{S_2}^o$ are the equilibrium P_{S_2} values at the metal/scale and scale/gas interfaces, respectively.

If we plot k_p vs. $\ln P_{S_2}^o$, the slope will be

$$\frac{dk_p}{d \ln P_{S_2}^o} = \frac{d}{d \ln P_{S_2}^o} K' \{ (P_{S_2}^i)^{-1/6} - (P_{S_2}^o)^{-1/6} \} \quad [9]$$

$$= \frac{P_{S_2}^o d}{d P_{S_2}^o} K' \{ (P_{S_2}^i)^{-1/6} - (P_{S_2}^o)^{-1/6} \} \quad [10]$$

$$= \frac{K'}{6} \{ (P_{S_2}^o)^{-1/6} \} \quad [11]$$

³The defect notation of Kröger and Vink (14) has been used to denote doubly ionized anion vacancies, $V_s^{\cdot\cdot}$, and excess electrons, e' .

The slopes of the curves for three temperatures in Fig. 20 are indeed in rather good agreement with the prediction of Eq. [11]. As the external $P_{S_2}^0$ increases, the slope decreases; as the temperature increases, the slope increases because K' of Eq. [6] increases at higher temperatures. The dependence of k_p on the ambient $P_{S_2}^0$ is consistent with a change in the point defect concentration gradient in response to a change in $P_{S_2}^0$.

If grain boundary sulfur diffusion were the rate limiting diffusion step, the diffusivity of sulfur through grain boundaries also would depend on $P_{S_2}^0$, but no prediction of mathematical dependence is possible. The slope of the k_p vs. $\ln P_{S_2}^0$ plot might also be valid for grain boundary diffusion. Since the melting point for MoS_2 is reported as 1185°C, temperatures of 850°-950°C would seem sufficiently high for bulk diffusion in the sulfides to dominate the transport step. However, the very fine grain size of the scale would favor grain boundary diffusion. After weighing these factors, volume diffusion of sulfur ions over anion vacancies is suggested to be the rate-limiting step for the parabolic sulfidation of Mo.

Sulfidation of pure Mo in H_2S/H_2 gas mixture.—To test further the conclusion that the growth of the two-layered Mo_2S_3/MoS_2 scale at high temperatures occurs according to a classical Wagnerian sulfur ion diffusion-limited mechanism, a few experiments were conducted in H_2S/H_2 gas mixtures, as summarized in Fig. 16. For temperatures of 850°, 900°, and 950°C, the H_2S/H_2 ratio was adjusted so that the equilibrium activity of S_2 was held constant at 1 torr. In the absence of extraneous effects, such as the hydrogen doping of the sulfide scale, classical parabolic oxidation theory involving local equilibrium at the scale/gas interface would predict that the kinetics should depend only on the sulfur activity in the gas phase, not on the nature of the molecular oxidant species. However, the parabolic sulfidation rates for H_2S/H_2 runs reported in Fig. 16 are about a factor of ten higher than those for the molecular S_2 experiments at 850° and 900°C, and a factor of five higher at 950°C. However, for H_2S/H_2 experiments at 940° and 950°C, a dark green deposit accumulated in the cool section of the reaction tube. X-ray diffraction provided a peak corresponding to the principal MoS_2 peak. Thus, some evaporation of the MoS_2 scale (probably as MoS_3 vapor) may have reduced the rate constant reported for 950°C. The parabolic rate constant for 950°C for Fueki *et al.* (3) was lower than that from this work, probably because they used a different gas mixture ($P_{H_2} = P_{H_2S} = 20$ torr, $P_{S_2} = 2$ torr) in a closed system, while in this study, the P_{H_2S}/P_{H_2} was adjusted to achieve $P_{S_2} = 1$ torr in a flowing system, with $P_{H_2} = 0.575$ and $P_{H_2S} = 0.425$.

The more rapid sulfidation rates in H_2S/H_2 gases cannot be explained by an easier molecular dissociation of H_2S compared to S_2 because the kinetics are parabolic, demonstrating diffusion-limited kinetics. A reasonable explanation for higher rates in H_2S/H_2 compared to those in S_2 at the same sulfur activity is that the sulfide scale was doped by hydrogen. Stoltz and Wagner (15) discussed the possible doping of oxides with hydrogen (and water vapor) both as H^+ and as H^- species. Zelouf and Simkovich (16) explained an increased sulfidation rate for Fe to form FeS in terms of an increase in cation vacancy concentration with dissolved interstitial protons for variable P_{H_2} at fixed P_{H_2S}/P_{H_2} . No previous defect studies for MoS_2 and Mo_2S_3 are available to interpret a possibility or mechanism for hydrogen doping. But the open-layered structure of MoS_2 suggests that some intercalation or substitution of solutes is possible. For an increase in the bulk anion vacancy concentration of Mo sulfides, a dopant hydrogen ion would need a negative net charge, *e.g.*, either as an interstitial H_i^- or as a substitutional ion at an anion site H_s^- . Because of the very large size of the negative hydrogen ion ($R = 2.08\text{\AA}$ for six-fold coordination), the substitutional ion would be favored. This model should lead to an electrical neutrality condition of $[H_s^-] = 2[V_s^-]$ when the dopant content exceeds the concentration of native defects in the pure sulfides. Support for this interpreta-

tion must await further experimentation, preferably by electrical conductivity measurements. From Fig. 16, the higher sulfidation rate at 900°C for $P_{S_2} = 1$ torr with $P_{H_2} = 380$ torr from this study compared to $P_{S_2} = 1$ torr with $P_{H_2} = 20$ torr from Fueki *et al.* (3) is also consistent with hydrogen doping. Likewise, the relative drop in the hydrogen doping effect for 950°C compared to the extrapolation of the 850° and 900°C behavior would suggest that the native defects at 950°C are not exceeded to the same extent by dopant-generated defects as the temperature is increased.

Summary and Conclusions

The kinetics and mechanism of sulfide scale growth on pure molybdenum have been investigated in an elemental sulfur (S_2) atmosphere and in H_2S/H_2 gas mixtures for the temperature range of 700°-900°C.

The following conclusions were reached:

1. Below about 750°C, time-independent (linear) kinetics were observed; the linear scaling rate was on the order of 10^{-8} g/cm²s. The activation energy for the linear sulfidation kinetics is 103.4 ± 21.2 kJ/gm mol.
2. For temperatures of 850°C and higher, parabolic scaling behavior was observed, with rate constants on the order of 10^{-11} g²/cm⁴s. The activation energy for the parabolic sulfidation kinetics is about 148 kJ/mol.
3. For all experimental temperatures, the sulfide scales had a uniform thickness and a columnar morphology. The MoS_2 crystals have a strong epitaxial relationship with the metal. The surface orientation of the metal affected the sulfidation rate.
4. For the linear kinetics, a sulfide crystal nucleation step is believed to be rate limiting. The microcrystalline nature of the scale caused by the two equivalent but incompatible epitaxial orientations of MoS_2 crystals on Mo introduces scale porosity.
5. For parabolic behavior, a bulk diffusion process of sulfur ions is the rate-limiting step. After the scale reaches some thickness, Mo_2S_3 crystals form beneath the MoS_2 scale and the kinetics are reduced somewhat.
6. The parabolic rate constants of sulfidation in H_2S/H_2 gas mixtures were about one order of magnitude higher than those for elemental sulfur, possibly because of hydrogen doping (intercalation or substitution) of the MoS_2 scale.

Chevron Research Company, Richmond, California 94802

ABSTRACT

The indium activity in liquid In-Sb solutions is measured in the following high temperature solid-state galvanic cells

and

The measurements indicate a moderate negative deviation from ideal solution behavior and are in close agreement with previous studies. The results are compared with the available calorimetric and phase-diagram determinations and are found to be consistent with them. An expression for the standard Gibbs energy of formation of solid InSb is presented that is consistent with the direct EMF measurements, calorimetric studies, reported phase diagram, and results of this study. The nonrandom two-liquid theory is found to adequately represent the liquid mixture thermodynamic data.

Indium antimonide is the only existing intermetallic compound in the In-Sb system; it exhibits a high electron mobility and presents the lowest bandgap energy of the group III-V semiconducting compounds (1-3). The pure compound and mixed crystals containing InSb are of current interest as host materials for a variety of solid-state electronic devices (4-7). As the chemical processing of these materials often involves the melt and the analysis of such processes frequently assigns an equilibrium boundary condition, knowledge of the solid-liquid phase diagram is important. Furthermore, the phase fields for uninvestigated multicomponent systems can be estimated from consideration of the binary limits alone. The interpolation of the multicomponent phase diagrams between the binary edges generally involves use of a solution model to describe the composition and temperature dependence of the excess Gibbs energy. The success of a model should be determined by its ability to represent not only the binary-phase diagram, but also the mixture enthalpy and entropy. With this objective in mind, solid-state electrochemical measurements of the In activity in In-Sb melts are reported and an analysis of the available phase-diagram and thermochemical information for both the mixture and pure compound is presented.

A considerable number of experimental characterizations of the thermodynamic properties for the In-Sb system have been reported. Presented in Table I is the melting temperature of InSb, $T_f[\text{InSb}]$, as determined by several investigators. It is noted that InSb is the only III-V compound having T_f below that of a component element [Sb]. Also shown in Table I is a summary of the enthalpy of fusion of InSb, $\Delta H_f^\circ[\text{InSb}]$. As can be seen, there exists a maximum difference of 13.3 kJ · mol⁻¹ in the reported values of $\Delta H_f^\circ[\text{InSb}]$. The mixing of pure In and pure Sb produces a negative enthalpy change as determined calorimetrically by several investigators (15, 23-28). The different measurements are in good agreement, with the published range for the maximum exothermic enthalpy of mixing, ΔH^M , of 2345-3725 kJ · mol⁻¹ for temperatures in the range of 910-1184 K. The enthalpy of mixing is not a symmetric function of composition; the maximum exo-

thermic ΔH^M is located in the reported range $x_{\text{In}} = 0.55-0.61$. The more recent results of Rosa *et al.* (28), obtained at five temperatures in the same calorimeter, indicate that the maximum ΔH^M shifts to a lower magnitude at increased Sb content as the temperature is increased. The phase diagram for the In-Sb system has been reported by several investigators (15, 19, 22, 29) who found a simple eutectic on the Sb-rich side of the compound at a composition of $x_{\text{Sb}} = 0.682$ and a temperature of 767 K. The In-InSb eutectic is practically degenerate, having a melting temperature approximately 1 K below that of pure In at a composition $x_{\text{Sb}} = 0.007$.

Of primary importance in the understanding of solid-liquid phase equilibria in III-V compounds and solid solutions is an accurate description of the liquid-phase solution behavior. The multicomponent solid solutions are often nearly ideal, but the liquid phase for most III-V systems shows negative deviations from ideal behavior. The calculation of liquidus temperatures proves to be sensitive to the model employed for the liquid-phase thermodynamics. As these models are generally based on a formulation of the excess Gibbs energy of the mixture, a direct determination of the composition dependence of

the Gibbs energy of mixing, ΔG^M , would aid in the assessment of various proposed models. To date, there have been three experimental determinations of component activities in liquid In-Sb solutions. Terpilowski (30) measured In activities in an electrochemical cell using a double bromide salt and found negative deviations throughout the entire composition range. Similarly, Hoshino *et al.* (31), using a double iodide salt concentration cell, measured In activities that were in fair agreement with the results of Terpilowski. As is often the case with this method, the excess enthalpies and entropies reported in these two studies were quite different, and further discrepancies are found when compared to calorimetric data. Furthermore, Terpilowski (30) and Hoshino and co-workers (31) assumed that the In ions transported in the fused salt electrolytes were monovalent; this assumption directly affects the activity calculated from the measured cell EMF.

The possible uncertainty in the In oxidation state for these cells prompted Chatterji and Smith (32) to investigate the activity of In with a galvanic cell using a solid oxide electrolyte in which In ions are known to be trivalent and the transported oxygen ion divalent. Four compositions were studied, all of which were in the In-rich portion of the phase field, where this technique is not as reliable. In addition, Chatterji and Smith (32) used air as the reference electrode, thus requiring knowledge of the Gibbs energy of forming indium sesquioxide from the elements. Therefore, a second electrochemical cell was evaluated using a mixture of pure In metal and indium sesquioxide as the working electrode and air as the reference electrode. The resulting logarithm of the indium activity is then proportional to the difference in the measured EMF of the above two types of cells. This difference is small in value (6.5-37 mV for the compositions studied) compared to the measured EMF's of the two individual cells (920-1160 mV) and includes the uncertainties of two experiments, though the possible errors are probably systematic and cancel. A third-law analysis indicated the expression for $G_r^\circ[\text{In}_2\text{O}_3]$ of Chatterji and Smith (33) to be inconsistent with other available thermodynamic data (34).

For these reasons, the following solid-state electrochemical cells were investigated

In both cells, the working electrode consisted of the mixture of a liquid In-Sb alloy at the composition of interest and the most stable oxide, indium sesquioxide. In the first cell type, the reference oxygen partial pressure was established with a mixture of CO + CO₂ of known composition, while the second cell type utilized pure liquid indium and its stable oxide as the reference electrode. The open-circuit potential, E , of concentration cell [I] can be related to the indium activity, a_{In} , by the following expression

$$a_{\text{In}} = (p_{\text{CO}_2}/p_{\text{CO}})^{-3/2} \exp \{3FE/RT - 3\Delta G^\circ[\text{CO}-\text{CO}_2]/2RT + \Delta G_r^\circ[\text{In}_2\text{O}_3]/2RT\} \quad \text{[1]}$$

where $p_{\text{CO}_2}/p_{\text{CO}}$ is the ratio of the partial pressure of CO₂ to that of CO in the reference gas mixture, $\Delta G^\circ[\text{CO}-\text{CO}_2]$ is the standard Gibbs energy change for the reaction

and $\Delta G_r^\circ[\text{In}_2\text{O}_3]$ is the standard Gibbs energy change for the formation of 1 mol of indium sesquioxide.

Cell type II gives the simple relationship between the measured cell voltage and temperature to the indium activity

$$\ln a_{\text{In}} = -3FE/RT \quad \text{[3]}$$

The first cell is advantageous in that the gaseous reference electrode provides a more reversible electrode and

generally serves as a better buffer for oxygen. Thus, temperature coefficients of these cells were found to be in closer agreement with calorimetric values, though the calculated activities are subject to uncertainty in not only the temperature and measured voltage but also in $p_{\text{CO}_2}/p_{\text{CO}}$, $\Delta G^\circ[\text{CO}-\text{CO}_2]$ and $\Delta G_r^\circ[\text{In}_2\text{O}_3]$. In addition, the use of the CO-CO₂ reference electrode is superior to air since the O₂ partial pressure can be adjusted to closely match that established in the working electrode. However, the use of pure In-In₂O₃ as a reference electrode is advantageous in that the only errors involved are those associated with the measurement of the voltage and temperature. Thus, in this study, indium activities were measured in liquid solutions with antimony by means of the oxygen-ion conducting solid electrolyte, calcia-stabilized zirconia. Both the investigation of solutions throughout the entire composition range and the use of a solid oxide electrolyte should eliminate possible ambiguities in the oxidation state of the In ion that was assumed by earlier workers employing a halide-based concentration cell.

Experimental

A complete description of the experimental design and procedure has been given previously (34-36). Extreme care was taken to minimize the oxygen content of the inert gas blanket. Data acquisition was automated with a microcomputer system. The alloys were formed by mixing powdered InSb (Orion Chemical Company, 325 mesh, 99.999% purity) with either pure antimony (Cominco American, high purity, lot EM 2139) or pure indium (Orion Chemical Company, 325 mesh, 99.999% purity, lot no. 2449) to obtain the desired composition. Indium sesquioxide (Alfa Inorganics, 99.999% purity) was placed on top of the alloy or the pure indium in each cell. The CO-CO₂ reference gas mixture (22.169 ± 0.02% CO₂, 2.349 ± 0.02% CO, and balance Ar) was a primary standard procured from Matheson Gas Products.

When a new alloy composition was formed by adding pure elemental material to a previously studied composition, it was found to give inconsistent results. This inconsistency was apparent in a changing EMF temperature coefficient as the temperature was cycled and was probably due to incomplete mixing. Thus, for each composition studied, an alloy was synthesized from the pure elements.

Results

The open-circuit equilibrium potential for cells [I] and [II] was measured throughout a predetermined temperature range, and the results are plotted in Fig. 1 and 2. The EMF measured for cells using the CO-CO₂ gaseous mixture as the reference electrode is shown in Fig. 1, while Fig. 2 depicts the more direct measurements employing the pure metal reference electrode. Only the measurements made in the final temperature cycle are shown. It was found that several cycles were required before reproducible EMF temperature variations were obtained. As can be seen, the measured potentials are linear in temperature over the range investigated.

The activity of indium was calculated with Eq. [1] or [3] at 973 K using linear regression coefficients for the straight lines shown in Fig. 1 and 2. These results are given in Table II, along with the antimony activity calculated by integration of the Gibbs-Duhem equation. Also listed in Table II are the corresponding activity coefficients, γ_{In} , and the resulting molar Gibbs energy of mixing, ΔG^M . The partial molar enthalpy of In calculated from the temperature dependence of the cell potential exhibited considerable scatter, particularly with use of the pure metal/metal oxide reference electrode. Similar scatter was observed in the results for the gallium activity in Ga-Sb melts (36). This inconsistency is common in these types of measurements and does not reflect on the primary results of EMF measurements-Gibbs energy changes. The results of the activity measurements are graphically shown in Fig. 3 and depict a negative deviation from ideal solution behavior. Shown for comparison are the molten salt electrolyte results of Terpilowski (30)

Fig. 1. Experimental cell voltages as a function of temperature for cell type [I]. Least squares line shown.

at 923 K and of Hoshino *et al.* (31) at 900 K and also the solid oxide electrolyte results of Chatterji and Smith (32) at 973 K. As can be seen, the results of all four investigations are in relatively good agreement. The results of the molten salt electrolyte work shows a slightly more negative deviation in component-rich solutions than this work, though the difference is within the experimental error involved.

The smoothed values for the indium and antimony activities are indicated by the solid lines in Fig. 3 and are combined to give ΔG^M , which is plotted as a function of composition in Fig. 4. Also summarized in Fig. 4 is the experimental enthalpy of mixing as measured by several investigators (23-26). The primary results of this work can be combined with the primary results of the calorimetric investigators to produce the entropy of mixing, ΔS^M . Shown in Fig. 4 is ΔS^M calculated from ΔG^M presented

here and from two of the ΔH^M determinations. For comparison, the ideal entropy of mixing is plotted; the excess entropy of mixing can be seen to be nearly zero in the composition range $0.0 < x_{In} < 0.4$ and positive in more indium-rich solutions.

Discussion

Calculation of the phase diagram.—The In-Sb binary phase diagram is well known, and thus a convenient check of the consistency of the available solution thermodynamic data is a calculation of the liquidus. The conditions of solid-liquid equilibrium stipulate equivalence of the temperature, pressure, and component chemical potentials in both phases, subject to the constraint of an equal number of lattice sites for In and Sb in the solid compound. Neglecting any pressure dependence, the combination of these requirements results in the following simple relationship between the liquidus composition, x_{In} , and temperature, T_l

$$x_{In}(1 - x_{In}) = \exp [\vartheta_{InSb}(T_l)] / \Gamma_{InSb}(x_{In}, T_l) \quad [4]$$

The ϑ_{InSb} term is the reduced reference state chemical potential change and is defined by

$$\vartheta_{InSb} = (\mu_{InSb}^o - \mu_{In}^o - \mu_{Sb}^o) / RT \quad [5]$$

where μ_i^o is the standard state chemical potential for the solid compound InSb or the liquid components In and Sb. The quantity Γ_{InSb} is a measure of the deviation of the liquid solution from ideal behavior at the liquidus temperature and composition of interest and is simply the product of the liquid-phase component activity coefficients, γ_i

$$\Gamma_{InSb} = \gamma_{In}\gamma_{Sb} \quad [6]$$

Choosing the standard state for all species to be the pure component at the temperature, pressure, and state of

aggregation of interest, ϑ_{InSb} is simply the molar Gibbs energy difference between the solid compound and the pure liquid elements and is made dimensionless upon division by RT . Several paths of state change can be formulated to estimate this molar Gibbs energy change, each requiring a different data base. One such sequence, first proposed by Wagner (37) and later applied to III-V binary systems by Vieland (38), is to change the temperature of the pure compound from the one of interest, T , to $T_f[\text{InSb}]$, melt the compound, subcool the resulting equimolar mixture to T , and separate the solution into the pure elements. The resulting expression for ϑ_{InSb} is

$$\vartheta_{\text{InSb}} = \ln \left[\frac{\gamma_{\text{In}}[T, x = 0.5] \gamma_{\text{Sb}}[T, x = 0.5]}{4} \right] - \frac{\Delta S_f^\circ[\text{InSb}]}{R} \left(\frac{T_f[\text{InSb}]}{T} - 1 \right) + \frac{1}{RT} \int_T^{T_f[\text{InSb}]} \frac{\Delta C_p}{T} dT \quad [7]$$

Here, ΔC_p is the molar heat capacity difference between the stoichiometric liquid and the compound. Substituting this relationship into Eq. [4], neglecting the ΔC_p term [$\Delta C_p = 5.52 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$ at $T_f[\text{InSb}]$ (11)], and explicitly indicating the principal temperature dependence of the activity in terms of the relative partial molar enthalpy, $\Delta \bar{H}_i$, and entropy, $\Delta \bar{S}_i$, results in the following equation for the liquidus temperature

$$T_l = \frac{\Delta H_f^\circ[\text{InSb}] + \Delta \bar{H}_{\text{In}}[x] + \Delta \bar{H}_{\text{Sb}}[x] - \Delta \bar{H}_{\text{In}}[x = 0.5] - \Delta \bar{H}_{\text{Sb}}[x = 0.5]}{\Delta S_f^\circ[\text{InSb}] + \Delta \bar{S}_{\text{In}}[x] + \Delta \bar{S}_{\text{Sb}}[x] - \Delta \bar{S}_{\text{In}}[x = 0.5] - \Delta \bar{S}_{\text{Sb}}[x = 0.5]} \quad [8]$$

A second expression for the reduced standard state chemical potential difference represents the molar Gibbs energy change of the following process: solid InSb is reduced to the natural elements at the temperature of interest (the reverse formation reaction), followed by a thermal sequence similar to that used in the previous analysis but applied to Sb since the melting temperature of Sb, $T_f[\text{Sb}]$, is above that of InSb. The expression for ϑ_{InSb} is

$$\vartheta_{\text{InSb}} = \left\{ \Delta G_f^\circ[\text{InSb}, T] - \Delta S_f^\circ[\text{Sb}][T_f[\text{Sb}] - T] - \int_T^{T_f[\text{Sb}]} \frac{\Delta C_p[\text{Sb}]}{T} dT \right\} / RT \quad [9]$$

Here $\Delta G_f^\circ[\text{InSb}, T]$ is the standard Gibbs energy of formation of InSb at the temperature of interest and $\Delta C_p[\text{Sb}]$ is the heat capacity difference between liquid and solid Sb. Substituting this expression for ϑ_{InSb} into Eq. [4], while again neglecting the $\Delta C_p[\text{Sb}]$ term [$\Delta C_p[\text{Sb}] = 0.42 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$ at $T_f[\text{Sb}]$ (39)], yields the alternative expression for the liquidus temperature

$$T_l = \frac{\Delta H_f^\circ[\text{InSb}] - \Delta H_f^\circ[\text{Sb}] - \Delta \bar{H}_{\text{In}}[x] - \Delta \bar{H}_{\text{Sb}}[x]}{\Delta S_f^\circ[\text{InSb}] - \Delta S_f^\circ[\text{Sb}] - \Delta \bar{S}_{\text{In}}[x] - \Delta \bar{S}_{\text{Sb}}[x]} \quad [10]$$

In this relationship $\Delta H_f^\circ[\text{InSb}]$ and $\Delta S_f^\circ[\text{InSb}]$ represent the standard enthalpy and entropy of formation of InSb, respectively. Comparing Eq. [8] and [10], it is evident that the "formation" expression (Eq. [10]) is a more critical test of the consistency between the solution properties and the measured liquidus, as the liquid mixture information required in Eq. [10] is relative to the pure components, while, in Eq. [8], it is relative to the stoichiometric liquid. However, the enthalpy of fusion and melting temperature required in Eq. [8] are directly measurable, whereas the standard enthalpy and entropy of formation are generally obtained from the temperature dependence of $\Delta G_f^\circ[\text{InSb}, T]$ and thus subject to more uncertainty.

The InSb phase diagram shows simple eutectic behavior in the Sb-rich portion. Equating the chemical potential of Sb in the liquid mixture to that of pure solid Sb, and using the same sequence developed in Eq. [7] to determine the reduced standard state chemical potential change but applied to solid Sb, results in

$$T_l = \frac{\Delta H_f^\circ[\text{Sb}] + \Delta \bar{H}_{\text{Sb}}[x]}{\Delta S_f^\circ[\text{Sb}] + \Delta \bar{S}_{\text{Sb}}[x]} \quad [11]$$

As in Eq. [10], the $\Delta C_p[\text{Sb}]$ term is assumed to be negligible.

Given in Table III are the results of calculating the liquidus temperatures with either the "fusion" (Eq. [8]) or "formation" (Eq. [10]) expressions. The partial molar enthalpies of the components were obtained from the calorimetric enthalpy of mixing investigations of Yazawa *et al.* (24), and the partial molar entropies of the components were calculated from the measured component activities from this work. The smoothed values of the component activities used in these calculations are also listed in Table III. A melting temperature for InSb of 800 K was used in conjunction with the experimental enthalpies of fusion listed in Table I to calculate the liquidus temperatures with the "fusion" equation. The values of $\Delta H_f^\circ[\text{InSb}]$ used were the smallest (8) and largest (18) experimental determinations, along with the selected value of $49.4 \text{ kJ} \cdot \text{mol}^{-1}$ (16). There are four EMF studies of the standard Gibbs energy of formation of solid InSb available in the literature (40-43). The standard enthalpy and entropy of formation of InSb, required in the "formation" equation, can be determined from the temperature dependence of these measurements. The value for $\Delta H_f^\circ[\text{Sb}]$ was taken from Hultgren *et al.* (39) as $19,870 \text{ J} \cdot \text{mol}^{-1}$, and $T_f[\text{Sb}]$

was assumed to be 904 K. Table IV gives the liquidus temperatures determined from Eq. [11], using the smoothed activity measurements of this work and also of Terpilowski (30) and Hoshino *et al.* (31). Also found in Tables III and IV are the liquidus temperatures determined by assuming that the solutions exhibit ideal behavior. Finally, these results are compared with the experimental liquidus temperatures as determined by Liu and

Peretti (19). The results of these calculations using the "fusion" equation in conjunction with the smoothed activity measurements of this study, $\Delta H_f^\circ[\text{InSb}] = 49.4\text{ kJ} \cdot \text{mol}^{-1}$ (16), and the enthalpy of mixing of Yazawa *et al.* (24) are graphically displayed in Fig. 5. For comparison,

Fig. 5. Liquidus temperatures for the In-Sb system calculated from Eq. [8] and [11]. (o): This study. (Δ): Terpilowski (30). (\square): Hoshino *et al.* (31). (—): Experimental results of Liu and Peretti (19).

Fig. 5 also shows the liquidus temperatures calculated from the actual activity measurements of Terpilowski (30) and the smoothed values of Hoshino *et al.* (31). The results of Chatterji and Smith (32) were obtained over an insufficient composition range to be compared.

Several conclusions can be made from these calculations. First, the negative deviation observed in the various EMF measurements is supported by these calculations, as is seen by comparing the calculated liquidus temperatures with the ideal temperatures. The enthalpy of fusion reported as $37.7\text{ kJ} \cdot \text{mol}^{-1}$ (8) appears to be too low, and the use of the experimental $\Delta H_f^\circ[\text{InSb}]$ range of $46.9\text{--}51.0\text{ kJ} \cdot \text{mol}^{-1}$ give liquidus temperatures consistent within the experimental error for at least one of the three activity measurements. The results of this study tend to support a higher value of $\Delta H_f^\circ[\text{InSb}]$; the results of Terpilowski support the lower $\Delta H_f^\circ[\text{InSb}]$ values. It is noted that the use of different enthalpy of mixing data has a negligible effect on the calculated temperatures. Finally, the results in the antimony-rich region indicate that the activities of this work and of Hoshino *et al.* (31) are in close agreement, while the work of Terpilowski (30) yields considerably lower liquidus temperatures.

A more stringent test of the thermodynamic consistency of the various data is found in using the formation equation. Figure 6 shows the liquidus temperatures calculated using the results of Sirota and Yushkevich (42), Abbasov and Mamedov (40), and Terpilowski and Trzebiatowski (43) for the standard enthalpy and entropy of formation and the smoothed activities of this work. Of the four experimental values for $\Delta H_f^\circ[\text{InSb}]$ and $\Delta S_f^\circ[\text{InSb}]$ available, the values given by Nikol'skaya *et al.* (41) and Sirota and Yushkevich (42) are in good agreement. As can be seen, fairly close agreement is observed, though the use of the values of Abbasov and Mamedov (40) yielded significantly lower temperatures. Again for comparison, the formation liquidus temperatures were calculated with the molten salt EMF activity measurements. Figure 7 depicts the results of using either the results of Terpilowski (30) or Hoshino *et al.* (31) in conjunction with the extremum for $\Delta H_f^\circ[\text{InSb}]$ and $\Delta S_f^\circ[\text{InSb}]$ (40, 43). The results of Terpilowski (30) show considerable discrepancy with the reported phase diagram, while good consistency is found with the results of this study or of Hoshino *et al.* (31) and with use of the lowest values of $\Delta H_f^\circ[\text{InSb}]$ and $\Delta S_f^\circ[\text{InSb}]$ (43).

Gibbs energy of formation of InSb(c).—An alternate expression for $\Delta G_f^\circ[\text{InSb}]$ can be derived using the results of this study as follows. Consider the following reaction scheme

Fig. 6. Liquidus temperatures for the In-Sb system calculated from Eq. [10] and the results of this study. The standard enthalpy and entropy of formation of InSb taken from: (o) Terpilowski and Trzebiatowski (43), (□) Sirota and Yushkevich (42), (△) Abbasov and Mamedov (40). The solid line represents the experimental results of Liu and Peretti (19).

Fig. 7. Liquidus temperatures for the In-Sb system calculated from Eq. [10] and the EMF activity measurements of: (o) Terpilowski (30), (□) Hoshino *et al.* (31). The standard enthalpy and entropy of formation of InSb taken from: open, Terpilowski and Trzebiatowski (42); closed, Abbasov and Mamedov (40). The solid line represents the experimental results of Liu and Peretti (19).

The Gibbs energy change for the first reaction is simply the Gibbs energy change upon mixing equal moles of In and Sb. The Gibbs energy change for reactions [13] and [14] can be approximated by

$$\Delta G^{\circ}[13] = -\Delta H_f^{\circ}[\text{InSb}]\{1 - T/T_f[\text{InSb}]\} \quad [15]$$

$$\Delta G^{\circ}[14] = \Delta H_f^{\circ}[\text{Sb}]\{1 - T/T_f[\text{Sb}]\} \quad [16]$$

where the small temperature dependence of the enthalpy and entropy of fusion of InSb and Sb has been neglected. Upon summation of the above reactions, the overall reaction is found to be the desired formation reaction, and the standard enthalpy and entropy of formation are given by

$$\Delta H_f^{\circ}[\text{InSb}] = 2\Delta H^{\text{M}}[x = 0.5] + \Delta H_f^{\circ}[\text{Sb}] - \Delta H_f^{\circ}[\text{InSb}] \quad [17]$$

and

$$\Delta S_f^{\circ}[\text{InSb}] = 2\Delta S^{\text{M}}[x = 0.5] + \Delta H_f^{\circ}[\text{Sb}]/T_f[\text{Sb}] - \Delta H_f^{\circ}[\text{InSb}]/T_f[\text{InSb}] \quad [18]$$

By using the results of Yazawa *et al.* (24) for $\Delta H^{\text{M}}[x = 0.5]$, the enthalpy of fusion as given by Blachnik and Schneider (16), the results of this study to determine $\Delta S^{\text{M}}[x = 0.5]$, and by taking $\Delta H_f^{\circ}[\text{Sb}]$, $T_f[\text{Sb}]$, and $T_f[\text{InSb}]$ as given previously, the following equation is derived for $\Delta G_f^{\circ}[\text{InSb}]$

$$\Delta G_f^{\circ}[\text{InSb}] = -35,220 + 25.54(T/\text{K}) \text{ J} \cdot \text{mol}^{-1} \quad [19]$$

Table V summarizes the various results reported for the standard enthalpy and entropy of formation of solid InSb. The values determined by molten salt EMF studies are given for the average temperature of those measurements. Also listed are two high temperature calorimetric investigations of the standard formation enthalpy which are in excellent agreement with Eq. [19]. For comparison, the standard entropy derived from the equimolar activity results of the two molten salt studies (30, 31) is also given.

There are several different ways to test the consistency of these various results. The primary result of the EMF formation work is the Gibbs energy of formation of InSb. Thus the derived expressions should produce $\Delta G_f^{\circ}[\text{InSb}]$ values in close agreement with the EMF values. Table VI lists two values of $\Delta G_f^{\circ}[\text{InSb}]$ calculated from the derived equations and are compared to the measured results. As can be seen, the equations derived using the activity measurements of this work and of Hoshino *et al.* (31) are within the range of experimental error for the EMF results and the range produced by varying the enthalpy of fusion of InSb and enthalpy of mixing. The result found

in using the activity studies of Terpilowski (30) gives Gibbs energies which are too low.

A second consistency test involves a third law calculation of $\Delta H_f^\circ[\text{InSb}]$ from the following relationship

$$\Delta H_f^\circ[\text{InSb}, 298.15 \text{ K}]$$

$$= T \left\{ - \left[\frac{\Delta G_f^\circ[\text{InSb}, T] - \Delta H_f^\circ[\text{InSb}, 298.15 \text{ K}]}{T} + \frac{\Delta G_f^\circ[\text{InSb}, T]}{T} \right] \right\} \quad [20]$$

The first term on the left is the free energy function and can be calculated from

$$- \left[\frac{\Delta G_f^\circ[\text{InSb}, T] - \Delta H_f^\circ[\text{InSb}, 298.15 \text{ K}]}{T} \right] = \Delta S_f^\circ[\text{InSb}, 298.15 \text{ K}] + \Delta_f^\circ[S(T) - S[298.15 \text{ K}]] - \Delta_f^\circ[H(T) - H[298.15 \text{ K}]]/T \quad [21]$$

Thus, the free energy function, calculated from both low and high temperature heat capacities, can be combined with the Gibbs energy of formation of InSb from the various sources to give a calculated value of $\Delta H_f^\circ[\text{InSb}, 298.15 \text{ K}]$. The calculated result can then be compared to that measured independently by calorimetry. Taking the high temperature heat capacity of In from Hultgren *et al.* (39), for Sb from Glassner (46), and for InSb from Lundin *et al.* (13) and the absolute entropy for the elements from Hultgren *et al.* (39) and for InSb from Renner (47), and combining this with the values of $\Delta G_f^\circ[\text{InSb}, T]$ yield the results shown in Fig. 8. The results using measurements of the four EMF formation studies are given by the solid lines and are compared with the

value selected by Hultgren *et al.* (12) though the direct measurements available in the literature show considerable scatter as summarized in Table VII.

Although the results of these calculations are not definitive, the derived expression for $\Delta G_f^\circ[\text{InSb}]$ using the data of Terpilowski (30) gives values which are low. It is noted that the expression derived with the results of this work give constant values of the calculated $\Delta H_f^\circ[\text{InSb}, 298.15 \text{ K}]$ as required.

As a final comparison, the phase diagram for In-Sb is again calculated using the standard enthalpy and entropy given by Eq. [19]. These results are presented in Fig. 9, and it is found that the activity measurements of this work and of Hoshino *et al.* (31) give excellent agreement between the calculated and experimental phase diagram. The liquidus temperatures calculated with the data of Terpilowski (30) are low. It should be noted that this method requires the melting temperature of the compound to be predicted exactly. Similar liquidus temperature calculations with the other derived equations again gave excellent agreement, thus supporting the composition dependence commonly reported for the activity. In

Fig. 9. Liquidus temperatures for the InSb system calculated from Eq. [10] and [19]. (a): This study. (Δ): Terpilowski (30). (□): Hoshino *et al.* (31). The solid line represents the experimental results of Liu and Peretti (19).

summary, it can be concluded that the expression for $\Delta G_f^\circ[\text{InSb}]$ derived here, Eq. [19], is consistent with other available Gibbs energy determinations, with calorimetric results, and with the reported phase diagram.

A solution model for representing the results.—An equimolar liquid solution of In and Sb exhibits unusual properties near the melting temperature. These properties include anomalous values for the heat capacity (11), viscosity (52), and velocity of sound (53) for temperatures up to 20 K above the melting temperature. Direct x-ray scattering curves for liquid InSb have been measured at 813 K (54, 55) and result in a radial distribution function having a first maximum at 3.2 Å, with a corresponding coordination number of 5.7. Crystalline InSb, on the other hand, exhibits a maximum at 2.80 Å and has a coordination number of 4, thus indicating that the zinc-blende structure is not retained upon melting. In addition, an examination of the radius of the first coordination sphere for both the pure liquid elements and the liquid solution establishes that the nearest neighbors in InSb are atoms of different kinds. Thus, the atoms in liquid InSb tend to form unlike pairs and may even form covalent clusters in a small temperature range above $T_f[\text{InSb}]$.

These considerations suggest that any solution model to be used for the description of the liquid-phase nonidealities of In-Sb mixtures must account quantitatively for the effects of nonrandomness of the thermochemical properties. In addition, the model should adequately represent not just a particular quantity but all of the pertinent data, in this case, the measured component activities along with the reported binary-phase diagram and enthalpy of mixing. The ability of several solution models to meet these criteria has been examined; the details of this comparison are provided elsewhere (56). With the use of a data base consisting of the liquidus measurements of Liu and Peretti (19), the enthalpy of mixing data of Rosa *et al.* (28), and the In activity measurements of this work along with those of Hoshino *et al.* (31) and Chatterji and Smith (32), it was shown that the nonrandom two-liquid (NRTL) equation (57) provided the most consistent representation of the In-Sb liquid phase. The activity coefficient of In as given by the NRTL equation is

$$\ln \gamma_{\text{In}} = x_{\text{Sb}}^2 \left\{ \tau_{21} \left(\frac{\exp(-\alpha_{12}\tau_{21})}{x_{\text{In}} + x_{\text{Sb}} \exp(-\alpha_{12}\tau_{21})} \right)^2 + \tau_{12} \frac{\exp(-\alpha_{12}\tau_{12})}{(x_{\text{Sb}} + x_{\text{In}} \exp[-\alpha_{12}\tau_{12}])^2} \right\} \quad [22]$$

The numerical values of the adjustable parameters were determined by a maximum likelihood algorithm (58) and found to be $\tau_{12} = 3.039 \times 10^3/(T/\text{K}) + 0.913$, $\tau_{21} = -839.6/(T/\text{K}) - 1.823$, and $\alpha_{12} = 0.315$. The standard deviations as estimated by the algorithm were $\sigma_{\tau_1} = 4.8 \text{ K}$, $\sigma_{\Delta H_m} = 134 \text{ J} \cdot \text{mol}^{-1}$, $\sigma_{\alpha_{12}} = 0.016$, and $\sigma_{\tau_{12}} = 0.008$.

Conclusions

Component activities in liquid solutions containing In and Sb were measured with a solid-state galvanic cell and were found to give moderate negative deviations from ideal behavior. The measured activities showed close agreement with other reported EMF activity measurements and support the assumption that the indium ion is monovalent in the fused salt electrolytes used in previous studies. The system exhibited a negative enthalpy of mixing having a maximum near $x_{\text{Sb}} = 0.42$. The combination of these results showed a significant positive excess entropy of mixing. Comparison of the reported phase diagram (19) with various thermodynamic results indicated that the results of Hoshino *et al.* (31) and of this work were consistent, whereas the work of Terpilowski (30) showed marked discrepancies. Furthermore, these calculations supported a value of the enthalpy of fusion of InSb of $49.4 \text{ kJ} \cdot \text{mol}^{-1}$. A new expression for the standard Gibbs energy of formation of solid InSb was derived, with the standard enthalpy and entropy given by

$-35.22 \text{ kJ} \cdot \text{mol}^{-1}$ and $-25.54 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}$, respectively. This result was shown to be consistent with the available $\Delta G_f^\circ[\text{InSb}]$ determinations, the calorimetric investigations, the reported phase diagram, and the activity measurements of this study. Liquid-phase x-ray scattering investigations suggested the tendency of pairing between In and Sb atoms. This observation was quantified with the aid of the nonrandom two-liquid theory. Thus, it can be concluded that the high temperature thermodynamic properties for the solid and liquid In-Sb system are experimentally well defined and consistent.

Thermal Stresses in Heteroepitaxial Beta Silicon Carbide Thin Films Grown on Silicon Substrates

H. P. Liaw^{*1} and R. F. Davis

Department of Materials Engineering, North Carolina State University, Raleigh, North Carolina 27695

ABSTRACT

Microcracks were observed in epitaxial β -SiC thin films grown on (111) Si substrates by chemical vapor deposition (CVD) from SiH_4 and C_2H_4 entrained in H_2 . A one-step process and a more commonly used two-step process were employed. The latter was comprised of an initial chemical conversion of the Si surface, via the deposition of C alone and a subsequent deposition of both C and Si to form the β -SiC film. In contrast, no cracks were revealed in the β -SiC film grown on (100) Si by using either process. However, the growth of high quality, reproducible films occurred only when the two-step technique was used. The resulting thermal stresses in the β -SiC films deposited on both (111) and (100) Si substrates were calculated. The tensile strength of the deposited single-crystal films was estimated to be in the range of 1.88×10^8 - 3.36×10^8 N/m². Possible solutions to minimize crack initiation and growth will be discussed.

The achievement of epitaxial growth of single crystal thin films depends as critically on the substrate material as it does on the growth technique or environment employed during the growth. The ideal substrate for the vapor-phase epitaxial growth of the cubic (zinc blende structure) β -SiC films is obviously a single crystal of the same material, primarily because of the exact matching of the lattice constant and the coefficient of thermal expansion. However, the few β -SiC single crystals currently available (usually obtained from the reaction of molten Si with its graphite container) are very small in size, irregular in shape, and highly twinned. Nominally hexagonal α -SiC single crystals have been successfully employed as substrates in CVD processes below 1873 K (1, 2). However, they are uncommon (usually obtained from a commercial Acheson furnace), small in size, irregular in shape, and, most importantly, they normally contain significant quantities of Al and/or N, which are electrically active in SiC. If the deposition temperatures exceed 1873 K, α -SiC becomes the predominant phase which grows on these crystals (1, 2). Therefore, in order to obtain electronic quality β -SiC single-crystal thin films of larger area, it is presently necessary to employ foreign substrates.

In choosing foreign substrates for heteroepitaxial film growth, one must carefully consider the physical and chemical compatibility between the deposited film and the substrate. Differences in crystalline nature, lattice constant, melting point, vapor pressure, and coefficient of thermal expansion are all of vital importance in the at-

tainment of an epitaxial film. To meet these requirements, the number of potential substrate materials is normally very limited.

Silicon, although not a perfect candidate material, is the next logical choice as a substrate for the epitaxial growth of β -SiC films. It has been employed in this capacity by a number of workers (3-21) because it is chemically compatible with SiC and can be obtained in single-crystal form in ultrahigh purities at reasonable cost. It has also been used in the β -SiC deposition research described herein. However, it does have some major limitations which must be surmounted in order to grow these films in single-crystal form.

One of the constraints associated with the use of Si for the growth of SiC is the maximum deposition temperature's being limited by the melting temperature of Si (≈ 1693 K). Another problem is the thermal tensile stresses introduced into the film upon cooling from the high deposition temperature. Thermal stresses and resultant fracture have also been observed in several other heteroepitaxial film and substrate combinations, e.g., Si or AlN on sapphire (22, 23) and Si on spinel (24). The following paragraphs discuss the results of the characterization and calculations of the residual stresses present in the β -SiC film/Si substrate combination after cooling to room temperature.

Film Growth

The single-crystal Si substrates employed in this research were n-type and p-type, with reported resistivities in the range of 37-420 Ω -cm and 10-50 Ω -cm, respectively. All were 1° or 6° off axis from the (100) plane and 2° or 4° off axis from the (111) plane.

¹Present address: Advanced Micro Devices, Incorporated, Sunnyvale, California 94086.

A cold-wall, RF-heated, barrel-type CVD system containing a SiC-coated graphite susceptor was employed for the deposition. The chamber pressure, gas flow rates, and temperature were independently and electronically controlled to prevent fluctuations in nucleation rate. Reproducible β -SiC films were obtained by a two-step process. Initially, C was deposited on and reacted with the Si substrate to form an approximately 15 nm thick chemically converted layer containing Si and C in progressively varying ratios as a function of depth.² This was followed by the deposition of both Si and C to form the β -SiC films. This procedure allowed epitaxy of the films on the off-axis oriented (111) and (100) Si substrates.

The chemical conversion noted above was conducted from room temperature to a temperature above 1523 K³, using a 1 sccm flow of C₂H₄ (ethylene) in a 3000 sccm flow of H₂ under a total pressure of 0.1 MPa. The β -SiC deposition was conducted within the temperature range of 1590-1610 K, using 2, 1, and 3000 sccm flow rates for SiH₄, C₂H₄, and H₂, respectively, under a total pressure of 0.1 MPa⁴. The final thickness of the deposited β -SiC films was in the range of $1.0-7.5 \times 10^{-6}$ m, depending on the duration of the deposition.

The existence of the epitaxial growth of β -SiC as the only SiC polytype and the single crystallinity of these deposited films were determined by Laue transmission and pole figure x-ray diffraction procedures, as well as reflection and transmission electron diffraction. The characterization of the surfaces and the results of the fracture process caused by thermal stresses during cooling were conducted using optical and scanning electron microscopy techniques. Details of the equipment, instrumentation, and employment of these procedures are presented in Ref. (25).

Results

At the outset of this research, deposition of β -SiC on (111) and (100) Si was conducted without the initial chemical conversion process. Although the resulting films were usually monocrystalline, especially if deposited at the higher growth temperatures, the surfaces of the films were frequently unacceptable in terms of growth pit density and roughness and were nonreproducible. This was especially true of films grown on (100) Si. Additional problems were prevalent in the (111) films.

As the conditions for the occurrence of epitaxy and single crystallinity of the β -SiC films grown on (111) Si were improved by judicious changes in the deposition parameters, microcracks began to be observed in the films, as shown in Fig. 1. The presence of a converted (111) layer often mitigated the severity and depth of the fracture process, but did not prevent it. These cracks were determined to be along the $\langle 110 \rangle$ and to be parallel to two of the sides of the triangles, which formed in the Si surface at the initiation of the deposition and which frequently migrated through the film. Crack lines were seldom found in the third direction. This cracking in the films was also frequently seen to extend into the Si substrate, as revealed in Fig. 2. At no time was crack formation observed in the β -SiC films grown on (100) Si substrates, regardless of the process method employed. However, the only reproducible films of sufficient quality for microelectronic purposes were grown on chemically converted (100) Si, as described in Ref. (25).

Figure 3 contains an SEM micrograph of the fractured cross section of the β -SiC film and the (111) Si substrate. The fracture lines shown in the Si were realized as a result of the fracture process used to prepare the SEM

²An extensive characterization study of this converted layer is now ongoing and will be reported in the near future.

³The temperature of chemical conversion varies with time because the susceptor is heated rapidly from room temperature and does not reach equilibrium during the conversion process.

⁴Although it is common, especially in the chemical deposition of polycrystalline SiC, to use a methylchlorosilane as the input gas, these gases decompose into C and Si containing gases which decompose at different rates in the temperature range employed in the present research. As a result, SiC and free Si or free C are normally produced.

Fig. 1. Crack lines on the top surface of a (111) β -SiC thin film grown on a (111) Si substrate using the two-step process. (a) reveals the density of the crack lines, and (b) shows that the crack lines are parallel to the sides of the triangular surface defects.

Fig. 2. An example of a crack generated during cooling as a result of thermal stresses at the (111) β -SiC/(111) Si interface. Note the extension of this fracture through the film, as well as into the substrate.

Fig. 3. SEM micrograph of a fracture cross-section of the (111) β -SiC grown on (111) Si substrate. Note the increasing curvature of the Si fracture lines resulting from the increasing compressive stresses in this material as one gets nearer the Si/SiC interface. Similar results are found in (100) Si substrates.

sample; however, their curvature is indicative of the residual compressive stresses present at room temperature in this material, especially near the Si/SiC interface. Additional higher magnification SEM pictures taken in cross section from the left (Fig. 4a) and right (Fig. 4b) sides of the same sample show the considerable but opposite curvature of the fracture lines resulting from the tensile stresses in the (111) β -SiC film. The degree of bending of the fracture lines is an indication of the relative magnitudes of the stresses in the film and in the substrate.

Another indication of the stress which the SiC film experiences after cooling is revealed by the satellite spots along the zone axes in the transmission Laue pattern shown in Fig. 5 and 6. The samples for Laue studies were prepared by selectively etching a 0.01m diameter center area of the Si substrate, using a mixture of HF and HNO₃.

Fig. 4. The top surface and the fracture cross section of an epitaxial β -SiC thin film grown on a (111) Si substrate. (a) is taken from the left-hand side of the sample, and (b) is taken from the right-hand side of the same sample. Similar but less curved fracture lines are found in (100) Si and (100) β -SiC substrates and films. Bar = 10 μ m.

Fig. 5. (a) x-ray transmission Laue pattern and (b) the indexes of the resulting spots of an epitaxial β -SiC film grown on a (111) Si substrate.

Fig. 6. (a) x-ray transmission Laue pattern and (b) the indexes of the resulting spots of an epitaxial β -SiC film grown on a (100) Si substrate.

The remainder of the substrate was covered in an acid insoluble mounting wax which could be removed with acetone. A residual stress was maintained in the film, as shown in the Laue patterns. The films were found to be transparent, with a light yellowish color typical of high purity crystals and films of this material.

It is obvious that the Laue spots for the (111) and (100) β -SiC films have the characteristic 3-fold and 4-fold symmetries, respectively. Because of the difficulty of printing the entire patterns, the additional but weaker spots, plotted from the x-ray negative, are shown in Fig. 5b and 6b. Most of the spots could have been routinely indexed. However, the (111) pattern contained twelve spots, in three groups of four which were very close to the (111) spots which were more difficult to identify. Further investigations showed that these satellite-like spots were on three zone axes and on two rings which corresponded to the (111) β -SiC reflections from the K_α and K_β characteristic radiations of the Cu target. Normally, bending of

crystallographic planes as a result of residual stresses causes streaks along the zone axis. However, because a Cu target was used to produce the "white" radiation, wherever the reflection from the characteristic radiation satisfied Bragg's law, a spot occurred instead. Thus, these satellite spots note the existence of residual stresses in the grown (111) film.

The (100) pattern also contained extra spots very close to the (221) spots. In this case, it was determined that the extra spots were on two zone axes and on two rings which corresponded to the (220) β -SiC reflections from the K_α and K_β characteristic radiations of the Cu target. Again, this indicated the existence of curved planes, which formed as a result of stresses in the (100) β -SiC films.

Discussion

In choosing a substrate for thin film growth, it is desirable to have one which contracts the same as or more than the film after cooling from the deposition temperature. This will normally prevent cracking because the film is either unstressed or in compression. Unfortunately, as shown in Table I, the thermal expansion coefficient of β -SiC is greater than that of Si; thus, upon cooling, the resulting film will be in tension, as noted above, which is the stress state which leads to extended crack formation in brittle materials, as shown in Fig. 1 and 2. In the present system, this is compounded by the fact that the expansion coefficient for β -SiC increases with temperature to a greater extent than Si.

As also shown in Table I, there is an additional very large lattice mismatch of $\approx 25\%$ between β -SiC and Si. This may be accommodated by the creation of a large number of misfit dislocations at the interface. However, the pile-up of these dislocations can result in the accumulation of extra half-planes and the formation of additional microcracks.

The thermal stress (σ_f) in the CVD film can be calculated using the following equation (28)

$$\sigma_f = \Delta\alpha \cdot \Delta T \left(\frac{E}{1 - \nu} \right) \quad [1]$$

where $\Delta\alpha$ is the difference in the coefficient of thermal expansion between the film and the substrate, ΔT is the difference between the growth temperature and the room temperature, E is the Young's modulus of the film, and ν is the Poisson's ratio of the film.

It has been proven by Brantley (29) that the effective elastic constants, $E/(1 - \nu)$, are invariant for all directions within the (100) and the (111) planes. They can be expressed as

$$\left(\frac{E}{1 - \nu} \right)_{(111)} = \frac{6}{4S_{11} + 8S_{12} + S_{44}} \quad [2]$$

and

$$\left(\frac{E}{1 - \nu} \right)_{(100)} = \frac{1}{S_{11} + S_{12}} \quad [3]$$

Table I. Lattice constant and the coefficient of thermal expansion for β -SiC (26) and Si (27)

Properties	β -SiC	Si
Lattice constant (nm)	0.4359	0.5430
Coefficient of thermal expansion (cm/cm K)	3.8×10^{-6} at 473 K 4.3×10^{-6} at 673 K 4.8×10^{-6} at 873 K 5.2×10^{-6} at 1073 K 5.8×10^{-6} at 1273 K 5.5×10^{-6} at 1673-2073 K	2.5×10^{-6} at 300 K 3.1×10^{-6} at 400 K 3.5×10^{-6} at 500 K 3.8×10^{-6} at 600 K 4.1×10^{-6} at 700 K 4.3×10^{-6} at 800 K

where S_{ij} are the values of the elastic compliance. Sometimes, the elastic stiffness values (C_{ij}) are readily available instead of S_{ij} values for certain materials. The conversion of the C_{ij} values to the S_{ij} values can be achieved according to the following equations

$$S_{11} = \frac{C_{11} + C_{12}}{(C_{11} - C_{12})(C_{11} + 2C_{12})} \quad [4]$$

$$S_{12} = \frac{-C_{12}}{(C_{11} - C_{12})(C_{11} + 2C_{12})} \quad [5]$$

and

$$S_{44} = \frac{1}{C_{44}} \quad [6]$$

Table II provides the values of elastic stiffness and compliance for both β -SiC (26) and Si (29). The invariant values of $E/(1 - \nu)$ for directions within the (111) and (100) planes are summarized in Table III. Values for Si are also listed for reference in Table III.

If we take the average coefficient of thermal expansion of β -SiC in the temperature range of 293-1673 K to be $4.9 \times 10^{-6} \text{ K}^{-1}$ and that of Si to be $3.9 \times 10^{-6} \text{ K}^{-1}$, the estimated thermal stress using the above equations, in the β -SiC film will be $3.36 \times 10^8 \text{ N/m}^2$ on a (111) Si substrate and $1.88 \times 10^8 \text{ N/m}^2$ on a (100) Si substrate, assuming the growth temperature is 1603 K. It is clear that using a (100) Si substrate instead of a (111) Si substrate will reduce the thermal stress in a β -SiC film by almost half. Because the β -SiC films on a (111) Si substrate contain cracks and those on a (100) Si substrate do not, the tensile strength of the deposited single crystal β -SiC thin films is estimated to be in the range of 1.88×10^8 - $3.36 \times 10^8 \text{ N/m}^2$. Furthermore, it has been reported by Bradt *et al.* (30) that the tensile strength for NC 203 hot-pressed polycrystalline SiC⁵ is approximately $3.10 \times 10^8 \text{ N/m}^2$. Although possibly fortuitous, this is in agreement with the calculated range of values for the parameter for the pure β -SiC single-crystal films grown in this research.

The off-axis orientation of the (111) Si substrates may also affect the magnitude of the resulting thermal stresses in the β -SiC film. It has been found in this study that Si wafers sliced at an angle of 4° off the (111) orientation have less cracks than similar wafers at an angle of 2° off this orientation. The exact reason for this phenomenon is

⁵Norton Company, Worcester, MA. This material contains approximately 1.5% Al_2O_3 as a sintering aid, 2.5%W from the comminution process, and $\leq 0.05\%$ each of Ti, Co, Ca, and Mg. It fractures in a transgranular mode.

Table II. Values of elastic stiffness^a and compliance^b for both β -SiC and Si

	β -SiC	Si
C_{11}	2.89	1.657
C_{12}	2.34	0.639
C_{44}	0.554	0.7956
S_{11}	1.256	0.768
S_{12}	-0.562	-0.214
S_{44}	1.805	1.26

^a In units of 10^{11} N/m^2 .

^b In units of 10^{-11} N/m^2 .

Table III. Calculated values for the effective elastic constant^a $E/(1 - \nu)$ for both β -SiC and Si

	$(E/(1 - \nu))$ (111)	$(E/(1 - \nu))$ (100)
β -SiC	2.572	1.441
Si	2.290	1.805

^a In units of 10^{11} N/m^2 .

not known at this time. However, it may be related to the fact that Young's modulus has the largest value along the (111) direction.

The use of long cooling times (up to 3.6×10^3 s) after deposition does not solve the problem of cracking. The use of thinner Si substrates has also been recognized as a possible solution because thermal stresses can be partially relieved by warping of the entire substrate/film combination. However, it proves experimentally difficult to obtain a sufficiently thin substrate (estimated to be the same order of the grown film) which can be handled to conduct the additional processing steps necessary for device fabrication. Moreover, a slight pressure from the back side of the deposited sample will tend to break the film. Therefore, the use of very thin substrates is not a desirable approach to solving the problem of crack initiation in this system.

Deleterious lattice misfit effects can often be reduced by using compositionally graded layers (31) to change the lattice constant, in either small abrupt steps or in a continuous manner, from its initial value (which typically matches the substrate) to that of its final value. This method necessitates the existence of a wide range of solid solutions among the various components in the substrate and the thin film system. It has been used extensively in depositing III-V semiconductor materials. Unfortunately, no solid solution between Si and C exists which could be used to produce a graded layer for this purpose. Furthermore, it has been reported (32) that in order to grow a truly crack-free structure which is under tension (*e.g.*, $\text{GaAs}_{0.6}\text{P}_{0.4}$ on GaAs), it is necessary to use a graded region about $30 \mu\text{m}$ in thickness. This is impractical because the total thickness of the desired epitaxial film is usually much less than $30 \mu\text{m}$ and is difficult in our RF-heated system because the temperature of the growth surface decreases as the film thickness increases.

As inferred above, if a foreign substrate must be employed, the most viable solution for the crack initiation problem in the present research should be the use of a substrate with a coefficient of thermal expansion equal to or larger than that of β -SiC to ensure that the film will be unstressed or under only slight compression after cooling. Sapphire (Al_2O_3) is one material which falls into this category, with the coefficient of thermal expansion being $8.40 \times 10^{-6} (\text{K}^{-1})$ at 25° - 800°C (33). However, Al_2O_3 tends to decompose slightly at the temperatures normally employed for the epitaxial growth of β -SiC, and it may result in autodoping of the growing film (Al is a p-type dopant in SiC). Thus, its usefulness may be limited.

Summary

Single-crystal thin films of β -SiC have been successfully grown on (100) Si using a two-step process of initial chemical conversion of the Si surface via a Si-C reaction and subsequent deposition of both Si and C from SiH_4 and C_2H_4 , respectively, carried in H_2 . Similar procedures using (111) Si substrates result in microcracking formation in the films after cooling. Characterization by optical microscopy and SEM x-ray diffraction techniques reveal the extent of microcracking and residual stress in the substrate/thin film system. Subsequent thermal stress calculations reveal that the stress in the (100) β -SiC films is approximately half that in the (111) films. Furthermore, because of the absence of microcracking in the (100) films, the tensile strength of these films is estimated to be between 1.88 and $3.36 \times 10^8 \text{ N/m}^2$.

Technical Note

Densified Deposited Oxide Films for Surface Passivation

Wendell D. Eades, Anthony M. McCarthy,* and Richard M. Swanson**

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

Deposited silicon dioxide films have been investigated as an alternative to thermal oxide for passivation of the silicon surface. These films are of interest in the fabrication of solar cells and integrated circuits because they offer decreased junction movement and good interface properties without thickness constraints (1, 2). We have investigated the possibility of hybrid deposited-thermal silicon dioxide films, and we have compared them to both solely thermal and solely deposited oxide films.

Samples were fabricated from a quartered n-type Czochralski-grown <100> silicon wafer with a doping of $6 \times 10^{14} \text{ cm}^{-3}$. A back-side predeposition of phosphorous was performed to ensure good ohmic contact for electrical measurements. All samples were given an RCA clean (3), including a 50:1 HF dip immediately preceding the final rinse, prior to the first deposition or oxidation. Sample 1 was thermally oxidized at 1000°C for 90 min in O_2 with a 2% HCl ambient derived from trichloroethane (4), and annealed in argon at that temperature immediately afterwards. Sample 2 was oxidized at 1000°C for 20 min in a low partial pressure oxygen ambient (2% O_2 , 0.5% HCl in argon). After an anneal in argon at the oxidation temperature, it was brought to 850°C and pulled slowly. The thermal oxide thickness was 100Å. Silicon dioxide was then deposited in an Applied Materials AMS-2600

Table I. Oxide thickness, flatband voltage, and midgap interface state densities for the four types of oxide investigated

Sample	Oxide type	Oxide thickness (Å)	Midgap interface trap density ($\text{cm}^{-2} \text{eV}^{-1}$)	Flatband voltage (V)
1	Thermal	905	1.1×10^9	-0.03
2	Deposited on thermal	910	1.0×10^9	-0.01
3	Deposited	830	1.4×10^9	0.14
4	Thermal under deposited	1060	1.2×10^9	0.00

Table II. Generation lifetime summary for the four types of oxide investigated

Sample	Oxide type	Average lifetime (μs)	Standard deviation
1	Thermal	318	14
2	Deposited on thermal	197	23
3	Deposited	660	149
4	Thermal under deposited	528	33

Fig. 3. Oxide breakdown field values for oxide deposited onto a bare silicon surface and densified in argon at 1000°C.

Fig. 2. Oxide breakdown field values for oxide deposited on top of a previously grown 100Å film and then densified in argon at 1000°C.

Fig. 4. Oxide breakdown field values for thermal oxide grown at 1000°C in O₂ with 2% HCl underneath a previously deposited oxide film.

Silox Reactor at a temperature of 450°C and atmospheric pressure. Flow rates used were 90 liter/min N₂, 350 cm³/min O₂, and 35 cm³/min SiH₄. This oxide was then densified (1) in argon for 20 min at 1000°C. For sample 3, about 1200Å of oxide was deposited onto bare silicon and later densified at 1000°C in argon for 20 min. Sample 4 also received 1200Å of deposited oxide onto a bare surface, but was densified and thermal oxide grown underneath it simultaneously. The densification/oxidation was performed at 1000°C for 15 min in O₂ with a 2% HCl ambient. An anneal in argon followed. At the conclusion of each sample's argon anneal, it was cooled to 650°C (3°-6°C/min) in argon and pulled slowly to avoid the possibility of quenched-in defects (5). Following removal of any oxide on the back sides of the samples, 1 μm of aluminum was deposited on both sides of the wafers by E-beam evaporation. Capacitors of area 0.0036 cm² were defined photolithographically following a postmetallization anneal in forming gas.

Oxide thickness, flatband voltage, and the density of interface traps were measured using the high-low frequency capacitance method (6). The results for typical capacitors are presented in Table I. The densified deposited oxide has slightly less positive fixed charge than the other samples, all of which have a thermally grown oxide right at the interface. Interface trap densities for all samples were in the 1-2 × 10⁹ cm⁻² eV⁻¹ range. Using the error analysis of Nicollian and Brews (6), we estimate error bars of 1 × 10⁹ cm⁻² eV⁻¹ for the midgap interface state densities. Hence, the densities measured here must be considered equal to within the accuracy of the method.

Measurements of the generation lifetime of the samples were made using the modified linear sweep method (7), as implemented in the program GLiP4 (8). No correction was made for the perimeter current contributions. Aver-

age values and standard deviations for the lifetime are given in Table II. The deposited oxide sample shows the greatest mean lifetime, but it also has the poorest uniformity. Comparison of the oxide preparation conditions suggests the presence of HCl is a critical factor in uniformity. With regard to average lifetime, we note the samples receiving a thick deposited oxide initially (samples 3 and samples 4) had a higher value than those thermally oxidized initially (1 and 2).

Oxide breakdown measurements were also performed on all samples. The voltage was increased at a rate of 50 V/s, and the breakdown voltage was defined to be the bias at which the leakage current first exceeded 2 μA. Fifty capacitors spaced over a 1 cm² area in the center of each wafer were probed in order to obtain a distribution of values. To compare the intrinsic breakdown strength of each form of oxide, we discarded the five worst values on each sample and calculated the average breakdown field and standard deviation, σ . The thermal oxide was found to have both the greatest average breakdown field (8.9 MV/cm) and the tightest distribution ($\sigma = 0.2$ MV/cm) and the densified deposited oxide the poorest average (8.4 MV/cm) and worst scatter ($\sigma = 0.4$ MV/cm). Both hybrid oxide samples had averages of 8.6 MV/cm and standard deviations of 0.3 MV/cm. Histograms of all measured data are presented in Fig. 1-4.

Based on the results presented here, we conclude that the growth of a thin layer of thermal oxide underneath a previously deposited oxide film is a promising alternative to thermal oxide for thick film high lifetime applications. Furthermore, improved uniformity and higher throughput could likely be achieved using low pressure rather than atmospheric deposited oxide, and merits investigation.

The Equilibrium Constant for the Reaction $H_2S + 3H_2O + (Li_{0.66}K_{0.34})CO_3 \rightleftharpoons 4H_2 + CO_2 + (Li_{0.66}K_{0.34})SO_4$ at Elevated Temperature

S. W. Smith and S. M. Kapelner
(pp. 405-407, Vol. 130, no. 2)

David A. Shores and Mary L. Orfield:¹ The subject paper has described an experimental study of the sulfation of molten 62%Li₂CO₃-38%K₂CO₃ by reaction with H₂S (in the ppm range) in a mixture of H₂-H₂O-CO-CO₂. The compositions of both the gas and the salt were analyzed. From these data, along with thermodynamic data from the literature, the authors have calculated the Gibbs energy of formation of 0.66Li₂SO₄-0.34K₂SO₄. However, their results and the calculated values of Gibbs energy may be questioned on two issues: (i) the gas compositions reported in their Table II do not correspond to equilibrium mixtures, and (ii) mole fractions have been used to represent activities in the molten salt mixtures.

In their experimental arrangement, the authors attempted to ensure that the gas equilibrated with the salt and that the gas itself reach equilibrium. The predominant species in the gas are H₂-H₂O-CO-CO₂; *i.e.*, the concentration of other species, such as H₂S, reaction products from H₂S, or vaporized salt species, are quite small in comparison with the major species. Therefore, the equilibrium represented by the water-gas-shift reaction.

may be used to check approximately whether the measured gas compositions correspond to equilibrium at the temperature of the gas-salt reaction. Values of the equilibrium constant for the above reaction were calculated from well-established thermodynamic data² at the temperatures of the gas-salt reaction. They are shown in Table I. Also listed in Table I are values of the equilibrium constant calculated from the experimental gas compositions in Table II of Smith and Kapelner's paper. The experimental equilibrium constants are significantly different from the expected values. The former correspond to equilibrium at temperatures far below the temperatures of the

Table I. Equilibrium constants for the water-gas-shift reaction

Run	Temp. (°F)	Calculated K_{eq}	Measured K_{eq}
1	1096	0.324	2.15×10^{-3}
2	1200	0.434	5.74×10^{-3}
3	1200	0.434	5.74×10^{-3}
4	1200	0.434	6.63×10^{-3}
5	1200	0.434	6.07×10^{-3}
6	1306	0.564	2.32×10^{-2}

gas-salt reactions (in the range 300°-550°F). One possible explanation is that in withdrawing samples of gas for analysis the water-gas-shift reaction continued within the nickel tube as the gas cooled down to room temperature. In any case, the gas compositions listed in Smith and Kapelner's Table II are not appropriate to the reaction being studied, but appear to have been used to calculate the equilibrium constant listed in Table I.

The existence of compounds in the binary phase diagrams of K₂CO₃-Li₂CO₃ and K₂CO₃-K₂SO₄ suggest that activity coefficients in the salt mixtures under consideration will not be unity. However, the authors have used mole fractions to represent activities in the equilibrium constants listed in Table I. Indeed, from the work of Pelton *et al.*,³ one can estimate the activity coefficient of K₂CO₃ for the melt in run 3 (Table I) to be 0.033. Using such data,³ one can also calculate the Gibbs energy of formation for the liquid mixture 0.66Li₂SO₄-0.34K₂SO₄, taking activity coefficients into account. To cite one example, the value obtained at 649°C (1200°F), 252,200 cal/mol, is significantly smaller than the comparable value, 272,700 cal/mol, reported in Smith and Kapelner's Table III. In view of these criticisms, the derived values of the Gibbs energy of formation of 0.66Li₂SO₄-0.34K₂SO₄ are questionable. The values calculated from the data of Pelton *et al.*³ appear to be more reliable.

S. W. Smith and S. M. Kapelner:⁴ In the discussion of Shores and Orfield above, the calculated values of the Gibbs free energy are questioned on the bases that the gas compositions do not correspond to equilibrium mixtures and that mole fractions were used in place of activities. Some comment on each of these questions is in order.

The gas mixtures indeed were not in equilibrium, and no attempt was made to reach equilibrium. On the contrary, the experimental apparatus was designed to minimize the shift reaction by keeping the stainless steel inlet tube as short as practicable. It had been shown earlier by Vogel⁵ that several feet of tubing is needed to reach equilibrium in this temperature region. Additionally, it was expected that poisoning by adsorbed H₂S on the surface of the tube would further reduce the amount of shift. The measured compositions indicated that the maximum shift was only a few percent, as expected. Gas samples were taken through 99.98% Al₂O₃ tubes as well as the Ni tubing reported in the paper without altering the results. It was on this basis that the measured gas compositions (essen-

³A. D. Pelton, C. W. Bale, and P. L. Lin, "Calculation of Thermodynamic Equilibria in the Carbonate Fuel Cell," Vol. 1, Final report to the U. S. Department of Energy, Contract no. DE-AC02-79ET15416, May 1981.

⁴United Technologies Corporation, Power Systems Division, South Windsor, Connecticut 06074.

⁵W. M. Vogel and C. D. Iacovangelo, *This Journal*, **124**, 305 (1977); W. M. Vogel, Personal communication.

tially the same as the input compositions) were used to calculate the values reported in our Table III.

With respect to the use of mole fractions to represent activities in the calculation of the equilibrium constants, there is no doubt that when reliable values for activities are available they should be used to calculate thermodynamic constants. If the activities are sufficiently well known over the range of the experiment, it would be appropriate to use them to recalculate the tabulated equilibrium constants. It should be pointed out, however, that the practical use of data of this type is usually to calculate the sulfate/carbonate composition for a given set of experimental conditions. If $K_{(\text{act})}$ is known, the composition may be calculated over any range where the activities are available. If $K_{(\text{mol})}$ is known, the correct composition may also be calculated, but one is at hazard if attempting to extend the range much beyond the original data.

Pore Size Distribution in Porous Silicon Studied by Adsorption Isotherms

G. Bomchil, R. Herino, K. Barla, and J. C. Pfister
(pp. 1161-1164, Vol. 130, no. 7)

V. P. Bondarenko, A. M. Dorofeev,⁶ and L. V. Tabulina:⁷

In the paper under discussion, the adsorption isotherms method was used to investigate porous silicon. Interesting experimental data on specific surface and pore size distribution are presented. However, the interpretation of these results is ambiguous; therefore, it is necessary to make some remarks.

The BJH method⁸ was used by the authors to determine pore size distribution in the porous silicon. By this method, the distribution is obtained from the desorption isotherms, a technique valid only for cylindrical pores.⁹ For porous silicon, interpretation of the experimental results is difficult, owing to the complex, noncylindrical shape of pores. In fact, as shown in their Fig. 2, the desorption isotherm (for example, for a porous silicon sample, corresponding to a forming current density of 80 mA/cm²) is sharper than the adsorption one. Isotherms of this shape are typical for pores with narrow regions.^{9,10} Analyzing the experimental data,¹¹ we can infer that the above-mentioned narrow regions are located near the surface of the porous silicon layer, e.g., the pores are bottle-like. In our opinion, the decrease of the apparent density of porous silicon through the thickness (their Fig. 5) is an additional argument for bottle-like shaped pores.

We have found that plasma etching of porous silicon up to the depth of 1 μm helps to achieve the equilibrium pressure value more rapidly during the isotherm procedure. Obviously, it may be explained by the removal of the subsurface dense layer of porous silicon.

Considering the facts above, we can assume that the pore size distribution shown in their Fig. 4 yields reliable information for the subsurface layer, but not for the entire volume of the porous silicon.

Another point concerns the electrolyte composition for silicon anodic treatment. Ethanol-aqueous hydrofluoric solution was used as electrolyte rather than the conventional aqueous solutions. Actually, the use of an alcoholic electrolyte results in a better homogeneity of the porous silicon layer. However, the results of our experience lead us to assert that the proposed electrolyte is not suitable for long-term use. Analysis allows us to conclude that electrolyte which has volatile solvents change in time be-

cause of evaporation. Moreover, gas evolution and the increase of electrolyte temperature at high forming current density result in enhanced alcohol evaporation.

The last point is connected with the specific surface value of porous silicon samples. As seen in their Fig. 2, the adsorption isotherm of the porous silicon sample, corresponding to the forming current density of 240 mA/cm², is located higher than the one of 80 mA/cm². However, the higher adsorption corresponds to the higher specific surface.⁹ It contradicts the data of their Table I, where the specific surface 205 m²/cm² for the sample treated at $j = 240$ mA/cm² and 225 m²/cm² for $j = 80$ mA/cm² are presented.

G. Bomchil, R. Herino,¹² and J. L. Ginoux:¹³ The comments by Boudarenko, Dorofeev, and Tabulina (BDT) on our paper are much appreciated. In particular, the contradiction that they point out between the results in Table I and isotherms presented in our Fig. 2 allow us to realize that a normalization error in the plot of the adsorbed nitrogen volumes V_{N_2} was present, so that the adsorbed gas scales were not the same for each curve. Exact quantitative results are obtained when all plotted values of V_{N_2}/V_p are multiplied by a factor (the sample weight), which is 1.19 for the sample formed at 80 mA/cm² (full line) and 1.75 for the sample formed at 240 mA/cm² (dotted line). Corrected curves are shown on Fig. 1, and are in agreement with data presented in Table I and Table II in the original paper.

The main point of the BDT remarks concerns the relation between the isotherm shape and the geometrical pore shapes. Let us briefly recall that in the classical classification,¹⁴ type A isotherms correspond to cylindrical pores (radius r_n) open at both ends. However, tubular tubes containing widened parts where radius r_w is less

than $2r_n$ or complex pores system consisting of randomly connected tubes of various diameters will exhibit the same shape of isotherm. On the other hand, type E is characteristic of ink-bottle-shaped pores, with $r_n < 2r_w$. For type A isotherms, the desorption branch is commonly used for the determination of the pore radius distribution. For type E isotherms, Everett¹⁵ concludes that the adsorption branch is to be preferred. In the case of porous silicon, the obtained isotherms present an intermediate shape between type A and E; this suggests that we are in presence of neither perfect cylindrical pores, nor ink-bottle-shaped pores. Anyway, referring to Mikhail and Robens,¹⁶ it is very difficult to classify an actual pore system on the only basis of the theoretical isotherm shapes.

As stated in our paper, the pore radius distributions were obtained from the desorption branch of the isotherm by using the BJH analysis. The same calculations were performed using the adsorption branch, but results were not plotted as this analysis leads to pore sizes smaller just by 10% and presents the same relative behavior for the radius distribution of the different samples. From a practical point of view, the use of the adsorption or desorption branch of the isotherm leads to the same classification of porous silicon samples prepared in different electrochemical conditions.

Coming back to the actual pore shapes, we believe that our porous silicon samples consist in a complex system of interconnected tubular pores, with a few proportions of widened parts where $r_w > 2r_n$. Two arguments can support this description. First, it appears that the radius corresponding to the maximum of the distribution curves is only 15-30% less than the value of the most frequent pore radius defined by $r = 2V_s/S_{BET}$, where V_s is the porous volume and S_{BET} the surface area of the sample. This indicates that our samples are mostly formed by cylindrical pores with similar radius. In addition, the presence of hysteresis loops in our isotherms indicates that these tubular pores are interconnected. A second argument is given by transmission electron microscopy (TEM) cross-sectional photographs of porous layers that we have recently obtained.¹⁷ An example is shown Fig. 2, where details of the sample structure can be seen, with empty spaces appearing black in the porous structure. The sample, prepared at a current density of 80 mA/cm², presents pores with a mean orientation perpendicular to the surface and to the interface with bulk silicon. Pore dimensions are quite uniform along the whole thickness of the layer. This is confirmed by other observations near the surface or in other parts of the sample which present the same pore dimensions. The structure is not formed by perfect silicon rods and cylindrical holes, but presents a distribution of lateral branches. The length of these branches is no more than a few times the pore diameter. Only from TEM observations, a quite narrow pore size distribution can be expected, with diameters ranging between 50 and 100Å, which is in excellent agreement with the value determined by adsorption isotherms.

BDT description of porous silicon appears quite different from ours, as they assume the presence of very narrow necks located near the surface of the layer. As such surface sublayer cannot be seen by TEM or inferred from isotherms, we have performed plasma etching of porous samples in the same way as reported by BDT. Porous silicon samples 20 μm thick were prepared in exactly the same electrochemical conditions, and then etched in a SiF₆ plasma down to 1.6 and 6.6 μm. After analysis in the same conditions, no difference can be seen in the isotherms obtained for etched and unetched samples: the ra-

Fig. 2. TEM dark field cross-sectional photograph of the porous silicon film (1) and the silicon substrate (2).

dius distribution does not change with depth. Moreover, we did not observe any differences in kinetics and time required to reach the equilibrium pressure. Consequently, the results presented in our paper do yield reliable information for the whole volume of the porous layer. The assumption of ink-bottle-shaped pores in our samples can be rejected. The slight decrease with depth in the porous silicon density which was observed only in the case of the lowest current density (10 mA/cm²) cannot be related to drastic changes in the pore dimensions.

Consequently, it seems that the differences between our measurements and that of BDT have to be related to the preparing conditions of the samples. The porous layers obtained in alcoholic electrolytes present much better homogeneity and crystalline quality than layers prepared in conventional aqueous electrolytes.¹⁸ Conversely to BDT experience, we have found no difficulties using alcoholic electrolytes, providing that elementary precautions are taken: the cell is covered, the electrolyte is changed for each sample, the solution is carefully stirred. A crude calculation indicates that gas evolution during electrolysis cannot evaporate noticeable quantities of ethanol, even if the gas is saturated. However, at the highest current density, the electrolysis times are quite short, and the slight increase of the electrolyte temperature which occurs does not provoke drastic changes in the electrolyte composition. In our opinion, there are only advantages in using alcoholic solutions in the preparation of porous silicon layers.

Electrochemistry of Coal Slurries

II. Studies on Various Experimental Parameters Affecting Oxidation of Coal Slurries

Patrick M. Dhooge and Su-Moon Park
(pp. 1029-1036, Vol. 130, no. 5)

H. G. Linge:¹⁹ Dhooge and Park have analyzed the kinetics of coal oxidation from the anode current (*i*) of slurried coal in ferric sulfate or ceric sulfate anolytes (total metal

ion concentration C). Their analysis and conclusion are invalid, since the coal oxidation is a mediated electrolysis reaction in these analytes.^{20,21} The anode current is therefore primarily determined by the anolyte concentration (C_r) of Fe(II) or Ce(III)

$$i = F k_a A C_r \quad [1]$$

where F is the Faraday constant, k_a a first-order rate constant, and A the anode area. For a limited time interval, the rate of coal oxidation (R_o) is dependent only on coal characteristics and the anolyte redox potential^{20,21}

$$R_o = R_c w (C_o/C_r)^\beta \quad [2]$$

where R_c is a coal characteristic, w the coal weight, C_o the anolyte concentration of Fe(III) or Ce(IV), and the fraction β is an apparent charge-transfer coefficient. The anode current is a different function than R_o of the system parameters, even at steady state when $R_o = F^{-1}i$. This is seen by combining Eq. [1] and [2] with $C = C_o + C_r$, providing the general relationships

$$\begin{aligned} i &= Z ((I - i)/i)^\beta \\ Z &= F R_c w \\ I &= F k_a A C \end{aligned} \quad [3]$$

where Z is a coal characteristic and I a system characteristic. I equals the maximum i value attainable when all anolyte iron (cerium) is present as Fe(II) and Ce(III) but is not directly dependent on the coal properties.

Simplified analytical solutions to Eq. [3] are possible for (i) high and (ii) low coal reactivities in the anolyte.

By high coal reactivity, we mean that sufficient to limit any buildup of oxidant from the electrode reaction. Hence, $C_r \sim C$, $i \sim I$ in Eq. [3] and, therefore

$$i = I(1 - [I/Z]^{1/\beta}) \quad [4]$$

valid for $Z > I$, which provides a more explicit definition of "reactive" coal.

By low coal reactivity, we mean that enabling significant buildup of oxidant until $C_o \sim C$, i.e., $i < I$ in Eq. [5]. Therefore

$$i = Z^{1/\beta+1} I^{\beta/\beta+1} \quad [5]$$

valid for $Z < I$, which provides a more explicit definition of "unreactive" coal.

Inspection of Eq. [4] reveals immediately that i is practically independent of Z for reactive coals, especially for small β values. Coal type and weight have then little influence on the anode response, but i is almost proportional to anode area and anolyte metal concentration; i can also be sensitive to the slurry stirring rate at high anode potentials when anodic mass-transport control prevails. Evidently, these dependences provide false information on the coal oxidation kinetics, since Eq. [2] is not directly dependent on any of these terms.

Equation [5] shows that the coal properties have a significant influence on i for low coal reactivities ($Z < I$), but the experimental dependence of i on coal weight here is attenuated and less sensitive than in Eq. [2]. This explains why i "saturates" with increasing slurry density for some coals (Dhooze and Park), even though R_o is always directly proportional to w (see Eq. [2]). i is also still dependent on I . Again, significant increases in i can result from this term, even though the coal oxidation kinetics are not directly affected. However, compared to Eq. [4], the influence of A and C is attenuated via the fractional power $\beta/(\beta + 1)$, and the effect of increasing these variables diminishes progressively.

For any given coal, Eq. [4] must ultimately break down, because I can be arbitrarily increased at least threefold, e.g., by changing C from 10^{-3} to $1M$. The condition $Z > I$ reverses when $C > R_c w/k_a A$, and Eq. [5] is therefore the more general solution of Eq. [3], valid for a wide range of

coal reactivities in sufficiently concentrated analytes. This is the reason why the i - C curves for reactive coals tend to be linear only in dilute analytes, but this experimental trend cannot be used to justify a first-order mechanism for the coal oxidation reaction. Similarly, considerable caution has to be exercised in the mechanistic interpretation of the experimental anode-current activation energy.

Su-Moon Park and David E. Stilwell:²² The comments offered by Dr. Linge are based on his misconceptions in using electrochemical relationships. We would like to point out that his comments refer more to our first paper on the subject,²³ than that which he cited.

First, Linge stated that our analysis was invalid since the coal oxidation is a mediated electrolysis reaction. We wish to point out that we were the first to reach the conclusion that coal oxidation is a mediated or catalytic process, based on our extensive experimental data.²³ Electrochemists have been known to call them: redox, electron shuttle, catalytic, or mediated reaction mechanisms, but these all refer to the same phenomenon. This is a rather minor point, and we wish to make it clear that our analysis and conclusions cannot be invalid simply because we did not use the same terminology as he did.

Our more important comments pertain to the invalidity of the equations evoked by Linge. First of all, Eq. [1] in his comment is only valid in the mass-transfer limiting region where k_a should be more properly replaced by m_o , the mass-transfer coefficient. At smaller overpotentials, the well-known Butler-Volmer equation must be employed with simplification only possible after reasonable assumptions have been made regarding overpotential and mass-transfer considerations, i.e.

$$i = i^0 \left[\frac{C_{O(O,t)}}{C_O^*} \exp\left(\frac{-\alpha n F}{RT} \eta\right) - \frac{C_{R(O,t)}}{C_R^*} \exp\left\{\frac{(1-\alpha)n F}{RT} \eta\right\} \right]$$

where i^0 is the exchange current, C_o and C_r are concentrations of the oxidant and reductant, respectively, at the electrode surface at any time, t , and in the bulk, expressed by subscript (O, t) and superscript*, respectively, η is the overpotential, and α is the transfer coefficient. Of course, i^0 is related to the charge-transfer coefficient, k^0 , by a relation, $i^0 = n F A k^0 (C_o)^{1-\alpha} (C_r)^\alpha$.

Since Linge did not specify any conditions, we can only assume that Eq. [1] refers to a mass-transfer limiting current. If not, then this alone causes us to question any subsequent equations that are based on its use. Under mass-transport-controlled conditions, Eq. [1] can be used to estimate the concentration of electroactive reductant, i.e., Fe^{2+} or Ce^{3+} in this case. Here, k^0 is the heterogeneous standard rate constant for charge transfer in centimeters per second.

Equation [2] in his comments does not appear in one of the references cited by Linge for its source;²¹ we have no ready access to his other reference.²⁰ One can write down a relation as Eq. [2] provided that coal particles are regarded as electrodes to transfer electrons to the solution species, i.e., Fe^{3+} or Ce^{4+} in this case. Then R_c should contain parameters related to the exchange current between coal and the solution species. One should, however, include the reverse current term as shown in the above Butler-Volmer equation, unless it is assumed that the polarization controlled by the ratio of C_o/C_r is in the Tafel region. Yet, Anthony and Linge²¹ ran their experiments near the equilibrium potential, the conclusion of which became the basis of Linge's current comments. Equations [1] and [2] cannot be combined, since they are based on different assumptions and also they are not correct.

We therefore wish to point out that one can derive any equations, but they may not have any physical meaning

²⁰D. A. J. Swinkels *et al.*, NERDDC Research Report, Contract no. 80/0210, B. H. P. Central Research Laboratories, Shortland, N.S.W., 2307, Australia (July 1981, April 1982, January 1984).

²¹K. E. Anthony and H. G. Linge, *This Journal*, **130**, 2217 (1983).

²²Department of Chemistry, University of New Mexico, Albuquerque, New Mexico 87131.

²³P. M. Dhooze, D. E. Stilwell, and S.-M. Park, *This Journal*, **129**, 1719 (1982).

unless assumptions made are met in the experiments. Take Eq. [3] in Linge's comment. The equation appears perfectly valid algebraically, but it has absolutely no physical meaning. Consider, for example, that at constant Z and I , the right-hand side of the equation decreases with increasing i , while the left-hand side increases. This necessitates changes in supposedly constants, Z and I . Any discussions based on this equation would, therefore, be invalid.

In summary, we are pointing out two reasons for invalidity of Eq. [3] in Linge's comment. First, Eq. [1] and [2] are valid only under the experimental conditions specified above. Second, these two equations cannot be combined to obtain Eq. [3]. The major confusion in deriving Eq. [3] came from the indiscriminate use of rate constants; charge-transfer rate (k^0), first-order reaction rate (k_a here?), and mass-transfer rate (m_o) are all different from each other. We have seen how Eq. [3], resulting from this combination, does not carry any physical significance. We welcome Dr. Linge's sending any literature/documents/data that detail the derivation of equations used in his comments. Our points made in this reply

can be found in any standard textbooks of electrochemistry.^{24,25}

Finally, we wish to make comments concerning our analysis and conclusions based on our data. Our techniques for obtaining kinetic data were based either on the current-time profile of Fe^{2+} oxidation at controlled potentials in a stirred solution before and after perturbation by coal or on a steady-state approximation. Here, we assumed that rates of reaction between coal slurries and an oxidant are rate limiting, and thus the rate of Fe^{2+} generation, monitored by the anodic current in the mass-transfer region, should approximate the rate of reactions between Fe^{3+} and coal.

In conjunction with these comments, we request that authors in *This Journal* cite, whenever possible, only literature that is readily available and that editors and referees see to it that this is observed. Also, when a mathematical relation is used, "conventional" symbols should be used and assumptions made should be fully specified.

Surface Phenomena in Composite Electroless Coatings Containing Polycrystalline Diamond

N. Feldstein* and T. S. Lancsek

Surface Technology, Inc., Princeton, New Jersey 08540

Composite electroless coatings have been accepted as commercial coatings primarily due to the resulting outstanding wear characteristics. A survey of the state of the art and its evolution was recently published (1).

Due to the autocatalytic nature of electroless plating compositions it has been stipulated (2) that the particles which are to be dispersed within the electroless plating bath and then codeposited must be non-catalytic and inert in order to prevent the homogeneous decomposition of the electroless plating compositions. Examination (1) of composite electroless coating generally reveals a uniform dispersion of the particulate matter within the metallic matrix, with some particles exposed from the outer surface of the composite.

There does not appear to be any specific orientation in the exposure of the particles, nor does there appear to be any orderly fashion as to the degree by which these particles are exposed above the surface.

In an extensive examination of particulate matter for potential composite electroless coatings, Christini et al (3) noted that diamond, particularly polycrystalline diamond, has a tendency to form metallic sites onto exposed diamond particles in isolated regions. The degree of this tendency was found (3) to be dependent upon plating conditions and the nature of the plating bath chosen (e.g., nickel-boron vs. nickel-phosphorous).

Though diamond exists in various forms, polycrystalline diamond produced by a shock synthesis method (4) has found several commercial applications as applied in composite electroless coatings, stemming from several unique characteristics achieved with this form of diamond in comparison to others. The successful commercial adaptation of this specific form of

diamond has resulted in additional interest as to the non-catalytic properties and inertness of this polycrystalline form of diamond when used along with electroless plating baths.

The present method provides a new approach to the examination of discrete polycrystalline diamond exposed from the metallic matrix. This new method appears to be effective even though the number of exposed diamond particles has been reduced due to commercial practices. The new method is based upon the interaction of previously prepared composites with electroless plating baths which are free of any particles, and observation of the resulting surface roughness.

EXPERIMENTAL PROCEDURE

Miscellaneous coated substrates with exposed particles of polycrystalline diamond in an electroless nickel matrix were used as a test vehicle. These substrates were contacted with an electroless nickel plating bath (nickel-phosphorous type). The degree of overcoat thickness was varied by varying the plating time; the resulting surface roughnesses were monitored. Roughness measurements were conducted using a Surf-Indicator, product of Gould, Inc., El Monte, California. Fig. 1 represents the resulting roughness measurements. In all cases, the initial roughness increased, leading to a leveling-off phenomenon. The electroless plating baths chosen for use in this study were all commercially available baths, and their use was in accordance with the specification of the supplier.

Table I demonstrates the results of applying the overcoat onto two plated discs, both containing an electroless nickel composite polycrystalline diamond. Disc A is a

*Electrochemical Society Active Member.

commercial product which was smoothed subsequent to the plating step; in so doing, a significant amount of the outer diamonds resulting from the plating operation were removed. Disc B is a laboratory-prepared disc, also containing the polycrystalline form of diamond with a smoothing operation subsequent to the plating. The diamond size (4 micron) chosen for Disc B in Table I is the same as that chosen in the substrate preparation for Fig. 1. It should be noted that 10 minutes of overcoating results in about 3.5 microns of thickness.

Though the smoothing operation removes a significant amount of exposed particles and also lowers the surface roughness, a few particles are still present and exposed from the outer surface (Ref. 1, Fig. 8).

Examination of the results for Disc A in Table I shows a slight tendency for the initial roughness to increase with no major effect thereafter up to about 5 minutes of overcoat. A similar trend appears to take place for Disc B. In none of the cases examined is there any initial tendency for the roughness to decrease with overcoat variations. Therefore, it is believed that the observed tendency demonstrates that the diamond used (polycrystalline diamond) is, in fact, catalytic and not inert, probably due to sites which lead to the deposition of electroless nickel onto them. These sites are of catalytic nature, and it is these sites that may have partially contributed to Christini et al's (3) observation as to the phenomenon of nucleation bonding. In any event, the presence of such catalytic sites would lead to the random metallic build-up.

SUMMARY AND CONCLUSIONS

Based upon roughness measurements with varied coating thicknesses of electroless nickel composition, it has been demonstrated that the exposed particles (polycrystalline diamond) provide catalytic tendency which results in the plating of the diamonds. At times the plating onto the diamond particles is in preferential rate to the plating onto the nickel matrix, thereby resulting in an increase in the initial surface roughness. No

change in surface roughness corresponds to a precise replication of the composite surface with the electroless layer free of the particulate matter. In either case, no initial decrease in surface roughness has been observed which would account for a selective "fill-in" by the secondary layer between exposed particles. Selective "fill-in" could only take place if the exposed polycrystalline diamond particles are truly non-catalytic and inert. It is conceivable that the catalytic sites associated with the polycrystalline diamond may be due to its unique morphology and/or residual transition metals used in its synthesis (5,6). The present observations and conclusion are further supported by previous observations that diamond, particularly the polycrystalline form, has the tendency to decompose electroless plating baths (2,3,7).

Table I. Roughness Measurements of Composite Coatings Previously Smoothed

	Roughness	
	Disc A	Disc B
Control (no overcoat)	16.6 AA	14.7 AA
2 min. overcoat	19.3 AA	14.9 AA
5 min. overcoat	16.2 AA	14.2 AA
10 min. overcoat	14.9 AA	14.3 AA

Molecular Beam Epitaxial Growth on Radiation-Heated Substrates

S. C. Palmateer, B. R. Lee, and J. C. M. Hwang*

General Electric Company, Electronics Laboratory, Syracuse, New York 13221

Growth of epitaxial layers on GaAs substrates without indium-mounting is essential for improvements in throughput of a molecular beam epitaxy (MBE) system. The elimination of indium-mounting will also improve backside morphology and avoid any indium incorporation in GaAs/AlGaAs layers during molecular beam epitaxial growth.

We have succeeded in growing GaAs epilayers on 2" wafers by radiation heating of the substrate. A coating of Ti/W (~3000Å thick) is sputtered on the backside of the GaAs wafer prior to epitaxial growth. The wafer is loosely held in a ring-shaped holder with molybdenum clips. Figure 1 illustrates the substrate holder arrangement. The temperature variation across a 2" wafer is $\pm 15^\circ\text{C}$, as shown in Figure 2. The temperature response of the wafer is excellent compared to heating through a 2" molybdenum block using indium mounting. This fast temperature response is important for the growth of heterostructures containing both GaAs and AlGaAs layers; the temperature of the wafer can be ramped from 600°C (for GaAs growth) to 700°C (for AlGaAs growth) within 3 seconds. The morphology of epilayers grown on radiation heated wafers is comparable to the morphology of epilayers grown on substrates mounted with indium.

Figure 3 shows a plot of theoretical⁽¹⁾ and experimental 77K mobility for n-type (Si-

doped) GaAs. Solid circles represent epilayers grown on indium mounted wafers, while open circles are mobilities measured on radiation heated wafers. Comparable 300K and 77K mobilities are obtained using both heating techniques. Hall measurements done across a 2" wafer show excellent uniformity ($\pm 5\%$) in carrier concentration and mobility. 4K photoluminescence measurements across a wafer are uniform and comparable in intensity to wafers grown on indium mounted substrates.

Figure 4 shows a plot of four electrochemical profiles done across a 2" wafer. These measurements exhibit excellent doping (d) and thickness (t) uniformity ($\pm 2\%$) across a 2" wafer.

Field effect transistors are being processed to compare uniformity of device characteristics; the results will be reported elsewhere.

ACKNOWLEDGEMENTS

We would like to acknowledge the help of Shirley J. Nitzke for the Ti/W sputtering.

R. Kötz

Brown, Boveri & Cie, Baden, Switzerland

Heterojunction formation by photoelectrochemical alteration of semiconductor surfaces is reported. Growth of a new semiconducting phase at the n-CuInSe₂/I⁻-I₂-Cu⁺ interface is achieved by controlling electrochemical parameters. The interfacial layer is identified as CuISe₃Se⁰ and exhibits p-type conductivity. Under illumination the interphase mediates efficient charge transfer between CuInSe₂ and the I⁻/I₂ redox couple while inhibiting semiconductor dissolution.

Current interest in CuInSe₂ systems from its exceptional optoelectronic properties, resulting in the development of efficient solid state (1) and photoelectrochemical (2) solar cells. Performance of the latter pivots on the growth of an interfacial layer induced by specific electrolyte composition, resulting in a substrate-film-electrolyte structure. In this note we explore the location of the photoactive junction and the circumstances leading to the CuInSe₂ surface transformation.

Interfacial films were grown on back ohmic contacted, epoxy insulated and etched (112) faces of n-CuInSe₂ by operation as photoanodes in an electrolyte consisting of 1 M I⁻, 0.05 M I₂, 0.02 M CuI and 2 M HI. This involved, cyclic polarization of the electrode between the potential limits of short circuit and open circuit or leaving it at the maximum power point. Film quality was monitored by the photocurrent-voltage output. Generally 3 - 4 intermediary etches were required to optimize the film performance.

Scanning electron micrographs of the electrochemically treated CuInSe₂ electrodes show that a polycrystalline film consisting of randomly oriented, flat, hexagonal crystallites is grown on the CuInSe₂ substrate (3). Crystallite sizes range between 2 - 5 microns. A cross-section of a cleaved electrode evidences that the film does not penetrate deeper than 2 microns into the substrate even after pro-

key words: Semiconductor Interfaces, Solar Energy, Photoelectrochemistry

longed operation (5 weeks) in a solar cell, but appears to completely cover the substrate growing into microscopic cavities.

The distinct crystallite geometry suggests that a chemically well defined compound is grown at the CuInSe₂/electrolyte interface. X-ray diffraction analysis of the crystallites identifies the new phase as consisting of mainly CuISe₃ and up to 30 % elemental Se. No evidence for formation of polycrystalline CuI was found.

Chemical reactions of illuminated CuInSe₂ with the electrolyte constituents obviously transform the semiconductor surface to generate the CuISe₃-Se⁰ phase. In the absence of Cu⁺ in the electrolyte, elemental Se⁰ and triangular crystallites of CuI have been detected on photocorroded CuInSe₂ surfaces (3). CuI is partly soluble in iodide solution forming CuI₂⁻. Addition of Cu⁺ to the solution probably raises the surface concentration of CuI₂⁻ to a critical value required to initiate CuISe₃ film growth. CuISe₃ crystals have been previously prepared by reacting stoichiometric mixtures of CuI and Se in HI medium under hydrothermal conditions (4). The reactants employed in the hydrothermal synthesis of CuISe₃ are thus provided by the electrolyte and the semiconductor components in our cell while the reaction enthalpy is probably supplied by the photopotential.

Fig. 1 compares UPS energy distribution curves, N(E) of the untreated CuInSe₂ single crystal and the CuInSe₂/CuISe₃-Se⁰ structure, with the Fermi levels E_F aligned to the edges of the valence band. E_Vⁿ and E_V^p for the two samples differ by 0.65 eV. |E_Vⁿ - E_V^p| is 0.85 eV for CuInSe₂ and 0.2 eV for the film. With a bandgap, E_g^p of 2 eV for CuISe₃ (5) and for Se (6), the film is thus a p-type semiconductor. Measurement of the relative work functions, φ, of the two samples with the vacuum levels aligned also indicate that the E_F's differ by 0.65 V. Hence E_Vⁿ(CuInSe₂) = E_V^p(film). Adding the electron affinity, χⁿ of 4.58 eV (7) to the E_gⁿ of 1 eV for CuInSe₃ the absolute value of E_V^p is estimated to be 5.58 eV.

The energetics of the structure are given in Fig. 2. Experimental and literature values for various electronic parameters indicated with superscripts n and p refer to n-CuInSe₂ and p-CuISe₃-Se⁰, respectively. An estimate for the work function of the I⁻-I₂-Cu⁺-HI electrolyte of $\phi^e=5.1$ eV is obtained by adding the measured redox potential of +0.2 V (SCE) to the more recent value of (NHE)=4.7 eV (8). Comparison of E_F^n , E_F^p and ϕ^e yields a potential of at least 0.65 eV at the substrate/film junction and of 0.2 eV ($\Delta\phi$) at the film/electrolyte interface. This implies a p-n junction between the solids and a rectifying junction at the electrolyte contact. The spectral response and the anodic photocurrent, however, attest the light absorption and photogeneration of h⁺ in the n-CuInSe₂ (2,3). A barrier at the film/electrolyte interface would impede h⁺ transfer to I⁻. The high quantum efficiency and the photovoltage of 0.42 V (2) argue against such a barrier and suggest that the principal potential drop occurs in the p-n junction with the electrolyte providing an ohmic contact. Interactions between the semiconductor and electrolyte upon immersion may account for the energetic difference, $\Delta\phi$, as the scheme in Fig. 2 disregards the effects of pH and specific adsorption.

Adsorption of Thiourea on Passivated Iron

An Infrared Spectroscopy and Radiotracer Study

J. O'M. Bockris,* M. A. Habib,* and J. L. Carbajal

Department of Chemistry, Texas A&M University, College Station, Texas 77843

Since adsorption of thiourea markedly influences the inhibition of electrochemical corrosion (1), it is important to know the extent and variation of thiourea adsorption with potential of the corroding object. We report here the adsorption of thiourea on iron as measured by the in-situ Fourier Transform Infrared Spectroscopy and by parallel measurements by means of radiotracers.

An iron rod (99.9995%) of 0.6 cm diameter clad with heat shrinkable teflon tube was used as the electrode for the IR study. The electrode surface exposed to a solution film of about 1μ thick was of 0.6 cm diameter. A Digilab FTS-20E spectrometer system was used. Detailed optical arrangements and experimental procedures are reported elsewhere (2). The counter and reference electrodes were a Pt coil and a calomel electrode, respectively.

For the radiotracer technique, a glass scintillator NE901 of 3 mm thick and 3 cm diameter with a 3000 Å thick vacuum deposited layer of iron was used as a working electrode. C^{14} labeled thiourea obtained from ICN radiochemicals, was used in a buffer borate solution of pH = 8.4.

A cathodic pretreatment for the iron at -0.74 V (NHE) for 30 minutes was followed by a potential step to 0.3 V where the passive film was grown for 50 minutes (3). The passive film was about 20-30 Å thick.

The electrode was potentiostatically polarized in the region of -0.2 V to 1.1 V NHE at an interval of 200 mv and IR spectra were recorded at each potential. The spectra reported here were obtained by subtracting from the spectra at various potentials, the reference spectra at -0.2 V; the spectra are thus termed differential spectra.

For the radiotracer measurements, the radioactive signal from C^{14} of adsorbed thiourea is guided by a light pipe placed behind the scintillator to a photomultiplier (EMI 9635QB) connected to a multichannel

analyzer (EG&G 7100). The number of counts detected by the multichannel analyzer was recorded as a function of potential and was converted to surface excess (4).

In Fig. 1, the differential IR spectra of adsorbed thiourea at various potentials are shown. IR peaks at 1652, 1616, 1506, 1458, and 1385 cm^{-1} are found to vary with electrode potential. The peak at 1652 and the broad band at 1616 cm^{-1} correspond to the N-H scissoring (bending) vibration (5). The peak observed at 1506 cm^{-1} corresponds to the N-C-N stretching vibration (5). This peak is shifted from 1407 cm^{-1} in free thiourea to 1506 cm^{-1} in adsorbed state due to an increased double bond character of the carbon to nitrogen bond (5) as the thiourea molecule is expected to adsorb with its sulfur end toward the metal (6),

The peak at 1458 cm^{-1} also corresponds to the 1417 cm^{-1} band of free thiourea and thus can be assigned to the NH_2 rocking vibration and N-C-N and C=S stretching vibration (5). The nature of vibrations is changed slightly on adsorption through the sulfur atom.

The area under the peaks corresponds to the amount of adsorbed thiourea on the electrode. The integrated peak areas are plotted as a function of potential in Fig. 2. Areas under all the above mentioned peaks except the broad band at 1616 cm^{-1} are found to increase to a maximum at 0.9 V with increase of potential in the anodic direction. With further increase of potential above 0.9V, the peak areas except that of 1616 cm^{-1} increase with increase of anodic potential and becomes constant above 1.1 V. This signifies adsorbed thiourea molecules.

In the active region, i.e., at potentials lower than -0.2 V, due to corrosion of iron, no regular or reproducible spectra were obtained.

From the radiotracer measurements, the adsorption of thiourea on passive iron is also found to pass through a maximum at 0.9 V (Fig. 2). The maximum area of the IR peaks for the electrode at 0.9 V are normalized with respect to the maximum coverage determined by the radiotracer method at 0.9 V. Variations of the adsorption of thiourea with electrode potential as determined by the FTIR and radiotracer method are in reasonable agreement above 0.4 V. The discrepancy at potentials < 400 mV may be due to the difference in the strength of $(\text{NH}_2)_2\text{CS-Fe}$ interaction with potential. It is well known that amplitude of the observed absorption band will vary with the molecular orientation, being zero when the dipole derivative is parallel to the surface and giving a maximum value when it is perpendicular (7). Thus, the orientation of the adsorbed thiourea at the potential (0.9 V) where the IR absorption bands are normalized to surface excess value by the radiotracer, will change and hence affect the integrated area of the absorption band as the potential of the electrode is changed. The radiotracer method, of course, is insensitive to these orientational changes. The area of the peak at 1616 cm^{-1} , unlike other peak areas, does not decrease with increase of potential above 0.9 V, and the radiotracer measurements show a decrease beyond 0.9 V; but when all the peak areas are added together and plotted as a function of potential, a net decrease beyond 0.9 V is observed.

In-situ FTIR spectroscopic method combined with radiotracer measurements allow quantitative determination of the potential dependent adsorption of thiourea on passivated iron from an aqueous solution.
