The Phase-Transition Phenomenon in a Sodium Sulfate Crystal

M. Sakaguchi,* M. Ohta,* and S. Miyazaki

Department of Applied Chemistry, Faculty of Engineering, Niigata University, Niigata, Japan

ABSTRACT

The V \rightleftharpoons I phase-transition reactions of a Na₂SO₄ crystal in the pure Li⁺-, K⁺- or Cs⁺-blended Na₂SO₄ samples were investigated in various atmospheres (N₂, dry air, or wet air). In all samples, both the V \rightarrow I and the I \rightarrow III phase-transition reactions proceeded rapidly, but the III \rightarrow V phase-transition reaction hardly proceeded at all after several hours in N₂ or dry air. In wet air, however, the reaction proceeded rapidly. This fact suggested that the migration of the constituent ion was accelerated as soon as the ions on the crystal surface were hydrated. All phase-transition reactions were suppressed by the existence of the foreign materials which were isostructural with the host crystal before the reaction.

Many studies have been carried out for the phase transition of a Na₂SO₄ crystal which is known to exist in three metastable modifications (phases IV, III, II) between phase V (low temperature orthorhombic structure) and phase I (high temperature hexagonal structure) (1-7). Most of the studies were limited to the V \rightarrow I phase transition and/or the I \rightarrow III phase transition. However, although no detailed study for the III \rightarrow V phase transition has been carried out, Eysel (2) pointed out the sluggishness of the reaction.

Sakaguchi *et al.* have found recently that the kinetics of phase-transition reactions of a ZnS crystal (8, 9) and a metal phthalocyanine crystal (10) were characteristically affected by the heating atmosphere or impurities contained in the crystal.

We were interested, therefore, in investigating how the III \rightarrow V phase-transition reaction is affected by the adsorption of water vapor on the hygroscopic surface of a Na₂SO₄ crystal.

The present work was carried out to study the role of water vapor contained in a reacting atmosphere on the phase-transition reaction in pure and foreign-cation containing Na₂SO₄ crystals.

Experimental

Materials.—The starting material used was prepared by evaporation to dryness of an aqueous solution of Na₂SO₄ (Junsei Chemical Company, Limited; guaranteed reagent grade) or of Na₂SO₄ to which Li₂SO₄ (Koso Chemical Company, Limited; guaranteed reagent grade), K₂SO₄ (Junsei Chemical Company, Limited; guaranteed reagent grade), or Cs₂SO₄ (Mitsuwa Chemical Company, Limited; purity: 99.9%) was added to the amount of 10 mole percent (m/o). This was followed by vacuum drying for 2h at 130°C, and then grinding (325 ~ 400 mesh). The composition of the starting materials is determined by a x-ray powder diffraction method: the Li⁺-blended Na₂SO₄ sample contains 80 m/o phase V (orthorhombic Na₂SO₄ crystal) and 20 m/o trigonal LiNaSO₄ compound. The K⁺-blended Na₂SO₄ sample contains 90 m/o phase V and 10 m/o hexagonal (K,Na)₂SO₄ solid solution. The Cs⁺-blended Na₂SO₄ sample contains 90 m/o phase V and 10 m/o orthorhombic Cs₂SO₄ crystal.

The pure and blended Na₂SO₄ samples used for the III \rightarrow V phase-transition reaction at 25°C were prepared by removing the bound water (11) contained in the starting material. That is, the bound water was removed by heating the starting material at 750°C in N₂, then the sample was ground (325 ~ 400 mesh) in dry air of about 10% relative humidity (RH) at 25°C in order to prevent the read-sorption of water vapor.

The gases used were prepared as follows: N₂ was prepared by evaporation of pure liquid N₂. The dry air (10% RH) or the wet air (100% RH) was prepared by leaving it in contact with CaCl₂ or distilled water for more than 12h at 25°C in desiccator.

Key words: phase transition, sodium sulfate, adsorption, atmosphere.

Procedure.—The phase-transition phenomena in the pure and blended Na₂SO₄ samples during heating or cooling in N₂ flow (100 ml/min) were investigated by using an apparatus which enabled a simultaneous measurement of high temperature x-ray diffraction and differential thermal analysis (DTA) (Rigaku Denki Company, Limited).

The III \rightarrow V phase-transition phenomena in the pure and blended Na₂SO₄ samples at 25°C in the dry air or wet air were investigated by measuring the peak height of the x-ray powder diffraction trace. The fraction of the reaction (*F*) was calculated by following equation

$$F = \frac{(V_{28.0} + V_{29.0})}{1.2(III_{22.6} + III_{23.6}) + (V_{28.0} + V_{29.0})} \times 100 (\%)$$

where III_{22.6}, III_{23.6}, V_{28.0}, and V_{29.0} represent the peak heights at 2 θ = 22.6°, 23.6°, 28.0°, and 29.0° on the x-ray powder diffraction trace, respectively.

Results and Discussion

The phase-transition reaction of the pure Na₂SO₄ sample in N₂ flow was continuously examined by using simultaneous high temperature x-ray diffraction and DTA, as shown in Fig. 1. During the heating process, the diffraction peak of the phase V disappeared, while that of the phase I appeared at 251°C with a simultaneous endothermic effect on the DTA curve. In the cooling process, the diffraction peak of the phase I disappeared at 233°C, while that of the phase III appeared with an exothermic effect on the DTA curve. However, the diffraction peak of the phase V did not emerge even if the sample was cooled to 25°C. These results were similar to that obtained by Eysel (2).

Analogous experiments were carried out on the Li⁺-, K⁺- and Cs⁺-blended Na₂SO₄ samples in N₂ flow. The results obtained are shown in Table I. On heating, the V \rightarrow I phase-transition reaction proceeded at 252°C in both the Li⁺- and K⁺-blended Na₂SO₄ samples similar to that in the pure Na₂SO₄ sample, but occurred about 10°C higher

Fig. 1. High temperature x-ray diffraction trace and DTA trace on an undoped Na₂SO₄ crystal in N₂ flow.

Fig. 2. III \rightarrow V phase transition in undoped and Li⁺-, K⁺-, or Cs⁺-doped Na₂SO₄ samples in wet and dry air at 25°C. These samples were pre-treated at 750°C for 1 h in N₂. ○: Undoped. ●: Li⁺-doped. ▲: K⁺-doped. ■: Cs⁺-doped.

(262°C) in the Cs⁺-blended Na₂SO₄ sample. On cooling, the I \rightarrow III phase-transition reaction proceeded at 229°C in the Cs⁺-blended Na₂SO₄ sample similar to that in the pure Na₂SO₄ sample, but occurred about 10° and 35°C lower (221°, 186°C) in the Li⁺- and K⁺-blended Na₂SO₄ samples, respectively. The composition of the (K,Na)₂SO₄ solid solution in the K⁺-blended Na₂SO₄ sample became rich in Na near 650°C during heating, while a phase III Na₂SO₄ crystal was separated from the Na-rich solid solution at 186°C with an exothermic effect on the DTA curve on cooling. As with the pure sample, the diffraction peak of the phase V in any blended Na₂SO₄ sample did not emerge even when these were cooled to 25°C.

Figure 2 is a log-log plot for the results on the III \rightarrow V phase-transition reaction in the pure and Li⁺-, K⁺- or Cs⁺-blended Na₂SO₄ samples at 25°C in both the dry and the wet airs. The reaction in any Na₂SO₄ sample did not proceed in the dry air within 400 min, but rather accelerated considerably in the wet air. The rate of the reaction in the wet air decreased in the order Cs⁺-blended > pure > K⁺-blended > Li⁺-blended. While the reaction in the dry air proceeded gradually for 3 months.

On the basis of these results, the effect of a foreign cation on the phase-transition reaction of a Na₂SO₄ crystal can be considered to be as follows: it is known that the phases V, III, and I of a Na₂SO₄ crystal are orthorhombic, orthorhombic (quasi hexagonal), and hexagonal, respectively. Then, the V \rightarrow I phase-transition reaction in the Cs⁺-blended Na₂SO₄ sample might be considerably suppressed as a result of the stabilizing ("epitaxialcy") (12) of the phase V due to the existence of a Cs₂SO₄ crystal, which is isostructural with a phase V Na₂SO₄ crystal. However, the promotive effect for the V \rightarrow I phase-transition reaction in the Li⁺- or K⁺-blended Na₂SO₄ sample could not be detected, in spite of the existence of a LiNaSO₄ compound or a (K,Na)₂SO₄ solid solution which is isostructural with a phase I Na₂SO₄ crystal. That is, it is likely that the phase transition of a Na₂SO₄ crystal is considerably suppressed by the existence of foreign material, which is isostructural with the host crystal before the re-

Table I. Phase transition of undoped and Li⁺-, K⁺-, or Cs⁺-doped Na₂SO₄ samples in N₂ flow

Sample	Phase-transition point (°C)	
	Heating process V \rightarrow I	Cooling process I \rightarrow III*
Undoped	251	233
Li ⁺ -doped	252	221
K ⁺ -doped	251	186
Cs ⁺ -doped	262	229

* The form II appeared transiently during the I \rightarrow III phase-transition reaction.

action. Consequently, both the I \rightarrow III and III \rightarrow V phase-transition reactions in the K⁺- or Li⁺-blended Na₂SO₄ sample were also considerably suppressed as a result of the epitaxialcy of phases I and III with the hexagonal (K,Na)₂SO₄ and the trigonal LiNaSO₄ phases, respectively.

The promotive effect of the water sorbed on the crystal surface in the III \rightarrow V phase-transition reaction must be caused by accelerating the migration of the constituent ion because the crystal lattice was relaxed by the hydrate formed on the crystal surface layer (13).

Furthermore, the accelerative effect on the III \rightarrow V phase-transition reaction in the Cs⁺-blended sample (which is a mixture of Na₂SO₄ and Cs₂SO₄) resulted from promoting the sorption of water vapor on a Na₂SO₄ crystal in the neighborhood of a Cs₂SO₄ crystal because a Cs₂SO₄ crystal is more hygroscopic than other crystals.

Isotope Labeling Studies of the Oxidation of Silicon at 1000° and 1300°C

J. A. Costello*¹ and R. E. Tressler

Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

Oxygen-18 profiles in thermal oxides grown on silicon at 1000° and 1300°C in sequential oxidation steps in the parabolic oxidation regime indicate a change in the dominant oxygen transport process. At 1000°C, oxygen-18 pile-up at the surface and at the oxide/silicon interface is consistent with a large flux of oxygen via molecular oxygen permeation and very slow diffusion of lattice oxygen ions ($D_o = \sim 4 \times 10^{-15}$ cm²/s). At 1300°C, the oxygen-18 concentration is uniformly high across the oxide, which suggests a much larger lattice oxygen diffusivity and a total flux due to lattice oxygen diffusion which contributes significantly to the supply of oxygen to the growth interface.

Owing to its importance in the semiconductor industry, the oxidation of silicon has been extensively studied. It is generally accepted that the oxidation process in the parabolic growth regime is controlled by the permeation of oxygen molecules through the oxide film (1-3). Indirect evidence supporting this conclusion includes platinum marker experiments (4), the linear oxygen partial pressure dependence of the parabolic oxidation rate (1), and the correspondence with oxygen permeation studies of fused silica (5). The most direct evidence comes from isotope labeling studies. The technique involves the sequential oxidation of the silicon in oxygen-16- and oxygen-18-rich environments. Following the oxidation treatments, an appropriate measurement technique which can discriminate between the two oxygen isotopes is used to profile each across the oxide film. The most common include nuclear reaction resonance and secondary ion mass spectrometry (SIMS). The location of each isotope in the oxide profiles provides information about the migrating species which control the oxidation reaction.

The nuclear reaction resonance technique was used by Rosencher *et al.* (6) to investigate silicon oxidation in dry oxygen at 930°C. The oxygen isotope profiles resulting from the double oxidation sequence revealed that the majority of oxygen-18 isotope accumulates near the oxide-silicon interface. This result and the correspondingly low oxygen-18 concentration in the bulk oxide indicated that the permeation of the oxidant to the interface is responsible for the parabolic oxidation of silicon, as proposed by Deal and Grove (1). A thin oxygen-18-rich layer (7-12Å) was observed near the oxide surface, which was explained as isotope exchange between the oxidant and the lattice bound oxygen at the oxide surface. It has been reported that the exchange mechanism is enhanced by trace amounts of water in the oxidation environment (7). Rosencher *et al.* assumed that the water content in their system was in the ppm range in light of the shallowness of the exchanged layer.

A superior detection sensitivity is obtained using the SIMS technique. The analysis provides a direct measure of the isotope concentration profile and eliminates the laborious deconvolution procedures required by the nuclear reaction resonance technique. However, profile broadening due to ion beam mixing must be accounted for when considering the measured profile. Cristì and Condon (8) reported ion microprobe mass analyzer results for silicon doubly oxidized at 700°C. Similar to Rosencher *et al.*, an interstitial diffusion (permeation) of oxygen molecules was suggested as the mechanism controlling oxidation. Isotope exchange with the lattice oxygen was observed at the oxide surface, and a diffusion coefficient corresponding to oxygen diffusion via the oxygen sublattice was calculated to be $\sim 10^{-19}$ cm²/s at 700°C. It was

calculated that a diffusion coefficient of this low magnitude was insufficient to support the observed oxidation rate. Recent work by Rouse *et al.* (9) demonstrates the sensitivity of the SIMS technique when applied to the double oxidation experiment. Using a purified oxygen gas having a reduced oxygen-18 background, a slightly decreasing isotope profile was measured through the bulk oxide in addition to the isotope build up in the new oxide and at the oxide surface as previously described. The profile indicated that permeation mechanisms control the oxidation and that exchange of the diffusing oxidant occurs throughout the oxide. The exchange rate is much higher at the oxide surface. Special treatment of the gases minimized the water content in the system, suggesting that these artifacts were not water related.

In the present study, double oxidation of silicon was investigated at 1000° and 1300°C. Differences in the isotope profiles obtained by SIMS are discussed in terms of the competing transport processes.

Experimental Procedure

Boron-doped silicon (100) having a 3-5 Ω-cm resistivity was used in this investigation. Samples were prepared from a full wafer by dicing into 1/4 × 1/4 in. squares, the sample size required by the SIMS holder. The first oxidation was performed in dry oxygen at 1000°C for 2h. The oxide thickness as measured by ellipsometry was 103 nm. The background oxygen-18 concentration in the gas was 0.2%. The second oxidation was performed in an isotope exchange furnace where following the evacuation of the oxidation chamber, an oxygen-18 enriched gas is introduced (10).¹ The percentage of oxygen-18 in the gas was adjusted to approximately 40% each time. In the enriched gas, samples were oxidized at 1000° and 1300°C for 10 and 35 min, respectively.

Isotope profiling of the samples was accomplished using the SIMS mode of the Gatan scanning ion microprobe.² The ion beam consisted of positive argon ions accelerated to 7 keV and focused to a diameter of approximately 100 μm. Adjustable beam rastering and signal gating were set for optimum depth resolution. A focused electron gun provided charge neutralization of the sputtering surface during profiling. Three mass settings were continuously monitored during profiling, including oxygen-16, oxygen-18, and silicon-30.

Results and Discussion

The SIMS profile shown in Fig. 1 corresponds to the silicon sample oxidized in the oxygen-18 enriched gas at 1000°C for 10 min. The silicon-30 mass is monitored to indicate that proper charge neutralization is provided with the electron gun. This process is characterized by a uniform silicon signal across the oxide, as shown in Fig. 1.

Fig. 1. SIMS data for silicon sample oxidized at 1000°C for 2h in dry oxygen-16 followed by 10 min in oxygen-18-enriched gas.

Signal instability at the oxide surface was typically less than 30s in duration. The changing oxygen signals, however, correspond to actual concentration variations of each isotope across the oxide film. Upon reaching the oxide silicon interface, a sharp drop in signal of up to 3 orders of magnitude occurs in each case. In the silicon, the oxygen counts approach system background levels. The relatively high background signal for oxygen-16 in the silicon is caused by electron stimulated desorption (ESD) from the electron beam interacting with the sample surface. This signal does not significantly contribute to the overall oxygen-16 signal when profiling through the oxide.

The isotope profiles can be better analyzed by converting the data into the oxygen-18 fraction as a function of depth. The oxygen-18 fraction is obtained by dividing the oxygen-18 signal by the sum of the two oxygen signals. An experimentally measured sputtering rate of 17 nm/min in the oxide was used to convert to units of depth. Figures 2 and 3 are profiles for samples oxidized 10 and 35 min, respectively, at 1000°C in the oxygen-18-rich environment. As found by other investigations, the isotope is concentrated at the oxide-silicon interface as well as at the surface. The maximum isotope concentration corresponds to the amount of oxygen-18 enrichment of the oxidizing gas (~ 40%). The minimum concentration

Fig. 2. Oxygen-18 profile for 10 min reoxidation sample at 1000°C.

Fig. 3. Oxygen-18 profile for 35 min reoxidation sample at 1000°C.

which is found in the bulk oxide (Fig. 2) is equal to the background concentration of oxygen-18 in the original oxidizing gas (0.2%).

The observed profiles are explained in terms of the transport mechanisms present, as well as by the exchange of the oxidant with the lattice oxygen. The accumulation of oxygen-18 isotope near the oxide-silicon interface results from the permeation of oxygen molecules through the oxide and formation of new oxide at the oxide/silicon interface. The decreasing profile near the oxide surface into the bulk oxide is explained by the diffusion of the oxygen isotope through the oxygen sublattice following exchange at the oxide surface. A diffusion coefficient for the isotope of 4×10^{-15} cm²/s was calculated from the initial profile using the complementary error function. This

value is in good agreement with literature values for oxygen diffusion in fused silica (11, 12). As indicated in previous investigations, a diffusion coefficient of this magnitude could not by itself provide sufficient flux of oxygen to cause the observed oxidation rate. In addition to the isotope diffusion into the bulk from the oxide surface, the isotope can diffuse into the bulk from the newly formed oxide. This is apparent from the sloped isotope profiles near the original oxide-silicon interface.

The isotope profiles for samples oxidized at 1300°C were quite different. As shown in Fig. 4 for the 10 min oxidation, the oxygen-18 isotope profiles were uniform across the oxide. This result implies that lattice diffusion of oxygen is significant at this temperature and contributes to the supply of oxidant to the growth interface; a

Fig. 4. Oxygen-18 profile for 10 min reoxidation sample at 1300°C.

calculated profile using oxygen diffusivity values in fused silica from the literature approximates the observed flat profile. The single activation energy reported for the parabolic oxidation of silicon (27 kcal/mol) holds up to near the melting point, however, and is much lower than the value reported for lattice diffusion (70 kcal/mol) by Sucov (11). This would imply that the oxidant supply at 1300°C is dominated by the permeation mechanism. The activation energy value reported by Sucov has been questioned by other investigators (12, 13), who suggest that the lattice diffusion of oxygen is characterized by a much lower activation energy. The temperature dependence of the lattice diffusion mechanism is currently being investigated by the authors using the present technique. It is interesting to note that other silicon-base materials such as SiC, TiSi₂, and MoSi₂ exhibit an increase in the activation energy for the parabolic oxidation at temperatures above 1400°C (14, 15). This change in activation energy may correspond to control of oxidation by the lattice diffusion mechanism.

This discussion has not addressed the possibility that the oxygen-18 profiles are the result of an exchange reaction between the permeating isotope species and point defects (presumably oxygen vacancies) in the oxide. The isotope profile would then be flatter at 1300° than at 1000°C if the vacancies were created at the gas/SiO₂ interface and diffused much more rapidly at 1300° than at 1000°C. Future experiments will discriminate between these two possibilities.

Summary

Silicon oxidation in the parabolic growth regime at 1000° and 1300°C was investigated using isotope labeling experiments with SIMS for profiling. At the lower temperature, the measured profiles indicate that the oxidation process is controlled by the permeation of oxygen molecules through the oxide film to the oxide-silicon growth interface. Isotope exchange and subsequent diffusion via the oxygen sublattice apparently occurs near the oxide surface. A calculated value for the lattice diffusivity of oxygen is significantly below the value necessary to sustain the observed oxidation rate; this corroborates the domination of the oxidation process by permeation. At the higher temperature, the lattice diffusion of oxygen is significantly increased, which may lead to domination of

the oxidation rate by lattice diffusion at higher temperatures. An alternative interpretation of the observed oxygen-18 profiles may be that the exchange reaction between permeating O₂ and vacant lattice sites causes the observed profiles if the vacancies are created at the gas/SiO₂ interface and diffuse much faster at 1300° than at 1000°C.

Denuded Zones in Czochralski Silicon Wafers

ABSTRACT

Denuded zones in the near-surface regions of Czochralski silicon wafers were investigated by means of both optical microscopy (OPM) and transmission electron microscopy (TEM). The results of this investigation show that the (nearly defect-free) denuded zones formed near the wafer surface depend strongly on the initial oxygen concentration and the thermal history of the wafers, *e. g.*, wafer annealing-temperature sequence, gas ambient, and annealing duration. Clear denuded zones were observed in wafers annealed under conditions in which the oxygen out-diffusion process is enhanced, *e. g.*, in a high-low, two-step anneal (1050°C for 16h and 800°C for 16h), in a nonoxidizing ambient. A high initial oxygen concentration ($1.5 \times 10^{18} < [O]_i < 2.0 \times 10^{18} \text{ cm}^{-3}$), using the old ASTM calibration factor (ASTM F121-79), is required for the detection of a denuded zone, since defect generation in the bulk resulting from oxygen precipitation provides the demarcation layer.

It has been found that microdefects existing in the active region of Czochralski (CZ) silicon wafers have many detrimental effects on the performance of semiconductor devices, such as minority carrier lifetime degradation, junction leakage enhancement, etc. (1-4). Therefore, it is desirable to eliminate these detrimental effects by providing a nearly microdefect-free zone, which is commonly referred to as a "denuded zone," in the active region of silicon wafers.

It has been previously reported (5-19) that denuded zones can form in the near-surface region if wafers are subjected to a proper preannealing treatment before normal device fabrication processes. The depth of the denuded zones depends strongly on the wafer preannealing conditions, *e. g.*, annealing temperature sequence, gas ambient, and time. However, the reported effects of these conditions are not conclusive.

Two major mechanisms of denuded zone formation have been suggested. One is the oxygen out-diffusion mechanism (9, 10, 15, 17). It is proposed that interstitial oxygen atoms which enter silicon wafers during crystal growth can diffuse out of the wafer surface when subjected to high temperature annealing. This causes a zone of oxygen interstitial undersaturation near the wafer surface, resulting in a nearly microdefect-free (denuded) zone, since oxygen precipitation does not occur there. The other mechanism is one involving the retardation of oxygen precipitation at the wafer surface by excess silicon interstitials. Craven and Korb (19) believe that excess silicon interstitials generated in the near-surface region of wafers during oxidation will annihilate some vacancies, which are supposed to act as the nucleation sites of oxygen precipitates, resulting in a retardation of oxygen precipitation in the near-surface region. From this, a clear denuded zone will then be formed. On the other hand, they believe that excess vacancies generated in the near-surface region during preannealing in HCl containing ambient will enhance the oxygen precipitation, and under this condition, no clear denuded zone can be formed near the surface. They offer experimental results confirming their proposed mechanism.

In this paper, the effects of initial concentrations of oxygen and carbon in the wafers, and the effects of wafer annealing variables, such as temperature sequence, gas ambient, and time, on the formation and width of the denuded zone are reported, having been investigated by optical microscopy (OPM) and transmission electron microscopy (TEM). The active mechanism of denuded zone

formation, as supported by the experimental results obtained, is discussed.

Experimental Procedures

The wafers were n- and p-type, with a diameter of 3 in., a thickness of 500 μm , a (100) orientation, and an interstitial oxygen concentration $[O]_i$ in the range of $1.30 \times 10^{18} \leq [O]_i \leq 1.89 \times 10^{18} \text{ cm}^{-3}$, as measured by infrared absorption (ASTM F 121-79). These oxygen concentration values are approximately a factor of 2 larger than the values calculated using the new ASTM document, F 121-80. The wafers were subjected to specific annealing temperatures with different annealing sequence, gas ambient, and time.

Several seed-end wafers were subjected to a high-low, two-step annealing. They were first annealed at 1050°C for 16h in Ar, followed by an anneal at 800°C in dry O_2 for 0, 4, or 16h. The OPM results showed a denuded zone depth of about 20 μm on all of these wafers, with a similar high density of microdefect etch pits (about $2.9\text{-}3.0 \times 10^9 \text{ cm}^{-2}$) confined to the bulk.

The annealing ambient also plays a very important role in denuded zones in silicon wafers. In this investigation, only the effect of the annealing ambient at the high temperature step was studied, since oxygen out-diffusion at low temperatures (*e. g.*, 800°C) is very slow and can be neglected. Three seed-end wafers were subjected to high-low, two-step annealing in three different ambients (1050°C for 16h in Ar, dry O_2 , or $\text{N}_2 + 3\% \text{ HCl}$, respectively), followed by 800°C for 16h in dry O_2 .

Annealing duration at the first step, 1050°C, of high-low, two-step annealing is very important, since it affects the amount of oxygen diffusing out of the wafer surface. We annealed several seed-end wafers at 1050°C in Ar for 1, 4, or 16h, respectively, followed by annealing at 800°C for 16h in dry O_2 .

Subsequently, the wafers were sawn and broken into small, 2 \times 3 mm rectangular pieces with edges in $\langle 110 \rangle$ directions. For OPM samples, six small pieces were arbitrarily chosen from the central region of a wafer. These were stacked face-to-face (mirror surfaces) and bonded with epoxy glue and were mounted with a black Bakelite mounting powder with the $\{110\}$ surfaces facing the bottom of the mount. In this way, the wafer surfaces were protected by the epoxy glue from etching, only cross-sectional surfaces were subjected to the etchant, and accurate measurements of denuded zones were achieved. The cross section was prepared on the $\{110\}$ surfaces which were polished and Wright etched (20) to delineate the defects.

The distributions of defect etch pits on the $\{110\}$ wafer cross sections were examined by optical microscopy. The depth of the denuded zones was measured from the wafer

* Electrochemical Society Active Member.

Key words: denuded zones, silicon microdefects, sequential annealing.

Fig. 1. An OPM photomicrograph of the cross-sectional, $\{110\}$ surface, of a seed-end wafer annealed at 1050°C for 16h in Ar and at 800°C for 4h in dry O_2 , after 8 min in Wright etch, showing clear denuded zones of $\sim 20\ \mu\text{m}$ at the subsurface regions with a high density of etch pits in the bulk.

surface to the "boundary," where the defect etch pits appeared in significant numbers. The defect depth distribution below the wafer surface was further obtained by TEM. Rectangular wafer pieces with a $\{110\}$ surface, measuring $2 \times 3\ \text{mm}$, were step-thinned to increasing depths from the front surface (see Fig. 1) and subsequently jet-thinned from the back side. TEM specimens of $\{110\}$ cross section were also prepared, by grinding and polishing a composite of six small pieces to a thickness of 8 mil and then thinning to transparency by chemical etching in a $\text{HF}:\text{HNO}_3$, 1:4 solution (18).

Results and Discussion

Temperature effects.—The results of this study show that the thermal history of a wafer can affect the denuded zone formation. The effects of annealing conditions are now considered. Figure 1 shows the microdefect distribution for $\{110\}$ cross section of a seed-end wafer after a high-low, two-step anneal. The density of etch pits is high in the bulk region and decreases gradually toward the wafer surface. This corresponds to the decrease of interstitial oxygen concentration toward the surface due to oxygen out-diffusion during annealing (9). The depth of denuded zones formed on all these wafers was about $20\ \mu\text{m}$, regardless of the annealing time for the low temperature (800°C) anneal. This suggests that the denuded zones were mainly formed during the first-step, high

Fig. 2. This foil surface is a $\{110\}$, cross-sectional surface, thinned by the immersed chemical thinning method. c(left): A cluster of oxygen precipitates and dislocations with a dislocation helix in the bulk of the wafer, $\sim 150\ \mu\text{m}$ below the $\{100\}$ front surface.

temperature (1050°C) anneal. This result is reasonably consistent with Andrews (21) regarding the denuded zone depth for a dry oxidation anneal at 1100°C for 4h, when allowance is made for the temperature and time via the Dt product. Oxygen out-diffusion at 800°C is much slower than at 1050°C, since the diffusivity of oxygen in silicon, calculated according to Takano and Maki (22), is about 6.5×10^{-11} cm²/s at 1050°C, while only 4.8×10^{-13} cm²/s at 800°C. These values are in good agreement with Stavola *et al.* (23). Therefore, oxygen out-diffusion at the low temperature step is negligible. At 1050°C in Ar, the dissolved interstitial oxygen atoms will out-diffuse from the wafer surface to the ambient. The interstitial oxygen concentration below the surface is lowered wherever oxygen concentration is not supersaturated, and oxygen precipitation is negligible in this region. However, the interstitial oxygen concentration in the bulk of the wafer remains high and is supersaturated. Oxygen atoms will tend to precipitate in the form of amorphous SiO₂ in the bulk during the anneal, forming the denuded zone at the subsurface region of the wafer during the first-step, high temperature anneal. The denuded zone remains relatively stable during the subsequent low temperature anneal if the interstitial oxygen concentration remains low inside the zone.

The TEM results show that the microdefects appear only in the region about 50 μm below the front surface. In the region less than 50 μm, the microdefect density was too low to be detected by TEM. The microdefects in nondenuded regions of the wafers after high-low, two-step annealing observed by TEM were mostly oxygen precipitates with punched-out dislocation loops (see Fig. 2a and 2b). A few stacking faults (not shown) and dislocation helices (see Fig. 2c) were observed. It is also noticeable that the shapes of the punched-out dislocation loops, when viewed from <100> and <110> directions, are different (compare Fig. 2a and 2b). The basic geometry of the loops is that they are rhombus-shaped with sides aligned in <112> directions on {111} planes. They are punched out in <110> directions (24). The loops appear rhombus-shaped for the oblique <110> directions from a {100} surface plane (24) (see Fig. 2a). However, when viewed along the <110> directions, the appearance of the punched-out dislocation loops may vary from near-square to near-rectangular shapes (see Fig. 2b), depending on the specific <110> direction in which dislocations were punched out and the specific {110} plane.

Many authors have reported that the denuded zones could form at the wafer surfaces after a low-high, two-step annealing (8, 12, 13). In our experiments we annealed several seed-end wafers in a low-high, two-step condition

Fig. 3. An OPM photomicrograph of the cross-sectional, {110} surface of a seed-end wafer, annealed at 800°C for 16h in dry O₂, and at 1050°C for 16h in Ar, after 60s in Wright etch, showing high density microdefect etch pits uniformly with no clear denuded zone formed.

(800°C for 16h, in dry O₂, followed by 1050°C for 1, 4, or 16h in Ar, respectively). However, the results showed that no denuded zones formed at the surfaces of any of these wafers. The microdefect etch-pit density of about 3.2×10^{10} cm⁻³ was uniformly distributed over the entire cross-sectional surfaces of the wafers (see Fig. 3). Since oxygen out-diffusion at 800°C is small, and the driving force for oxygen precipitation in silicon wafers is large at this temperature, the interstitial oxygen atoms precipitate rapidly both in the bulk and at the surface of the wafer. During the subsequent high temperature annealing, some of the precipitates formed at the low temperature step, whose size is greater than the critical radius, r^* , for oxygen precipitation at 1050°C, will continue to grow, and some of the precipitates, whose size is smaller than r^* , will shrink both at the wafer surface and in the bulk (7, 15). The critical radius increases with increasing annealing temperature and, in this investigation, it is about 10 Å at 1050°C (7). After 16h annealing at 800°C, the size of the oxygen precipitates may grow to about 350 Å-square (25), which is much greater than the critical radius, r^* , for oxygen precipitates at subsequent 1050°C annealing. Thus, shrinkage of the precipitates will not occur at subsequent 1050°C annealing. Therefore, denuded zone formation is unlikely after a low-high, two-step annealing.

It may be noted that the density of etch pits on the cross section of the wafer annealed at 800°C for 16h in dry O₂ without subsequent high temperature anneal is much lower than for wafers annealed by a low-high or a high-low, two-step treatment (compare Fig. 4a and 3). Since the maximum nucleation rate reported was generally near 750°C for oxygen precipitation in silicon (7, 15), it was expected that a high density of microdefects would form in the wafer after an anneal at 800°C for 16h. TEM observations show a high density of microdefects have indeed formed in the wafer (see Fig. 4b). The microdefects were too small to be completely delineated by the Wright-etch technique. The etch pits in Fig. 4a may only be the result of large microdefects with dislocation loops around them. When this low temperature anneal was followed by a high temperature anneal (1050°C for 1, 4, or 16h in Ar), only stacking faults were observed with TEM.

Annealing ambient effects.—Figure 1 shows that denuded zones of about 20 μm in depth formed in a seed-end wafer after being annealed in an Ar ambient. The microdefect etch-pit distribution on the {110} cross-section surface of a seed-end wafer after being annealed in an oxidizing ambient (dry O₂) is shown in Fig. 5. Only very narrow denuded zones (≈ 5 μm) are present near the wafer surfaces, since the oxygen out-diffusion process is slower in the oxidation ambient than in an inert ambient. Another seed-end wafer was annealed in N₂ + 3% HCl ambient. Wide and clear denuded zones (about 25-30 μm) were formed in the subsurface region of the wafer (see Fig. 6) after being annealed. However, Hu (26) stated that the addition of 1% HCl to the oxygen ambient was not distinguishable from a pure-oxygen ambient for oxygen precipitation in silicon wafers. The experimental results of Craven and Korb (19) also showed that no apparent denuded zones were formed in HCl containing ambients, whereas clear denuded zones were formed in the oxygen ambients. They explained that the excess vacancies generated in HCl ambient enhanced the oxygen precipitation, since, they believed, these vacancies could act as the nucleation centers of oxygen precipitates, while excess silicon interstitials generated during oxidation annihilated some vacancies, resulting in a retardation of oxygen precipitation in the near-surface region. However, de Kock and van de Wijgert (27) indicated that silicon self-interstitials could act as nucleation centers of oxygen precipitates, and, thus, enhance the oxygen precipitation process in silicon.

The results of our investigation disagree with the results of Hu and of Craven and Korb mentioned above. Wide and clear denuded zones were formed in HCl containing ambients. During annealing in an HCl containing

Fig. 4. An OPM photomicrograph (a), and a TEM micrograph (b) of a seed-end wafer, annealed at 800°C for 16h in dry oxygen. a(left): The low density etch pits are randomly distributed throughout the cross sections of the wafer after 8 min in Wright etch. No obvious denuded zones formed at the subsurface region. b(right): Very high density of tiny microdefects in the wafer, $\sim 135 \mu\text{m}$ below the $\{100\}$ front surface. (Multiple-beam condition.)

ambient, excess vacancies were generated in the subsurface region of the wafer (19, 28, 29). We believe that these vacancies enhanced the oxygen out-diffusion process, and resulted in a wider denuded zone at the wafer surface than those formed in a non-HCl containing ambient. Therefore, oxygen out-diffusion appears to be the dominant mechanism for denuded zone formation, according to this investigation.

Annealing-time effects.—OPM results show that for annealing duration at the first step, of 0 to 4h at 1050°C, the wafers did not have a clear denuded zone at the surfaces. When this duration was increased to 16h, denuded zones of about $20 \mu\text{m}$ wide were formed (see Fig. 1). This result agrees favorably with the optimum anneal time of 16h calculated by Andrews (21) for oxygen-out diffusion during a dry oxidation anneal at 1050°C.

Initial oxygen concentration.—In addition to seed-end wafers, several tang-end wafers with $[\text{O}]_i = 1.30 \times 10^{18} \text{ cm}^{-3}$ (ASTM F121-79) were examined after a high-low, two-step anneal. OPM observation showed that there were only a few etch pits existing over the entire cross-sectional surface of these tang-end wafers. No meaningful measurements of denuded zones are possible for these tang-end wafers, as Series *et al.* (10) also pointed out. However, for these tang-end wafers, oxygen precipitation

is minimal in the bulk because of their low initial oxygen concentration levels.

Initial carbon concentration.—To examine the effect of carbon concentration, several seed-end wafers sliced from two CZ crystals with different initial carbon concentrations were annealed, employing the same high-low, two-step conditions (1050°C for 16h in Ar, followed by 800°C for 16h in dry O_2). One of these two CZ crystals had a carbon concentration ($7.0 \times 10^{16} \text{ cm}^{-3}$), or 1.4 ppma, seven times as high as the other one (0.28 ppma). The OPM observations show that denuded zones were formed at the subsurface region in all of these wafers, regardless of the carbon concentrations. It has been shown that carbon-oxygen complexes can act as nucleation centers for the precipitation of oxygen (30). However, during the first step, 1050°C annealing, the interstitial oxygen atoms diffuse out of the wafer surface and lower the oxygen concentration in the subsurface region to an undersaturated level, and oxygen precipitation at the subsurface region will not occur, despite the high concentration of carbon atoms existing in this region. Further, since both the diffusivity and the concentration of carbon atoms in silicon are quite small compared to oxygen, it is also unlikely for carbon atoms to precipitate out as carbide particles (31). Hence, the effect of the initial carbon concentration on the formation of precipitate nuclei may be

Fig. 5. An OPM photomicrograph of the cross-sectional $\{110\}$ surface of a seed-end wafer, annealed for 16h in dry O_2 at both 1050°C and 800°C. Very narrow denuded zones ($<5 \mu\text{m}$) were formed in the subsurface region.

Fig. 6. An OPM photomicrograph of the cross-sectional, $\{110\}$ surfaces of a seed-end wafer, annealed at 1050°C for 16h in $\text{N}_2 + 3\% \text{HCl}$ and at 800°C for 16h in dry O_2 . Wide and clear denuded zones of 25-30 μm were formed in the subsurface regions.

insignificant in the region where oxygen undersaturation exists, *i. e.*, in the near-surface region.

Summary and Conclusions

In this study, almost-defect-free denuded zones, formed in CZ silicon wafers heat-treated under different thermal histories, have been investigated. The principal results are as follows.

1. A high-low, two-step annealing (first, at 1050°C, then at 800°C) results in a clear denuded zone at the wafer surface, while the reverse sequence, *i. e.*, a low-high, two-step annealing (first, at 800°C, then at 1050°C) does not.

2. Annealing in an inert or an HCl containing inert ambient results in a much wider denuded zone (20-30 μm) than in an oxidation ambient ($\approx 5 \mu\text{m}$).

3. An annealing time of 16h at 1050°C is sufficient to form a denuded zone $\approx 20 \mu\text{m}$ wide.

4. A high initial oxygen concentration ($1.5 \times 10^{18} < [\text{O}]_i < 2.0 \times 10^{18} \text{ cm}^{-3}$), [old ASTM method (ASTM F121-79)] sufficient to induce bulk precipitates in the wafer, is required to delineate the oxygen out-diffused layer.

5. The highest carbon concentration present in the silicon wafers ($7.0 \times 10^{16} \text{ cm}^{-3}$) exerted no significant effect on the denuded zone formation.

6. The above results support the view that oxygen out-diffusion is the dominant mechanism for the formation of denuded zones in Czochralski silicon crystal wafers. These results do not agree with the excess-silicon-interstitial mechanism proposed by Craven and Korb (19).

Cathodoluminescence of $\text{Ca}_{1-x}\text{Mg}_x\text{S:A}$ ($A = \text{Eu}$ or Ce)

Hiroyuki Kasano, Kouichi Megumi, and Hajime Yamamoto*

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Cathodoluminescent properties of Eu^{2+} - or Ce^{3+} -activated MgS and $\text{Ca}_{1-x}\text{Mg}_x\text{S}$ phosphors are investigated at 300 K. It is found that MgS:Eu (0.01 mole percent [m/o]) exhibits a high energy efficiency ($\sim 16\%$) and an improved water-resistance if residual oxide content is less than 1 m/o. Under these highly sulfurizing conditions, MgS is confirmed to be completely miscible with CaS in any compositional ratio. The composition $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S:Eu}$ (0.05 m/o), Ba (0.1 m/o), whose color coordinates are comparable to the red phosphor $(\text{Y}_{0.964}\text{Eu}_{0.036})_2\text{O}_2\text{S}$, exceeds the latter in brightness by 15% at 18 kV excitation. Additionally, Eu^{2+} -activated alkaline-earth binary sulfides are examined. A complete miscibility is ascertained in the pseudobinary system where the difference in cation radius is less than 0.035 nm. Stress-induced peak shifts are observed in MgS:Eu and $\text{A}_{1-y}\text{B}_y\text{S}$ (A or $B \equiv \text{Mg}, \text{Ca}, \text{Sr}$ or Ba , $A \neq B$). Some mechanisms for these shifts are proposed.

It has been pointed out (1) that alkaline earth sulfides can be excellent cathodoluminophors when doped with proper activators. Among rare earth-activated phosphors, very high energy efficiencies were reported in green CaS:Ce ($\sim 22\%$) and red $\text{CaS:Eu}, \text{Ce}$ ($\sim 16\%$) (2) both of which utilize f-d transitions of the rare earth ions. However, energy efficiency has seldom been reported on for alkaline earth sulfides other than CaS . This is because poor chemical stability (3) prevents them from being used for practical applications. Therefore, it is preferable from the standpoints of both chemical stability and chromaticity control to form solid solutions with CaS . Some properties of these pseudobinary sulfide phosphors have been reported in the CaS-SrS system (completely miscible (4)), CaS-MgS system (partially miscible) (5), and CaS-BaS system (partially miscible) (6). However, cathodoluminescence in rare earth-doped phosphors has been investigated only in the CaS-SrS system (7).

This paper deals with the preparation and cathodoluminescent properties of MgS -based phosphors (MgS and $\text{Ca}_{1-x}\text{Mg}_x\text{S}$) activated with Eu and/or Ce . It is emphasized that the CaS-MgS system is completely miscible when fired in a highly sulfurizing atmosphere, and that $\text{Ca}_{1-x}\text{Mg}_x\text{S:Eu}$ exhibits promising luminescent properties. Peak shifts of an Eu^{2+} emission band observed in alkaline earth sulfides are also discussed.

Experimental

Magnesium sulfide-based phosphors are prepared by the method illustrated in Fig. 1: on firing MgS , MgSO_4 (optical grade, Hakushin Kagaku Laboratory Company, Limited) mixed with Eu and/or Ce compounds (4N, Rare Metallic Company, Limited) were used as a starting material. Carbonate was used for CaS . The mixtures charged in a quartz boat were first heated at 1100°C in a H_2S stream (4N, Seitetsu Kagaku Company, Limited) for 3 or 4 h. Then, the product was lightly ground and refired at 1200°C for 3 h in a sulfurizing atmosphere. This process was repeated once again. During the last firing, PCl_3 was introduced into a reaction tube for 30 min. The compound PCl_3 (5N, E. Merk Company), was reserved in a quartz bubbler at 25°C and carried with argon at partial pressures of $4 \sim 8 \times 10^3$ Pa. Calcium sulfide was obtained in a similar manner. Compound $\text{Ca}_{1-x}\text{Mg}_x\text{S:A}$ was prepared by firing a mixture of $(1-x)$ mole fraction of CaS:A and x mole fraction of MgS:A at 1200°C in H_2S for 1 or 2 h. In some cases, $\text{Ca}_{1-x}\text{Mg}_x\text{S:Eu}$ was directly synthesized from CaCO_3 , MgSO_4 , Eu_2O_3 , and H_2S . A similar firing process was also used with PCl_3 doping.

The sulfide percentage of the fired products was estimated by weighing before and after firing. This is because an x-ray diffraction analysis showed that the products were simply composed of the sulfide and the oxide, and because the transport loss during the run could be ignored. Grain size, lattice constant, impurity concentration, and chlorine content were measured by SEM, x-ray

diffraction, spectrophotometric, and chemical analyses, respectively. Cathodoluminescence was measured at 300 K with a demountable cathodray apparatus. An electron-beam current was typically 100 nA, and the accelerating voltage was 18 or 27 kV. Raster size was 2×1 cm^2 . Emission was observed through a glass window with a grating monochromator (Nikon P-25) and a photomultiplier (RCA 7265). All spectra were corrected for monochromator transmission and photomultiplier response, and given in terms of emission intensity per unit wavelength interval as a function of wavelength. The spectral resolution limit was 0.02 eV. Brightness and energy efficiency were measured with a photometer radiometer (United Detector Technology II A) and given as relative values to the standard sample, i. e., $(\text{Y}_{0.964}\text{Eu}_{0.036})_2\text{O}_2\text{S}$ for a red phosphor and $\text{ZnS:Cu}, \text{Al}$ (P-22) for a green phosphor. The sample screen was formed by sedimentation of the stirred phosphor powder in ethyl alcohol onto a steel substrate. Screen weight was kept to be 9-11 mg/cm^2 .

Waterproof testing of MgS:Eu was carried out at 300 K. First, 50 mg of MgS:Eu powder was stirred in 1000 ml of deionized water for a desired time. Then, the phosphor was rinsed in ethyl alcohol and formed into the screen, as mentioned above.

Results

Influence of sulfurized ratio on characteristics of MgS:Eu .—There has been little reported on the emission efficiency of MgS:Eu , although the emission spectrum

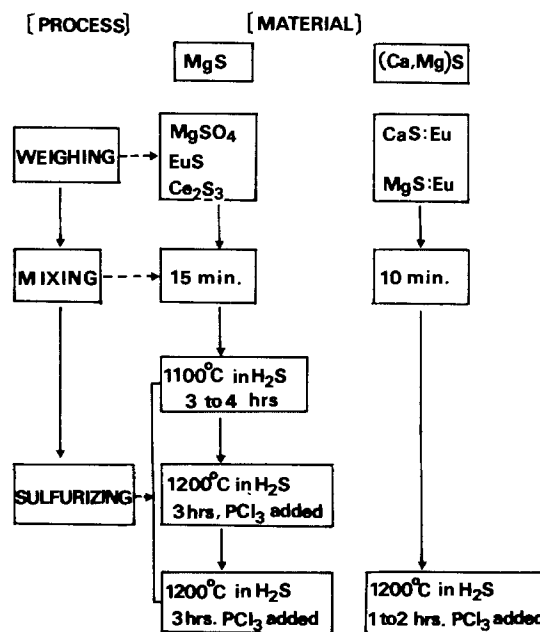

Fig. 1. Firing process of MgS -based phosphors

* Electrochemical Society Active Member

peaked at 591 nm (300 K) was shown to be narrower than those of CaS:Eu and SrS:Eu (8). In this study, it was found that the energy efficiency as well as chemical stability of MgS:Eu are strongly dependent on the sulfurized ratio of the host material, as was typically shown in Fig. 2, where the Eu concentration involved was kept to 0.04 mole percent (m/o). The fact that phosphor properties are noticeably improved with increasing sulfurized ratio is indicated in Fig. 2. This is especially so in a highly sulfurized region, where the grain size rapidly increases and the lattice constant approximates to 5.2015 Å for a sulfurized ratio above 85%. The slightly large value of the ultimate lattice constant compared with that of undoped MgS ($a = 5.200$ Å) is thought to be caused by Eu doping. Energy efficiency exceeds 120% relative to $(Y_{0.964}Eu_{0.036})_2O_2S$, the red phosphor used for color TV, when the sulfurized ratio exceeds 99%. This means that the absolute efficiency exceeds 15.5% in this sulfurized range, where the full width at half maximum (FWHM) of the Eu^{2+} band approaches 1130 cm^{-1} . For simplicity, the term "half-width" is used in the figures of this paper instead of the term "FWHM." These high efficiencies have not yet been reported in any other phosphor activated only with Eu. It is noteworthy that such an efficient phosphor was obtained with Eu concentrations less than 1/100 of that in Y_2O_2S , 1/5 of that in SrS, and 1/2 of that in CaS. Efficiencies of the alkaline earth sulfides were found to be in the order

The MgO is very hard to completely sulfurize in H_2S , in contrast to CaO, SrO, or BaO. The fact that the firing products were sulfurized above 98% in the present work is mainly due to the effect of PCl_3 flux. Similarly, both grain growth and Eu diffusion are markedly promoted by PCl_3 doping.

To examine chemical stability, a waterproof test of MgS:Eu was carried out. The data are shown in Fig. 3.

Fig. 2. Characteristics of MgS:Eu(0.04 m/o) dependent on sulfurized ratio of host material.

Fig. 3. Degradation of MgS:Eu(0.04 m/o) due to chemical reaction with water. Sulfurized ratio is used as a parameter.

The CL efficiencies of four samples whose sulfurized ratio differ are normalized by those obtained prior to rinsing. It is found that increased sulfurized ratios make the phosphor more resistive to water; in a 99% sulfurized case, the efficiency remains 96% of the initial value even after the phosphor was rinsed for 1h. Degradation may be caused by surface layer reoxidation, because MgO was clearly detected in the degraded sample by x-ray diffraction analysis. Extrapolatedly speaking, the degradation may be ignored if the sulfurized ratio reaches 100%.

Influence of activator concentration on energy efficiency of MgS:A.—Solubility of Eu or Ce in MgS is supposed to be less than that in CaS since the ionic radius of Mg^{2+} (0.65 Å) is rather small compared with that of Ca^{2+} (0.99 Å). Concentration dependence of efficiency η is illustrated in Fig. 4. Maximum value of η in MgS:Eu would be obtained at about 0.01 m/o of Eu. This value is 1/5 that of the CaS:Eu case (2). However, optimum Ce concentration in MgS:Ce is about 0.04 m/o, which is comparable to the CaS:Ce case (2). However, η in MgS:Ce is lower by about 30% than in CaS:Ce ($\eta \approx 110\%$ relative to P-22). When using $MgCO_3$ as a starting material, η remains at still lower levels because the sulfurized ratio is somewhat lower (about 97%). Moreover, the coactivator Ce in MgS:Eu, which was expected to improve η drastically (2), brought no fruitful result. Although one example MgS:Eu (x m/o), Ce (0.28x m/o) is shown in Fig. 4, a similar conclusion was obtained in any mole ratio of Ce to Eu. The relatively low η levels observed in MgS:Eu, Ce may be due to some kinds of lattice defects introduced by Ce codoping. This is because the shape of the η curve resembles that of MgS:Ce and also because the optimum Eu concentration shifts toward the higher side compared with the MgS:Eu case.

Composition dependence of CL in $Ca_{1-x}Mg_xS:A$.—To observe the properties of the pseudobinary phosphor, $Ca_{1-x}Mg_xS:A$ ($A = Eu$ or Ce) was synthesized from $CaS:A_1$ ($A_1 = 0.1$ m/o Eu or 0.04 m/o Ce) and $MgS:A_2$ ($A_2 = 0.04$ m/o Eu or 0.04 m/o Ce) by heating the sulfide mixture with a desired ratio at $1200^\circ C$ in H_2S . As was de-

Fig. 4. Variation in CL efficiency of Eu- or Ce-activated MgS as a function of activator concentrations.

scribed above highly sulfurized (99%) MgS grows to 10 μm in size with an excellent crystalline quality. Using this type of MgS, we succeeded in obtaining Ca_{1-x}Mg_xS:A with an optical composition ratio, *i.e.*, the CaS-MgS system was found to be completely miscible by x-ray diffraction analysis, although partial miscibility (14% MgS in CaS and 12% CaS in MgS) (5) was reported previously. The miscibility gap was probably due to the low-sulfurized ratio of MgS. Mutual solubility of CaO and MgO are limited to within 5% from the end components (9). Variation in lattice constant is shown as a function of compositional ratio x in Fig. 5. Vegard's law was found to hold in the CaS-MgS system.

Cathodoluminescent properties of Ca_{1-x}Mg_xS:Eu are also included in Fig. 5. Both peak wavelength λ_0 , and full width at half maximum, *i.e.*, half-width ΔW of the Eu²⁺ band vary with x . Peak wavelength reaches the longest one, 658 nm, at $x \approx 0.35$. In a composition range of $x < 0.6$, ΔW increases with increasing x , but becomes constant in $x \geq 0.6$ except around 0.95 (anomaly point) where ΔW rapidly increases. The other anomaly point exists at about 0.05, where a slight broadening of ΔW was observed. The CL band becomes more asymmetrical at these anomaly points. The lattice constant also deviates slightly from Vegard's law near these points, as is shown in Fig. 5. Judging from these results, crystalline quality is disturbed at compositions near these points where alloying is somewhat difficult. This is confirmed by x-ray diffraction analysis. The composition dependence of a splitting index b/a in a high-angle ($\sim 85^\circ$) diffracted x-ray line is shown in Fig. 6, *i.e.*, a ratio of the dip height "b" between the CuK _{α 1} line and the CuK _{α 2} line to the peak height "a" of the CuK _{α 1} line in comparison with the variation in η . A larger b/a value corresponds to a lower crystalline quality. The figure indicates that b/a rapidly increases at compositions near 5% from the end members of the alloy, where η locally drops. A decrease in η is additionally observed in the broad ranges of compositions, $0.3 \leq x \leq 0.5$ and $0.7 \leq x \leq 0.8$. The decrease in the former range implies an inferior crystalline quality as suggested from b/a , while that in the latter range does not. It is believed that the η drop in the former range is due to an insufficient firing, but the latter case may be essential, since further firing at

Fig. 5. Characteristics of Ca_{1-x}Mg_xS:Eu dependent upon compositional ratio x . Half-width ΔW means full width at half maximum.

Fig. 6. Comparison of CL efficiency with crystalline quality in Ca_{1-x}Mg_xS:Eu as a function of compositional ratio x .

1200°C in H₂S easily improved both η and b/a in the former but not in the latter.

Similar anomalies were observed in the Ce-activated case. The λ_0 and ΔW in the Ce³⁺ band of Ca_{1-x}Mg_xS:Ce(0.04 m/o) are illustrated in Fig. 7. As is well known in MgS (1), CaS (2), and SrS (10), the Ce³⁺ band has a second peak on the lower energy side of the main peak, corresponding to the spin-orbit splitting of the Ce³⁺ ground state. Here, ΔW includes the contribution of the both emission bands. It is found that ΔW expands linearly with the increase of x , though anomalously at $x \approx 0.05$ and 0.95. Around 0.65 of x , λ_0 and η take the longest and minimum values, respectively. This is different from the case of Eu²⁺ activation. However, it is noteworthy that η in Ca_{1-x}Mg_xS phosphors becomes lowest at $x \approx 0.7$ both in Eu²⁺ and Ce³⁺ activated cases. In Ca_{1-x}Mg_xS:Ce, the η observed is far lower in comparison with the value expected from that of

Fig. 7. CL properties of $\text{Ca}_{1-x}\text{Mg}_x\text{S}:\text{Ce}(0.04 \text{ m/o})$ as a function of x . Full width at half maximum ΔW is represented as half-width in the figure.

$\text{Ca}_{1-x}\text{Mg}_x\text{S}:\text{Eu}$. Therefore, η in $\text{Ca}_{1-x}\text{Mg}_x\text{S}:\text{Eu}$, Ce is at a level similar to that in $\text{Ca}_{1-x}\text{Mg}_x\text{S}:\text{Eu}$.

Highly bright red phosphor $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}:\text{Eu}$.—Chromatic shift in $\text{Ca}_{1-x}\text{Mg}_x\text{S}:\text{Eu}$ (0.05 m/o) dependent upon x is shown on the CIE x - y color coordinates in Fig. 8. By varying x , chromaticity changes from deep red ($x = 0.695, y = 0.303$) to orange ($x = 0.575, y = 0.425$), along with the high (x, y) locus of the pure spectral radiation. Red phosphors suitable to a color TV system are obtained in composition range $x = 0.85 \sim 0.92$, where the y value can be adjusted to $(\text{Y}_{0.964}\text{Eu}_{0.036})_2\text{O}_2\text{S}$ ($x = 0.648, y = 0.344$) by means of the Eu concentration. The x values of these alloy phosphors are somewhat larger than $(\text{Y}_{0.964}\text{Eu}_{0.036})_2\text{O}_2\text{S}$. This is preferable from the viewpoint of color coordination, since the freedom of color display design becomes broader. Fur-

Fig. 8. CIE chromaticity diagram showing color coordinates of $\text{Ca}_{1-x}\text{Mg}_x\text{S}:\text{Eu}$. Some other phosphors are also included for comparison.

thermore, $\text{Ca}_{1-x}\text{Mg}_x\text{S}:\text{Eu}$ has a red body color and, thus, does not need to be pigmented.

The data in Fig. 5, 6, and 8 are for samples prepared simply by heating the mixture of Eu-activated CaS and MgS at 1200°C in a H_2S atmosphere. This is conventional, but is not the best method to improve η . The phosphors with high brightness were prepared first by firing the undoped 1:9 mixture of CaS and MgS at 1200°C for 3h and then refring the mixture of Eu_2O_3 and $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}$ at 1200°C for 2.5h both in the H_2S atmosphere. Brightness B and η of $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}:\text{Eu}$ are shown in Fig. 9a as a function of Eu concentration. Maximum brightness was given at 0.05 m/o of Eu. The y value of the color coordinate was 0.345 at Eu concentrations of 0.045 m/o or less, and decreased above 0.05 m/o. To improve η, y m/o of BaS was further added to $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}:\text{Eu}$ (0.04 m/o) during the firing process. This is because BaS has been found in our experiment to be effective for Eu diffusion in CaS (11). By varying y, B , and λ_0 of $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}:\text{Eu}$, Ba moved as shown in Fig. 9b. An enhanced brightness was observed in the y range below 1 m/o, whereas λ_0 monotonically increased with increasing y . The η and B reach maximum at $y \approx 0.1$ m/o. The decrease in η with the increase of y was partially caused by mechanical damage introduced while crushing the products. This is because the products cohered severely with increasing y . Cathodoluminescence of highly sulfurized $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}:\text{Eu}$ (0.05 m/o), Ba (0.1 m/o) exceeds $(\text{Y}_{0.964}\text{Eu}_{0.036})_2\text{O}_2\text{S}$ in brightness by about 15% when excited at 18 kV, as indicated in Fig. 9. This implies that the absolute efficiency exceeds 14%. There have been few reports of red cathodoluminophors with such high brightness in such a low Eu doping range. Exciting current dependence of efficiency in $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}:\text{Eu}$, Ba (0.1 m/o) is shown in Fig. 10. For 0.04 m/o Eu, η is nearly independent of the current in this experimental range, although a slight increase was observed in a low current region. On the contrary, a clear current dependence was found in the case of 0.01 m/o Eu. Excitation-voltage dependence of η was inverse in these two Eu concentrations. The excitation current density corresponding to a typical color TV set is about 100 nA (Fig. 10).

Discussion

Energy efficiency in $\text{MgS}:\text{Ce}$.—Maximum energy efficiencies observed in the experiment for Ce- or Eu-

Fig. 9. CL properties of highly bright $\text{Ca}_{0.1}\text{Mg}_{0.9}\text{S}:\text{Eu}$ (x m/o), Ba (y m/o). From (9a) and (9b), optimum concentrations for brightness are found to be $x = 0.05$ and $y = 0.1$.

Fig. 10. Exciting current dependence of efficiency in Ca_{0.1}Mg_{0.9}S:Eu (x m/o), Ba(0.1 m/o). The cases $x = 0.01$ and 0.04 m/o are illustrated.

activated alkaline earth sulfides are shown in Fig. 11 as a function of an ionic radius of cation. As was indicated above, η_{\max} in MgS:Ce stayed at an unreasonable level. This is lower, by about 50%, than the value expected from the extrapolated curve in Fig. 11. This gap may be caused by (i) the difference in the ionic radius between Ce³⁺ and Mg²⁺, (ii) the difference in valency between Ce³⁺ and Mg²⁺, or (iii) the influence of residual oxygen in MgS. As is well known, the ionic radius of Ce³⁺ (1.01Å) is about 50% larger than that of Mg²⁺ (0.65Å). In such simple rock salt structures as alkaline earth sulfides, it is certain that impurities larger than a host ion in size are difficult to incorporate compared with the case of a host with lower crystal symmetry, because lattice flexibility is lower in the former. The differences in optimum Eu concentration

Fig. 11. Maximum CL efficiencies observed in this experiment for Eu- and Ce-activated alkaline earth sulfides.

among alkaline earth sulfides mentioned above is thought to be related to solubility in the sulfides. However, this anomaly is not simply due to stress caused by the difference in size between Ce³⁺ and Mg²⁺, because η is sufficiently high in MgS:Eu, where the ionic radius difference between Eu²⁺ (1.15Å) (12) and Mg²⁺ is larger than the former. This brings to mind the Mg-S phase diagram where no compound other than MgS has yet been found, although AS_{1-x} (A = Ca, Sr, and Ba) was reported (12). This implies that cation vacancies are easily generated in CaS, SrS, and BaS when excess sulfurization takes place, whereas the situation is different in MgS. That is, in the former sulfides an excess charge of a Ce³⁺ ion can be compensated in such a way as to generate a Ce₂S₃ structure locally in the matrices. As is well known (13), Ce₂S₃ is easily formed from CeO₂ by heating at 900° ~ 1400°C in a H₂S atmosphere. This Ce₂S₃ is considered to be γ -type in the former sulfides, because Ce₂S₃ powder shows a red body color (13) in the CaS matrix when it is not sufficiently diffused. The γ -Ce₂S₃ crystallizes with a defect cubic structure (14), the electronic requirements for tetrahedral bonding being fulfilled by the incorporation of a lattice vacancy on one-third of the cation sites. In other words, γ -Ce₂S₃ is stable in the excess-sulfurized CaS matrix. Actually CL efficiency in CaS:Ce containing no coactivators exceeds 80% that of CaS:Ce doped with PCl₃, if fired under excess-sulfurized conditions.

However, MgO could not be sulfurized perfectly in this experiment. As a result, it is likely that (i) Ce³⁺ ion charge compensation due to introduction of the cation vacancies is not completely performed, or (ii) residual oxygen atoms in MgS prevent the f-d transition of a Ce³⁺ ion. Therefore, the smallest alkaline metal Li was diffused into MgS:Ce as a charge compensator in an additional experiment. In this experiment, the mixture of MgS:Ce(0.05 m/o) and Li(1 m/o to MgS:Ce) was fired at 1200°C for 1h in a vacuum-sealed quartz ampule or in a H₂S stream. Phosphors thus obtained were tested, and the results are summarized in Table I. The detected Li concentration in fired phosphors is two orders of magnitude lower than the charged one. This is probably due to active reaction of Li with the quartz boat. It is plausible, based on the data in Table I, that Li metal is rather harmful in MgS:Ce for the f-d transition of a Ce³⁺ ion. We confirmed experimentally that radiation from a Ce³⁺ ion in MgS was not enhanced by codoping of other alkaline metals Na, K, Rb, and Cs. This result agrees with that described above: radiation enhancement by PCl₃ doping was not observed for MgS:Ce. At this stage, it seems that the low CL efficiency in MgS:Ce results from the existence of oxygen atoms in quantities a few tens times as much as cerium in mole fraction. A killer mechanism by the residual oxygen is still unclear. One possibility is a Ce₂O₂S formation. The Ce₂O₂S is nonluminescent.

Peak shifts of Eu-band in alkaline earth sulfides.—As was typically shown in Fig. 5, peak wavelength of the Eu²⁺ band varies according to the composition of the alkaline earth sulfide host. Generally, these peak shifts are explained in connection with the crystal field strength, such as 10 Dq, which is governed by both a lattice constant and an ionicity of the cation (8). However, the profile shown in Fig. 5 cannot be reasonably explained by this model. It is indicated that the stress fields imposed on an Eu²⁺ ion also cause peak shift in addition to the native crystal field. Both green and red shifts were observed as follows.

Green shifts.—Peak wavelength of MgS:Eu is shorter than that in CaS:Eu, which is the shift inverse to that expected from the periodic table. To clarify this phenomenon, peak positions of Eu²⁺ and Ce³⁺ bands in various alkaline earth sulfides were measured at 300 K (summarized in Table II) with 10 Dq and the ionic radius ratio of an activator to a host cation. For reference, the peak wavelength of the Mn²⁺ band is also included. As is well known, radiative emissions from Eu²⁺ or Ce³⁺ ions are due to f-d transitions. Energy splitting of the d state by the native crystal field

Table I. Effect of Li codoping in MgS:Ce. Prefired sample was MgS:Ce (0.05 m/o) mixed with 1 m/o of Li. Firing conditions were at 1200°C for 1 h in a vacuum-sealed (closed) tube or in H₂S

Li in pre-fired sample	Firing method	CL at 27 kV		Analyzed value in phosphor	
		$\eta\%$ (relative to ZnS:Cu, Al)	Peak (nm)	Ce (ppm)	Li (ppm)
None	in closed tube	80	522.2	100 ~ 500	—
Yes	in H ₂ S	68	520.7	100 ~ 500	50 ~ 100
Yes	in closed tube	<1	—	50 ~ 100	50 ~ 100

Table II. Peak positions of Eu²⁺, Ce³⁺, and Mn²⁺ bands in alkaline earth sulfides, comparing with 10 Dq and ionic radius ratios of activator to host cation

Host	10 Dq (cm ⁻¹)*	Peak wavelength (nm)			Ionic radius ratio**		
		Eu (0.1%)	Ce (0.04%)	Mn (0.2%)	r_{Eu}/r_{AE}	r_{Ce}/r_{AE}	r_{Mn}/r_{AE}
MgS	19,500	591	521	~700	1.77	1.55	1.23
CaS	18,750	651	520	585	1.16	1.02	0.81
SrS	17,400	616	503	~550	1.02	0.89	0.71

* Calculated based on Ref. (8) and (18).

** Pauling ion radii.

10 Dq increases monotonically from BaS to MgS. Since radiation occurs corresponding to an electron transition from the lower d level to the ground state, a larger value of 10 Dq generally gives a longer peak wavelength. For Mn²⁺ activators where radiation is due to d-d transitions, the peak position must be influenced more by the crystal field strength, as was reported in (Zn, Cd)S:Mn (15). The data in Table II are roughly subject to this rule except for MgS:Ce and MgS:Eu. In the latter, the largest green shift is observed, even though it was confirmed by ESR data that an Eu²⁺ ion substituted a Mg site, forming no "off-center" (8). A comparison of the spectrum data with the ionic radius ratio leads to the conclusion that local stress imposed on activator ions from the neighboring lattice (denoted as type I stress) is an important factor in green shift. According to the configurational coordinate model, distance R_0 between the lowest energy points of two adiabatic potential curves, which represent the excited state and the ground state, is governed by electron-phonon coupling. It is supposed that in the cases of MgS:Ce and MgS:Eu, R_0 shrinks because the lattice constant of MgS differentially expands around Ce or Eu atoms incorporated in the lattice sites. If this is so, a red shift of the excitation spectrum must be simultaneously observed in addition to the green shift of the emission spectrum. Nakao (8) reported 80 K excitation spectra where the transition from the ground state to the $^8\Gamma_4(t_{2g})$ band in MgS:Eu was slightly on the lower energy side of that in CaS:Eu; namely, the red shift was shown in the excitation spectrum.

Red shift.—A distinctive peak shift was observed in the pseudobinary host crystals, as was typically shown in Fig. 5 (Ca_{1-y}Mg_yS:Eu) and 7 (Ca_{1-y}Mg_yS:Ce). Emission spectra shift toward the lower energy side in the alloyed composition range. These "red" shifts were common at least in Eu-activated binary sulfides A_{1-y}B_yS except for Ca_{1-y}Sr_yS. Peak wavelength λ_0 in A_{1-y}B_yS:Eu is shown in Fig. 12 as a function of composition parameter y , which is not necessarily equal to the alloy composition. Here, y is taken as the composition of a sulfide having a larger chemical potential, i. e., A_{1-y}B_yS where $\mu_{AS}^i < \mu_{BS}^i$. In the CaS-MgS system, $y = 1 - x$ because $\mu_{MgS}^i < \mu_{CaS}^i$. Although 10 Dq simply varies with y , the change in λ_0 with y significantly deviates from the proportional rule. Longest peak wavelength λ_m in each pseudobinary was plotted as a function of the difference in ionic radius $|r_A - r_B|$ in Fig. 13, where the kink wavelength at $y \approx 0.4$ was taken only in the Ca_{1-y}Sr_yS:Eu case. A certain regularity is present for the red shift as indicated in Fig. 12 and 13: (i) the composition corresponding to λ_m is nearly constant in each pseudobinary ($y \approx 0.35$ or 0.65) and (ii) λ_m is sensitive to

$|r_A - r_B|$; λ_m increases with $|r_A - r_B|$ in a completely miscible region but is vice versa in a partially miscible region. It is suggested from (ii) that the red shift is caused by lattice stress due to the difference in the ionic radius of the divalent host cations. This stress is denoted here as type II stress. With the increase of $|r_A - r_B|$, elastic strain increases. Therefore, red shift is emphasized until plastic deformations happen due to the cluster or grain-boundary formations. Here, the red shift decreases as a result of the partial release in stress. Red shift is believed due to a structural change in energy bands as was reported by Cardona (16) for silver and cuprous halide pseudobinaries.

As to the mechanism of resulting type II stress, a periodic composition model is proposed on the basis of the following, 1-3, predictions coupled with the metallurgical rule described in 4.

Fig. 12. Peak shifts observed in alkaline earth binary sulfide A_{1-y}B_yS:Eu, where $\mu_{AS}^i < \mu_{BS}^i$, as a function of composition parameter y .

Fig. 13. Longest peak wavelengths in alkaline earth binary sulfide as a function of difference in cation radius.

1. Judging from Fig 7 and 12, internal stress reaches a maximum at $y \approx 0.35$ in pseudobinary sulfides.

2. For Eu- or Ce-activated Ca_yMg_{1-y}S, η hits a minimum around $y = 0.35$.

3. Nevertheless, crystalline quality of Ca_{0.35}Mg_{0.65}S is rather good according to x-ray diffraction data shown in Fig. 6, which means $y = 0.35$ is a stable alloy composition.

4. In a pseudobinary alloy system where a crystal structure is cubic with $r_A \neq r_B$, a generated elastic strain energy hits a minimum along a $\langle 100 \rangle$ direction and a maximum along a $\langle 111 \rangle$ direction (17). In this case, the different kinds of cations are generally inclined to take a split arrangement with each other along the $\langle 100 \rangle$ direction. The horizontal stripes along a $\langle 100 \rangle$ axis in a TiO₂-SnO₂ system are a typical example of this splitting. These stripes are caused by a periodic change in composition due to the spinodal dissolution (18). Also, in an alkaline earth sulfide pseudobinary, an alloying BS into AS may be accompanied with such a periodic microstructure as BS preferably occupying one of $\{100\}$ planes of a unit cell.

According to this model, structural alteration along the $\langle 100 \rangle$ axis results in uniaxial stress. This stress must reach maximum when one $\{100\}$ plane of an AS unit cell is completely replaced by BS: namely, $y \approx 0.35$ (5/14 of A atoms is replaced in the NaCl-type crystal structure). Since $\mu_{AS}^I < \mu_{BS}^I$ is provided in this section, composition $y \approx 0.35$ is thought to be most stable in the AS-BS pseudobinary system, and that of $y = 0.65$, i. e., an alloy composition where one $\{100\}$ plane of a BS unit cell is completely replaced by AS, is the next most stable. This is indicated based on a free energy vs. alloy composition curve generally given for the binary system. Even in the partially miscible system shown in Fig. 12 and 13, this structural alteration is thought to occur in each alloyed region. In these partially miscible pseudobinaries, emission from the BS-rich alloy was found to be very weak compared to the AS-rich alloy. Consequently, an emission spectrum of the binary was still apparently single-peaked, although intensity was decreased corresponding to increasing BS.

Finally, the compositional difference for λ_m shown in Fig. 12, i. e., $y = 0.35$ and $y = 0.65$, is discussed. As is con-

Fig. 14. Stress effects on peak shift of Mg_{1-y}Ca_yS:Eu as a function of y . If type I stress were ignored, λ_p profile must have a peak at $y = 0.35$, similar to Eu-activated binary sulfides without MgS.

sidered above, peak shift is principally subject to the modified crystal field potential, that is, the sum of 10 Dq, the homopolar local stress causing the green shift (type I stress) and the uniaxial stress causing the red shift (type II stress). For pseudobinaries containing MgS:Eu, type I stress plays an important role, as was shown in Table II. Then, λ_m shifts from $y \approx 0.35$ (determined from 10 Dq plus type II stress) to $y \approx 0.65$, as schematically illustrated in Fig. 14. If the influence of type I stress were ignored, the λ_p profile must be very similar to that of Mg_{1-y}Ca_yS:Ce.

Conclusion

It is confirmed that a highly sulfurized (up to 99%) condition is essential for MgS phosphors, although MgO is difficult to completely convert to MgS. As the sulfurized ratio increases, the important characteristic of the phosphor, such as crystalline quality, radiative efficiency, and resistivity to water, were remarkably improved. Under these highly sulfurized conditions, MgS was found to form a solid solution with CaS in any compositional ratio. The compound Ca_{1-x}Mg_xS:Eu having a reddish body color is promising for the red cathodoluminophor since η is sufficiently high ($\sim 15\%$) under europium concentrations as low as 0.01 \sim 0.05 m/o.

The f-d transitions of rare earth ions such as Eu²⁺ and Ce³⁺ are strongly influenced in the alkaline earth-sulfide hosts by some kinds of lattice stresses, in addition to the crystal field potential ordinarily subject to both the lattice constant and ionicity (19). Emission wavelength exhibits green shift due to homopolar stress localized around activator ions when the ionic radius is greater than site radius. However, red shift is observed in binary sulfides where the difference in cation radius exceeds 0.02 nm. As to the origin of this red shift, uniaxial stress due to periodic microalteration in composition along the $\langle 100 \rangle$ axis is proposed because the certain regularities are present between the composition and the maximum peak wavelength in the binary. This model must be hereafter verified experimentally.

Acknowledgments

Resolution of Fast and Slow Charging Processes in Ruthenium Oxide Films: An AC Impedance and Optical Investigation

J. Rishpon and S. Gottesfeld*

Department of Chemistry, Tel Aviv University, Ramat Aviv 69978, Israel

ABSTRACT

Ellipsometry and ac impedance measurements were employed for *in situ* investigation of anodic oxide films on Ru and of oxide films formed by thermal decomposition of Ru chloride. An instrumental setup for experiment control, data acquisition, and data analysis in automated measurements of the ellipsometric parameters and of the ac impedance is described. The effects of the applied bias and of proton concentration in solution on the rate of the double injection process of protons and electrons were studied. The charging process in the oxide film could be resolved into a faster mode, attributed to the charging of grain surfaces, and a slower bias dependent mode, which apparently involves incorporation of aqueous protons into oxide grains. The slower mode of charging is associated in hydrous oxide films with an effective diffusion coefficient of 10^{-11} - 10^{-12} cm²s⁻¹. The overall impedance due to the faster mode of charging in hydrous films in 0.1-1M acid solutions is smaller than 0.1 Ω cm², and this fast mode becomes diffusion controlled in solutions 10⁻³M in acid. However, in relatively dry films, e.g., "as-immersed" thermal oxide films, slower bias dependent rates are found for the fast mode of proton injection, probably due to a bias-dependent diffusion of protons along oxide grain surfaces.

The kinetics of "double injection" in oxide films, which involves the reversible uptake of ions and electrons, resulting in the net incorporation of a hydrogen or metal atom into an oxide structure, is of interest in several fields of electrochemistry: (i) it is the basis of the electrochromic characteristics of oxides such as WO₃ and MoO₃ (1), as well as anodic (2, 3) and sputtered (4, 5) iridium oxide and anodic rhodium oxide films (6), (ii) it seems to be the key for the electrocatalytic properties of such oxides, some of which exhibit activity in cathodic processes, e.g., H₂ evolution at WO₃, and some in anodic processes, e.g., oxygen evolution at iridium oxide or ruthenium oxide films, and (iii) it has been shown (7, 8) that even in simple Faradaic processes the electrochemical reactivity of hydrous oxides varies strongly depending on the extent of coupling between the internal redox system of the oxide and the redox system in solution. The activity of this internal redox system seems to depend, in turn, on the rate of the double injection process (8).

The process of double injection can be written in the following way for the case of electron-proton injection into a hydrous oxide, e.g., of Ru

i.e., a H atom is incorporated into a hydrous oxide by injection of an electron from the ohmic contact and a proton from solution, thus lowering the formal oxidation state of Ru by one unit. The reverse electro-oxidative process involves the double ejection of an electron and a proton. It can be seen that in the investigation of the kinetics of this reaction the elementary processes of interfacial transfer and of bulk transport of both an electron and a proton have to be considered. In previous investigations of hydrous oxides belonging to this family (9), it has been demonstrated that the effective conductivity of the oxide film with respect to the double injection process may change by several orders of magnitude as a function of applied bias. This happens particularly for these oxides which change from a "bleached" to a "colored" form as a function of applied bias, with the bleached form exhibiting the lowered effective conductivity. In such cases, the bleached form of the oxide may exhibit also blocking or nonblocking behavior in faradaic reactions as a function of the potential of the redox couple in solution (7, 8).

Optical measurements were applied in the past to the study of hydrous oxide films and provided information on hydrous oxide growth on metal substrates regarding the film thickness and its porous and hydrous nature (8),

Key words: ellipsometry, proton diffusion, double injection.

as well as the detailed variations in the films optical properties with applied potential (10, 11). The ac technique has been applied previously to the study of charging processes in hydrous films in aqueous as well as nonaqueous media (9, 12). In the last contribution (12), a theoretical detailed analysis of the form of the impedance plot (Z plot) for the double injection process has been described, where control by charge transfer and by one-dimensional diffusion normal to the film surface have both been considered. The result is a Z plot which may include a semicircular branch at higher frequencies due to the interfacial resistor (in parallel combination with the double layer capacitor), followed at lower frequencies by a branch due to diffusion through the film. This last branch, which is due to one-dimensional diffusion through a layer of finite thickness, is equivalent from an electrical point of view to the impedance of a finite transmission line (with capacitive termination), and is given by the following expression (13)

$$Z_D = Z_{D0} \text{ctnh}(i\omega L^2/D)/(i\omega L^2/D)^{1/2}; Z_{D0} = L^2/DC_T \quad [2]$$

where L is the film thickness, D the effective diffusion coefficient, L^2/D the characteristic diffusion time in the film, and C_T represents the total charge capacity of the film associated with the diffusion-controlled process, measured at a low frequency such that $\omega \ll D/L^2$. A similar description, in terms of a finite transmission line, for the charging of iridium oxide films by hydrogen has been given in Ref. (9).

In the work presented here, we investigated the optical characteristics and the ac impedance of ruthenium oxide films. The investigation included ellipsometric and ac impedance measurements performed on anodic Ru oxide films, formed by constant potential anodization or by potential multicycling of Ru metal in acid solutions. Measurements of the ac impedance were performed also on thermal Ru oxide films, produced by thermal decomposition of $\text{RuCl}_3 \cdot 3\text{H}_2\text{O}$ on gold substrates. The interest in Ru oxide was due to the following two reasons: (i) investigation of the features controlling the exceptional electrocatalytic properties of anodes based on Ru oxide point to the nature and the activity of the internal redox process in the film as a key factor (14) and (ii) contrary to Ir or Rh, which have one extra electron per ion in the +3 state as compared with Ru, the $d-\pi^*$ band in Ru oxide is not expected to be filled by bringing the oxidation state down to Ru^{+3} (15). As a result, Ru oxide films do not tend to "bleach," and it is not expected that the transport rate of electrons in Ru oxide would be strongly affected by applied bias, other than, perhaps, following extreme cathodization (16). Thus, effects of bias on the rate of double injection in Ru oxide films may depend more strongly on the variations of the proton transport rate with applied potential. Compared with previous ac impedance investigations of oxide films in aqueous solutions (9, 17, 18), we extended the measurements in this work to lower frequencies, down to the millihertz range. This extension allowed the resolution of slower bias-dependent charging processes in Ru oxide films.

Experimental

Electrode preparation.—Ru rod (Johnson & Matthey 99.9%) was inserted in a Teflon or epoxy housing so as to expose a single surface of a disk to the solution and mechanically polished to a mirror finish.

Ruthenized gold electrodes were prepared by electroplating Ru on a gold foil from a RuCl_3 , 0.1N HCl solution, as described by Vukovic *et al.* (19). The solution was prepared from ruthenium III chloride trihydrate (Aldrich).

Thermal ruthenium oxide electrodes were prepared by repetitive immersion of a gold plate in a 5 mg/ml RuCl_3 solution, drying over a hot plate, and then heating in air at 350°C (20). Pt wire or gauze were used as a counterelectrode, and a SCE as a reference electrode. All potentials are reported *vs.* SCE, unless otherwise specified.

The experimental set up.—Figure 1 shows a schematic diagram of the system for automated ellipsometry and ac impedance measurements employed in this work. An S-100 microcomputer is used for experiment control and data acquisition and analysis in both the ellipsometric and the impedance measurements. In the ellipsometric measurement, the microcomputer controls the rate of revolution of a rotating analyzer with an accuracy of 1:5000 ($\omega = 250 \pm 0.05$ Hz). This level of stability is achieved by on-off control of a simple dc motor, applied according to the cycle time continuously clocked by the computer. This stability of revolution allows one to obtain a precision of 10^{-2} deg in phase angle reading, after averaging for less than a second. The sinusoidal output of the photomultiplier is digitized by an A/D converter and analyzed by the microcomputer, using a fast algorithm which yields the three Fourier coefficients for the signal after each single cycle. The values of Δ and ψ for the reflecting surface are then calculated by the computer from these coefficients, and further numerical analysis gives film thickness and refractive index.

In the impedance measurement mode, the microcomputer scans the frequency of an oscillator between 5×10^{-3} – 4×10^3 Hz by a voltage ramp applied from a D/A unit. (The high frequency limit is set by the response of the existing A/D.) Exactly the same algorithm employed for the analysis of the optical sinusoidal waveform is employed also to evaluate the amplitude and phase of the periodic current signal resulting from the ac potential perturbation. Presentation of the experimental ac impedance results as either a complex z plot or a complex C plot ($C = 1/j\omega Z$) could be chosen. The last form of presentation turned out to be advantageous when the overall charge capacity and the resolution of several charging processes are of interest, as is the case for the system investigated here. [In all the figures containing complex capacitance plots, the capacitance units are in millifarads (mF), and the frequencies in hertz are designated on the curves.]

Results

Ellipsometric-reflectometric measurements.—Figure 2 depicts results reported previously (8) for the growth of an oxide film on ruthenium metal by constant potential anodization or by cyclic potential multipulsing. Figure 3 shows results obtained for the cyclic multipulsing mode of growth on our home-built automatic ellipsometer, and the similarity of the results obtained for the optical properties of the Ru oxide film can be verified. While some variation in n_{film} is found in a set of growth experiments, the following features were reproducible: (i) the uniform isotropic film growth model appeared to be a reasonable, if not a perfect model for both modes of film growth. (ii) The optical properties of the films grown at constant anodic potential are close to those reported for the film formed by oxygen adsorption from the gas phase on Ru metal (21),¹ and the absorption coefficient in the visible is exceptionally high compared to any other reported value for anodic oxides in a wet environment. Goel *et al.* have evaluated the complex refractive index spectrum for single-crystal RuO_2 in the visible and the UV (22). They obtained for, $\lambda = 546$ nm, $n_{\text{RuO}_2} = 1.9-0.9i$, which may be considered in good agreement with the result of our ellipsometric analysis for the anodic Ru oxide film, bearing in mind the microcrystalline structure of the latter. (iii) The film grown by cyclic potential multipulsing is seen to be of a more open structure and a larger water content, as judged from the smaller values of both n_{film} and k_{film} . Furthermore, as pointed out before (8), the "multipulsed film" can be grown up to a thickness exceeding 1000Å, while the film grown on Ru by constant potential anodization reaches a limited thickness of ca. 300Å.

One of the solutions for the ellipsometric results obtained for oxygen adsorption on ruthenium, which, for some reason, was regarded unreasonable, yielded for the surface layer formed a value of $n_{\text{film}} = 3 - i$ (18).

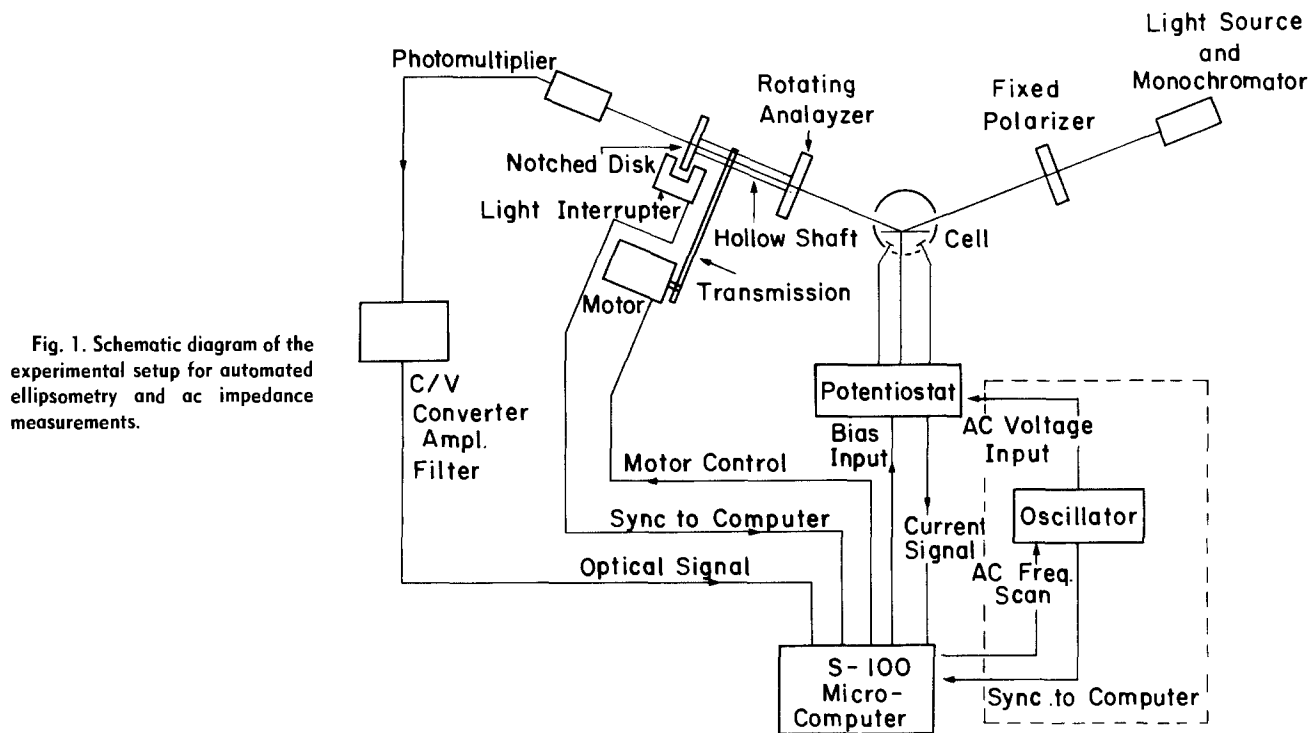

Fig. 1. Schematic diagram of the experimental setup for automated ellipsometry and ac impedance measurements.

Figure 4 shows the measured variations in Δ , ψ , and the reflectance as a function of applied bias for a Ru electrode covered by an oxide film grown under constant applied anodic potential in $0.5M H_2SO_4$. It can be seen that cathodization brings about a lowering of several degrees in Δ , combined with an increase of several degrees in ψ . It can be seen that the cathodic process is relatively slow, and develops further with holding under a constant cathodic applied potential. It can also be seen that the optical effect can be reversed by the reapplication of anodic potentials. Such variations in Δ , ψ , and the reflectance could be quantitatively accounted for in the framework of a single-film model by a combination of an increase in film thickness and a lowering in n_{film} (both the real and imaginary components) under cathodic applied potentials. For example, a Ru oxide film 280\AA thick with $n_{film} = 3.5-0.8i$, as found following growth under constant anodic potential, would bring about a change of: $\delta\Delta = -3^\circ$; $\delta\psi = +2^\circ$, and $\delta R/R = -10\%$ if its thickness would grow to 310\AA and its complex refractive index be at the same time lowered to $3.45-0.7i$. This optical evidence for a slow process of film swelling under cathodic applied potentials was helpful in the clarification of the ac impedance results obtained at low modulation frequencies, as discussed below.

AC impedance measurements—Teflon-mounted Ru rod electrode.—Figure 5 shows the complex capacitance plot ($C = 1/j\omega Z$) obtained for oxide films grown on the Ru rod electrode, which served also in the optical investigation. (The ohmic drop in solution is not subtracted.) It can be seen that the plots contain a semicircular feature, which reflects the fast charging process in the hydrous film, followed by an additional feature at lower frequencies. The plot of the diameter of the semicircular branch vs. the optically evaluated film thickness is shown in Fig. 6. The plot is reasonably close to a straight line with zero intercept. This dependence of film capacitance on thickness seem to be evenly distributed along its width. This result implies film uniformity, and supports, therefore, the assumption made in the evaluation of the optical properties. In the measurements in $0.5M H_2SO_4$, the apparent electrical behavior in the frequency domain corresponding to the semicircle is very simple, since the impedance associated with any transfer or transport process in the film is small compared with the ohmic resistance in solution. The semicircle is thus simply due to the charging of the anodic film through the solution resistor alone ($1.2-1.6\Omega$). On the basis of these results, it can only be concluded that the total resistance due to both proton and electron

Fig. 2. Experimental points and computer-fitted curves for a uniform film growth model, for the growth of anodic Ru oxide films on Ru in $0.5M H_2SO_4$, as reported previously (8). I(left): by cyclic multipulsing at 0.5 Hz between 1.225 and $-0.3V$. II(right): at constant potential of 1.225V. Thickness in angstroms designated. The ellipsometric measurements were taken at 546 nm.

Fig. 3. Experimental points and the computer-fitted curve for a uniform film growth model, for oxide growth on Ru in 0.5M H_2SO_4 by cyclic multipulsing. These results were obtained with the new computer-operated ellipsometric setup (Fig. 1). The solution for the complex refractive index of the film was: $n_f = 1.65 - 0.39i$. ($\lambda = 546$ nm.)

transfer and transport is less than $0.1 \Omega \text{ cm}^2$ in this fast mode of charging of anodic Ru oxide films. Work with Ru electrodes of a much smaller area may yield more quantitative information on the kinetics of this fast charging mode in hydrous Ru oxide in acid solutions.

Figure 7 shows the effect of the lowering of the acidity in solution on the complex capacitance plot. Bringing the

Fig. 4. Variations of $\Delta\psi$, $\Delta\Delta$, and the reflectance (for light linearly polarized at 45°) during a cathodic and subsequent anodic applied potential scan. The potential was held for 2 min at each potential, and for 40 min at $-0.1V$.

Fig. 5. Complex capacitance plots, measured at 0.5 (upper curve) and at 0.0V (lower curve) in 0.5M H_2SO_4 , following oxide film growth on Ru at 1.225V for 10 min. Solution resistance not corrected. Disk area: 0.52 cm^2 .

Fig. 6. Oxide capacitance (due to the fast charging mode) at 0.5V in 0.5M H_2SO_4 as found from the diameter of the semicircle in the complex C plot, plotted vs. the optically evaluated thickness for film growth by multipulsing for 2, 4, 8, 12, and 16 min. Disk area: 0.22 cm^2 .

acidity down to 5 mM H_2SO_4 , but maintaining the total electrolyte concentration at a high level (0.5M Na_2SO_4) results in the replacement of the semicircular main branch by a circular arc, very close in shape to a quarter-circle. This is the shape expected for a capacitor charged via a Warburg impedance, due to semi-infinite diffusion of the charging species (9). This result, therefore, confirms the selective consumption of protons in the charging process in hydrous Ru oxide, according to Eq. [1]. The diffusion coefficient can be calculated from Fig. 6 according to the frequency corresponding to the maximum of Imag C in the complex C plot: $\omega_{\max} = 1/\sigma^2 C^2$, where $\sigma\omega^{-1/2}(1-j)$ is the Warburg impedance, and $\sigma = RT/(F^2[C]D^{1/2})$, ($[C]$ being the concentration of the diffusing species). The result for D of the diffusing species in this case is $1 \times 10^{-5} \text{ cm}^2/\text{s}$, in accordance with HSO_4^- ions being involved in the process of diffusion from solution towards the electrode surface.

The other plot in Fig. 7 was obtained in a Na_2SO_4 solution containing no added acid. Following subtraction of the solution resistance, a fast feature is revealed, followed

Fig. 7. Complex capacitance plots for the Ru/RuO_x electrode. Oxide was grown in 0.5M H₂SO₄ for 10 min at 1.225V, and the electrode then transferred to a 5 mM H₂SO₄ + 0.5M Na₂SO₄ solution (upper plot), or to a 0.5M Na₂SO₄ solution (lower plot). Measurements taken at 0.72V RHE in each solution. (Equivalent to a potential of 0.5V SCE in 0.5M H₂SO₄.) Disk area: 0.52 cm². Solution resistance corrected.

by much slower charging processes. The fast charging process involves ca. 25% of the total number of fast charging sites in the same oxide film in strong acid solution. It seems that ca. 25% of the fast charging sites are available for simple "double layer charging" in which Na⁺ (and, perhaps, SO₄⁻) ions may participate in the reversible oxide charging process. This is, probably, the percentage of sites located at the outer surface of the film or in contact with larger solution-filled pores.

As mentioned above, the complex capacitance plot in Fig. 5 contains, in addition to the semicircular branch which reflects a fast process of double injection, an additional feature at very low frequencies. However, it turned out to be quite difficult to obtain reliable information on the low frequency branch from measurements with Teflon- or epoxy-mounted Ru rod electrodes. Minute penetration of the electrolyte solution between the rod and the insulating Teflon housing caused considerable irreproducibility of the very small currents measured at such low frequencies. Furthermore, such currents tended to increase with time of immersion and of anodic polarization for a particular electrode used. This problem brought us initially to a conclusion that these low frequency currents were primarily due to this leakage artifact (18). However, by using a different electrode configuration, of Ru deposited on a gold foil, the leakage problem was removed, and it could be demonstrated that the very low frequency feature is indeed associated with a charging process in Ru oxide, as discussed below.

Ruthenized gold foil electrode.— This electrode gave very reproducible results of ac currents in the very low frequency (VLF) domain and, furthermore, showed a very clear and reproducible dependence of the VLF branch on the applied bias. Figure 8 shows the two well-resolved charging branches for the ruthenized gold electrode in 0.5M H₂SO₄ at 0.5V, following potential multicycling to induce oxide growth. The same figure contains also simulation of this electrical behavior by an equivalent circuit, which appears in the insert. The following features are noticeable: (i) the higher frequency branch is again due to a simple RC series combination — R_{soln} in series with the capacitance of fast charging sites in the oxide. (ii) The low frequency branch could not be simulated by a single RC series combination. It could be well fitted, however, by a finite transmission line model, the total capacitance of which at $\omega \ll D/L^2$ is about twice that of the fast

Fig. 8. Complex capacitance plot for a Au/Ru/RuO_x electrode in 0.5M H₂SO₄ at 0.5V. Oxide was formed by 50 triangular potential multicycles between 1.22 and -0.3V. Points: experimental. Smooth curve: simulation by the equivalent circuit depicted, with the following parameters: $C_{\text{fast}} = 7.0$ mF; $R_{\text{soln}} = 1.6\Omega$; $C_{\text{slow}} = 13$ mF; $L^2/D = 1.0$ s; $\sigma' = 600\Omega$ s^{1/2}. (C_{slow} is equivalent to C_T in Eq. [2].)

charging sites, with a typical time constant $\tau = L^2/D$ of 1.0s. (With further oxide film growth, both capacitors, C_{fast} and C_{slow} , grew together.)

Figure 9a shows that the slower charging process is associated with an even larger capacitance at 0.0V. Furthermore, at this potential, the slow charging process could be best simulated by a series combination of an interfacial resistor and a finite transmission line. The need here of the additional resistor in the slow charging branch is particularly clear from observation of the Z plot given in Fig. 9b: the semicircular feature which appears in the Z plot at the higher frequencies is due to an R-C parallel combination, and is typical for the case where a charge transfer resistance, which precedes the diffusional transport, becomes significant (12). (This is a good example where a specific feature is immediately apparent from examination of the Z plot. In contrast to this case, the basic resolution of the slow and fast charging processes is not easily apparent from a Z plot, but shows very clearly in the C plot, as in Fig. 8.) The insert in Fig. 9 shows the equivalent circuit which simulates the complex plane plot obtained for the Ru/RuOx system at 0.0V.

Figure 10 exhibits the behavior recorded under a higher positive applied potential of 1.0V, together with the plot obtained at 0.5V, which is repeated in this figure for direct comparison. At 1.0V, the slow charging process practically disappears. Only the fast charging sites in the oxide are seen to be active at the higher applied bias.

It can be seen from Fig. 8-10 that yet another additional parallel branch, probably of a transmission line character, has to be used in the equivalent circuit to account for deviations from pure capacitive behavior at "ultra low" frequencies (ULF), i.e., at $\omega \ll D/L^2$, where D is the typical diffusion time in the slow charging process discussed above. This ULF region, for which only the high frequency end is covered in these measurements, was simulated by assuming an additional parallel transmission line for which the Warburg factor σ' was estimated. This last branch is designated by Z_D' in the equivalent circuits and the (very rough) estimate of σ' is given in the captions. Such an ultra-slow charging process may perhaps reflect film growth (24), and may thus be associated with the much slower transfer and transport of Ru ions in the film.

Fig. 9. a(above): Same as Fig. 8, but for a bias of 0.0V vs. SCE. The parameters in the simulation are: $R_{\text{soln}} = 1.6\Omega$; $C_{\text{fast}} = 3 \text{ mF}$; $C_{\text{slow}} = 32 \text{ mF}$; $L^2/D = 3\text{s}$; $R_{\text{ct}} = 20\Omega$; $\sigma' = 400\Omega \text{ s}^{1/2}$. (C_{slow} is equivalent to C_T in Eq. [2].) b(right): The same results for 0.0V SCE, presented in the form of a complex impedance plot (Z plot). The smooth curve is based on the same circuit with the same parameters as described for Fig. 9a.

Thermal Ru oxide films.—Figure 11 shows the complex capacitance plots obtained for thermal ruthenium oxide under three applied potentials in the “as-immersed” state, and Fig. 12 shows the same plots after 30 cycles of potential multipulsing have been applied to the thermal oxide. The following features are apparent: (i) following multicycling (Fig. 12), the fast charging sites in the thermal oxide behave in much the same way as in the anodic oxide, yielding at 1.0 and at 0.5V similar semicircular branches, corresponding to charging via the solution resistance alone. However, prior to multicycling (Fig. 11), the branch corresponding to fast charging is in the form of a depressed circular arc, with a significantly lower capacitance at 0.5 than at 1.0V. (ii) The VLF charging process seems to be much slower in the case of the thermal oxide as compared with the anodic oxide. This is reflected by the absence of a second well-resolved arc in the complex capacitance plot at 0.5V (Fig. 12), which can be clearly seen in the VLF region in the case of the anodic Ru oxide film (Fig. 8). (iii) Although the VLF charging process is slower, its amplitude at 0V seems to be larger in the thermal oxide than in the anodic Ru oxide. (Compare Fig. 12 and 9a.)

Discussion

The nature of the faster and slower charging modes in the oxide.—The following picture is suggested for the charging process in the Ru oxide films investigated in this work: the process can be seen to be well resolved into faster and slower charging modes. The faster mode is associated with proton uptake, but about 25% of the fast charging sites in the film can be apparently charged by ions other than H^+ if the concentration of proton donors is lowered well below 10^{-3}M . At a concentration level of 10^{-3}M of proton donors in solution (HSO_4^- ions in our case) the charging is found to be controlled by the diffusion of proton donors from solution towards the oxide surface (Fig. 7). The rate of the fast charging process in acid solutions is high, and, at this point, it can be claimed only that the impedance associated with it is significantly smaller than the resistance of the solution, i.e., $\ll 1 \Omega \text{ cm}^2$.

A slower charging mode, which is well resolved in the plots for the oxide film on ruthenized gold, results in an

electrical behavior of a finite transmission line, shown before to be typical for a process of diffusion through oxide films of finite thicknesses undergoing the double-injection process (12). The typical diffusion time associated with this slower mode is of the order of 0.1-s. For a diffusion length of 100-1000Å, which corresponds to the film thicknesses measured optically in this work, such diffusion times mean an effective diffusion coefficient in the film of $D = 10^{-11}\text{-}10^{-12} \text{ cm}^2/\text{s}$. This is three to four orders of magnitude smaller than the effective diffusion coefficient found for the fast charging mode in hydrous electrochromic films of e.g., anodic iridium oxide or anodic rhodium oxide (2, 7). As pointed out above, this slower process is clearly apparent in the thermal oxide at 0.0V, at which potential it is associated with a relatively large capacitance.

A model which seems to account for all these results involves the charging of grain surfaces in a hydrous microcrystalline structure as the fast charging mode, while charging of the bulk of the grain accounts for the slower charging mode. The slower mode is apparently associated with incorporation of aqueous protons during the cathodic half-cycle, and thus with a partial hydration and swelling of the oxide grains. The nature of the well-resolved slower mode of charging is substantiated by three aspects of the experimental results: (i) the dependence of its amplitude and rate in the anodic oxide on applied bias, demonstrated in Fig. 8-10, (ii) the results presented in Fig. 4 of slow variations in the optical properties of the oxide film under cathodic applied potentials, and

Fig. 10. Complex capacitance plots for the Au/Ru/RuOx electrode measured (I) at 0.5, and (II) at 1.0V. (The plot obtained at 0.5V includes the well-defined arc due to the slower charging mode, while the plot obtained at 1.0V includes the semicircle due to fast charging alone.)

Fig. 11. Complex capacitance plots for an "as-immersed" thermal Ru oxide electrode (on gold substrate) in 0.5M H₂SO₄. ▲ ▲ ▲ : 1.0V. ○ ○ ○ : 0.5V. □ □ □ : 0.0V.

(iii) the large amplitude and slow kinetics of the VLF charging mode found at 0V for the thermal Ru oxide on a gold substrate (Fig. 11 and 12). The dependence of the VLF branch on bias as found for the anodic oxide films means that the slow charging mode is enhanced under cathodic applied potentials, and is thus associated with a slower and more radical form of oxide reduction. The optical results (Fig. 4) supplement the results of the impedance measurements by showing that a slow process in the oxide, which occurs under cathodic applied potentials, is associated with the generation of a more hydrous and slightly thicker ruthenium oxide film, most probably due to the incorporation of aqueous protons into oxide grains. The optical measurements also demonstrate that anodization is capable of reversing this process, apparently by the ejection of the excess aqueous protons. The charging of the bulk of oxide grains, especially if accompanied by significant hydration, as suggested, may be associated with the relatively smaller diffusion coefficient of 10^{-11} - 10^{-12} cm²/s as evaluated from the simulations shown in Fig. 8 and 9. The charging of grain surfaces, which requires only the transport of protons along aqueous pores or along inner surface trapping sites (see below), may be associated, however, with a much higher effective diffusion coefficient. Finally, the results for the slower charg-

ing mode obtained for the thermal oxide support the model suggested in two ways: they show, by the presence of the slow charging branch at 0.0V, that it is associated with a process within the Ru oxide phase, rather than with any process at the Ru/RuOx interface, since such interface does not exist at all in the Au/RuOx (thermal) electrode. Furthermore, the absence of the slower charging mode at 0.5V in the thermal oxide and its sluggish appearance at 0.0V are explained by the larger barrier required for H₂O incorporation into the less hydrated structure of the thermal oxide. It thus seems that under a relatively thin outer hydrous layer (ca. 100-1000Å) the underlying thermal oxide is water free, and further water incorporation is slow and requires a significant cathodic overvoltage.

Slow effects in hydrous oxide films, which occur on a time scale much longer than that of the fast reversible charging mode, were described before. Thus, the electrochromic response in Ir, and particularly in Rh oxide, was shown to become sluggish following prolonged excessive cathodization (6-8). This phenomenon was explained by a slow excessive incorporation of water which lowers the electronic conductivity in the oxide film. Glarum and Marshall recently reported complex capacitance plots for nickel oxide films containing a VLF branch (17), which is

Fig. 12. Same as Fig. 11, but following 30 cycles of potential multipulsing between 1.22 and $-0.3V$. \cdots : $1.0V$. \blacktriangle : $0.5V$. \circ : $0.0V$.

probably due to a similar slow process in nickel oxide. It should be stressed again that only by the use of the ruthenized gold foil electrode, which has no structural features that can bring about solution penetration problems, could the very low frequency branch be recorded reproducibly, and the process ascribed to bulk grain charging quantitatively analyzed.

The rate of grain boundary charging in "semi-dry" oxide films.—The results in Fig. 11 and 12 contain some interesting information on the mode of charging in the "as-immersed" thermal oxide. After multicycling, the charging process is represented by the regular semicircular branch due to fast charging of (surface) sites in a hydrous layer, which is rate limited only by ohmic solution resistance (Fig. 12). In the "as-immersed" thermal oxide, however, the depressed circular arcs (Fig. 11) mean that the charging process is relatively slower, and behaves electrically as a combination of a large number of parallel RC branches with a continuous spectrum of charging times. Interestingly, under such circumstances, *i.e.*, when the structure has not been properly hydrated, the response is faster and the completeness of charging is better at more positive potentials: while there is no difference between the extents and the rates of charging at 0.5 and at 1.0V in the hydrated oxide layer (Fig. 12), the rate and extent of charging seem to be significantly higher at 1.0 than at 0.5V prior to hydration (Fig. 11). Dry Ru oxide is expected to exhibit very satisfactory electronic conductivity at both 0.5 and 1.0V. The reason for the difference in the rates of charging at 0.5 and 1.0V must be, therefore, traced to differences in the rate of protonic diffusion in the relatively dry oxide, induced by the applied bias. A bias-dependent diffusion coefficient for the diffusion of hydrogen in a hydrous oxide was described in Ref. (9): expressing the diffusion coefficient as a product of a frequency K_a and a jump distance d , *i.e.*, $D = Kad^2/2$, it was argued that K_a could be the electrochemical rate constant of a surface deprotonation reaction. Written here for Ru oxide, this surface deprotonation process may be described as follows

where each event of deprotonation may be followed by a proton jump (coupled, possibly, with an e jump) to a neighbor surface site. The frequency of surface deprotonation events may thus dictate the frequency of the individual diffusional jumps, while the distance of an individual jump may be identical to the distance between

adjacent proton trapping sites, located at the surface of the oxide grain (9). It can be realized from Eq. [3] that the residence time of protons at an oxide surface site may be shorter the higher the positive applied potential. This is true as long as the potential difference falls essentially across the oxide-electrolyte interface, as is expected for the electronically conducting Ru oxide.

A bias-dependent surface protonic diffusion process seems to explain the results of Fig. 11: in a relatively dry Ru oxide structure, the electronic component of transport should not pose a significant barrier for charging, but the small water content forces the proton to diffuse along oxide grain surfaces. Under such conditions of surface diffusion control, the double injection process is seen to be significantly faster at more positive applied potentials. It thus seems that these oxides exhibit enhanced activities under more positive potentials not only thanks to ejection of excess water (6-8). The enhanced activity may be also due to an increase in the rate of protonic transport, the proton diffusion along grain surfaces being assisted by the positive applied potentials (Eq. 3). In any case, interpretation of a measured apparent conductivity for the double proton-electron injection process in this type of oxides in terms of electronic conductivity alone (5) is questionable, as these results for thermal Ru oxide seem to suggest.

Technical Note

The Mechanism of Plasma Oxidation on Floating Silicon Substrates

K. K. Ng and J. R. Ligenza

AT & T Bell Laboratories, Murray Hill, New Jersey 07974

Oxidation in plasma environment offers the opportunities of fast oxidation rates and low temperature processing. An oxygen plasma can be formed in a microwave, RF, or dc discharge. Oxidation on externally biased substrates is referred to as plasma anodization while on unbiased substrates it is referred to as plasma oxidation (1-3). The origin of plasma anodization is believed to be due to negative oxygen ions, but the exact mechanism has been a subject of discussion, and no model has been generally accepted. The growth rate for constant voltage anodization was observed to be parabolic. The mechanism of plasma oxidation is seldom explained in literature and its data are more limited. The growth rate in this case was also found to be parabolic (4). Nonparabolic behavior was observed (5) but it was interpreted as being due to the coexistence of sputtering. In this experiment, plasma oxidations were performed at a variety of substrate positions and the thickness distributions of oxide across the wafers were recorded and analyzed in order to understand the oxidation process.

The plasma apparatus used is shown in Fig. 1 and its features are similar to that described in Ref. (6). Tantalum hot hollow electrodes with rolled foil structure (7) were used, and the pumping arms were designed to minimize oxygen partial pressure around the electrodes to avoid their oxidation. Different pedestals were also made in order to support the silicon wafers in different schemes in

the positive column of the plasma. A dc plasma is advantageous in this experiment since the plasma potential monotonically decreases along its column. All the experiments were performed with an argon pressure of 0.30 torr, oxygen pressure of 0.10 torr, plasma current of 3.0A, for a period of 1.0h. The substrate temperature was measured by the thermocouple to be $\approx 250^{\circ}\text{C}$. Silicon wafers of 75 mm diam were used unless otherwise specified, and the oxide thickness was measured by ellipsometry. The oxide distributions for a bisected wafer placed parallel to the axis of the plasma column is shown in Fig. 2. The oxide thickness is widely nonuniform along one direction but reasonably uniform along the other. This is clearly an electric field effect exerted by the plasma. The fact that the two halves display similar peaks indicates that the oxide was not deposited from sputtering the quartz wall. Since for a dc plasma, the plasma potential changes monotonically along its column, there must exist a current in the silicon substrate. In fact, if the wafer sits on a quartz pedestal, the current must enter the wafer from the end close to the anode and leave from the other. From this argument, and further experimental evidence that follows, plasma oxidation is in fact local plasma anodization, biased not externally but by the plasma potential itself.

To relate this plasma oxidation to anodization, typical Langmuir probe characteristics are shown in Fig. 3. The horizontal axis represents voltage on the substrate (V_{sub})

Fig. 1. Schematic diagram for the dc plasma oxidation system.

Fig. 2. Thickness distribution of oxide while the bisected wafer was placed parallel to the plasma column.

and the vertical axis represents current density flowing away normally from the surface to the plasma. The wall potential V_w is defined as the substrate voltage for zero current. Above this V_w , current flows away from the silicon surface to the plasma, and the reverse happens for substrate voltage below V_w . As mentioned before, since the plasma potential changes monotonically along its column, the wall potential also varies accordingly. The two curves shown in Fig. 3 represent the characteristics at two different locations, with the left curve (lower V_w) corresponding to the surface near the cathode. These characteristics show the extremes at the wafer ends and they vary continuously with position. The voltage difference between V_{w1} and V_{w2} was measured to be $\approx 25V$. For the sake of argument, the substrate potential is taken to be the same at different locations by assuming that the internal current, and thus the resistive voltage drop, is small.

Fig. 3. Langmuir probe characteristics for different parts of the silicon surface. The parallel shift is caused by the difference in wall potentials. The curve with a lower V_w corresponds to the surface close to the cathode.

By drawing a vertical line between the extremes of the two wall potentials for some arbitrary common substrate voltage, one can see that current enters the wafer from the anode side (negative J) and leaves the wafer from the cathode side (positive J). By comparing the oxide thickness distribution in Fig. 2, it can be seen that oxide grows faster with a positive current than with a negative current.

The data for silicon substrates placed perpendicular to the plasma column are shown in Fig. 4. In Fig. 4(a) and 4(b), the current enters the side facing the anode and leaves from the other. Again the data show that oxidation is more efficient with a positive current (surface facing cathode), a condition in which all the plasma anodizations are carried out. In Fig. 4(c), the silicon was backed by a

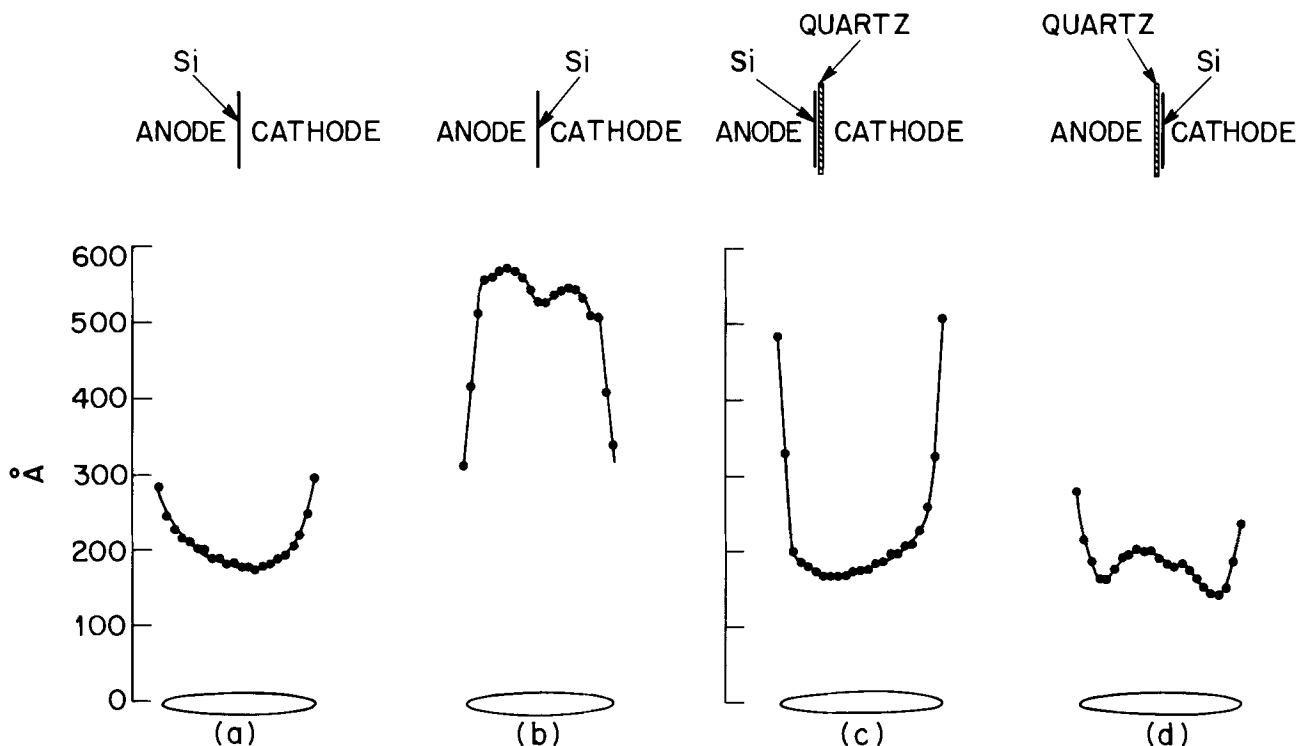

Fig. 4. Thickness distribution of oxide while the silicon wafer was placed perpendicular to the plasma with (a) surface facing anode, (b) surface facing cathode, (c) surface facing anode and backed by quartz plate, (d) surface facing cathode and backed by quartz plate.

quartz plate and current enters the center of the wafer and leaves around the edge, where the oxide film is observed to be thicker. In Fig. 4(d), current enters around the edge and leaves at the center. All the above observations are consistent with the model proposed. It has to be mentioned that when samples were placed perpendicular to the plasma column, a slightly stronger glow was observed around the edge, and the higher ion density may account for some of the oxide formation around the edge of the wafer. Ligenza (1), and Ray and Reisman (8) reported nonuniform oxides on floating substrates, but little explanations were given. The model also explains the parabolic growth in plasma oxidation seen by Ligenza (4), since this process is equivalent to anodization with a constant low anodization voltage, biased by the plasma internally.

Additional experiments were performed with other parameters varied one at a time. When 38 mm wafers were used instead of 75 mm, they showed very similar oxide distributions. When the substrate doping was increased, the overall oxide thickness was increased due to a larger internal current, but the oxide distributions were again similar. Oxide was also grown on wafers having a platinum coating at the back surface, and results indicated reduced oxide thickness with only a slight improvement on the distribution.

These experiments can only point out the first order effects. They cannot, however, resolve the details in oxidation kinetics. One of the questions remaining to be answered is whether oxidation takes place on the silicon surface when its substrate potential is exactly equal to the local wall potential. Due to the fact that the plasma has a flickery appearance, this cannot be resolved experimentally. Compounding this, there also exists a radial field from the center of the plasma to the chamber wall. An-

other factor is that the disk geometry of the wafers played some role in balancing the internal current density. All these factors make it difficult to account for all the details of oxide distributions observed, such as the dips at the centers of the two halves shown in Fig. 2. Nevertheless, the conclusion that oxidation is related to the passage of current through the silicon surface is apparent.

In summary, it is found that the mechanism of dc plasma oxidation on floating silicon substrates is actually due to local anodization caused by currents which are induced by the spatial variations of plasma potentials in an inhomogeneous plasma. Because of this nature, to obtain uniform oxide on an unbiased substrate is difficult, with the portion of the wafer close to the cathode being oxidized at a higher rate.

Electrochemical Properties of B_2S_3 - Li_2S - LiI Vitreous Electrolytes

M. Menetrier, A. Levasseur, and P. Hagemuller

Laboratoire de Chimie du Solide du CNRS, Université de Bordeaux I, 33405 Talence Cedex, France

ABSTRACT

The electrochemical properties of new Li^+ ion conducting glasses belonging to the B_2S_3 - Li_2S - LiI system have been investigated. The electronic conductivity is at least 10^6 times lower than the ionic one ($\sigma_e < 10^{-9} \Omega^{-1} \text{cm}^{-1}$ and $\sigma_i \approx 10^{-3} \Omega^{-1} \text{cm}^{-1}$ at 25°C for the best ionic conductors); the electrochemical stability range determined by cyclic voltammetry is about 4.5V from lithium metal.

The energy crisis has focused large interest on energy saving problems, which involves energy storage for later use. Direct electrochemical storage of electricity is actually an attractive way because of the large use of electricity which is the most convenient energy vector, and of its adaptability to vehicle traction as well as to stationary applications. In that way, an efficient electricity storage is essential for the development of new alternative energies like photovoltaic conversion or transformation of the wind energy.

One of the most advanced electricity storage systems could be a lithium // intercalation compound secondary battery, although, so far, the reactivity problems of liquid organic electrolytes do not allow a good cycling behavior.

Recently, new vitreous materials with a rather attractive lithium ionic conductivity have been developed (1-5).

Synthesis and ionic conductivity of glasses belonging to the B_2S_3 - Li_2S and B_2S_3 - Li_2S - LiI systems performed in our laboratory have been described previously (4, 5).

This paper shows that their electrochemical characteristics (electronic conductivity and electrochemical stability range) should allow their use as electrolytes in lithium "all-solid-state" batteries working at room temperature.

All experiments have been carried out with a $0.28B_2S_3$, $0.33Li_2S$, $0.39LiI$ glass, which is among the best glasses obtained in the ternary system [$\sigma \approx 10^{-3} \Omega^{-1} \text{cm}^{-1}$ at 25°C for a bulky material and $4 \cdot 10^{-4} \Omega^{-1} \text{cm}^{-1}$ for pressed powder pellets (5)].

Electronic Conductivity

The first feature of an electrolyte must be a very low electronic conductivity. It was determined from the dc polarization technique proposed by Yokota (6).

Experimental.—Bulky glass samples or pressed powder pellets (10 t/cm^2 , 1 cm diam, 1 mm thick) were used with blocking electrodes consisting of sputtered gold or platinum on both sides. A fixed potential was applied between those electrodes, and the current measured with a Keithley 616 electrometer was recorded *vs.* time.

The cell was placed in an airtight glass container (under argon atmosphere) which was in a grounded Faraday box.

Results and discussion.—The application of a voltage is followed by a first current response, which decreases quickly with time; it corresponds to the motion of Li^+ ions within the material. Once a steady-state situation is attained, these ions, blocked along the gold or platinum electrodes, do not move any longer. The measured current is, therefore, of electronic origin.

The variation of current *vs.* time is shown in Fig. 1 for a given value of the applied voltage. A steady state is usu-

ally obtained within 24h (or even less when the sample is not depolarized by a short circuit between two experiments).

Figure 2 shows the variation of the steady-state current *I* *vs.* applied voltage *V*. These values correspond to Ohm's law when the voltage *V* is lower than 60 mV, so that *I* is small. As *V* increases, overvoltages at the gold (or platinum)/glass interfaces become significant and the real voltage applied to the sample is $v < V$ (Fig. 3). Therefore, Ohm's law cannot be used to calculate the resistance from the values of *V* and *I* when *V* exceeds 60 mV.

Decomposition of the sample was observed for an applied voltage of 7.5V.

The values of σ_e (determined from the slope of the linear part of the former diagram) (Fig. 2) for pressed pellets

Fig. 1. Variation of $\log I$ *vs.* time for a gold/glass pellet/gold cell. Applied voltage: 50 mV.

Fig. 2. Variation of the steady-state current *I* *vs.* applied voltage *V* for a gold/glass/gold cell.

Fig. 3. Applied (V) and real voltage (v) in a gold/glass/gold cell

or bulk glass are smaller than $10^{-9}\Omega^{-1}\text{cm}^{-1}$ at 25°C , which is really negligible compared to $10^{-3}\Omega^{-1}\text{cm}^{-1}$ for total (*i.e.*, ionic) conductivity determined by ac measurements.

Estimation of self-discharge in a battery.—The self-discharge current of a $\text{Li} //$ intercalation compound (such as TiS_2) battery with a sulfur glass as electrolyte can be estimated from the value of σ_e . For example, it would correspond to the use of less than $20\ \mu\text{g}$ of TiS_2 per year in a $1\ \text{cm}^2$ area battery; in other words, its influence would be practically negligible. This result is confirmed by the constant open-circuit voltage given by a $\text{Li}/\text{glass}/\text{TiS}_2$ battery for over 8 months.

Electrochemical Stability Range

The electrochemical stability range has been determined using the cyclic voltammetry method which was first applied to solid materials by Rigaud (7, 8).

Experimental.—The electric circuit and electrode configuration on the sample are shown in Fig. 4. The sample is a pressed powder pellet of glass. The three electrodes are constituted as follows: (i) the working (WE) and counterelectrodes (CE) were sputtered gold or platinum, and (ii) the reference electrode (RE) was an Ag/Ag^+ couple realized with a mixture of Ag_3SI (in which Ag^+ ions are mobile and which is also a good electronic conductor), with powdered metallic silver. The potential of the redox couple is situated in a zone where no electrochemical reaction occurs in the vitreous sample. As sample and reference materials are not conductors of the same type of ion, there is a junction potential at the glass/RE interface. Ag/Ag^+ is therefore not really a reference electrode, but is, rather, a comparison electrode. Its potential *vs.* lithium metal, measured with a sulfur glass as electrolyte, is 2.14V .

Cycling started with anodic polarization and the speed of voltage sweeping was $1\ \text{V}/\text{mn}$.

Fig. 4. Electric circuit and cell configuration for voltammetry studies.

Fig. 5. Cyclic voltammogram of a ternary $\text{B}_2\text{S}_3\text{-Li}_2\text{S-LiI}$ glass. Reference electrode: Ag/Ag^+ couple.

As before for the electronic conductivity studies, the sample was placed in a special airtight container under argon atmosphere, and cycles were realized at 25°C .

Results and discussion.—Figure 5 shows the voltammogram obtained for a $0.28\text{B}_2\text{S}_3, 0.33\text{Li}_2\text{S}, 0.39\text{LiI}$ glass.

The cathodic reaction which limits the existence region is the reduction of Li^+ ions occurring at a 2.1V potential, which is close to the thermodynamic potential because of the quick migration speed of the Li^+ ions to the electrode. During the return process, an oxidation peak is observed, which corresponds to the reoxidation of one part of the lithium formed. As no reaction was detected between glass and lithium (even for long-time contact at 50°C), the other part of the lithium formed is supposed to constitute an alloy with the gold electrode. A similar phenomenon was reported by Rigaud (7).

The anodic part of the diagram has been assigned to the oxidation of sulfide ions for the following reasons: (i) the anodic process of a binary glass ($\text{B}_2\text{S}_3\text{-Li}_2\text{S}$) is similar to that of ternary glasses ($\text{B}_2\text{S}_3\text{-Li}_2\text{S-LiI}$), and (ii) the addition of lithium iodide to a powdered binary or ternary glass causes the appearance of the oxidation peak of I^- ions at a very low potential (Fig. 6a), which also occurs with pure LiI at 100°C (Fig. 6b).

The aspect of the oxidation curve and the decrease of the current with the number of anodic sweep (Fig. 7) show that the oxidation process is limited by the diffusion of the S^{2-} ions to the electrode, which indicates that these ions are poorly mobile in the glass compared to the Li^+ ions. Furthermore, the fact that I^- ions in ternary glasses are not oxidized shows that they really belong to the matrix and are too large to move.

As the anodic process is limited by diffusion, it is not possible to extrapolate the oxidation peak to determine the anodic limit of the stability range. That limit was therefore arbitrarily fixed as a $5\ \mu\text{A}/\text{cm}^2$ current density, considering that a lower current does not show any electrochemical reaction, but is due to an ionic motion as

Fig. 6. Anodic part of voltammogram with: (a, left) glass + LiI mixture, and (b, right) pure LiI (100°C).

Fig. 7. Evolution of anodic voltammograms for a ternary $\text{B}_2\text{S}_3\text{-Li}_2\text{S-LiI}$ glass with the number of anodic sweeps. Only three sweeps are shown.

mentioned in the second part of the present paper. The reason is that the sweeping speed does not allow reaching steady-state conditions.

The electrochemical stability range of the ternary glass is thus about 4.5V from lithium metal.

Conclusions

The electrochemical characteristics of new vitreous sulfide electrolytes have been determined.

Their electronic conductivity is negligible and does not create a significant self-discharge in batteries.

The voltammetry study suggests that the stability range of the ternary glass allows using lithium metal as a negative electrode (and of course of a LiAl alloy, whose potential is + 0.3V vs. lithium metal), and intercalation compounds with high potential vs. lithium as positive electrodes, without decomposition of the electrolyte.

These properties and the good ionic conductivity [exceeding $10^{-3}\Omega^{-1}\text{cm}^{-1}$ at 25°C (5)] allow their use as an electrolyte in experimental "all-solid-state" batteries working at room temperature according to the scheme: Li (or LiAl alloy)/glass/lithium intercalation compound.

The study of such cells is in progress and will be described elsewhere.

Lifetime Studies in H₂/Br₂ Fuel Cells

G. G. Barna,* S. N. Frank,* T. H. Teherani,* and L. D. Weedon

Texas Instruments, Incorporated, Dallas, Texas 75265

ABSTRACT

A fully computerized system has been set up for the life testing of H₂ electrodes in 48% HBr, and of H₂/Br₂ fuel cells. Given a fuel cell design with dry H₂ and no anolyte loop, the prime parameters influencing the operating lifetime are the hydrophobicity of the anode and the electrolyte transport property of the membrane. A systematic optimization of all the parameters has generated fuel cells that have operated for 10,000h at 2 A/in.², with no significant degradation.

During the development of Texas Instruments Solar Energy System (TISES), a major emphasis in the fuel cell portion of the program was the optimization of the initial performance of the gas diffusion, Pt-black-catalyzed, H₂ electrode. Having developed the fabrication process to the level where these electrodes reproducibly performed at the kinetically controlled limit (1), attention was focused on the lifetime performance of these electrodes and fuel cells. Life testing was initiated with a datalogger and a manual plotting of the data. During the next 4 yr, this system was continuously upgraded to the level where all aspects of the life testing, *i.e.*, current cycling, continuous monitoring of the voltages, data acquisition and reduction, were all under full computer control.

There were many reasons for establishing such a life testing system. First, lifetime data had to be generated on both anodes and fuel cells. Second, these life tests provided a vehicle for the development and refinement of analytical techniques for the diagnosis of failure modes. Third, it also allowed for the evolution of peripheral hardware necessary to run these long-term experiments. This paper will describe the life test data generated on the H₂ electrode in HBr, and on the H₂/Br₂ fuel cells, the degradation modes, and some of the other principal parameters affecting the lifetime of these fuel cells.

Experimental

The Teflon-bonded Pt-black-catalyzed gas diffusion electrodes were prepared as previously described. Life testing was performed in two parallel systems: in a half-cell mode with the described electrode, or in a fuel cell mode, with a SiC-covered electrode. Since the setup and analysis was quite distinct in these two modes, they will be described separately.

Half-cell studies.—The electrode was placed in a Teflon cell, with the necessary gas and electrolyte ports for diffusing H₂, purified through Pd, behind the electrode and the electrolyte (8.9M HBr) in front of the electrode (Fig. 1). A Pt-foil served as a counterelectrode; a 6.9M HBr/1M Br₂ reference electrode, connected through a narrow capillary tube in the cell body, sensed the electrode potential at ~ 1 mm away from the edge of the H₂ electrode. After the initial evaluation of some necessary electrochemical parameters, the test cell was connected to the computer. It was then load cycled at 4, 3, and 2 A/in.² (620, 465, and 310 mA/cm², respectively) for 4h at each current density, with ~ 2 min on open circuit between the successive current steps. Voltages were recorded both at the beginning and end of each current step, and in the open-circuit condition. The computer continuously monitored the potential of the anode; if it went more positive than a certain prescribed limit, the current was automatically decreased to the next lower level, or ultimately to zero. At the conclusion of the testing, the cell was disconnected from the computer, and the pertinent electrochemical parameters were again measured.

Fuel cell studies.—The electrode, coated with a thin layer of SiC powder, was assembled into a fuel cell with an appropriate membrane and a porous carbon (or graphite) Br₂ electrode (Fig. 2). The SiC layer served as an electrolyte matrix, as these fuel cells were run with dry H₂ and no free flowing anolyte. Electrolyte management on the anode side was maintained solely by the judicious choice of the membrane. The design criteria were that the membrane possess a high enough electrolyte diffusion so that the SiC matrix, on the anode, would remain adequately wetted. The fuel cell was then connected to an electrolyzer which maintained the fuel concentration at the desired level, usually 1M Br₂/6.9M HBr, throughout

* Electrochemical Society Active Member.

Fig. 1. Schematic of the anode life test cell

the duration of the test. Purified hydrogen was allowed to diffuse behind the anode. The fuel cell was connected to the computer, which adjusted the load to a steady 2 A/in.² (310 mA/cm²), or sometimes higher. Cell potential was monitored constantly and recorded once every 4h along with an OCV value. Again, if the cell voltage dropped below a prescribed limit, the computer placed the cell on open circuit.

Computer system.—Data acquisition, storage, and analysis were all performed on a dedicated Fluke 1720 Instrument Controller connected to the life test cells through a Fluke 2400A Measurement and Control Link. A block dia-

gram of the system is shown in Fig. 3. Both units were remote from the laboratory in clean, air-conditioned space. The 2400A was programmed by uploading programs from the 1720A and was then independent of the 1720A. Data were down-loaded from the 2400A into the 1720A for permanent storage on 5.25 in floppy disks. The controlling and monitoring software was developed in-house, and is all in BASIC.

In addition to the current/voltage/time data files for each life tested anode/fuel cell, a completely separate set of data files were also generated. These files contained two significant portions. First, using a standard format as in Table 1, all the material parameters and the definable processing steps were recorded. For each of the 63 parameters, there could be typically 3-10 specific attributes, evolved throughout the process development phase. The second portion of this data file contained both quantitative and qualitative operating parameters that were obtained throughout the life test cycle (e.g., peak power and limiting currents at various time intervals, operating voltages, etc.). Using this data base from all the life tested anodes/fuel cells, correlations could be made between the materials/processing parameters and the resulting operating characteristics. The results of some of these correlations will be described.

Results

The total extent of the life testing effort is described in Table II. A total of 235,896h of life testing has been performed, with the pertinent data on the longest sustained anode (12,072h) and 1 and 10 in.² fuel cells (10,056 and 2,832h, respectively) lifetests shown in Fig. 4-8.

Half-cell studies.—The two major parameters used in the diagnosis of anode performance and degradation mode were the low polarization slope (LPS) and the limiting current. The LPS is a measure of the dV/dI , with a H_2 partial pressure of 1, in the range of $\eta = 0-3$ mV. This is an iR -free value, generated by subtracting the internal resistance obtained by standard current interrupt techniques, using an in-house-built current interrupter. It can be shown (2) that $(LPS)^{-1}$ is a function of i_0 , a purely kinetic value free of any diffusional effects. Hence, a change in $(LPS)^{-1}$ with time is solely a function of a change in the active catalyst area or of the kinetic rate. In contrast, a change in the limiting current, obtained with 5% H_2/N_2 , which is kinetically limited at $t = 0$ only, can be due to either kinetic or diffusional losses. Therefore, by following the change in $(LPS)^{-1}$ and I_{lim} (5% H_2/N_2) with time, the

Fig. 2. Schematic of the fuel cell life test cell.

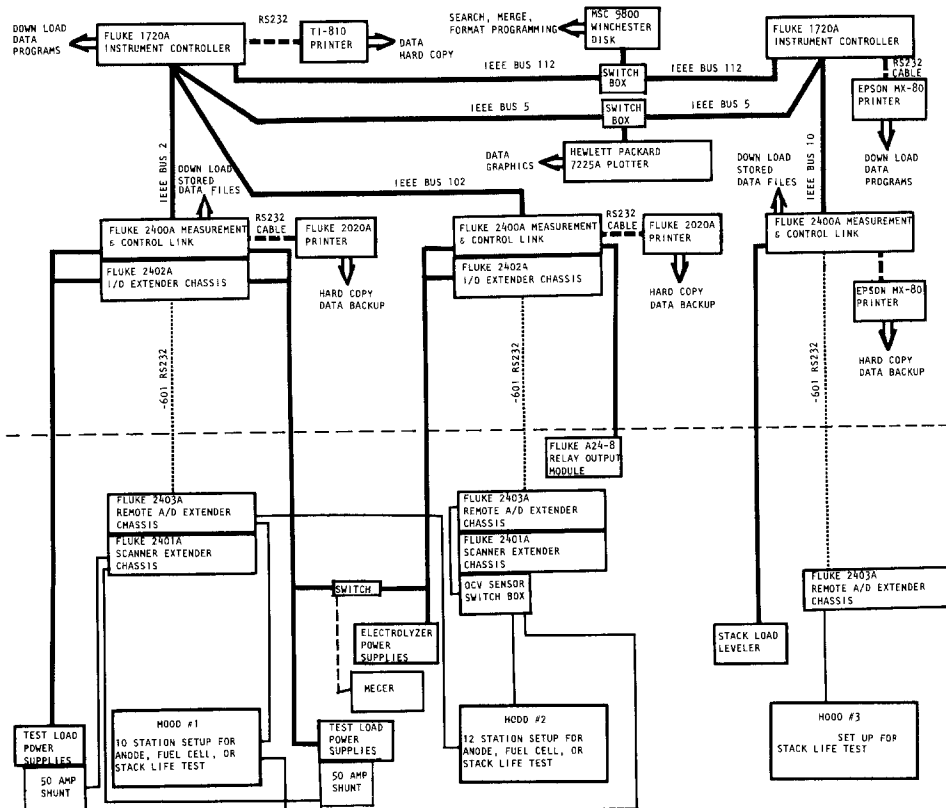

Fig. 3. Block diagram of life test computer system.

degradation mode of an electrode can be determined from the relative changes, as shown in Table III.

These parameters were generated at the beginning and the end of each life test, and at various random intervals in between. The data were reduced by the appropriate software to graphical representation, as in Fig. 9. Other quantitative descriptions of the life testing were the time

increments to a 25% and 50% decay in I_{lim} , and the % (LPS)⁻¹ at these times, determined from the plot in Fig. 9. Another useful quantitative description of the anode performance is the scaling factor, defined as

$$\text{Scaling Factor} = \frac{I_{lim}(100\% H_2)}{I_{lim}(5\% H_2/N_2) \times 20}$$

Since any gas diffusional limitations are eliminated when going from 5% to 100% H₂ (3), this parameter is a measure of ionic diffusion losses in the anode. This factor was therefore determined at the beginning and at the end of the life testing. Finally, the time for which the anode sustained 4 A/in.² (620 mA/cm²) was also recorded, as this value has been empirically found to be a good descriptor of the quality of the anode. These quantitative operating parameters, along with a description of the degradation anode, were then employed in the processing *vs.* performance correlations.

Fuel cell studies.—A large number of life tests were initiated. Some were left undisturbed such that a degradation rate could be established. Other tests, such as those involving the effect of membrane properties, were terminated when the useful information has been collected. In addition to the periodically recorded polarization values, the life testing was interrupted at random intervals and computer-controlled current/voltage data were generated and recorded. These data were reduced to plots of peak power *vs.* time and peak current *vs.* time (Fig. 6 and 8). At the end of each test, all these data were further reduced to quantitative parameters to be used in the fabrication *vs.* performance correlations. This data generated included: (i) the operating voltage at the applied current density and the times when this voltage has decreased by 5%, 10%, and 15%, (ii) similar data in terms of overvoltage, (iii) peak power at $t = 0$, and the times when the peak power has reached 90%, 80%, 65%, and 50% of the original value, (iv) the I_{max} value at the specific decay times found in (iii), and (v) total running time and reason for termination of the life test. The failure mode determination was made from all the available data after the autopsy of the dismantled cell. A summary of the reasons for the termination of all the 1 in.² fuel cell life tests are shown in Table IV.

As mentioned previously, the structure of the data files allowed for data analysis in terms of performance *vs.* fabrication parameters. In effect, this permitted sorting of

data according to variations in any of the processing parameters. The results of this kind of analysis for fuel cells are shown in Fig. 10 and 11. It has to be emphasized that these data are an average of all the available data on fuel cells that met a certain set of specifications, e.g., 25% TFE in the anode catalyst layer, sintered at 327°C, with all the other parameters not necessarily the same.

Discussion

Analysis of the half-cell data such as that in Fig. 9, suggests that the anodes typically decay by a flooding mechanism, sometimes aided by the effects of poisoning. This is supported by the correlations that were run on the data. The trends indicate that a higher sintering temperature, which would be expected to cause the TFE in the catalyst layer to flow more and hence make the catalyst more hydrophobic, does decrease the rate of decay and extends the operating life time of these electrodes. Similarly, increasing the TFE content of the catalyst increases the running and decreases the degradation rates. These are the anticipated results if the decay mode is due to a flooding mechanism.

As seen from Table IV, the biggest challenge in life testing is keeping the peripherals and the external sources of poisons from degrading the test. Of the 87 fuel

cells life tested, only 21 reached the state where they were terminated for actual degradation or failure.

Analysis of the fuel cell lifetime data shows that anode hydrophobicity and membrane properties are the two key parameters. While not providing the highest activity (i.e., limiting current), the more hydrophobic anodes give fuel cells with longer operating life. The relative decay rates of fuel cells with anodes of different TFE content and sintering temperatures are shown in Fig. 10. This correlation is quite predictable.

As stated before, the choice of membranes was dictated primarily by the requirement that it possess high enough electrolyte transport properties to keep the anode fully wetted, since the system constraints resulted in a fuel cell design with an absence of an anolyte loop, and the use of dry H₂. As a result of this design, a "worst case" situation is shown in Fig. 12. This fuel cell was assembled with a du Pont membrane with essentially zero electrolyte transport properties. While it still provides a stable operation at current densities of up to 450 mA/cm², at higher current densities the anode gradually dries up, which shows up as a voltage loss. However, if the current density is decreased at this time, the anode rewets and the polarization returns to the original value. Hence, for a fuel cell of this design, the optimum membrane is one with larger electro-

lyte transport values, such as the RAI P1010 membrane (a styrene-based sulfonic acid polymer) with an electrolyte "leakage" of ~ 0.3 cm³/in.²/h, from a 1M Br₂/6.8M HBr catholyte.

One problem that became apparent as a result of our database management system was that these membranes were not identical from lot to lot. Using two lots of these RAI membranes, P1010 and R1010, the average lifetimes of fuel cells, with the major anode parameters being the same, were significantly different (Fig. 11). Since the Br₂ diffusion and resistance values for these membranes are very similar, the difference is attributed to some undefined contaminant in the R1010 membranes.

In terms of scale-up, going from a 1 to a 10 in.² fuel cell, there is a typical degradation of 30% or less in both the normalized peak powers and current densities, slightly less than that shown in Fig. 6 and 8. The decrease in performance is probably less than these values, since the pumping constraints allowed for a 7 cm³/in.²/min catholyte flow in the 1 in.² cell, but only 3 cm³/in.²/min in the 10 in.² cell. However, the operating parameters of this 10 in.² fuel cell, 244 W/ft² and 4 A/in.² at *t* = 0 and the reasonable degradation shown in Fig. 8 are still significantly superior to most other devices currently being developed.

Long-term life testing has shown some effect on the active Pt catalyst. The major effect, a net loss of Pt, is typi-

cally associated with an inadvertent brief pulsing of the anode to a high positive potential, where Br₂ is generated within the catalyst layer. In the normal operating mode, since the anode is posed at the reversible hydrogen potential, any Br₂ diffusing to the anode will be immediately reduced. As long as the H₂ supply is not interrupted, there should be no loss of Pt. We have also seen Pt recrystallization in one particular case of an 8700h anode life test, which also showed a 37% loss in total Pt loading. Pt agglomeration is not expected to occur at the low operating temperature (~ 30°C). It is assumed that this electrode

may have suffered a brief positive pulse, during the numerous necessary interruptions to the life testing. This would cause Pt to dissolve and subsequently to recrystallize upon reduction. We do not, as yet, have sufficient data to suggest that there is some fundamental mechanism responsible for the gradual degradation of the catalyst.

Conclusion

After a total of 235,896h of anode/fuel cell life testing, the main parameters determining fuel cell operating lifetime have been found to be the hydrophobic nature of the anodes and the properties of the membrane. It has been shown that anode development cannot be solely guided by the obtaining of the largest current possible at $t = 0$. Such an anode is too hydrophilic to last extensively. There is a trade-off in making anodes more hydrophobic, where the initial performance is lower, but the operating endurance is better. The control of anode flooding is of primary concern, as these anodes (operating at 25°-50°C) have shown no catalyst sintering after 12,000h. Mem-

branes can be selected on the basis of their electrolyte transport properties, but certain intangibles, such as impurities, can have a marked effect. But, optimizing all these parameters independently and then in conjunction with all other factors such as electrolyte purity, cell design, etc., H₂/Br₂ fuel cells have been run for > 10,000h without significant degradation. The actual lifetime of these fuel cells is thus well in excess of 10,000h, limited in practice by the failure of the peripherals.

On the Relation Between the Overpotentials and Structures of Graphite Fluoride Electrode in Nonaqueous Lithium Cell

N. Watanabe,* R. Hagiwara, and T. Nakajima

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto-shi, Sakyo-ku, 606, Japan

ABSTRACT

A study was made of the relation between the cathode overpotentials and structures of two kinds of graphite fluorides, $(CF)_n$ and $(C_2F)_n$ in nonaqueous lithium battery. The overpotential of $(CF)_n$ electrode decreased with increasing interlayer spacing and decreasing thickness of the crystallite along the C axis. However, it was found that the overpotential of $(C_2F)_n$ electrode primarily depended on the amount of the defects which would be present in the form of polynuclear aromatic carbon rings in $(C_2F)_n$. The defects in $(C_2F)_n$ would give the short circuiting paths for the transfer of a lithium ion in diffusion layer. The higher discharge potential of $(C_2F)_n$ than that of $(CF)_n$ was mainly attributed to the effect of the defects contained in $(C_2F)_n$.

Poly(carbon monofluoride), $(CF)_n$, has many excellent characteristics as a cathode material for lithium battery in nonaqueous electrolyte systems (1-4). Besides this well-known graphite fluoride, poly(dicarbon monofluoride), $(C_2F)_n$, which was recently found in our laboratory, has also high possibilities as a new active mass owing to the higher discharge potential than that of $(CF)_n$ in 1M lithium perchlorate-propylene carbonate solution (5-7). Graphite fluorides are obtained in the form of a paracrystallite by the direct fluorination of carbon materials at high temperatures. For example, when natural graphite is used as a starting material, $(CF)_n$ is formed around 600°C, while $(C_2F)_n$ is prepared at a lower temperature of 350°-400°C. With increasing fluorination temperature, the composition changes from $(C_2F)_n$ to $(CF)_n$ via their mixture, in which $(CF)_n$ content increases with increasing temperature. It is noted that $(C_2F)_n$ is prepared only from a highly crystallized graphite, such as natural graphite or graphitized petroleum coke, at a relatively low temperature (8). The carbon layers of graphite fluoride consist of an infinite array of trans-linked cyclohexane chairs without

aromatic nature. Both in $(CF)_n$ and $(C_2F)_n$, carbon atom with sp^3 -hybridized orbital is covalently bonded to fluorine. $(CF)_n$ is regarded as a first stage compound, whereas $(C_2F)_n$ is of the second stage, the structure of which has been recently investigated in detail (9).

The electromotive force of $(CF)_n$ -Li cell was calculated to be 4.57V by Margrave *et al.* (10) on the assumption that the discharge reaction produces carbon and lithium fluoride. However, the open-circuit voltage (OCV) of a real cell composed of lithium and graphite fluoride prepared from natural graphite is around 3.2-3.3V at 25% discharge in 1M $LiClO_4$ -propylene carbonate solution. It is lower by more than 1V than the calculated value. For this fact, Whittingham (11) and Watanabe *et al.* (5, 6) have proposed that the cell reaction is the formation of a graphite intercalation compound of lithium fluoride. The analysis of discharge products (12) and OCV's in different solvents (13) have indicated that the cell reaction includes the formation of a graphite intercalation compound of lithium fluoride solvated by solvent molecules. The flat discharge potential of graphite fluoride-Li cell suggests that the discharge reaction proceeds heterogeneously, namely by the formation of a ternary intercalation compound of

* Electrochemical Society Active Member.

graphite, followed by the decomposition to carbon, lithium fluoride, and solvent molecule. This would maintain the constant thickness of a so-called diffusion layer through which a solvated lithium ion is transferred to the electrode surface. It has been proposed that a fairly large overpotential of graphite fluoride cathode is due to the delay of lithium ion transfer in the diffusion layer consisting of the ternary intercalation compound of graphite (6), which is consistent with the fact that the cathode overpotential increases with increasing size of solvated lithium ions (13).

This paper is concerned with the relation between the cathode overpotentials and structures of $(CF)_n$ and $(C_2F)_n$. The overpotentials are discussed on the basis of the results obtained by x-ray diffraction, ^{19}F -NMR, and ESR measurements.

Experimental

$(CF)_n$ and $(C_2F)_n$ -type graphite fluorides were prepared by fluorination of Madagascar natural graphite, petroleum coke (original and heat-treated at 2800°C), vapor-grown carbon fiber (heat-treated at 3000°C) and exfoliated graphite in fluorine gas of 1 atm at temperatures between 290°-600°C. Some of $(C_2F)_n$ -type graphite fluorides were prepared via graphite intercalation compound of MgF_2 and F_2 (GIC) (14). Synthetic conditions are listed in Table I.

Sample L was heat-treated in fluorine gas of 1 atm at 400°, 500°, 550°, and 600°C for 24h to investigate the heat-treatment effect on $(C_2F)_n$. In addition to the heat-treatment in fluorine atmosphere, treatment *in vacuo* at 400°C was also performed for comparison.

The prepared samples were analyzed by means of elemental analysis, x-ray diffractometry, ^{19}F -NMR and ESR spectroscopies. NMR measurements were made using a Crossed Coil NMR Spectrometer (Varian WL 109) with scanning of the magnetic field at a fixed radio frequency of 15 MHz. ESR measurements were carried out by the aid of Nihon Denshi, JES-3BX with scanning of the magnetic field at a fixed radio frequency of 9.4 GHz (X-band).

Discharge of graphite fluorides was performed at a fixed current density of 0.5 mA/cm² in 1M LiClO₄-propylene carbonate solution at 25°C. The polarization curves were also obtained in the range of 10⁻⁷-10⁻³ A/cm². Preparation of electrodes and cell assembly were the same as those reported previously (13).

Results and Discussion

The relation between crystallinity and cathode overpotential of graphite fluorides.—Figure 1 shows the plots of the cathode overpotentials of $(CF)_n$ at 25% discharge against the interlayer spacing, $d_{(001)}$ and half-width, $\beta_{(001)}$ of (001) diffraction line. The overpotential decreased with increasing $d_{(001)}$ and $\beta_{(001)}$. Since the thickness of

Fig. 1. The cathode overpotentials of $(CF)_n$ -type graphite fluorides in lithium cells (0.5 mA/cm², at 25% discharge) as a function of $d_{(001)}$ and $\beta_{(001)}$.

monolayer of graphite fluoride is the same among all the samples, the space between monolayers increases with increasing $d_{(001)}$. The half-width, $\beta_{(001)}$ is inversely proportional to the thickness of the graphite fluoride crystallite along C axis. As the crystallite size and $d_{(001)}$ spacing of graphite fluoride strongly depend on the crystallinity of a starting carbon material, these factors can be controlled by choosing the starting carbon material as well as reaction temperature. It has been already pointed out that the overpotential of graphite fluoride electrode depends on the rate of transfer of solvated lithium ion in the diffusion layer (13). The increase in the space between monolayers of graphite fluoride with increasing $d_{(001)}$, and the decrease in thickness of the crystallite along C axis would facilitate the transfer of lithium ion in the diffusion layer on the discharge process (Fig. 2). It was confirmed prior to this experiment that the overpotential was independent of the particle size of graphite fluoride. It means that the rate of discharge reaction is not determined by the transfer of lithium ion among the particles but by that inside the particles of graphite fluoride.

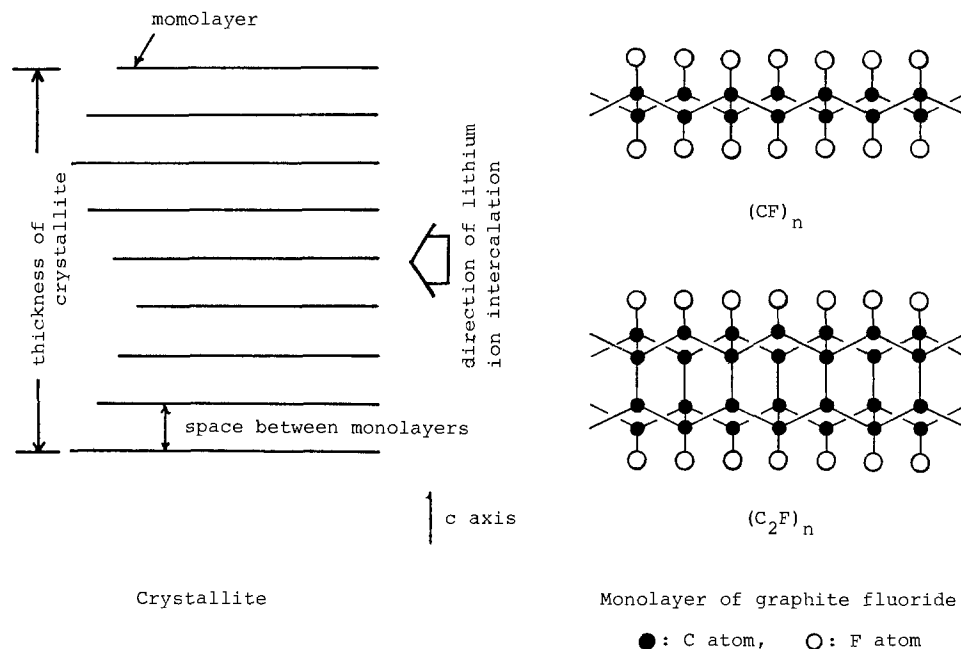

Fig. 2. Schematic illustrations of graphite fluorides.

However, it is difficult to prepare $(C_2F)_n$ -type graphite fluorides with large differences in crystallinity, $d_{(001)}$, and $\beta_{(001)}$, because starting carbon materials and reaction temperature are limited in this case. $(C_2F)_n$ can be prepared only from a highly graphitized carbon material such as natural graphite at 350–400°C (8). Ungraphitized petroleum coke with low crystallinity gives only $(CF)_n$ at any temperature. For every $(C_2F)_n$ prepared, the overpotential at a current density of 0.5 mA/cm² was about 0.9V, which corresponded to the minimum value for that of $(CF)_n$.

Figure 3 shows the typical discharge curves of $(CF)_n$ and $(C_2F)_n$. The flatness of discharge potential for $(CF)_n$ was improved with increasing crystallinity of the sample while the discharge potential decreased. In other words, the height and flatness of discharge potential are compensative with each other. Even for $(CF)_n$, the overpotential was decreased approaching to that of $(C_2F)_n$ by choosing a carbon with low crystallinity as a starting material and by fluorinating at a low temperature; however, the flatness of discharge potential was inferior.

The effects of the heat-treatment of $(C_2F)_n$ on the discharge characteristics and structure.—Figure 4 and Table II show the discharge characteristics of heat-treated $(C_2F)_n$ in lithium battery. With increase of the heat-treatment temperature, the discharge potential decreased and the flatness of discharge potential was improved at the beginning of discharge. The effects of the heat-treatment at 400°C on discharge characteristics were scarcely observed. As can be seen in Table II, the decrease of discharge potential is caused by the increase of

overpotential rather than the decrease of open-circuit voltage. In the present work, as described below, the improvement of crystallinity of $(C_2F)_n$ by the heat-treatment was not found as far as the analysis by x-ray diffractometry was concerned. Nevertheless, the overpotential was fairly changed by the heat-treatment.

With increasing temperature of the heat-treatment in fluorine gas, the color of $(C_2F)_n$ gradually changed from black to white, while the weight of the sample scarcely changed, except for that heat-treated at 600°C, whose weight decreased by 1%–2%. The $d_{(001)}$ and $\beta_{(001)}$ were also unchanged by the heat-treatment for every sample, which indicates that the improvement of crystallinity was not achieved by this treatment. The F/C ratio, $d_{(001)}$, and $\beta_{(001)}$ were 0.66 ± 0.02 , 0.81 ± 0.01 nm and $3.2^\circ \pm 0.2^\circ$, respectively.

Figure 5 shows ¹⁹F-NMR spectra of $(C_2F)_n$, where two kinds of resonance absorptions were observed. One was very broad with peak-to-peak width, $\Delta H'$ of 9.0 ± 0.1 G, and the other was sharp one with $\Delta H'$ of 1.5 ± 0.1 G. No change of linewidth was observed by the heat-treatment. Differential gradient method showed that the narrow absorption line was Lorentzian, which is related to homogeneous system where the energy absorbed from oscillating magnetic field is distributed so that the spin system may maintain the thermal equilibrium through the resonance process. The narrow linewidth would correspond to motional narrowing, which means that fluorine atoms make weak chemical bonds with carbon atoms, therefore having higher activity than those covalently bonded. This

600	3.24	2.14	1.10	710

absorption line decreased as the heat-treatment temperature increased and almost disappeared at 600°C . A slight decrease of the open-circuit voltage, shown in Table II, might be caused by the decrease of these fluorines weakly bonded with carbon atoms. The decrease of absorption intensity by the heat-treatment was slightly larger *in vacuo* at 400°C than in fluorine gas at the same temperature. The broad absorption line was approximately gaussian, where each spin is situated in different local fields, which causes the line broadening. By taking the linewidth and peak intensity into consideration, this spin component is attributable to the major part of fluorine atoms in graphite fluoride, namely, fluorine atoms covalently bonded to carbon atoms. Consequently, there are two kinds of fluorine species in $(\text{C}_2\text{F})_n$. For $(\text{CF})_n$

Curve e: 550°C in F_2 . Curve f: 600°C in F_2 . $\nu = 15 \text{ MHz}$. $H_0 = 3750\text{G}$. $MA = 0.5\text{G}$.

prepared from highly graphitized carbon at around 600°C , only one broad absorption line was observed with the same $\Delta H'$ as that of $(\text{C}_2\text{F})_n$, which means that $(\text{CF})_n$ has only a covalent bond between fluorine and carbon atoms.

Figure 6 shows the results of ESR measurements. ESR spectra of $(\text{C}_2\text{F})_n$ gave a single peak with a constant g value of 2.004 having no dependence on the heat-treatment temperature. From the g value, the radicals observed are reasonably ascribed to carbon. As the g value was also 2.004 in case of $(\text{CF})_n$, the radicals are the same kind, even though the intensity of the signal was much smaller than that of $(\text{C}_2\text{F})_n$. As shown in Fig. 6, the peak-to-peak width, $\Delta H'$, increased rapidly with increasing heat-treatment temperature, however, gradually increasing above 500°C . Furthermore, the differential gradient method showed that the type of the absorption line was changed from lorentzian to gaussian with increasing heat-treatment temperature. The P value (the product of the peak-to-peak height with the square of the linewidth of a differential absorption line) approximately corresponding to radical concentration decreased monotonously with increasing heat-treatment temperature.

From the above results, the following discussion is derived. The ESR measurement indicates that $(\text{C}_2\text{F})_n$ contains a small amount of unreacted carbon which is so randomly distributed as being unable to be detected by x-ray diffractometry and elemental analysis. The presence of unreacted carbon was recently confirmed by a high resolution electron microscope (15). It is regarded as a kind of defect which would be present in the form of polynuclear aromatic carbon rings in $(\text{C}_2\text{F})_n$. This carbon produces carbon radicals by making covalent bonds partially with fluorine atoms or the cleavage of double bond. The black color of $(\text{C}_2\text{F})_n$ is therefore caused by these defects. Namely, the defects in the $(\text{C}_2\text{F})_n$ heat-treated at low temperatures have fairly long conjugated π systems, so the π - π^* transition energy is in the range of visible lights. The n - π^* transition by the delocalized radicals is also in this range. The fluorine species giving a narrow absorption line detected in ^{19}F -NMR measurements have weak chemical bonds with the unreacted carbon. With increasing heat-treatment temperature, the double bonds are cleaved to make covalent bonds with mobile fluorine species, which causes the decrease and localization of radicals. Consequently, the broadening of the line width and the transformation from lorentzian to gaussian are observed in ESR spectra. At the same time, the intensity of the narrow-width line is lowered in NMR spectra. In this way, the defect concentration decreases with increasing heat-treatment temperature. By the destruction of the conjugated π systems, the light absorption shifts out of the visi-

ble light range and the color of $(C_2F)_n$ is changed to white. The difference between the heat-treatments in fluorine gas and *in vacuo* was not so remarkable at 400°C. The interaction between fluorine gas and the carbon radicals inside the graphite fluoride (16) would not be so strong at such a temperature. It is interesting to estimate the absolute radical concentration in graphite fluoride. The comparison was made using carbonized dextrose as a standard sample whose spin density has been already known (17). According to this method, the order of radical concentration in $(C_2F)_n$ was 10^{20} - 10^{21} spins/g, which means that it has one radical per several tens to several hundreds of carbon atoms. The radical concentration in $(CF)_n$ was less than tenth part of that in $(C_2F)_n$ heat-treated at 600°C.

The effects of the defects in $(C_2F)_n$ on the discharge characteristics can be described as follows. The defects are in the form of polynuclear aromatic carbon rings in $(C_2F)_n$. Around these defects, the chemical bond between carbon and fluorine atoms would be so weak that the ternary compounds, $C_2 \cdot F^{\delta-} \cdot Li^{\delta+} \cdot zS$, produced by the discharge reaction (13) might be more easily decomposed to carbon, lithium fluoride, and solvent molecules, which would make the transfer of lithium ion easier. Such defects in $(C_2F)_n$ are considered to be a kind of short circuiting path that decreases the overpotential. This factor would be dominant in case of $(C_2F)_n$. For $(CF)_n$, this kind of effect is much smaller than in $(C_2F)_n$ because the defect concentration is much lower. The heat-treatment of $(C_2F)_n$ is just the elimination of the defect which lowers the overpotential. The improvement of the flatness of discharge potential would arise from the decrease of the defect concentration inside the graphite fluoride crystallite by heat-treatment.

The difference in the discharge performance between $(CF)_n$ and $(C_2F)_n$.—Figure 7 shows typical cathodic polarization curves of $(CF)_n$ (sample A), $(C_2F)_n$, and that heat-treated at 600°C (sample K) at 25% discharge. All the samples were prepared from Madagascar natural graphite. Their open-circuit voltages were almost the same, $3.27 \pm 0.02V$ at 25% discharge. In every case, the plots of cathode potentials against the logarithms of current densities gave a straight line in the range of less than $10^{-4} A/cm^2$ with a bending point at the current density of 10^{-6} - $10^{-5} A/cm^2$. However, the current-interrupter method revealed that no activation overpotential was present in this region. It can be said that the rate-determining step of the discharge reaction is the transfer of lithium ion into graphite fluoride layers in the whole region in Fig. 7.

Two factors must be taken into consideration to evaluate the difference in discharge potentials between $(CF)_n$ (sample A) and $(C_2F)_n$ (sample K). One is the thickness of graphite fluoride crystallite along the C axis, discussed above, and the other is the short circuiting paths which

Fig. 7. Galvanostatic polarization curves of graphite fluorides (at 25% discharge). $(CF)_n$: sample A. $(C_2F)_n$: sample K.

arise from the defects in graphite fluoride, also discussed above. The space between monolayers of graphite fluoride was found to be almost the same for both $(CF)_n$ and $(C_2F)_n$ when they were prepared from a highly graphitized carbon material (9). The discharge potential of $(C_2F)_n$ (sample K) was higher by 0.3-0.4V than that of $(CF)_n$ (sample A) in the range of 5×10^{-6} - $5 \times 10^{-4} A/cm^2$, being, however, decreased by 0.2V with heat-treatment at 600°C in fluorine gas. This difference in the discharge potentials between the original and heat-treated $(C_2F)_n$'s is attributed to the decrease in the defect concentration. $(C_2F)_n$ with more short circuiting paths gives the higher discharge potential than the heat-treated one. Consequently, the difference in the discharge potentials between $(CF)_n$ (sample A) and heat-treated $(C_2F)_n$ ($\leq 0.1V$) would be mainly due to the difference in the thickness of the crystallite of graphite fluoride along C axis, which was 3 nm for heat-treated $(C_2F)_n$ and 6 nm for $(CF)_n$ (sample A) by the approximate calculation from the half-width of (001) diffraction line, $\beta_{(001)}$. The transfer of lithium ion between graphite fluoride layers would be faster in heat-treated $(C_2F)_n$ with the thinner crystallite than in $(CF)_n$ on the discharge process.

Acknowledgments

The authors wish to thank Dr. Fujinobu Nakamura of Kyoto University for his assistance in ^{19}F -NMR measurement, and Professor Yukio Kanaji and Mr. Shigehito Deki of Kobe University for their assistance in ESR measurement. Fluorine gas used in this study was supplied by courtesy of Daikin Kogyo Company Limited, which is also gratefully acknowledged.

Low Temperature Performance Characterization of Lithium Sulfuryl Chloride Cells

Michael Binder,* Sol Gilman,* William Wade, Jr., and Charles Walker, Jr.

U.S. Army Electronics Technology and Devices Laboratory, ERADCOM, Power Sources Division, Fort Monmouth, New Jersey 07703

ABSTRACT

Lithium sulfuryl chloride cells containing various concentrations of LiAlCl_4 were constructed and discharged at 2.5 mA/cm^2 constant current at 25° and -32°C . The solid discharge product in the cathode was analyzed and found to contain only LiCl . No sulfur or other lithium salt was found. An explanation of the reduced capacity and decreased operational voltage of these cells discharged at -32°C is offered. At electrolyte concentrations $\geq 0.75M$ cathode capacity is primarily limited by conductivity, while for electrolyte concentrations $\leq 0.75M$, diffusion appears to be the limiting factor. The decreased operational voltage for cells discharged at -32°C is due to a decrease in the amount of catalytically produced Cl_2 .

The $\text{Li/SO}_2\text{Cl}_2$ primary cell has received widespread research and development interest ever since initial reports on its discovery appeared (1-3). The cell consists of a lithium anode, inert porous carbon cathode on expanded nickel screen (which serves as both a structural support and current collector), and a SO_2Cl_2 solution serving a dual role as both ionizing solvent for dissolving the conducting LiAlCl_4 electrolyte salt and as an active cathode depolarizer.

In these cells (known as soluble or liquid cathode cells), the liquid SO_2Cl_2 cathode remains in physical contact with the lithium anode and has the obvious advantage of minimizing mass-transfer effects associated with supplying oxidant to electrode-electrolyte layers. Spontaneous chemical reaction of anode and cathode is prevented by formation of a passivating insoluble film of LiCl on the anode surface as soon as lithium and the oxyhalide solvent come in contact. The LiCl film has relatively low electronic conduction and forms an electronically insulating interphase between metal and solution (4). This protective film slows internal self-discharge and is responsible for providing potentially long shelf life.

The $\text{Li/SO}_2\text{Cl}_2$ cell has higher open-circuit voltages than analogous Li/SOCl_2 cells, which eventually should translate into higher load voltages and higher energy densities for fully engineered cells. Although both types of cells have high boiling and low freezing points, and thus broad temperature windows for battery applications, $\text{Li/SO}_2\text{Cl}_2$ should be safer because at room temperature and medium current drains ($\leq 2.5 \text{ mA/cm}^2$) only LiCl and SO_2 are formed and no sulfur (1).

Elemental sulfur (or other insoluble sulfur species) are undesirable products in lithium cells since differential thermal analysis studies have identified exothermic reactions occurring between lithium and elemental sulfur at 150°C (5). This temperature may easily be reached under cell abuse conditions such as cell shorting or forced overdischarge. Lack of sulfur in discharged $\text{Li/SO}_2\text{Cl}_2$ cells implies that SO_2Cl_2 would be more abuse resistant for lithium-based cells than SOCl_2 .

In addition, SO_2 formed is soluble up to $\sim 1.0M$ in SO_2Cl_2 (1, 6), precluding internal pressure buildup during or after discharge. The $\text{Li/SO}_2\text{Cl}_2$ cell has an observed open-circuit voltage of $3.91V$ at room temperature. At low-to-medium discharge rates, the load voltage remains constant until close to end of discharge, when a rapid voltage drop occurs (1). Although system performance characteristics and electrochemical reactions taking place in ambient temperature cells have been fairly well described (1-3), low temperature performance characterizations have been generally neglected. Better understanding of

overall reaction mechanisms and reaction products formed during discharge is necessary in order to improve low temperature cell performance in $\text{Li/SO}_2\text{Cl}_2$ cells, as for Li/SOCl_2 cells (7, 8), decreased cell performance at low temperatures or at increased discharge rates is primarily attributable to cathode polarization. Electrochemical reduction of SO_2Cl_2 at porous carbon cathodes is limited by the capacity of the cathode for retaining the LiCl discharge product as it precipitates within pore structures. Therefore, cell performance is limited by accumulation of LiCl in the pores of the cathode.

Because basic information is needed to further improve the cathode, this paper explores limitations introduced at low temperatures and medium current drains and attempts to explain these results and offer possible solutions to relieve poor low temperature performance. We also present results of analytical studies aimed at characterizing chemical and electrochemical reactions occurring during cell discharge.

Experimental

Detailed description of laboratory electrochemical cells, experimental procedures, cell component fabrication, as well as discharge experiments, have been described earlier (1). Briefly, our experimental arrangement consisted of a porous carbon cathode sandwiched between two lithium anodes in an all-Teflon cell housing. Both the cathode and two anodes had nickel-screen current collectors. The porous cathode was constructed using United XC-6310 a high area carbon that had previously been shown to yield highest overall performance among the carbons tested for $\text{Li/SO}_2\text{Cl}_2$ cells (1). The cathodes had an area of 5 cm^2 on one side. We should point out that, in this paper, we are following the generally accepted convention and measure total cathode area by taking twice the geometric area ($l \times w$) of our cathodes. This is because our cells are constructed with both sides of the cathode facing lithium anodes.

In order to identify and characterize insoluble products formed in the cathode during discharge, spent cathodes from cells discharged to $1.5V$ at constant current were removed, rinsed with distilled SO_2Cl_2 to dissolve any adhering LiAlCl_4 electrolyte, heated under vacuum to drive off the sulfuryl chloride rinse solution, and the discharge products within the dried cathode extracted with distilled water. These water solutions were then analyzed for Li^+ , Cl^- , SO_4^{2-} , and Al^{+++} ions. Lithium ion concentrations were determined by atomic absorption, while the Cl^- concentration was determined using potentiometric titration with $0.1M \text{ AgNO}_3$. Despite rigorous washings with sulfuryl chloride, we could not exclude the possibility of having occluded or adhered LiAlCl_4 electrolyte remaining in the cathode. Thus, true Cl^- concentration, due to only LiCl discharge product, was calculated by measuring the Al^{+++} concentration colorimetrically and subtracting the

* Electrochemical Society Active Member.

Fig. 1. Cathode load potential vs. a lithium reference and total cathode life as a function of temperature for Li/1.5M LiAlCl₄-SO₂Cl₂/C cells discharged at constant current of 2.5 mA/cm².

stoichiometric Cl⁻ concentration (*i.e.*, four Cl⁻ for every Al⁺⁺⁺) attributable to occluded LiAlCl₄ from total chloride concentrations measured potentiometrically. In all cases, this chloride correction was less than 5% of the total measured Cl⁻ concentration. As a check, we also analyzed the aqueous wash solutions using a Dionex 2120i Ion Chromatograph, and the results agreed well with results of the wet chemical analysis.

Results and Discussion

Figure 1 plots both cathode voltage and cathode capacity as a function of operating temperatures during constant current discharge. Loss of cell performance at reduced temperatures is quite pronounced. Both cathode voltage and capacity remain fairly constant down to temperatures ~0° and -10°C, respectively, where both decline sharply. The discharge curves for these cells are fairly flat, even at low temperatures, and show fairly well-defined transition times in the discharge curves (where cell voltage declines sharply). We will discuss and attempt to explain capacity losses and load voltage reduction at reduced temperatures in that order.

Cell capacity reduction at lower temperatures.—The following factors which may contribute to diminished cell capacity at reduced temperatures are considered individually along with their relevant analytical data: (i) precipitation of electrolyte salt, (ii) alternate cell products formed, and (iii) ohmic and concentration polarization.

Precipitation of electrolyte salt.—If precipitation of the LiAlCl₄ electrolyte salt in the cathode pores occurs at reduced temperatures, we would expect considerable reduction in cathode life due to the blocking of the cathode pores by LiAlCl₄ and the resulting ion transport limitations. However, the linearity of the conductivity curves shown in Fig. 2 as well as simultaneous visual observations in conductivity cells of LiAlCl₄-SO₂Cl₂ electrolyte solutions as their temperatures were slowly reduced to -60°C, clearly ruled out precipitation of any solid material. It is unlikely that supersaturated solutions of LiAlCl₄-

Fig. 2. Specific conductivity as a function of temperature for various LiAlCl₄-SO₂Cl₂ concentrations.

SO₂Cl₂ electrolyte could be formed at low temperatures in our conductivity cells since the platinized electrodes would have surely provided adequate nucleation sites for precipitation to occur. The fact that no precipitate is formed implies that we can safely rule out electrolyte precipitation as the cause of decreased cathode life during low temperature operation.

Alternate cell products.—It is possible that different cell-discharge mechanisms are operational at reduced temperatures and cause additional insoluble discharge products, such as Li₂SO₄ or Li₂S₂O₄, to form. These materials may more effectively clog active cathode pores than LiCl, thus causing premature cathode failure. In order to test this possibility, spent cathodes from Li/SO₂Cl₂ cells discharged at 2.5 mA/cm² at -32°C were removed from their cells and the insoluble product quantitatively analyzed for Li⁺, Cl⁻, and SO₄⁼ ions. Table I summarizes results found for four cathodes discharged at -32°C.

The Li⁺/Cl⁻ ratio was 1.07 ± 0.12. The fact that this ratio was unity within experimental error already implies that only LiCl is formed. No other insoluble (in SO₂Cl₂) lithium salt is deposited in the cathode. However, the low and variable collection efficiency for solid product in the cathode based on the coulombs transferred still leaves open the possibility that another soluble lithium salt was formed. Such a salt, if formed, would not appear at the cathode, but could, nevertheless, allow a ratio of unity for the Li⁺/Cl⁻ found in the cathode. Such salts cannot be Li₂SO₄ or Li₂S₂O₄, as has been proposed for thionyl chloride cell products (9), since their solubilities in sulfuryl chloride were measured to be less than 5 × 10⁻⁴M at room temperature.

Table I. Chemical analysis of discharged cathodes taken from Li/1.5M LiAlCl₄-SO₂Cl₂ cells discharged at -32°C and 2.5 mA/cm² constant current to 1.5V

	Cathode Li ⁺ /Cl ⁻	Electrolyte SO ₄ ⁼ /Cl ⁻	Cathode collection efficiency
Run 1	0.97	0.066	67%
Run 2	0.89	0.0032	63%
Run 3	1.26	0.13	110%
Run 4	1.06	0.09	79%
	1.04 ± 0.11		80 ± 15%

It is unlikely that solubility Li_2SO_4 or $\text{Li}_2\text{S}_2\text{O}_4$ increases as temperature is lowered; therefore, we can safely rule out these two salts as products since, had they been present, our measured Li^+/Cl^- ratio for the solid cathode discharge product would have been much larger than unity.

Presence of SO_4^- was also of interest in our product analysis study. One proposed chemical precursor of SO_4^- in these cells is SO_3Cl^- which could form according to mechanisms outlined by Blomgren (9).

If LiSO_3Cl was indeed formed, then after dissolving our cathode precipitate in water, the Li^+/Cl^- as well as the $\text{SO}_4^-/\text{Cl}^-$ ratio should be close to unity. The fact that our measured $\text{SO}_4^-/\text{Cl}^-$ ratio was about one order of magnitude less than unity convinces us that we can safely rule out SO_3Cl^- as a predominant product of sulfur chloride cathode reduction at low temperatures. Thus, the only discharge product is LiCl . No major parallel discharge mechanism exists. The traces of SO_4^- observed were probably due to contamination by water, which yields the well-known hydrolysis product chlorosulfonic acid, which forms SO_4^- in water solutions.

For cathodes discharged at room temperature, the collected Li^+ and Cl^- agreed well with the number of coulombs transferred (collection yield averaged greater than 92%). The collection yield, however, for cathodes discharged at -32°C represented only approximately 85% of the theoretical yield. This discrepancy may be due to: (i) LiCl precipitated in locations other than the cathode, (ii) formation of uncollected soluble lithium salts, (iii) poor product collection efficiency due to crumbling of low temperature discharge cathodes, (iv) or not all of the carbon cathode material's being collected.

Since elemental sulfur is a known product of cell discharge reactions in the Li/SOCl_2 system (9), we wanted to determine whether it was produced in $\text{Li}/\text{SO}_2\text{Cl}_2$ cells during discharge at -32°C .

Separators, cathode, and remaining electrolyte taken from $\text{Li}/\text{SO}_2\text{Cl}_2$ cells discharged at $2.5 \text{ mA}/\text{cm}^2$ at -32°C , were rinsed with SO_2Cl_2 and dried. Extraction with CS_2 yielded $\sim 75 \text{ mg}$ of a yellow waxy material whose ultraviolet spectrum in tetrahydrofuran was unlike that of stock sulfur solutions (10). If we assume that absorption at 2850\AA for our known solution corresponds entirely to sulfur, the calculated maximum concentration of sulfur present in the extract was only $\sim 1 \text{ mg}$. Since control experiments on undischarged cathodes also yielded this same waxy material, probably a reaction product of Triton X-100 (a surfactant present in TFE-30 emulsions) with SO_2Cl_2 , sulfur is ruled out as a major discharge product.

To summarize, analytical results show that LiCl is the only major insoluble cathode discharge product of $\text{Li}/\text{SO}_2\text{Cl}_2$ cells at -32°C . No sulfur is produced.

Ohmic and concentration polarization.—The specific conductivity of various concentrations of $\text{LiAlCl}_4\text{-SO}_2\text{Cl}_2$ solutions as a function of temperature is shown in Fig. 2. In going from 25° to -32°C , specific conductivities of 1.5M solutions decrease linearly by approximately a factor of three, while specific conductivities of 0.25M solutions change only slightly. Other researchers have also noticed that changes in specific conductance of $\text{LiAlCl}_4\text{-SO}_2\text{Cl}_2$ solutions with temperature (slope of the lines in Fig. 2) in the range of 22° to 60°C are larger for higher electrolyte concentrations (11). We did not correct our electrolyte concentrations for density; our estimate of temperature dependence of electrolyte density indicates changes less than 10% over the range of 25° to -30°C . The question arises as to whether increased electrolyte resistance encountered at low temperature could in itself be a significant contribution to decreased cell operating voltage or whether it is simply causing other effects indirectly. During cell discharge, even in regions of steepest voltage dropoff at 25° and -32°C , galvanostatic pulse experiments indicate that the pure resistive component of the cathode does not exceed 40% of the total cathode voltage polarization. We cannot attribute the sudden voltage drop at end of life to loss of active cathode surface area

since effective surface area would have to be diminished by several orders of magnitude in order to show polarization of several tenths of a volt. This would require all but small fractions of the carbon cathode be electrically isolated from conduction paths by insulating coatings of LiCl . If cathode surface area were mostly insulated, it would be unlikely that the resistive portion of total voltage polarization would remain low.

We can therefore conclude that although increased ohmic polarization in the cathode pores contributes somewhat to decreased cathode capacity, it apparently does not make the most significant contribution.

We next examine the dependence of cathode capacity on electrolyte concentration. Cell capacities (which are primarily determined by cathode performance) as a function of electrolyte concentration at both 25° and -32°C and $2.5 \text{ mA}/\text{cm}^2$ constant current discharge are shown in Fig. 3. For electrolyte concentrations $\leq 0.75\text{M}$, both 25° and -35°C cell capacity data nearly coincide and increase approximately linearly with concentration.

For electrolyte concentrations $> 1.0\text{M}$, the cell capacity curve at -32°C levels off with increasing electrolyte concentrations and lies well below the extrapolated linear relationship found for lower electrolyte concentrations. Although cells discharged at 25°C also show a leveling off in capacity vs. electrolyte concentration curve (not shown here), this leveling-off point occurs at concentrations $\geq 2.5\text{M}$ and results in only slightly higher cell capacities. The fact that the -32°C capacity vs. temperature curve remains relatively unchanged for electrolyte concentrations $\geq 1.0\text{M}$ implies that from a practical view, in $\text{Li}/\text{SO}_2\text{Cl}_2$ cells, one may reduce electrolyte concentrations from 1.5 to 1.0M while maintaining identical overall cell capacities for -32°C cell discharge.

In order to understand the capacity vs. electrolyte concentration curves of Fig. 3, it is helpful to first study morphological differences between LiCl deposited during -32° and 25°C discharge for various electrolyte concentrations. Postdischarge SEM of cathode surfaces taken from cells following constant current discharge at -32°C for various electrolyte concentrations are shown in Fig. 4. The LiCl deposits on the discharge cathode surfaces taken from the 1.5M electrolyte cell was distinctly glassy. As electrolyte concentrations were decreased, the resulting postdischarge LiCl deposits on their respective

Fig. 3. Cell capacity plotted against electrolyte concentration for both room temperature and -32°C discharge at $2.5 \text{ mA}/\text{cm}^2$.

Fig. 4. Postdischarge SEM of surfaces of cathodes taken from cells of Fig. 3. These cathodes had all been discharged at 2.5 mA/cm^2 to a 1.5 V cutoff at -32°C , but differed in the cell electrolyte concentration. A (top): $\text{Li}/1.5\text{M LiAlCl}_4\text{-SO}_2\text{Cl}_2/\text{U.C.}$ B (second from top): $\text{Li}/1.0\text{M LiAlCl}_4/\text{SO}_2\text{Cl}_2/\text{U.C.}$ C (third from top): $\text{Li}/0.75\text{M LiAlCl}_4\text{-SO}_2\text{Cl}_2/\text{U.C.}$ D (bottom): $\text{Li}/0.5\text{M LiAlCl}_4\text{-SO}_2\text{Cl}_2/\text{U.C.}$

cathode surfaces appeared less glassy and seemed more crystalline in nature. These results should be contrasted to SEM data on 25°C discharged cathodes (not shown here), where even for the 1.5M electrolyte concentration, the discharge product definitely appeared crystalline.

We will first present what we feel is a reasonable explanation of these morphological observations and then present a rationalization for the shapes of the capacity *vs.* concentration curves in Fig. 3.

Crystallinity or glassiness of precipitating deposits may be related to electrolyte concentration and temperature through the well-known Von Wiemann ratio, W , which re-

lated precipitate size to solubility, S , and supersaturation, Q

$$W = \frac{Q - S}{S}$$

Small values of W correspond to large-sized crystals, while large values of W correspond to granular or glassy deposits. Since supersaturation Q is independent of temperature and concentration for a particular current drain, the ratio W should vary with solubility. The solubility is temperature sensitive through its dependence on the mean activity coefficient, which is a function of the dielectric constant, temperature, and ionic strength. Qualitatively, as the temperature is lowered, the dielectric constant, mean activity coefficient, and thus LiCl solubility all decrease. The net result is smaller sized crystals or even a glassy deposit of LiCl . Reducing electrolyte concentration at a given temperature increases the ionic strength and the mean activity coefficient, decreasing W and increasing the crystal size of the precipitate. This is what has been observed.

For electrolyte concentrations $\leq 0.75\text{M}$, final accumulations of LiCl deposits in the cathode pores are small and fairly crystalline at all discharge temperatures; electrolyte conductivities are not seriously changed at either 25° or -32°C .

For electrolyte concentrations $\leq 0.75\text{M}$, temperature alone does not appear to play a very important role in influencing cell capacity since both capacity *vs.* concentration curves almost coincide. This is understandable since, for electrolyte concentrations $\leq 0.75\text{M}$, electrolyte specific conductivity is not very strongly temperature dependent, as shown in Fig. 2.

The concentration regions where discharged cathodes have similar morphological appearances seem to indicate that a common factor is dominant.

The approximate linear relationship shown between cathode capacity and electrolyte concentrations $\leq 0.75\text{M}$ for both 25° and -32°C discharge is suggestive of a diffusion-related dependence. Our basic hypothesis is that cathode capacity is a strong function of two separate current density terms. The first term, i_{app} , is the constant current load applied to the cathode. The second term is an intrinsic limiting current, i_L , which depends on the physical state and extent of discharge of the porous cathode.

This limiting current, defined in the same manner as the limiting current in the Nernst diffusion equation

$$i_L = \frac{nFDC}{\delta}$$

represents the maximum transport rate of Li^+ through cathode pores to reach available cathode reaction sites and is proportional to the Li^+ ion diffusion coefficient and concentration.

As long as $i_{\text{app}} \ll i_L$, which would be the case for either fresh cathodes that contain little LiCl deposits or for low values of i_{app} , the cathode can easily maintain the constant current load by allowing adequate Li^+ ion flow to cathode reaction sites without any severe concentration polarization.

However, as the cell discharge reaction proceeds and the cathode pores become filled with solid insulating LiCl discharge product, Li^+ ion diffusion through the deposit becomes increasingly difficult and i_L therefore decreases.

At this point, $i_{\text{app}} \sim i_L$, and severe cathode concentration polarization occurs. This concept of concentration polarization in the porous cathode appears to explain the rather long times (several minutes) required to reach open-circuit potentials when almost fully discharged cells are removed from load. Since at this point the carbon cathode is blocked with LiCl product, it takes a long time for ionic equilibrium to be reestablished within the cathode matrix.

We will show that i_L , which ultimately determines useful cathode life, is proportional to both Li^+ concentration

and extent of cathode discharge. This should explain the linear relationship between cathode capacity and electrolyte concentration.

Let us assume that δ , which normally represents the diffusion-layer thickness, represents an increasing volume of LiCl products formed in the cathode pores. This is not unreasonable since the solid LiCl acts as a concentration gradient and hinders flow of Li^+ and SO_2Cl_2 to the cathode interior. If we further assume that δ can be represented as a linear function of discharge time, t , in the form $\delta = A + Bt$, where A and B are constants, then it is clear that i_l is a function of t . Specifically, the limiting current increases linearly with concentration and is inversely proportional to discharge time.

The concept of equating the diffusion layer thickness, δ , with a solid buildup of LiCl in the porous cathode is not unreasonable. Figure 5 shows voltage sweeps of porous cathodes obtained during 25°C constant current discharge. The decrease of the apparent limiting currents as a function of discharge time are indicative of the cathode being blocked by LiCl deposits.

To summarize: decreased cathode capacity at electrolyte concentrations $\leq 0.75\text{M}$ during 25° and -32°C discharge reflects the reaching of diffusion limits for mass transport of SO_2Cl_2 and/or Li^+ ions in the cathode pores due to choking of pores by precipitation of solid LiCl reaction product. Concentration limits from depletion of Li^+ transport species are strongly suggested by sensitivity of cell capacity to LiAlCl_4 electrolyte concentration.

For electrolyte concentrations $\geq 0.75\text{M}$, the capacity vs. concentration plot of Fig. 3 at -32°C parallels electrolyte conductivity vs. concentration plot shown in Fig. 6, which also shows leveling off at higher electrolyte concentrations. This implies that, although transport limitations are no doubt important, conductivity is the limiting factor.

The leveling off in the -32°C capacity vs. concentration curve of Fig. 3 may be simply due to the inelastic nature of the Teflon binder at low temperatures. Cathode capacity depends on cathode elasticity since the porous cathode must expand sufficiently to accommodate the LiCl

Fig. 5. Potentiometric polarization sweeps of a cathode (0.5 cm^2) in a $\text{Li}/\text{SO}_2\text{Cl}_2$ half-cell at various times during constant current discharge. The constant current level of $5\text{ mA}/\text{cm}^2$ is shown by the dashed line as i_{appl} .

Fig. 6. Replotted data of Fig. 2 showing specific conductivity of $\text{LiAlCl}_4\text{-SO}_2\text{Cl}_2$ solutions as a function of concentration for 25°, 0°, and -30°C.

deposits. If the Teflon binder does not stretch adequately, the cathode will tend to crack rather than swell. Decreased elasticity of the Teflon binder at reduced temperature is evident from the fact that discharged cathodes were stiff and rigid even after warming to room temperature; carbon particles did not adhere well to the screen and tended to flake off rather easily. This breaking of carbon-to-carbon and carbon-to-screen contact was not observed with cathodes discharged at room temperature. This disruption of original cathode structure results in capacity losses.

The above is in agreement with observations that cathodes discharged to a 1.0V cutoff at -32°C, then warmed to 25°C, and further discharged at 25°C exhibited the same total ampere-hours expected for normal uncycled 25°C discharged cathodes. This was not due to a time dependent self-healing of the cathode since cells discharged at low temperatures, allowed to warm to room temperatures, then brought down to -32°C for additional constant current discharge showed no considerable capacity increase.

Voltage reduction at reduced temperatures.—The plot of cell operating voltage vs. temperature shown in Fig. 1 appears discontinuous at temperatures $\leq 0^\circ\text{C}$. From a simplified Tafel equation for irreversible reduction reactions, closed-circuit cathode voltages would be expected to be linear with temperature. The discontinuity in operating voltages vs. temperature plot of Fig. 1 suggests that changes in cell reaction mechanism are occurring at temperatures $\leq 0^\circ\text{C}$. This can be explained as follows: normally, high operating potentials for $\text{Li}/\text{SO}_2\text{Cl}_2$ cells discharged at temperatures $\geq 0^\circ\text{C}$ correspond to reduction of molecular Cl_2 produced by thermal decomposition of SO_2Cl_2 . The decomposition is catalyzed by highly active carbon cathodes or added catalysts (12, 13) as suggested previously (1) for room temperature discharge

At reduced temperatures, where thermally activated catalytic dissociation of SO_2Cl_2 at carbon cathodes is incapable of maintaining adequate Cl_2 production for current drains applied, lower cell potentials are a result of direct reduction of SO_2Cl_2 . Since the $\text{Li}/\text{SO}_2\text{Cl}_2$ couple has a lower potential than does the Li/Cl_2 couple, the cathode operates at lower potentials. This is also true during later stages of discharge, when catalytic activity of the carbon cathode has been reduced and Cl_2 production is limited.

Addition of Cl_2 to cells where catalysis is slow (as would be the case when low surface area Shawinigan acetylene carbon black is used to make cathodes), has already been shown by Liang *et al.* (6) to substantially improve cell

operating voltages over wide temperature ranges in Li/SO₂Cl₂ cells. This is a result of accelerated Cl₂ utilization. Our argument that formation and subsequent utilization of Cl₂ increases operating cell voltages is further substantiated by experiments performed at various temperatures with 1.5M LiAlCl₄-SO₂Cl₂ electrolyte saturated with Cl₂ both in the electrolyte and void space above the cell prior to cell discharge.

Maximum solubility of Cl₂ in SO₂Cl₂ at room temperature is less than ~1.0M (1, 6). Typical constant current cell discharge curves and Cl₂-saturated cells shown in Fig. 7 illustrate two important differences when compared with unsaturated base lines. First, operating voltages for Cl₂-saturated electrolytes were indeed higher than for unsaturated base lines, and voltage enhancement became more pronounced as cell discharge temperatures decreased. At 25°C, addition of Cl₂ does not increase operating voltages significantly, since for high area carbon used in this study, the cathode itself is fully capable of producing adequate amounts of Cl₂ from heterogeneous dissociation of SO₂Cl₂. At reduced temperatures, however, thermally activated dissociation is essentially frozen out, and the cathode is incapable of supplying adequate Cl₂ for the particular current drain. Addition of Cl₂ from an external source results in increased cell plateau voltages of up to ~0.5V.

Cell operating voltages at early points in cell discharge for Cl₂-saturated electrolyte cells are inserted as open circles in Fig. 8. It is clear that the voltage vs. temperature line at temperatures below 0°C extends toward the Cl₂ data points down to -30°C and implies that if the cathode were capable of maintaining adequate amounts of Cl₂ on its own, operating voltages would be higher.

Measured specific conductivities of Cl₂-saturated 1.5M LiAlCl₄-SO₂Cl₂ electrolytes do not differ significantly from that of unsaturated electrolytes over the temperature range of -30° to 25°C. Thus, higher operating voltages observed with Cl₂-saturated solutions are not simply due to decreased IR losses but rather are due to the mechanisms outlined above.

Both experimental and theoretical work in our laboratory is currently underway to elucidate the detailed nature of SO₂Cl₂ dissociation processes at porous carbon cathodes and the physical and chemical factors in porous carbon cathodes operating voltages and capacities. Preliminary results have already been reported (14).

A second difference between Cl₂-saturated cells and base-line cells is that cells with Cl₂-saturated electrolytes showed substantially decreased capacities when compared to base-line cells. A few possible explanations are offered.

Fig. 7. Cathode potential vs. lithium as a function of time for constant current discharge for two Li/SO₂Cl₂ cells. The solid line refers to a cell whose electrolyte and void space above the electrolyte solution was saturated with Cl₂. The dashed line refers to a control cell.

Fig. 8. Cathode load potential vs. lithium reference (copied from Fig. 1). The added points represent plateau voltages for Cl₂-saturated cells.

Initially, Cl₂ dissolved in electrolyte within the cathode volume is rapidly utilized and LiCl reaction product is homogeneously deposited within the pores. However, as cell discharge proceeds, the cell first utilizes all dissolved Cl₂ contained within the cathode pore interior. Diffusion of Cl₂ from electrolyte bulk occurs preferentially at the interface of the cathode surface with the bulk electrolyte solution. These deposits formed at cathode surfaces have greater tendencies to clog surface entrances to pores and limit transport, thus resulting in premature cell failure.

When electrolyte solutions are saturated with Cl₂, equilibrium SO₂Cl₂ dissociation into SO₂ and Cl₂ shifts to the left, and less dissolved SO₂ exists in solution. Since SO₂ strongly coordinates Cl⁻ ions due to pi bonding between low lying 3d orbitals of sulfur and 3p orbitals of Cl⁻ (15), reduced SO₂ concentrations imply diminished complexation and more free Cl⁻ remaining in solution. Higher Cl⁻ concentration provides greater likelihood of LiCl formation and premature cell failure.

When Cl₂ is present, lithium can react directly with Cl₂ dissolved in the solution to form LiCl

Since no volatile products are formed in this reaction, the LiCl film may be more compact and block the cathode more efficiently than LiCl formed simultaneously with SO₂.

Decreased capacity with Cl₂-saturated electrolytes disagrees with results of Liang *et al.* (6), who found increased cell capacity in similar cases. The difference may result from physical properties of the carbon blacks used. Liang *et al.* used Shawinigan acetylene black (surface area: 65 m²/g), while we used United XC-6310 (surface area: 1000 m²/g). Differences in surface areas may effect Cl₂ utilization rate. Another reason may be the lower electrolyte concentrations used by Liang *et al.*

Acknowledgments

We wish to thank Dr. Wishvender K. Behl for assistance in preparing electrolyte salts and for stimulating discussions. We also wish to acknowledge the able technical as-

sistance of Edward Collins in assembling cells and performing various low temperature discharge experiments. Don Eckert assisted greatly in obtaining the SEM. The assistance of Paul Bramhall during initial stages of this work is also acknowledged.

Manuscript submitted Nov. 4, 1983; revised manuscript received March 23, 1984.

The U.S. Army Electronics Technology and Devices Laboratory assisted in meeting the publication costs of this article.

Solvent Mixing Effects on the Electrode Characteristics of Secondary Li/TiS₂ Cells

Yoshiharu Matsuda,* Masayuki Morita, and Ken-ichi Takata

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwa-dai, Ube, Yamaguchi, Japan

ABSTRACT

Charge-discharge characteristics of Li negative and TiS₂ positive electrodes have been studied in LiBF₄ solutions of tetrahydrofuran (THF), 1,3-dioxolane (DOL), and their mixture. Solvent mixing effects on the charge-discharge characteristics were investigated. Charge-discharge potentials at the Li electrode in THF-DOL/LiBF₄ were more stable than those in THF/LiBF₄ and DOL/LiBF₄, and they showed the least variation with the cycles. Ionic behavior in the solutions is discussed through the data of current-potential curves of the electrodes and electrolytic conductivity of the solutions. With respect to the TiS₂ electrode, charging efficiency in THF was seemingly the best, but the efficiency variation with the cycle in DOL-THF was very small. It was concluded that advantages of solvent mixing should be evaluated totally in Li/TiS₂ cells.

A variety of ambient temperature Li secondary cells with positive electrodes of layered compounds has been proposed during past several years (1, 2). In the course of the development of the cells, it has been noted that the choice of an electrolyte system is of special importance in the rechargeability of the Li electrode (3, 4). Koch and his co-workers found that 2-methyltetrahydrofuran/lithium hexafluoroarsenate (2Me-THF/LiAsF₆) is an excellent electrolyte system for secondary Li electrodes (5-7). The Li cycling efficiency was further improved by the addition of alcohols to 2Me-THF/LiAsF₆ (8). Foos and McVeigh proposed polymethoxymethanes as a stable and efficient solvent for Li electrodes (9). However, it has been also pointed out that the charge-discharge characteristics of positive electrodes such as TiS₂ are influenced by electrolytic solutions (10-12). It is important to know which of the electrodes governs the cell performance in a

practical secondary Li cell. Therefore, the effects of electrolytic solution on both negative electrode and positive electrode should be examined concurrently.

Up to the present, solutions consisting of ether solvents are most promising as an organic electrolyte solution of the secondary Li cell. In this work, tetrahydrofuran (THF), 1,3-dioxolane (DOL), and their blends were mainly used as a solvent, and the solvent mixing effects on both TiS₂ positive electrode and Li negative electrode were demonstrated. THF tends to decompose on the Li electrode as well as to cause Li dendrite deposition (4, 13). DOL/LiClO₄ solution is susceptible to detonation (14), and DOL tends to polymerize in its LiAsF₆ solution (8). However, it may be possible to reduce these faults by blending the solvents and by using other electrolytic salts. For instance, Johnson *et al.* obtained good cell performance by using DOL-1,2-dimethoxyethane/Li closoborane (15). The Li cycling characteristics in THF-diethylether/LiAsF₆ blend electrolytes were also investigated (7, 16). In the

* Electrochemical Society Active Member.

present paper, the charge-discharge characteristics of the Li electrode and the TiS_2 electrode were studied in lithium tetrafluoroborate (LiBF_4) solutions of THF-DOL blends. The results were compared with those in the solutions consisting of the pure solvents.

Experimental

Materials.—The solvents were purified and dehydrated by distillation. THF (Toyo Soda Manufacturing) was first distilled in presence of CuCl at 66°C . Then it was fractionally distilled after the addition of CaH_2 (17). DOL (Tokyo Kasei Kogyo) was refluxed over CaH_2 for 48h followed by distillation at 75°C . Then metallic Na chips were added and the solution was stirred for 48h or longer. Finally, it was distilled at 75°C again. The electrolytic salt was anhydrous LiBF_4 (Morita Chemical Industries, > 98%). It was further dried under reduced pressure at 80°C for 24h or longer. The desiccated LiBF_4 was dissolved in the solvents (1.0M [mol dm^{-3}]) under a dry Ar atmosphere.

Lithium foil was obtained from Kyokuto Metal Industries, sealed under Ar. TiS_2 powder (Mitsuwa Chemical, > 99.8%) was used as received.

Test cells.—A cylindrical Teflon cell (volume: $1.33\text{ cm}^2 \times 1.5\text{ cm}$) was used for cycling tests of the electrodes. In the Li electrode experiments, both test electrode and counterelectrode were Li foil disks ($1.33\text{ cm}^2 \times 0.02\text{ cm}$, 0.014g). Polypropylene nonwoven cloth impregnated with the electrolytic solution was sandwiched between two electrodes. A Ni mesh was used as a current collector. A Li fragment on the tip of Ni wire was placed close to the test electrode as a reference electrode. For cycling tests of the TiS_2 electrode, one of the Li electrodes was replaced with the TiS_2 electrode in the cylindrical cell. The TiS_2 positive electrode was prepared by mixing the TiS_2 powder (0.029g) with scaly graphite (Nakarai Chemicals, C-325, 0.088g) and Teflon powder (Mitsui Fluorochemical, Teflon-6J, 0.012g). Thus, the cell performances would be cathode limited. The graphite used here was well crystallized. It was preliminarily established that this kind of graphite was virtually inactive itself and did not accelerate the decomposition of the electrolytes. The mixture was molded into tablet with a pressure of $4.4 \times 10^3\text{ kg cm}^{-2}$. However, the preparative conditions have not been optimized yet, and the electrochemical characteristics of the TiS_2 positive electrode as presented here would not be the best possible. It was merely as a standard procedure in order to investigate the solvent mixing effects.

A beaker-type glass cell was also used for measuring current-potential relationships at Li and TiS_2 electrodes. The volume of the cell was 100 cm^3 . A Li chip and a Li sheet with large surface area were used as the reference electrode and the counterelectrode, respectively.

Measurements.—The charge-discharge tests of the Li electrode were mainly carried out by a cycling procedure in which Li was discharged at 1 mA ($= 0.75\text{ mA/cm}^2$) for 10 min followed by charging at the same current density for 10 min. The variation of the electrode potential was measured during the first 30 cycles. Li cycle efficiency was determined by Koch's method (18), in which a Ni sheet was used as the substrate. The plating and stripping current densities (i_p , i_s) were 2 mA/cm^2 , and the plated charge (Q_p) was 0.2 C/cm^2 . The cycling test of the TiS_2 electrode was conducted by galvanostatic discharge and charge ($0.5\text{ mA} = 0.38\text{ mA/cm}^2$). The voltage limits were 1.75V for discharge and 3.5V (or 3.0V) for charge. Current-potential curves of the electrodes were potentiostatically measured, where the electrode potential was stepwise changed at first from the rest potential to discharging ones and then changed to charging potentials. All experiments were carried out in a dry Ar atmosphere at room temperature ($18^\circ\text{--}20^\circ\text{C}$), except for conductivity measurements, which were carried out by a usual bridge method at 30°C .

Results and Discussion

Li electrode.—Figure 1 shows the charge-discharge curves of Li electrodes in THF/LiBF_4 and DOL/LiBF_4 . The potential variation with cycling in THF/LiBF_4 was

Fig. 1. Charge-discharge curves of the Li electrodes in 1M LiBF_4 solutions of THF and DOL. Current density: 0.75 mA/cm^2 .

relatively small, but the potentials varied by a few tens of millivolts during 10 min in each cycle. However, in the DOL solution, the potential difference between charge and discharge gradually increased with cycling, even though the potential variation in each cycle was small. The charge-discharge curves in the mixed electrolyte, DOL-THF/LiBF_4 , are shown in Fig. 2, where the mixing ratio is 1:1 volume (54 mole percent [m/o] DOL). There are two attractive characteristics in the mixed solution, compared with those in the solutions consisting of the pure solvents. The one is that charging and discharging potentials remain almost constant during 10 min in each cycle. The other is that the potential variation with cycling is extremely small. In addition, dendritic deposition of Li which was liable to occur in THF/LiBF_4 took place scarcely in the DOL-THF/LiBF_4 solution. It seemed that the mixed DOL-THF holds concurrently the good points which DOL and THF have individually.

Anodic and cathodic current-potential relations at Li electrodes were measured in a beaker-type cell. The current-potential curves in THF, DOL, and DOL-THF (1:1 volume) are shown in Fig. 3. The curves were first measured in the anodic direction and then measured in the cathodic one. The solid curves in Fig. 3 indicate that the measurements were carried out without stirring the solutions and the broken curves correspond to the measurements with solution stirring. Current densities without stirring in DOL-THF/LiBF_4 were higher than those in THF/LiBF_4 or DOL/LiBF_4 at given potentials. That is, polarization of the Li electrode for both anodic (discharge) and cathodic (charge) reactions in the mixed solution was smaller than that in THF or DOL. This is compatible with the results shown in Fig. 1 and 2, where lower overvoltages were observed during charge and discharge in the mixed solution than in THF or DOL. In these electrolytic solutions the Li electrode reactions

are mostly controlled by mass-transfer process, if the potential is somewhat far from the reversible potential. In the present case, two mass-transfer processes would be possible: one is Li^+ ion diffusion in the electrolytic solu-

Fig. 2. Charge-discharge curves of the Li electrode in 1M LiBF_4 solution of DOL-THF (1:1 volume). Current density: 0.75 mA/cm^2 .

Fig. 3. Current-potential curves of the Li electrodes in 1M LiBF₄ solutions. (○, —): DOL-THF (1:1 volume). (◇, - - -): THF. (▽, —): DOL. (○, ◇, ▽): solution not stirred. (—, - - -, - - -): solution stirred.

tion and the other is Li⁺ ion diffusion across the Li passivating film (4). As shown in Fig. 3, the current densities, especially in THF and DOL-THF, were dependent on solution stirring. Therefore, the processes were mainly controlled by Li⁺ ion diffusion in the solution, and not by Li⁺ ion diffusion across the Li passivating film. The current increase with solution stirring at more negative potentials (~ -1.0V) in THF was probably due to increase in true surface area of the electrode by dendritic deposition of Li. In DOL, however, the current increase with solution stirring was rather small. The results shown in Fig. 3 suggest that the diffusion rate in the mixed solution is higher than those in the solutions consisting of neat solvents.

Solvent mixing effects were also observed in electrolytic conductivity of the solution. Figure 4 shows the conductivity of LiBF₄ in THF, DOL, and DOL-THF (1:1 volume) as a function of LiBF₄ concentration. The conductivity of the mixed solution was higher than that of THF/LiBF₄ or DOL/LiBF₄. This means that the ionic mobility, or the diffusion rate, of Li⁺ ion in the mixed solution is higher than that in THF or DOL, and then it is

Fig. 4. Conductivity of LiBF₄ in THF (◇), DOL (▽), and DOL-THF (1:1 volume) (○) at 30°C.

consistent with the results shown in Fig. 3. Ionic mobility is virtually determined by size of solvated ion and viscosity of solution (19, 20), as shown in Stokes' equation

$$u = \frac{|z|e}{6\pi\eta_0 r_s} \quad [2]$$

where u is ionic mobility, η_0 is solvent viscosity, r_s is Stokes' radius of the ion, and other symbols have their usual meanings. It was presumed that a suitable solvation state of Li⁺ ion in DOL-THF and/or lowering of viscosity by blending THF and DOL mainly contribute to higher diffusion rate of Li⁺ ion (21). The suitable ion solvation might also be responsible for the stable potential change during the cycle in mixed DOL-THF. Consequently, solvent mixing effects on the conductivity would highly relate to those on the Li electrode characteristics. However, further details of Li⁺ ion behavior will be discussed elsewhere (21).

Li cycle efficiency determined by Koch's method (18) is shown in Fig. 5. In spite of low plating and stripping current densities (2 mA/cm²) and low plated charge (0.2 C/cm²), the efficiency in DOL/LiBF₄ was much less than those in others. The efficiency variation in THF/LiBF₄ was quite similar to those obtained by Koch and Young (22). There was no great effect on the efficiency in initial cycles by mixing THF with DOL, but it seemed that the efficiency variation with cycle number in DOL-THF was less than that in THF. However, quantitative values of the efficiency were not presented here because of their lesser reproducibility. Further investigations of the solvent mixing effects on the cycle efficiency are now in progress under various experimental conditions.

TiS₂ electrode.—Figure 6 shows the current-potential curves of the TiS₂ electrode in THF/LiBF₄, DOL/LiBF₄, and DOL-THF (1:1)/LiBF₄. The measurements were carried out in the direction of arrows on the curves. A hysteresis observed on each cathodic curve seems to originate from partial reduction during the measurement. Some difference in zero-current potential was detected between three electrolytic solutions. This is probably due to variations in the state of charge and in the degree of relaxation of the electrode during the measurement and not to the change in the electrolyte itself. The order of current density at given potential was DOL-THF > THF > DOL, which was similar to the case of the Li electrode. However, the TiS₂ electrode reaction

is not limited only by mass-transfer process, in contrast to the Li electrode reaction. The detail of reaction [3] is complicated. The reaction involves not only charge-transfer process and Li⁺ ion diffusion in the solution but also ion transfer in pores of the electrode mixture and the transfer

Fig. 5. Cycle efficiency of the Li electrodes in THF (▽), DOL (◇), and DOL-THF (1:1 volume) (○). Substrate: Ni sheet. $Q_p = 0.2 \text{ C/cm}^2$, $i_p = i_s = 2 \text{ mA/cm}^2$.

Fig. 6. Current-potential curves of the TiS_2 electrodes in 1M LiBF_4 solutions of THF (A), DOL (B), and DOL-THF (1:1 volume) (C).

in the layered structure of TiS_2 crystal (11). Although it is not clear which step is rate determining in the TiS_2 electrode reaction, one might expect from the current-potential curves that blending THF and DOL has a good effect on the charge-discharge reaction of the TiS_2 electrode.

The charge-discharge curves of the TiS_2 electrode in THF/LiBF_4 , DOL/LiBF_4 , and $\text{DOL-THF(1:1)/LiBF}_4$ are shown in Fig. 7, 8, and 9, respectively. As open-circuit voltages became almost constant within 1h, the measurements were carried out after standing the cells for 1h. Further standing before the cycle did not show any change in the first cycle capacity. Discharge (or charge) time of 10h corresponds to $x = 0.72$ in Eq. [3] from the calculation based on the TiS_2 weight. Equivalence of Li used

Fig. 7. Charge-discharge curves of the Li/TiS_2 cell. Electrolyte: THF/LiBF_4 (1M). Current density: 0.38 mA/cm^2 .

Fig. 8. Charge-discharge curves of the Li/TiS_2 cell. Electrolyte: DOL/LiBF_4 (1M). Current density: 0.38 mA/cm^2 .

in this study as the counterelectrode was about 7.8 times of that of TiS_2 (see Experimental). Accordingly, variation of cell voltage is mainly attributable to the potential change at the TiS_2 electrode. Charge-discharge efficiencies in THF were seemingly better than those in DOL and DOL-THF, during the first five cycles. In DOL-THF/LiBF_4 , discharge capacity at the first cycle was comparable to that in THF, but efficiency of the first charge was ca. 50% of the first discharge. However, the subsequent charging efficiencies no longer decreased and were more than 80% of corresponding discharge. Thus, if any side reactions are not involved, it is considered that charge and discharge of TiS_2 in DOL-THF/LiBF_4 reversibly cycle in the range of about $0.4 \leq x \leq 0.7$. Similar cycling behavior was observed in the DOL solution, except for relatively low capacities of the first discharge and the subsequent charge.

Extended cycling efficiencies of the Li/TiS_2 cells were also examined with the same test cell. Charge-discharge curves in THF and DOL-THF(1:1) are shown in Fig. 10 and 11, respectively. Viscosity of the DOL/LiBF_4 solution tended to increase with cycles extended over a long time. This would be due to polymerization of DOL initiated by small amount of acids (23), which were either contained as impurity in the original LiBF_4 or evolved electrochemically during charge-discharge cycles. Thus, cycling efficiencies in DOL steeply decreased after five cycles. Charge-discharge efficiency in THF/LiBF_4 decreased

Fig. 10. Charge-discharge curves of the Li/TiS_2 cell. Electrolyte: THF/LiBF_4 (1M). Current density: 0.38 mA/cm^2 .

gradually after the sixth charge, and the cycle became impossible after the thirteenth charge. At the end of this cycling, Li dendrite deposition was observed even in the porous polypropylene separator. It was thought that short circuits were formed between the positive and negative electrodes through the dendrite. Charge-discharge capacities (Ah) in DOL-THF kept almost constant, except for the first discharge. After 40 cycles, however, charge-discharge efficiencies decreased slowly, and the capacities were exhausted practically after 45 cycles. A rise in the viscosity was not observed in DOL-THF/LiBF₄, in contrast to the DOL solution. Since the cells were initially cathode (TiS₂) limited, total accumulated cell capacity might be evaluated for theoretical capacity of TiS₂ used (so-called FOM_{TiS₂}). Resulted FOM_{TiS₂}'s were about 7 in THF, 1.5 in DOL, and 9 in DOL-THF. However, increasing in the cycle number in DOL-THF would be owing primarily to the improved cycling characteristics at the Li electrode in that solution.

X-ray diffraction of the TiS₂ electrodes was examined after the cycles. Diffraction intensities of TiS₂ were decreased with cycling in every solution. This suggested that the layered structure of TiS₂ crystal diminished with cycling. From the fact that the efficiency of the first charge in DOL-THF was much different from that in THF, it was supposed that the solvent took part in the charging reaction of TiS₂. However, no marked difference was detected in x-ray diffraction data between two solutions. Further detailed investigations should be required to clarify the relation between the electrolyte composition and cycling characteristics of the TiS₂ electrode. Cycling efficiency of the Li/TiS₂ cell with the DOL-THF(1:1) solvent was not very high, so far as the present work, but it will be improved by changing experimental conditions such as preparation of the TiS₂ electrode and the test cell construction.

Conclusions

Solvent mixing effects on the electrode characteristics of Li/TiS₂ cells have been investigated in the DOL-THF system, and the results are summarized as follows.

1. Charge-discharge potentials at the Li negative electrode in a DOL-THF blend were more stable than those in neat THF or DOL. The Li electrode in DOL-THF/LiBF₄ showed the least polarization. These seemed to relate that the electrolytic conductivity of LiBF₄ was improved by mixing the solvents.

2. Current-potential relations at the TiS₂ positive electrode suggested higher cyclability of TiS₂ in DOL-THF than in THF or DOL. Initial charging efficiency in DOL-THF was rather low, but its variation with the cycle was very small.

3. The total cycle performance of the cell was initially the best in THF/LiBF₄, because the cells used in this work

were cathode (TiS₂) limited. With increasing the cycle number, however, the cell performance became anode (Li) limited, and then the cycle life of the cell with DOL-THF/LiBF₄ was the best.

ABSTRACT

A general method for computing parasitic intercell currents in series connected electrochemical cells with common electrolytic path is described. This method covers systems operating with constant as well as variable parameters such as usually are encountered in practice. The Li/SOCl₂ battery is selected to illustrate the evolution of parasitic intercell currents in the course of battery discharge.

Often, it is necessary to construct a battery having a high energy density that must be able to operate at high power outputs. One way that this goal can be accomplished is by selecting a lithium battery and using bipolar electrodes, which provide a compact series connection of the individual cells. Such a design is very attractive. However, because of the reactivity of metallic Li when in contact with an electrolyte, only a reserve configuration is practical, which means that a continuous electrolytic path through all of the cells must be provided for either filling the battery or flowing the electrolyte.

Our purpose in this communication is to discuss the effects of current flowing in the common electrolytic path on the operational characteristics of batteries and other electrochemical devices. Although most of the treatment is general, the results are illustrated using a Li/SOCl₂ battery employing thin disk-shaped cells of bipolar construction.

Theoretical

Qualitatively, intercell current is an ionic current that originates in one cell and terminates in another cell. This current does not perform any useful work; on the contrary, it is considered a parasitic current resulting not only in the loss of power but also in the loss of capacity, and it may contribute to the premature failure of individual cells by the formation of passive films or by the corrosion of structural parts.

The operation of a battery is a dynamic event consisting of a series of consecutive elementary processes wherein the slowest determines the overall rate. To illustrate, let us consider the Li/SOCl₂ system (Fig. 1). Two processes occur at the negative; they are the charge transfer reaction (oxidation) and the transport of Li⁺ ions through the protective LiCl film whose thickness depends on the electrolyte composition and the rate of battery discharge (1). The situation at the positive is far more complex because, first, the reaction takes place within the confines of a porous structure, and, second, the physicochemical properties of the electrolyte change in the course of battery discharge. In spite of this complexity, each elementary process obeys, at least approximately, a generalized Ohm's law, *i.e.*, it can be described by an equation of the type, $j = kX$, relating the flux j to the driving force X through a phenomenological rate constant k . Such a description suggests that an electric circuit analog can be used to represent the overall process occurring in the interior of the cell.

Equivalent circuit analog.—An electric circuit analog of a reserve battery during discharge is shown in Fig. 2. This representation greatly simplifies the real situation and yet permits the treatment of the intercell currents in a more general way than similar models that have appeared in the literature (2-7). Here, the phenomenological coefficients associated with ionic current in the segments of the

electrolyte in the fill path and the feed line into the entrance port of the cell are replaced by equivalent resistances, $R_{t,i}$ and $R_{f,i}$, respectively. This replacement requires that the current distribution on the cross section of the

* Electrochemical Society Active Member.

electrolytic path be uniform, which, in practice, is only approximately correct. Further, if we assume that the potentials in the electrolyte at the entrance port to the cells, $\bar{\phi}_i$, are uniform and equal to a longitudinal average between the cell electrodes and that the electrodes are equipotential with the potential difference of $V_i = V_{c,i} - V_{a,i}$ between them, then the loop equations for the current, J_i , in the external load, R_i , and for the circulating currents in the fill path, J_i , are given, respectively, by

$$J_1 R_1 = \sum_{i=1}^N V_i \quad [1]$$

and

$$-J_{i-1} R_{t,i} + J_i (R_{t,i} + R_{t,i+1} + R_{t,i}) - J_{i+1} R_{t,i+1} = \bar{\phi}_{i+1} - \bar{\phi}_i, \quad (i = 1, 2, \dots, N-1) \quad [2]$$

where we neglect the potential drop across the separator.

Since the circulating current, J_i , flows in the reverse direction in the i th segment of the fill path, then

$$J_0 = J_N = 0 \quad [3]$$

Furthermore, the intercell current into a cell, I_i , is given by

$$I_i = J_i - J_{i-1}, \quad (i = 1, 2, \dots, N) \quad [4]$$

while the total electrode current into a cell, *i.e.*, the anodic current, $I_{a,i}$, is

$$I_{a,i} = J_1 + J_{i-1}, \quad (i = 1, 2, \dots, N) \quad [5]$$

Finally, we have the requirement that the bipolar plate be equipotential, *i.e.*

$$V_{a,i+1} = V_{c,i}, \quad (i = 1, 2, \dots, N-1) \quad [6]$$

where again the potential drop across the separator is ignored.

Reformulation of applicable equations.—The N Eq. [1] and [2] can be solved for J_1 and J_i if $\bar{\phi}_i$ and V_i can be expressed in terms of the $I_{a,i}$ and I_i . To obtain the needed information, it is necessary to consider in some detail the current and potential distributions within a cell that is operating in the presence of intercell current. Results for a cell having cylindrical symmetry have been given elsewhere (2); however, a treatment is given in Appendix A in order to provide the results relevant to the further discussion. Thus, suppressing the cell index when all quantities in an equation refer to the same cell, the potentials at the entrance ports of the cells and the potential differences across the cells are, respectively

$$\bar{\phi} = \bar{\phi}_0 + I R_p \quad [7]$$

and

$$V = U_c - U_a - (I_a + I\sigma_c) R_z \quad [8]$$

Here, the potential to the entrance port in the absence of the intercell current is

$$\bar{\phi}_0 = (V_a - U_a) \sigma / \sigma_c + (V_c - U_c) \sigma / \sigma_a \quad [9]$$

and the impedance to the intercell current at the entrance port and the internal cell impedance are, respectively

$$R_p = \frac{r_c}{\pi a \delta^* (\kappa_a + \kappa_c)} \left[\frac{I_1(b/r_c) K_0(a/r_c) + K_1(b/r_c) I_0(a/r_c)}{I_1(b/r_c) K_1(a/r_c) - K_1(b/r_c) I_1(a/r_c)} \right] \quad [10]$$

and

$$R_z = \frac{1}{\pi (b^2 - a^2) \sigma} \quad [11]$$

The functions I_ν and K_ν , ($\nu = 0, 1$), are the modified Bessel functions of the order ν , which arise because of the symmetry of the cell. Other quantities are defined as follows: the characteristic depth of penetration, the effective electrode resistivities, and the effective cell resistivity are given respectively, by

$$r_c^2 = \frac{1}{2} \delta^* \left[\frac{2\kappa_a \kappa_c (\kappa_a + \kappa_c) + \delta^* (\kappa_a^2 \kappa_c + \kappa_c^2 \kappa_a)}{2\kappa_a \kappa_c (\kappa_a + \kappa_c) + \delta^* (\kappa_a + \kappa_c) \kappa_a \kappa_c} \right] \quad [12]$$

$$1/\sigma_\nu = 1/\kappa_\nu + \frac{1}{2} \delta^* / \kappa_\nu, \quad (\nu = a, c) \quad [13a]$$

$$1/\sigma = 1/\sigma_a + 1/\sigma_c \quad [13b]$$

Having the information developed in Appendix A and summarized in Eq. [7]-[13], we are in a position to complete the description of the battery model, *i.e.*, to express Eq. [1] and [2] in terms of the circulating currents. This is a relatively simple matter for Eq. [1]. Starting with Eq. [8] and combining it with Eq. [4] and [5], we get the potential depression across a cell

$$U_i - V_i = (J_1/\sigma_i + J_{i-1}/\sigma_{a,i} + J_i/\sigma_{c,i}) R_{z,i} \sigma_i \quad [14]$$

Summation of both sides of Eq. [14], taking into account Eq. [3], and substitution of the result into Eq. [1] yields

$$J_1 \left[R_1 + \sum_{i=1}^N R_{z,i} \right] = \sum_{i=1}^N U_i - \sum_{i=1}^{N-1} J_i R_{z,i}^* \quad [15]$$

where

$$R_{z,i}^* = R_{z,i+1} \sigma_{i+1} / \sigma_{a,i+1} + R_{z,i} \sigma_i / \sigma_{c,i} \quad [16]$$

A more complex procedure is required to express Eq. [2] in terms of J_i and J_i . Following the development presented in Appendix B, we use Eq. [6], [7], [9], and [14] to rewrite the right side of Eq. [2] and obtain

$$-J_{i-1} R_{t,i}^* + J_i (R_{t,i}^* + R_{t,i+1}^* + R_{z,i}^* + R_{b,i}) - J_{i+1} R_{t,i+1}^* = U_i^* - J_1 R_{z,i}^*, \quad (i = 1, 2, \dots, N-1) \quad [17]$$

where the equivalent feed line resistance is

$$R_t^* = R_t + R_p - R_z \sigma^2 / (\sigma_a \sigma_c) \quad [18]$$

and the equivalent open-circuit potential of a cell is

$$U_i^* = U_{c,i} - U_{a,i+1} \quad [19]$$

Equations [15] and [17] with Eq. [3] constitute the set of N equations that must be solved to obtain the circulating currents, J_1 and J_i ($i = 1, 2, \dots, N-1$).

Intercell current and potential distributions.—Using the relations developed in Appendix A, we have for the local anodic and cathodic current densities

$$i_a = \sigma(U-V) - \frac{\sigma \delta^* (\kappa_a + \kappa_c)}{2 r_c^2 \sigma_c} (\bar{\phi} - \bar{\phi}_0) \quad [20]$$

and

$$i_c = \sigma(U-V) + \frac{\sigma \delta^* (\kappa_a + \kappa_c)}{2 r_c^2 \sigma_a} (\bar{\phi} - \bar{\phi}_0) \quad [21]$$

respectively, where the radial potential distribution is

$$\bar{\phi} - \bar{\phi}_0 = \frac{I r_c}{\pi a \delta^* (\kappa_a + \kappa_c)} \left[\frac{I_1(b/r_c) K_0(\tau/r_c) + K_1(b/r_c) I_0(\tau/r_c)}{I_1(b/r_c) K_1(a/r_c) - K_1(b/r_c) I_1(a/r_c)} \right] \quad [22]$$

and $U = U_c - U_a$ is the open-circuit potential.

Equations [20] and [21] show clearly the effect of the intercell current, I , and the potential depression, $U-V$, on the local charge transfer current density. Their radial dependence is contained in the term determined by Eq. [22], where, from the properties of the modified Bessel functions, we find that for positive I , $\bar{\phi} - \bar{\phi}_0$ is a positive, monotonically decreasing function of the radius, r . Inspection of Eq. [20] and [21] reveals that if the intercell current, I , is of the same sign as the potential depression, $U-V$, then current reversal is possible only on the anode, while if these quantities are of the opposite sign, then current reversal can take place only on the cathode. Since $U-V$ is positive for a discharging cell, for positive I , *i.e.*, for intercell current into the cell, reversed current can occur on the inner portion of the anode, proceeding from $r = a$ outward to $r = r_0$, *i.e.*, that is to where $i_a = 0$, while for negative intercell current, reversed current is possible on the inner portion of the cathode. Such a current reversal would force the cell to act as an electrolyzer over the affected electrode area.

The total amount of reversed current is calculated by integrating the local current density, either Eq. [20] or [21], over the affected electrode area, $\pi(r_0^2 - a^2)$. The result is either

$$I_a(r_o) = \pi(r_o^2 - a^2) \sigma (U-V) - I\gamma\sigma/\sigma_c \quad [23]$$

or

$$I_c(r_o) = \pi(r_o^2 - a^2) \sigma (U-V) + I\gamma\sigma/\sigma_a \quad [24]$$

where

$$\gamma = 1 - \frac{r_o}{a} \left[\frac{I_1(b/r_o) K_1(r_o/r_o) - K_1(b/r_o) I_1(r_o/r_o)}{I_1(b/r_o) K_1(a/r_o) - K_1(b/r_o) I_1(a/r_o)} \right] \quad [25]$$

and where r_o is either the radius for zero c.d. on the anode or the cathode, respectively.

Computational results.—Equations [15] and [17] describe a battery model in which the cell parameters can vary from cell to cell. Indeed, this will be the case, since in a discharging battery the intercell currents vary from cell to cell. Thus, in general, the N in Eq. [15] and [17] can be solved only numerically.

A simpler case is that with constant coefficients that are uniform from cell to cell, where the solution can be obtained in closed form. Equations [15] and [17], with constant and uniform parameters, reduce to

$$J_i(R_1 + NR_z) = NU - R_z \sum_{i=1}^{N-1} J_i \quad [26]$$

and

$$-J_{i-1}R_t^* + J_i(2R_t^* + R_z + R_1) - J_{i+1}R_t^* = U - J_iR_z, \quad i = (1, 2, \dots, N-1) \quad [27]$$

respectively, with the only reference to a particular cell occurring on the circulating currents.

This set of N equations can be solved using the method of undetermined coefficients (see Appendix C). The results are as follows

$$J_1 = \frac{N(1-\xi)U}{R_1 + N(1-\xi)R_z} \quad [28]$$

$$J_i = J_p \left(1 - \frac{\lambda^{N-i} + \lambda^i}{\lambda^N + 1} \right), \quad (i = 0, 1, \dots, N) \quad [29]$$

and from Eq. [4]

$$I_i = J_p \frac{\lambda - 1}{\lambda^N + 1} \left(\lambda^{N-i} - \lambda^{i-1} \right), \quad (i = 1, 2, \dots, N) \quad [30]$$

where

$$J_p = \frac{R_1 U}{R_1 + N(1-\xi)R_z} \left(\frac{1}{R_1 + R_z} \right) \quad [31]$$

$$\lambda = 1 + \frac{R_1 + R_z}{2R_t^*} + \sqrt{\frac{R_1 + R_z}{2R_t^*} \left(2 + \frac{R_1 + R_z}{2R_t^*} \right)} \quad [32]$$

and

$$\xi = \frac{R_z}{R_1 + R_z} \left[1 - \frac{(\lambda^N - 1)(\lambda + 1)}{N(\lambda^N + 1)(\lambda - 1)} \right] \quad [33]$$

Application to Li/SOCl₂ Battery

The principal disadvantage of a common electrolytic path is the continuous discharge of the cells which results in an underutilization of the reactants as well as in a loss of power. In marginal designs, circulating currents may contribute to thermal management problems. Additionally, the post-test examination of a number of discharged Li/SOCl₂ batteries of the reserve type has revealed the dendritic growth of metallic Li in cells at the negative end and evidence of an oxidation reaction in cells at the positive end.

In what follows, we will begin by examining the characteristics of the intercell and circulating currents in batteries with uniform and constant parameters; next, we will illustrate the effect of changing parameters upon the distribution of these currents; and, finally, we will briefly consider implications involving current reversal.

Constant parameters.—The uniformity of battery parameters can be approximately realized only in battery designs employing flowing electrolyte and operating at constant power output. In other designs, such assump-

Table I. Data for modeling of intercell currents

tions have only limited validity; nevertheless, they serve the useful purpose of illustrating how the electrochemical and design parameters interact, and thus can provide guidance on an approach to minimize the intercell currents.

Figures 3a-3c show the change in the computed distributions of the intercell and circulating currents as a function of the number of cells. The parameters used in these and the following calculations are assembled in Table I. In each case, the load resistance was chosen to be 0.5Ω per cell so as to make the load current approximately the same for all of the batteries and the fill-tube and feed-line resistances were approximated by the expressions, respectively

$$R_t = \frac{l_t}{\pi r_t^2 \kappa_t} \quad [34]$$

and

$$R_f = \frac{1}{2\pi d \kappa_f} \ln \left(\frac{a}{r_t} \right) \quad [35]$$

where l_t and r_t are, respectively, the length and radius of the segment of the fill tube that connects two cells, d is the thickness of the annular feed line into each cell, and κ_t and κ_f are the effective conductivities of the electrolyte in the fill tube and feed line, respectively. In addition, we assumed $\kappa_a = \kappa_c = \kappa \epsilon_z$, $\kappa_f = \kappa \epsilon_f$, and $\kappa_t = \kappa$, where ϵ_z and ϵ_f indicate the respective porosities.

Qualitatively, all of the batteries exhibit a maximum in the circulating currents at the central cells; whereas, the intercell currents are largest at the end cells and change their sign from positive to negative, *i.e.*, from entering a cell to exiting a cell at the negative and positive ends of the battery, respectively. Interestingly, for batteries having a small number of cells (Fig. 3a), all cells generate intercell currents. However, with an increase in the number of cells, *e.g.*, for $N = 40$ (Fig. 3b), the centrally located cells contribute significantly less, and for $N = 80$ (Fig. 3c), the majority of the cells do not contribute to the intercell current at all, *i.e.*, a large section of the battery does not suffer underutilization of its reactants.

The rapid decrease in the intercell current for the centrally located cells, particularly when N is large (Fig. 3c), implies that a battery can be viewed as consisting of segments near each end, OB and CE, where a substantial underutilization of reactants occurs, and a central segment, BC, where cells operate with equal anodic and cathodic currents. Furthermore, if the intercell current exceeds a critical value, which depends on the potential depression and thus on the cell load, additional segments may be identified, OA and DE: namely, those where the electrode current is reversed over part of an electrode. The effect of reversed current is illustrated in Fig. 4a-4c, wherein photographs of the feed-line region of a series stack show clear evidence of electrochemical activity at the positive (Fig. 4a), and negative (Fig. 4b) ends, and no measurable amounts at the center (Fig. 4c).

The λ parameter.—For a given number of cells, the relative distributions of both the circulating and intercell currents depend on the value of the parameter λ . This parameter is given by Eq. [32] and is a function of the ratio: $(R_1 + R_z)/(R_1 + R_p - R_z \sigma^2 / \sigma_a \sigma_c)$, *i.e.*, it depends on the battery de-

Fig. 4. Effect of intercell current at the cell entrance and within the annular feed line. a (top left): Cell located at negative end. $I > I_a^*$; metallic Li and direction of its growth are indicated by arrows. b (top right): Cell located in the central region of an 80-cell assembly. c (bottom): Cell located at the positive end. $I > I_c^*$; corrosion products indicated by arrow.

sign (dimensions) as well as on the properties of the electrolyte and the kinetics of charge transfer reaction. For large values of R_i , λ will be large, while for large values of R_e , λ will be near unity.

For large numbers of cells, λ gives the ratio of intercell currents for adjacent cells in the segments near the ends of the battery, i.e., Eq. [30] yields either

$$I_{i+1}/I_i \approx 1/\lambda, \quad i \approx 1 \quad [36]$$

or

$$I_{i+1}/I_i \approx \lambda, \quad i \approx N \quad [37]$$

since, according to Eq. [32], $\lambda > 1$.

In general, the effect of λ on J_i and I_i is more complicated. In particular, Fig. 5 shows plots of J_i/J_p and I_i/J_p vs. λ in a 40-cell battery. It is seen that for $i = 1$, curves J_i/J_p and I_i/J_p coincide, in agreement with Eq. [4]; moreover, they increase monotonically with an increase in λ . For $i > 1$, the I_i/J_p ratios decrease with increasing i and, furthermore, each exhibits a maximum, which shifts towards $\lambda = 1$ as i approaches $N/2$. The J_i/J_p ratios increase with i as i approaches $N/2$ for all values of λ . It is noteworthy that for all values of i , J_i/J_p approaches unity for large λ .

Due to the symmetry, for $i > N/2$ the I_i/J_p change sign and increase in magnitude as i approaches N . Similarly, the J_i/J_p decrease with an increase in i , when $i > N/2$.

Figure 6 illustrates the effect of the number of cells in a battery on the circulating and the intercell currents, again

expressed as J_i/J_p and I_i/J_p ratios. Evidently, the dependence on N is substantial only for $\lambda < 2$ and $N < 40$.

The current distributions can be summarized as follows: for λ near unity, the tails of the current distributions extend into the battery, and for $N < 40$ the shape of the tails depends on N ; while for large λ , the terminal cells carry most of the intercell currents independent of the value of N . However, large values of λ generally result from large values of R_i rather than from small values of R_e , so that, according to Eq. [31], J_p becomes small so that generally the intercell currents even in the end cells are small for large λ .

In practice, volumetric energy density constraints and conditions imposed either on the time required for activating a battery employing static electrolyte or on the pressure drop for flowing electrolyte designs result in values of λ near unity and produce intercell current distributions that tail slowly off into the battery. However, after the cells are nearly discharged, intercell current distributions corresponding to large values of λ can occur.

Fig. 5. Plot of normalized circulating, J_i/J_p , and intercell currents, I_i/J_p , as functions of the design factor, λ . The numbers indicate the value of i .

Fig. 6. Plot of the normalized circulating currents J_1/J_p and J_3/J_p and the intercell currents I_1/J_p and I_3/J_p as functions of design for $N = 10$ (—), $N = 40$ (- - -), and $N = 80$ (· · · ·).

Reversal of electrode currents.—The effect of the intercell current, I , on the radial distribution of the anodic and cathodic currents is shown in Fig. 7a and 7b for a 10-cell and an 80-cell battery, respectively.

Results that are presented in Fig. 3a and 3c and those in Fig. 7a and 7b indicate that the intercell current into the first two cells of the 10-cell battery stack and into the first eight cells of the 80-cell assembly exceed their critical values, I_a^* , and experience current reversal at their negative. Only one of the cells located at the positive end of the 10-cell battery and five of the cells of the 80-cell assembly suffer current reversal at their positive. This is illustrated in Fig. 8 for the 80-cell battery, where the dimensionless depth of penetration of the reversed current, $(r_o - a)/r_e$, is plotted as a function of the cell number. Evidently, the depth of reversed current penetration is a linear function of the cell number and has the same slope, except for sign, at either end of the battery. This linearity follows from Eq. [20] and [21] and by the asymptotic behavior of the modified Bessel functions for large arguments, since in all practical cases, a/r_e is a large number.

Specifically, under the conditions that $a \gg r_e$, $\tau \approx a$, and $J_1 \gg J_p$, Eq. [20] and [21] can be approximated by

$$i_a \approx \frac{\sigma}{2\pi \tau_e a \sigma_c} [I_a^* - Ie^{-(r-a)/r_e}] \quad [38]$$

and

$$i_c \approx \frac{\sigma}{2\pi \tau_e a \sigma_a} [I_c^* + Ie^{-(r-a)/r_e}] \quad [39]$$

where the critical intercell currents are

$$I_a^* = 2\pi a \tau_e \sigma_c J_1 R_z \quad [40]$$

and

$$I_c^* = 2\pi a \tau_e \sigma_a J_1 R_z \quad [41]$$

If the intercell current exceeds I_a^* , then current reversal takes place on the anode; whereas, if the intercell current is more negative than $-I_c^*$, then current reversal takes place on the cathode.

Furthermore, if the number of cells is large, then the intercell current for cells near the negative end of the battery can be approximated by

$$I_i \approx J_p (\lambda - 1) / \lambda^i, \quad i \approx 1 \quad [42]$$

and near the positive end by

Fig. 7. Plot of the electrode currents as a function of $(r - a)/r_e$. Solid lines indicate anode, and dashed lines indicate the cathode for the cell numbers that are shown. a(left): For 10-cell battery. b(right): For 80-cell battery.

Fig. 8. Plot of normalized penetration depth of reversed current (r_{o-a}/r_e) vs. cell number for an 80-cell battery.

$$I_i = -J_p (\lambda - 1) / \lambda^{N+1-i}, i \approx N \quad [43]$$

Upon substitution of Eq. [42] and [43] into Eq. [38] and [39] with i_a and i_c set to zero, respectively, and r taken to be r_o , we obtain

$$\frac{r_{o,i} - a}{r_e} = -i \ln \lambda + \ln \left[\frac{J_p (\lambda - 1)}{I_a^*} \right], i \approx 1 \quad [44]$$

and

$$\frac{r_{o,i} - a}{r_e} = -(N + 1 - i) \ln \lambda + \ln \left[\frac{J_p (\lambda - 1)}{I_c^*} \right], i \approx N \quad [45]$$

which are straight lines with slopes $-\ln \lambda$ and $\ln \lambda$, respectively, and whose intercepts for $i = 1$ and $i = N$ differ by $\ln (\sigma_a/\sigma_c)$ (Fig. 8).

The total reversed current on an electrode, given by either Eq. [23] or [24], becomes, in this approximation, either

$$I_a(r_o) \approx I_a^* \frac{\sigma}{\sigma_c} \left[1 - \frac{I}{I_a^*} + \ln \left(\frac{I}{I_a^*} \right) \right], I \geq I_a^* \quad [46]$$

or

$$I_c(r_c) \approx I_c^* \frac{\sigma}{\sigma_a} \left[1 + \frac{I}{I_c^*} + \ln \left(\frac{-I}{I_c^*} \right) \right], I \leq -I_c^* \quad [47]$$

where for large N , Eq. [42] and [43] can be used to obtain I .

Variable parameters.—The assumption that the dimensional and physicochemical parameters remain uniform from cell to cell in the course of the Li/SOCl₂ battery discharge is not realistic. For example, the uniformity of the electrode spacing, δ^* , cannot be maintained because (i) for a fixed position of the bipolar plates the surface of the dissolving Li recedes and (ii) the reaction front penetrates into the expanding structure of the positive electrode (8). These processes proceed at rates that depend on the electrode currents in the cell; consequently, δ^* will vary from cell to cell as the battery discharges.

Of the various parameters, only R_i can be taken as remaining reasonably constant in the course of battery dis-

charge. Other parameters, such as R_z and R_f^* , certainly will change with time during the discharge depending on the amount of charge transferred; therefore, to solve Eq. [15] and [17] during discharge, we must assign to them a functional dependence on time. This assignment requires consideration of the elementary processes summarized in Fig. 1. Here, we shall consider changes in the conductivity of the electrolyte in the cell in the region near the cathode, κ_c , and in the conductivity of the electrolyte in the feed line, κ_f , and neglect changes in other parameters such as δ^* and U^* . The change in κ_c represents the precipitation of LiCl within the porous structure of the cathode, which occurs during the discharge of the cell and increases R_z , while the change in κ_f arises from the presence of undesired deposits in the feed line, e.g., due to electrode processes taking place at or near the entrance port due to reversed current, and can either increase or decrease R_f . In the Li/SOCl₂ battery, these deposits appear in the form of dendritic growth of metallic Li in the direction toward the fill tube at the negative end (Fig. 4a) and in the form of insoluble corrosion products at the positive end (Fig. 4c). In our calculations, we limit changes to those due to current reversal at the anode.

Linear functions of transferred charge will be assumed (see Appendix D). Specifically, for a small change in time, dt

$$d\kappa_c = - \frac{\kappa_c I_c}{T J_1(0)} dt \quad [48]$$

where $J_1(0)$ is the initial load current, T is the expected lifetime of the cell, and I_c is the cathode current at the time t , which is obtained from Eq. [5] by observing that $I_{a,i+1} = I_{c,i}$. Initially, $\kappa_c = w \kappa_{c0}$, where w is a computational factor introduced to account for cell deficiency arising from component variations. After an amount of charge $wT J_1(0)$ has been transferred, $\kappa_c = 0$ and a cell is considered to be fully discharged. Similarly

$$d\kappa_f = - (\kappa_d - \kappa) \frac{V_d I_a(r_o)}{F V_f} dt \quad [49]$$

where κ_d is the conductivity of the undesired deposit, V_d is the volume occupied by an equivalent weight of the deposit, $V_f = \pi(a^2 - r_f^2)d$ is the volume of the feed line, F is the Faraday constant, and $I_a(r_o) < 0$, is the total reversed current on the anode, Eq. [23]. Initially, $\kappa_f = \kappa_{f0}$; however, after an amount of charge $\epsilon_f V_f F / V_d$ has been transferred, the feed line is filled by the deposit and $\kappa_f = \kappa_d \epsilon_f$. Subsequent transferred charge was ignored.

Figures 9 and 10 show the computed time evolution of the circulating and intercell currents for a 40-cell battery. Specifically, Fig. 9 illustrates the time dependence when κ_d is large, i.e., when growing Li dendrites fill the feed path, while Fig. 10 examines their behavior for small κ_d , which is usually associated with the precipitation of corrosion products.

The time evolution of circulating and intercell currents for large κ_d is shown in Fig. 9a-9d. Because the cells are uniform initially, at the moment of activation of the battery, i.e., at $\tau = 0$, where $\tau \equiv t/T$, the current distributions are symmetric (Fig. 9a). However, with the passage of time, the symmetry is destroyed, giving rise to a rapid increase in the intercell current generated at the negative end of a battery at the expense of adjacent cells (Fig. 9b). At the same time, the circulating currents increase slightly at the negative end. It is noteworthy that the distribution at the positive end remains essentially unaffected. Toward the end of discharge, at $\tau = 1.0$, some of the cells in the central region become fully discharged. Under those conditions, the circulating currents become small and a reversal of the intercell current at the negative end of a battery occurs (Fig. 9c). Such a behavior is a result of the load current that is being supplied by the cells that are not fully discharged, bypassing the discharged cells of the central region through the fill tube. With further passage of time, at $\tau = 1.2$ (Fig. 9d), this situa-

Fig. 9. Time evolution of the circulating (left scale, light lines) and intercell (right scale, heavy lines) currents for a 40-cell battery that is uniform initially. $\kappa_d = 100$ S/cm. a: $\tau = 0$, $J_1 = 6.73$ A. b: $\tau = 0.15$, $J_1 = 6.70$ A. c: $\tau = 1.05$, $J_1 = 2.06$ A. d: $\tau = 1.2$, $J_1 = 0.042$ A.

tion develops fully and shows reversal of the intercell current in cells other than the end cells.

For small κ_d , as illustrated in Fig. 10a-10c, the effect is quite different. The symmetry in the distributions of the circulating and intercell currents is maintained throughout the period of the discharge, but with their values diminishing with time. Toward the end of discharge (Fig. 10b), the distributions of these currents change radically yet maintain their symmetry. The intercell current changes its direction at two additional points, A and B in Fig. 10b. With further increase in time, *i.e.*, at $\tau = 1.2$, the resulting intercell currents increase and substantially exceed their initial values (Fig. 10c).

Figures 11a-11c illustrate the computed time-dependent distribution of intercell and circulating currents when a few cells, namely, cells 29, 30, and 31, are assumed to be deficient with $w = 0.2$. It is seen that in the early period, *i.e.*, for $\tau = 0.15$, the distribution of the circulating current exhibits a depression (point A in Fig. 11b), as well as the asymmetry in the distribution of intercell and circulating currents caused by increasing κ_t . With further progress in time, we note a rapid change in the distributions of both currents. In particular, for $\tau = 0.35$ (Fig. 11c), the intercell current changes sign in the third cell, then becomes more negative with increasing cell number until,

at the 29th cell, it undergoes an abrupt change in sign and increases in magnitude in the 32nd cell, where it is equal to the magnitude of circulating current in the previous two segments of the fill tube. Calculations for other deficiency factors indicate similar evolution except for the time scale. Thus, for $w = 0.9$ the same development is not achieved until $\tau = 1.05$.

This large intercell current occurs in cells that are not yet fully discharged, so that according to Eq. [40], I_a^* can still be small. This situation can result in large reversed currents at the anodes of these cells. The hazard is compounded by large, heat producing circulating currents in the fill tube connecting nearby cells.

Implications of reversed electrode currents.—As indicated in Fig. 4a, in the case of current reversal the growth of dendritic lithium is observed at the negative end of the stack. Since the intercell currents are usually rather small, no serious problems are expected. However, on occasions when quality control is not maintained during production, there is a finite probability for the occurrence of large reversed currents and the subsequent development of internal shorts during the activation or the operation of a battery. Specific designs for reduction or elimination of such currents are generally considered proprietary information. One method of reducing intercell

Fig. 10. Time evolution of the circulating (left scale, light lines) and intercell (right scale, heavy lines) currents for a 40-cell battery that is uniform initially $\kappa_d = 10^{-6}$ S/cm. a: $\tau = 0$, $J_1 = 6.73$ A. b: $\tau = 1.05$, $J_1 = 2.15$ A. c: $\tau = 1.2$, $J_1 = 0.056$ A.

Fig. 11. Time evolution of the circulating (left scale, light lines) and intercell (right scale, heavy lines) currents for an 80-cell battery that initially has cells 29-31 deficient with $w = 0.2$. Other cells have $w = 1$. $\kappa_d = 100$ S/cm. a: $\tau = 0$, $J_1 = 6.70$ A. b: $\tau = 0.15$, $J_1 = 6.60$ A. c: $\tau = 0.3$, $J_1 = 0.73$ A.

currents is through the introduction of auxiliary electrodes (9). This method, however, might not be a general solution to the problems caused by internal currents in batteries employing static electrolyte since their magnitude and distribution vary with the operation of a battery especially toward the end of discharge and during over-discharge.

The methods for achieving control of intercell currents must rely on increasing the values of R_i and R_r for the system. In general, in order to eliminate the undesirable effects of intercell currents, R_i and R_r should be maximized.

Concluding Remarks

Intercell currents will always be generated in series connected electrochemical devices with a common electrolytic path. Generally, the major areas of concern are the effects of these currents on the power output and capacity of these devices. However, in Li power sources, the electrochemical processes that generate the intercell currents must be considered as well, because these processes result in the formation of undesirable byproducts if the intercell currents exceed their critical values. In particular, the undesirable reaction product is the dendritic growth of lithium. Beyond this, the electrochemical device can be inactivated by the production of passive films or excessive corrosion of component parts.

The calculations of the time evolution of the intercell and circulating current distributions, while based on a model of wide applicability, were limited in scope to two effects only. Here, we examined the effect of the increase in cell resistance due to the decrease in electrolyte conductivity near the cathode, and the effect of the change in feed-line resistance due to deposits near the cell inlet port. This method can be extended to cover in a realistic manner more complex situations by including additional discharge effects. One obvious limitation of this approach is that the cell parameters cannot be given a radial dependence.

APPENDIX A

Cell Discharge Characteristics with Intercell Current

Within a cell outside of the electric double layer, we assume that the potential, ϕ , and the c.d., j , obey Laplace's equation and Ohm's law. Selecting cylindrical coordinates, with the Z axis on the axis of circular symmetry, we can write these as, respectively

$$\frac{1}{r} \frac{\partial}{\partial r} \left[r\kappa(z) \frac{\partial \phi(r,z)}{\partial r} \right] + \frac{\partial}{\partial z} \left[\kappa(z) \frac{\partial \phi(r,z)}{\partial z} \right] = 0 \quad [A-1]$$

and

$$j_z = -\kappa(z) \frac{\partial \phi(r,z)}{\partial z} \quad [A-2]$$

$$j_r = -\kappa(z) \frac{\partial \phi(r,z)}{\partial r} \quad [A-3]$$

where, for simplicity, the conductivity, κ , is taken to have no radial dependence.

The problem can be made one dimensional by introducing the longitudinal averages

$$\overline{\kappa\phi(r)} = \frac{1}{\delta^*} \int_0^{\delta^*} \kappa(z)\phi(r,z) dz \quad [A-4]$$

and

$$\bar{j}_r = \frac{1}{\delta^*} \int_0^{\delta^*} j_r(r,z) dz \quad [A-5]$$

i.e., $\kappa\bar{\phi}$ and \bar{j}_r are functions of r only. Here, δ^* is an effective cell thickness, i.e., the distance between the electrode surfaces, not including the thicknesses of the electric double layers, which we shall assume to be negligibly thin. Upon integration with respect to z using Eq. [A-2] to replace the partial derivatives of ϕ with respect to z by the z component of the c.d. at the electrode-electrolyte interface, and introduction of Eq. [A-4], Eq. [A-1] becomes

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \kappa\bar{\phi}}{\partial r} \right) - \frac{1}{\delta^*} [i_c(r) - i_a(r)] = 0 \quad [A-6]$$

where $i_c(r) = j_z(r, \delta^*)$ and $i_a(r) = j_z(r, 0)$, are the cathodic and anodic c.d.'s, respectively, just outside of the double layer (dl).

To construct a solution to Eq. [A-6], it is necessary to express $i_c(r)$ and $i_a(r)$ in terms of $\kappa\bar{\phi}(r)$. This can be done only approximately with the aid of an idealized plot of the longitudinal distribution of $\phi(r,z)$, as illustrated in Fig. A-1. The potential difference between electrodes, $V = V_c - V_a$, can be expressed as

$$V = U - \eta_a(r) - \eta_c(r) - \int_0^{\delta^*} \frac{j_z(r,z)}{\kappa(z)} dz \quad [A-7]$$

in which $U = U_c - U_a$, where U_a and U_c are, respectively, the anode and cathode potentials in the absence of current flow, and $\eta_a(r)$ and $\eta_c(r)$ are their respective overpotentials.

Using Fig. A-1 and the trapezoidal rule to evaluate approximately the integrals in Eq. [A-4] and [A-7], we have

$$\overline{\kappa\phi(r)} = \frac{1}{2} \{ \kappa_c [V_c - U_c + \eta_c(r)] + \kappa_a [V_a - U_a - \eta_a(r)] \} \quad [A-8]$$

and

$$V = U - \eta_a(r) - \eta_c(r) - \frac{1}{2} \delta^* [i_c(r)/\kappa_c + i_a(r)/\kappa_a] \quad [A-9]$$

where κ_a and κ_c are conductances at $z = 0$ and $z = \delta^*$, i.e., at the anode and cathode surfaces just outside of the electric double layer, respectively.

Assuming linear current-potential relationships, $i_a = k_a \eta_a$ and $i_c = k_c \eta_c$, and using them to eliminate the overpotentials from Eq. [A-8] and [A-9], we get

$$\kappa_c i_c / k_c - \kappa_a i_a / k_a = 2(\overline{\kappa\phi} - C) \quad [A-10]$$

and

$$i_c / \sigma_c + i_a / \sigma_a = U - V \quad [A-11]$$

where the σ_ν ($\nu = a, c$) are given by Eq. [13a], and

Fig. A-1 Idealized plot of the distribution of the potential $\phi(r,z)$ for a particular value of r . Sign convention:

$$U_a = V_a - \phi_1, U_c = V_c - \phi_4; \\ \eta_a = \phi_1 - \phi_2, \eta_c = \phi_3 - \phi_4;$$

$$\int_0^{\delta^*} \frac{j_z}{\kappa} dz = \phi_2 - \phi_3.$$

$$C = \frac{1}{2} [\kappa_c(V_c - U_c) + \kappa_a(V_a - U_a)] \quad [\text{A-12}]$$

Equations [A-10] and [A-11] can be solved simultaneously for i_a and i_c , and their difference then used to reformulate Eq. [A-1]. Thus

$$i_a = \chi [\kappa_c(U - V)/k_c - 2(\overline{\kappa\phi} - C)/\sigma_c] \quad [\text{A-13a}]$$

and

$$i_c = \chi [\kappa_a(U - V)/k_a + 2(\overline{\kappa\phi} - C)/\sigma_a] \quad [\text{A-13b}]$$

where

$$1/\chi = \kappa_a/(k_a\sigma_c) + \kappa_c/(k_c\sigma_a) \quad [\text{A-14}]$$

After some algebraic manipulations, we obtain

$$(i_c - i_a)/\delta^* = (\overline{\kappa\phi} - \kappa\phi_0)/r_e^2 \quad [\text{A-15}]$$

where r_e is given by Eq. [12] and

$$\overline{\kappa\phi_0} = \frac{1}{2} (\kappa_a + \kappa_c) \overline{\phi_0} \quad [\text{A-16}]$$

in which $\overline{\phi_0}$ is given by Eq. [9]. Substitution of Eq. [A-15] into [A-6] yields

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \overline{\kappa\phi}}{\partial r} \right) - \frac{(\overline{\kappa\phi} - \kappa\phi_0)}{r_e^2} = 0 \quad [\text{A-17}]$$

Boundary conditions are obtained from the requirements that the radial current at the entrance port, where $r = a$, will be the intercell current, I , and at the outer radius, where $r = b$, it will be zero. Using Eq. [A-3] and [A-5], we find

$$\left. \frac{\partial \overline{\kappa\phi}}{\partial r} \right|_{r=a} = - \frac{I}{2\pi a \delta^*} \quad [\text{A-18a}]$$

and

$$\left. \frac{\partial \overline{\kappa\phi}}{\partial r} \right|_{r=b} = 0 \quad [\text{A-18b}]$$

Here, we have neglected the intercell current entering the cell within the electric double layer.

The solution to Eq. [A-17] is of the form

$$\overline{\kappa\phi} - \kappa\phi_0 = A K_0(r/r_e) + B I_0(r/r_e) \quad [\text{A-19}]$$

where A and B are coefficients to be determined from the boundary conditions, Eq. [A-18]. After some manipulations, we obtain Eq. [22], where the definitions

$$\overline{\kappa\phi} = \frac{1}{2} (\kappa_a + \kappa_c) \overline{\phi_0} \quad [\text{A-20}]$$

and Eq. [A-16] have been applied.

By using Eq. [A-15], Eq. [A-13] can be rewritten as Eq. [20] and [21], respectively. By integrating Eq. [20] over the area of the anode, the total anodic current can be found. The result, from which Eq. [8] is derived by rearrangement, is obtained by setting $r_o = b$ in Eq. [23].

APPENDIX B

Evaluation of the Term $\overline{\phi_{i+1}} - \overline{\phi_i}$ in Eq. [2]

Let $U = U_c - U_a$ be the cell potential in the absence of current flow, then from the definition: $V = V_c - V_a$

$$U - V = U_c - V_c - U_a + V_a \quad [\text{B-1}]$$

Using Eq. [B-1], either of the terms $V_c - U_c$ or $V_a - U_a$ can be eliminated from Eq. [9]. Thus, either

$$\overline{\phi_0} = V_a - U_a - (U - V)\sigma/\sigma_a \quad [\text{B-2}]$$

or

$$\overline{\phi_0} = V_c - U_c + (U - V)\sigma/\sigma_c \quad [\text{B-3}]$$

Expressing $\overline{\phi_{o,i+1}}$ and $\overline{\phi_{o,i}}$ by means of Eq. [B-2] and [B-3], respectively, and using Eq. [6], we get

$$\begin{aligned} \overline{\phi_{o,i+1}} - \overline{\phi_{o,i}} &= U_{c,i} - U_{a,i+1} - (U_{i+1} - V_{i+1}) \sigma_{i+1}/\sigma_{a,i+1} \\ &\quad - (U_i - V_i) \sigma_i/\sigma_{c,i} \end{aligned} \quad [\text{B-4}]$$

The term: $\overline{\phi_{i+1}} - \overline{\phi_i}$ in Eq. [2] can be evaluated with the aid of Eq. [7]; thus

$$\overline{\phi_{i+1}} - \overline{\phi_i} = \overline{\phi_{o,i+1}} - \overline{\phi_{o,i}} + I_{i+1}R_{p,i+1} - I_iR_{p,i} \quad [\text{B-5}]$$

Using relationships, Eq. [4], [B-4], and [14], Eq. [B-5] can be expressed in terms of circulating currents, J_i and J_i . The result is

$$\begin{aligned} \overline{\phi_{i+1}} - \overline{\phi_i} &= U_i^* - J_i R_{z,i}^* + J_{i-1} R_{p,i}^* \\ &\quad - J_i (R_{p,i}^* + R_{p,i+1}^* + R_{z,i}^*) + J_{i+1} R_{p,i+1}^* \end{aligned} \quad [\text{B-6}]$$

where

$$R_{p,i}^* = R_p - R_z \sigma^2 / (\sigma_a \sigma_c) \quad [\text{B-7}]$$

and R_z^* and U_i^* are defined in Eq. [16] and [19], respectively. Substitution of Eq. [B-6] into Eq. [2] yields Eq. [17].

APPENDIX C

Solution of Eq. [26] and [27]

by the Method of Undetermined Coefficients

Equation [27] has a solution, in terms of J_i , that can be written as a sum of a particular solution of the non-homogeneous equation, $J_{p,i}$, and a general solution of the homogeneous equation, $J_{h,i}$

$$J_i = J_{p,i} + J_{h,i} \quad [\text{C-1}]$$

A suitable particular solution to Eq. [27] is the constant

$$J_p = (U - R_z J_i) / (R_z + R_i) \quad [\text{C-2}]$$

For the homogeneous equation, we seek a solution in the form

$$J_{h,i} = A \lambda^i + B \lambda^{-i} \quad [\text{C-3}]$$

where A and B are coefficients satisfying Eq. [3] and λ is either root of the characteristic equation

$$\lambda^2 - [2 + (R_i + R_z)/R_i^*] \lambda + 1 = 0 \quad [\text{C-4}]$$

one of which is given by Eq. [32].

Applying Eq. [3], we have

$$J_p + A + B = 0 \quad [\text{C-5a}]$$

$$J_p + A \lambda^N + B \lambda^{-N} = 0 \quad [\text{C-5b}]$$

Solving Eq. [C-5] for A and B and substituting into Eq. [C-3], we get Eq. [29], where J_p is given by Eq. [C-2].

To obtain J_i , we return to Eq. [26] and evaluate the sum appearing there by the use of Eq. [29] and the results for the sum of a geometric series. Thus, with

$$\sum_{i=0}^N J_i = J_p N \xi (R_z + R_i) / R_z \quad [\text{C-6}]$$

where ξ is given by Eq. [33], we find Eq. [28], which, in turn, produces Eq. [31] upon substitution into Eq. [C-2].

APPENDIX D

Derivation of Eq. [48] and [49]

A number of the parameters we use depend on the depth of discharge. For simplicity, we have chosen to let only two of them vary with time. These two were chosen because their variation introduces many of the effects observed in Li/SOC₂ batteries upon discharge.

We assume that the electrolyte conductivity near the cathode decreases linearly with charge transferred to the cathode and that after charge Q_c has been transferred κ_c will be essentially zero and the useful life of the cell expended. Initially, the conductivity near the cathode is given by

$$\kappa_c(0) = w \kappa_{\epsilon_z} \quad [\text{D-1}]$$

where w is a factor that is introduced to account for the possibility that a particular cell might not have the designed lifetime. The expected lifetime, T , is defined by the relationship

$$Q_c = w T J_i(0) \quad [\text{D-2}]$$

where $J_i(0)$ is the initial load current. Therefore

$$\frac{d\kappa_c}{dQ_c} = - \frac{\kappa_c(0)}{Q_c} = - \frac{\kappa_{\epsilon_z}}{T J_i(0)} \quad [\text{D-3}]$$

Setting $dQ_c = I_c dt$, where I_c is the total cathode current, we have Eq. [48].

Similarly, we assume that the electrolyte conductivity in the feed line, κ_f , changes linearly between the initial value

$$\kappa_f(0) = \kappa \epsilon_f \quad [D-4]$$

and the final value

$$\kappa_f = \kappa_d \epsilon_f \quad [D-5]$$

with the charge, Q_f , transferred to the anode under reversed current conditions. The total charge that can be transferred before the feed-line volume, V_f , is fully occupied by deposit is

$$Q_f = \epsilon_f V_f F / V_d \quad [D-6]$$

where V_d is the volume occupied by an equivalent weight of the deposit and F is the Faraday constant. Therefore

$$\frac{d\kappa_f}{dQ_f} = - \frac{(\kappa_d - \kappa) \epsilon_f}{Q_f} = - \frac{(\kappa_d - \kappa) V_d}{V_f F} \quad [D-7]$$

Setting $dQ_f = I_a(r_o) dt$, where $I_a(r_o)$ is the total reversed anode current, we have Eq. [49].

Rechargeable Lithium/Chromium Oxide Cells

Y. Takeda, R. Kanno, Y. Tsuji, and O. Yamamoto*

Department of Chemistry, Faculty of Engineering, Mie University, Tsu, 514, Japan

ABSTRACT

The charge and discharge behaviors of organic electrolyte lithium cells with chromium oxides, Cr_2O_5 , Cr_3O_8 , and amorphous chromium oxide ($\alpha\text{-Cr}_3\text{O}_8$) as the cathodes have been examined, where $\alpha\text{-Cr}_3\text{O}_8$ was obtained by heat-treating the mixture of Cr_3O_8 and water. The lithium cells with these chromium oxides gave satisfactory discharge performances in term of energy density. The cycling characteristics of the cells have been examined for various ranges of charge transferred in the chromium oxide electrode, such as 0.1-0.3, 0.4-0.6, and 0.7-0.9 e^-/Cr . The $\text{Li}/\text{Cr}_3\text{O}_8$ cells showed a poor cycling performance for the whole range of charge transferred. The rechargeability of the $\text{Li}/\text{Cr}_3\text{O}_8$ cells was good, in the range 0.4-0.6 and 0.7-0.9 e^-/Cr , but poor in the range 0.1-0.3 e^-/Cr . The $\text{Li}/\alpha\text{-Cr}_3\text{O}_8$ cells worked well as a rechargeable cell for the whole range of charge transferred.

A wide variety of metal oxides and chalcogenides with two-dimensional layer structures or three-dimensional framework tunnel structures has been studied as the cathode material for secondary organic electrolyte lithium batteries (1-2). Most previous works have focused on two-dimensional metal chalcogenides such as TiS_2 , although metal oxides with framework structure such as V_6O_{13} (3), Cr_3O_8 (4), and a number of MO_2 oxides with the rutile structure (3) have demonstrated reversible lithium incorporation. Of these cathode materials, Cr_3O_8 has been reported to have the highest energy density and the highest cell voltage. The calculated theoretical energy density of the couple $\text{Li}/\text{Cr}_3\text{O}_8$ is 1210 Wh/kg based on experimental utilizations of Cr_3O_8 , a value which is about two times higher than that of the Li/TiS_2 couple (5). The open-circuit voltage and the averaged discharge voltage at a current drain of 0.5 mA/cm² for the $\text{Li}/\text{Cr}_3\text{O}_8$ couple were 3.8V and approximately 3.0V, respectively. The cell voltage is comparable to that of commercially available primary lithium batteries with manganese dioxide or carbon fluoride cathodes. However, it has been reported that the energy density of Cr_3O_8 drops to around 500 Wh/kg at 1 mA/cm² after 20 cycles (1). In this study, the cyclic behaviors of lithium cells with Cr_2O_5 and Cr_3O_8 chromium oxides were examined in detail. In addition, an amorphous phase of chromium oxide, obtained by the heat-treatment of Cr_3O_8 and water, was examined as a cathode material for secondary lithium batteries.

Experimental

The chromium oxides were prepared from CrO_3 according to the phase diagrams of Kubota (7) and Wilhelmi (8). Cr_2O_5 and Cr_3O_8 were obtained by heating CrO_3 for 24h at 340° and 270°C, respectively, in an autoclave. The x-ray diffraction patterns of the reaction products were in good agreement with those reported previously (8, 9). Amorphous chromium oxides were prepared by heating a mixture of Cr_3O_8 and water. The mixture of 0.7g Cr_3O_8 and 30 ml water was well mixed and heated for 24h at a temperature of 110°-300°C. The chromium-oxygen stoichiometry was determined by reducing the sample to Cr_2O_3 using TGA (Rigaku Denki TG4) in open air.

The cells used for electrochemical tests were constructed in a cylindrical configuration. The anode was a disk of lithium foil of 15 mm diam. The separator was a microporous polypropylene sheet. The cathode consisted of a mixture of 0.1g chromium oxide, 0.15g graphite, and 0.04g Teflon powder, which was pressed into a tablet of 13 mm diam under a pressure of about 9 MPa. The cathode thickness was around 0.6 mm. In order to see the characteristics of the rechargeable miniature cells, coin-type cells were also made, which had an external diameter of 12.5 mm and an external thickness of 2.5 mm. The cathode was a mixture of 0.085g chromium oxides, 0.01g acetylene black, and 0.01g Teflon powder, which was pressed into a tablet of 7.5 mm diam. The current density was based on the cross section of the cathode tablet. The

electrolyte was 1M LiClO_4 in 1:1 propylene carbonate-1,2 dimethoxy ethane by weight. The organic solvents were dried (10, 11). Lithium perchlorate (Nakarai Chemicals extra-pure reagent) was dried for 2h at 120°C and then for 5h at 200°C *in vacuo*.

All the electrochemical measurements were carried out after at least one overnight stand under zero current flow. The x-ray patterns were obtained using a Rigaku Denki diffractometer with $\text{CuK}\alpha$ radiation. X-ray photoelectron spectroscopy (XPS) spectra were measured ($\text{Cr } 2\text{P}_{3/2}$) with a Shimadzu ESCA 750 spectrometer. Spectra of Au were used as a standard for the chemical shift.

Results and Discussion

Table I shows the chromium-oxygen stoichiometry and the results of x-ray diffraction analysis for samples of CrO_x , which were obtained by heat-treating mixtures of Cr_3O_8 and water at various temperatures. The oxygen content in the samples decreases with increasing the heat-treatment temperature. The samples heated at 200°C were very hygroscopic and had about 3% free water, the exact amount of which depended on the period of exposure to atmosphere. Samples heated over 250°C had no free water and were not hygroscopic. The x-ray diffraction data indicate that Cr_3O_8 -water mixtures transfer to an amorphous phase ($\alpha\text{-Cr}_3\text{O}_8$) by heating. It could be that Cr_3O_8 particles absorbed water and are crashed to very small particles when water is driven out by heating. The mixture of Cr_2O_5 and water showed no remarkable change in the chromium-oxygen stoichiometry or x-ray diffraction patterns by heat-treating below 270°C.

The XPS spectra of $\alpha\text{-Cr}_3\text{O}_8$ obtained by heating at 250°C are shown along with those of various chromium oxides in Fig. 1. Cr_5O_{12} and CrO_2 were prepared by the method reported previously (6). By a computer fitting method, the spectra of the higher oxidation state chromium oxides, $\alpha\text{-Cr}_3\text{O}_8$, Cr_3O_8 , Cr_2O_5 , and Cr_5O_{12} can be resolved into two peaks, near 576.4 and 579.0 eV, which correspond to the values of chemical shifts of $\text{Cr}^{3+}2\text{P}_{3/2}$ in Cr_2O_3 (576.5 eV) and $\text{Cr}^{6+}2\text{P}_{3/2}$ in CaCrO_4 (578.8 eV), respectively. The intensity ratio of the Cr^{3+} to Cr^{6+} spectra was fitted to the calculated value from the ratio of Cr/O obtained by TGA. The $\text{Cr}^{3+}/\text{Cr}^{6+}$ ratio in Cr_3O_8 , 1:2.7, is also in agreement with that obtained from magnetic measurements, 1:3 (12). That is, Cr_3O_8 , $\alpha\text{-Cr}_3\text{O}_8$, Cr_2O_5 , and Cr_5O_{12}

Table I. Characteristics of Cr_3O_8 with water heat-treated at various temperatures

Heating temp (°C)	x in CrO_x	Observed phase	Energy density* (Wh/kg)
Crude Cr_3O_8	2.64	Cr_3O_8	1020
200	2.63	amorphous	760
250	2.55	amorphous	1130
270	2.55	amorphous	1170
300	2.41	amorphous	500

* Based on a 2.0V cutoff at 500 $\mu\text{A}/\text{cm}^2$.

Fig. 1. XPS spectra of Cr $2P_{3/2}$ region for various chromium oxides

are presented as the mixture of Cr^{6+} and Cr^{3+} oxidation state. White and Roy also reported that chromium in Cr_3O_8 , Cr_2O_5 , and Cr_5O_{12} exhibits two valences of III and VI (13).

Figure 2 shows the open-circuit voltage (OCV) as a function of charge transferred in Cr_3O_8 , $a-Cr_3O_8$, and Cr_2O_5 at room temperature, where $a-Cr_3O_8$ was prepared by heating at $250^\circ C$. A constant current of 0.5 mA/cm^2 was passed through the cell for some period, and the cell voltages on open circuit were considered as the quasi-OCV when the deviations at the measured cell voltage was within 10 mV for 1h. The OCV curve for the cell $Li/a-Cr_3O_8$ is similar to that for the cell Li/Cr_3O_8 . The OCV's of

Fig. 2. OCV vs. charge transferred (e^-/Cr) curves for the cells with Cr_3O_8 (\circ), $a-Cr_3O_8$ (\bullet), and Cr_2O_5 (Δ).

Fig. 3. Constant current ($500\ \mu A/cm^2$) discharge curves for the cells with Cr_3O_8 (\square), $a-Cr_3O_8$ heated at $200^\circ C$ (\circ), $250^\circ C$ (\bullet), $270^\circ C$ (Δ), and $300^\circ C$ (\blacktriangle).

both the cells decrease gradually with increasing x at least up to $x = 1.4$. In the case of the Li/Cr_2O_5 couple, the OCV curve shows a voltage plateau at 3.1V from $x =$

Fig. 4. Cycling behavior of the cells with Cr_3O_8 , $a-Cr_3O_8$, and Cr_2O_5

0.2-0.9. The x-ray diffraction patterns of the electrochemical reaction products $\text{Li}_{3-x}\text{Cr}_3\text{O}_8$, $\text{Li}_{2-x}\text{Cr}_2\text{O}_5$, and $\text{a-Li}_{3-x}\text{Cr}_3\text{O}_8$ have been examined. $\text{Li}_{3-x}\text{Cr}_3\text{O}_8$ ($0 \leq x \leq 1.0$) and $\text{Li}_{2-x}\text{Cr}_2\text{O}_5$ ($0 \leq x \leq 1.0$) showed only broad diffraction lines, and no change of the d values was observed. No diffraction lines due to lower oxidation chromium oxides and no ternary compound such as LiCr_3O_8 (14) was observed. In the case of $\text{a-Li}_{3-x}\text{Cr}_3\text{O}_8$, no diffraction line was observed in the range of 2θ of 10° - 80° . These results suggest that the crystals of chromium oxides become too small of particles during Li^+ insertion and reaction products appear amorphous. The cracking of the crystal lattice during electrochemical Li^+ insertion has been observed in the $\text{Li}/\text{single-crystal MoO}_3$ cell (15). The different shape of the OCV vs. e^-/Cr curves indicates there is a difference in the electrode reactions between the $\text{Li}/\text{Cr}_3\text{O}_8$ or $\text{Li}/\text{a-Cr}_3\text{O}_8$ couple and the $\text{Li}/\text{Cr}_2\text{O}_5$ couple.

Constant current (0.5 mA/cm²) discharge curves obtained at room temperature for cells with $\text{a-Cr}_3\text{O}_8$ prepared at various temperatures are shown in Fig. 3. The discharge performance of $\text{a-Cr}_3\text{O}_8$ is affected by the preparation temperature. The energy density, calculated from the discharge curves, based on the weight of the chromium oxides and to a 2.0V cutoff are shown also in Table I. The highest energy density, 1170 Wh/kg, was obtained for the cell with $\text{a-Cr}_3\text{O}_8$ treated at 270°C . This value is

slightly higher than that for the cell with the nontreated Cr_3O_8 . The dynamic discharge curve for the cell with $\text{a-Cr}_3\text{O}_8$ treated at 250°C is similar to the OCV curve shown in Fig. 1. The significantly lower energy density for the cell with $\text{a-Cr}_3\text{O}_8$ treated at 300°C may be due to the low oxidation state of Cr, 4.8, in the $\text{a-Cr}_3\text{O}_8$. In our previous paper, we reported that the energy density of cells with lower oxidation state chromium oxides such as Cr_3O_{12} , CrO_2 , and Cr_2O_3 , the average oxidation number of which is less than five, are considerably lower than those of cells with Cr_3O_8 and Cr_2O_5 .

In Fig. 4, the charge-discharge curves for the cells with Cr_3O_8 , Cr_2O_5 , and $\text{a-Cr}_3\text{O}_8$ heat-treated at 250°C are shown. The discharge and charge current densities are 0.5 and 0.25 mA/cm², respectively. For the cells with Cr_3O_8 and $\text{a-Cr}_3\text{O}_8$, the first cycle discharge and charge curves closely resemble the fifth cycle in overall shape. The charge curve for the cell with Cr_3O_8 shows a flat region in the final stage of the charging, where the decomposition of electrolyte may be occurring.

In the case of Cr_2O_5 , the second cycle discharge capacity reduces to about 65% of the initial cycle. During the second charge cycle, the cell voltage increases extremely rapidly with charging time.

In order to help understand the detail of the charge-discharge process for the chromium oxide cathode cells,

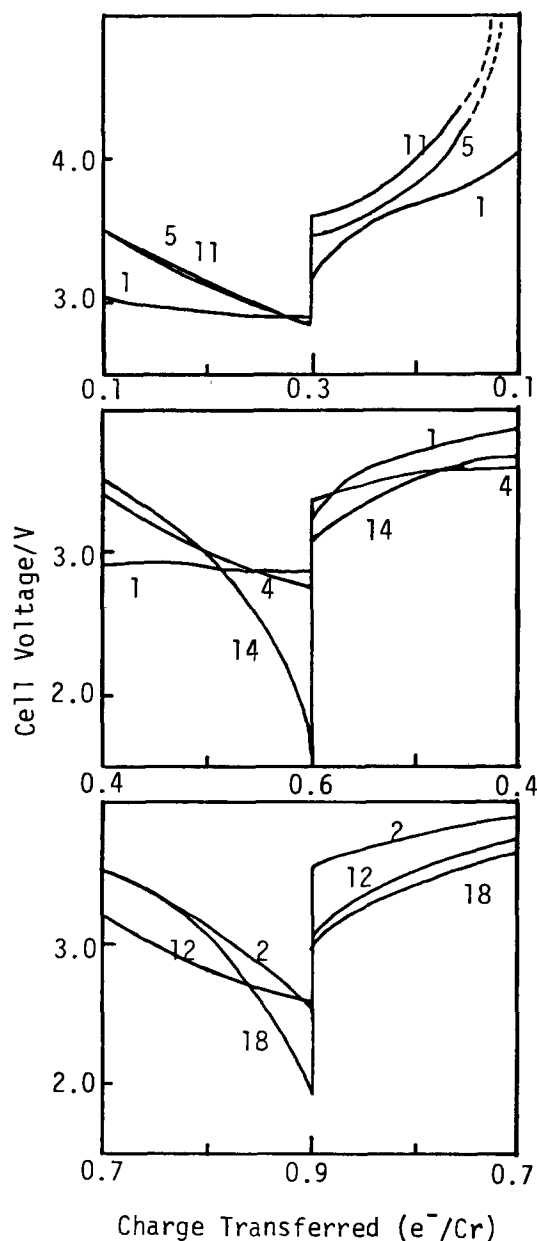

Fig. 5. Cycling behavior of the $\text{Li}/\text{Cr}_2\text{O}_5$ cells

Fig. 6. Cycling behavior of the $\text{Li}/\text{Cr}_3\text{O}_8$ cells

cycling curves were examined for various charge transferred ranges in the chromium oxide electrode, such as 0.1-0.3, 0.4-0.6 and 0.7-0.9 e^-/Cr ratio. Charge and discharge current densities were $0.5 \text{ mA}/\text{cm}^2$. Figure 5 shows the cycle data for cells with Cr_2O_3 . In the charge transferred range of 0.1-0.3 e^-/Cr , the charging efficiency falls to 80% after five cycles, where charging efficiency was calculated to 4.5V cutoff. However, the discharging efficiency decreases in the ranges of 0.4-0.6 and 0.7-0.9 e^-/Cr ratio after several more than ten cycles.

The cells with Cr_3O_8 show good rechargeability in the deep charge transferred region as shown in Fig. 6. In the e^-/Cr range of 0.7-0.9, the 200th charge and discharge profiles show no significant degradation compared to the first ones, whereas, in the range of 0.1-0.3 e^-/Cr , the charging efficiency rapidly falls with cycling. In Fig. 7, the charge-discharge behavior of cells with $\alpha\text{-Cr}_3\text{O}_8$ are shown. These cells have good cycling performance. Even in the e^-/Cr range of 0.1-0.3, no remarkable change is found after 50 cycles. Charging voltages are less than 4.0V, except for the first few cycles. The good rechargeability of cells with $\alpha\text{-Cr}_3\text{O}_8$ may be due to the large effective surface area of $\alpha\text{-Cr}_3\text{O}_8$ because the charge and discharge profiles depended on the current density. The cells with Cr_3O_8 predischarged to 1.0 e^-/Cr ratio showed good rechargeability in the range of 0.1-0.3 e^-/Cr . Their good performance may be due to the transformation of Cr_3O_8 to the amorphous phase by predischARGE, which was

Fig. 7. Cycling behavior of the $\text{Li}/\alpha\text{-Cr}_3\text{O}_8$ cells

Fig. 8. Cycling behavior of the coin-type $\text{Li}/\alpha\text{-Cr}_3\text{O}_8$ cell

confirmed by x-ray analysis. Although Cr_2O_3 also becomes amorphous on discharge, cells with Cr_2O_3 predischarged to a 1.0 e^-/Cr showed poor rechargeability. The difference in rechargeability between Cr_2O_3 and Cr_3O_8 may be explained by the structural difference in the two amorphous phases " Li_xCrO_y " formed by the discharging process of the two oxides.

Figure 8 shows the discharge curves of the coin-type cells with $\alpha\text{-Cr}_3\text{O}_8$ heat-treated at 250°C . The charge and discharge currents were $220 \mu\text{A}$, and the depth of discharge was 0.8%. As can be seen, no significant change in the charge-discharge curves is observed during 950 cycles. This type of rechargeable miniature cell could be used in electronic devices, such as an electronic wrist watch, in combination with a solar cell. Since the current consumption of the latest standard watch is $2\text{-}3 \mu\text{A}$, the $200 \mu\text{Ah}$ discharge will be equivalent to 3-4 days of discharge.

From the above experimental results, the high oxidation chromium oxides, especially amorphous chromium oxide formed from Cr_3O_8 , is considered to be a promising cathode materials for organic electrolyte lithium cells with high energy density and good rechargeability.

ABSTRACT

The ac impedance measurement has proved to be a useful electrochemical technique for mainly qualitative studies of electrochemical and corrosion systems. Even for complicated systems such as coated metals in corrosive environments this technique has been used with success. The system chosen for the present study is an ARMCO iron plate, coated with a SrCrO₄-pigmented styrene acrylic polymer, and immersed for several weeks in an aqueous NaCl solution. Impedance measurements analyze a system under test into its constituting phenomena. The dependence of system parameters on coating layer thickness, NaCl concentration, and pigmentation of the coating during the immersion time provides insight into the corrosion and protection mechanisms at the coating/metal interface, besides the behavior of the coating itself.

In the last years, the study of corrosion prevention by organic coatings has shown a remarkable development. For the manufacturer as well as for the user, it is indeed of great interest to know the protection mechanism and the anticorrosive properties of the coating.

Therefore, it is not sufficient to gather information about the physical properties of the coating, *e.g.*, its thickness, its porosity, its dielectric constant, etc.; one must also consider the electrochemical interaction between the corrosive medium and the metal, whether affected by the coating or not.

The impedance measurement is a well-known electrochemical technique used to monitor the corrosion of metals and to investigate its mechanisms (1-7).

Coated metals have also been investigated with the impedance technique (2, 8-31). The purpose of this work is to show that the behavior of the sample is reflected quite well by the ac impedance characteristic, when some system parameters are varied.

Experimental

The metal used in this investigation is Armco iron; before coating application, the iron plate is polished with 600 grit paper, cleaned ultrasonically, and degreased with ethanol.

A water-base emulsion coating is chosen, which consists of Ercusol AS250 (a styrene acrylic polymer) and red iron oxide and strontium chromate pigments. The coated samples are mounted in a three-electrode cell, depicted elsewhere (15, 18).

The coated metal is covered with Scotchrap corrosion protection tape to delimit a circular surface with an apparent area of 28.3 cm². A glass cylinder is then cemented

to the protection tape with silicone sealant to form a cell and is filled with an aqueous sodium chloride solution.

The cell is open to the air. The counterelectrode is a platinum grid, and the reference electrode is an SCE.

Coating layer thickness, NaCl concentration, presence of chromate pigment in the coating, and immersion time are the investigated parameters of which samples 1 to 4 are representative (see Table I).

The impedance is always measured at the corrosion potential, using a Schlumberger Solartron 1170 frequency response analyzer, connected to a Tacussel Pit 20-2X potentiostat. The analyzer is controlled by a Tektronix 4051 desktop computer to perform automatic measurements and data transmission. The frequency ranges between 10 kHz and 10 mHz.

The amplitude of the superimposed sinusoidal voltage is 20 mV. The results are plotted in the complex plane. The corrosion potential of the samples is also measured as a function of time.

Results

Figure 1 gives the variation of the impedance curve of sample 1 as a function of immersion time; Fig. 2 is a detail.

A few hours after immersion, only two arcs are observed in the complex plane presentation of the imped-

Fig. 2. Expanded plot of Fig. 1

ance data; for longer immersion times (days), the curve is completed with a third one. For instance, the impedance characteristics of sample 1 after 10, 16, and 28 days, respectively, are shown in Fig. 1 (complete plot) and 2 (expanded plot). After 10 days, a first arc is found at frequencies higher than 1 kHz (high frequencies or HF), a second one between 1 kHz and 50 mHz (intermediate frequencies or IF), and a third one under 50 mHz (low frequencies or LF). Table II sites the different arcs in the chosen frequency range for all the curves and samples, and mentions the corresponding field of the real impedance part (R). The area of the HF arc of sample 1 decreases gradually as a function of time. The area of the IF arc however increases during the first three days, then decreases continuously and finally disappears completely; it is this arc which in the beginning takes the biggest portion of the total impedance curve. Afterward, the LF arc becomes relatively more important.

The results for sample 2 lead to similar observations. However, the impedance values, especially those of the HF arc, are much higher than in the former case, and the general decrease occurs slower than for sample 1 (see Fig. 3 and 4). The successive increase and decrease of the IF arc is also much more pronounced (see also Table II).

In the case of sample 3 (Fig. 5 and 6), a linear shape of the IF part is noticed. It is quite clear that here the HF impedances are much higher than for sample 1. The LF arc also gains relative to the IF arc during immersion.

Sample 4 exhibits completely modified impedance curves (Fig. 7). After 28 days' immersion, the real impedance value at 10 mHz still reaches more than $6 \cdot 10^7 \Omega \text{ cm}^2$, indicating a far greater impedance scale than for the other samples. The figure shows also the usual decrease of the impedance values during immersion.

Figure 8 illustrates the corrosion potential dependence on immersion time for three samples. The open-circuit potential of sample 1 falls relatively fast at the beginning of the immersion, then moves to a first and a second plateau.

Sample 2 shows a much slower potential decay. The potential of sample 3 remains constant, at about -120 mV/SCE . The potential/time dependence of sample 4 is not represented in Fig. 8, because it is rather unstable.

For samples 1 and 2, after some 10 days' immersion, blistering of the coating surface is observed, with no visible perforation onto the metal surface. The growth of the blisters must have progressed gradually, only gradual no sudden changes in the other observations, such as the im-

Table II. *f* and *R* ranges of the different arcs in the impedance curves of Fig. 1-6.*f* = frequency and *R* = real impedance value ($\Omega \cdot \text{cm}^2$)

	10 days (+)	Sample 1 (Fig. 1 and 2) 16 days (x)	28 days (o)
arc 1 HF	$f > 1 \text{ kHz}$ $R < 3.1 \times 10^4$	$f > 1.5 \text{ kHz}$ $R < 2.3 \times 10^4$	$f > 600 \text{ Hz}$ $R < 1.6 \times 10^4$
arc 2 IF	$1 \text{ kHz} > f > 50 \text{ mHz}$ $3.1 \times 10^4 < R < 5.2 \times 10^5$	$1.5 \text{ kHz} > f > 500 \text{ mHz}$ $2.3 \times 10^4 < R < 1 \times 10^6$	$600 \text{ Hz} > f > 10 \text{ Hz}$ $1.6 \times 10^4 < R < 2.2 \times 10^4$

arc 2 IF	$20 \text{ Hz} > f > 200 \text{ mHz}$ $5.9 \times 10^5 < R < 8.7 \times 10^5$	$60 \text{ Hz} > f > 25 \text{ mHz}$ $2.6 \times 10^5 < R < 1.4 \times 10^6$	$300 \text{ Hz} > f > 200 \text{ mHz}$ $6.6 \times 10^4 < R < 1.9 \times 10^5$
arc 3 LF	$f < 200 \text{ mHz}$ $R > 8.7 \times 10^5$	$f < 25 \text{ mHz}$ $R > 1.4 \times 10^6$	$f < 200 \text{ mHz}$ $R > 1.9 \times 10^5$
	3 days (+)	Sample 3 (Fig. 5 and 6) 70 days (x)	
arc 1 HF	$f > 50 \text{ Hz}$ $R < 3.8 \times 10^5$	$f > 150 \text{ Hz}$ $R < 8 \times 10^4$	
arc 2 IF	$f < 50 \text{ Hz}$ $R > 3.8 \times 10^5$	$150 \text{ Hz} > f > 30 \text{ mHz}$ $8 \times 10^4 < R < 5.3 \times 10^5$	
arc 3 LF	—	$f < 30 \text{ mHz}$ $R > 5.3 \times 10^5$	

pedance, were noticed; the solution of the cell gets yellow colored by diffusion of chromates from the coating.

Sample 3 shows neither of the two phenomena, and sample 4 shows blistering, but there is no yellow coloring of the solution because there are no chromates in the coating.

Discussion

Compared to what can be found in the case of uncoated iron, the coated samples presented here exhibit extremely high impedances, *e.g.*, sample 4 shows a real impedance part of almost $2.5 \times 10^8 \Omega \text{ cm}^2$ at 10 mHz after 1 day immersion, most likely because only a very small fraction of the apparent surface area is active. As time goes on, the impedances are reduced, mainly because the density of pores perforating the coating is growing and consequently raising the active fraction of the total electrode area. The reduction of the impedances in the case of sample 2 is slower than for sample 1 because the perforation of a thicker coating takes more time.

Our measurements confirm the generally accepted matter (9, 13, 14) that the HF arc in the impedance curve corresponds with the impedance of the coating layer itself, and that at lower frequencies the latter impedance is augmented with the impedance resulting from the faradaic processes, connected with the metallic corrosion.

Thus, increasing the thickness of the coating should cause a wider HF arc, as the ionic resistance of the coating is increased. This is indeed what could be found by comparing the results of sample 1 and sample 2.

For samples 1, 2, and 3, the impedance part, reflecting the faradaic processes, appears to increase in the beginning of the immersion, and to decrease subsequently, suggesting that after immersion some active sites are passivated by a particular process, and that they are depassivated again by another process after longer immersion.

The growing importance of the LF arc relative to the HF arc can be explained by an expansion of the active sites under the coating, as indeed this accelerates the overall corrosion and makes the mass transport of active components through the coating increasingly rate controlling.

As to the impedance of the coating, obviously the NaCl concentration in the bulk solution has a marked effect on the coating behavior: a lower NaCl concentration in the cell of sample 3 causes a higher ionic resistance of the coating, and a larger HF arc. The lack of yellow coloring of the solution of sample 3 should also be remembered, pointing out that there must be a smaller exchange of substances between the solution and the coating, and a lesser degree of coating penetration by the solution.

Fig. 3. Complex impedance diagram of sample 2 after 23h (+), 5 days (x), and 49 days (o); complete plot. Parameter: frequency.

Fig. 4. Expanded plot of Fig. 3

Fig. 5. Complex impedance diagram of sample 3 after 3 (+) and 70 days (x); complete plot. Parameter: frequency.

Fig. 6. Expanded plot of Fig. 5.

Fig. 7. Complex impedance diagram of sample 4 after 25h (+), 4 days (x) and 28 days (o); complete plot. Parameter: frequency.

Moreover, the NaCl concentration seems to affect not only the coating, but also the faradaic process, as the IF arc of sample 3 shows a different shape from the impedance characteristic of samples 1 and 2.

Of the four samples, number 4 shows the biggest impedance range, which must be due to the important ionic resistance of the coating. So the absence of chromates in the coating produces a prominent enlargement of its ionic resistance, or otherwise stated, the chromate pigment increases in a radical way the conductivity of the coating. The chromate pigment is a water-soluble substance—sparingly however, to ensure a sufficiently long inhibitive action—which is not completely bound by the present latex coating (32).

The first plateau in the open-circuit potential of sample 1 is presumably determined by the $\text{Cr}^{6+}/\text{Cr}^{3+}$ equilibrium; the chromate pigment supplied by the coating can indeed be reduced by the iron. After a longer immersion time (more than 100 days), the potential moves towards the corrosion potential of uncoated iron in the same environment. An additional observation in the corrosion process is the blistering of the coating surface.

The slower decay of the potential and the slower variation of the impedance curve for sample 2 point out that a thicker coating can only retard this corrosion process.

The constant potential behavior and the apparently intact surface condition of sample 3 suggest that the iron is passivated by the chromates present in the coating, whereas this could not happen to the former samples due to the higher Cl^- concentration in the bulk solution.

Thus far, replying on the foregoing results and observations, it is possible to give the following description of the investigated system. On immersing the coated iron sample, water is taken up by the coating and penetrates through existing pores and via the boundaries of latex particles onto the metal, in this way dissolving chromates from the pigment reservoir in the coating. During the immersion, other substances such as O_2 and Cl^- , diffuse from the bulk solution into the coating. Only when a pore reaches the iron surface does an electrochemical interaction occur. It is a fact that chromate pigment in a coating not only plays a definite part in the conductivity of the coating, *i.e.*, that the presence of chromate pigment reduces the ionic resistance of the coating, but is also able to affect an anticorrosive action on iron (20, 33-36). It is a foregone conclusion, however, that a high ohmic resistance or a slow diffusion of passivating substances can maintain or accelerate the active state, even if there is a sufficient amount of pigment in the coating. This makes it difficult to find out whether there is passivation or not

Fig. 8. Variation of corrosion potential E with immersion time t . +: sample 1. x: sample 2. o: sample 3.

(20, 33). Besides, chloride anions are known to breakdown the passivation layer; they raise the minimum required pigment concentration to obtain a passive layer (20, 36, 37).

So, it is thought that when the chloride concentration at the metal/solution interface is below a certain limit, *i.e.*, in the beginning of the immersion or when the bulk concentration is low, the chromates are able to protect the iron, producing the Cr^{3+} component, which is reflected by the behavior of the open-circuit potential. However, the passivation reduces the electroactive area, thus increases the IF part in the impedance curve. Nothing happens to the protection as long as the Cl^- limit is not exceeded, which is only the case for sample 3.

For samples 1 and 2, the Cl^- limit is exceeded after a certain immersion time and passivity breaks down, causing the known consequences on the potential, the impedance, and the surface aspect.

So, the Cl^- concentration in the bulk solution is obviously another important factor controlling the system. It affects also the coating: there seems to exist another critical Cl^- concentration above which a marked diffusion of chromate from the coating can occur, together with an important reduction of the ionic resistance of the coating.

An increasing thickness logically enlarges the ionic resistance of the coating and delays the mentioned deterioration.

In any case, the pore density increases with time, as well as the contact area at the pore basis, and this is reflected by the decrease in the HF impedances, and the relatively growing importance of the mass transfer (LF) part.

Conclusions

An immersed coated metal was subjected to impedance measurements. Varying some system parameters such as coating layer thickness, concentration of NaCl in the solution, and pigmentation of the coating has a marked influence on the characteristic impedance curve. The dependence on immersion time also supplies much information about the physical and electrochemical system behavior.

Electrochemical Behavior of Passive Iron in Acid Medium

I. Impedance Approach

M. Keddam, J.-F. Lizée, C. Pallotta,¹ and H. Takenouti

Groupe de Recherche no. 4 du CNRS, "Physique des Liquides et Electrochimie," associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

Wide frequency range impedance measurements are applied to a kinetic investigation of passive iron in various acidic media. Special care was taken in the electrode preparation to reach stable current densities ($7 \mu\text{A} \cdot \text{cm}^{-2}$ in $\text{Fe}/1\text{M H}_2\text{SO}_4$, 25°C). Impedance data were obtained as a function of potential and temperature in the steady state. An original approach to the nonsteady-state behavior is introduced by combining transient response to the time dependence of the impedance. Contributions from transport in the film and interfacial impedance are separated. The classical view of high field conduction mechanism is refined with respect to the generality of the description and also to the film properties in various environments leading to the concept of chemically dependent high field ion migration. Low frequency behavior in the millihertz range supported this conclusion by ruling out the idea of diffusion-controlled passive current. The capacitance observed is attributed to the film-growth kinetics.

In the last ten years, passivity was mainly investigated by means of *in situ* optical techniques and non-*in situ* surface spectroscopies (1-8). These studies resulted in a certain amount of information on the chemistry of passive layers, but their use is often confined to weakly or mildly aggressive media (*e.g.*, boric-borate-buffered solutions). In these media, however, kinetics studies are difficult because the passive current is very low, often at the level of the background current of oxygen reduction or of the feedback current of most regulating devices. However, during the same period, the electrochemical behavior of passive metals in acid media was disregarded. Therefore, in spite of marked progress in nonsteady-state electrochemical methods such as impedance measurements at very low frequencies by FFT or by correlation techniques, the most elaborate concepts on passivity formulated from classic experiments were not thoroughly worked out (9-18).

Vetter assumed that the major part of applied overvoltage is located in the passive film following a high field conduction process (17). The film growth is also supposed to be governed by this field, whereas the passive current is determined by a chemical process taking place at the film/solution interface and closely related to the stoichiometry of the film material (18). Difficulties in analyzing the kinetics of passive electrodes are in major part due to the overlapping of several elementary processes such as charge transfer at interfaces, transport properties across the film, and film growth. The problem can also be formulated in terms of the potential profile between the metal and electrolyte or of the rate-determining step involved in the passive current. The separation of these contributions may be improved by measuring the electrode impedance over a wide frequency range or by recording current or potential transients performed over a wide range of time. In the case of small perturbations, these two techniques are related through the Fourier transform. It is then possible to distinguish between the steady state and transient phenomenon and to obtain relevant information on the potential distribution and concentration distribution across the interface.

The existence of a passive film may lead one to describe the system by an equivalent circuit. Although it seems fruitful as a guiding representation, this approach is only a way to translate experimental data or theoretical predictions and does not in any way provide new information on the physico-chemical system itself. In many cases, several designs of equivalent circuits may be found, which show the difficulty of attributing unambiguously a given element to a definite elementary process. Along the same lines, the arrangement of the

electrical elements should not be construed to be identical with the postulated steps in the real system. In highly intricate systems, it often turns out that circuit elements are frequency dependent and the representation tends to lose its advantage.

Early impedance measurements used for studying passivity of metals were usually aimed at capacitance determination in order to estimate film thickness or dielectric properties of the film material. Furthermore, the potential dependence of the high frequency capacitance was tentatively related to the semiconducting character of the film through the Mott-Schottky relation (19-21).

One of the most controversial points is the electrical resistance of the passive film. There is an apparent contradiction between good electronic conductivity and a high electrical field assisting ionic currents across the film. If a major part of the applied overvoltage is located across the film, a nearly linear dependence of the resistance with respect to potential is expected, regardless of whether the conduction process is ohmic or high field. Surprisingly enough, no investigations were made to check this basic point. Current transients generated by potential perturbations were interpreted by Vetter in terms of an electrochemical potential driven from its equilibrium, at the solution/film interface, as responsible for film growth (9). More recently, ion diffusion across the film was considered as a limiting step by Sukhotin *et al.* (22, 23), but this model was not clearly supported by experimental data. Macdonald *et al.* (24, 25) developed a "point defect" description of film growth. According to these authors, the steady-state passive current is determined by the diffusion of ions or ions vacancies in the film.

Many impedance measurements on the passivity of iron were performed at frequencies greater than 1 Hz. This frequency domain is too high to give access to the relaxation of film thickness and even to the transport properties of the film. Haruyama *et al.* (26) performed impedance measurements in the millihertz range on passive iron, mostly in a boric-borate buffer solution. Impedance of metals in the active, active-to-passive, and passive ranges were extensively studied by Epelboin *et al.* (27-29) and Armstrong *et al.* (30, 31). However, treatment of their results on the passive film was restricted to bidimensional layer models and, therefore, ignored film growth and potential distribution in the layer depth.

This brief literature review leads to the conclusion that Vetter's views on passive iron are the most complete ones. They have largely stimulated the present work, which is devoted to a detailed analysis of electrode impedance.

Impedance of Passive Electrodes: A General Framework

Complex impedance techniques are widely used to examine electrochemical processes. On a very general basis,

¹ Postdoctoral fellow of the Consejo Nacional de Investigaciones Científicas y Técnicas de la República Argentina.

the electrode impedance can be formally represented as a potential-dependent resistance $R(E)$. The change of this resistance with potential is noninstantaneous since it involves finite rate processes such as transport phenomena and/or physico-chemical transformation at the interface, which gives rise to the overall nonlinear behavior of the system.

The simplest way to describe this feature in the frequency domain is through a single (nondistributed) relaxation. Then the impedance Z can be expressed as

$$\frac{1}{Z(\omega)} = \frac{1}{R(E)} \left(1 - \frac{A(E)}{1 + j\omega\tau} \right) \quad [1]$$

where ω is the angular frequency ($\omega = 2\pi f$, f in Hz), τ a relaxation time constant, $j = \sqrt{-1}$, and $A(E)$ a nondimensional parameter.

According to this equation, the impedance $Z(\omega)$ is identical to $R(E)$ at very high frequencies compared to $1/\tau$, since under those conditions $R(E)$ can be regarded as frozen. At zero frequency, the impedance tends to the polarization resistance R_p , given by

$$\frac{1}{R_p} = \frac{1}{Z(0)} = \frac{1}{R(E)} [1 - A(E)] \quad [2]$$

Schematic Nyquist representations of Eq. [1] are given in Fig. 1 according to the value of $A(E)$. In most systems, this low frequency limit can be approached only by extending the measurement towards the millihertz range. In the case of passive systems, the polarization curve is extremely flat, and the polarization resistance is practically infinite within the experimental accuracy.

Early studies on the impedance of passive electrodes were carried out only in the range of medium frequencies, e.g., 50 Hz, and concluded at the capacitive behavior of the passive film. In this context, no attempt was made to establish a connection with the dc properties of the passive electrode. Further analysis of impedance data in the intervening low frequency domain is needed, since it may reflect three-dimensional processes in the film such as ion transport and growth mechanism.

The so-called resistance of the film is sometimes discussed with reference to the ratio of the dc potential to the dc current. The electrochemical systems being essentially nonlinear, this consideration is completely irrele-

vant except under very particular conditions described below. A restricted class of nonlinear systems can be described by a generalized Ohm's law relating the dc current flowing through the system to the dc voltage according to

$$R(E) = \frac{E}{I} \quad [3]$$

where $R(E)$ is identical to the high frequency limit of the resistance governed by the general Eq. [1] according to

$$\frac{1}{Z} = \frac{1}{R(E)} \left[1 - \frac{E}{R(E)(1 + j\omega\tau)} \frac{dR(E)}{dE} \right] \quad [4]$$

This property provides an easy criterion for discriminating this class of systems and is perfectly verified by nonisothermal metallic or semiconducting resistors exhibiting respectively impedances of the types a and b in Fig. 1. In these systems the potential dependence of $R(E)$ arises from its temperature dependence through Joule's law. In the case of electrochemical systems, no absolute potential scale can be defined. Consequently, Eq. [3] cannot be checked against impedance data. The derivative of Eq. [3] could be applied to constant current systems (passive electrodes)

$$\frac{dR(E)}{dE} = \frac{1}{I} \quad [5]$$

Equation [5] clearly means that any change of voltage induces a proportional change in the resistance value according to the generalized Ohm's law. It should be emphasized that activated charge transfer or conduction processes do not obey this law, as will be shown in the next section.

Experimental Procedure

An accurate measurement of electrode impedance at low frequencies for passive iron in a strongly acid medium is extremely difficult. This is due to an underlying attack taking place between metal and embedding material (9, 12). In this work, this problem is overcome as explained below, and steady-state passive currents as low as $7 \mu\text{A} \cdot \text{cm}^{-2}$ were observed during a week for Fe/1M

H₂SO₄ at 25°C. This enables one to obtain reproducible data at very low frequencies.

Electrodes.—The working electrode was prepared from iron rod of 5 mm diam (Johnson-Matthey) as received without any heat-treatment. The cross section of rod was allowed to contact with electrolyte, thereby forming a disk electrode, the surface of which was 0.2 cm². The remaining surface of rod was first covered with an epoxy-phenolic varnish cured at 200°C, then embedded in a thermosetting phenol resin at 200°C under pressure (3.5 bar). The electrode thus prepared was polished by emery paper of up to 1200-grade under running water, rinsed with ion-exchanged water, and immediately set in a cylindrical electrolytic cell. A Pt-gauze of large surface area (200 cm²) surrounding the cell wall is used as a counterelectrode. Potential was measured and referred against a mercurous sulfate electrode in saturated K₂SO₄ (SSE) located in the solution bulk.

Solutions.—Various acid solutions were prepared of p.a. reagents (Merck "proanalysis" quality) and ion-exchanged water. These solutions are H₃PO₄, H₂SO₄, HNO₃, and HClO₄, 1M concentration.

Phosphate and sulfate media of different pH's were prepared by the mixture of molar acid and 1M KH₂PO₄ or 1M Na₂SO₄ in varied proportions. The electrolytic cell of ca 0.3 liter of solution was deaerated by Ar bubbling and maintained at constant temperature.

Devices.—The polarization of electrode interface and impedance measurements were carried out with a Solartron-Schlumberger equipment, electrochemical interface 1186, and Frequency Response Analyzer 1250. Very low frequency data ($f < 0.01$ Hz) were obtained also by FFT processing (Fourier Analyzer: Hewlett-Packard 5451C) of the current response to a stepwise potential perturbation.

Procedures.—Prior to impedance measurements, the electrode was prepolarized at a passive potential, 0.85V in most cases, for 24h. It was found in preliminary experiments that the electrode impedance continued to change for a long period after the passive current reached its steady-state value.

To investigate the potential dependence of the impedance, the potential was then switched to the selected value. Approximately an additional 1h was needed after that to reach the steady-state current and to perform the measurements. No significant dependence of the results on the initial polarization potential was observed.

Results and Discussion

Steady-state measurements.—The passive range extends between the Flade potential and oxygen evolution in general (transpassive dissolution in perchlorate media). From the Flade potential ca. -0.2V, the current decreases with potential. Beyond 0.2V, the current is independent of potential, except in phosphate medium, in which a slight current change can be observed. This so-called full passive range is mainly dealt with in this paper and allows one to define a constant passive current density I_p . The I_p values obtained for various experimental conditions are summarized in Table I. As can be seen, at a given temperature and pH, the passive current increases proportionally as the charge-to-size ratio of anions: PO₄³⁻ > SO₄²⁻ > NO₃⁻ > ClO₄⁻.

In solutions of a given anion, the concentration of which is kept constant, the passive current decreases at increasing solution pH. Regardless of anions, the following relation was observed at 25°C

$$\frac{d \log I_p}{dpH} = -0.78 \quad [6]$$

It was also found that the passive current depends on temperature. Arrhenius plots obtained in 1M H₃PO₄ are shown in Fig. 2. An apparent activation energy of ca. 12 kcal · mol⁻¹ was calculated. In sulfate solutions at pH = 1, the same value for the activation energy was recorded,

Table I. Influence of the electrolyte composition and temperature on the steady-state passive current and the diameter R_{HF} of HF loop

Solution	pH	T (°C)	I_p ($\mu A \cdot cm^{-2}$)	R_{HF} (k Ω)	$R_{HF} \cdot I_p$ (mV)
H ₃ PO ₄ 1M	1.0	25	58.0	10.7	124
		37	130.0	4.9	127
H ₃ PO ₄ + KH ₂ PO ₄ 1M	2.2	25	27.6	23.1	128
H ₃ PO ₄ + KH ₂ PO ₄ 1M	2.8	25	12.2	53.6	131
H ₃ PO ₄ + KH ₂ PO ₄ 1M	3.4	25	3.4	205.4	140
H ₂ SO ₄ 1M	0.03	25	8.2	74.0	122
		50	55.0	10.5	116
H ₂ SO ₄ + Na ₂ SO ₄ 1M	1.0	25	3.0	193.4	116
H ₂ SO ₄ + Na ₂ SO ₄ 1M	1.8	25	0.3		
H ₂ SO ₄ 0.5M	0.4	25	4.8	121.0	117
HNO ₃ 1M	0.0	25	3.9	117.0	91
		37	8.65	55.0	95
HClO ₄ 1M	0.0	25	0.22	2260.0	97
		45	2.0	251.0	100

All values were obtained at $E = 0.65V$.

whereas in 1M HClO₄, the value was found to be ca. 15 kcal · mol⁻¹.

Electrode impedance.—Figure 3 shows an example of the impedance diagrams obtained for two different solution compositions, in the full passive range. In this figure, three frequency domains can be separated: (i) a capacitive loop at relatively high frequencies (HF capacitive loop), (ii) an inductive loop at medium frequencies (MF domain), and (iii) another capacitive domain for low frequencies (LF capacitive loop).

These diagram features were obtained regardless of potential, solution anion, pH value (0-3.4), and temperature, provided that the electrode was polarized in the full passive range. The only difference observed between these impedance diagrams was the diameter of each loop and its frequency domain.

HF capacitive loop.—This loop is close to a semicircle centered below the real axis (depressed semicircle) as also generally observed on solid electrodes including noble metals (33). The capacitance values determined at the maximum of the imaginary part lie between 10 and 50 $\mu F \cdot cm^{-2}$ depending on the experimental conditions. If analyzed in terms of a parallel R-C circuit at each frequency,

Fig. 2. Arrhenius plot for Fe/1M H₃PO₄, $E = 0.60V$

Fig. 3. Complex impedance diagrams: (a) Fe/1M H₃PO₄, 37°C, E = 0.65V; (b) Fe/1M H₂SO₄, 25°C, E = 0.35V.

it is noteworthy that the frequency dependence is reflected particularly on the resistive component (34, 35). Aspects related to this frequency dependence were not investigated in greater detail in this paper. The interest is focused on the real axis intercept R_{HF} , which must be regarded as a property of the electrode at a sufficiently high frequency to freeze the modulation of the film thickness. Charge transport and/or interfacial charge transfer at the metal/film and film/electrolyte interfaces may be involved at the same time, which is hardly distinguishable.

Separation of the interfacial and film contributions to R_{HF} can be performed on the basis of its potential dependence. As illustrated in Fig. 4, R_{HF} increases linearly with potential in the full passive range. It can hence be written as

$$R_{HF} = R_{HF}^{Flade} + K(E - E^{Flade}) \quad [7]$$

where E^{Flade} is the Flade potential, R_{HF}^{Flade} indicates R_{HF} value extrapolated back to E^{Flade} , and K is a constant. The values of R_{HF}^{Flade} and K are dependent on solution composition and are shown in Table II.

Equation [7] actually suggests that R_{HF} can be split into a contribution located in the film bulk (R_{film}), which is proportional to film thickness, and another contribution linked with charge transfer processes at the film boundaries (R_i).

Consideration of the product $R_{HF}I$ provides deeper insight into the nature of the resistive component of the impedance. A constant value of this quantity is related to an

Fig. 4. Potential dependence of R_{HF} . Fe/1M H₂SO₄, 25°C

Table II. R_{HF}^{Flade} and K values related to Eq. [7] for different solutions at 25°C

Solution	K (kΩ · V ⁻¹ · cm ²)	R_{HF}^{Flade} (kΩ · cm ²)
H ₂ SO ₄ 1M	7.0	9.5
H ₃ PO ₄ 1M, pH = 1.0	0.93	1.1

H ₃ PO ₄ + KH ₂ PO ₄ 1M, pH = 2.2	2.5	2.3

irreversible charge transfer obeying a Tafel law, whereas, according to the foregoing introduction, $R_{HF}I$ can be also used as a characterization of the conduction mechanism in the film.

The product $R_{HF}I$, where I is the measured current density at a given applied potential, is compared for various solutions in Fig. 5.

First, variations at potentials less anodic than the full passive range were investigated. In Fig. 6, the polarization curve near the active-passive transition potential obtained in 1M H₂SO₄ is shown. In the same figure, three impedance diagrams (A to C) obtained at the corresponding points on the steady-state polarization curve are also shown. In these diagrams, the features of impedance diagram change drastically as the polarization point approaches active-passive transition. The zero frequency limit of the impedance for point A is negative, in agreement with the negative slope of the polarization curve. The product $R_{HF}I$ is independent of potential in the low anodic potential range. The value of this product is close to 70 mV at potentials close to the active-passive transition potential, then increases and reaches a value equal to 100 mV at 0.3V for solutions of pH > 1 (Fig. 5). Beyond this potential, the electrode is polarized in the full passive range where I becomes the passive current density independent of potential. $(I_p) \cdot R_{HF} \cdot I_p$ increases linearly with potential showing a similar variation for all solutions investigated as shown in Fig. 5. However, the position of the straight lines is dependent on solution pH following 60 mV/pH law for a given anion. The linear relationship between $R_{HF} \cdot I_p$ and the potential is qualitatively in agreement with Eq. [5]. However, the experimental slope of 0.06 is in disagreement with the unit slope expected from Eq. [5]. If an ohmic drop was actually involved in a passive film of potential dependent thickness, it would concern only a small fraction of the overpotential located within the film. In other words, a rough model as that described by Eq. [5] is able to account only qualitatively for the resistive component of the impedance of passive iron [Fig. 1, A(E) = 1].

It is noteworthy that in spite of large differences between passive currents observed in various solutions (cf. Table I), the slope of $R_{HF} \cdot I_p/E$ is essentially the same for

Fig. 5. Potential dependence of $R_{HF} \cdot I$ for iron in different solutions at 25°C. Δ : 1M H₂SO₄. \bullet : 1M H₃PO₄. $+$: 1M (H₃PO₄ + KH₂PO₄), pH = 2.2. \circ : 1M (H₃PO₄ + KH₂PO₄), pH = 2.8.

all solutions. This establishes some kind of similarity in the electrochemical properties of the passive film in all solutions investigated. This result will be of importance for the modeling of the passive electrode. Surprisingly, this behavior seems to occur even more generally, taking into account similar experiments performed by Crevecoeur *et al* (34) on aluminum in ammonium pentaborate/ethylene glycol solutions. From Fig. 1 of Ref. (34), one can calculate a slope equivalent to $d(R_{HF} \cdot I_p)/dE$ of about 0.07. If, as suggested by Vetter (17) for iron and commonly assumed for valve metals, the movement of ions through the film obeys a high field migration, the $R_{HF} \cdot I_p/E$ dependence is easily understood. The current I flowing through this film is expressed by

$$I = I^0 \exp\left(\frac{BE}{l}\right) \quad [8]$$

where $B = \frac{z\alpha F}{RT}$, a = half-jump distance, z = electric charge of the mobile species, T = temperature, and l = film thickness. According to Eq. [8]

$$\frac{d(RI)}{dE} = \frac{l}{BE} \quad [9]$$

the slope corresponds to the argument of the exponential Eq. [8]. From the experimental data, $d(R_{HF} \cdot I)/dE = 0.06$ and assuming $a = 5\text{\AA}$, a reasonable value for an oxide lattice parameter, the calculated electric field is ca. $3 \cdot 10^6 \text{ V} \cdot \text{cm}^{-1}$ at 25°C or a change in thickness of the order of $35\text{\AA} \cdot \text{V}^{-1}$, in agreement with the literature of valve metals.

The conclusions regarding the properties of the passive film partially support Vetter's view of the dominating role of the electric field. More precisely, regardless of the experimental conditions, the steady-state seems only

compatible with a particular value of this field. It is established that the film thickness remains practically the same at a given potential. Changes in the ionic dissolution current across the film must be entirely accounted for by the pre-exponential factor of the high field equation. However, it is to be remarked that these conclusions are based on a whole set of impedance data for the same value of the mean steady-state electric field in the film. No direct evidence is provided in favor of Eq. [8] in terms of current-electric field plot. Deviation from the stationary field can only be obtained under nonsteady-state conditions that give rise to either growth or dissolution of the film.

In an attempt to estimate the value of R_{HF} during the transient response to a stepwise change of potential, the impedance-time profile was sampled using the data storage facilities of the 1250 analyzer. Because of the deviation of the HF arc from a perfect semicircle, two frequencies were selected: one close to the top of the loop and the other one two or three times smaller. It was checked that errors arising from the contribution of the transient current response to the correlation remain negligible.

In Fig. 7 and 8 the transient current response (curve a) and R_{HF} profile (curve b) in 1M H₃PO₄ solution after potential steps of 0.4V in anodic and cathodic directions are shown. The amplitude of this potential step was such that the system was perturbed far beyond the linearity domain.

Figure 9 shows the change of $R_{HF}I$ as a function of time. A steadily decreasing transient is found. This result is obviously incompatible with an irreversible charge transfer at interfaces and a high field conduction mechanism in the film bulk. Under these assumptions, Eq. [8] predicts that $R_{HF}I$ would simply reproduce the smooth increase of "I" from its initial to its final value following the potential step. The origin of this behavior can be clarified in some extent. If a Tafel law is postulated for the interfacial

Fig. 7. a: Current/time response resulting from a potential anodic step from 0.4 to 0.8V. b: R_{HF} /time relationship measured during the anodic transient. R_{HF} calculated from impedance at 4 and 1.6 Hz. Fe/1M H_3PO_4 , 25°C.

charge transfer, the constant value of $R_t I$ can be deduced from Fig. 5 by extrapolating back to the zero-thickness region and thereby, the change of R_{film} during the transient estimated. Applying this procedure, it is found that the variations of R_{film} between initial and final states of the passive film cannot be restituted correctly with a constant value of $R_t I$. Instead, a value of $R_t I$ decreasing with the current during the transient must be used. This strongly suggests an explanation based on a partially reversible interfacial charge transfer rather than a deviation of the conduction mechanism from the exponential law at high field strength. This explanation is even more convincingly supported by the time response of $R_{\text{HF}} I$ during a backward cathodic potential step. $R_{\text{HF}} I$ steadily increases from an initial value as low as 0.04V (Fig. 9). In this case,

the evaluation of the film resistance by assuming the constant value 0.1V of $R_t I$ would lead to a negative value of R_{film} . However, a partially reversible interfacial transfer (i.e., smaller values of $R_t I$ associated with small anodic currents) during the cathodic transient consistent with this experiment occurs. On the whole range of currents covered by anodic and cathodic transients, i.e., between 1.38 and 52 μA , the charge transfer parameter $R_t I$ has to vary from 0.055 to 0.129V. The steady-state value 0.1V lies in the midrange. The dependence of $R_{\text{HF}} \cdot I_p$ with passive current through anions at constant pH (Table I) also supports this view. However, additional contributions to the impedance measured during the transient arising from side reactions related to the growth or dissolution of the film may also be considered.

Fig. 8. Same as Fig. 7, but in cathodic direction from $E = 0.8\text{-}0.4\text{V}$.

Fig. 9. Anodic and cathodic R_{HF}/I time dependence from Fig. 7 and 8.

Medium frequency domain.—The iron/acid interface polarized in the fully passive range exhibits an inductive loop in the medium frequency range. This behavior is observed only if the electrode is carefully protected against undermining attack between metal and insulating material (37).

The associated characteristic time constant τ can be defined by the frequency at the bottom of the inductive loop. The product $I_p\tau$ is potential dependent and goes through a minimum by $E = 0.6V$ for $1M H_3PO_4$. This minimum value is of the order of $70 \mu C \cdot cm^{-2}$ and was found to remain between 70 and $180 \mu C \cdot cm^{-2}$ for each composition and temperature investigated. This explains why the inductive behavior was not observed in $HClO_4$ solutions. In these solutions, the passive current is as low as $0.1 \mu A \cdot cm^{-2}$ and the characteristic frequency might fall at a fraction of millihertz. This inductive behavior was also observed on aluminum in an ammonium pentaborate-ethylen glycol solution (36) and is obviously equivalent to the overshoot mentioned in early studies of the transient response of Al and other valve metals. Its origin was thoroughly discussed in terms of bulk or surface relaxation. On the basis of impedance data, it was recently attributed to the buildup of a surface charge (36). It can be noticed that the inductive effect is not observed with Ni and thus might be related to an intermediate oxidation step in the film (37).

Low frequencies domain.—As shown in Fig. 3, the electrode impedance exhibits a capacitive branch in the low frequency domain. Similar to the behavior observed in the high and medium frequency ranges, this branch appears at higher frequencies for a higher passive current. Consequently, accurate measurements in this region are easier in phosphate media and at temperature greater than $25^\circ C$. The capacitance Γ calculated in H_2SO_4 and H_3PO_4 exhibits a slight frequency dependence. If $1/\Gamma^2$ is plotted as a function of frequency, a roughly linear relationships is found as shown in Fig. 10. The limiting capacitance at zero frequency does not depend much on experimental conditions. For instance, Γ changes only from 40 to $55 mF \cdot cm^{-2}$ when a temperature rise increases the current from 63 to $370 \mu A \cdot cm^{-2}$ in $1M H_3PO_4$ (Fig. 10).

FFT signal processing as applied to the transient response allowed one to investigate with better accuracy the frequency range below 1 mHz. Current responses to anodic and cathodic steps, shown in Fig. 11, are clearly

Fig. 10. Γ^{-2} /frequency dependence for various experimental conditions. $Fe/1M H_3PO_4$, $E = 0.65V$. \square , $25^\circ C$, $I_p = 63 \mu A \cdot cm^{-2}$. \bullet : $37^\circ C$, $I_p = 130 \mu A \cdot cm^{-2}$. \circ : $54^\circ C$, $I_p = 370 \mu A \cdot cm^{-2}$. $+$: $Fe/1M H_2SO_4$, $E = 0.4V$, $50^\circ C$, $I_p = 55 \mu A \cdot cm^{-2}$. Limiting zero frequency Γ values in $mF \cdot cm^{-2}$: 40.5, 44.3, 55.1, and 61, respectively.

Fig. 11. Anodic and cathodic current/time transients resulting from potential steps. Fe/1M H₂SO₄, 25°C. $E = 0.6V$. A: $\Delta E = 0.03V$. B: $\Delta E = 0.10V$.

asymmetrical, even for amplitude as low as 0.03V. Even if linearity requirements are not completely fulfilled, it was verified that the mean value of the anodic and cathodic Nyquist loci reproduces accurately the complex impedance measured by ac signal at the same potential as proved by a comparison of Fig. 12 and 3a. The capacitance deduced from the cathodic Nyquist locus is practically independent of the frequency and close to 25 mF · cm⁻² in 1M H₃PO₄ at 25°C. In contrast, the anodic response yields a capacitance exhibiting a frequency dependence.

The physical origin of this low frequency branch is easily understood by emphasizing its strict connection with the existence of an infinite polarization resistance or, in other words, with the process ensuring a constant passive current in the steady state. Owing to the particular accuracy of FFT techniques in this frequency range (32), it can be concluded from the shape of the diagram in the low frequency range that diffusion is not the controlling process. According to the data obtained at high frequencies,

Fig. 12. Nyquist representation calculated by FFT processing of potentiostatic step experiments. The impedance is the mean value from a cathodic (0.7-0.6V) and an anodic (0.6-0.7V) response.

the electrode process can be described as a chemically dependent high field conduction mechanism. Consequently, the low frequency capacitance arises from the potential dependence of the film thickness, and it is worth discussing the value of Γ with respect to the amount of electricity stored in the film. Assuming a film composed of a trivalent iron oxide (specific gravity 5g · cm⁻³) and with a thickness of 35Å V⁻¹; this leads to a capacitance of ca. 3 mF · cm⁻², whereas Γ is approximately ten times greater. In other words, only one tenth of the alternating current is stored in the film, while the remaining component corresponds to a modulation of the dissolution current across the film. However, it is doubtful whether this ratio between dissolution and growth components remains independent of the frequency. Different responses in frequency dependence of Γ and possibly to the inductive behavior. This variation in frequency response is suggested by the fact that the diameter of the inductive loop is also approximately one-tenth of R_{HF} over the whole experimental conditions investigated.

Conclusion

Impedance analysis of passive iron permitted the separation of the transport properties in the film from the charge transfer at interfaces, on one hand, and the film growth, on the other hand.

A resistance obeying a linear dependence on the potential is found as expected from the existent theories. The charge transfer contribution is partially reversible as established from nonsteady-state experiments. A high field-assisted ion migration with an electric field of the order of 3 · 10⁶ V · cm⁻¹ or a thickness of ca. 35Å · V⁻¹ is corroborated.

The capacitive behavior observed in the low frequency range is related to film growth and allowed to estimate the ratio of the film forming current to the dissolution current under nonsteady states.

The passivation current depends on electrolyte composition through the charge carrier concentration in the film (pre-exponential term in the high field equation), whereas the film thickness seems to remain independent of the electrolyte investigated. On the whole, the electrode process can be described as a chemically dependent high field assisted ion migration. It is significant that the value of the passive current determines unambiguously the most important parameters involved in the characterization of the system.

Cyclic Voltammetric Studies and Caustic Cracking of Steel at Various Temperatures

Andrzej Wieckowski,¹ Edward Ghali,* and Huy Ha Le

Department of Mining and Metallurgy, Laval University, Laval, Quebec, Canada G1K 7P4

ABSTRACT

Cyclic voltammetric studies were carried out for an iron electrode and for pressure vessel quality steel A516 in 1 and 7.73M sodium hydroxide solutions as a function of temperature. Cyclic voltammograms for strained electrodes of steel were also made. The stress corrosion cracking susceptibility was measured by the slow strain rate method. The examined temperature range was between 25° and 105°C. A correlation was found between the electrochemical behavior of unstrained electrodes (cyclic voltammograms) and the susceptibility to caustic cracking. A critical zone of temperatures, above which cyclic voltammograms are sensibly different and stress corrosion cracking occurs, was obtained.

The resistance of steel to corrosion and stress corrosion cracking (SCC) in caustic soda solutions is an important issue in various industrial applications, including the electrolysis and dissolution of minerals performed in steel containers. The need for corrosion prevention, as well as the commercial interest in iron alkaline batteries, stimulated numerous investigations of the electrochemical behavior of iron in alkaline media. Surveys of the pertinent papers are available (1, 2). Most of the studies, especially those under single-scan or cyclic voltammetry conditions, have been carried out at normal temperatures, but some high temperature investigations reported up-to-date indicate that the i-E profiles obtained at low and high temperatures are different (3-5). No systematic study of the effect of temperature on the cyclic voltammetry of iron electrode has been made.

It is worthwhile to add that the practical examples of failures in sodium hydroxide solution have occurred largely above room temperature. A statistical analysis of industrial failures done by Schmidt *et al.* (6) showed that 5% NaOH solution caused stress corrosion cracking above 95°C and a 50% NaOH solution above 40°C. A collective survey on the caustic cracking of mild steel, which deals with more recent data (7), indicates that no cracks below ca. 50°C were reported by industrial sources. The examination of other results (8, 9) for the caustic cracking of steel as a function of temperature and concentration of

the sodium hydroxide solution shows that the limits of the caustic danger zone may be varied by a number of other factors, especially environmental and metallurgical ones.

In this study, the effect of temperature on the cyclic voltammograms of an iron and a steel in the range of 25°-105°C were studied, the upper limit depending on the concentration of the NaOH solution. Also, stress corrosion cracking susceptibility of the steel was studied employing the slow strain rate method at different temperatures. Since temperature is dominant factor in SCC susceptibility, it is important to examine its effect on the electrochemical behavior and the relation of this to cracking.

Experimental

The experiments were carried out in a two-compartment, all-Teflon cell, equipped with circulating system (all-Teflon, Cole-Palmer pump, C-7149-20). The reference electrode compartment (saturated calomel electrode) and the main cell were connected by a thin bridge filled with the supporting electrolyte and terminated with a Teflon Luggin capillary. The tip of the capillary was situated less than 1 mm from the center of the working electrode. The counterelectrode was a rolled platinum wire, 0.5m long, installed in the main cell. The working electrode (0.28 cm²) was made of Teflon-embedded pure iron (ferrovac) of the following composition (in percentage); C(0.007), Mn(0.001), Si(0.006), S(0.007), P(0.002), Ni(0.04), N(0.003), Cr(0.01), Mo(0.01), and Cu(0.014).

The electrode was polished with emery paper of various grades (from 100 to 600), followed by rinsing in distilled

water. After mounting in the electrochemical cell filled with the deaerated test electrolyte at a constant temperature, the electrode was cathodically activated at -1.1V for 5 min. The electrolyte was deaerated in the thermostated container (2 liter capacity) of the circulating system by prepurified argon. The temperature of the solution in the cell was maintained with an accuracy of $\pm 0.2^\circ\text{C}$. All potentials are given with respect to the normal hydrogen electrode.

The slow strain-rate tests were conducted with an MTS machine. The test cell was similar to that used for cyclic voltammetry experiments, with the exception that it was possible to incorporate the working steel electrode tension specimens, machined according to ASTM standards. The steel A516 (pressure vessel quality) of the following composition (in percentage) was used in these experiments

C	Mn	P	S	Si
0.24	1.15	0.008	0.007	0.25
Cu	Ni	Cr	Mo	Sn
0.044	0.025	0.033	0.004	0.002

The caustic solutions employed were 1 and 7.73M. Preliminary results showed that the more susceptible strain rate for SCC was $2.6 \times 10^{-6} \text{ s}^{-1}$. 10^{-5} s^{-1} gave less SCC, but these two strain rates were employed to examine the effect of temperature. The elongation of the specimens was measured by the use of Gage marks on the reduced section of the specimen. Also, the reduction in area was determined for every sample by measuring the diameter of the reduced section before and after testing. The surface of the specimen was well cleaned with acetone and rinsed with distilled water. After inserting in the test cell, the electrode was cathodically polarized at -1.1V for 5 min. The temperature of the electrolyte in the cell was controlled by a Chromel-Alumel thermocouple to an accuracy of $\pm 2^\circ\text{C}$. Working electrodes (0.28 cm^2) from A516 steel were also machined for cyclovoltammetric studies.

Results and Discussion

Cyclic voltammetry studies.—The cyclic voltammetry studies were made for different scan rates from 5 to 500 mV s^{-1} . Six scan rates were examined in this region, since the voltammograms have almost showed the same shape, only a noble shift of the peak potential and an increase in the peak current as a function of the increase in the scan rate was observed, the results presented here are limited to the rate of 50 mV s^{-1} , which is considered as an average speed. Figure 1 shows the evolution of the voltammograms recorded at 25°C : approximately 30 cycles were needed to obtain a stable profile. The evolution of the curves (indicated by the directions of arrows) as well as the initial (broken line) and the final shape of the potentiodynamic plots are in agreement with the results of other authors (1, 3, 10). Similar evolution of the i - E profiles was observed at 35°C , but the current density of peak III (Fig. 1) was ca. 30% lower. It was also noted that in the case of peaks III and V, a certain resemblance is present especially in the formation of a shoulder as a sequence of successive cyclation (shoulders B and B', Fig. 1).

Figure 2 shows the voltammetric behavior of iron at higher temperatures. At 45°C , the evolution of the voltammograms was still observed, but the upward shift of peak III and V and the downward shift of peak VI were very slow. It should be noted that peak III which prevailed at the lower temperatures is reduced substantially. At 55°C , peaks III and V practically disappear. Moreover, only a few cycles were needed to obtain stable conditions (at $t > 55^\circ\text{C}$, no significant difference was found between the first and the stable profiles). Peak II systematically increases with temperature (5) and at $t > 55^\circ\text{C}$ predominates over the other anodic peaks. At 95°C , the potentiodynamic plots are similar to that obtained by Macdonald and Owen in 1.0M LiOH at 200°C (3).

Fig. 1. The cyclic voltammetry of iron electrode at 25°C in 1M NaOH : the first scan (broken line) and subsequent profiles are shown. The shift of particular peaks (denoted by Roman figures) is indicated by arrows. The attention on anodic shoulders of peak III and peak V is drawn by letters B and B', respectively. Scan rate: 50 mV s^{-1} . Electrode area: 0.28 cm^2 .

Fig. 2. The cyclic voltammograms of iron electrode in 1M NaOH at various temperatures: (a) 45° , (b) 55° , (c) 65° , (d) 75° , (e) 85° , and (f) 95°C . First scans are indicated by broken lines, stable profiles by solid lines. Scan rate: 50 mV s^{-1} . Electrode area: 0.28 cm^2 .

Comparison of the voltammograms obtained at low ($t < 45^\circ\text{C}$) and high temperatures shows that the dissolution-precipitation mechanism (11-12) which most probably accounts for the formation and evolution of peaks III and V, is no longer operating above 55°C . It is also clearly seen that peak II should be attributed to the active-passive behavior of iron, the inference being in agreement with that of Armstrong and Baurhoo (5). As shown by Parkins (13), the potential region of caustic cracking of mild steel coincides with that of the active-passive transition of the steel, so that cracking susceptibility should be by consideration of peak II, obtained at low and high scan rates, rather than that of peak III, as it has incorrectly been suggested earlier (14).

Similar voltammetric experiments carried out with A516 steel, showed the same tendency as in Fig. 2, but peaks III and V practically disappeared at 65°C rather than at 55°C with iron.

The observation concerning the temperature-dependent iron oxide (hydroxide) redox couple represented by peaks III and V, with the equilibrium potential situated exactly in the region of the maximum susceptibility of SCC (13) (Fig. 1), is concluded to be relevant to the discussion of a critical temperature for SCC phenomena (13). The critical temperature of 50°C , below which no stress corrosion cracking occurs under industrial conditions, coincides with a dramatic decrease in the tendency for the formation of peaks III and V on iron and with a substantial decrease on A516 steel. Therefore, it seems that the formation of a passive layer by the dissolution-precipitation mechanism below a critical temperature is responsible for a reparation mechanism in the initial stages of crack formation.

One of the proposed mechanisms of SCC can be: crack growth arises from an enhanced anodic dissolution reaction on oxide-free surfaces which have been created by the rupture of the passivating oxide films as a result of the localized plastic strain at the tip of a SCC. The crack advances by a rapid anodic dissolution and subsequent passivating film formation. This film is then ruptured by further plastic strain and the process repeats. This suggested that the mechanism should show transgranular propagation of the fracture. Fractographic studies confirmed this aspect; however, initiation and early stages of propagation showed clearly intergranular features which can be interpreted in terms of the pre-existing path theory for initiation and early stages of propagation.

Effect of temperature and concentration.—It is interesting to compare here the voltammograms of unstrained and strained electrodes as a function of temperature and concentration.

In 1M NaOH, for temperatures below 65°C , strained specimens in the elastic range of A516 steel gave almost the same pattern of voltammograms as that obtained with stable electrodes: the dominating peak was peak III. In presence of plastic deformation, peak II was well identified and the peak current is enormously increased, while peak III was increased by a factor of 3 and remained the most important. For temperatures above 65°C , no major difference was observed between the evolution of cyclic voltammograms for unstrained and elastic deformed electrodes; as in the case of stable electrodes, we noted the disappearance of peak III in spite of the increase of peak II, and this latter was not sensibly changed because of an elastic deformation. In the plastic deformation region, the peak current II was even doubled. This means that plastic deformation, like temperature, has an important influence on the active-passive behavior of steel, which is believed to be closely related to SCC phenomena.

For more concentrated solutions of NaOH (7.73M, for example), the observations made above for stable and deformed (elastic or plastic) electrodes were verified. Below 65°C , in this concentrated solution peak III current was decreased by a factor of 2; meanwhile, peak II current was double or even tripled with respect to that obtained in 1M; however, the peak III remained higher than peak

II. It can be stated that the difference in height between the peaks current II and III was reduced as a function of the increase in concentration of NaOH. This was true for stable or strained (elastic and plastic) specimens. At temperatures above 65°C , the tendency in 7.73M NaOH was the same as that in 1M NaOH: peak II increased while peak III disappeared. The evolution of peak II was very important with a plastic deformation (doubled) like that found in dilute solution of NaOH (1M).

The combined effect of concentration and temperature have, as it is expected, an influence on the peaks current, i.e., on the mechanisms of caustic embrittlement. An increase in concentration from 1 to 7.73M and an increase in temperature from 80° to 105°C led to an increase of peak II by a factor of 1.5. This was appreciable, since peak II was already important at 80°C . This was observed for stable or strained electrodes.

Slow strain-rate SCC studies.—Correlation between the voltammetric behavior of iron at different temperatures (Fig. 2) and temperature dependent caustic cracking susceptibility of A516 steel (Fig. 3 and 4), which validates the above hypothesis, will be shown below by using slow strain-rate technique.

The potential of maximum susceptibility of A516 steel to stress corrosion cracking (13) in 7.73M NaOH was found to be -733 mV. This potential was imposed during slow strain-rate ($2.6 \times 10^{-6} \text{ s}^{-1}$ and 10^{-5} s^{-1}) experiments at different temperatures. The results obtained in 7.73M NaOH are shown in Fig. 3. For both strain rates, the reduction of the surface area (ROA) of the specimen decreased (the susceptibility of A516 steel to SCC increased) with temperature. The first monotonic drop in ROA is followed by a distinctive downward curvature which leads to a new ROA vs. T line. In effect, the overall plot may be approximated by two straight lines with different slopes, the second (high temperature one) being more negative than the first. Similar results were obtained in 1.0M NaOH, but the SCC effects were less pronounced and the curvature of the ROA vs. temperature plot was less marked.

It should be noted that the intersection of the ROA vs. T straight lines (the change of the slope) occurs in the temperature region where the peaks III and V practically dis-

Fig. 3. Effect of temperature on the reduction of area of steel A516 (PVQ) in 7.73M NaOH. Potential imposed $E = -733$ mV. v means the rate of deformation.

Fig. 4. Portion of Gage length of steel A516 (PVQ) at fracture location in 7.73M NaOH. Potential-imposed E : -733 mV. Rate of deformation: $2.6 \times 10^{-6} \text{ s}^{-1}$. (a): $T = 35^\circ\text{C}$. (b): $T = 55^\circ\text{C}$. (c): $T = 85^\circ\text{C}$. (d): $T = 105^\circ\text{C}$.

appeared from the voltammograms of the nonstrained electrodes (Fig. 2 and test). Therefore, the inference made above that the mechanism of the electrochemical contribution to SCC is different below and above a critical temperature ($50^\circ\text{--}65^\circ\text{C}$) is substantiated not only by the correlation of the industrial vs. voltammetric data [Ref. (6) and (7) and Fig. 2], but also by the interdependence of the SCC laboratory test results and the voltammetric behavior of iron (Fig. 3 vs. Fig. 2).

The reduction of the surface area of specimens investigated in NaOH solutions below 65°C , and especially at 25°C , was close to that observed in air, which indicates the virtual absence of SCC.

Figure 4 shows different types of fractures of A516 steel in 7.73M NaOH solution. For temperatures below 65°C , the ductile tensile fracture was the classic "cup and cone" failure, with considerable necking characteristic of plastic deformation prior to the failure. Similar fractures were observed during tests carried out in air. As the temperature increased ($t > 65^\circ\text{C}$), numerous secondary cracks in the reduced section were seen (Fig. 4). At 105°C , those cracks, which are indicative of severe SCC failure, became deeper and wider. Decrease of the strain rate from 10^{-5} to $2.6 \times 10^{-6} \text{ s}^{-1}$ caused a measurable increase in the number of the secondary cracks as well as contributed to the larger reduction of the surface area and of the elongation of the specimens.

Conclusions

1. No major differences were observed in the voltammograms of unstrained and elastic-strained electrodes. With plastic deformation the shape of the voltammograms remained the same, but peak II is wider for strained electrodes, especially at high temperatures and concentrated solutions.

2. The temperature has an influence on the evolution of the cyclovoltammograms of iron in caustic solutions. With an increase in temperature, the peak II increased while peak III decreased, but this latter stayed the most important peak for temperatures below a critical one (55°C for iron and 65°C for A516 steel). Above this critical zone of temperatures, peak III disappeared and that is accompanied by a marked evolution of peak II.

3. The increase in concentration of caustic solutions gave the same influence on the peaks II and III as the elevation of temperature. The combined influence of temperature and concentration showed that peak II was quite important at concentrated solutions of NaOH at 105°C .

4. There is a certain correlation between the cyclic voltammogram of steel (strained or not) and its resistance to caustic cracking. A critical region of temperatures is observed for the examined steel where the cyclic voltammograms showed disappearance of the peaks III and V and broadening of the anodic peak II in the same time of the appearance of fragile cracking accompanied by surface reduction, elongation decrease, and secondary cracks. The absence of peak III and V and the increase of peak II above a critical region of temperatures marked the susceptibility of the metal to SCC.

ABSTRACT

The electrodeposition of polycarbazole by passing a constant current through a solution of carbazole in *N,N*-dimethylformamide containing 0.1M tetra-*n*-butyl ammonia perchlorate has been followed using multiple beam laser interferometry. The deposited film was used as an electrode in the electrochemical oxidations of Fe^{2+} , $\text{Fe}(\text{CN})_6^{4-}$, and hydroquinone (H_2Q). While the oxidation of H_2Q proceeds in a diffusion-controlled manner, the others show interesting differences.

In previous papers, we reported (1, 2) following the deposition of a relatively thick polypyrrole layer on gold by laser interferometry. The fringe patterns yielded refractive index gradients which were easily converted to concentration-time/distance profiles. The Nernstian boundary layer thickness becomes obvious and measurable, as does, from its growth, the progress and path of electrolysis.

In continuation of this type of approach to polymer-coated electrodes, we have investigated the electrodeposition of polycarbazole (another of the depositable conducting polymers) using multiple beam laser interferometry to study the behavior of the electrodeposited film as an electrode material. For this purpose, the electrochemical oxidations of Fe^{2+} , $\text{Fe}(\text{CN})_6^{4-}$, and hydroquinone (H_2Q) were carried out at a bare platinum surface and also on a polycarbazole film deposited on the platinum. The choice of electroactive materials was based on consideration of the charge on the ions or molecule. At the film-covered electrode, the oxidation of charged ions produces concentration-distance or concentration-time profiles showing significant deviation from those of the bare electrode. The above profiles for H_2Q show very little deviation at the two electrodes. These deviations have been analyzed in terms of permeability of the electronically conducting film.

Experimental

The experiments were carried out in a Fabry-Perot Interferometer giving Fizeau-type multiple-beam-wedge fringes, which is similar in design to cells previously reported (3, 4). The cell was 1.39 mm thick, and the electrodes, which were made of platinum, were separated by 6 mm. The electrodes were made by sputtering platinum on semicircular glass disks (3 cm long and 1.3 cm radius). The disks were soaked in chromic acid for about 4h to remove grease, etc. They were then washed with water and alcohol. The curved regions and the flat portions of the plates were covered with cellophane tapes, leaving only the long side of the disk to receive the sputtered platinum. To make electrical contact to the platinum, a small quantity of silver epoxy was painted at one of the edges of the sputtered disks. The thickness of the platinum layer on the glass disk was 100Å.

The experimental arrangement consisted of a Spectra-Physics Model 122 He-Ne single-mode laser as light source, a Sony Model AVC-3210 video camera, a Sony AV-3650 half-inch video recorder, and a 26 in. monitor. The interferometer was mounted on a brass support between the pole pieces of the electromagnet.

Electrodeposition of polymers was carried out galvanostatically at several c.d.'s: 0.10 mA cm⁻², 0.55 mA cm⁻², 1.10 mA cm⁻², 1.52 mA cm⁻², 3.20 mA cm⁻², and 7.6 mA cm⁻². The fringe system was recorded and analyzed at 30,

60, 120, 180, 240, 360, and 900s of electrolysis, and the complete experiment was video taped for replay and examination.

N,N-dimethylformamide (DMF) was obtained from MCB (ACS reagent-grade) and was used as received. Tetra-*n*-butyl ammonium perchlorate (South Western Analytical Chemicals) was dried under vacuum for 24h before use. The hydroquinone (J. T. Baker) sample was recrystallized from hot water before use. FeSO_4 and $\text{K}_4\text{Fe}(\text{CN})_6$ were of analar-grade chemicals. Double distilled water was used in all the experiments.

The refractive index of the solutions was measured using a Bausch and Lomb precision Abbe refractometer thermostated at 25°C.

The electrodeposition (5) of polycarbazole was carried out by passing a constant current through 60 mM carbazole solution in DMF containing 0.1M tetra-*n*-butyl ammonium perchlorate with the anode and cathode positioned in a vertical (V-position) configuration. The deposit was washed with acetone and air dried before use. For interferometric studies, the cell is filled with about 2 ml of the solution after mounting the electrodes in the desired configuration.

All the experiments reported here were carried out in a deep-vertical (V) or cathode over anode (C/A) configuration.

Results and Discussion

Electrodeposition of polycarbazole.—The electrochemical oxidation of carbazole at a platinum anode produces a golden yellow polymeric film of polycarbazole on the electrode at c.d.'s of about 0.50 mA cm⁻². Figure 1 shows the impressed voltage vs. current density plot, and it reveals a plateau from 0.50 to 2.50 mA cm⁻². The deposition of the polymer was also carried out by raising the c.d. beyond 2.50 mA cm⁻², but it produces deleterious effects on the film—it easily peels off the electrode. The deposit obtained at these higher c.d.'s has purple streaks on the upper middle portions of the electrode. This can be prevented by applying a magnetic field during the deposition process. The film thickness has been varied by controlling the duration for which the electrolysis was carried out. All the electrochemical experiments reported here were carried out by controlling the surface excess at 7.24 μmol cm⁻² giving a nominal thickness of 0.25 mm.

The deposition of the polymer was followed by multiple beam laser interferometry. Figure 2 shows the interferogram obtained during an electrolysis at 0.58 mA cm⁻². A smooth downturn of the fringes was observed at the anode indicating a decrease in refractive index of the medium in that region. At this electrode the oxidation of carbazole occurs to produce a cation ($n = 1$), which upon polymerization produces the film (6) and a decrease in concentration and refractive index. The complementary

Fig. 1. Potential-current plot for the electrodeposition of polycarbazole at a platinum electrode. The voltage was measured at 360s of electrolysis upon passing a constant current.

reaction at the cathode (during the above electrolysis) was the reduction of carbazole to its anion radical ($n = 1$) (7). Since the anion radical is known to react rapidly with the medium to regenerate carbazole, the refractive index of the medium in this region was not significantly altered during the electrolysis except at the highest c.d.'s.

Since the deposition of the polymer occurred at the anode, the fringes at this electrode have been analyzed in detail. The fringe shift (F) during this deposition varied linearly at the electrochemically active surface with the square root of electrolysis time suggesting a diffusion-controlled oxidation as expected from "Sand's behavior" (8) (see subsequent discussion). This linearity in F vs. \sqrt{t} breaks down at c.d.'s $> 2.5 \text{ mA cm}^{-2}$ because of the onset of convection in the electrochemical cell. A plot of fringe

Fig. 2. The interference patterns observed at the anode during the electrolysis of 60 mM carbazole in N,N -dimethylformamide containing 0.1M tetra- n -butyl ammonium perchlorate. The fringe pattern was recorded at 420s. Left side is the cathode and right side is the anode.

shift as a function of c.d. at two selected periods of electrolysis shows the pattern in Fig. 3. In the higher c.d. region, the fringes are not well defined beyond 30s of electrolysis. At these c.d.'s, the deposits on the electrode were brittle. The convective flow which occurs during the deposition was also followed using holographic interferometry (9). This flow resulted in violet streaks appearing on the yellow deposits. The origin of the color is not clear, but it may be due to the free radical's getting trapped on/in the yellow polymer.

The deposition of the polymer was also conducted in magnetic fields of 1.0, 3.0, and 6.0 kG with a view to obtaining smooth deposits (10). The interferometric fringes were smoother in the presence of a magnetic field, and the deposition of the polymer was free from violet streaks. Scanning electron micrographs (SEM's) were taken of the samples obtained in the magnetic field. Figure 4 shows the SEM picture obtained in a 6.0 kG magnetic field.

The interferometric fringes in the magnetic field were compared with the zero field patterns. The concentration-distance profiles during electrolysis are shown in Fig. 5. The negative ΔC values at zero field indicates the existence of strong convection in the cell.

Behavior of polycarbazole electrode towards electrolytic oxidations.—The Pt/polycarbazole electrode response towards the oxidation of H_2Q was examined in aqueous sulfuric acid (1M) and in phosphate buffers of pH 6.0. Galvanostatic electrolysis produces interferometric patterns of the conventional types (11, 12), with the fringes at the anode showing a downturn due to decrease in refractive index in that region. The growth of the Nernst diffu-

Fig. 4. A scanning electron micrograph recording of an electrodeposited polycarbazole. $i_0 = 0.55 \text{ mA cm}^{-2}$. Duration of electrolysis: 1260s. Magnetic field strength = 6.0 kG. Magnification: 2000 \times .

Fig. 5. The relative concentration changes during electrolysis of 60 mM carbazole in DMF containing 0.1M tetra-n-butyl ammonium perchlorate at the anode. The top curve is obtained in a magnetic field of 3 kG. The lower curve was obtained at zero field. $i_0 = 1.17 \text{ mA cm}^{-2}$. The profile refers to an elapsed time of electrolysis of 420s.

sion layer during this electrolysis proceeds steadily until the electrolysis of the supporting electrolyte begins. The fringe shift (F) in a galvanostatic electrolysis is given by

$$F_{(0,t)} = \frac{2I}{nF} \cdot k \sqrt{\frac{t}{11D}} \quad (0.546) \quad [1]$$

where n is the number of electrons consumed at the electrode, F is the Faraday, and D is the diffusion coefficient of the molecule. k is defined as

$$k = \frac{2ta}{\lambda} \quad [2]$$

where t is the thickness of the cell, a is the correlation constant between refractive index and concentration of H_2Q , and λ is the wavelength of laser light (6328Å). A plot of F vs. \sqrt{t} for the electrolysis of H_2Q is shown in Fig. 6. With a view to comparing its behavior at an uncoated electrode, the electrolysis of H_2Q solutions were also carried out at a platinum electrode. The data obtained in these experiments are also shown in Fig. 6. The results obtained at the two electrodes are comparable to one another but have different slopes consistent with the c.d.'s used.

The growth of the Nernst diffusion layer proceeds smoothly during electrolysis of H_2Q , and the relative changes in concentrations from the electrode surface to the bulk were followed by recording the fringes at different times. Figure 7 shows the plot of relative concentrations as a function of the distance from the electrode surface at Pt/polycarbazole and Pt. The concentration changes are very similar at the two surfaces, suggesting that H_2Q is oxidized at our near the polymer surface.

Fig. 6. The plot of maximum fringe shift vs. \sqrt{t} during electrochemical oxidation of 60 mM hydroquinone in 1.0M H_2SO_4 .

Fig. 7. The relative changes in concentration of H_2Q as a function of distance from the electrode at 360s of electrolysis of 60 mM H_2Q in 1M H_2SO_4 at Pt and platinum covered with polycarbazole film (Pt/PC).

The impressed voltage changes with time during an electrolysis of H_2Q at a Pt/polycarbazole electrode are shown in Fig. 8 for two selected c.d.'s of 0.294 or 0.588 mA cm^{-2} . These plots for the electrolysis of H_2Q at a Pt anode are very close to identical. The similarities observed at the two electrodes suggest the mechanisms of oxidation of H_2Q are following identical pathways at the two types of electrodes.

The electrochemical oxidations of inorganic ions such as aquo Fe^{2+} and $\text{Fe}(\text{CN})_6^{4-}$ at Pt/polycarbazole follow different pathways from bare Pt. The oxidation of Fe^{2+} in 1M H_2SO_4 in the interferometric cell produces an upturn of the fringes at the anode, indicating an increase in the refractive index of the medium. The counterelectrode process during the electrolysis was the reduction of hydrogen ion. At low c.d.'s ($< 0.55 \text{ mA cm}^{-2}$), the production of

Fig. 8. The impressed voltage vs. time plot during an electrolysis of 60 mM H_2Q in 1M H_2SO_4 at platinum and Pt/PC electrodes. The impressed current density was kept constant at 2.94 or 5.88 mA cm^{-2} .

Fig. 9. A plot of maximum fringe shift vs. square root of time of electrolysis of 0.50M FeSO_4 in 1M H_2SO_4 at a Pt or Pt/PC anode. The current density was kept constant at 0.58 mA cm^{-2} .

hydrogen was slow, and hence no significant convection (13) was noticed in the central part of the cell. The fringe shift at the Pt anode varies linearly with the square root of the time of electrolysis, as shown in Fig. 9, suggesting a diffusion-controlled behavior. The electrolysis carried out with higher c.d.'s showed deviations from linearity due to the onset of hydrodynamic flows produced in the cell. The results obtained at the Pt/polycarbazole anode showed two significant deviations: (i) the fringe shift at this electrode was not linear with $t^{1/2}$ during the progress of electrolysis and (ii) the fringe shift at longer times (>240s) was almost constant during extended periods of electrolysis.

Figure 10 shows the concentration-distance plots during the electrolysis of FeSO_4 at Pt and Pt/polycarbazole anodes. The extent to which the region around the electrode is depleted differs in the two situations. While at a Pt surface the depletion region increases with continuation of the electrolysis, this growth was not significant with Pt/polycarbazole. This difference is attributed to the flux differences at the two electrodes: the flux of Fe^{2+} at the polymer surface and the flux within the polymer.

The electrolysis of $\text{K}_4\text{Fe}(\text{CN})_6$ in aqueous KCl medium between two Pt electrodes is well documented (14). The oxidation of $\text{Fe}(\text{CN})_6^{4-}$ occurs at $E_{\text{pa}} = 0.36\text{V vs. SCE}$ and consumes 1e in this electrolysis. The galvanostatic electrolysis of $\text{K}_4\text{Fe}(\text{CN})_6$ in the Fabry-Perot interferometer produces fringe patterns like those shown in Fig. 10. The

analysis of the fringes at the anode shows the fringe shifts are proportional to the square root of time (see Fig. 11). However, with Pt/polycarbazole as the anode in the experiments, the above plots show deviations from those for Pt. At higher c.d.'s (>1.10 mA cm^{-2}), the fringe shift was constant beyond 120s of electrolysis in a way similar to that observed with Fe^{2+} . This constancy was not observed at Pt in either case.

The diffusion gradients for H_2Q are established from the beginning of the electrolysis and progress throughout the electrolysis, indicating oxidation at or near the polymer surface, the porous conducting polymer appearing to have an areal resistance of about $40 \Omega \text{ cm}^{-2}$. A contrasting situation develops when the ions [Fe^{2+} or $\text{Fe}(\text{CN})_6^{4-}$] pass into the polymer film. Part of the diffusion layer appears to be inside the polymer layer in contrast to the neutral H_2Q results. The film thus behaves like a polyelectrolyte where the presence of negative and positive charges in the film brings out the above type of behavior. It should also be remembered that these films were produced under low c.d. or high magnetic field, i.e., low concentration polarization, and should have reasonable electronic conductivity. Hence, simple ions could be discharged at various depths in the polymer, including at the electrode itself. The concept of just part of the concentration gradient's being inside the polymer layer does not totally explain the $\text{Fe}^{2+}/\text{Fe}(\text{CN})_6^{4-}$ results, although in Fig. 10, adding the thickness of the polymer layer (0.25 mm) to the observed diffusion layer (0.15 mm) gives 0.4 mm, a value very comparable to the bare electrode diffusion layer thickness. It seems more likely that the polymer is also behaving to some extent as a polyelectrolyte.

Fig. 10. The relative concentration changes during electrolysis of 0.50M FeSO_4 in $1\text{M H}_2\text{SO}_4$ at Pt anode or Pt/PC anode plotted as a function of distance from the electrode.

Fig. 11. A plot of maximum fringe shift vs. square root of time of electrolysis of $0.05\text{M K}_4\text{Fe}(\text{CN})_6$ in 1M KCl at an impressed constant current of 0.58 mA cm^{-2} .

Electrodeposition of CdTe Thin Films

R. N. Bhattacharya and K. Rajeshwar*

Department of Chemistry, The University of Texas at Arlington, Arlington, Texas 76019-0065

ABSTRACT

Cadmium telluride thin films were fabricated on Ti and Nesatron® substrates by electrodeposition and characterized by x-ray diffraction, scanning electron microscopy, energy dispersive x-ray analyses (EDAX), optical transmission measurements, and photoelectrochemical (PEC) studies. The deposition-bath preparation procedure was slightly modified from the literature method to permit initial speciation of TeO₂ and thereby increase the loading level of Te in the film. New data are presented on the electrochemistry of the deposition process and on the cyclic voltammetric behavior of TeO₂ containing electrolytes in the pH range from ~0.7 to 11.0. The films after suitable annealing in an Ar atmosphere show x-ray diffraction behavior consistent with a hexagonal structure. Data from EDAX show that the Cd/Te ratio in the film is sensitive to the annealing process. Concomitantly, the conductivity also changes from p-type to n-type, as shown by PEC measurements on the films containing a protective α -PbO₂ coating in contact with alkaline polysulfide electrolytes. Finally, some preliminary data are presented on PEC cells based on these CdTe thin films in a nonaqueous electrolyte system comprising the ferrocene/ferrocenium ion redox couple.

Of the emerging materials for solar cell applications, CdTe is one candidate which has received much attention in recent years (1). Two features in the optical characteristics of this material are particularly attractive for photovoltaic conversion of sunlight: (i) its energy bandgap of 1.5 eV, which provides an optimal match with the solar spectrum and thus facilitates its efficient utilization and (ii) the direct mode of the main optical transition which results in a large absorption coefficient and in turn permits the use of thin layers (1-2 μ m) of active material.

Electrodeposition methods have been successfully employed for the fabrication of cadmium chalcogenide thin films in general (2) and CdTe in particular (3). In principle, both anodic and cathodic deposition are possible, although more precise control of film stoichiometry is obtained with the latter approach. The conditions to be met to achieve cathodic deposition of compounds have been analyzed by a previous author (4). The key factor here is the extent to which the deposition potential of the less noble component (*i.e.*, Cd in this case) is shifted relative to that of the noble species (*i.e.*, Te in this case) by the free energy gained from compound formation. For CdTe, the difference in standard potentials (0.954V) is greater than ($G_{\text{CdTe}}/298/2F$) (G_{CdTe} = free energy of formation of CdTe) such that Cd remains the potential-determining species throughout the stability range of the compound (3a, 4). Parametric variables for controlling film stoichiometry have been established by previous authors, and both n- and p-type layers have been electrodeposited (3a, 3b).

Information on the characteristics (structural, morphological, compositional, and electronic) of electrodeposited CdTe thin films, effect of thermal treatment, and electrochemistry involved in the deposition process, however, is limited in the literature (3a, 3b); therefore, we have undertaken a systematic study of these aspects in our laboratory. Our findings to date are presented in this paper along with some preliminary results bearing on photoelectrochemical (PEC) applications.

Experimental

Substrates.—Substrates for CdTe electrodeposition were either Ti or Nesatron® glass from commercial sources. These substrates were carefully degreased and rinsed with acetone followed by air-drying. In the case of Ti, the substrates were then polished by garnet finishing paper and etched with 10% HF. They were then preheated in an Ar stream (containing ~0.5% O₂) at ~650°C till a change in color to sky-blue was noted. This procedure was found to be essential for good adherence of the films.

Chemicals.—All chemicals were of Analar® or Pura-tronic® grade purity and were used as received. Deionized water was used in all cases.

* Electrochemical Society Active Member

Electrodeposition bath and procedure.—The deposition bath was slightly modified from the one originally used by Panicker *et al.* (3a), which consisted of CdSO₄ (1M) and TeO₂ (10⁻⁵-10⁻³M), the pH being adjusted to 2.5-3.0 with H₂SO₄. We speciated the TeO₂ initially with NaOH (~pH 9-10) and then brought the solution into the acidic pH range (1-3) by slow addition of H₂SO₄. The initial solution in NaOH permits introduction of a higher TeO₂ conc. in the bath for the growth of p-type films.

Nominal deposition potentials ranging from -0.65 to -0.85V (*vs.* SCE)¹ and current densities in the range ~0.3-0.5 mA/cm² were employed. A conventional three-electrode cell was employed, the counterelectrode being either a Pt spiral or a glassy C electrode. In some cases, a twin-anode deposition system [comprising an active Te anode, *cf.* Ref. (3a)] was also used. All depositions were carried out at temperatures above ambient (40°-60°C) since microscopic examination of room-temperature films showed them to have poor physical characteristics (grain size and morphology) (see below). This observation is consistent with previous findings (3b). No significant differences were observed for various films grown within the above temperature window such that further differentiation is not made for the results described below.

Photoelectrochemical (PEC) characterization.—In view of the fact that CdTe is not photoelectrochemically stable in aqueous solutions, two methods were adopted for their PEC characterization. In the first one, a coating of α -PbO₂ (~1000Å thick) was deposited on the CdTe film surface by electroless deposition from a bath containing 1 × 10⁻²M PbOAc, 1.2M NH₄OAc, and 6 × 10⁻²M K₂S₂O₈ according to procedures described elsewhere (5). These coated films were tested in alkaline polysulfide electrolyte. In the second approach, a nonaqueous electrolyte comprising methanol, tetrabutyl ammonium perchlorate as the supporting electrolyte and ferrocene/ferrocenium ion as the redox species was employed. In either case, an ELH tungsten-halogen lamp was used for illuminating the CdTe film. Three-electrode geometry comprising a Pt pseudoreference electrode was used for these measurements.

Instrumentation.—A Princeton Applied Research (PAR) electrochemistry system consisting of a Model 173 potentiostat/galvanostat, a Model 175 Universal Programmer, and a Model 179 digital coulometer was employed for electrochemical deposition and PEC analyses. X-ray diffraction data were obtained on a Rigaku Rotaflex Model RU 200 powder diffractometer using CuK α radiation. Energy dispersive analysis of x-ray fluorescence (EDAX) and scanning electron microscopy (SEM) were carried out on a Philips Model P505 unit.

Optical measurements on CdTe thin films were performed on a Cary Model 219 spectrophotometer. These

¹ All potentials herein are quoted w.r.t. SCE unless otherwise specified.

Fig. 1. Variation of rest potential with pH for a Pt wire in contact with the CdTe plating bath at 25°C.

measurements were performed in the conventional transmission mode utilizing Nesatron substrates. Film thicknesses were measured on a Sloan Dektrak instrument (Sloan Technology Corporation, Santa Barbara, California).

Results and Discussion

Deposition bath electrochemistry.—Figure 1 illustrates the variation in rest potential with pH for a Pt wire in contact with 1M CdOAc and $1.0 \times 10^{-2}M$ TeO₂ at 25°C. Protonation of the TeO₂ species is believed to be the major potential-determining equilibrium and the measured slope of 55 ± 5 mV would be consistent with the following equilibrium (6)

Existence of species of the type HTeO₃⁻ and TeO₃²⁻ (see below) is predicated by the amenability of TeO₂ to speciation with NaOH.

Figure 2a contains cyclic voltammograms for a $5.0 \times 10^{-4}M$ solution of TeO₂ at pH 2.4 at varying scan rates in the range 100-500 mV/s. A set of quasireversible anodic and cathodic waves is observed. The peak separation is a sensitive function of scan rate (see inset). The species responsible for this behavior do not seem to undergo

Fig. 2. a(left): Cyclic voltammograms for Pt microelectrode in a $5.0 \times 10^{-4}M$ soln of TeO₂ at pH 2.4. The inset shows the variation of peak separation, ΔE_p , and peak current ratio, i_c/i_a with scan rate, ν . b(right): Plots of peak current, i_p for the anodic and cathodic waves in Fig. 2a vs. $\nu^{1/2}$.

Fig. 3. Cyclic voltammogram (scan rate: 100 mV/s) for a Pt microelectrode in a $2.0 \times 10^{-2}M$ solution of TeO₂ at pH ≈ 0.7 . The dashed line corresponds to data similar to those in Fig. 2a (see text).

complicating chemical reactions either preceding or following charge transfer since the peak current ratio remains sensibly close to unity at all scan rates investigated (cf. inset). Additionally, adherence to the classical linear i_p vs. $\nu^{1/2}$ behavior (i_p = peak current, ν = potential scan rate) is observed for this electrochemical reaction (cf. Fig. 2b) confirming the diffusion-limited characteristic of the charge-transfer process. Based on these data, it seems reasonable to attribute the observed voltammetric behavior to sluggish redox reactions (at least on the Pt surface) involving dissolved HTeO₃⁻/HTeO₄⁻ species in the bulk electrolyte. If instead of terminating the scan at 0V, the potential is swept to $\sim -0.4V$, a reduction peak becomes clearly evident with concomitant development of a black deposit on the electrode surface (cf. Fig. 3). This deposit is stripped from the electrode on the positive-going scan. This behavior is clearly due to the deposition of Te as described by either of the following reactions.

Note that the pH dependencies of the reduction potential for these two reactions are different (-0.04 and $-0.07V$ per unit change in pH, respectively). The two species

HTeO_3^+ and HTeO_3^- presumably coexist in equilibrium via a reaction of the type (6)

Complications in the redox behavior of HTeO_3^- species (Eq. [1]) from this equilibrium could explain the features in the cyclic voltammograms shown in Fig. 2a.

In basic electrolytes, an overall shift in redox behavior to negative potentials is observed (cf. Fig. 4). The predominant Te species in the basic pH range are probably TeO_3^{2-} and TeO_4^{2-} (cf. Eq. [1]). Reduction of either of these species, possibly via reactions of the type represented by Eq. [5] and [6]

is sluggish on Pt as evidenced by the fact that voltammograms analogous to that in Fig. 3 could not be observed down to very low scan rates.

Film characterization.—Optical properties.—Figure 5 presents the optical absorption characteristics of representative CdTe thin films on Nesatron substrate for varying film thicknesses in the range 1000–3500 Å. Data are shown in terms of both absorbance vs. wavelength (Fig. 5a) and transmittance vs. wavelength plots (Fig. 5b). These measurements enable computation of the absorption coefficient, α , via the relationship $\alpha = (d_2 - d_1)^{-1} \ln T_1/T_2$ where d and T are the film thickness and percentage of transmittance, respectively (7). Plots of α^2 vs. $h\nu$ will then yield the energy bandgap, E_g . Two such plots are shown in Fig. 6 using α values computed from 1000 and 3300 Å (Fig. 6a) and from 1000 and 3600 Å (Fig. 6b), respectively. The value extrapolated from the plots for E_g is 1.41 ± 0.01 eV; this value is somewhat lower than that quoted for single-crystal CdTe [1.5 eV, cf. Ref. (1)]. Two reasons can be put forth for the occurrence of nontrivial absorption at energies below E_g ; namely, the presence of (i) free Te in the deposit and/or (ii) states in the bandgap arising from significant disorder in the thin film relative to the single-crystal case. The observation of pronounced “tailing” in optical absorption curves for CdTe thin-films prepared in our laboratory by the electrodeless method seems significant in this regard (8). The presence of free Te in these films was established by x-ray diffraction (8), although free Te does not manifest to the same extent in similar data on our electrodeposited CdTe films (see below). It is, therefore, possible that both factors are important here.

X-ray diffraction—As-deposited films both on Ti and Nesatron substrates were amorphous as shown by x-ray diffraction. Annealing of these films at temperatures in the range 600°–650°C in an Ar atmosphere enabled development of a hexagonal crystal structure ($a = 4.58$ Å and $c = 7.50$ Å). Typical x-ray diffractograms are shown in Fig. 7a and 7b for CdTe thin-films electrodeposited on Nesatron and Ti, respectively. Relevant analyses based on these data are exemplified in Table I for the Ti substrate. Low temperature (< 350°C) annealing of these films produced the cubic modification in essential agreement with the findings of previous authors (3a, 3b).

Fig. 5. a(top): Plots of absorbance vs. wavelength for electrodeposited CdTe thin films on Nesatron substrate. Parameter is film thickness. b(bottom): Plots of percentage of transmittance vs. wavelength for electrodeposited CdTe films on Nesatron substrate. Parameter is film thickness.

EDAX/SEM.—Figures 8a and 8b show typical EDAX data on a CdTe thin film on Nesatron and Ti substrates, respectively. Both the observed peak patterns and the computer fit to these data based on the peak assignments to individual elements are shown in the figure. The “background” signals from the Nesatron substrate interfere with semiquantitative estimates of the relative Cd:Te ratio in the film (cf. Fig. 8a). Such estimates for the Ti case, however, yield an average ratio of ~45:55.

Figure 9 shows the SEM photographs of a representative CdTe thin film on Nesatron at two different magnifications. The film morphology is fairly typical of these

Fig. 4. Cyclic voltammogram (scan rate: 200 mV/s) for a Pt microelectrode in a 5.00×10^{-4} M soln of TeO_2 at $\text{pH} \approx 11$.

Fig. 6. Plots of α^2 (α = absorption coefficient) vs. $h\nu$ for electrodeposited CdTe films using data from 1000 and 3300 Å films (Fig. 6a) and from 1000 and 3600 Å films (Fig. 6b).

Fig. 7. Partial x-ray diffractograms for electrodeposited CdTe thin films on (curve a) Nesatron and (curve b) Ti. The films were thermally annealed prior to measurement.

materials (3a, 3b), although its sensitivity to substrate material is quite striking (cf. Fig. 9 and 10).

Photoelectrochemistry.—Liquid contacts offer a convenient means of assessing changes in film stoichiometry and corresponding variations in electronic conductivity brought about by prior treatment. The utility of PEC methods for monitoring such changes is illustrated by typical data in Fig. 11. The data in Fig. 11a are for an as-deposited CdTe thin film (i.e., no thermal treatment) on Ti substrate, whereas the curves in Fig. 11b pertain to another film subjected to prior thermal treatment (~600°C in Ar atmosphere for ~50 min). In both cases, the CdTe film surface had a protective coating of α -PbO₂ to prevent it from undergoing PEC corrosion (see above). Alkaline polysulfide was used as the redox electrolyte. The dark current flow shown in Fig. 11a and 11b arises from the conducting α -PbO₂ overlayer. Electronic carriers in the underlying CdTe substrate serve only to “bias” the conductivity of this overlayer (9). Consider Fig. 11a. Bandgap illumination of the CdTe layer creates electron-hole pairs. A large fraction of these pairs recombine. Some of the photogenerated carriers, however, traverse the field at the CdTe/PbO₂ junction and augment the charge transfer processes occurring at the PbO₂/electrolyte interface. The enhancement of cathodic current flow at this interface on illumination of CdTe, minimal changes in the anodic regime, and the positive shift in the

rest potential of the CdTe/PbO₂ electrode on illumination (cf. Fig. 11a) are all consistent with the presence of a p-type CdTe film underneath the PbO₂ overlayer. On thermal treatment, the Cd/Te ratio is increased (a result borne out by EDAX measurements) and the nonstoichiometry in the resultant film renders it n-type (cf. Fig. 11b). Note the negative shift in the rest potential for this film

on illumination—a behavior consistent with n-type conductivity in the underlying semiconductor layer (9). The lack of asymmetry in the current voltage characteristics on illumination (compare Fig. 11a and 11b) is best explained by the presence of a “leaky” n-CdTe/PbO₂ interface.

The PEC method of ascertaining carrier type in semiconductor thin films as described above would be partic-

Fig. 10. SEM photograph of an electrodeposited CdTe thin film on Ti. Magnification same as in Fig. 9b.

ularly useful in cases wherein more conventional Hall or hot-probe measurements would be precluded by the high conductivity of the substrate [cf. Ref. (3b)].

Fig. 11. Steady-state current-voltage scans for electrodeposited CdTe thin films on Ti in polysulfide redox electrolyte (Na₂S/NaOH/S, 3M each before (a, left) and after (b, right) thermal treatment of the films. Data are compared in each case in the dark and under illumination with white light from a tungsten-halogen lamp (uncorrected light intensity $\approx 60 \text{ mW/cm}^2$). The electrolyte was quiescent and the potential scan rate was 100 mV/s. The films had a protective coating of $\alpha\text{-PbO}_2$ (see text).

Fig. 12. Photoelectrochemical behavior in chopped white light (80 mW/cm^2) of an electrodeposited CdTe thin film (Ti substrate) in methanol/TBAP (0.5M) electrolyte containing ferrocene/ferricenium ion redox couple (0.2M/0.5 mM). The film area (uncorrected for surface roughness) was 1 cm^2 . The film was subjected to prior thermal treatment. The inset shows for comparison the corresponding behavior of an n-CdTe single crystal (0.2 cm^2) at 60 mW/cm^2 . In both cases, a Pt pseudoreference electrode was employed, and the potential scan rate was 100 mV/s.

Photoelectrochemical cells.—CdTe is characterized by its extreme susceptibility to PEC corrosion in aqueous electrolytes (see above), and the problem is even worse in thin films relative to the single-crystal case (10). In our search for alternative redox electrolytes, we have found the methanol/tetrabutyl ammonium perchlorate/ferrocene/ferricenium ion system (11) to be effective in suppressing PEC corrosion. Typical measurements on three-electrode PEC cells based on this electrolyte are shown in Fig. 12; both for an electrodeposited CdTe thin film and an n-CdTe single crystal for comparison (*cf.* inset). Note that the PEC behavior is consistent with n-type behavior of the film after thermal treatment (*cf.* Fig. 11b). The solar cell parameters for this nonoptimized cell geometry are short-circuit current density (1.5 mA/cm^2) and open-circuit potential ($\sim 300 \text{ mV}$). The fill factor is much inferior to the single-crystal case, indicating substantial degradation in cell efficiency through carrier recombination. Thus the performance characteristics of these films in terms of solar cell applications are admittedly modest at present, although the facile reduction observed for the photogenerated ferricenium ion in the negative going scan for single-crystal CdTe (*cf.* inset, Fig. 12) underlines the problem with nonoptimum location of the ferrocene/ferricenium ion couple with respect to the CdTe band-edges and offers the encouraging prospect of better performance with a redox couple having a more positive standard potential. The results of further optimization of PEC cells based on electrodeposited CdTe thin-films will be reported at a later date.

Acknowledgments

This research was made possible by a sub-contract (No. XL-3-03048-01) from the U.S. Department of Energy and the Solar Energy Research Institute (SERI). The authors also thank R. N. Noufi of SERI for many valuable discussions and for the x-ray diffraction data. Thanks also to J. M. Owens and D. K. De of the Department of Electrical Engineering for generous donation of their time and the facility for film thickness measurements.

Manuscript received Jan. 4, 1984.

A Photoelectrochemical Storage Cell with n-CdSe and p-CdTe Electrodes

H. J. Gerritsen,¹ W. Ruppel, and P. Würfel

Institut für angewandte Physik der Universität, Universität Karlsruhe, D-7500 Karlsruhe, Germany

ABSTRACT

Charge and energy storage is presented for a photoelectrochemical cell, in which in a CdSO₄ electrolyte one electrode, n-CdSe, is photodecomposed under illumination, and the other electrode, p-CdTe, is photoelectroplated by Cd. These processes lead to a galvanic cell with Se on CdSe as one electrode, and Cd on CdTe as the other electrode. The discharge products, when the cell is discharged in the dark, are the original photosensitive semiconductors. Each of these photosensitive electrodes, as well as their combined performance, is discussed, together with the source of irreversibilities for this method of photoelectrochemical energy conversion.

Known photoelectrochemical cells or photoelectrochemical storage cells convert light energy into chemical energy in a redox system like S/S²⁻ in the liquid, or use bulk storage in a third electrode (1-3). More recently, n-MoSe₂ has been used in various bromine redox electrolytes (4). In these studies corrosion of the semiconductor has been avoided at all costs. In contrast, the work reported here is based on such corrosion, because the chemical energy storage comes from light-induced decomposition of the surface of the semiconductors. Be-

sides photoelectrochemical cells, storage of energy in the electrolyte has been investigated (5-8). These devices are, however, based on quite different physical principles than are involved in the present paper. Closer to our work, is the work by Skotheim (9), who used a combination of p-CdTe and n-CdS, but with a polysulfide redox couple as photovoltaic cell.

Photocorrosion, namely, decomposition of ionic electrodes by light, with subsequent ion migration in the cell is a thermodynamically irreversible process. Nevertheless, it may at least be partly reversed, as any irreversible process, when an increase in entropy in the surroundings

¹ Permanent address: Department of Physics, Brown University, Providence, Rhode Island 02912.

is taken into account. Solar radiation constitutes an energy current at high temperature, being accompanied by a low entropy current. Solar radiation may, therefore, be used to restore a discharged battery at the expense of increasing the entropy outside the battery. Charging a discharged lead accumulator by an illuminated p-n junction solar cell would be an example of this concept.

In this paper, we will describe an accumulator into which a type of solar cell is incorporated. It consists of two photosensitive semiconductor electrodes of the composition A^+B^- in an electrolyte. Irradiation of the electrodes raises the free energy of the system A^+B^- by converting it into $A + B$

In the dark, the process is reversed, and, conducted properly, may deliver electrical energy to an external load.

As photosensitive electrodes, we will use n-CdSe and p-CdTe. Their principles of performance as photosensitive electrodes in an electrolyte will be described below. A photoelectrochemical storage cell using both of these electrodes will also be presented below. The chosen electrodes have no particular merits for application but serve to demonstrate this concept and the problems of photoelectrochemical charge and energy storage. The photocorrosion is not completely reversed upon illumination.

Electrodes

CdSe.—Polycrystalline disks of n-CdSe were used with a thickness of 1 mm and an area of 0.5 cm². They were cut from low resistivity (0.5 Ω cm n-type) rods grown according to the Piper-Polich method. They were subsequently polished, washed in acetone, and etched for 30s in aqua regia, HCl:HNO₃ (4:1 by volume), washed in distilled water, rinsed in a 10% (by weight) KCN solution in water for 2 min, and washed in distilled water. The dry crystal was then attached to a plexiglass holder with some molten phenolphthalein on a hot plate and further secured with epoxy, which at the same time prevented any electrolyte to shorten out the crystal by getting at the back of it. Electric contact was established by bringing a drop of an alloy of gallium-indium, which is liquid at room temperature, at the back side of the crystal and inserting a copper rod in it. This liquid metal wets the semiconductor well and makes a good ohmic contact.

The CdSe disks were then placed in a 0.1M CdSO₄ solution with, as counterelectrode, a strip of Cd metal. A variable voltage could be applied between the CdSe disk and the Cd, and the resulting current measured with a Keithley electrometer. Figure 1, taken from earlier work (10), shows the result. The sign convention chosen for the bias voltage is that it represents the voltage of the semiconductor, taking the Cd as at zero voltage. The current is chosen as positive when in the electrolyte the current, and thus the Cd²⁺, flows from the Cd metal to the semiconductor. The measurements were done in a N₂ atmosphere, though not much difference results when they are done in air.

It is by now a well-established fact [see, for example, Ref. (11-13)] that photocorrosion of cadmium chalcogenides proceeds in two different ways, depending on whether the semiconductor is n- or p-type. In n-type CdSe, immersed in an aqueous electrolyte, a potential barrier is formed, similar to the Schottky barrier at a semiconductor-metal interface (12). This surface barrier, when illuminated, will drive the light-generated majority carriers into the bulk of the semiconductor, while the minority carriers, in this case the holes, will assemble at the interface with the electrolyte. There they may either oxidize some ion in the solution, for example oxidize the reduced state of a redox couple, or they may proceed to oxidize the surface of the semiconductor (2). In our case this would occur via

Fig. 1. Current voltage curve of n-CdSe in the dark and with 5 mW 6328 Å illumination. The electrode is immersed in a 1M CdSO₄ solution with Cd metal as a counterelectrode. The positive direction of current flow is that of positive charge flowing toward the CdSe electrode. Taken from Ref. (10).

where the Se⁰ would stay back on the surface as a brown film and Cd²⁺ would diffuse out into the electrolyte.

Figure 1 shows the rectifier characteristics of the n-CdSe semiconductor in the dark. Bandbending in a semiconductor in contact with an electrolyte, leading to efficient separation of the light generated electron-hole pair, has been observed in many systems, as summarized in Ref. (12). Thus in the forward direction, the n-CdSe is negatively biased with respect to the Cd counterelectrode. Absorption of a photon in the depletion layer results in a subsequent separation of the photogenerated hole and electron such that the minority carrier moves to the semiconductor-electrolyte interface where it oxidizes CdSe to Se⁰ and Cd²⁺. As can be seen in Fig. 1, this process requires a bias voltage above about +0.5V for the Cd²⁺ to leave the CdSe.

Next, the semiconductor was given a bias voltage in the back direction, at which little dark current flows. Subsequently, the light was turned on for several minutes and the total charge flow measured, indicative of the amount of photocorrosion. The CdSe was then externally short-circuited with the Cd electrode. A dark current was observed in the opposite direction of the previous photocurrent, indicating partial restoration of the photocorrosion of the CdSe. On a fresh crystal and for a photogenerated charge of 35 mC/cm², the return charge after 1/2h was 25 mC/cm² or 70%, while for the larger photogenerated charge of 200 mC/cm² only 25% had returned in 1/2h. After repeated recycling, at which in the dark the bias with respect to the Cd electrode was reduced to zero but in the light was raised to +0.5V, some reduction in photosensitivity was observed, while the return charge in the first half-hour was typically between 20% and 50%.

CdTe.—The CdTe disks were cut from rods grown from the melt by a modified Bridgman method. They were p-type and of rather large resistivity, about 8000 Ω cm. Cleaning was done by washing in acetone followed by brief etching in a 2% brominated methanol solution, followed by 20 min etching in 0.5% brominated methanol and washing in methanol. Ohmic contact was made to the disk by putting a drop of an aqueous solution of H₂AuCl₄ on the surface of the p-CdTe, which results in formation

of a gold electrode. The holder was similar to the one described for CdSe, except that a small brass spring was used instead of the GaIn alloy, to serve as contact between the gold electrode and the copper finger.

The current-voltage characteristic of p-CdTe in a 0.1M CdSO₄ solution with Cd metal as counterelectrode, as described for CdSe, is shown in Fig. 2, taken from Ref. (10). The sign convention is the same as in the former case. Positive current flow in p-CdTe under illumination consists of photogenerated electrons forced to the surface by the field inside the semiconductor. The reaction at the surface can now be represented by

What happens subsequently depends on the composition of the electrolyte. In our case, where Cd²⁺ ions were present in large quantity in the electrolyte, free Te²⁻ ions cannot exist in the solution and CdTe will be reformed immediately. This amounts to a plating of the illuminated CdTe with cadmium metal.

In order to examine the reversibility of the photocorrosion of the CdTe electrode, we exposed it to light at zero voltage bias. With light, even at zero voltage bias, the electrode covered itself with a Cd layer, easily visible to the eye. These Cd films were removed when the Cd-covered CdTe was connected externally to a bar of Te in the solution. Quantitatively, a 2 min exposure of CdTe to a low power HeNe laser transported 11 mC of Cd onto the CdTe surface. After 6 min in the dark, the restoring current had dropped to 1/10 of its initial value and the Te had accepted back 5 mC of the Cd. When the CdTe was exposed to the laser for 5 min, 33 mC of Cd was deposited on it. By connecting it subsequently in the dark to the Te electrode, a reverse charge flow of 12 mC was measured in 20 min, again in the time for the current to drop to 1/10 of its initial value. Thus, in relatively short times, the Te electrode had received back 46% and 37%, respectively, of the Cd photodeposited on the CdTe. If one repeats the experiment many times, a further gradual reduction in photoefficiency is observed. Probably, some Cd is buried and trapped in the CdTe, and also conversion from large crystallite size (about 1 × 1 mm) to a smaller size may take place.

Storage Cell with n-CdSe and p-CdTe Electrodes

A storage cell, which includes the storage capacities of both photosensitive semiconductors discussed so far, is obtained when the n-CdSe and p-CdTe serve as electrodes and the Cd counterelectrode is omitted. It is shown in Fig. 3. A silicon p-n photocell, though not absolutely necessary, helps considerably to increase the current during the illumination part of the cycle.

Under illumination, both photodecomposition and photoplatin, as discussed above, occur (Fig. 4). Se forms as photocorrosion product on n-CdSe, and Cd on p-CdTe. When the two semiconductors are connected, light forces Cd²⁺ ions out of the CdSe onto the CdTe, where it will form Cd. The electrons needed for this flow through the external connection from the CdSe to the CdTe.

In the dark, one can expect the chemical cell, consisting of a layer of Cd on the CdTe and of Se on the CdSe, to discharge, whereby Cd will go into solution as Cd²⁺ from the CdTe electrode and onto the Se-covered CdSe, where it will reform CdSe. The electrons for the discharge of the Cd²⁺ will have flown through the external conductor from the CdTe to the CdSe. This flow is opposite to the electron flow in the light. This concept is that of a reversible battery, activated with light, in which the different kinds of photocorrosion reactions at both semiconductor electrodes are taken advantage of.

The CdSe and CdTe crystals in the 0.1M CdSO₄ electrolyte connected with each other were irradiated with a 75W incandescent lamp. A small (0.1V) potential developed, and a current of 1 μA flowed from the CdSe to the CdTe. Larger currents were obtained when the cell was biased, as noted before. A photocurrent of 60 μA was measured for a bias of 0.5V, conveniently obtained from an illuminated silicon p-n junction. It increased to 300 μA when two such junctions were connected in series to give the n-CdSe a potential of +0.9V with respect to the p-CdTe. The data given below apply to the case of two junctions in series.

The storage effect was mainly due to the semiconductor electrode reactions and not to electrolysis driven by the bias voltage, as follows from the observation that light only on the Si n-p junctions caused a photocurrent of 24 μA, on both the Si n-p junctions and on the CdSe of 190 μA, and on Si, CdSe, and CdTe of 260 μA.

Fig. 2. Current-voltage curve of p-CdTe in the dark and with 5 mW 6328Å illumination for conditions as in Fig. 1. The positive direction of current flow is, as in Fig. 1, that of positive charge flowing toward the CdTe electrode. Taken from Ref. (10).

Fig. 3. Photoelectrochemical cell with n-CdSe and p-CdTe as electrodes in an aqueous 1M CdSO_4 electrolyte. An auxiliary bias voltage is provided under illumination by a Si p-n photocell.

Considerable amounts of charge could be stored. By illuminating for 50 min, during which the photocurrent dropped from 260 to 190 μA , a charge of 1.3C on 1 cm^2 was stored, of which 0.36C returned in the dark during 10h. The reverse reaction in the dark drops off relatively fast, towards the end always accompanied by somewhat unstable behavior (Fig. 5). The smaller the photogenerated charge, the shorter the time during which large reverse dark currents flow. Figure 5 shows further the slight decrease in photoresponse during three cycles, at a somewhat constant initial reversed current, corresponding to a dark voltage of about -0.12V . While the photogenerated charges in the three subsequent cycles were 0.20, 0.18, and 0.175 C/cm^2 , the return charges were about 15% of the former after 1h in the dark.

Equally important as the recuperation of the charge is the property of the battery to make good use of the ab-

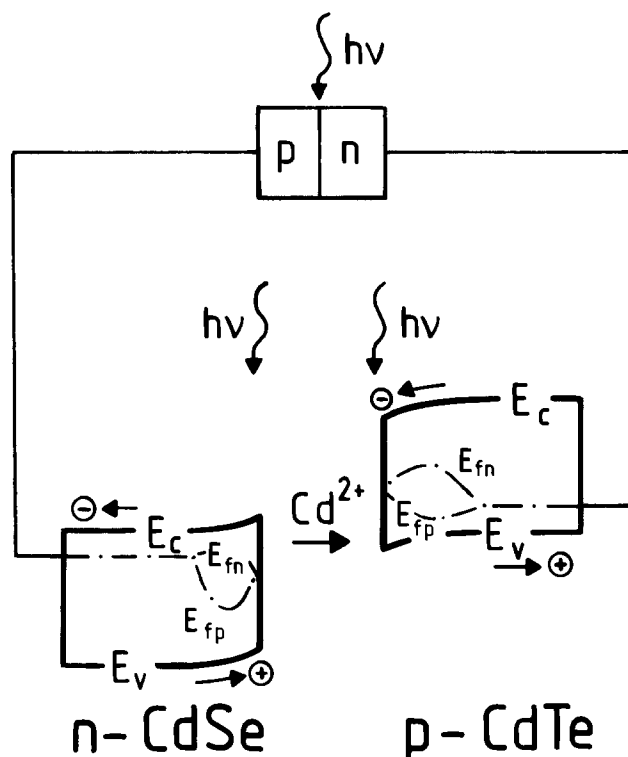

Fig. 4. Charge flow in the n-CdSe and p-CdTe electrodes and in the electrolyte under illumination, as it leads to the photodecomposition and plating reactions discussed in the "Electrodes" section. For the illuminated semiconductor electrodes, the spatial distribution of the bandedges E_c and E_v , and of the quasi-Fermi-levels E_{fn} and E_{fp} , whose gradients act as the driving forces for the charge flow, are roughly sketched.

sorbed photons in transferring Cd^{2+} ions from CdSe to CdTe under illumination. In this respect, the cadmium chalcogenides are well qualified. For instance, p-type CdTe in an alkaline electrolyte has been reported to have very high quantum efficiencies of up to 0.97 elementary charges transferred per absorbed photon (14). Measurements on the CdTe used in our experiments gave a quantum efficiency of 0.16 (0.18 when corrected for reflection) at a wavelength of 6328Å of the HeNe laser.

While we have monitored the discharging of the battery in the dark under short-circuit conditions, discharging close to open-circuit conditions would be required in order to get out most of the energy stored in the battery during illumination. The open-circuit voltage between the Se on CdSe and the Cd on CdTe electrodes which transforms the transferred charge to stored energy was 0.65V and did only little depend on the amount of transferred charge.

Conclusions

Light-induced charge storage in an electrochemical cell was demonstrated for single photosensitive n- and p-type semiconductor electrodes. The combined action of both

Fig. 5. Three subsequent charging and discharging cycles of the photoelectrochemical cell in Fig. 3. Note the different scales for the negative charging current under illumination and the positive discharging current in the dark.

photosensitive electrodes was presented. While the reported observations demonstrate the feasibility of this principle of photoelectrochemical energy conversion, the actual charge recuperation is far from being complete. The charge recuperating in the dark is only approximately one-quarter of the photogenerated charge. This incomplete charge return is caused by various irreversibilities.

A parameter that determines to a large extent the main source of irreversibilities is the length of the time intervals of the charging period of the battery in the light and of the subsequent discharging in the dark. An extended illumination period causes the n-CdSe to photodecompose into a large depth. The CdSe is then shielded from the illumination. Furthermore, the Se-layer is not entirely restored to CdSe in the dark, or may even fall off from the electrode when becoming too heavy. Similarly, the p-CdTe, when electroplated by too thick a Cd-layer, is buried and isolated from both the radiation field and the electrolyte.

A further parameter that has not been optimized in the observations presented above is the fraction of light incident on either photosensitive electrode, and on the auxiliary Si n-p junction. Optimally, the two electrodes must be illuminated such that the photoinduced minority carrier currents be equal, providing for an equal photodecomposition rate of the n-CdSe and photoplate rate of the p-CdTe. Insufficient illumination of one electrode leads to different rates of formation of Se on CdSe and of Cd on CdTe. This difference inevitably involves electrolysis of the aqueous electrolyte, and the corresponding charge cannot be regained in the dark. Unbalanced illumination would in addition convert the less illuminated electrode to a back-biased rectifier series resistance as is obvious by inspection of Fig. 4. This strongly limits the current flow and thereby the photochemical reaction rates in the cell.

The mentioned irreversibilities occur in conjunction with others, such as the degradation of the crystal structure of the electrode approaching an amorphous state upon repeated cycling. Furthermore, the excess Se on the n-CdSe electrode may convert this electrode in the direction to p-type, as has been observed with Te on n-CdTe (15). Only the detailed investigation of all irreversibilities can show whether they may be suppressed to an extent that the photoelectrochemical energy conversion based on the principles presented in this paper may eventually find practical application.

Further study of the degree of reversibility of the n- and p-type photocorrosion under a variety of conditions, combined with a study of the surface morphology, is being considered.

Comparison of Behavior of Single-Crystal and Polycrystalline CdS in Photoelectrochemical Cells

James H. Reeves and Michael Cocivera*

The Guelph-Waterloo Center for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1

ABSTRACT

Capacitance in the dark and photoresponse were determined from single-crystal CdS $\langle 001 \rangle$ and polycrystalline CdS (deposited cathodically from dimethylsulfoxide). Three different solvents employed (water, triethyleneglycol dimethyl ether and acetonitrile) gave results that lead to essentially the same conclusion. Thus, single-crystal CdS having a "clean" surface gives identical onset and shut-off potentials that are the same as the flatband potential determined from Mott-Schottky (MS) plots of capacitance data. These MS data are independent of the scan direction for the potential. Surface sulfur that results from photooxidation causes the onset to shift negative of the shutoff. Also, the MS intercept becomes dependent upon the scan direction of the potential. These results can be explained by the effect of the oxidation level of the surface sulfur on the flatband potential. In contrast, for fresh polycrystalline CdS that has not been subjected to photo-oxidation, the onset potential is negative of the shut-off potential. These and other results can be used as evidence that the growing process incorporates one or more sulfur containing impurities that are uniformly distributed throughout the film.

Recently, there has been some interest in the use of cathodically deposited, polycrystalline CdS films (1) as a component in photovoltaic cells (PVC) (2). In addition, this film has been used in photoelectrochemical cells (PEC) as an uncoated (3a) and a coated photoanode (4). While some structural and compositional characterization has been reported (3), more information concerning the properties of the film could be helpful in understanding its response in a PVC and the effects of protective coatings in a PEC. Consequently, additional studies of the behavior of this film and single-crystal CdS in PEC's are reported in this paper. In particular, the value of the flatband potential (V_{FB}) determined from Mott-Schottky plots is compared with onset potentials determined from chopped light studies in water and in triethyleneglycol dimethyl ether, which appears to be a convenient solvent for electrochemical studies. For both single-crystal and the polycrystalline film, these parameters depend upon the history of the surface. In addition, the response of the polycrystalline film is consistent with the presence of one or more electrochemically reducible impurities.

Experimental

Materials.—Doubly distilled deionized water was used in all experiments involving aqueous systems.

Triethyleneglycol dimethylether (TGDE), obtained from Aldrich Chemical Company, was refluxed over lithium aluminum hydride (LAH) at 70°-80°C (at 1-2 mm Hg) for 3-5h. The activity of the LAH in the ether was verified by pipeting a small amount of the solution into methanol, after which the ether was distilled directly into the electrochemical cell (distillation temperature 70°-80°C). The cell was brought to atmospheric pressure using dry nitrogen (Canox) and connected to a nitrogen-filled glass rack where TGDE saturated nitrogen was passed continuously into it. Although the age of the solvent appeared to have no direct effect on the experimental results, the ether was replaced every 3-5 days.

Acetonitrile (spectroscopic-grade, Burdick Jackson Laboratories, Incorporated) was passed over an activated alumina column directly into the electrochemical cell, which was purged continuously with acetonitrile-saturated dry nitrogen.

Sodium sulfate, potassium ferrocyanide, and potassium ferricyanide were reagent grade and used as received. Tetraethylammonium perchlorate (TEAP), obtained from Kodak, was recrystallized from deionized water and dried at 100°C under vacuum in a drying pistol for at least 4h. Sodium trifluoromethanesulfonate was synthesized from freshly distilled trifluoromethanesulfonic acid by the addition of sodium hydroxide to a ca. 10% solution of the

acid in water to attain pH 7. The soluble salt was recovered by removing the water, first at reduced pressure on a rotary evaporator and then in a drying pistol at 100°C. Both TEAP and sodium trifluoromethanesulfonate were stored under vacuum in a desiccator.

Semiconductor electrodes.—Two ca. 10g single crystals of CdS (6 Ω -cm resistivity) were donated by Eagle Picher Corporation. Electrodes were cut from the crystals by means of a wire saw using diamond grit paste. An ohmic contact was made by electrodepositing nickel metal onto the surface of the semiconductor at a constant current density of 1 mA/cm² from an aqueous solution of 0.8M NiCl₂, 30 g/l boric acid, and 0.39 g/l sodium laurylsulfate at 44°-55°C. The nickel coated surface was attached to copper with indium, and the liquid junction occurred at the $\langle 001 \rangle$ face. The crystal orientation was determined using a Hilger & Watts Y290 four-circle x-ray diffractometer. The surface of the electrode was then covered with an insulating compound so that only 0.02-0.04 cm² of the semiconductor was exposed. In order to insure that the photoeffects observed were due to properties of the semiconductor rather than to its interaction with impurities present in the insulator, five different materials [parafin, 5 min epoxy (Devcon), Epoxy-patch (Dexter Corporation), and Bostik polymer, and RTV silicon rubber adhesive sealant (GE)] were tried. The most durable insulation proved to be 5 min epoxy coated with the silicon adhesive. Before each experiment, the semiconductor was etched for 10-20s with concentrated hydrochloric acid, rinsed thoroughly with deionized water, and dried with warm air from a heat gun. When extensive oxidation of the crystal had occurred, the surface was lightly sanded with 3/0 Carborundum polishing paper before the HCl etch. Finally, the semiconductor electrode was immersed in the photoelectrochemical cell and cycled over the potential range +1 to -1V in the dark for 15-30 min prior to data collection.

Polycrystalline CdS was cathodically deposited at 110° from reagent-grade dimethyl sulfoxide (DMSO) containing 0.055M CdCl₂ and 0.19M sulfur (1). A current density of 2.5 mA/cm² resulted in films ranging in thickness from 1600 to 9600Å (3a) for 50-300s. The substrate for the deposition in most photoresponse experiments was Mo foil, which was cut by means of a punch to provide flags with 1 cm² area. The flags were etched for 5 min in 5 ml of concentrated HCl containing five to ten drops of hydrogen peroxide, then rinsed thoroughly with deionized water, and dried with acetone. They were then mounted in a Teflon holder, which permitted electrical contact to a copper wire lead by means of a nylon set screw. For capacitance measurements in the dark, platinum wire (0.1

cm diam, 1 cm long) sealed in glass and rounded at the end served as the CdS substrate. In some cases, the CdS electrodes were etched for 10s in 0.1M hydrochloric acid. Some electrodes were annealed under vacuum in a drying pistol at 100° or 250°C in an argon atmosphere. Electrodes that were not used the same day in which they were grown were stored in a vacuum desiccator.

Cell design.—Two cell designs were used. For experiments involving capacitance measurements, a three-neck round-bottom flask was fitted with a large surface area Pt-foil auxiliary electrode, a semiconductor working electrode, and a reference electrode separated from the test solution by either a medium porosity glass frit inside a Luggin capillary or a solvent-soaked filter paper inserted into a capillary tip. Flatband potentials were within 40 mV for the two reference designs. The reference electrodes used were aqueous Ag/AgCl/sat KCl for water, Ag/Ag⁺ (0.1M) for acetonitrile, and a Cd/Cd²⁺ (0.1M) for TGDE. The nonaqueous reference electrodes were calibrated by means of cyclic voltammetry (CV) of 0.002M benzoquinone (Fisher, sublimed) in the appropriate solvent (5). All potentials are reported relative to SCE. The cell was purged continuously with nitrogen introduced with stainless steel syringe needle.

Photoresponse was measured either in this cell or a cylindrical glass cell with a Pyrex window. In the latter the semiconductor electrode is located 0.5-1 cm from the optical flat, and a coiled Pt-wire auxiliary electrode and the reference electrode bridge are positioned immediately behind the working electrode. Dry N₂ was introduced either directly into the solution or passed over it through a glass tube. Stirring was accomplished by means of a small magnetic stirring bar.

Electrochemical experiments were carried out using either a PAR Model 173 potentiostat/galvanostat equipped with a Model 176 current follower or a Bioanalytical Systems (BAS) Model CV-1B cyclic voltammetry unit. The potential sweep generator of a BAS Model CV-1A was used as the programmer for the PAR 173. Results were recorded on a Heath Model SR-207 X-Y recorder.

For capacitance measurements, a Hewlett-Packard Model 4204A oscillator was used to superimpose 2.5 mV ac signal of the appropriate frequency (100 Hz-10 kHz) on the dc voltage ramp (2-3 mV/s) applied to the electrochemical cell. Using a PAR Model 5204 lock-in amplifier, the 0° and 90° components of the resulting current were resolved and recorded on a Nicolet Model IIIA Digital Explorer Oscilloscope equipped with a Model 201 plug-in unit.

Data were analyzed by assuming an equivalent circuit containing a resistance in series with the space charge capacity (C_{sc}). Thus, C_{sc} was calculated by means of the equation $1/C_{sc} = \omega A_{out}/(A_{in}^2 + A_{out}^2)$, in which A_{in} and A_{out} are the 0° and 90° components of admittance calculated from the equivalent current, respectively. For single-crystal electrodes in water and acetonitrile solutions, this equation reduced to $1/C_{sc} = \omega/A_{out}$ because $A_{in} \ll A_{out}$, i.e., $\omega^2 \tau^2 C_{sc} \ll 1$. For the less conductive TGDE solution, the A_{in} is a significant fraction of A_{out} (between 0.1 and 0.4) and could not be ignored in the calculations.

In-phase and out-of-phase currents as a function of potential were analyzed using a Rockwell Aim 65 computer programmed to calculate the slope, the x-intercept (V_{FB}), their respective uncertainties, and the correlation coefficient. In all experiments, dc dark currents were less than 1 μ A over the entire potential range investigated (typically +1 to -0.7V for single-crystal CdS and +1 to -0.4V for the polycrystalline materials, indicating no faradaic component to the impedance). The absence of significant frequency dispersion for single-crystal samples over the frequency range 1-10 kHz suggests that the surface-state capacity (C_{ss}) does not make a significant contribution to the equivalent circuit at these frequencies.

Irradiation of the semiconductor was accomplished using either a 100W mercury lamp, a 150W mercury-xenon lamp (Oriol Corporation), or a 300W ELH quartz-

iodine projector lamp (GE). In each case, the beam was passed through a 5 cm water filter and a series of lenses so that a uniform beam of 40-100 mW/cm² was focused on the semiconductor. The power output of the lamp was determined with an Eppley thermopile. A rotary sector was used to provide periodic illumination of the electrode in chopped light experiments for which potential sweep rates of 10-20 mV/s were generally used. Power curve determinations were carried out under N₂ in a cylindrical Pyrex cell using a 12 cm² indium-doped tin oxide counterelectrode connected to the SCE across a variable load (EICO resistance decade box). The electrodes were immersed in a solution containing 0.4M KCl, 0.2M K₄Fe(CN)₆·3H₂O, and 0.01M K₃Fe(CN)₆. No attempt to optimize cell conditions for maximum power was made, and results were not corrected for the absorption of light by the solution.

Results and Discussion

Power measurements.—Efficiencies for conversion of light to electrical power were determined to insure that the single-crystal CdS was properly mounted and that the surface treatment did not have a deleterious effect. Power measurements for the polycrystalline film have been reported (4).

The photocurrent/photovoltage characteristics of three single-crystal CdS electrodes in H₂O using a Fe(CN)₆⁴⁻³⁻ couple gave efficiencies between 5.7% and 7.4% based on 40 mW cm⁻² incident light from the full spectrum of a 150W Xe arc lamp. The short-circuit current, open-circuit

The cross designates zero for the Y-direction (current) for each trace.

voltage, and fill factor were, on the average, 4.5 mA/cm², 1.1V, and 0.65, respectively. No correction was made for light intensity decrease due to solution absorption, and photoetching (6) was not employed to improve performance. For comparison, the maximum efficiency, open-circuit voltage and short-circuit current under very similar conditions are reported to be 9.5%, 1V, and 6 mA/cm², respectively (7a). Thus, it appears that single-crystal CdS electrodes, which are used in the studies described below, are of reasonably good quality. The polycrystalline film provides a substantially lower efficiency of 0.1%-0.2% based on 100 mW cm⁻² incident light from a 150W Xe lamp (4).

Chopped light and capacitance in water.—When the surface of single-crystal CdS is carefully prepared, both the capacitance data and the chopped light experiments give the same flatband potential in water and triglyme. Thus, for the chopped light experiment when the surface is fresh, a positive potential sweep (-1.0 to -0.5V SCE) gives an onset potential of -0.76V vs. SCE (Fig. 1a), which is identical to the potential at which the photoanodic current stops (shut-off potential) for the negative potential sweep (-0.5 to -1.0 or -1.2V vs. SCE) (Fig. 1b). Mott-Schottky (MS) plots of the capacitance data (Fig. 2) (1-10 kHz) give a flatband potential of -0.73V, which is identical to the value reported previously (8, 9) and agrees well with the value obtained from the chopped illumination studies above. These results are obtained when the electrode is freshly prepared, *i.e.*, HCl etched prior to use. Under these conditions the capacitance data (and V_{FB}) are independent of the direction of potential scan. Furthermore, the lack of any substantial frequency dispersion in the MS plots verifies that surface-state capacitance does not make appreciable contribution in the frequency range employed. From the slope of the MS plots the donor density, n_D is calculated (10) to be $8.7 \times 10^{15}/\text{cm}^3$ and the bulk conductivity of $0.3 \Omega^{-1} \text{cm}^{-1}$ is calculated using $n\mu$ in which the carrier density $n = n_D$, e is the electronic charge, and μ ($\sim 200 \text{cm}^2/\text{Vs}$) is the carrier mobility.

When the surface is purposely oxidized by extending the positive sweep to 0.0V (SCE) to increase the duration and extent of the photoanodic current, the flatband potential (from MS and from chopped light) depends on the ramp direction. In fact, the MS results are identical with the chopped light results, *i.e.*, starting at a negative potential causes a negative shift in the flatband relative to the

clean surface, whereas there is no shift when the ramp is started at a positive potential. Thus, for chopped light, the shut-off potential remains unchanged at about -0.70V; however, the onset shifts progressively in the negative direction so that at the third cycle the onset occurs at -1.0V (Fig. 1c). After extensive oxidation the photoresponse for the cathodic scan resulted in a resurgence photo-oxidation negative of the -0.6 to 0.7V region (Fig. 3b).

AC impedance measurements after the electrode has been oxidized slightly (chopped illumination while the potential is cycled once between -1.2 and -0.5V) give capacitance data that are now dependent upon the potential scan direction (Fig. 2). Under these conditions, the MS plots are still linear with the same slope; however, the intercepts are -0.76V (1.0 to -0.5V scan) and -0.90 (-0.7 to +1.0V scan). For the latter, the potential was held at -1.0V prior to the scan. In this regard, the capacitance data seem more sensitive than the onset potential measurement, *i.e.*, the amount of sulfur resulting from one cycle between -1.2 and -0.5V during chopped illumination is not sufficient to cause a measurable shift in the onset potential. After extensive chopped light oxidation of single-crystal CdS in H₂O, the MS plots are no longer linear, and the capacitance values are larger than those for a fresh electrode.

We have purposely chosen conditions (Na₂SO₄ in H₂O) that other workers (7, 8) have employed to produce surface sulfur by photo-oxidation. Consequently, we propose the following description to account for the chopped light and MS results. With a fresh sample having no appreciable sulfur on the surface, the onset and shut-off potentials are identical, indicating that V_{FB} may be determined by potential sweep in either direction during chopped illumination. However, once sulfur is adsorbed on the surface in appreciable amounts, it can shift V_{FB} when it is reduced to form S_n^{2-} in which $n > 1$. In other words, surface sulfur in a reduced form can act in the same manner as S^{2-} in solution, which is known to chemisorb to single-crystal CdS (8b) and cause a shift in V_{FB} to values as negative as -1.45V (SCE) depending on concentration (9). This reduced form would be generated for the negative to positive potential scan used for the ac impedance and chopped light experiments. However, surface sulfur is not reduced during the cathodic scan until the potential is negative of V_{FB} . Sulfur in the unreduced form does not shift V_{FB} and, therefore, the shut-off potential is not

Fig. 2. (—): Mott-Schottky plots of freshly etched single-crystal CdS in aqueous 0.50M Na₂SO₄ at 1 kHz (○) and 10 kHz (×). (---): Mott-Schottky plots at 10 kHz for single-crystal CdS after the potential was swept to -0.60V under chopped illumination. The arrow indicates the data obtained for the anodic sweep direction.

Fig. 3. Chopped light (a) anodic and (b) cathodic linear potential sweep voltammograms for single-crystal CdS in water after illumination at 0V for 1 min. Scan rate 10 mV/s, potential vs. SCE; exposed surface area 0.05 cm².

shifted in the negative direction. Consequently, the cathodic scan for ac impedance and chopped light gives a realistic measure of V_{FB} for moderately oxidized surface. In Fig. 3b, the photoresponse of CdS that has been oxidized more extensively exhibits a resumption of photoanodic current negative of the shut-off potential. This behavior is consistent with our description since the dark cathodic current at potentials negative of the shutoff can be attributed to the reduction of sulfur which is oxidized during the light-on phase.

Fig. 4. Chopped light (a) anodic and (b) cathodic linear potential sweep voltammograms of freshly etched (0.1M HCl, 10s) and dried (100°C, vacuum) polycrystalline CdS in aqueous 0.50M Na₂SO₄. Sweep rate, 10 mV/s; potential vs. SCE; exposed surface area, 0.5 cm².

For polycrystalline CdS films in aqueous Na₂SO₄, a variable onset potential also occurs. In this case, however, even the fresh film has an onset potential that differs from the shut-off potential (Fig. 4). Thus, for fresh films starting with an initial potential of -1.1V and sweeping in the positive direction to various potentials (-0.5 to 0.0V), the onset occurs immediately at about -1.1V vs. SCE. However, the return sweep in the negative direction gives a shut-off potential ranging from -0.60 to -0.65V. These results are essentially the same for a variety of treatments of the film, *i.e.*, unetched films that were freshly grown and dried prior to use or samples that were prepared 1-3 days before use. The age of the growing solution also did not appear to affect the onset and shut-off potentials. Various methods of drying (vacuum desiccator, vacuum pistol at 100°C, and Ar atmosphere at 250°C) gave the same difference between onset and shut-off potentials. The high temperature treatment provided films with the lowest dark currents at potentials positive of -0.8V, but these increased substantially after the first chopped light cycle, indicating surface oxidation. Etched films (0.1M HCl) gave the same results as unetched films. In all these cases, the films exhibit a substantial dark cathodic current at -1.0V.

These results may be explained in general by invoking grain boundaries and surface defects. However, a more specific description which is based on the close analogy between the effects observed for surface-oxidized single-crystal CdS and those for unoxidized polycrystalline CdS would be that the polycrystalline film contains unreduced or partly reduced sulfur.

Chopped light and capacitance in TGDE.—The study was extended to TGDE because the explanation presented above requires that the effects should be independent of solvent. Although TGDE apparently has not been employed for electrochemical studies, it seems attractive for this purpose since it is easily purified and has a rather large potential range (-1.5 to +1.0V vs. SCE). In this solution, the chopped light results are similar to those in water for single-crystal CdS (Fig. 5). Thus, for a fresh electrode, the onset and shut-off potentials are -0.85 and -0.80V, respectively, vs. SCE. After purposely oxidizing the surface by scanning to +0.1V under illumination, however, the onset shifts to *ca.* -1.0V; and at potentials

Fig. 5. Chopped light linear potential sweep experiments in TGDE solutions containing 0.20M NaCF_3SO_3 . (a) Anodic and (b) cathodic voltammograms of freshly etched single-crystal CdS, (c) anodic and (d) cathodic voltammograms of single-crystal CdS after the potential was swept to +0.1V under chopped illumination. negative of the shut-off potential (-0.6V), dark cathodic current develops (shoulder at ca. -0.8 and peak at -1.08V). The dark currents are similar to those observed for single-crystal CdS in acetonitrile (5).

The MS plots for single-crystal CdS in TGDE are similar to those in H_2O with the capacitance values and carrier density about the same and a V_{FB} of -0.85V (Fig. 6). Very little frequency dispersion (1-10 kHz) is observed, and the capacitance values are not dependent upon the direction of the potential scan when the electrode is fresh. After the surface of the electrode has been oxidized by illumination for one cycle between -1.22 and +0.48V, the capacitance data are no longer independent of the direction of poten-

tial scan, although the MS plots remain linear and the slopes are the same for both scan directions (Fig. 6). Thus, the intercepts for the cathodic scan (+0.48 to -0.62V) and the anodic scan (-0.92 to +0.48V) are -0.76 and -1.18V, respectively. For the latter, the electrode was biased at -1.5V for a few minutes prior to scan. The similarity between these results and those obtained in H_2O indicates that the same description concerning surface sulfur probably applies. Consequently, for single-crystal CdS, the onset potential reflects the extent to which surface sulfur is present.

The chopped light results for polycrystalline CdS in TGDE are similar to those in H_2O in that the onset poten-

tial (-1.1V) differs from the shut-off potential (-0.72V). These results are consistent with the description that the film contains a reducible sulfur impurity and rules out the possibility that a specific interaction between water and the film surface is responsible.

Earlier work (5) indicated that capacitance data for single-crystal CdS in acetonitrile are frequency dependent and that the MS plot gave frequency-dependent intercepts. We find that freshly etched single-crystal CdS electrodes in acetonitrile give little frequency dispersion in the region 1.3-0.2V (Fig. 7) and that this method gives $V_{FB} = -0.93V$, in reasonable agreement with $-0.85V$ obtained from chopped-light experiments (5).

In summary, Mott-Schottky and chopped-light results indicate that surface sulfur causes V_{FB} to depend on the scan direction of the potential. This dependence occurs because sulfur on the surface of CdS can be reduced at sufficiently negative potentials. Since freshly etched single-crystal CdS does not exhibit this behavior, it is possible that the previously observed inconsistencies associated with the slopes and intercepts of MS plots for CdS (11) may be caused by the presence of surface sulfur. Although the behavior of polycrystalline CdS film is similar to that of the single crystal, there is one notable difference. The dependence of V_{FB} on scan direction occurs even before any photoanodic process has occurred. Consequently, one possible explanation is that one or more impurities similar to sulfur are incorporated in the film during the electrochemical deposition process.

Acknowledgments

We are pleased to acknowledge very useful discussions with Dr. A. S. Baranski, Dr. M. Bennett, Dr. A. C. McDonald and Dr. W. R. Fawcett. We thank Dr. P. Szczecinski for preparation and power measurements of the single-crystal electrodes, and Dr. G. Ferguson for determination of the crystal orientation. This work was supported in

part by a grant (to M. C.) from the Natural Sciences and Engineering Council of Canada.

ABSTRACT

The basic photoelectrochemical behavior of tetragonal p-type α -ZnP₂ has been investigated for the first time. The photoinduced current as a function of applied voltage and the spectral distribution of the photoresponse were measured in alkaline solutions (pH 13). Photosensitivity up to 580 nm in the visible range of the spectrum has been observed. From a linear Mott-Schottky relation, an approximate value of the flatband potential ($V_{FB} = -0.7 \pm 0.05 V_{SCE}$) at pH 13 for monoclinic β -ZnP₂ has been determined. As a function of pH, V_{FB} shows Nernstian behavior. For tetragonal α -ZnP₂, V_{FB} could not be determined. The onset of the cathodic photocurrent ($\approx -0.4 V_{SCE}$ at pH 13) indicates, however, a somewhat more positive V_{FB} for α -ZnP₂. Upon illumination with visible light, hydrogen evolution from alkaline EDTA solutions containing ZnP₂ powders loaded with a catalyst is very efficient. For α -ZnP₂ loaded with 0.5 weight percent of RuO₂, a formal quantum efficiency of 12% is found at 470 nm.

Much effort has been devoted in the last few years to the search for new materials or material combinations for the photoelectrolysis of water with visible light. One class of compounds to which little attention has been paid so far, at least with respect to the conversion of solar energy, is the series of monoclinic transition metal phosphides and arsenides MX₂ with, e.g., M = Cu, Ni, Zn and X = P, As. In a previous publication (1), we have reported a first photoelectrochemical investigation of one of these, i.e., p-type monoclinic β -ZnP₂, which should be ideally suited for solar cell applications both because of the abundance of its constituents and due to its direct bandgap of ≈ 1.5 eV. While the flatband potential V_{FB} could only be estimated before (1), we report in this paper new capacity measurements from which V_{FB} can be determined unambiguously.

Much before the discovery of β -ZnP₂ (2), another modification of this compound had been reported in the literature (3). In contrast to β -ZnP₂, this tetragonal α -ZnP₂ modification was found to have an indirect bandgap around 2.1 eV (2, 4).

In the following, we shall describe first photoelectrochemical measurements on single-crystal α -ZnP₂ electrodes. For both modifications, a first account of the hydrogen evolution on catalyst covered semiconductor particles shall be given.

Experimental

Crystal growth and electrode fabrication.— α - and β -ZnP₂ are synthesized in a two-step process. First, Zn metal and red electronic-grade phosphorus are sublimed in a quartz ampul, yielding Zn₃P₂. After purification of Zn₃P₂ by a further sublimation, this compound is phosphidized to ZnP₂ in an atmosphere of excess phosphorus. The pressure in the ampuls depends on the temperature and the amount of excess phosphorus. At temperatures of 800°-850°C and at pressures around 10 bar, the black β modification results, from which single crystals are obtained in a phosphorus atmosphere by sublimation. The red α modification is obtained by sublimation under stoichiometric conditions or low phosphorus pressures in the same temperature regime. Large single crystals require a very good stabilization of temperature and pressure.

The as-grown crystals of the β modification had resistivities around 1000 Ω cm. These could be lowered down to ≈ 10 Ω cm by annealing the crystals in a phosphorus pressure of 10 bar and at temperatures up to 500°C.

For α -ZnP₂, however, resistivities in the range of $\approx 10^5$ Ω cm could not be significantly reduced, even by annealing

the crystals at temperatures up to 700°C at 10 bars. Thus, a different doping procedure will have to be found.

For all experiments on β -ZnP₂ single crystals described below, the as-grown (100) face (without polishing) was exposed to the electrolyte. Electrical contacts were made by first sputtering gold on both sides of the crystals. After a brief heat-treatment (30s at 400°C in air) the current-potential curves generally showed excellent linearity up to the highest voltages which could be applied without overheating the samples. Thus the contacts were found to be perfectly ohmic.

Platelets of α -ZnP₂ were obtained by cleaving large single crystals perpendicular to the tetragonal C-axis. They were contacted in the same way as described above. In this case, however, the contacts were not strictly ohmic.

The electrodes were prepared in the usual way (1) after the Au contact on the face to be exposed to the electrolyte had been removed. All electrodes were etched in H₂O:HCl:HNO₃ = 1:2:2.

Experiments with single-crystal electrodes.—The solutions used for these measurements were made from deionized water and reagent-grade chemicals. The Mott-Schottky plots were obtained from admittance measurements as a function of electrode potential in the frequency range from 150 Hz up to 20 kHz. The real and imaginary part of the admittance were measured simultaneously by modulating the electrode potential with a 10 mV_{pp} sine wave and by recording the potential drop induced by the cell current across a small resistor with an Ithaco Dynatrac 393 lock-in amplifier. All signals were calibrated with a Hewlett-Packard 4440 B decade capacitor.

For a resistor and a capacitor C_p in parallel, the imaginary part of the admittance is proportional to the capacitance while for a series circuit the series capacitance C_s has to be calculated using both the real and the imaginary part of the admittance. In all of the data reported below, the real part of the admittance was small enough such that within the experimental errors $C_p = C_s$.

The photocurrent spectra and the photocurrent-potential curves were recorded using standard lock-in techniques. Illumination was provided by a 450W xenon lamp filtered through a ZEISS PMQII double-prism monochromator. Intensities were measured with a Moletron PR 200 pyroelectric radiometer.

Preparation and modification of powdered ZnP₂.—Both α - and β -ZnP₂ powders were made by crushing small crystals in an agate mortar.

α -ZnP₂/0.5 weight percent (w/o) Rh and β -ZnP₂/0.5 w/o Rh.—500 mg of the appropriate ZnP₂ were added to a red solution of 4.54 mg Rh₄(CO)₁₂ (Strem Chemicals) in 4 ml of CH₂Cl₂. The mixture was stirred and then sonicated for 0.5h. The solvent was evaporated. The powder was dried and heated at 160°C for about 2h. In the IR spectra of these compounds, no CO absorptions were observed.

α -ZnP₂/0.5 w/o RuO₂ and β -ZnP₂/0.5 w/o RuO₂ (RuCl₃ method).—A suspension of 1g of the appropriate ZnP₂ and 0.76 ml of a 0.05M RuCl₃ · 3H₂O (Drijfhout) solution in 1N HCl was stirred and then sonicated for 0.5h. The solvent was evaporated. The powder was dried and subsequently heated in an oven at 400°C for 6h under a stream of air.

β -ZnP₂/0.5 w/o RuO₂ (RuO₄ method).—2.4 ml of a solution, containing 130 mg of RuO₄ (Alfa Chemicals) in 50 ml of distilled water (ca. 6.24 mg of RuO₄) were added dropwise to a sonicated suspension of 1g of β -ZnP₂. No visible reaction took place. The mixture was stirred for 26h. The black powder was filtered, stirred with 100 ml of distilled water, and centrifugated. After removal of the water, the powder was dried above KOH.

Illumination experiments with ZnP₂ powders.—Illuminations were carried out with an Oriel XBO 450W xenon lamp, using a Schott KV-418 cutoff filter. The flat reaction vessel, thermostated at 40°C, containing 75 mg of the ZnP₂ powder in 75 ml of solution, adjusted to pH 13, was equipped with a gas burette, connected with a paraffin filled expansion flask. The produced hydrogen was measured volumetrically at atmospheric pressure.

Monochromatic measurements were performed using a Bausch and Lomb high intensity monochromator. A cutoff filter (KV-370) was used to prevent second-order radiation effects. Light intensity at 470 nm was determined by ferrioxalate actinometry (5). The reaction vessel was fitted with a septum and a valve. 50 μ l gas samples were taken at intervals with a syringe through the septum. The formed hydrogen was monitored on a Varian 3700 gas chromatograph with TC detection using a 1.3m \times 44 mm (id) glass column, packed with mol sieve 5 Å at 40°C. Argon was used as the carrier gas; the flow was 20 ml/min.

Results and Discussion

Single-crystal electrodes.— β -ZnP₂ Figure 1 shows the Mott-Schottky plots obtained from the imaginary part of

the measured admittance for several frequencies between 150 Hz and 20 kHz. The electrolyte used was 1M Na₂SO₄, adjusted to pH 13 by the addition of NaOH. For all frequencies, the plots are reasonably linear, but below \approx 1.5 kHz a significant shift of the intercepts with the potential axis in the negative direction is seen to occur. The concomitant increase of the capacity might be due to the increasing contribution of surface states towards low frequencies (6). Since the curves deviate only slightly from one another at frequencies above 1.5 kHz we can deduce the flatband potential with reasonable accuracy. From Fig. 1, we get $V_{FB} = -0.7 \pm 0.05 V_{SCE}$. In the absence of a knowledge of the surface roughness, we can at best give a rough estimate of the doping concentration N_A . Assuming a roughness factor of 2 and a dielectric constant $\epsilon = 10$ (7), we obtain N_A of $\approx 7 \times 10^{17} \text{ cm}^{-3}$ from the slope of the Mott-Schottky plots.

Due to the highly negative position of the flatband potential $V_{FB} = -0.7 V_{SCE} = -0.46 V_{NHE}$, the hydrogen evolution reaction on the illuminated β -ZnP₂ electrode is strongly exothermic. This explains the steep rise of the photocurrent-potential curves on the bare semiconductor surface, which has been found before (1). The small photovoltage achieved at pH 14 with redox couples such as Fe³⁺/Fe²⁺ triethanolamine (TEA) with a reversible potential of $-1 V_{SCE}$ (1) is also consistent with the negative V_{FB} . Furthermore, as expected in our previous paper (1), the flatband potential does indeed shift by approximately 60 mV per pH unit. This can be seen in Fig. 2, which shows the Mott-Schottky plots at a frequency of 4.7 kHz for several pH values. The electrolyte used in this case was 0.5M K₂SO₄. The electrode had a somewhat smaller doping level than the one described above.

In the next section we examine photoelectrochemical hydrogen evolution from sulfide solutions over β -ZnP₂ powders. As anions such as S²⁻ may cause a cathodic shift of V_{FB} , we have also examined the influence of sulfide on V_{FB} at the β -ZnP₂/electrolyte interface. In contrast to the large shift as a function of pH, the addition of sulfide at pH 13 results only in a small negative shift of V_{FB} . This is displayed in Fig. 3, in which the Mott-Schottky plots for a frequency of 10 kHz are shown before (*) and after (+) the addition of $\approx 7 \cdot 10^{-2} \text{ MS}^{2-}$.

α -ZnP₂.—Since we have not yet performed any doping experiments on the tetragonal α -ZnP₂ crystals (other than annealing them in a phosphorus atmosphere), the photo-

electrochemical results on the highly resistive electrodes are of a somewhat preliminary nature. In particular, we have not yet been able to measure the flatband potential because of an excessive frequency dependence of the Mott-Schottky plots. For the powder experiments, however, we do not expect any major changes for a more highly doped material.

Despite the low doping level, we have only measured a cathodic photocurrent characteristic of a p-type semicon-

ductor. The photocurrent-potential curves show a step rise near the onset potential $V_{on} \approx -0.4 V_{SCE}$ at pH 13, and saturation is attained very rapidly for low light intensities. This is shown in Fig. 4, in which the photocurrent-potential curves are displayed for four different light intensities covering a range of 3 decades. All the curves are normalized to unit intensity. The latter was varied by introducing neutral density filters, the transmission of which differed by a factor of 10 each, in front of the monochro-

Fig. 3. Space charge capacity of β -ZnP₂ in 1M Na₂SO₄, pH 13 before (*) and after (+) the addition of $7 \times 10^{-2} M S^{2-}$. ($\nu = 10$ kHz).

Fig. 4. Normalized photocurrent-potential curves for an α -ZnP₂ photocathode in 1M Na₂SO₄ at pH 13 for different illumination intensities, $\lambda = 470$ nm. The respective intensities are, in arbitrary units: (---) 1, (—) 0.1, (····) 0.01, and (- - -) 0.001.

mator ($\lambda = 470$ nm). There is a much slower rise to the saturation value at the higher light intensities, signifying increased recombination near the electrode surface. For (more intense) white light illumination, this effect is even more drastic. In this case, saturation is no more achieved at high intensities even up to potentials of $-5 V_{SCE}$. Provided that the electrodes can be suitably doped, it should be possible to eliminate this drawback in the future.

The measured cathodic-dark current was negligible in the potential range displayed in Fig. 4 (below $0.1 \mu A$). The addition of sulfide to the electrolyte did not affect the photocurrent-potential curves appreciably. Hence a significant shift of the flatband potential due to the adsorption of S^{2-} can probably be ruled out for α -ZnP₂ as well.

In Fig. 5, is depicted the quantum yield (uncorrected for reflection) as a function of wavelength for an electrode potential of $-3 V_{SCE}$ and at an intensity for which saturation is reached (see also Fig. 4). We have encountered an appreciable variation of the quantum yield of different electrodes. Figure 5 can be regarded to represent the behavior of a typical electrode. The values are comparable to those found in β -ZnP₂ (8), but of course the rise as a function of decreasing wavelength (or rather increasing

photon energy) is much slower due to the indirect nature of the energy gap.

Powders: characterization of the materials.— α -ZnP₂.—The x-ray powder diffractogram of the untreated red α -ZnP₂ reveals the presence of a few percent of β -ZnP₂. Upon application of a catalyst, *viz.* Rh or RuO₂, and the accessory heat-treatment, no reflections disappear, nor can new lines be observed. Likewise, the diffractogram remains unchanged after prolonged illumination. Apparently, α -ZnP₂ is not susceptible to temperatures up to 400°C or visible irradiation.

β -ZnP₂.—The untreated black β -ZnP₂ contains a small amount of another compound, the diffraction lines of which can be most probably assigned to Zn₃P₂. After illumination, the diffractogram also reveals the presence of traces of α -Zn₃(PO₄)₂. Deposition of Rh onto the particles and further heating to 160°C gives no noteworthy changes in the x-ray pattern. However, application of RuO₂, either from RuCl₃ and subsequent calcination at 400°C, or from RuO₄, leads to significant changes. Apart from the Zn₃P₂ lines, also reflections, attributable to α -Zn₃(PO₄)₂ occur in the diffractogram in both cases. The diffractograms of β -ZnP₂ loaded with Rh or with RuO₂, measured after illumination, also show new reflections of low intensity, which we have not been able to assign.

Powders: photochemical production of hydrogen.—Upon bandgap excitation of particles of the p-type semiconductors, α -ZnP₂ ($E_g \approx 2.1$ eV) and β -ZnP₂ ($E_g \approx 1.5$ eV) electron-hole pairs are generated

From the position of the flatband potential (*vide supra*), electrons in the conduction band will have sufficient energy to reduce water to give hydrogen

The holes can be used for oxidation. In this work, we have sacrificed EDTA, cysteine, and sulfide as donors in the anodic processes. Following loss of an electron, EDTA and cysteine are known to undergo kinetically irreversible reactions, which prevent the thermodynamically favorable backreaction (9). Depending on thermodynamic and kinetic considerations, both oxidation of the substrate and of the semiconductor material may occur. In competition with the oxidation of the organic substrate, anodic dissolution of ZnP₂ can take place, which can be described according to the equation

Fig. 5. Quantum yield spectrum of an α -ZnP₂ electrode in 1M Na₂SO₄ at pH 2. Electrode potential $-3 V_{SCE}$.

Free energy values of $\text{Zn}(\text{OH})_2$ and H_3PO_3 are to be found in Ref. (10). Jordan has calculated a standard enthalpy of formation for $\alpha\text{-ZnP}_2$ $\Delta H_f^{298} = -24.3 \text{ kcal mol}^{-1}$ as well as the standard entropy of $\alpha\text{-ZnP}_2$ $S_0 = 14.4 \text{ e } \mu\text{mol}^{-1}$ (11). This ΔH_f^{298} value is in fairly good agreement with the experimental value of $-20.4 \text{ kcal mol}^{-1}$, determined by Alikhanyan *et al.* (12). Using these thermodynamic data, calculated by Jordan, we have computed the potential corresponding to Eq. [3] to be $E = -0.95 \text{ V}_{\text{NHE}}$ at pH 13. This value is fairly well comparable with that calculated for GaP [$-1.07 \text{ V}_{\text{NHE}}$ at pH 13 (13)]. So on thermodynamic grounds photocorrosion of ZnP_2 is a more favorable anodic reaction than water oxidation ($E_{\text{OH}^-/\text{O}_2} = +0.45 \text{ V}_{\text{NHE}}$ at pH 13) and is even easier than the oxidation of the used donors, but kinetic factors favor the latter processes. Nevertheless, photocorrosion of ZnP_2 has to be taken into account, as previously both α - and $\beta\text{-ZnP}_2$ have been found to be unstable under certain conditions (1).

Apart from anodic dissolution, cathodic decomposition of ZnP_2 according to

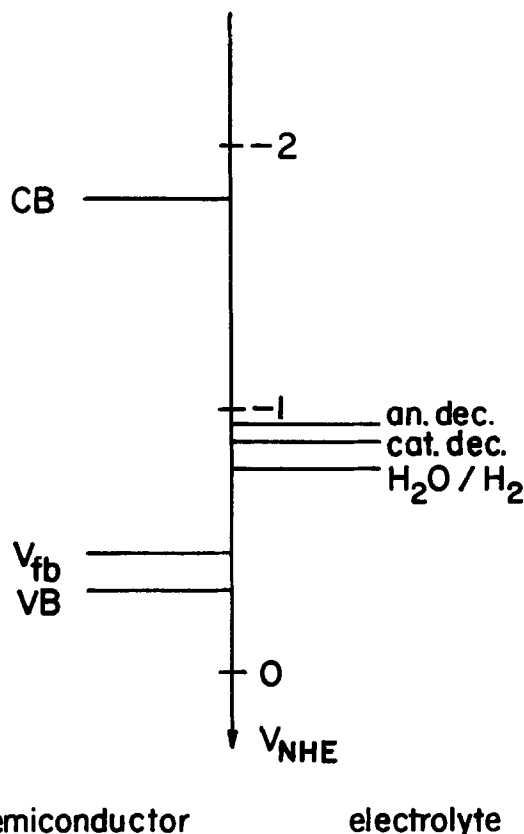

has to be considered as well. From the values given in Ref. (10, 11), we have calculated $E = -0.89 \text{ V}_{\text{NHE}}$ at pH 13.

Relative energy levels at the ZnP_2 -electrolyte interface are given below.

EDTA substrates.—Figure 6 shows the hydrogen production as a function of the illumination time from a 0.1M EDTA solution at pH 13 and 40°C for various α - and $\beta\text{-ZnP}_2$ powders. Apart from the first hour, the untreated powders hardly show hydrogen formation. Deposition of Rh onto $\alpha\text{-ZnP}_2$ gives no perceptible improvement. However, application of RuO_2 evidently enhances the activity, and sustained hydrogen evolution is observed.

For $\beta\text{-ZnP}_2$, the best results are obtained with Rh. In this case, RuO_2 , formed from either RuCl_3 or RuO_4 , also improves the rate of hydrogen formation. Yet, in compari-

Scheme 1. Energy levels at the $\beta\text{-ZnP}_2$ /electrolyte interface at pH 13. For $\alpha\text{-ZnP}_2$, V_{FB} is somewhat more positive according to the photocurrent onset ($\approx -0.4 \text{ V}_{\text{SCE}}$). The position of the bandedges is also different due to the different bandgaps.

Fig. 6. Hydrogen production as a function of the illumination time [EDTA] = 0.1M, pH = 13, $T = 40^\circ\text{C}$, and $\lambda > 418 \text{ nm}$. \square : $\alpha\text{-ZnP}_2$. \circ : $\beta\text{-ZnP}_2$. \blacktriangle : $\alpha\text{-ZnP}_2/0.5 \text{ w/o Rh}$. \circ : $\beta\text{-ZnP}_2/0.5 \text{ w/o Rh}$. \blacksquare : $\alpha\text{-ZnP}_2/0.5 \text{ w/o RuO}_2$. \bullet : $\beta\text{-ZnP}_2/0.5 \text{ w/o RuO}_2$. \triangle : $\beta\text{-ZnP}_2/0.5 \text{ w/o RuO}_2$ (RuO_4 method).

son with $\alpha\text{-ZnP}_2/0.5 \text{ w/o RuO}_2$, the less pronounced effect may be due to the fact that $\beta\text{-ZnP}_2$ is not stable under oxidative and/or heating conditions, as could be deduced from the x-ray diffractograms. As the $\alpha\text{-ZnP}_2/0.5 \text{ w/o RuO}_2$ powder clearly displays the highest activity, we have carried out further experiments using this system.

Figure 7 shows the rate of hydrogen evolution from a 0.1M EDTA solution over $\alpha\text{-ZnP}_2/0.5 \text{ w/o RuO}_2$ particles vs. the wavelength of the light employed (O). The spectral dependence has three important features. A steep increase around 530 nm is observed, which corresponds to the bandedge of approximately 2.1 eV. A decrease in efficiency occurs towards lower wavelengths, where the light penetrates less deeply into the material and surface recombination becomes more important. Moreover, an appreciable subbandgap response is found. So far, we have no satisfactory interpretation of this phenomenon. It cannot be caused by reactions in the dark, because, as shown in Fig. 7, the rate of hydrogen production in the absence of light is relatively unimportant and amounts to only a few percent of the values measured under illumination. Photodissolution of $\alpha\text{-ZnP}_2$ can only account for a minor part of the hydrogen production at these longer wavelengths, as appears from an independent experiment in the absence of EDTA (\cdot). The hydrogen production at $\lambda = 650 \text{ nm}$ and $\lambda = 520 \text{ nm}$ amounts to ca. 3% and 15% of the values obtained in the presence of EDTA, respectively. In the absence of EDTA the anodic

Fig. 7. Rate of hydrogen production over $\alpha\text{-ZnP}_2/0.5 \text{ w/o RuO}_2$ particles in aqueous suspension upon illumination at pH 13 and 40°C as a function of wavelength (corrected to constant energy). \bullet : [EDTA] = 0. \circ : [EDTA] = 0.1M. Under dark conditions, the rate of hydrogen production is as indicated by the full line (dark level).

counter-reaction must be dissolution of α -ZnP₂ into Zn²⁺ and PO₃³⁻ ions, according to Eq. [3]. Consequently, in the presence of EDTA, the figures can be regarded as upper limits for photocorrosion, since EDTA is expected to stabilize the ZnP₂ material. Presumably, the subbandgap effect can be understood by the presence of intermediate levels, likely arising from the occurrence of other photoactive defects or surface states. These levels may act as efficient recombination centers. On the contrary, if the recombination process is relatively slow, accumulation of charge onto the surface will be possible, where this charge will then react with adsorbed species. A similar subbandgap effect has been previously reported to occur in SiC (14).

For one wavelength, viz, $\lambda = 470$ nm, where the rate of hydrogen production reaches about two thirds of its maximum value (at $\lambda \approx 530$ nm), and at room temperature, we have determined the formal quantum efficiency, defined as

$$\Phi = \frac{\text{number of atoms of H}}{\text{number of incident photons}} \times 100\%$$

For a suspension containing 1 mg/ml α -ZnP₂/0.5 w/o RuO₂ and 0.1M EDTA at pH 13, we find a value for Φ of 12%. This will correspond to the lower limit for the true quantum yield. For the photochemical to chemical energy conversion (combustion energy of H₂), we calculate a value of ca. 6%.

In the case of β -ZnP₂ powders, we have encountered difficulties in measuring the rate of hydrogen evolution as a function of the wavelength. The dark reaction for the system β -ZnP₂/0.5 w/o RuO₂/EDTA gives approximately the same values as the α -ZnP₂/0.5 w/o RuO₂/EDTA system. Under light conditions, the rate of hydrogen formation increases by a factor 2-4, depending on the wavelength. Cathodic decomposition according to Eq. [4] cannot *a priori* be ruled out in view of the comparable values of $E_{\text{H}_2\text{O}/\text{H}_2} = -0.78$ V_{NHE} and $E_{\text{cat.dec.}} = -0.89$ V_{NHE} at pH 13. The hydrogen production with concomitant photocorrosion of β -ZnP₂/0.5 w/o RuO₂, measured in the absence of a donor, is about the same as the hydrogen formation in the dark with EDTA. The x-ray diffraction pattern of β -ZnP₂, recorded after the illumination experiment, shows the presence of oxidation products. From its anodic instability and its inactivity under these conditions, we conclude that β -ZnP₂ is unattractive with respect to PEC applications in aqueous powder suspension systems.

Other substrates.—Apart from EDTA, which is a valuable compound, we have also sacrificed sulfide as an electron donor. H₂S is an abundant waste product, and therefore the cleavage of H₂S into H₂ and S or polysulfide is a process of potential industrial significance.

Figure 8 shows the hydrogen formation from a 0.1M sulfide solution at pH 13 over β -ZnP₂ particles as a function of the illumination time.

A substantial decline in the hydrogen production is shown, after which a plateau is reached and no further hydrogen is released. Although on thermodynamic

grounds ($E = -0.45$ V vs. NHE at pH 13) sulfide is expected to be a good substrate for hydrogen production, parameters such as adsorption may provide an explanation for the ceasing of the process.

Adsorption of sulfide may cause poisoning of the catalytically active sites at the surface, or may even lead to chemical reactions with the material. In a previous paper on hydrogen formation from alkaline sulfide substrates over CdS powders, we have reported that addition of sulfite makes the process more efficient because in the anodic reaction thiosulfate is formed (15). In the present case, addition of sulfite has clearly a negative influence on the hydrogen evolution.

We have also used cysteine as a donor, as its behavior will be interjacent to that of an organic donor such as EDTA and sulfide, because of the presence of a sulfidic group. The results, given in Fig. 9, are in agreement with these expectations. It is true that the hydrogen productions do not reach a plateau, but they remain behind the values observed with EDTA. Again, the α -ZnP₂/0.5 w/o RuO₂ displays the highest activity.

Conclusion

So, in conclusion, we can state that α -ZnP₂ is an attractive material in view of its good optical properties. A large fraction of the solar spectrum is absorbed. Loaded with 0.5 w/o RuO₂, the formal quantum yield for hydrogen formation from EDTA (0.06 mol H₂ einstein⁻¹ at $\lambda = 470$ nm) compares favorably with the value of 0.04 at $\lambda = 436$ nm reported recently for a system consisting of platinized CdS, a semiconductor with similar optical properties, and of 0.1M EDTA (16).

However, before this material can be applied on a large scale, the contribution of photocorrosion under various conditions should be studied in detail. Possible problems with respect to dissolution of α -ZnP₂ have then to be solved.

On the other hand, β -ZnP₂ seems much less useful – at least in aqueous powder suspension systems – due to its instability and its disappointingly low activity for the production of hydrogen.

Acknowledgments

Technical assistance by Mr. K. Timmer and by Mr. L. Gantert is gratefully acknowledged. This research was supported by grants from the Netherlands' Ministry of Economic Affairs and from the EC-Solar Energy R&D-Programme, Project D as well as by the NEFF (National Energy Research Fund of Switzerland). We appreciate the donation of semiconductor-grade red phosphorus by Aluisse Corporation, Switzerland. One of us (H.v.K.) would like to express special gratitude to Ms. M. Lübke from the Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin, Germany, for her help in some of the capacity measurements.

Effective Medium Theory for Perfluorinated Ionomers and Blends

William Y. Hsu

E. I. du Pont de Nemours and Company, Central Research and Development Department, Experimental Station, Wilmington, Delaware 19898

ABSTRACT

The effective medium theory is applied to delineate transport and elastic properties of perfluorinated ionomers and their blends. The predicted critical dependence of current efficiency on blend morphology is verified experimentally in sulfonate/carboxylate and sulfonamide/carboxylate blends.

Perfluorinated ionomers are composed of carbon-fluorine backbone chains with perfluoro side chains containing sulfonate, carboxylate, or sulfonamide groups. The general chemical formula is

These ionomers possess exceptional transport, thermal, chemical, and mechanical properties and have been employed as membrane separators, acid catalysts, and polymer electrodes.

In this paper, we shall discuss the composite (1) and percolation (2, 3) nature of wet perfluorinated ionomers, outline an effective medium theory (4) to model their elastic moduli (5), and generalize the theory to track the morphological dependence (6) of ion transport and selectivity in perfluorinated ionomer blends.

Composite and Percolation Nature of Wet Ionomers

The unique transport properties of perfluorinated ionomers can be traced to a spontaneous phase separation occurring in wet polymers: the conductive aqueous-phase forms domains that are randomly distributed in the insulative fluorocarbon phase (1). This clustering phenomenon is very general and has been observed in other ionomers (7). Ion transport in wet ionomers is, therefore, dominated by the connectivity of ion clusters and percolation among them (2).

The essence of percolation can be qualitatively understood as follows (3). At low aqueous content, conductive clusters are scarce and isolated so that macroscopic ion transfer would be difficult. As the water content is increased, the clusters begin to associate until a threshold concentration, f_0 , is reached. At this stage, a macroscopic association of clusters pervading the whole polymer is formed and the system becomes conductive. Above f_0 , the macroscopic association of clusters becomes denser and the conductivity, σ , increases according to the power law

$$\sigma = \sigma_0(f - f_0)^t \quad [1]$$

where f is the volume fraction of the aqueous phase, t is a universal constant that normally depends on the spatial dimensionality only and is typically $1 \cdot 7$ in 3D, and σ_0 is a prefactor that depends on the type of ionomers and caustic concentration. For perfluorinated ionomers, f_0 is typically 8 ~ 10 volume percent (v/o). Figure 1 summarizes our transport data, which were obtained using published methods (2, 8). The universal character of (σ/σ_0) is clearly exhibited. Experimentally, t is 1.53 ± 0.10 , which agrees quite well with theoretical expectation.

The range of validity of Eq. [1] may appear unexpectedly wide at first sight from Fig. 1. However, Stinchcombe (9) had found theoretically on Bethe lattices that the critical regime for percolation theory is $0 \leq (p - p_c) \leq z^{-1}$, where p is the fraction of occupied bonds in a Bethe lattice of coordination number z and p_c is the critical value of p . For $z = 4$ and $p_c = 0.5$, the critical regime would extend to $(p - p_c)/p_c = 0.5$, which is much larger than the corresponding values from other phase transition problems (10). Our data are certainly consistent with Stinchcombe's theory. In addition, a wide critical range for Eq. [1] has also been observed in thick film resistors based on conductive pyrochlores (11) and carbon/polyvinylchloride composites (12), and for the dielectric analogue of Eq. [1] in Ag/KCl composites (13).

Effective Medium Theory

Physical properties of composite systems can also be modeled by the effective medium theory (4) under proper conditions (6, 14). In this approach, we imagine replacing the composite system by a homogeneous medium that has the same macroscopic properties and physical constants as the composite system. Changes in relevant fields are then evaluated when a small portion of the effective medium is replaced by one of the component materials that made up the composite. To ensure self-consistency, we require the average change in these

Fig. 1. Log-log plot of normalized conductivity (σ/σ_0) vs. the excess volume fraction of aqueous phase ($f - f_0$). The straight line is a fit of theory (Eq. [1]) to data. The slope t is 1.53 ± 0.10 .

fields to be zero when the components are dispersed randomly. When applied to the bulk and shear moduli, K and G , of wet perfluorosulfonate ionomers, a pair of equations (5, 15) that relate K and G to the elastic moduli [K_w , $G_w (= 0)$, K_p , and G_p] of water and dry fluoropolymer emerge. Eliminating K , we obtain a cubic equation for G , the effective shear modulus of the composite (5)

$$32G^3 + \alpha G^2 + \beta G + \lambda = 0 \quad [2]$$

where

$$\alpha = 24(K_w + K_p) + 12[fK_w + (1-f)K_p] + 16G_p(5f - 2) \quad [3a]$$

$$\beta = 27K_wK_p + 12(K_w + K_p)G_p(5f - 2) - 12G_p[fK_w + (1-f)K_p] \quad [3b]$$

$$\lambda = 9K_wK_pG_p(5f - 3) \quad [3c]$$

Using this method, we have computed the tensile modulus E of a 1200 EW perfluorosulfonate ionomer at room temperature and for $f \leq 0.4$. The theoretical result is compared to data (16) in Fig. 2 and has also been fitted to the following empirical form (16)

$$E = E_0 \exp[-A/f2(1-f)] \quad [4]$$

where $E_0 = 4.01 \times 10^4$ psi, and where A is 3.31 which is within 15% of the experimental value 2.94. In the above comparison, the only inputs to the theory were the water content and the known moduli of water and dry ionomer: $K_w = 2.55 \times 10^{10}$ dyn-cm² at 20°C and atmospheric pressure, $K_p = 3.47 \times 10^{10}$ dyn-cm⁻², and $G_p = 9.22 \times 10^8$ dyn-cm².

The advantages of effective medium theory are its conceptual and mathematical simplicity and its versatility. It will now be generalized to include morphological effects (6).

Fig. 2. Comparison of theoretical and experimental values of the tensile modulus for a 1200 EW perfluorosulfonate ionomer. Data are from Ref. (16).

Morphological Effects

Consider a collection of oriented spheroids. They can be either prolate $a \geq b = c$ or oblate $a = b \geq c$, where a, b, c are the semi-principal axes of an ellipsoid. The geometry and orientation are depicted in Fig. 3. For both cases, the eccentricity e of the spheroids is $[1 - (c/a)^2]^{0.5}$, where $0 \leq (c/a) \leq 1$ is the aspect ratio. The remaining space is now completely filled with spheroids of a different material but of the same eccentricity and orientation. Let σ_1 and σ_2 represent the diagonal component of the conductivity tensor along the field direction for the two media, respectively. Following the spirit of the previous section, we obtain a quadratic equation for the effective conductivity, σ , of the composite medium

$$[1 - F(e)]\sigma^2 + \{\sigma_1[F(e) - f_1] + \sigma_2[F(e) - f_2]\}\sigma - \sigma_1\sigma_2F(e) = 0 \quad [5]$$

where f_1 and f_2 are the volume concentrations of the two media, and where the function F depends on the shape of the spheroid (cf. Fig. 4)

$$F(e) = \frac{(1 - e^2)}{2e^3} \left\{ \ln \left(\frac{1 + e}{1 - e} \right) - 2e \right\} \quad [6a]$$

for the prolate case, and

$$F(e) = \frac{1}{e^2} \left\{ 1 - \left(\frac{\sqrt{1 - e^2}}{e} \right) \arctan \left(\frac{e}{\sqrt{1 - e^2}} \right) \right\} \quad [6b]$$

for the oblate case. Equation [5] is generally applicable when

$$10^{-2} \leq (\sigma_1/\sigma_2) \leq 10^2 \quad [7]$$

A unique feature of this model is that the shape of the inclusions can be continuously altered between lamellar ($e = 1$) and spherical ($e = 0$) for the oblate geometry, and between fibrillar ($e = 1$) and spherical ($e = 0$) for the prolate case. For the spherical limit ($e = 0$, $F = 1/3$), Eq. [5] reduces to the standard form given in the literature (4).

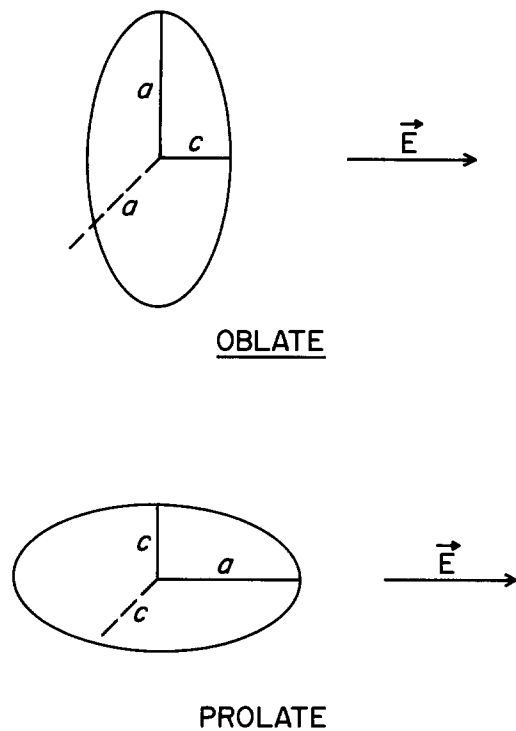

Fig. 3. Geometry and orientation of spheroids. The ellipse is a projection of the spheroid under consideration onto the a - c plane and E is the applied field.

Ion Selectivity in Ionomer Blends

The morphological information contained in Eq. [5] is most conveniently illustrated with blends of perfluorinated ionomers since the various ionomers have very different properties, and since the domain morphology in blends can be altered and controlled by rheology. We define the current efficiency as the fractional contribution to the total current by the Na^+ ions. For the ionomers

Fig. 4. Eccentricity dependence of the F function (Eq. [6])

Fig. 5. Cross-sectional micrograph of a pressed film of 25% carboxylate and 75% sulfonate blend of perfluorinated ionomers. The elongated regions (arrows) are the carboxylate phase.

Fig. 6. Current efficiency of perfluorinated carboxylate/sulfonate blends. Open circles and vertical bars are average data and experimental uncertainty, respectively. The three continuous curves are predicted behavior of oriented oblate spheroids with lamellar (top curve) to almost spherical (bottom curve) morphologies; the aspect ratios c/a are, from top to bottom, 0.01, 0.25, and 0.995, respectively.

Table I. Ionic conductivities and current efficiency of 1100 EW perfluorinated ionomers

Ionomer	σ_{Na}^+ ($10^{-3}\Omega^{-1}\text{cm}^{-1}$)	σ_{OH^-} ($10^{-3}\Omega^{-1}\text{cm}^{-1}$)	c.e. (%)
Sulfonate	18.0	13.6	57
Carboxylate	6.99	0.61	92
Sulfonamide	1.44	0.25	85

under consideration, the c.e.'s and ionic conductivities are listed in Table I. Appropriate ratios of the conductivities obviously satisfy the validity conditions Eq. [7]. Assuming independent Na^+ and OH^- channels, the composite conductivity and c.e. can be evaluated.

Typical pressed films of the blends have a pronounced lamellar morphology, as shown in Fig. 5. For perfluoro-sulfonate/carboxylate blends, the computed c.e. for oriented oblate spheroids at three eccentricities are plotted as function of blend composition and compared to experimental data in Fig. 6. Obviously, the computed c.e. for the lamellar morphology agrees very well with the data. Notice the dramatic difference between spherical and lamellar morphologies. For the spherical case, the c.e. increases slowly and turns over gradually as the carboxylate content is increased. In contrast, the c.e. rises steeply and turns over rapidly with the lamellar morphology. To verify this pronounced morphological dependence, the rheology of a 25% carboxylate/75% sulfonate blend is altered to produce the abnormal spherical morphology (Fig. 7). In contrast to its lamellar counterpart and in agreement with the theoretical prediction, this film has an unusually low c.e., as shown in Table II.

The lamellar morphology, however, may not always be desirable. It is beneficial in the above example because it has prevented OH^- ions from flowing through the conductive but poorly selective sulfonate phase. By the same token, the lamellar morphology would also hinder OH^- ions from reaching the selective and relatively conductive carboxylate phase in perfluorosulfonamide/carboxylate blends. The resultant c.e. is distinctly concave (Fig. 8), in marked contrast to the convex curvature of sulfonate/carboxylate blends. Consequently, despite sulfonamide ionomers are more selective than sulfonate, the c.e. of sulfonate/carboxylate blends could surpass comparable

Fig. 8. Computed ion selectivity (c.e.) of lamellar perfluorinated ionomer blends.

sulfonamide/carboxylate blends with a lamellar morphology. This predicted anomaly was confirmed in perfluorinated ionomer blends containing 50% carboxylate (Table II). In this case, due to the low conductance of sulfonamide, spherical or tubular morphology can better promote ion flow through the selective carboxylate phase.

Conclusion

In summary, we have applied the effective medium theory to delineate the elastic properties of perfluorinated ionomers and their blends. The theory has also been

Fig. 7. Cross-sectional micrograph of a pressed film of similar composition as Fig. 5. The rheology, however, has been adjusted to produce spherical carboxylate domains (arrow). The dark line from upper left-hand corner to central bottom is due to fold over the microtomed sample film.

Table II. Morphological dependence of c.e. for 25% carboxylate and 75% sulfonate blends of perfluorinated ionomers

Morphology	Predicted c.e. (%)	Observed c.e. (%)
Spherical (Fig. 7)	62	56
Lamellar (Fig. 5)	86	89

Table III. c.e. of perfluorinated ionomer blends containing 50% carboxylate. The EW is approximately 1100, and the blend morphology is predominantly lamellar

Blend	Predicted c.e. (%)	Observed c.e. (%)
Sulfonate/carboxylate	90	91
Sulfonamide/carboxylate	87	86

extended to include morphological dependence. The principal predictions were verified with perfluorosulfonate/carboxylate blends and perfluorosulfonamide/carboxylate blends. We demonstrated that a universally preferred morphology beneficial to all ionomer blends does not exist. The ideal morphology must be individually determined based on component properties.

Cyclic Voltammetry in Solutions of Aluminum Bromide and KBr in Aromatic Hydrocarbons

III. The Behavior of Ag and Cu

M. Elam, E. Peled,* and E. Gileadi*

Department of Chemistry, Tel Aviv University, Ramat Aviv 69978, Israel

ABSTRACT

The electrochemical behavior of AgBr and CuBr has been studied in a solution consisting of 0.80M KBr and 1.0M Al₂Br₆ in ethylbenzene. A significant crystallization overpotential is observed for Cu on Pt, while silver exhibits only a marginally small crystallization overpotential. Measurements of the diffusion coefficients by different methods and comparison with earlier results yield values in the range of $(1.1-2.9) \times 10^{-6}$ cm²/s (corresponding to Stokes radii of 9-4Å), except for Cu, which yields a value of $(10-21) \times 10^{-6}$ cm²/s. These high apparent values are probably due to catalytic decomposition of the solvent caused by the presence of cuprous ions. The relatively high value for the diffusion coefficient of mercuric ions in toluene reported in an earlier publication is probably due to the same effect.

In a previous publication (1) the electrochemical behavior of dilute solutions of SnBr₂ and PbBr₂ in solutions of 1.0M Al₂Br₆ and 0.80M KBr in ethylbenzene was studied. Only the divalent state of Pb and Sn were observed in the available potential region, between aluminum deposition on the cathodic side and bromine evolution (or bromination of the solvent) on the anodic side. A nucleation overpotential of ca. 30-40 mV was observed for the deposition of both metals on Pt. The electrodeposition of aluminum was inhibited by low concentrations of PbBr₂, while SnBr₂ exhibited no such effect. The diffusion coefficients were estimated as 1.1×10^{-6} cm²/s for lead and 2.7×10^{-6} cm²/s for tin. Formation of a thermodynamically unstable Al/Pb alloy at sufficiently cathodic potentials was indicated.

*Electrochemical Society Active Member.

The relevant literature was surveyed briefly in our previous paper (1) and in greater detail in an earlier publication (2).

In the present paper, the electrochemical properties of dilute solutions of AgBr and CuBr in the same solvent system were studied. The diffusion coefficients were determined by three independent methods, and cyclic voltammograms were measured with the aid of a microcomputer used both to control the experiments and to analyze and plot the results.

Experimental

All measurements were performed in rigorously dried solutions of 1.0M Al₂Br₆ and 0.80M KBr in ethylbenzene, inside a glove box containing purified argon. The methods of purification of the electrolyte and the solvent were

described previously (3-5). Silver bromide (ROC/RIC, anhydrous 99.9%) and cuprous bromide (ROC/RIC, anhydrous 99%) were used without further purification.

The cell and the electrodes employed for the measurements of cyclic voltammograms were described in the first paper in this series (3). A microcomputer (Delta Products) based on an IEE 696, bus S-100, and Zilog Z80 microprocessor with 64K RAM was used to control the experiments. The triangular waveform was generated through a 12 bit D/A converter (Tecmar). The software developed allows determination of the voltage limits, the sweep rate, and the number of repetitions. Before each run, the solution was stirred for 20s and left quiescent for 30s. Each voltammogram shown represents the average of at least three runs. The voltammograms were displayed on a 24 in. graphic video monitor (Leedex Model 100) and recorded on 8 in. floppy disks for further analysis, including replotting and analyzing the results, such as the peak potential and peak current *vs.* the concentration and the sweep rate in the usual manner. In some cases, the value of the potential $E_{p/2}$ at half the peak current was used instead of E_p , since it could be determined with a higher degree of accuracy.

The potentiostatic transients were performed as described elsewhere (1). All potentials reported were measured against a reversible aluminum electrode in the same solution (RA1E).

Determination of the diffusion coefficients with a rotating disk system (Pine Instruments, Model ASR-2) were also performed inside the glove box. The solutions of $PbBr_2$ and $SnBr_2$ used in these measurements were prepared as described earlier (1).

Results and Discussions

Cyclic voltammograms for AgBr.—Two voltammograms taken in solution containing AgBr are shown in Fig. 1. The cathodic peak current, $i_p(c)$, is proportional to the concentration of AgBr at all sweep rates tested ($d \log i_p(c)/d \log C = 1.00 \pm 0.01$). The dependence of peak current on sweep rate is given by $d \log i_p(c)/d \log v = 0.48 \pm 0.01$, close to the value of 0.50 expected for a simple charge transfer process (6).

The potential at half-peak current ($E_{p/2}$) varies significantly with sweep rate and with peak current, as expected for an irreversible charge transfer process (6-8). The semilogarithmic plots shown in Fig. 2 are not linear but tend, at higher sweep rates, to the limiting values of $dE_{p/2}/d \log v = 29 \pm 3$ mV/decade and $dE_{p/2}/d \log i_p = 60 \pm 5$ mV/decade. However, $E_{p/2}$ depends on the concentration of AgBr ($dE_{p/2}/d \log C = 63 \pm 4$ mV/decade), as would be

Fig. 1. Cyclic voltammograms for AgBr. Sweep rates (in V/s): solid line - 0.396; broken line - 1.174.

Fig. 2. Cathodic half-peak potentials for AgBr as a function of (a) $\log i_p$ and (b) $\log v$. Concentration of AgBr: (curve 1) 3.3, (curve 2) 5.2, (curve 3) 7.8, and (curve 4) 11.4 mM.

expected for a one-electron reversible metal deposition process. Measurements of the reversible potential as a function of concentration yielded a Nernst slope of 57 mV/decade (9).

A further anomaly is found when the difference between the cathodic peak potential [$E_p(c)$] and the cathodic half-peak potential [$E_{p/2}(c)$] is considered. The difference $\Delta E = E_p - E_{p/2}$ should be $-0.77RT/nF = 0.020/n$ V at 25°C for the reversible deposition of an insoluble substance (10), and should increase with increasing sweep rate in the irreversible region. The values of ΔE found experimentally range from 10-20 mV only and they decrease with increasing concentration of AgBr.

Although the nucleation overpotential for silver deposition on clean platinum is relatively small (11), as indicated by the narrow overpotential range where a current maximum occurs in the pulse potentiostatic curves, it could be the cause of the discrepancies noted above. It should also be noted that different electroactive species may occur in this system (9, 12) giving rise to various reaction mechanisms occurring simultaneously, leading to unusual values of the observed diagnostic parameters.

Cyclic voltammetry for CuBr.—Typical cyclic voltammograms for solutions containing CuBr are shown in Fig. 3

Fig. 3. Cyclic voltammograms for CuBr. Sweep rates (mV/s) (curve 1) 12 and (curve 2) 21.

Fig. 4. Cathodic peak potentials for CuBr as a function of: (a) $\log v$ and (b) $\log i_p$. Concentrations of CuBr: (curve 1) 2.6, (curve 2) 3.9, (curve 3) 6.5, (curve 4) 10.2, (curve 5), 16, and (curve 6) 23 mM.

for two sweep rates. The anodic peak has the characteristic shape (1, 13) corresponding to the oxidation of metallic Cu to Cu^+ . A second anodic peak, which would correspond to the oxidation of monovalent to divalent copper, could not be detected in the whole potential region up to bromine evolution. This confirms our earlier findings (9) that the reversible potential for the $\text{Cu}^+/\text{Cu}^{2+}$ couple is more positive than the bromine-evolution potential and that monovalent copper is much more stable than divalent copper in this solvent system. Note the relatively large difference between the anodic and the cathodic peak potentials in Fig. 3, which is caused by nucleation overpotential, as will be discussed below.

Fig. 5. Cathodic peak potentials as a function of $\log C$ (CuBr). Sweep rates (mV/s): (curve 1) 1.1, (curve 2) 2.2, (curve 3) 5.5, (curve 4) 12, (curve 5) 21, and (curve 6) 55.

Fig. 6. Comparison of the initial potentials for deposition of Ag or Cu on Pt and on the respective metal. Sweep rate: 12 mV/s. Curve 1: Ag deposited on Ag (or Cu on Cu). Curve 2: Ag (or Cu) deposited on Pt.

The cathodic peak potential changes with sweep rate and with peak current, as expected for an irreversible process. The slopes observed in Fig. 4 are $dE_p/d \log V = 33 \pm 1$ mV/decade and $dE_p/d \log i_p = 104 \pm 7$ mV/decade. Accordingly, the variation of peak current with sweep rate should be $d \log i_p/d \log v = 0.32$, while a somewhat higher value of 0.39 is found experimentally. The deviation of this last parameter from the expected value of 0.50 is most likely due to the high crystallization overpotential observed for copper on platinum (cf. Fig. 3). This also accounts for the fact that the peak potential is a function of the concentration of CuBr, as would be expected for a reversible process. The average slope $dE_p/d \log C$ shown in Fig. 5 is 58 ± 2 mV/decade, to be compared with a value of 49 ± 1 mV/decade reported in our earlier publication (9). The potential difference $\Delta E = E_p - E_{p/2}$, which should be equal to 20 mV for a reversible, one-electron process, exhibits a behavior similar to that shown above for AgBr, increasing slightly with sweep rate from 10 to 20 mV and decreasing with concentration of CuBr.

Nucleation.—Formation of metal deposits controlled by the rate of nucleation has been studied for some time

(14-18), and was described for different metals deposited from aqueous solutions (14) as well as from molten salt systems (19, 20).

Figure 6 shows the occurrence of nucleation overpotential. Curve 1 is taken in both cases on a platinum electrode freshly coated with the respective metal, while curve 2 is taken on a bare Pt electrode. Deposition of copper on platinum does not start until an overpotential of more than 120 mV is reached, at which point nucleation occurs and the deposition can proceed. Because of this overpotential, the surface concentration, as determined by the Nernst relation, is considerably higher than that in the vicinity of the reversible potential. This leads to a higher concentration gradient of copper ions when the surface concentration is suddenly depleted and hence to a sharp and high peak current. In the experiment shown in Fig. 6, it is more than twice that obtained on a copper electrode where a nucleation overpotential does not exist. Very similar results were obtained in a molten alkali nitrate system (14). Nucleation overpotential of silver on a clean platinum electrode is relatively small, as pointed out elsewhere (11), but still a sharp rise of current is observed.

A different experiment describing the same type of phenomenon is shown in Fig. 7, where current/time transients following a potential step from the open-circuit potential to the value marked, are plotted: At the most cathodic overpotential (-212 mV), the current decays in a regular manner with time ^{-1/2}. At less cathodic overpotentials, the current on the bare platinum electrode first decreases, but as soon as a layer of Cu is formed, nucleation overpotential diminishes and the current rises to the value it would have on a freshly prepared Cu electrode.

The coordinates of the maxima in Fig. 7 can serve as a diagnostic criterion for the type of nucleation process taking place. Thus, it was shown (11) that the relationship

$$i_{\max}^2 \cdot t_{\max} = k(nFC)^2 D \quad [1]$$

holds. The numerical constant k should be equal to 0.260 for progressive nucleation and to 0.163 for instantaneous nucleation. In order to evaluate experimentally the constant k , one has to determine the diffusion coefficient by an independent experiment. This was calculated from the slope of a plot of i vs. $t^{-1/2}$ taken at an overpotential of -212 mV (uppermost curve in Fig. 7). Using the value of $(2.1 \pm 0.1) \times 10^{-5}$ cm²/s obtained in this manner the constant k was found to be 0.25 ± 0.01 at low overpotentials and 0.18 ± 0.01 at high overpotentials. A plot of i_{\max} vs. $t_{\max}^{-1/2}$ is shown in Fig. 8. The transition of the slope between small and large values of t_{\max} is clearly seen. Thus instantaneous nucleation appears to be predominant at high overpotentials and slow progressive nucleation occurs at low overpotentials, in agreement with results reported for aqueous solutions (11).

The diffusion coefficients.—The diffusion coefficients of copper and silver were measured by three independent methods: from the peak current in cyclic voltammetry, from current decay following a potential step at high overpotentials (where nucleation is essentially instantaneous on the time scale used, say, in Fig. 7), and by determining the limiting current on a rotating disk electrode. The last method was also used to determine the diffusion coefficients of lead and tin in order to compare to results reported earlier (1) for these two elements.

A summary of these results is shown in Table I. The data obtained from cyclic voltammetry should be consid-

Fig. 8. Plots of current density as a function of (time)^{-1/2} for potentiostatic transients of CuBr on Pt. (xxx): i_{\max} vs. $t_{\max}^{-1/2}$. (ooo): i vs. $t^{-1/2}$ of the uppermost curve in Fig. 7.

ered the least reliable, since some degree of nucleation overpotential, causing a rise of i_p above that calculated for simple diffusion and deposition, occurs in all cases. Values of the diffusion coefficient of tetravalent titanium obtained in this laboratory (21) are also included in Table I.

Outstanding among the results shown in Table I is the exceptionally high value observed for copper. A value of $(10 \pm 1) \times 10^{-6}$ cm²/s obtained from rotating disk measurements would lead to a Stokes radius of ca. 1Å, about equal to the crystallographic radius of copper. It was assumed that cuprous ions act as catalysts for the electrochemical reduction of the solvent. This was confirmed by the low faradaic efficiency observed for electrodeposition of copper (ca. 65%), compared to 100% efficiency for lead and tin.

Polarization of the Molten Carbonate Fuel Cell Anode and Cathode

C. Y. Yuh* and J. R. Selman**

Department of Chemical Engineering, Illinois Institute of Technology, Chicago, Illinois 60616

ABSTRACT

A dual-porosity, agglomerate-type model for the porous anode and cathode of the molten carbonate fuel cell is developed and used to predict electrode performance in a small, differential-conversion, cell. The model is based on a phenomenological treatment of mass transport, electrode kinetics, and ionic conduction, combined with structural assumptions. The model predicts the steady-state performance, given a minimum number of structural parameters. Comparison with experimental data for a 3 cm² anode and cathode shows good agreement for plausible values of these parameters.

Both the anode and the cathode of the molten carbonate fuel cell are porous gas-diffusion electrodes. Porous electrodes have numerous industrial applications, primarily because they promote intimate contact of the electrode material with the electrolyte solution or melt, and with both solution and gaseous phase when a porous gas-diffusion electrode is used. Simulation of porous electrode performance is important for design purposes. It is necessary to establish a model which accounts for the essential features of an actual electrode without going into exact geometric detail. Ideally, the model should make use of parameters which can be established by measurements at solid electrodes and in bulk electrolyte. The theoretical analysis of porous electrodes is complicated because the contact of electrode and electrolyte in porous electrodes makes the ohmic conduction and mass-transfer processes occur both in series and in parallel with the electrode reaction, with no easy way to separate them. This work aims to make a contribution to improved simulation of porous gas-diffusion electrodes by an extension of the agglomerate model.

Review of Previous Work

In the past 20 years, several models have been developed to simulate the behavior of a porous gas-diffusion electrode. The simplest model is the "simple" (or flooded) pore model (1). This model, however, is too primitive, and in most cases predicts too low a value for the mass-transport-limited current. The thin film (2, 3) and finite-contact-angle meniscus models (4) are extensions of the simple pore model and account for variations in the wetting tendency of the electrolyte. In a pore with finite-angle meniscus (Fig. 1b), as in a flooded (Fig. 1a), most of the current is concentrated in a small part of the pore wall. In a film-covered pore (Fig. 1c), the electrode reaction, although less restricted, still tends to be concentrated in that part of the film which is close to the bulk electrolyte. Migration of reactants on the surface of the electrode has also been included (5). In real porous electrodes, there is a spectrum of pore sizes; to account for this, several types of dual-porosity models (6-8) have been developed. A relatively simple model is that developed by Giner and Hunter (9) for the Teflon-bounded oxygen electrode of low temperature alkaline fuel cells. They assumed that this electrode can be represented by parallel

Fig. 1. Schematic diagrams of flooded pore, meniscus, and thin film models.

cylindrical columns of microporous, flooded catalyst (agglomerates) held together by capillary forces and surrounded by gas phase. In their model, there is no film on the external surface of the agglomerate.

Most of the models cited above were restricted in their application to a particular system. The applicability of a certain model depends on the electrode structure and wetting characteristics of the electrolyte; these are obviously not the same in different kinds of fuel cells. Some simple models (thin film and flooded pore model) have been applied to the molten carbonate fuel cell (10-12) and fitted to a limited range of performance data. From postoperation micrographs of porous nickel anodes and nickel oxide cathodes, there is some reason to believe that the agglomerate model may represent electrode structure more adequately than the thin film model. However, the anode and cathode have different wetting characteristics, and it is necessary to account for this. Thus, the nickel anode is not well wetted under reducing conditions, which would correspond reasonably well with the absence of an extended film (dry agglomerate model). However, the cathode is very well wetted (contact angle 0°), and the agglomerates are probably covered by a film. Thus one needs, as also suggested by Giner and Hunter (9), to develop an extension of their agglomerate model. This is termed here the "filmed agglomerate model." An extension of the original agglomerate model is necessary also in a second respect. Giner and Hunter's model contains only one reactant species (dissolved oxygen) and neglects product activity variation (strong KOH electrolyte). The kinetics of both the molten carbonate anode and cathode involve several species dissolved in the melt. It is necessary to develop separate mass balances for these species, and couple them with the electrode-kinetic rate expression. This entails greater mathematical complexity.

Analysis

As shown in Fig. 2, the electrode structure can be pictured as one in which catalyst particles form agglomerates which, under working conditions, are flooded with electrolyte. When current is drawn from the electrode, reactant gas diffuses through the macropores, and dissolves in the electrolyte contained in the agglomerate. After diffusing a certain distance, it reacts at available sites on the catalyst particles.

Fig. 2. Schematic of porous structure

We make the following assumptions in order to simplify the mathematical analysis without detailing the actual geometry within the agglomerates.

1. The electrode is made up of a number of cylinders of catalyst with radius R and length L as shown in Fig. 3a and 3b. The agglomerate is flooded with electrolyte. If there is a film on the external surface, the film thickness δ is uniform.

2. The electrolyte and catalyst in the agglomerate cylinders are homogeneously mixed and form a quasicontinuum.

3. The Butler-Volmer equation is a suitable representation of the electrode kinetics. The transfer coefficients, α_a and α_c , are constant.

4. The transport of current through the electrolyte follows Ohm's law. The IR drop in the metal phase is negligible.

5. The gas-phase mass-transfer resistance is negligible.

6. The current flows in the cylinder only in the axial direction, *i.e.*, potential gradients in the radial direction are

Fig. 3. Schematic of porous electrode structure in two agglomerate models. (a): Dry agglomerate model. (b): Film agglomerate model. (c): Detail of film agglomerate model.

negligible, and concentration gradients in the axial direction are negligible.

7. The concentration of dissolved gases at the gas-electrolyte interface follows Henry's law. In the case of oxygen, this appears to be justified by the proportionality of observed limiting current at the cathode with oxygen partial pressure. However, there is uncertainty as to the form in which dissolved oxygen is present (superoxide, peroxide); this should affect the solubility behavior (13, 14).

8. The system is isothermal, isobaric, and at steady state.

9. The activity of CO_3^{2-} ions is everywhere equal to unity.

10. All physical parameters are constant.

The following generalized reaction takes place at the electrode surface

The species balance which incorporates diffusion and reaction is

$$\bar{D}_i \nabla^2 C_i = \frac{s_i A i_n}{n F} \quad [2]$$

Here i_n is the transfer current density at the electrode-electrolyte interface and can be expressed by the Butler-Volmer equation

$$i_n = i_0^b \prod_i (C_i/C_i^b)^{\gamma_i} \{ \exp(\alpha_a F \eta_s / RT) - \exp(-\alpha_c F \eta_s / RT) \} \quad [3]$$

The following dimensionless quantities are defined

$$\bar{C}_i = C_i/C_i^b, \quad \xi = r/R, \quad \zeta = z/L$$

Neglecting the diffusion term in the axial direction, we have

$$\frac{1}{\xi} \frac{\partial}{\partial \xi} \left(\xi \frac{\partial \bar{C}_i}{\partial \xi} \right) = s_i N_i i_n \quad [4]$$

for species i , where

$$N_i = \frac{R^2 A}{\bar{D}_i C_i^b n F}$$

We need one more equation, *i.e.*, the current balance. In the molten carbonate fuel cell, the anode and cathode have different current balance equations because only the cathode is covered by a film, whereas the anode may be treated as a "dry agglomerate."

Dry agglomerate model (anode).—Here the current balance is, for example, for hydrogen

$$\frac{d^2 \Phi_L}{dz^2} = - \frac{2n \bar{D}_1 F}{s_1 R} \left(\frac{dC_1}{dr} \right) \Big|_{r=R} \quad [5]$$

Equation [5] states that the diffusion flux of species 1 into the differential volume is related to the current generation inside the differential volume. For each species, the relationship depends on the stoichiometric ratio n/s_i in Eq. [1]. Here, the subscripts denote: 1 hydrogen, 2 CO_2 , and 3 H_2O . In dimensionless form

$$\frac{d^2 \psi_L}{d\zeta^2} = P_1 \left(\frac{d\bar{C}_1}{d\xi} \right) \Big|_{\xi=1} \quad [6]$$

where $P_1 = -2n \bar{D}_1 F C_1^b \phi L^2 / \kappa R^2 S_1$, $\psi_L = \phi \Phi_L$, and $\phi = F/RT$. The boundary conditions are

$$\zeta = 0, \quad \frac{d\psi_L}{d\zeta} = 0 \quad [7a]$$

$$\zeta = 1, \quad \psi_L = \psi_0 \quad [7b]$$

$$\xi = 0, \quad \frac{d\bar{C}_i}{d\xi} = 0 \quad [7c]$$

$$\xi = 1, \quad \bar{C}_i = 1 \quad [7d]$$

Filmed agglomerate model (cathode).—In the case of the cathode, the film exerts additional diffusion resistance. This will change boundary condition [7d] and also current balance Eq. [6].

For species 1, the diffusion flux in the film toward the electrode surface must be equal to the depletion rate caused by reaction at the external surface, plus the diffusion flux toward the interior of the agglomerate. In mathematical terms

$$\bar{D}_i \left(\frac{dC_i}{dr} \right) \Big|_{r=R} = D_i \frac{C_i^b (1 - \bar{C}_i^s)}{R \Delta} - s_i (1 - \epsilon) i_n / n F \quad [8]$$

In dimensionless form

$$\frac{d\bar{C}_i}{d\xi} - F' (1 - \bar{C}_i) + P_1'' i_n = 0 \text{ at } \xi = 1 \quad [9]$$

where

$$F' = 1/\epsilon \Delta, \quad P_1'' = \frac{s_i (1 - \epsilon) R}{n F C_i^b \bar{D}_i}$$

and $\Delta = \ln [(R + \delta)/R]$.

Equation [9] is substituted for the boundary condition [7d] in the case of a filmed agglomerate.

The current balance Eq. [6] has to be changed because both the film and the agglomerate conduct current. By a similar derivation at the cathode, except that the diffusion flux of species into the differential volume is represented by the flux in the film, (Fig. 3c)

$$\frac{d^2 \psi_L}{d\zeta^2} = P P_1 (1 - \bar{C}_i^s) \quad [10]$$

where

$$P P_1 = \frac{-2n F D_1 C_1^b \phi L^2}{\kappa R_1 (R + \delta)^2 \Delta S_1}$$

and

$$R_1 = \frac{\left\{ R + \frac{(R + \delta)^2 - R^2}{\epsilon} \right\}}{(R + \delta)^2}$$

Here, the subscript 1 stands for O_2 , and 2 for CO_2 . Finally, we have four partial differential equations for the anode and three for the cathode. The relationship between Φ_L and η_s can easily be expressed by the Nernst equation. The final unknowns are \bar{C}_i and ψ_L .

Input Parameters

The input parameters needed to apply the agglomerate model are the kinetic, transport, and thermodynamic properties of the electrode/electrolyte combination, as well as structural parameters of the porous electrode. In the case of the anode, we adopt the reaction mechanism proposed by Ang and Sammells (15). This mechanism predicts dependence of i_0^b and C_1 as follows

$$i_0^b = i_0^0 (\text{H}_2)^{0.25} (\text{CO}_2)^{0.25} (\text{H}_2\text{O})^{0.25} \quad [11]$$

It also predicts $\alpha_a = 0.5$ and $\alpha_c = 1.5$. For fuel oxidation at nickel in Li/K melt at 923 K, they obtained the standard exchange current density, $i_0^0 = 105 \text{ mA/cm}^2$. For fuel oxidation at Cu in Li/K melt, Lu (16) obtained a slightly lower i_0^0 , 72.4 mA/cm^2 .

Adequate investigations of the oxygen reaction kinetics are available only on gold electrodes. Appleby and Nicholson (17, 18) proposed two mechanisms for this reaction: (i) the "peroxide mechanism," leading to the kinetic expression

$$i_0^b = i_0^0 (\text{O}_2)^{0.375} (\text{CO}_2)^{-1.25} \quad [12]$$

$$\alpha_a = 1.5, \quad \alpha_c = 0.5$$

and (ii) the "superoxide mechanism," leading to

$$i_0^b = i_0^a(O_2)^{0.625}(CO_2)^{-0.75} \quad [13]$$

$$\alpha_a = 2.5, \alpha_c = 0.5$$

At 650°C and at a gold surface, in Li-K melt (62-38 mole percent [m/o]), i_0^a is 0.012 mA/cm² for the peroxide mechanism and 0.003 mA/cm² for the superoxide mechanism (17, 18, 19b).

There are no i_0^b values available for the less expensive metals used in practice. In particular, thus far, no i_0^b value has been determined at a smooth nickel oxide electrode because of the unstable character and unknown surface area of the nickel oxide matrix. However, using the above two mechanisms and applying them to porous electrodes, one can expect to obtain some insight concerning the value of i_0^b and the concentration dependence of i_0^b .

The ionic conductivity and viscosity of the electrolyte, as well as the diffusivity and solubility of the various dissolved gaseous species, are essential parameters in modeling the fuel cell electrodes. Values can be estimated or taken from surveys of these properties, as available in the literature (19a, 19b). Wilemski *et al.* (11), using the values listed in the IGT report (19b), have correlated the diffusivities, solubilities, and conductivities. These correlations are used in the present work.

Structural parameters are based on measured porosities and BET surface areas. The method of calculating the agglomerate radius, R , and the external surface area are described in Ref. (20).

Method of Solution

The solution of the model equations was carried out on a Harris-120 digital computer using a finite difference numerical procedure (21). Since the species balance Eq. [4] and current balance Eq. [6] and [10] are coupled only through the nonlinear reaction kinetics, we can solve them separately by the following algorithm: (i) linearize Eq. [4], (ii) solve the linearized Eq. [4] using Newman's subroutines (18) for solving a set of ordinary differential equations at some selected input value of ψ_L , (iii) the flux at the surface is expressed as a polynomial in ψ_L by simple interpolation. A fifth-order polynomial gives sufficient accuracy, and (iv) substitute the polynomial expression into Eq. [6] and [10] and solve again by linearization, using Newman's technique. Solutions of the nonlinear equations were obtained by iteration on the approximate linear solutions; convergence was usually achieved with ten iterations.

Results and Discussion

Tables I and II gave the transport and kinetic properties used as input to the agglomerate models. Geometric data for the nickel and nickel oxide cathode are taken from the IGT cell EPRI-56, and those for the copper anode from IGT cell RD-1 (22). In the dry agglomerate model, not all surface area measured by the BET method is wetted by the electrolyte. The surface on the "outside" of the agglomerate cylinder is dry and not available for

the electrochemical reaction. The pores inside the agglomerate are flooded due to the very strong capillary forces. The external area was calculated assuming that 90% of the measured porosity is macroporosity, *i.e.*, space between the agglomerates. This gave good results for both nickel and copper anodes. Figures 4 and 5 show how the concentration and overpotential distributions vary with respect to the polarization (terminal potential) of the electrode. Higher polarization causes a more nonuniform reaction distribution, which "squeezes" the reaction zone toward the bottom of the agglomerates. High exchange current densities and low electrolyte conductivities also have this effect. As expected, best overall electrode performance results from high exchange current density and ionic conductivity. Using kinetic parameters measured by Ang and Sammells (15) for a nickel anode and by Lu (16) for a copper anode, we can predict the performance. Figures 6 and 7 show that the predictions are in very good agreement with the experimental results. The fuel gas used in both cases is high Btu fuel humidified at 58°C, having equilibrium composition H₂ 54%, CO₂ 10.2%, CO 10.8%, and H₂O 25% at 650°C (cell temperature). It should be noted that this prediction still involves an adjustable parameter: namely, the ratio of macroporosity to microporosity. This ratio is the same for both nickel and copper anodes.

The application of this model to the cathode is more complicated. In the filmed agglomerate model, we need to estimate the film thickness (δ), which is not directly measurable. Tang *et al.* (23) have performed a systematic study of the effect of oxygen concentration on cathodic performance. For very low oxygen concentration (less than 3% oxygen) and high CO₂ concentrations, polarization curves show a clear limiting current; this allows us to

Fig. 4. Effect of overpotential on concentration profiles

Fig. 5. Effect of polarization on overpotential profiles

estimate δ , assuming limiting oxygen diffusion through a film. However, by adjusting the exchange current density, we can fit the rising portion of the polarization curve for these very low oxygen concentrations.

Using the exchange current density and the film thickness thus obtained, we can predict the polarization curves at other compositions characterized by high oxygen concentrations. As mentioned earlier, it is difficult to prepare an electrode of nickel oxide having a well-defined smooth surface and adequate stability in the carbonate melt. Therefore, fitting porous electrode data to the filmed agglomerate model is an attractive engineering approach to determining the kinetic parameters of oxygen reduction at a nickel oxide cathode.

In this work, it is assumed that the film thickness determined by fitting low oxygen polarization curves is independent of gas compositions and overpotential. This may not be true in practice, but it is a convenient assumption, since operating molten carbonate fuel cells are practically inaccessible to optical measurement *in situ*.

Fig. 6. Prediction of polarization curve at nickel anode

Fig. 7. Predicted polarization curve at copper anode

Figure 8 shows the effect of the local overpotential on the concentration profiles. Because the film is highly conductive, it can be expected that the axial overpotential distribution is very uniform. The analysis confirms this. Higher polarization tends to make the overpotential less uniform, but the effect is negligibly small. Parametric studies show that a very thin film and a high exchange current density yield the best electrode performance, in agreement with qualitative predictions (20).

To demonstrate the utility of the filmed agglomerate model for analyzing the cathodic rate process, selected experimental results are compared with predictions according to the peroxide or superoxide model. (Fig. 9 and 10). The peroxide mechanism appears to give a better fit than the superoxide mechanism. Note, however, that the peroxide mechanism would predict that the limiting current depends on the square root of oxygen partial pressure, whereas the experimental data strongly suggest a linear dependence (as reflected in our use of a Henry's coefficient for oxygen). The superoxide mechanism would predict an 0.75 power dependence on oxygen partial pressure, which is closer to the experimental evidence, although still too small. However, the superoxide mechanism predicts in any case much too high current density overall. Neither mechanism appears to predict correctly over the whole range; other mechanisms, or combinations of mechanisms, should be considered. Ob-

Fig. 9. Fitting of cathodic data by peroxide mechanism, Gas compositions 1-6 (Table III). Best fit: i_o^b (mA/cm²) = 1.91 (X_{O₂})^{0.375} (X_{CO₂})^{-1.25}.

Fig. 10. Fitting of cathodic data by superoxide mechanism. Gas compositions 1-6 (Table III). Best fit: i_o^b (mA/cm²) = 19.3 (X_{O₂})^{0.625} (X_{CO₂})^{-0.75}.

viously, more extensive data are also required for a definite identification of the oxygen reduction mechanism.

Effects of Electrode Geometry

We can also adjust the geometric parameters, such as the electrode thickness, to see how they affect the electrode performance. This is very important for design purposes where the objective is the optimizing the structure of an electrode. Too thin an electrode may not provide enough catalytic surface. Too thick an electrode may have too large an ohmic resistance. Figures 11 and 12 show typical examples of performance variation with varying electrode thickness. They clearly show a plateau-

Fig. 11. Optimization of nickel anode thickness with respect to performance. Gas composition: 80% H₂, 20% CO₂. Area factor (A) = 6080 cm²/cm³. Standard exchange current density = 110 mA/cm².

type optimum performance and indicate a range of electrode thicknesses for which overall electrode performance does not vary much.

Fig. 12. Optimization of nickel oxide cathode thickness with respect to performance. Gas composition: 15% O₂, 30% CO₂, 55% N₂. Area factor (A) = 5000 cm²/cm³. Standard exchange current density = 4.3 mA/cm²; peroxide mechanism assumed.

In the case of the anode, this may form the basis for fabricating a thicker electrode serving as an electrolyte reservoir, without sacrificing too much of the electrolyte performance. The existence of an optimum may be explained in terms of a compromise between the kinetic and ohmic resistances. The performance eventually drops if the electrode becomes too thick because of too much ohmic resistance, in spite of the larger surface area.

In the case of the cathode, a highly conductive film exists and the performance drops more slowly than in the case of the anode. Too thin an electrode causes a performance drop because the available surface area decreases in spite of the smaller ohmic resistance. In the case of the cathode, the external surface area covered by film produces most of the current, and decreasing it would cause a much faster performance drop than in the case of the anode. Since changing the electrode thickness is equivalent to "filling up" the macropore as shown in Fig. 13, the performance variation can also be interpreted in terms of anodic wetting. The reason is that the portion of the electrode below the electrolyte level in a macropore is essentially unutilized because of very high mass-transfer resistance. This result is consistent with experimental data, which show that in the case of the anode the degree of electrolyte filling has little effect on electrode performance under the usual operating conditions, i.e., 160 mA/cm² (24).

Conclusions

Two types of agglomerate models, discussed and quantitatively analyzed in this work, enable us to predict the distribution of potential and reaction rate in the molten carbonate fuel cell anode and cathode, and allow us to estimate the electrode utilization in each case.

The models described in this work are based on assumptions which naturally affect their applicability. In order to make the models more generally applicable, a number of assumptions may be removed or substantially altered. Ohm's law may be replaced by a more complicated expression to include ionic migration in the melt (25). Agglomerate flooding, film thickness variation, and coverage all can be varied with respect to temperature, gas composition, polarization, and melt composition if adequate empirical information is available. A nonisothermal model may be derived. The model can also be expanded to account for nonuniform porosity distribution. Finally, more efficient computation methods, e.g., orthogonal collocation, may be substituted for the conventional finite-difference method.

S. N. Flengas

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada, M5S 1A4

ABSTRACT

The thermodynamic properties of the quarternary molten salt system MnCl₂-NaCl-KCl-CsCl have been investigated by EMF measurements using a formation cell of the type

It was found that the partial molar free energies of mixing of MnCl₂ in the quarternary solutions are well represented by a previously developed expression given as

$$\overline{\Delta G}_{\text{MnCl}_2}^{\text{(in quarternary)}} = (1 - S)[(1 - t) \overline{\Delta G}_{\text{MnCl}_2}^{\text{(in MnCl}_2\text{-CsCl)}} + t \overline{\Delta G}_{\text{MnCl}_2}^{\text{(in MnCl}_2\text{-KCl)}}] + S \overline{\Delta G}_{\text{MnCl}_2}^{\text{(in MnCl}_2\text{-NaCl)}}$$

which is valid at constant X_{MnCl_2} . In this expression, $\overline{\Delta G}_{\text{MnCl}_2}^{\text{(in MnCl}_2\text{-CsCl)}}$ etc. refer to the corresponding partial molar free energy of MnCl₂ in the designated binary system having the same MnCl₂ content as the quarternary. The composition parameters S and t are defined as

$$t = \frac{X_{\text{KCl}}}{X_{\text{KCl}} + X_{\text{CsCl}}}, \quad S = \frac{X_{\text{NaCl}}}{X_{\text{NaCl}} + X_{\text{KCl}} + X_{\text{CsCl}}}$$

In previous publications from this laboratory (1, 2), theoretical equations have been developed from which the molar and partial molar properties of ternary and quarternary molten salt solutions may be calculated from available data on the component binary systems.

The thermodynamic properties of binary fused-salt solutions have been the object of several systematic investigations, and extensive compilations of thermodynamic data are available. However, similar information on ternary fused-salt solutions is limited to only a few selected systems, and for quarternary solutions there is hardly any information at all. Yet, systems of metallurgical importance are usually multicomponent, and the application of the thermodynamic approach to high temperature equilibria is restricted by the lack of experimental data. Thus, it is evident that expressions from which the ther-

modynamic properties of ternary and quarternary systems may be predicted from available information on the related binary systems should be of considerable theoretical and practical importance.

In the present investigation, the thermodynamic properties of MnCl₂ in the quarternary molten salt system MnCl₂-NaCl-KCl-CsCl have been obtained from EMF measurements using a formation cell of the type

For this system, the thermodynamic and structural properties of the binary solution MnCl₂-NaCl, MnCl₂-KCl, MnCl₂-CsCl, as well as of the ternary MnCl₂-NaCl-CsCl,

have been investigated in this laboratory and elsewhere (3-6).

It is of interest that the MnCl_2 -NaCl system is characterized by relatively low exothermic enthalpies of mixing which reach the maximum value of -1900 cal/mol at a composition of about 35 mole percent (m/o) MnCl_2 . Also, the change of volume on mixing indicates only slight positive deviations from additivity (6, 7). On the contrary, in the MnCl_2 -KCl and the MnCl_2 -CsCl systems, the enthalpies of mixing are strongly exothermic and the changes of volume on mixing show pronounced positive deviations from additivity, which is indicative of compound formation. For example, at 33 m/o CsCl the integral enthalpy of mixing in the MnCl_2 -CsCl system has a value of -5400 cal/mol at 700°C . Because of such pronounced differences in the properties of the binary systems, the quaternary system MnCl_2 -NaCl-KCl-CsCl should be considered as a test system for establishing the validity of the proposed theoretical expressions (1, 2).

Experimental

The alkali chlorides employed in the present work were reagent-grade materials, and the anhydrous MnCl_2 was 99.5 weight percent (w/o) pure. These salts were further dehydrated by heating under vacuum for several days at 200°C . The materials were handled and weighed in a dry box filled with anhydrous argon gas.

The cell design was similar to that used in the previous work (7). It consisted of a Mn indicator electrode immersed in the MnCl_2 -NaCl-KCl-CsCl molten solution of known composition, and a graphite-chlorine electrode which also dipped into a molten salt solution of the same composition. The two cell compartments were separated by an asbestos fiber diaphragm fused into silica glass (8).

The chlorine electrode was continuously flushed with anhydrous research-grade chlorine gas. The Mn electrode was made by placing a tungsten rod, 1/8 in. diam, and crushed electrolytic manganese metal in a stabilized zirconia ceramic tube closed at one end, which was heated to about 1400°C under an argon atmosphere. The molten Mn was allowed to solidify very slowly to avoid cracking as it passed through its crystallographic transformation (9). This electrode was about 10 mm diam by 4 cm long and was acid polished prior to use. During a run, the Mn electrode was operated under an atmosphere of deoxygenated argon gas.

The asbestos diaphragm had a resistance in the range 1000-2000 Ω . Its construction has been described elsewhere (8).

During a run, EMF readings were taken at intervals of about 25°C , up to approximately 850°C . Potentials were fully reproducible to within 2 mV during a temperature cycle, and cell reversibility was also established through polarization tests at currents of about 1 mA.

Volatility of MnCl_2 for the salt compositions used in this work was insignificant and did not affect the reproducibility of the EMF measurements during a temperature cycle.

Data Treatment and Results

Compositions in a quaternary system are represented (10) by points within the volume of an equilateral tetrahedron, as shown in Fig. 1, in which the four apexes correspond to the pure components MnCl_2 , NaCl, KCl, and CsCl, and the edges represent the six binary systems MnCl_2 -NaCl, MnCl_2 -KCl, MnCl_2 -CsCl, KCl-NaCl, KCl-CsCl, and NaCl-CsCl.

The triangular faces represent the four ternary systems MnCl_2 -NaCl-KCl, MnCl_2 -NaCl-CsCl, MnCl_2 -KCl-CsCl, and NaCl-KCl-CsCl.

It is a property of all equilateral tetrahedra that lines originating from any internal point P , drawn parallel to the four different faces, have a total length equal to one edge, and each of these segments may be taken to define the mole fraction of a particular component occupying an apex.

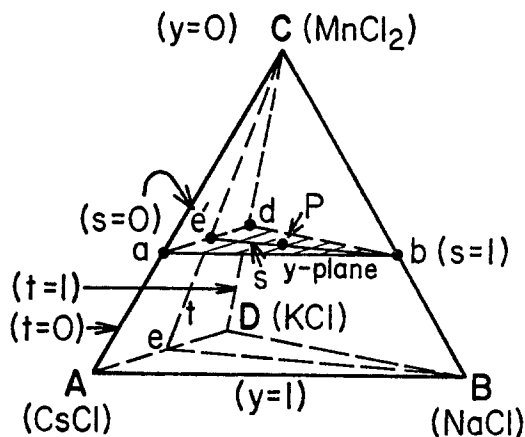

Fig. 1. Representation of compositions in a quaternary system in terms of the parameters y , t , and S , where

$$y = 1 - X_{\text{MnCl}_2}$$

$$t = \frac{X_{\text{KCl}}}{X_{\text{KCl}} + X_{\text{CsCl}}}$$

$$S = \frac{X_{\text{NaCl}}}{X_{\text{NaCl}} + X_{\text{KCl}} + X_{\text{CsCl}}}$$

Any composition P lies on a S plane which represents the intersection of y and t planes.

In view of the complexity of such three-dimensional plots, useful composition paths have been defined mathematically (2), and the composition parameters, y , t , and S have been defined by the following expressions

$$y = 1 - X_{\text{MnCl}_2} \quad [1]$$

where $1.0 \geq y \geq 0$

$$t = \frac{X_{\text{KCl}}}{X_{\text{KCl}} + X_{\text{CsCl}}} \quad [2]$$

where $1.0 \geq t \geq 0$, $t = 1$ along the MnCl_2 -KCl binary, and $t = 0$ along the MnCl_2 -CsCl binary

$$S = \frac{X_{\text{NaCl}}}{X_{\text{NaCl}} + X_{\text{KCl}} + X_{\text{CsCl}}} \quad [3]$$

where X is mole fraction.

Considering Fig. 1, in which MnCl_2 is placed at the apex of the tetrahedron, constant " t " represents the pseudoternary composition surface BeC . All compositions along that surface have in common the constant ratio of $X_{\text{KCl}}/X_{\text{KCl}} + X_{\text{CsCl}}$.

Also, constant " y " represents compositions along a pseudoternary surface parallel to the base of the equilateral tetrahedron having a constant X_{MnCl_2} content.

The intersection of the planes, t and y , defines the line " S " which has the following limiting values: within the binary MnCl_2 -NaCl at point " b ", $S = 1$, and at point e' within the ternary MnCl_2 -KCl-CsCl, $S = 0$.

The relationship between primary mole fractions and the composition parameters y , t , and S , is readily found as

$$X_{\text{CsCl}} = y(1-t)(1-S) \quad [4]$$

$$X_{\text{NaCl}} = yS \quad [5]$$

$$X_{\text{KCl}} = ty(1-S) \quad [6]$$

$$X_{\text{MnCl}_2} = 1 - y \quad [7]$$

Considering the S path be' , within the quaternary tetrahedron shown in Fig. 1, which is defined by the intersection of the y - and t -planes, all compositions along be' have the same X_{MnCl_2} content and the same ratio of KCl to CsCl. However, as S changes from 0 (point e') to 1 (point b), the amount of NaCl in the quaternary changes in proportion to S (Eq. [5]), and the value of any thermodynamic property measured along such an S composition path

$$\overline{\Delta G}_{\text{MnCl}_2} = -ZF(E - E^\circ) \quad [11]$$

$$\overline{\Delta H}_{\text{MnCl}_2} = -ZF B \quad [12]$$

$$\overline{\Delta S}_{\text{MnCl}_2} = ZFA \quad [13]$$

where A and B and the constants given in Table I, $E - E^\circ$ is given in millivolts, Z is the valence of the metal cation, and F is the Faraday constant expressed as 23.060 cal/mV eq.

The activities of MnCl_2 are calculated from the measured cell EMF's using the well-known Nernst equation written as

$$E_{\text{cell}} = E^\circ_{\text{MnCl}_2} - \frac{RT}{ZF} \ln a_{\text{MnCl}_2} \quad [14]$$

where E_{cell} and $E^\circ_{\text{MnCl}_2}$ are expressed in millivolts, and the ideal gas constant $R = 1.987$ cal/mol K.

Activities of the MnCl_2 calculated for Eq. [4] refer to pure molten MnCl_2 as the standard state of reference.

Partial molar heats of mixing, entropies of mixing, and activities of MnCl_2 calculated from the data, are also included in Table I. Plots of $E - E^\circ$ vs. temperature, for various X_{MnCl_2} , S , and t values are given in Fig. 2 and 3.

Discussion

The previously derived expression (2) for the calculation of the partial molar free energies of mixing in the quaternary system is

$$\overline{\Delta G}_{\text{MnCl}_2} = (1-S)[(1-t) \overline{\Delta G}_{\text{MnCl}_2}^{\text{in MnCl}_2\text{-KCl}} + t \overline{\Delta G}_{\text{MnCl}_2}^{\text{in MnCl}_2\text{-KCl}}] + S \overline{\Delta G}_{\text{MnCl}_2}^{\text{in MnCl}_2\text{-NaCl}} \quad [15]$$

The quantities $\overline{\Delta G}_{\text{MnCl}_2}^{\text{in MnCl}_2\text{-CsCl}}$, $\overline{\Delta G}_{\text{MnCl}_2}^{\text{in MnCl}_2\text{-KCl}}$, and $\overline{\Delta G}_{\text{MnCl}_2}^{\text{in MnCl}_2\text{-NaCl}}$ are the partial molar free energies of mixing of MnCl_2 in the designated binary systems having the same MnCl_2 content and temperature as the quaternary.

From Eq. [11] and [15], $E - E^\circ$ values were calculated and are given as dotted lines in Fig. 2.

The quantities $\overline{\Delta G}_{\text{MnCl}_2}$, for the three binary systems, plotted as $E - E^\circ$ vs. X_{MnCl_2} , were available from previous measurements (3) and are given in Fig. 4.

From Fig. 2 and 3, it is evident that the agreement between the experimental and calculated partial molar free energies of mixing expressed by the $E - E^\circ$ quantities is better than 3% over the investigated composition range of the quaternary system.

From Eq. [15], the expression for the activity of MnCl_2 in the quaternary system is readily derived as

$$a_{\text{MnCl}_2}^{\text{(in quaternary)}} = a_{\text{MnCl}_2}^{\text{(in MnCl}_2\text{-CsCl})} (1-S)^{(1-t)} \cdot a_{\text{MnCl}_2}^{\text{(in MnCl}_2\text{-KCl})} (1-S)^t \cdot a_{\text{MnCl}_2}^{\text{(in MnCl}_2\text{-NaCl})} S \quad [16]$$

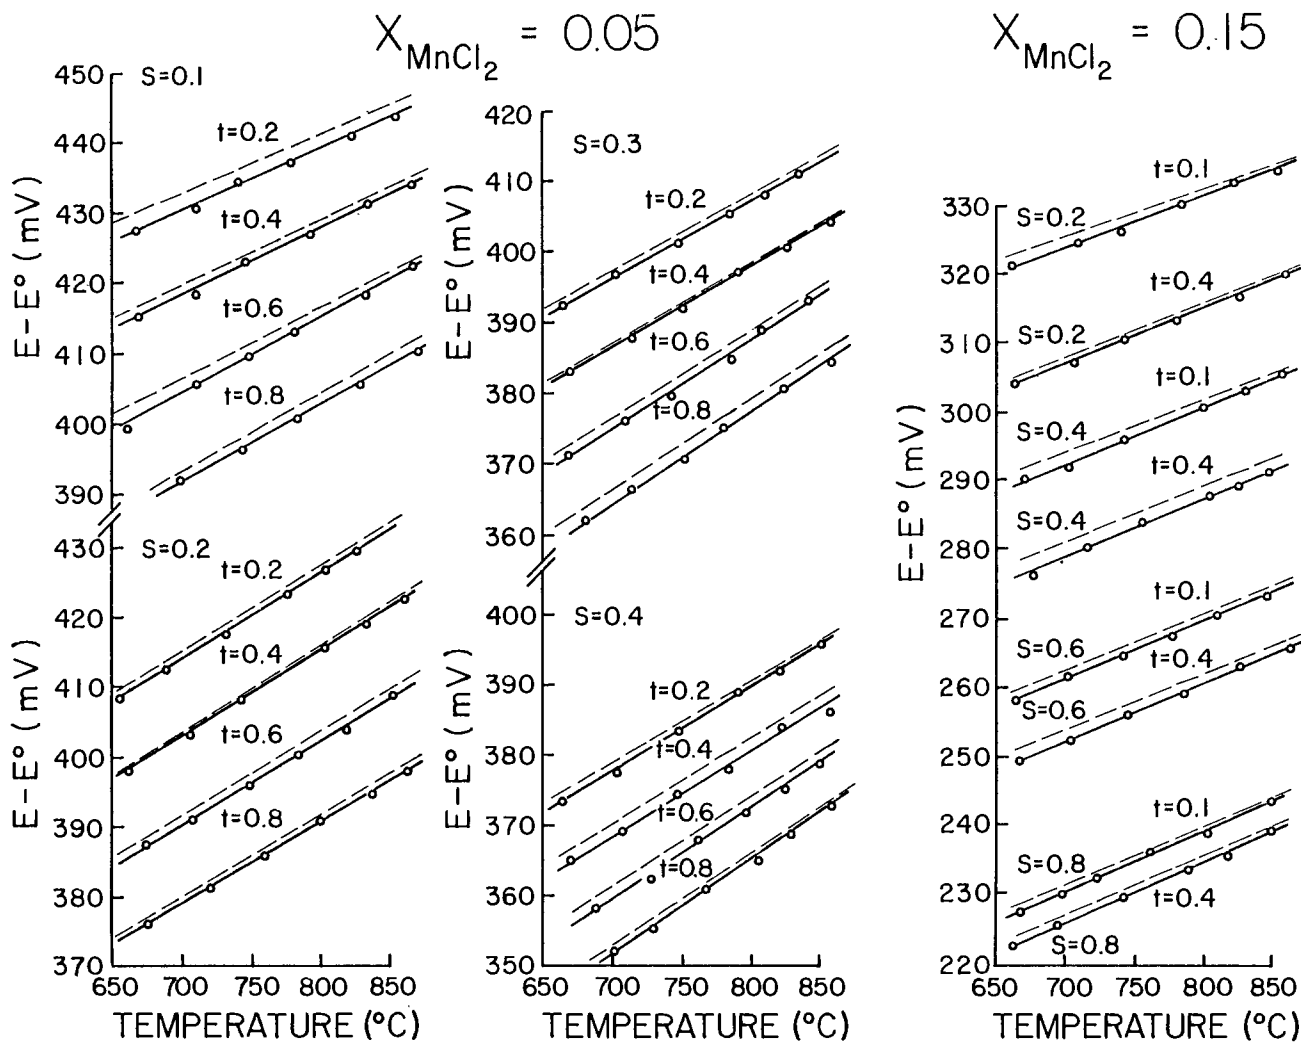

Fig. 2. EMF's of the cell

Mn	MnCl ₂	(X ₁)	Asbestos	MnCl ₂	(X ₁)	C (+)
(-)	NaCl	(X ₂)	fiber	NaCl	(X ₂)	(graphite)
	KCl	(X ₃)	diaphragm	KCl	(X ₃)	Cl ₂
	CsCl	(X ₄)		CsCl	(X ₄)	(g, 1 at.)

plotted as $E - E^\circ$ vs. temp. for various values of X_{MnCl_2} , S , and t in the quaternary system $\text{MnCl}_2\text{-NaCl-KCl-CsCl}$. E° represents $X_{\text{MnCl}_2} = 1$. Solid circles: experimental. Dashed lines: calculated from Eq. [11] and [15].

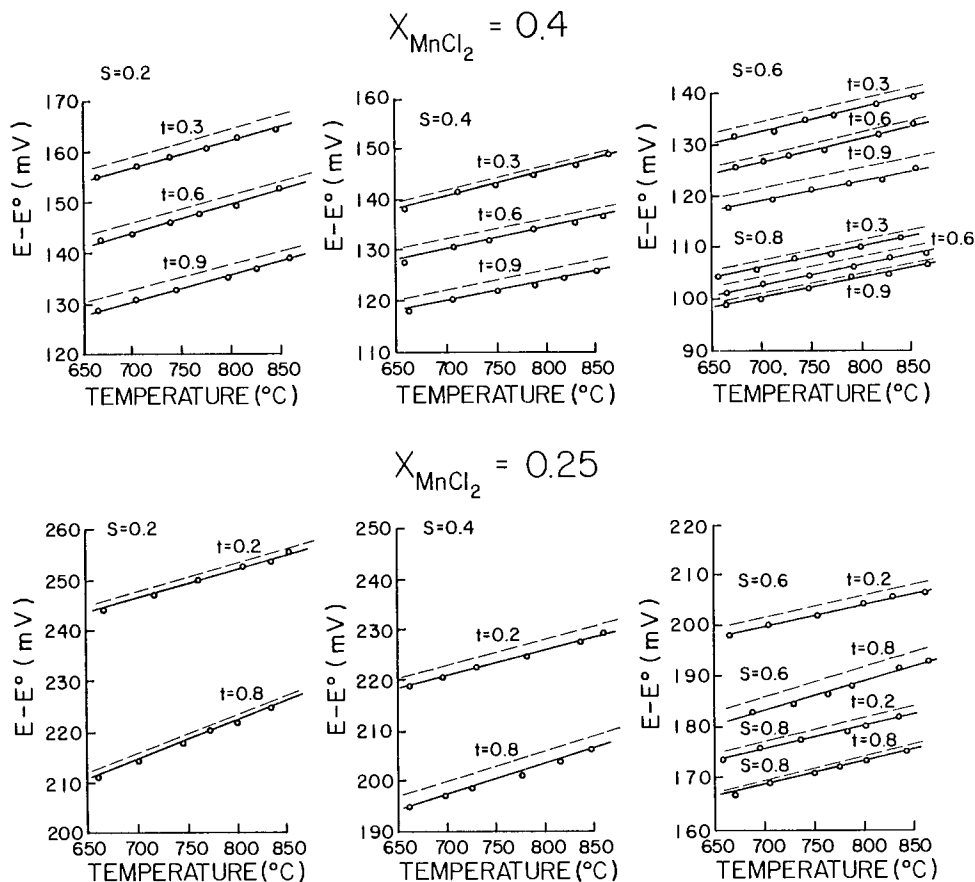

Fig. 3. Same as in Fig. 2, but with $X_{MnCl_2} = 0.4$ and 0.25 .

In terms of activity coefficients, Eq. [16] may be written as

$$\gamma_{MnCl_2}^{(in\ quaternary)} = \frac{(\gamma_{MnCl_2}^{in\ (MnCl_2-CsCl)})^{1-S}(1-t) \cdot (\gamma_{MnCl_2}^{in\ (MnCl_2-KCl)})^{1-St} \cdot (\gamma_{MnCl_2}^{in\ (MnCl_2-NaCl)})^S}{[17]}$$

where the quantities in parentheses represent activity coefficients in binary systems at compositions having the same X_{MnCl_2} values as in the quaternary.

Fig. 4. Plots of $E - E^\circ$ for the three binary systems (3) MnCl₂-NaCl, MnCl₂-KCl, and MnCl₂-CsCl and 700° and 800°C.

Plots of the partial molar free energies of mixing of MnCl₂ as functions of the parameters S at constant y and t values are given in Fig. 5 to 8.

Activities of MnCl₂ in the quaternary system, calculated from Eq. [16], are plotted as a function of X_{MnCl_2} at constant temperature and constant S and t values. The various curves correspond to different t values, and the composition path followed in this case starts from solutions very dilute in MnCl₂ and moves upwards through the quaternary to $X_{MnCl_2} = 0.4$.

These plots are given in Fig. 9 and include the few experimental points available for such a composition path. Again, agreement is indicated between Eq. [16] and the experimental values.

The partial molar enthalpies of mixing, $\Delta \bar{H}_{MnCl_2}$ shown in Table I, become more exothermic as t decreases, i.e.,

Fig. 5. Plot of the partial molar free energy of mixing of MnCl₂ as function of S , with y and t constant. Group of curves covers the entire composition surface of a Y-plane. Points: experimental. Straight lines: calculated from theory.

Fig. 6. Same as Fig. 5, but with $X_{\text{MnCl}_2} = 0.15$ Fig. 7. Same as Fig. 5, but with $X_{\text{MnCl}_2} = 0.4$

when the CsCl content of the melt increases. $\overline{\Delta H}_{\text{MnCl}_2}$ becomes less exothermic as S increases, i.e., when the NaCl content of these melts increases. As expected, the activities of MnCl_2 indicate pronounced negative deviations from ideality, particularly for the CsCl-rich melts.

Equations [15], [16], and [17] should be strictly valid for charge asymmetric molten salt solutions (2) like the system $\text{MnCl}_2\text{-NaCl-KCl-CsCl}$, in which the charge asymmetric component MnCl_2 is known to react with the alkali metal chlorides. Although as exact knowledge of the structure of such complexes is not necessary for a thermodynamic treatment, there are certain indirect indications regarding their probable configuration. For example, recent structural evidence (11) as well as mea-

Fig. 8. Same as Fig. 5, but with $X_{\text{MnCl}_2} = 0.25$ Fig. 9. Activity isotherms of MnCl_2 at 700°C , calculated at constant $S = 0.4$. Solid circles: experimental. Open circles and lines: calculated from theory.

surements of electrical conductivities and molar volumes (6, 12) suggest that solutions of MnCl_2 in alkali chloride melts appear to contain tetrahedrally coordinated complexes of the type MnCl_4^{2-} .

For a tetrahedral configuration, the following reaction is expected to occur upon mixing

and the enthalpies of mixing in binary melts containing alkali metal chlorides, should reach maximum values at a MnCl_2 content of 33 m/o. Deviations from ideality may be attributed to the relative stability, or strength, of such complexes. Experimental evidence (3) indicates that the observed negative deviation in the activities of MnCl_2 increases with increasing size of the alkali metal cations in the order $\text{Li}^+ \rightarrow \text{Na}^+ \rightarrow \text{K}^+ \rightarrow \text{Rb}^+ \rightarrow \text{Cs}^+$.

Such trends reflect the effects of competing interactions between the Mn^{2+} and A^+ cations for the same Cl^- anions in which the alkali chloride acts as a ligand donor and the reactive metal chloride MnCl_2 is the ligand acceptor. Alkali metal cations like Na^+ , because of their small size, are strongly attracted to their chloride anions and effectively the NaCl salt is less "dissociated" than the other alkali metal chlorides containing larger cations like K^+ or Cs^+ . The difference in the strength of the complexes which are formed when the reactive metal chloride, MnCl_2 , is mixed with either of the alkali chlorides of the type AlCl or BCl is simply reflected by the difference in the bond distances in configurations of the type Mn-Cl-A or Mn-Cl-B.

The spatial arrangement of such complexes within the ionic melt structure should be compatible with the requirement of local electrical neutrality and with the concept of interlocking anionic and cationic "quasi-lattices" as proposed by Temkin (13).

Conclusions

It has been shown that the thermodynamic properties of nonideal and nonregular charge asymmetric fused-salt systems may be calculated from data on component binary systems along composition paths representing constant content of the charge asymmetric component MnCl_2 . Although the derivation of Eq. [15] was based on the formation of complex species in the binary solutions, its application depends only on the availability of experimental data on binary systems.

Regarding quaternary systems, the introduction of the composition parameters y , t , and S serves in the planning of experiments and in reducing the large number of compositions to be studied in order to characterize a quaternary system adequately.

Also, the use of these composition parameters makes it possible to plot thermodynamic data along well-defined composition paths and to identify the effects of competing interactions on a charge asymmetric cation. For example, the complexing effects of CsCl or KCl on MnCl₂ become evident as the quaternary solutions become richer in CsCl, or in KCl, respectively.

The successful application of Eq. [15], [16], and [17] to such nonideal charge asymmetric fused-salt solutions indicates that in quaternary, and possibly even in higher order systems, reactions within the binary solutions account for most of the internal reactivity which is responsible for deviations from ideality. Thus, the formation of a higher order system represents mixing of such prereacted binary systems and the properties of the multicomponent system should be predictable.

However, it should be noted that Eq. [15], [16], and [17] are only applicable to the "acid," or higher valence, component of a charge asymmetric fused-salt mixture.

Reactions Involving Silver Ions and Silver Metal in Molten Nitrates

M. H. Miles,* G. E. McManis,* and A. N. Fletcher*

Chemistry Division, Naval Weapons Center, China Lake, California 93555

ABSTRACT

The electrochemical reduction of molten LiNO₃ on platinum or nickel electrodes produces insoluble Li₂O that passivates the cathode at high current densities. The presence of small amounts of silver ions prevents this passivation by undergoing reduction to silver metal in the form of dendritic deposits that increase the effective area of the electrode. The deposited silver is unstable in molten LiNO₃ and reacts with the melt to regenerate silver ions. Corrosion studies of silver coupons gave a weight loss rate of 280 μg h⁻¹cm⁻² in molten LiNO₃ at 350°C, but of only 5 μg h⁻¹cm⁻² in KNO₃ at 375°C. The presence of water in the LiNO₃ melt increases the corrosion rate of silver. Additions of Li₂O, LiNO₂, LiCl, or AgNO₃ to molten LiNO₃ significantly decreases the corrosion rate. The addition of oxide ions to a AgNO₃ containing melt produces a dark precipitate of Ag₂O in NaNO₃ or KNO₃, but not in LiNO₃. The decomposition reaction of Ag₂O into its elements is kinetically slow in molten nitrates with a rate similar to that observed in air.

The relatively low melting points of oxidizing molten salts such as nitrates and perchlorates makes them attractive for use in thermal battery cells where they can function as both the electrolyte and oxidizer (1, 2). Previous work has shown that the lithium salts of these compounds are electrochemically reduced much more readily than the sodium or potassium salts (3-5). At high current densities, however, the reduction of fused LiNO₃ or LiClO₄

produces insoluble Li₂O as a product (4-7). When Li₂O is formed at the electrode surface faster than it can be removed, thus blocking the reacting substance from reaching the electrode substrate, severe polarization occurs (2, 4, 7).

The performance of the cathode in oxidizing molten salts is greatly improved by the addition of small amounts of AgNO₃ to the electrolyte (2, 8). This work is focused mainly on the study of the reactions involving silver ions

in molten nitrate melts. Although previous reports suggest that the cathodically deposited silver is relatively stable in molten nitrates (9-13), our studies show that this stability is dependent on the electrolyte composition, the temperature of the melt, and the nature of any extraneous substances that may be present.

Experimental

The design of the electrochemical cell was similar to that of a previous study (14). The platinum and nickel working electrodes were in the form of wires sealed in glass and cut to a length to give a geometrical area of 0.10 cm² (0.45 cm length, 0.07 cm diam). The counterelectrode consisted of either a platinum wire coil at the bottom of the cell or a platinum wire spiral separated from the main cell compartment by a section of fritted glass tubing. All potentials were measured against a AgNO₃ (0.1M)/Ag reference electrode that is described elsewhere (14). Electrochemical studies were made with the cell placed in a fluidized sand bath (Tecam) where the temperature was monitored with a Chromel-Alumel thermocouple digital thermometer (Fluke, 2165 A). Temperature fluctuations observed with the cell placed in the center of the sand bath and the thermocouple positioned adjacent to the cell

* Electrochemical Society Active Member.

were generally less than $\pm 5^\circ\text{C}$. A modified cell was used in some experiments that allowed the temperature to be measured directly in the cell by means of a thermocouple inlet consisting of a section of glass tubing with an opening through the cell wall and extending into the melt. Temperatures measured in the cell were relatively constant during the experiments and, on the average, were within 2°C of the temperature measured outside the cell. In experiments requiring mass transport by diffusion, both the sand bath and the helium flow were turned off to give a quiescent solution free of vibrations. The hot sand surrounding the cell acted as a thermal insulator, thus the temperature measured in the cell remained constant within $\pm 1^\circ\text{C}$ for time periods up to 10 min.

The reagent-grade salts used in the cell were dried in a vacuum oven at 130°C for several days. The cell was always rinsed well with acetone (spectrophotometry suitable) and baked with a heat gun and then baked again in the sand bath prior to adding the salt. The bubbling of dried helium gas through the molten salt in the cell at 350°C for at least 1h was used to remove any residual water. Cyclic voltammetric studies of these melts using platinum electrodes gave no evidence of any water wave (4, 15). Generally, either 30.0g of predried LiNO_3 or 33.0g of NaNO_3 or KNO_3 were used in the cell to give a melt volume of 17.4, 17.8, or 17.7 cm^3 , respectively, at 350°C , based upon reported densities (16). For the study of mixed salts, the amount of each salt was calculated to give about this same volume of liquid.

The electrochemical measurements used a potentiostat/galvanostat (PAR 173) equipped with either a current follower plug-in (PAR 176) or a digital coulometer plug-in (PAR 179). Results were monitored with an X-Y recorder (Hewlett-Packard 7047 A) or a digital oscilloscope (Nicolet Model 206). In experiments involving potential scans, a PAR 175 programmer was used. The reproducibility of the potential scan experiments was improved by a standard conditioning of the working electrode between successive potential sweeps that involved an anodic treatment evolving NO_2 and O_2 , followed by a waiting time of 30s at the initial potential before beginning another sweep. For experiments involving exhaustive galvanostatic or potentiostatic electrolysis, a large platinum or nickel electrode ($A = 10 \text{ cm}^2$) was used in the molten nitrate solution that was rapidly stirred by the flow of helium gas to maximize mass transport.

Corrosion studies were conducted by placing a polished silver coupon ($2 \times 2 \text{ cm}$) into 20-23g of the molten nitrate solution and determining the weight loss of the silver after 2h. These experiments were conducted in a quartz tube with a cap that provided for helium stirring throughout the experiment to minimize any effects due to water. All experiments used helium gas (99.995%, oil and water-vapor free) that was passed through indicating Drierite and two tubes of phosphorus pentoxide (Aquasorb, Mallinckrodt) and a tube filled with fiberglass before being admitted into the nitrate melt. The helium was then exhausted through another P_2O_5 -filled tube to prevent any backflow of atmospheric water vapor. The glassware was always rinsed well with spectro-grade acetone and prebaked both with a heat gun and in the sand bath before the nitrate salt was added.

Results and Discussion

Voltammetric studies in molten LiNO_3 on both platinum and nickel electrodes reveal a large reduction peak similar to that shown in Fig. 1 (4, 17). The electrode reaction is the reduction of molten LiNO_3 to Li_2O and LiNO_2 (Eq. [1]); the peak is due to the blocking of the electrode surface by insoluble Li_2O rather than the usual depletion of the reactant in the diffusion layer. Due to resistive effects of the precipitated Li_2O on the electrode surface, the peak potential depends on the magnitude of the current and varies with both the potential sweep rate and the area of the electrode. Voltammograms for the reduction of molten nitrates vary when different electrode metals are used (18).

Fig. 1. Effect of AgNO_3 on the cathodic reaction in molten LiNO_3 at 350°C . Measurements were made in a helium atmosphere using a platinum wire electrode ($A = 0.10 \text{ cm}^2$) and a potential scan rate of 100 mV/s. Solid line: pure LiNO_3 . Dashed line: $\text{LiNO}_3 + 0.10 \text{ m/o AgNO}_3$.

As illustrated in Fig. 1, the addition of 0.10 mole percent (m/o) AgNO_3 permits the current to continue to increase, and thus no peak is observed. The reversible electrode reduction of silver nitrate

accounts for the relatively small peak observed at -0.18 V . The increased background current following this small peak, as well as the larger currents observed for the LiNO_3 reduction wave, indicates an increase in the effective surface area of the platinum electrode due to the deposited silver.

High current densities are required for many thermal battery applications. Therefore, constant current studies at 100 mA/cm^2 were made for the cathodic reactions. The results in Fig. 2 show that the reduction of LiNO_3 at 350°C in gently stirred solutions sustains 100 mA/cm^2 for only 105s before it severely polarizes. The addition of 0.10 m/o AgNO_3 completely prevents the onset of this passivation; in fact, the potential slowly increases during the cathodic reaction. Similar results were obtained with nickel electrodes. It is likely that Ag^+ and NO_3^- ions are being simultaneously reduced, thus the depositing silver gives a gradually increasing surface area, resulting in a decreasing

Fig. 2. Constant current cathodic studies at 100 mA/cm^2 in gently stirred solutions consisting of pure LiNO_3 (dashed line), $\text{LiNO}_3 + 0.10 \text{ m/o AgNO}_3$ (solid line), and $\text{LiNO}_3 + 1.0 \text{ m/o AgNO}_3$ (dash-dot line). Studies were made at 350°C using a platinum wire electrode ($A = 0.10 \text{ cm}^2$).

overtoltage for LiNO_3 reduction. In molten LiNO_3 containing 1.0 m/o AgNO_3 , the reduction of Ag^+ is apparently capable of sustaining 100 mA/cm^2 (Fig. 2). The potential remains very stable and close to that of the Ag^+/Ag reference electrode used. Other investigators have noted that AgNO_3 additions affect the cathodic reactions in molten nitrates (18, 19).

Exhaustive electrolysis experiments supplying large platinum or nickel electrodes ($A = 10 \text{ cm}^2$) with a constant current (10 mA) in vigorously stirred solutions gave inflections in potential that indicated depletion of the added silver ions. As illustrated in Fig. 3, the experimental inflections are close to $1.0 e^-/\text{Ag}^+$ for studies in molten NaNO_3 and KNO_3 , but no inflection could be detected in molten LiNO_3 . In fact, continuation of the experiments for time periods corresponding to more than $3 e^-/\text{Ag}^+$ failed to reveal any significant change in the potential in molten LiNO_3 . Experiments in equimolar $\text{LiNO}_3\text{-LiClO}_4$ at 350°C also failed to show any inflection in the potential. These results suggest that the deposited silver is not stable in molten LiNO_3 or $\text{LiNO}_3\text{-LiClO}_4$ at 350°C and undergoes corrosion reactions that, in effect, recycle the silver ions. The results shown in Fig. 3, however, were obtained at 1 mA/cm^2 . At high current densities, the rate of reaction [3] will exceed the rate of corrosion, and thus there will be a buildup of deposited silver on the electrode surface.

Constant potential coulometry offers the advantage of higher currents and shorter electrolysis times, and hence the effect of corrosion reactions on the measurement of e^-/Ag^+ can be minimized. Results for the reduction of AgNO_3 at -0.400V in molten LiNO_3 and KNO_3 at 375°C in vigorously stirred solutions are shown in Fig. 4. These curves differ from the normal exponential decrease in current with time in that a peak in the current is observed. This peak is likely related to the increase in the effective electrode surface area due to the depositing silver metal. Any reaction of the deposited silver with the melt would retard the increase in surface area and yield a smaller peak current as found in molten LiNO_3 .

Photomicrographs of platinum and nickel electrode surfaces following constant potential coulometry experiments in molten LiNO_3 at 375°C are shown in Fig. 5a and 5b. A thick bed of dendritic needles covers the platinum surface (Fig. 5a). The deposits on nickel electrodes tend to fall off easily during washing to remove the salt, hence the nickel surface can be seen at the edge of Fig. 5b. Nickel surfaces darken in molten nitrates, perhaps due to nickel oxide formation. Greater magnification reveals that the deposits on nickel are similar to those on platinum except for their much finer structure. Finer deposits were also observed on platinum in other experiments. A SEM micrograph of dendritic deposits on platinum is shown in Fig. 6a. Elemental analysis using energy dis-

Fig. 3. Exhaustive electrolysis studies of silver ion reduction on platinum ($A = 10 \text{ cm}^2$) at 375°C using a constant current of 10 mA. The molten salt was rapidly stirred by the flow of helium gas. Concentrations of AgNO_3 were 5.89×10^{-3} , 5.78×10^{-3} , and $5.69 \times 10^{-3}\text{m}$ (0.0405, 0.0491, and 0.0574, m/o) in LiNO_3 , NaNO_3 , and KNO_3 , respectively.

Fig. 4. Constant potential coulometry studies of the reduction of AgNO_3 on platinum ($A = 10 \text{ cm}^2$) in molten LiNO_3 and KNO_3 at 375°C . The working electrode was potentiostated at -0.400V vs. the Ag^+/Ag reference electrode. The melt was rapidly stirred by the flow of helium gas. Concentrations of AgNO_3 were 9.08×10^{-3} and $8.24 \times 10^{-3}\text{m}$ (0.0626 and 0.0832 m/o) in LiNO_3 and KNO_3 , respectively.

Fig. 5. Optical micrographs of electrode surfaces following constant potential coulometry studies similar to those shown in Fig. 4. a(top): Platinum electrode. b(bottom): Nickel electrode. Part of the deposit was lost from the nickel surface during the washing procedure exposing the darkened nickel surface (edge of Fig. 5b).

Fig. 6. a(top): Scanning electron micrograph of the silver deposits on a platinum electrode following constant potential coulometry studies similar to those shown in Fig. 4. b(bottom): EDX spectra for the same electrode showing that the deposits consist mainly of silver (Ag, $L_{\alpha 1} = 2.98$ keV, $L_{\beta 1} = 3.15$ keV). The silver deposits mask the detection of the platinum substrate (Pt, $L_{\alpha 1} = 9.44$ keV).

persive x-rays (EDX) shows that the surface deposits are essentially pure silver (Fig. 6b). The deposits of silver even mask the detection of the platinum substrate using EDX (Pt, $L_{\alpha 1} = 9.44$ keV). Results of Auger analysis were similar; the surface deposit was mostly silver metal with traces of oxygen, sulfur, and chlorine.

The increased surface area in coulometry experiments is also manifested by background currents that were considerably larger at the end of the electrolysis than those observed prior to adding AgNO_3 . Background currents were always higher in molten LiNO_3 than in KNO_3 due to the much higher energy barrier for the reduction of the latter salt (3, 4). After compensating for the background currents at -0.400V , the coulombs passed for 300s in Fig. 4 correspond to $1.0 e^-/\text{Ag}^+$ in molten KNO_3 and $1.1 e^-/\text{Ag}^+$ in molten LiNO_3 . Corrosion reactions as well as the increase in background current likely contribute to the higher coulombic value observed in molten LiNO_3 . Although there is some evidence in the literature for the existence of divalent silver ions (20), results of Fig. 3 and 4 indicate that the monovalent silver ion is primarily present in molten LiNO_3 , NaNO_3 , and KNO_3 .

Corrosion studies were made in molten nitrates using polished silver coupons and determining their weight loss over a 2h period. Results of these studies, summarized in Table I, confirm the electrochemical investigations by showing the instability of silver metal in molten LiNO_3 . The corrosion rate of silver, however, varies markedly

Table I. Weight loss studies of polished silver coupons in molten nitrates

Molten salt	Temperature (°C)	Cell atmosphere	Weight loss ($\mu\text{g h}^{-1} \text{cm}^{-2}$)
LiNO_3^a	350	air	1980

with the nitrate salt used as shown by the weight loss of $280 \mu\text{g h}^{-1}\text{cm}^{-2}$ in carefully dried molten LiNO_3 at 350°C , but only $5 \mu\text{g h}^{-1}\text{cm}^{-2}$ in KNO_3 at 375°C . The presence of other substances greatly affects the corrosion rate in molten LiNO_3 . The use of undried LiNO_3 (Baker, reagent grade) without any helium flow and with the cell opened directly to the air increased the corrosion rate to $1980 \mu\text{g h}^{-1}\text{cm}^{-2}$. Additions of LiNO_2 , Li_2O , AgNO_3 , or LiCl to molten LiNO_3 significantly decreased the corrosion rate. The presence of both LiNO_2 and AgNO_3 gave no measurable corrosion; in fact, a reaction occurs that forms silver metal in the melt. The corrosion rate diminished noticeably after several hours, as would be expected from the buildup of reaction products such as AgNO_3 , LiNO_2 , and Li_2O . Our values in Table I are in reasonable agreement with corrosion studies by Conte and Ingram (21). A much smaller corrosion rate for silver in molten LiNO_3 suggested by EMF measurements of activity coefficients by Boxall and Johnson (22) may be explained by their addition of AgNO_3 to the melts. The rate of silver weight loss measured in carefully dried molten LiNO_3 at 350°C is equivalent to a corrosion current density of 0.070 mA/cm^2 , that for a surface roughness factor of 15 attributable to silver deposits, could sustain the cathodic reaction indefinitely at 1 mA/cm^2 , as seen in Fig. 3.

These corrosion studies show that the potential of Ag^+/Ag reference electrodes in molten nitrates may change with time, especially if the silver metal in the reference electrode is in contact with molten LiNO_3 . Problems encountered in cell EMF measurements have suggested the corrosion of silver electrodes in fused nitrates (23, 24). Diffusion studies in molten $\text{Ca}(\text{NO}_3)_2\text{-KNO}_3$ also show evidence for the corrosion of silver electrodes and silver deposits (25, 26). Thermodynamic calculations of potential vs. pO^{2-} diagrams for silver in fused nitrates predict that silver is less stable in molten LiNO_3 than in the $\text{NaNO}_3\text{-KNO}_3$ eutectic melt (21). The small size of the Li^+ ion makes it a good oxide ion acceptor (Lux-Flood acid) that should enhance the corrosion of silver in LiNO_3 melts.

The corrosion of silver in molten salts can be conveniently studied by galvanostatically depositing silver onto a platinum electrode for a fixed time period and then reversing the current in anodic stripping experiments. Any corrosion of the deposited silver shortens the anodic time period. Table II presents results of such studies in several equimolar salt mixtures at 250° and 400°C . Corrosion is almost undetectable for experiments in $\text{NaNO}_3\text{-KNO}_3$ at 400°C , yet it can be quite significant in melts containing Li^+ ions. At 400°C , very little of the deposited silver can be detected electrochemically in molten $\text{LiNO}_3\text{-LiClO}_4$ due to the high corrosion rate. The calculation of corrosion

Table II. Percent of cathodically deposited silver that is recovered during anodic stripping experiments

Molten salt ^a	250°C	400°C
NaNO ₃ -KNO ₃	95%	95%
LiNO ₃ -KNO ₃	95%	90%
LiNO ₃ -NaNO ₃	85%	60%
LiNO ₃ -LiClO ₄	85%	5%

The silver was deposited onto a platinum electrode ($A = 10 \text{ cm}^2$) for 120s at 10 mA and then stripped off at the same current.

^a Equimolar mixture.

rates based on these galvanostatic studies is complicated by the unknown surface area of the deposited silver.

Potential scan studies of AgNO₃ reduction in molten LiNO₃ at 350°C are shown in Fig. 7. Distortions of the waveform occur at slow sweep rates that produce a flattened peak. At scan rates of 10 mV/s or less, a broad wave with no precise peak is observed. These distortions of the waveform are likely caused by the corrosion reaction of the deposited silver with molten LiNO₃ that alters the concentration gradient of silver ions at the electrode surface. A further complication is the increase in the effective electrode area during the potential scan due to the deposits of silver. At fast potential scan rates, both distortions are minimized, and the experimental peak currents obey the theoretical equation

$$i_p = 2.54 \times 10^5 n^3 A C^0 D^{1/2} \nu^{1/2} \quad [4]$$

for the reversible deposition of an insoluble substance at 350°C (27, 28). The condition of linear diffusion is applicable to the Pt wire electrode for scan rates greater than 0.1 V/s (27). A diffusion coefficient of $2 \times 10^{-5} \text{ cm}^2/\text{s}$ for the Ag⁺ ion in molten LiNO₃ at 350°C is obtained from this equation using scan rates varying 1000-fold (0.1-100 V/s) and correcting for the background currents to obtain $di_p/d\nu^{1/2} = 2.92 \times 10^{-2} \text{ A cm}^{-2} (\text{V/s})^{-1/2}$ (correlation coefficient = 0.9996, $n = 10$) for a melt containing $C^0_{\text{AgNO}_3} = 2.61 \times 10^{-5} \text{ mol cm}^{-3}$. The background currents were determined by similar measurements in the absence of AgNO₃. Extrapolations based on other studies yield a value of $2.7 \times 10^{-5} \text{ cm}^2/\text{s}$ for the diffusion coefficient of the Ag⁺ ion in LiNO₃ at 350°C (16, 29).

Cyclic voltammograms are shown in Fig. 8 for the reversible electrode reaction of AgNO₃ (Eq. [3]) in molten

Fig. 7. Potential scan studies of silver ion reduction on a platinum wire electrode ($A = 0.10 \text{ cm}^2$) in molten LiNO₃ at 350°C containing 0.10 m/o AgNO₃ ($1.46 \times 10^{-2} \text{ m}$ or $2.52 \times 10^{-5} \text{ mol/cm}^3$). Potential scan rates shown are 20, 50, 100, and 200 mV/s.

Fig. 8. Cyclic voltammograms for the electrode reactions of AgNO₃ (0.10 m/o) in molten LiNO₃ at 350°C using a platinum wire electrode ($A = 0.10 \text{ cm}^2$). Potential scan rates shown are 0.1, 0.2, and 0.5 V/s.

LiNO₃ at 350°C. The sharp drop in current following the anodic peak is characteristic for the depletion of a deposited metal (12, 13, 30, 31). At scan rates where the corrosion is negligible, the area under the anodic peak is equal to that under the cathodic peak. The cathodic peak current is considerably smaller than the anodic peak current, but the cathodic peak is broader and reduction continues after the cathodic sweep reversal up to about -0.15V.

A significant loss of reducible silver ions occurs with repeated cathodic and anodic studies in fused NaNO₃ or KNO₃ when a one-compartment cell is used. For example, constant potential coulometry studies of AgNO₃ in molten KNO₃ at 375°C yield the same amount of charge for both the cathodic and the following anodic reaction ($1.0 e^-/\text{Ag}^+$). The solution, however, darkens in color during the anodic reaction suggesting that oxide ions formed at the counterelectrode

combine with silver ions generated at the working electrode to yield the net cell reaction

that produces insoluble Ag₂O in the bulk solution. Studies in molten NaNO₃ gave similar results, showing loss of silver ions with repeated cathodic and anodic studies when a one-compartment cell is used. Equilibria reactions involving peroxide and superoxide ions may also occur in both melts (4, 7). The loss of reducible silver ions in such experiments could be significantly decreased by using a two-compartment cell that confines the oxide ions formed to the counterelectrode compartment, thereby hindering their reaction with the silver ions in solution. Results in molten LiNO₃ using a one-compartment cell were again quite different; there was no evidence for the formation of insoluble Ag₂O during the anodic reaction, and very little loss of silver ion activity occurs. The oxide ions produced at the counterelectrode during silver oxidation in molten LiNO₃ precipitate as insoluble Li₂O (4). These results suggest a solubility order of $\text{Li}_2\text{O} < \text{Ag}_2\text{O} < \text{K}_2\text{O}$; hence, insoluble Li₂O rather than Ag₂O forms in molten LiNO₃.

Thermodynamic calculations for the decomposition of Ag₂O

suggest that Ag₂O decomposition becomes possible at 140°C at a partial oxygen pressure of 0.21 atm. Although

perceptible decomposition of Ag_2O into its elements occurs above 160°C (20), the kinetics of this reaction are rather slow, as found in classical studies many years ago by Lewis and others (32-34).

The addition of Na_2O to a NaNO_3 - KNO_3 melt containing AgNO_3 produces an instantaneous dark precipitate and the loss of the electrochemical activity of the silver ions. This precipitate remains unchanged at temperatures up to 350°C , suggesting that the rate of decomposition of Ag_2O is quite slow in molten nitrates. At 400°C , the dark color of the precipitate gradually lightens over a time period of several hours and slight gas evolution can be detected. A comparison study of pure Ag_2O in a glass tube at the same temperatures revealed no significant difference in the rate of decomposition of Ag_2O in air over the rate in molten nitrates. It should be noted that many of our experiments with Ag^+ ions in molten nitrates produced specks of silvery film on the surface of the molten nitrates. These films could result from the free silver formed in Eq. [7] or from the reaction of Ag_2O with nitrite ions (21)

Possible corrosion reactions of silver and their estimated E° values at 350°C in molten LiNO_3 include

The latter three reactions are possible only when the reaction products are present at low activities. Under a helium atmosphere in a dry melt, reaction [10] would be the most likely corrosion reaction. The Ag_2O formed would be converted by the displacement reaction

into AgNO_3 and Li_2O . In agreement with the experimental studies (Table I), the presence of sufficient amounts of the end products (LiNO_2 , AgNO_3 , and Li_2O) in the melt can slow the corrosion rate or even reverse the reaction direction. Since the displacement reaction with Ag_2O does not occur in molten NaNO_3 and KNO_3 , the lower corrosion rates in these melts may be due to the formation of a passivating film of Ag_2O on the silver surface. Corrosion rates may also be related to the observation that the reduction of molten NaNO_3 and KNO_3 is kinetically slower than the reduction of molten LiNO_3 (4).

The addition of chloride ions to nitrate melts containing AgNO_3 produces a cloudy solution due to the formation of insoluble AgCl (35). Studies of the silver ion cathode in several molten nitrate mixtures before and after chloride addition show that AgCl is readily reduced; albeit, the experimental potentials are generally 0.3-0.4V more negative than those observed for the reduction of silver ions. In molten LiNO_3 - LiClO_4 mixtures, the addition of AgNO_3 produces a cloudy solution that suggests the presence of Cl^- ions either as an impurity or as a product of the self-decomposition reaction of LiClO_4 (5). No significant electrochemical activity was observed for Ag_2O in molten nitrates. This could be due to its observed tendency to coalesce and precipitate from the nitrate melt, whereas, AgCl is present as a fine suspension. Discussions of thermal battery cells utilizing AgNO_3 are presented elsewhere (36, 37).

Summary

The addition of AgNO_3 to molten nitrates permits the cathode to sustain current densities of 100 mA/cm^2 or larger. The electrochemical reduction of silver ions produces dendritic deposits of silver metal and yields values close to $1.0 e^-/\text{Ag}^+$. The corrosion rate for silver metal is

higher in molten LiNO_3 than in either molten NaNO_3 or KNO_3 . In fused NaNO_3 and KNO_3 containing silver ions, insoluble Ag_2O forms when oxide ions are present. In molten LiNO_3 , insoluble Li_2O forms rather than Ag_2O . The decomposition of Ag_2O in molten nitrates is slow at temperatures up to 400°C . Insoluble AgCl is electrochemically reducible in molten nitrates.

Photoelectrochemical Properties of Single-Crystalline n-SiC in Aqueous Electrolytes

H. Morisaki, H. Ono, and K. Yazawa

The University of Electro-Communications, Chofu-shi, Tokyo 182, Japan

ABSTRACT

The photoelectrochemical properties of n-SiC were studied in aqueous electrolytes. The onset potential of the anodic photocurrent in steady state was found to be about 1V more anodic than that of the photocurrent measured by the lock-in method ($-2V$ vs. SCE). This discrepancy was ascribed to the presence of transient photocurrent observed in the potential range between -1.9 and $+0.6V$ vs. SCE. Possible mechanisms of the transient photoresponse were examined. The flatband potential deduced from the Mott-Schottky plot of the C-V characteristics was found to shift into the cathodic direction of potential in the course of the photoelectrochemical measurements. The shift was explained by a hypothesis that thin oxide layer grows on the SiC surface during anodic polarization under strong illumination.

Silicon carbide (SiC) is a stable high temperature semiconductor material with 2.2 – 3.0 eV bandgap energy depending on the crystallographic structures: ~ 3 eV for various polytypes (α -SiC (2H, 4H, 6H, ...) and 2.2 eV for β -SiC (3C). Electronic properties of this material have been widely investigated, and several electronic devices such as blue light emitting diodes have already been fabricated (1).

In contrast to this, very few studies have been reported on electrochemical properties of SiC: the first systematic study on the photoelectrochemical behavior of this material has been reported by Gleria and Memming (2). They investigated charge transfer processes between SiC and various redox systems and observed that the flatband potential of this material in aqueous electrolytes is exceptionally cathodic ($\sim -1.6V$ vs. SCE at pH 1). We are attracted to this material from this point of view because, if this is true, the material would be a very good coating material for unstable small-bandgap semiconductors to make heterostructure photoanodes for photoelectrochemical energy conversion (3). At present, studies on the photoelectrolysis of water have been hampered by the lack of electrode materials with better performances (4-11).

In the present study, we have reexamined the photoelectrochemical properties of n-SiC in aqueous electrolytes and found that the onset potential of the photocurrent changed remarkably depending on the experimental conditions. We have also studied the stability of SiC electrodes in aqueous electrolytes under illumination.

Experimental

SiC electrodes used in the present experiments were made of single-crystalline n-type material (mostly 6H modification) grown at National Institute for Research in Inorganic Materials, Ibaraki, Japan. The ohmic contacts on the crystal were made by co-evaporation of Au and Ta. Copper wires were connected on the evaporated surfaces with Ag paste. The whole surface except the front plane of each sample was molded with epoxy resin. The front surfaces of the electrodes were etched in hydrofluoric acid (HF:46%) for 1 min before each measurement.

The photoelectrochemical measurements were made by using a Pt electrode as a counterelectrode, a saturated calomel electrode (SCE) as a reference electrode, a potentiostat, and a 500W Xe lamp combined with ND

filters and monochromator as a light source. When the photocurrents were measured by a lock-in amplifier, the light was chopped at a frequency in the range between 10 and 200 Hz.

The space charge capacitance of the electrodes was determined from measurements of impedance of the cell: a 1 μ A 1 kHz ac current was superimposed in the circuit, and both the ac potential difference between the semiconductor electrode and the counterelectrode as well as the phase difference between the ac current and the potential were measured by using a dual-phase lock-in amplifier.

Results

Steady-state photoelectrochemical properties of n-SiC.—Typical current-potential characteristics of n-SiC observed in 0.1N NaOH under illumination of 500W Xe lamp are shown in Fig. 1. Here, the potential was first swept from cathodic to anodic direction and the sweep direction was inverted at 2V vs. SCE. The sweep rate was 4 mV/s. The dark current (broken lines) is very low in the anodic polarization above $-0.5V$ vs. SCE. Note that the onset potential of the photocurrent (~ -1.0 vs. SCE) is not so cathodic as the previously reported value (2). This subject will be discussed later. We take hereafter the onset potential of the photocurrent as the potential where the current under illumination starts to deviate from the dark current. It is noted in the curve that a hysteresis loop is traced when the sweep direction is inverted. Apparently this is related to some corrosion of the electrode surface, because the photocurrent shows gradual decrease if the potential sweep is stopped at a certain potential more anodic than 0 V vs. SEC. The decrease in the photocurrent during the photoelectrochemical measurements recovers to the original value after dipping the electrode in HF for about 1 min, indicating that the corrosion is related to the formation of SiO₂ layer.

Current-potential characteristics of the n-SiC electrode measured in electrolytes with different pH values are shown in Fig. 2. It is noticed that the shift of the curve to the anodic direction occurs at a pH value between 11 and 12. The shift in the onset potential of the photocurrent is about 0.7V. As a possible explanation of this potential shift, we can venture that the dominant oxidizing species for the photo-oxidation change from OH⁻ ions to water molecules at some pH value between 11 and 12. The simi-

Fig. 1. Current-potential characteristics of an n-SiC electrode in 0.1N NaOH. The potential was first swept from cathodic to anodic direction and was inverted at 2V vs. SCE. The sweep rate was 4 mV/s. The light source was 500W Xe lamp (440 mW cm^{-2}).

lar effect has been observed in a TiO_2 photoanode (12). Alternatively, the results may be explained by some change in corrosion kinetics at the particular pH value.

Spectral distribution of photocurrent in n-SiC at 0 V vs. SCE is shown in Fig. 3. The main photoresponse starts to increase at about 410 nm, which corresponds to the band-gap energy of SiC (3.0 eV), although a weak tail is noted in the longer wavelength range. Similar long wavelength response has been observed by Gleria *et al.* (2). It is also noted in the curve that there is a small shoulder at about 320 nm, indicating that an optical transition to a higher subband becomes dominant for photons with larger energy. The maximum quantum yield in n-SiC is found to be about 4.5% at 1V vs. SCE, which is considerably lower than the values in oxide semiconductors such as n- TiO_2 , etc. (8).

Figure 4 is the time dependences of the photocurrent at a constant anodic potential (2V vs. SCE) observed in elec-

Fig. 2. Current-potential characteristics of the n-SiC electrodes at several pH values. The electrolytes used are (1) 0.01N NaOH (pH 12); (2) 0.1M $\text{Na}_2\text{SO}_4 + \text{NaOH}$ (pH 11); (3) 0.1N H_2SO_4 (pH 1). The light source was 500W Xe lamp.

trolytes with various pH values. At pH 14 (not shown), the reduction of photocurrent was very small. The reduction rates of the photocurrent for pH 11 and 12 at the initial stage (≤ 3 min) are about the same, whereas the rate for pH 13 is considerably slower than the former two cases. We notice that the initial photocurrent at pH 13 is somewhat lower than it is at pH 11 or 12. This type of uncertainty in the initial photocurrent was always observed in SiC electrodes after etching. Presumably, the rate of surface recombination will be changed by the surface treatment to some extent. It will be shown later that the photocurrent of SiC electrodes is strongly influenced by the surface recombination.

Transient photoresponse of n-SiC.—Figure 5 shows photocurrent-potential characteristics of n-SiC measured with a lock-in amplifier illuminating the electrode by chopped light of a Xe lamp. Here, the electrolyte used in the experiment was 0.1N NaOH. It should be emphasized that the potential for photoresponse (-1.9V vs. SCE) is well negative in this case (*cf.* Fig. 1). Similar results were obtained in 0.1N H_2SO_4 , the onset potential being about -1.2V vs. SCE . These values are in good agreement with

Fig. 4. Time dependence of the photocurrent at 2V vs. SCE. The electrolytes used are: (1) 0.1N NaOH (pH 13); (2) 0.01N NaOH (pH 12); (3) 0.1M $\text{Na}_2\text{SO}_4 + \text{NaOH}$ (pH 11). The light source was 500W Xe lamp.

Fig. 5. Photocurrent-potential characteristics of the n-SiC electrode in 0.1N NaOH measured with a lock-in amplifier. The chopper frequency was 150 Hz. The light source was 500W Xe lamp combined with a 30% (transmission) ND filter. This means that the light intensity is about 130 mW/cm².

the onset potential reported previously (2). Note that the photocurrent-potential characteristics appeared in the literature (2) have been measured by the lock-in technique.

Another point which we should like to emphasize is that the apparent photocurrent measured by this method is a function of the chopper frequency, especially in the potential range more cathodic than 0 V vs. SCE, the signal increasing with lowering frequency. Since the intrinsic (steady-state) photocurrent should be independent of the chopper frequency, the photoresponse measured by the lock-in method is supposed to include some transient component. Incidentally, it is usual with a transient response that the signal increases with increasing frequency due to the transient's being a greater fraction of the length of the pulse. The reason for the signal increase with lowering frequency in the present case is that the initial rise-rate of the transient photocurrent has not been as fast as the chopper frequency used in our present experiment.

In order to investigate further the relation between the steady-state and transient photoresponses, we measured the current-potential characteristics of n-SiC electrodes by illuminating the electrode surface intermittently while sweeping the electrode potential from cathodic to anodic direction. The results are illustrated in Fig. 6. We note that there are current spikes corresponding to some transient phenomena: the positive transient current (anodic transient) flows in the wide range of potentials from -1.9 to +0.6V vs. SCE, whereas the negative transient current (cathodic transient) flows at potentials more cathodic than -0.5V vs. SCE. The transient response was most enhanced at potentials around -1V in both directions.

The transient photoresponse was investigated also in the time dependence of the photocurrent at several different potentials, as shown in Fig. 7. It is noted in the figure that the time constant of the transient photoresponse lengthens with increasing anodic potential, being about 0.6s at -0.8V vs. SCE and about 1.8s at -0.2V vs. SCE.

In contrast to the transient responses, the steady-state photocurrent in the anodic direction starts to flow at about -1V vs. SCE and increases with increasing the anodic potential as already seen in Fig. 1. It is clear from the above experimental results that the current-potential characteristics measured by the lock-in technique include both the transient and steady-state photoresponses.

Capacitance-potential relationship of n-SiC.—In order to estimate the flatband potential as well as the donor density of n-SiC, we measured the differential capacitance as a function of potential. Figure 8 is the Mott-Schottky plot (C^{-2} vs. V) of the capacitance-potential relationship measured in 0.1N NaOH. The curves show

Fig. 6. Current-potential characteristics of the n-SiC electrode in 0.1N NaOH measured by illuminating intermittently. The potential sweep is from cathodic to anodic direction. The sweep rate is 4 mV/s.

straight lines in parallel at potentials more anodic than -0.7V vs. SCE. At more cathodic potentials below -0.7V vs. SCE, however, the curves deviate from the straight lines, the extrapolation of the curves intersecting with the potential axis at -1.15V vs. SCE. It was also noticed that the deviation from the straight portion is accompanied by the increase in the cathodic dark current, which is particularly notable at potentials more cathodic than about -1V.

Applying the well-known Mott-Schottky relation

$$C^{-2} = \frac{2}{q \epsilon \epsilon_0 N_D} \left[V - V_{FB} - \frac{kT}{q} \right] \quad [1]$$

to the straight portion of the curves in Fig. 8, we can estimate both the donor density N_D and the flatband potential V_{FB} (the other symbols have their usual meanings) from the curves in Fig. 8. Here, it should be emphasized that the flatband potential thus deduced is only an apparent value for electrodes with heterogeneous structure as in the present case (see the Discussion section).

The apparent flatband potential of n-SiC obtained from the Mott-Schottky plot strongly depends on the sequence

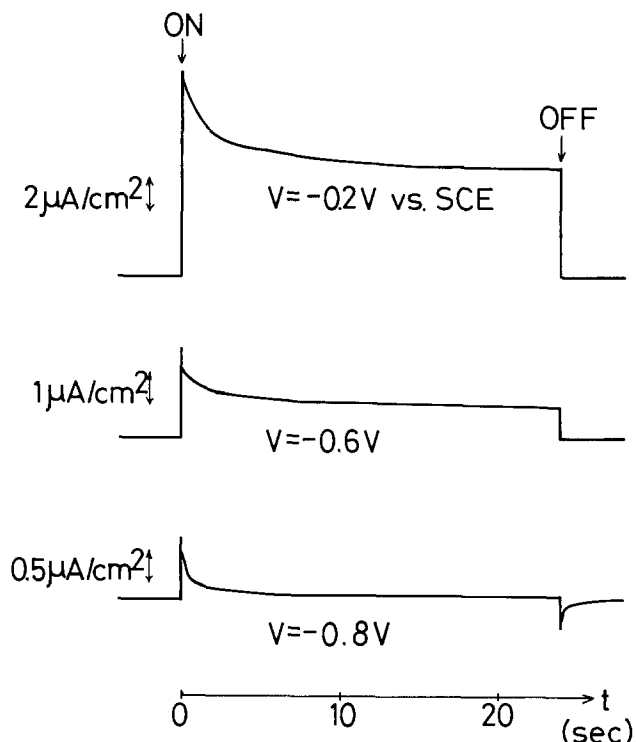

Fig. 7. Transient photoresponse of n-SiC in 0.1N NaOH. The light source was 500W Xe lamp.

Fig. 8. The Mott-Schottky plot of capacitance-potential relationship of n-SiC measured in 0.1N NaOH. The frequency of the measurement was 1 kHz. Curve 1 is the results immediately after etching the surface in HF (46%) for 1 min. Curve 2 is the results measured after the surface has been illuminated by a 500W Xe lamp for 10 min under anodic bias condition at 2V vs. SCE.

of photoelectrochemical measurements. Curve 1 in the figure is the results obtained immediately after etching the electrode surface in hydrofluoric acid for 1 min. The apparent flatband potential V_{FB} determined from the straight portion of the curve is within the range between -1.45 and -1.65 V vs. SCE. Curve 2, however, is the results obtained after the surface has been illuminated for 10 min by a 500W Xe lamp under anodic bias condition at 2V vs. SCE. Obviously, the apparent flatband potential shifts to the cathodic direction by about 1V, being in the range between -2.4 and -2.8 V vs. SCE.

The donor density of n-SiC used in the present experiment deduced from the slope of the curves is

$$N_D = 3.2 \sim 3.5 \times 10^{17} \text{ cm}^{-3} \quad [2]$$

being consistent with the values estimated from the conductivity measurement ($\sim 10^{17} \text{ cm}^{-3}$). Here, we have assumed that the relative dielectric constant ϵ of SiC is 10 (13).

Discussion

According to the surface characterization with ESCA, the surface of SiC is always covered with thin layer of SiO_x . Our experimental results indicate that the oxide layer on the SiC surface grows further during photoelectrochemical measurements, the growth rate being enhanced by illumination under anodic polarization, as noted in Fig. 1.

The low quantum yield of the photoresponse observed in Fig. 3 is apparently the consequence of the oxide formation on the electrode surface, the photocurrent being restricted by strong recombination of photogenerated carriers at the SiC/surface layer interface. The hole flux Φ'_h charge transferred to the electrolyte for the anodic photocurrent is given by

$$\Phi'_h = \frac{F_T}{F_T + F_R} \Phi_h \propto I_{\text{photo}} \quad [3]$$

where Φ_h is the flux of photogenerated holes supplied to the SiC-SiO_x interface, and F_T and F_R are the transfer rate through the surface layer and the recombination rate at the interface, respectively. The low quantum yield observed in SiC means that $F_T \ll F_R$ at the SiC-SiO_x interface.

The experimental results in Fig. 4 indicate that the growth rate of the surface layer is enhanced in less alkaline electrolytes, the rate of current reduction being more significant in electrolytes with lower pH values. Since the actual growth rate of the surface layer is expected to be determined by balance of the formation rate and dissolution rate of the film, the slower decay in the photocurrent at pH 13 would be explained by considering that the SiO_x layer is more soluble at the more alkaline electrolytes. We are now investigating the photoelectro-

chemical properties of SiC in a HF containing electrolyte (e.g., 0.1N NaOH:0.46%HF = 3:2) to appreciate the effect of SiO_x layer: preliminary results show that the photocurrent is about ten times larger than the results in Fig. 1 without showing any current reduction with time.

Next, consider the flatband potential of SiC and the related onset potentials for the photocurrent. Several characteristic potentials observed in the present experiments are tabulated in Table I. It is noted that the values are distributed in relatively wide range of potentials from -1.0 to -2.8 V vs. SCE.

The onset potential of the photoresponse measured by the lock-in method (-1.9 V vs. SCE) should be essentially equal to the value for the transient photocurrent, as stated before. This transient photoresponse will be discussed later.

The apparent flatband potential of n-SiC electrodes at pH 13 determined from the straight portion of the Mott-Schottky plot of our experimental results is about -1.5 V vs. SCE before the photocurrent measurement and about -2.5 V after the measurement. Memming *et al.* (2) have reported that the flatband potential of n-SiC in alkaline medium is about -2.1 V vs. SCE, this being an intermediate of the two values of the present study.

It should be noted that the interpretation of the Mott-Schottky plot is rather complicated when a surface layer is present on a semiconductor as in the present case. The flatband potential of a semiconductor electrode with heterogeneous structure can be determined from the intersection point of the C^{-2} vs. V line to the potential axis only if the heterogeneous structure of the semiconductor surface is such that the surface layer is the same as the bulk material with different donor density. In fact, the present situation is much more complicated because the surface layer is most probably SiO_x. This fact means that the flatband potential cannot be estimated from the Mott-Schottky plot in this case.

In spite of this, we believe that the actual flatband potential of SiC electrodes is not far from the intersection potential V_1 (-1.15 V vs. SCE) of the C^{-2} vs. V curves because of the following reasons: (i) the apparent flatband potentials deduced from the straight portion of the C^{-2} vs. V curves (~ -2.5 V after illumination) are not realistic because the values are far more cathodic from the onset of the cathodic current, (ii) the onset potential of cathodic dark current (-0.7 V) is reasonably close to V_1 , (iii) as stated before, the steep increase in differential capacitance corresponding to the kink in the C^{-2} vs. V curves is closely related to the increased dark current: in particular, the capacitance measured by the lock-in method was found to be difficult at potentials more cathodic than V_1 because of the increased real component of the ac current (the dark current), (iv) the onset potential of the steady-state photocurrent (-1.0 V) is very close to V_1 , and (v) the transient photoresponse is most enhanced in this potential range.

The discrepancy between the actual flatband potential and the apparent flatband potentials deduced from the straight portion of the C^{-2} vs. V lines is explained by the effect of the insulating layer (SiO_x) grown on the SiC surface. The effect of an insulating layer on the capacitance of semiconductor electrodes has been examined by De

Table I. Several characteristic potentials related to the flatband potential of n-SiC. The electrolyte used was 0.1N NaOH.

Gryse *et al.* (14). Assuming that there is no extra charge on the semiconductor surface, they have shown that the intersection potential of the Mott-Schottky plot should shift by

$$\Delta V = - \frac{2 \epsilon \epsilon_0 q}{C_1^2} N_D \quad [4]$$

from the real flatband potential, where C_1 is the extra capacitance stacked on the electrode surface. Applying the above relation to the present case, we can estimate the capacitance C_1 from the potential shift. Assuming that the actual flatband potential is about $-1.15V$ vs. SCE, the thickness of the surface layer deduced from this capacitance was 7.3 nm after HF etching and 19 nm after illumination. Here, the surface layer was assumed to be SiO_2 ($\epsilon = 4.0$) and other parameters used were $\epsilon(\text{SiC}) = 10$ and $N_D = 3.3 \times 10^{17} \text{ cm}^{-3}$.

It should be pointed out that the above estimation of the surface-layer thickness is only of first approximation, because details on the surface layer are unknown: various kinds of electronic charge introduced into the SiC-SiO_x interface (and/or within SiO_x) will also shift the flatband potential to some extent. In the metal-oxide-semiconductor (MOS) structure of Si devices, for example, similar potential shift is known to be induced by ion migration such as Na⁺ ions into the surface layer (15).

Finally, consider the transient photoresponse observed at potentials anodic than $-1.9V$ vs. SCE. At present, we are not certain whether the transient current is the faradaic one or it is due to the charging effect. The model, in either case, should explain consistently the fact that the transient anodic photocurrent is observed in a fairly wide range of the potential from cathodic to anodic polarization. For example, a simple model based on the charging effect of the surface layer capacitance due to photogenerated carriers should be excluded because, if this were the case, the anodic charging current would be observed only in the anodic polarization.

As a probable mechanism of the transient response based on the faradaic current, we have considered the possibility of photo-oxidation reaction which occurs transiently. Here, we tentatively assume that only the dominant reaction at the SiC-electrolyte interface is the photo-oxidation of water. Just after turning on the illumination, part of photogenerated holes in the vicinity of the SiC-SiO_x interface will charge transfer, probably by tunneling across the surface layer resulting in anodic current. The decrease in the photocurrent in the next step is then the back reaction which will become dominant only after the accumulation of oxidized species (O₂ molecules in the present model) at the surface. However, with this model it is hard to explain the transient response under cathodic polarization because the O₂ reduction is expected to proceed quite effectively under cathodic polarization.

It is also plausible that the transient photocurrent is related to the photocorrosion of SiC: the photodissolution of SiO_x may be enhanced only just after turning on the illumination. Similarly, the cathodic transient current is explained by some back reaction of the corrosion or adsorption of the chemical products, although we have not considered this possibility further.

As the other explanation to the transient photoresponse, we have considered the effect of localized states at the SiC-SiO_x interface. A schematic representation of the interface states is illustrated in Fig. 9. Here, the localized states are assumed to act as efficient hole traps, that is, the capture cross section for holes σ_h is much larger than that for electrons σ_e . Just turning on the illumination, some of the photogenerated holes will be captured in the hole traps charging the surface layer capacitance. This can occur even under weakly cathodic polarization because most of the potential is applied to the insulating surface layer, the band bending within SiC being small enough over a relatively wide range of the polarization.

Figure 10a is a possible equivalent circuit of the photoelectrochemical cell composed of the SiC electrode and the counterelectrode. Here, the current source means the

Fig. 9. A schematic representation of interface states which act as efficient hole traps. σ_h and σ_e are the capture cross sections for holes and electrons, respectively.

effect of photogenerated carriers, C_s is the depletion-layer capacitance, C_1 and R_p the capacitance and the parallel resistance of the surface layer on the SiC, respectively, C_H the Helmholtz layer capacitance, R_f means the effect of faradaic current, and R_l is the series resistance of the photoelectrochemical cell.

Assuming that $C_H \gg C_s$, C_1 and $R_p \gg R_l$, we have modified the equivalent circuit to the more simplified one as shown in Fig. 10b. Here, we have neglected the effect of faradaic current ($R_f = \infty$), assuming that the current is purely capacitive. The time constant of the transient response is then given by

$$\tau = R_p (C_1 + C_s) \quad [5]$$

Substituting $\tau = 1s$ and $C_1 = C_s = 0.1 \mu\text{F}$ as typical values, we get $R_p \approx 5 \text{ M}\Omega$ as the resistance of the surface layer.

So far, we have not discussed the photoelectrolysis product. Since O₂ evolution has not been observed directly, it is not possible to exclude the possibility that the entire photocurrent is associated with corrosion with formation of SiO_x (and perhaps CO₃²⁻). A steady corrosion

Fig. 10. A possible equivalent circuit of the photoelectrochemical cell composed of the SiC electrode and the counterelectrode (a) and the simplified model (b).

current of $200 \mu\text{A}/\text{cm}^2$ (Fig. 4) means the formation rate of SiO_2 and thus the dissolution rate of about $100 \text{ nm}/\text{min}$. Taking into account that the substantial increase in the oxide layer thickness estimated from the capacitance measurements is about 120 nm by 10 min illumination, it would be more natural to suppose that practically both the corrosion and photo-oxidation of water occurs simultaneously at the SiC-electrolyte interface.

Conclusion

We reexamined the photoelectrochemical properties of n-SiC in aqueous electrolytes and found that an insulating layer on the SiC surface (probably SiO_2) grows further during the photoelectrochemical measurement. The surface layer thickness was estimated from the capacitance measurements. It was found that the surface layer thus formed controls the rate of charge transfer as well as the flatband potential of the n-SiC electrodes. The onset potential of the anodic photocurrent in steady state was found to be about 1V more anodic than that of the photocurrent measured by the lock-in method (-2V vs. SCE). This discrepancy was due to the presence of transient photocurrent observed in the potential range between -1.9 and $+0.6\text{V}$ vs. SCE. We have concluded from a series of experimental studies that the flatband potential of n-SiC at pH 13 is about -1V vs. SCE, which is about 1V more anodic than the previously reported value. We have also investigated the transient photoresponse observed in the potential range near the flatband condition and proposed possible mechanisms for this phenomenon on the basis of the presence of the surface layer.

ABSTRACT

Electron transfer reactions in the open-spaced crystal of Prussian blue (PB) by photo-oxidation at a n-type semiconductor (n-TiO₂) are discussed. The reduction of PB at n-TiO₂ electrodes occurs, but the corresponding oxidation is not possible in the dark. The photo-oxidation of Prussian white (the reduced form of PB) does occur at n-TiO₂ electrodes in aqueous solutions at potentials about 600 mV less positive than that observed at metallic electrodes. The photo-oxidation of PB itself also occurs at n-TiO₂ electrodes at about 1100 mV less positive potentials. The fully oxidized form (Prussian brown) of PB, which can be prepared by photo-oxidation, is stepwise reduced to PB at -0.16V and to Prussian white at -0.35V vs. SCE. The energy level is represented.

We have very recently disclosed a versatile new method of preparation for Prussian blue film and its analogues on inert electrodes such as platinum (Pt), glassy carbon (GC), and SnO_2 (2-7). The spectroelectrochemistry (5) and its application for a stable electrochromic device (2) have been discussed. Recently reports by Neff *et al.* have shown a chemical method of preparation for a thin film

*Electrochemical Society Active Member.

of PB on Pt and gold (Au) electrodes and demonstrated the redox behavior of PB (8-10). Although mechanistic studies of chemical synthesis of the PB films demonstrated by Neff have not yet been reported, we have found that well-cleaned SnO_2 electrodes could not acquire the PB deposit by a simple dipping method (5). However, the electrochemical method employed by us can give quantitative formation concerning the PB de-

posit on various electrode surfaces (2, 3, 5). The spectroelectrochemistry of PB-modified SnO_2 electrodes has clearly revealed that the fully oxidized form of PB is a definite compound and shows only an absorption band at 420 nm in the visible region (5). The formula of PB is water-insoluble one, i.e., $\text{Fe}_4^{3+}[\text{Fe}^{\text{II}}(\text{CN})_6]_3$, which was previously determined by a coulometric study with a PB-modified SnO_2 electrode in 1M KCl (5). However, in 1M KCl, a fairly large background prevented a precise determination of the charge consumed at the oxidation wave of PB. In this paper, a refined result for a coulometric study is reported.

Electron transfer reactions in the open-spaced crystal of PB by photo-oxidation at a n-type semiconductor allow us to obtain the further understanding of PB. Recently, DeBerry and Viehbeck reported an electron transfer reaction at TiO_2 electrodes (1). However, they have described only the photo-oxidation of Prussian white (reduced form of PB) on both single-crystal and polycrystalline TiO_2 electrodes. In this paper, it will be shown that photo-oxidation of Prussian white (PW) and of PB do occur at n- TiO_2 electrodes in aqueous solutions at potentials less positive than that observed at metallic electrodes such as Pt, GC, and SnO_2 . These results also lead to consideration of the application of electron transfer reactions in the film on n- TiO_2 electrodes for an erasable optical signal recording system.

Experimental

A single-crystal TiO_2 sample was heated to 650°C in vacuum at 10^{-4} torr for 2-3h; this will be referred to as "the moderately doped sample" having a donor density of about $2 \times 10^{18}/\text{cm}^3$, as determined from a Mott-Schottky plot. The crystal sample (1 mm thick) was provided with an ohmic contact (11, 12) and mounted in a glass tube. The back and sides of the crystal were insulated from the solution with an ethylene-propylene copolymer, dissolved in toluene. This material was relatively impervious to attack from the solution of ferric-ferricyanide, which is a strong oxidant (5). The electrode was polished with alumina slurry and etched in $\text{HNO}_3/\text{HF}/\text{CH}_3\text{COOH}$ (5:3:3) for 15s prior to use (11, 12).

The SnO_2 electrodes used were thin films deposited on glass substrates (Corning, 10 Ω/\square films) and were used with an ohmic contact wrapped with a platinum wire (5). The PB films on TiO_2 electrodes were prepared in an aqueous ferric-ferricyanide solution of an equal-volume mixture of 20 mM $\text{K}_3\text{Fe}(\text{CN})_6$ in 0.01M HCl and 20 mM

FeCl_3 (pH = 2.0), as previously described (2-6). The electrodes were cathodically polarized in the above ferric-ferricyanide solution in the dark under a galvanostatic condition with a current density of 10 $\mu\text{A}/\text{cm}^2$. An electrode potential of about 0.15V vs. a saturated calomel electrode (SCE) was observed at the TiO_2 electrode during the formation of PB.

The light source used was a 150W xenon lamp. Electrochemical measurements were carried out with a PAR Model 173 instrument equipped with a Model 179 digital coulometer. 0.5M K_2SO_4 was used throughout as supporting electrolyte. The pH was adjusted to 4.0 by using dilute sulfuric acid. The cell used consisted of a SCE reference electrode and a Pt wire as the counterelectrode. Nitrogen gas was passed through the solution before the experiments and above the solution during the experiments, since the reduced form of PB, Prussian white, is oxidized to PB by oxygen (29).

Results and Discussion

Electrochemistry of PB on a SnO_2 electrode.—Figure 1 shows a cyclic voltammogram and a coulometric curve of a PB-modified SnO_2 electrode in 0.5M K_2SO_4 (pH = 4.0). The reductive and oxidative waves observed at 0.2V vs. SCE have been formulated as follows as the result of an *in situ* Mössbauer effect measurement, as previously discussed (6)

where Fe^{3+} , Fe^{II} , and K^+ are the high spin iron ions, the low spin iron ions, and the potassium ions, respectively. Only the high spin iron ions, Fe^{3+} and Fe^{2+} , are involved in the electron transfer reaction in the film (5, 6). The above mechanism was written under the assumption that the formula of PB is the "water insoluble one," $\text{Fe}_4^{3+}[\text{Fe}^{\text{II}}(\text{CN})_6]_3$. Ellis *et al.* assumed that the deposit obtained by a chemical method was "water soluble PB," $\text{KFe}^{3+}\text{Fe}^{\text{II}}(\text{CN})_6$ (9).

The electrochemical oxidation of PB occurred at the electrode potentials more positive than 0.8V. Interestingly, the second oxidation wave is clearly seen at about 1.2V vs. SCE, and the corresponding reduction peak does appear on the cathodic scan. The coulometric curves in Fig. 1 were simultaneously recorded on the cyclic

Fig. 1. Cyclic voltammograms of a PB-modified SnO_2 electrode with 6.2 mC/cm^2 as a total charge consumed at the reduction of PB. The film of PB was prepared at a current density of 10 $\mu\text{A}/\text{cm}^2$. The scan rate was 5 mV/s. The solution was 0.5M K_2SO_4 (pH = 4.0). The dashed lines show the integrated current-potential curves for the reduction and oxidation waves of PB.

voltammogram. On the scan from 0.6 to -0.2V , the integrated current of 6.2 mC/cm^2 was obtained. The coulometric curve came back to almost zero, indicating that no side reaction was involved in the waves at 0.2V . In the coulometric curve obtained on the scan from 0.6 to 1.5V and on the reverse scan, a small asymmetric behavior is observed, as shown in Fig. 1. On the scan from 0.6 to 1.4V in 1.0M KCl , a fairly large background prevented a precise determination of the charge consumed at the oxidation wave of PB [see Fig. 4 in Ref. (5)]. Such a large background seems to be due to the oxidation of chloride ions. However, the background level was very decreased in $0.5\text{M K}_2\text{SO}_4$. The asymmetric nature in the coulometric

curve, though, shown in Fig. 1, is obviously due to the small contribution of the background anodic current observed at potentials more positive than 1.3V even in $0.5\text{M K}_2\text{SO}_4$. Taking into account this background current, it can be fairly accurately estimated that the total charge required for the full oxidation of PB is 4.4 mC/cm^2 . The ratio of the charges obtained above is 0.71. This value shows directly that the averaged formula of PB in the film is "water insoluble PB," $\text{Fe}_4^{3+}[\text{Fe}^{\text{II}}(\text{CN})_6]_3$. Exactly the same conclusion has been drawn in our previous paper (5) from a similar coulometric measurement in 1.0M KCl , although the anodic background current was much larger than that in $0.5\text{M K}_2\text{SO}_4$.

Fig. 2. a(top): A cyclic voltammogram of a PB-modified TiO_2 electrode with 5 mC/cm^2 as a total charge consumed at the reduction of PB in the dark. The scan rate was 20 mV/s . The first scan was started from 0.6V vs. SCE to -0.6V , and the potential was reversed. b(bottom): Cyclic voltammograms of a PB-modified TiO_2 electrode. The electrode potential was scanned from -0.6 to 0.8V under pulsed illumination and then scanned from 0.8 to -0.6V in the dark. The scan rate was 20 mV/s .

Photoelectrochemical studies on n-TiO₂.—Well cleaned TiO₂ electrodes did not acquire PB deposit by the chemical method (9) proposed by Neff *et al.* However it was found that the electrochemical method would acquire quantitatively desired amounts of PB on n-TiO₂ electrodes, just as on SnO₂ electrodes. Figure 2a shows a voltammogram for PB on a n-TiO₂ electrode obtained in the dark on a scan from 0.6 to -0.6V. The blue color of the surfaces of the n-TiO₂ electrode was completely bleached by this reduction current. Therefore, the current observed at -0.25V is obviously due to the electrochemical reduction of PB leading to PW on the TiO₂ electrode. On the reverse scan, no current was observed in the dark at the potential examined here. On the second scan, again, no cathodic current was observed. These results indicate that only the reduction of PB occurred but that the corresponding oxidation was not possible on n-TiO₂ electrodes in the dark. When the electrode potential was kept at 0.6V for 30 min in the dark, the color of the surface of the n-TiO₂ electrode remained essentially unchanged, *i.e.*, transparent. This shows directly that the corresponding oxidation is not possible at n-TiO₂ electrodes in the dark. Note that no dark anodic current was observed, even when the electrode potential was scanned to 1.5V. This indicates that the oxidation of PB is also impossible on n-TiO₂ electrodes in the dark. These irreversible electron transfer reactions at semiconductor solution interfaces have been well characterized by many investigators (12-14).

Figure 2b shows a voltammogram obtained under illumination with chopped white light and in the dark, respectively, when the electrode potential was scanned from -0.6 to 0.8V and from 0.8 to -0.6V. The photocurrent due to the oxidation of PW commenced at about -0.4V *vs.* SCE, which was very close to the flatband potential (V_{FB}). The photocurrent increased with increasing electrode potential and reached a plateau at a potential less negative than 0.6V. Under the experimental conditions above, the color of the surface turned out to be blue. Such a color change could be seen with good contrast because the moderately doped n-TiO₂ was almost transparent. On the scan from 0.8 to -0.6V in the dark, the cathodic current peak appears at -0.28V. This dark current is obviously due to the reduction of PB which was formed under illumination, as described above.

Figure 3 shows the dependence of the dark cathodic current appeared at about -0.3V on the degree of photo-oxidation. The photo-oxidation of PW was carried out at 0.6V *vs.* SCE for different periods of time, and then the electrode potential was scanned to -0.6V in the dark. As shown in Fig. 3, the peak currents increased with increase in the duration of the photo-oxidation. Integrations of the photocurrent and the dark current were simultaneously measured in this experiment. The direct relationship of the integrated currents for the photoanodic oxidation and for the reduction in the dark emerges, as shown in Fig. 4. A perfectly straight line with a slope of about 0.8 was found. This slope suggests that the efficiency of the photo-oxidation of PW to PB is 80% on n-TiO₂ electrode. The remaining 20% of the photocurrent seems to be consumed in the oxidation of water. The identical efficiency is obtained at any potentials more positive than 0.0 V *vs.* SCE. This result indicates straightforwardly that the photo-oxidation of PW to PB is basically potential-independent as long as the electrode potential is fairly more positive than the flatband potential.

Figure 5 shows voltammetric curves for further oxidized forms of PB. The electrode was illuminated at 0.6V by white light just as in Fig. 3. The blue color of the film was changed to green. At the end of the photo-oxidation (the curve labeled c in Fig. 5), the color was brown, not green, indicating that the oxidation of PB was completed. It has been found in our previous paper (5) that the fully oxidized form of PB can be prepared electrochemically as a definite compound and is visually brown. As shown in Fig. 5, the voltammogram obtained in the dark showed two reduction peaks at -0.16 and -0.35V *vs.* SCE.

Fig. 3. Voltammograms of a PB-modified TiO₂ electrode. The electrode was illuminated at 0.6V, and, after the photo-oxidations, the dark cathodic scan was recorded. The charges consumed for the photo-oxidation of PW at 0.6V (Q_a) are 2, 3.7, and 5.2 mC/cm² for the curves labeled a, b, and c, respectively. The electrode potential was scanned at 20 mV/s.

Fig. 4. Relationship of the integrated currents for the photo-oxidation (Q_a) and for the reduction in the dark (Q_c) shown in Fig. 3.

The first reduction peak seems to be due to the reduction of the low spin iron ions, Fe^{III}, in the crystal. The blue color appeared at this reduction peak. The second peak is for the reduction of PB to PW, as discussed above. The efficiency of the photo-oxidation of PB to Prussian brown is somewhat less than the value of 80% which was obtained for the photo-oxidation of PW to PB, as discussed above. From the relationship of the integrated currents for the photoanodic oxidation of PB and for the reduction (the first wave in Fig. 5), a value of about 50% was obtained. In this case, the oxidation of water seems to compete with the oxidation of PB because the potential for water oxidation (13) is now near the energy level of the low spin iron ions in the film. After all PB is photo-oxidized to Prussian brown, the oxidation of water can be a major reaction at n-TiO₂ electrodes.

The reductions of Prussian brown and of PB start at a potential near the flatband potential ($V_{FB} = -0.4V$ *vs.* SCE). However, the reduction of Prussian brown starts at a potential more positive than V_{FB} by about 0.4V. This result seems to diminish an electron transfer mechanism via tunneling from the conduction band to Prussian

Fig. 5. Voltammograms of a PB-modified TiO_2 electrode. The charges consumed for the photo-oxidation of PW at 0.6V (Q_a) are 6.5, 10, and 15 mC/cm^2 for the curves labeled a, b, and c, respectively. Other conditions are as in Fig. 3.

brown. The reduction of electroactive species with redox potentials well positive of V_{FB} at TiO_2 electrodes has been examined in aqueous solutions (12, 13). The reduction peaks of the redox couples of $\text{IrCl}_6^{2-/-3-}$ and $\text{Fe}(\text{CN})_6^{3-/-4-}$ have been observed at -0.24V vs. SCE and 0.02V at an n- TiO_2 electrode in $0.5\text{M H}_2\text{SO}_4$ (12). However, in acetonitrile, couples with redox potentials more than 1.5V positive of V_{FB} were all reduced at potentials about 1V below the conduction bandedge (14). This has been explained by the location of intermediate levels in the bandgap of the n- TiO_2 electrode (12). In the case of the PB-modified TiO_2 electrodes, the behavior is similar to the situation of n- TiO_2 electrodes in aqueous solutions as reported by Noufi *et al.* (12). The dark reductions observed here can be explained by the large reorganization energy of the low spin iron ions, Fe^{III} , in the crystal or by the location of surface states closer to the conduction band due

to interaction of the redox centers in the crystal with the n- TiO_2 surface.

Figure 6 shows voltammetric and coulometric curves for the fully photo-oxidized form of PB. The coulometric curve shown in Fig. 6 indicates that the charges consumed are 3.5 and 5 mC/cm^2 for the reduction of Prussian brown and PB, respectively. The ratio of the charges obtained above is 0.7. The expected ratio is 0.75 if the formula of PB is the "water insoluble one," i.e., $\text{Fe}_4^{3+}[\text{Fe}^{\text{II}}(\text{CN})_6]_3$. The correspondence obtained above is a new direct proof that PB films prepared by the electrochemical method have the formula of $\text{Fe}_4^{3+}[\text{Fe}^{\text{II}}(\text{CN})_6]_3$.

The mechanisms of the photo-oxidations and reductions in the dark can be formulated as follows

Photo-oxidation

Dark reduction

where p^+ and A^- are a hole in the valence band and an anion of the supporting electrolyte, respectively. Note that the reactions of the low spin iron ions are tentatively formulated here as Eq. [3] and [4] based on the formula of $\text{Fe}_4^{3+}[\text{Fe}^{\text{II}}(\text{CN})_6]_3$. No direct proof that the anions are involved in these reactions has been obtained. The details have been under investigation.

The energy level is represented in Fig. 7. As shown in Fig. 7, the edge of the valence band is located at the potential ($\approx 2.8\text{V vs. SCE}$), fairly below the redox potentials of the iron ions in the film. Since the photogenerated hole can have an oxidizing power equal to E_v , the direct photo-oxidation of both the low and high spin iron ions would be possible

Fig. 6. Cyclic and coulometric curves of a "fully oxidized form of PB" modified TiO_2 electrode. The photo-oxidation of PW was carried out at 0.6V till the charge of about 12 mC/cm^2 was consumed. The scan rate was 20 mV/s .

Fig. 7. Relative energy positions of n-TiO₂ and the redox couples in the PB film. Fe³⁺ ⇌ Fe²⁺ and Fe^{III} ⇌ Fe^{II} represent the reactions of high spin iron ions and low spin iron ions in the film, respectively. E_c and E_v are bottom of the conduction band and top of the valence band, respectively.

However, the rapid oxidation of PW by Prussian brown could be expected by the theory of Marcus (28) because the difference of the redox potentials of two kinds of iron ions in the film is quite large (≈ 0.6 V). This seems to be the reason that only PB was produced by the photo-oxidation of PW until all PW is converted to PB (see Fig. 2 and 3).

The stability of the films on the n-TiO₂ electrode was excellent. Only 5% decrease was observed after 1×10^5 repeated cycles of an experiment similar to that shown in Fig. 3. Such high stability is extremely important for possible application as an erasable optical signal recording system. Photoactivated displays based on metal deposition (15, 16) and precipitation of viologens (17, 18) on semiconductor electrode have been reported. A recent report by Reichman *et al.* has shown the principles of a display based on precipitation of heptylviologen at a point on a p-GaAs electrode (18). However, because the contrast ratio for viologens on GaAs is not good (18), the use of a wide bandgap semiconductor is desirable to obtain a high contrast ratio. In addition, most of the viologen radical salts have shown an "aging effect" with consequently poor erasure behavior in electrochromic displays (19, 20). Therefore, the system represented here can be useful for these applications (1).

There have been several investigations on the electrical properties of a series of compounds of the type Fe₄[M(CN)₆]₃ (M = Fe^{II}, Ru^{II}, and Os^{II}) (21, 22). If PB acts as a semiconductor, energy situation and reaction kinetics would be controlled by charge carrier densities in the conduction and/or valence bands, and by the position of the Fermi level. However, no photocurrent was observed under illumination of He-Ne laser at PB-modified Pt and GC electrodes in solutions containing various redox couples (23). This indicates that the electron transfer reaction is essentially governed by a hopping mechanism between the redox centers in the PB film. It should be noteworthy

that an observed photoaction spectrum directly demonstrated that the bandgap transition of TiO₂, not of PB, was uniquely responsible for the production of a photocurrent. No semiconductor behavior of PB has been obtained.

Finally, it is noteworthy that Wrighton *et al.* have shown that the surfaces of n-type semiconductors such as Ge, Si, and GaAs can be modified with polyferrocenes, demonstrating that modified photoelectrodes are more durable than bare electrodes with respect to deleterious photoanodic passivation (24-27). The uses of the PB films for this purpose would be of special interest.

Poly(Thiophene): A Stable Polymer Cathode Material

J. H. Kaufman, T.-C. Chung, A. J. Heeger, and F. Wudl

Institute for Polymers and Organic Solids, University of California, Santa Barbara, Santa Barbara, California 93106

The development of electroactive materials made from conducting organic polymers has stimulated interest in their application in lightweight storage batteries (1-8). Primary research employing polyacetylene, $(\text{CH})_x$, has shown promise for this new technology. However, while $(\text{CH})_x$ behaves excellently as an n-doped (anode-active) electrode, instability of the p-doped (cathode-active) material at higher voltages (above 3.5V vs. Li) has been somewhat discouraging. In this communication, we report the use of electrochemically synthesized polythiophene (PT) as an electrode in an electrochemical cell. Without resorting to extraordinary techniques to insure purity, coulombic efficiencies of better than 95% have been obtained at voltages above 3.8V corresponding to doping levels of ~4%-5% per carbon. Such excellent stability at high voltage, coupled with high peak power and energy densities, suggest the use of polythiophene as the cathode material in an electrochemical storage battery, possibly employing polyacetylene as a counterelectrode.

Sample Preparation and Cell Construction

Polythiophene (Fig. 1) was polymerized electrochemically under dry box conditions. Films were grown either on platinum foil substrates or on conducting glass, using an aluminum counterelectrode with 0.1M monomer (either thiophene or dithiophene) dissolved in the starting electrolyte (0.5M LiClO_4 in acetonitrile). A constant current (0.05 mA/cm²) was applied across the cell. The resulting voltage (during electrochemical polymerization) was thereby kept relatively small compared with that used previously (9-12): 3.6V vs. Li using the dithiophene monomer or 4.6V using the thiophene monomer. The reaction at the electrode involves simultaneous polymerization and doping; for example

The substrate surface quickly becomes covered by the conducting polythiophene film; polymerization times used were about 2 min to grow a semitransparent film and about 1h to grow a film suitable for electrochemical measurements (~3 cm² with a mass of 1.8 mg). As grown, the polymer is oxidized with ClO_4^- as counterion at a concentration determined by the voltage applied during polymerization. Thin films prepared on conducting glass reveal the as-grown polymer to be translucent blue. Upon reduction to neutral, the sample changes to ruby red in color. Thicker films appear black in the oxidized state and became red when undoped (reduced) back to neutral polythiophene. A detailed description of the chemistry and the optical properties (carried out *in situ* during doping and undoping) will be reported elsewhere (13).

Battery cells were constructed with Pt films grown from dithiophene (polymerized at 3.6V) on platinum foil. After washing, the polymer electrode and a Li counterelectrode (pressed in Ni mesh and spotwelded to Ni wire) were inserted into rectangular glass tubing. The electrodes were separated by glass filter paper (previously heated under vacuum to remove water). The electrolyte

used in these initial studies was 1M LiClO_4 in propylene carbonate. Prior to use, the propylene carbonate was vacuum distilled, and the LiClO_4 was melted under vacuum in order to remove impurities and residual water. The evacuated rectangular glass was then sealed twice across the electrode leads. Subsequently, the cell was moved into a controlled-atmosphere dry box, where all measurements were made.

Experimental Techniques and Results

Measurements were made using computer-controlled electrochemical voltage spectroscopy (EVS) (14-16). The experiment starts after the electrochemical cell equilibrates at some initial voltage, V_0 . The cell is then displaced from equilibrium by a small potential step dV . Current through the cell is monitored via a shunt resistor. When the current falls below a designated minimum value, the current is integrated over time yielding the charge dQ that flowed in the step dV . The process is repeated until the cell potential reaches some preset extremum, at which point the sign of dV is reversed and the voltage stepped back to V_0 . This process can be repeated for any number of cycles. At each step the charge dQ that flowed in the step $V_0 + dV$ is stored on magnetic disk. The derivative dV/dQ is later integrated, yielding the voltage vs. charge relation for the cell.

The information obtained from EVS is similar to that obtained from cyclic voltammetry. Both the derivative dQ/dV vs. V (from EVS) and i vs. V (from cyclic voltammetry) measure the number of charges transferred as a function of energy. There are, however, some important differences. The minimum current in the EVS method can be made arbitrarily small, so that the system is in diffusion equilibrium. In cyclic voltammetry, electrode reactions are considered to be in equilibrium if the kinetics of charge transfer are rapid compared to mass-transport rates. The method, therefore, probes the surface of the polymer. However, the amount of charge stored on the surface of a polymer is typically orders of magnitude less than that accommodated in the bulk. By sacrificing speed, features corresponding to parts per million of doping can routinely be resolved with EVS.

Figure 2 shows the V vs. Q data for Pt vs. Li. The results are presented as V vs. y , where y is the dopant concentration in mole percent (m/o). For a given concentration of dopant, the charge per unit volume of dopant is $Q(y) = eAy\rho/M$, where e is the electronic charge, A is Avogadro's number, ρ is the polymer density, and M is the molecular weight of thiophene. The data were taken at $I_{\min} = 2 \mu\text{A}/\text{mg}$ with voltage steps $dV = 0.02\text{V}$ over the range 2.5V < $V_{\text{ext}} < 3.8\text{V}$. The corresponding dopant level varied from zero at the neutral point ($\approx 2.5\text{V}$ vs. Li) to a maximum of about 10% per thiophene ring or about 2.5% per carbon. Throughout this range, we obtained coulombic efficiencies greater than 95%. Cycles to cell potentials

Fig. 1. Chemical structure diagram of poly(thiophene)

Fig. 2. V vs. y curve (vs. Li) from EVS; the concentration is given in m/(per thiophene).

above 4.0V yielded better than 85% efficiency at doping levels $> 5.0\%$ per carbon. The neutral point was determined by comparing the *in situ* optical absorption spectrum (13) with that of pure chemically synthesized pristine polythiophene (17). At 2.5V (vs. Li), the two were virtually identical, with the onset of interband absorption at $\hbar\omega = E_g \approx 2$ eV, where E_g is the energy gap.

Charge injection (oxidation) occurs above ~ 3.5 V vs. Li. Preliminary attempts at n-doping (reduction) the polymer exhibited a threshold of approximately 1.6V. The potential difference between n- and p-type charge injection (oxidation and reduction thresholds) of ~ 1.9 V is consistent with the bandgap of polythiophene as measured by optical absorption (13). A similar agreement between optical and electrochemical measurements of the energy gap has been obtained with polyacetylene (15, 18).

Hysteresis is observed in the V vs. Q cycle, reminiscent of similar effects reported earlier for polyacetylene (15, 16). An analysis of the $(CH)_x$ data has demonstrated that charge is injected near the bandedge, but stored in gap center states associated with soliton pairs generated by structural relaxation around the injected charges (15, 16, 18). In polythiophene, because the ground state is nondegenerate, the coupling of π electrons to chain distortions leads to the formation of bipolarons (stabilized dications) (13). The charge-discharge relation is explained (13) in terms of charge injection near the bandedge, and charge removal from bipolaron gap states. *In situ* opto-EVS measurements reveal two absorption peaks in the bandgap of polythiophene, consistent with the creation of bipolaron states (13).

The internal resistance of the electrochemical cell was $\sim 100\Omega$. After charging to an open-circuit voltage of 3.8V, corresponding to $\sim 4.5\%$ doping (per carbon), short-circuit currents of about 20 mA/mg were obtained. At the same concentration, the maximum power density was 2.5×10^4 W/kg, based on the weight of doped polymer and the mass of lithium consumed. EVS cycles up to 4.2V ($\sim 6\%$ per carbon) demonstrated an energy density of 140 Wh/kg normalized in the same way. Corresponding values for polyacetylene (vs. Li) cells at 6% (per carbon) doping are ~ 25 mA/mg (short-circuit current), $\sim 3 \times 10^4$ W/kg (maximum power density), and ~ 176 Wh/kg (energy density)

(1). The latter numbers are based on the weight of the doped polymer and the mass of lithium consumed. These numbers are for comparison only; corresponding values for packaged cells would be lower.

Conclusion

The high voltages and excellent stability obtained with polythiophene employed as a cathode (vs. Li) suggest the construction of an all polymer battery consisting of a PT cathode and $(CH)_x$ anode. Such a cell should have an open-circuit voltage of ~ 2.8 V. The all-polymer construction may lead to power and energy densities (packaged) competitive with (or even superior to) conventional lead-acid batteries.

ABSTRACT

Linear potential scan and cyclic voltammetric behavior of the single-crystal RuO₂ (110), (001), (111), (101), and (100) surfaces in 0.5 mol/dm⁻³ H₂SO₄ solution have been studied. Significant differences in electrochemical characteristics observed in the hydrogen adsorption/desorption region have been correlated with the differences in composition and structure of the ideal, model surfaces of the RuO₂ single crystals. A cathodic/anodic pair of peaks H_{2C}, H_{2A} observed at about -0.3V (SCE) for the RuO₂ faces (110), (001), (111), and (101) has been ascribed to the reversible hydrogen adsorption/desorption on ruthenium sites. Another pair of peaks H_{1C} and H_{1A} at about $E = 0$ V (SCE), which appeared only on surfaces where oxygen is present, *i.e.*, faces (110) and (001) has been attributed to the hydrogen chemisorption on oxygen sites. The adsorption Temkin coefficients g have been estimated. The correlation between the chemisorption peak currents and the surface density of the ruthenium sites is presented and discussed in detail. An interesting kinetic effect has been observed for the (100) RuO₂ surface. The peak structure for RuO₂ (100) cannot be correlated with the properties of the ideal surface, probably because of the surface restructuring effects. The best electrocatalytical properties have been found for the (101) RuO₂ surface, good ones have been found for the (111) face, and poor for (110) and (001) faces.

Ruthenium dioxide is of considerable interest as a corrosion-resistant material for electrocatalytical evolution of chlorine and became widely used in chlorine industry in the form of mixed RuO₂ + TiO₂ coatings on titanium anodes (1-7). A significant decrease in the anodic oxygen overpotential has also been found for RuO₂ electrodes in comparison with other electrodes applied in today's electrometallurgy (8-10). Catalytic photodecomposition of water on n-TiO₂ has recently been shown to proceed at a higher rate when small amounts of RuO₂ are deposited on a photoanode surface (11). The RuO₂ crystals possess a metallic conductivity due to ruthenium d electrons, and any problems with the ohmic potential drop within the electrode material do not complicate their electrochemical behavior. A few comprehensive review articles concerning electrocatalytic and structural properties of RuO₂-based electrodes have recently been published (1, 2, 12).

Previous investigations have primarily been performed on thermal RuO₂ films (3-15) or small crystal cluster (16) electrodes because of unavailability of single crystals of sufficient size. Preliminary results of work on oxygen evolution on RuO₂ single crystals with several orientations have recently been announced (17). In this paper, we present voltammetric characteristics for single crystal RuO₂ "as-grown" surfaces (110), (001), (111), (101), and (100) in 0.5 mol/dm³ H₂SO₄ solutions. The use of single crystals with various orientations offers a new degree of freedom in studying the relations between the electrocatalytic properties and surface characteristics of the electrode. We describe the general correlations between the peak structure in cyclic voltammetry (CV) characteristics in the hydrogen adsorption region and the composition and structure of these different crystallographic orientations of the material.

Experimental

The RuO₂ samples were synthesized from ruthenium powder (Strem Chemicals, Incorporated), and oxygen by the method (18) of chemical vapor transport in a flowing gas system, a technique similar to that used by Reames (19) and Shafer *et al.* (20). Under high temperature conditions and in the presence of oxygen, volatile RuO₃ is formed from Ru or RuO₂ polycrystallites. The RuO₃ is transported by a gas stream to the cooler zone of a horizontal pipe furnace, where it decomposes and crystallizes in a ceramic boat in form of RuO₂ single crystals. Optimum conditions for this process were determined in previous work (18) to be: reaction temperature 1350°C, decomposition and crystallization temperature 1150°C, and the oxygen flow rate 60 cm/min at atmospheric partial pressure. The crystals obtained were of a few millimeters in size. The "as-grown" faces of single crystals were then oriented by the Laue backscattering x-ray diffraction method.

Crystals were mounted on a small copper plate by means of a conducting silver epoxy resin and insulated using epidian-5. The whole assembly was sealed to a glass tube holder. Electrodes with the following exposed faces were used for measurements: (001), (100), (101), (110), and (111). Geometrical surface areas of these electrodes were in the range from 0.005 to 0.04 cm².

No additional polishing of naturally grown surfaces was employed. Before each experiment, electrodes were rinsed with deionized water and kept in the solution, to be examined for 30 min. Electrodes were stored in dry state. This procedure seems to give the most ideal surfaces, at least in the case of RuO₂, for which good etchants are not known because of its extreme resistivity to corrosion. However, final preparation procedure as recommended for Pt single-crystal electrodes (21) has to leave

significant roughness on the surface and to expose other crystallographic faces.

Standard electrochemical two-compartment Teflon cells were used for measurement. All potentials were measured with respect to the saturated (KCl) calomel electrode, SCE. Pt foil was used as the counterelectrode.

An EG&G Model 173 Potentiostat and Model 175 Universal Programmer were employed for linear scan voltammetry (LSV) and CV experiments. In order to ensure a proper potential program, in some measurements two programmers were used allowing for automatic triggering of the desired voltage sequences.

Measurements were performed in 0.5 mol/dm³ H₂SO₄ solution prepared from the analytical-grade reagent and deionized water.

Results

Cyclic voltammograms for five "as-grown" crystals having (110), (001), (101), (111), and (100) surfaces indicate some systematic development of the peak structure, and because of this they are presented below in a preselected order. At first are shown CV and other characteristics for (110) and (001) faces which show more developed voltammograms. The current-voltage characteristics for the (100) surface are discussed at the end because this surface shows more complicated behavior than the remaining faces.

RuO₂ (110) surface.—Shown in Fig. 1 are the cyclic voltammograms for the (110) "as-grown" surface of single-crystal RuO₂ in 0.5 mol/dm³ H₂SO₄ solution. Two distinct peaks are observed in cathodic scan of CV curves. We attribute these peaks to the hydrogen adsorption reactions and label them H_{1c} and H_{2c}, respectively, in Fig. 1. Both reactions are quite reversible, and two anodic peaks corresponding to hydrogen desorption, labeled H_{2a} and H_{1a}, appear at nearly the same peak potentials as H_{2c} and H_{1c}, respectively. We note that the currents *i*_{p,a} and *i*_{p,c} for the peaks H₁ are about a factor of 2-3 smaller than those for the second pair of the reduction/oxidation peaks H₂. The dependence of the peak current upon the potential scan rate, *v*, for all four peaks observed in the hydrogen adsorption/desorption reaction region is linear indicating surface-controlled reactions. In Fig. 1 are shown CV curves for only three values of *v* for purposes of clarity. Similarly, as discussed earlier (22), for the case of voltammograms not involving hydrogen adsorption region, established CV characteristics do not differ significantly from LSV curves and well-reproducible voltammograms can be obtained after a few cycles.

Fig. 1. CV characteristics for the surface (110) of the RuO₂ single-crystal electrode in 0.5 mol/dm⁻³ H₂SO₄ solution. Scan rates: (1) 250, (2) 500, (3) 1000 mV s⁻¹.

The next two pairs of anodic/cathodic peaks appearing in the oxide rearrangement region (200–750 mV vs. SCE) on CV curves are labeled R_{1A}, R_{2A}, R_{1C}, and R_{2C} in Fig. 1. Their interpretation has been briefly discussed in previous paper (22).

The third region of electrode potentials is mainly determined by the oxygen adsorption reactions. First, reversible process occurs at the potential 950 mV (SCE) and the respective anodic and cathodic peaks are designated O_{1A} and O_{1C} in Fig. 1. The second surface process can be deduced from the voltammograms presented in Fig. 1 as proceeding at the potential approximately 1150 mV. The symbols O_{2A} and O_{2C} are used for the anodic and cathodic reactions, respectively.

In order to prove that five pairs of peaks H₁, H₂, R₁, R₂, O₁, and also O₂ correspond to the same but reverse electrode reactions, the potentiodynamic characteristics with sequentially increasing or decreasing E_i were analyzed (a typical example of this analysis is illustrated in Fig. 5 for the oxide rearrangement region). Detailed examination of these kinds of characteristics for the entire potential range provides a proof for above designation of peaks.

RuO₂ (001) surface.—A typical cyclic voltammogram for the (001) face is presented in Fig. 2. As in the case of the surface (110), two pairs of the anodic/cathodic peaks are observed on CV curves in the potential region of the hydrogen adsorption reactions. They are situated at the same peak potentials, about 0 and -300 mV (SCE), respectively. Because of this and also following results of structural considerations presented in interpretation section, we used the same designation of these four peaks as for the (110) face. Unlike in case of the latter surface, peak currents *i*_{p,c} and *i*_{p,a} for the reaction H₁ at (001) surface are comparable with those for the reaction H₂. It is seen from Fig. 2 that peaks H₂ are much broader than peaks H₁, suggesting existence of some repulsive surface interactions. A pronounced hydrogen evolution commences at about -620 mV (SCE). The oxide rearrangement reactions R_A and R_C proceed at the RuO₂ (001) face with the formation of only one pair of the reduction/oxidation peaks at ~500 mV (SCE). The oxygen adsorption region is again similar to that observed at (110) surface. However, peak potential for the reaction O₁ is now more positive by 50 mV. The same shift in potential should probably be ascribed to the reaction O₂.

RuO₂ (111) surface.—The surface (111) of the RuO₂ single crystals shows only one-peak behavior in the hydrogen adsorption region. This situation is illustrated in Fig. 3, where CV characteristics obtained in 0.5 mol/dm³

Fig. 2. Cyclic voltammogram for the RuO₂ (001) surface in 0.5 mol/dm⁻³ H₂SO₄ for *v* = 500 mV s⁻¹.

Fig. 3. Dependence of CV curves for the RuO_2 (111) surface in 0.5 mol dm^{-3} H_2SO_4 upon the potential scan rate v [mV s^{-1}]: (1) 100, (2) 200, (3) 500.

H_2SO_4 solutions are presented for three potential sweep speeds marked in the figure. Although the peak potentials $E_{p,c}$ and $E_{p,a}$ appear at -250 mV (SCE), not very different from those for the reaction H_2 at (110) and (001) surfaces, we mark differently the adsorption/desorption reactions at the face (111) for reasons discussed later in this paper. We note also that hydrogen evolution starts at lower overpotential ($E \approx -520$ mV) at the surface (111) than at surfaces described previously.

The (111) surface exhibits two-peak behavior in the oxide rearrangement reaction area, as seen in Fig. 3. Both reactions R'_{1A} (R'_{1C}) and R'_{2A} (R'_{2C}) are highly reversible. Despite the overlap of peaks R'_{1A} (R'_{1C}) and R'_{2A} (R'_{2C}) and the fact that their full appearance is not completely reversible, it can be seen from the CV curves that the peaks R'_{1A} and R'_{1C} , corresponding to the first surface reaction, are sharper and higher than those corresponding to the second reaction, R'_{2A} and R'_{2C} .

In the oxygen evolution region, no peaks are observed. However, from the shape of CV characteristics as well as from the i - V dependence, we can deduce that current is controlled by the surface reaction. We assume that this is the oxygen adsorption/desorption process which is to be denoted O'_{1A} and O'_{1C} , for the anodic and cathodic reactions, respectively.

RuO_2 (101) surface.—A cyclic voltammogram for RuO_2 (101) electrode is presented in Fig. 4 for $v = 500$ mV/s. It shows the lowest degree of development of the peak structure. In each of the three potential regions (hydrogen adsorption, oxide rearrangement, and oxygen adsorption), there is seen only one pair of the reduction/oxidation peaks. They are labeled H'_{2C} and H'_{2A} , R'_A and R'_C , O'_C , respectively, in Fig. 4. The H_2 reaction is superimposed on the following step of hydrogen evolution reaction and forms a prewave before sharp current increase due to hydrogen bubbling. It is to be noted that the latter process commences at a significant rate at a potential about -500 mV. The reversibility of reactions proceeding on (101) surfaces is illustrated in Fig. 5. For all inversion potentials, current steps are observed.

RuO_2 (100) surface.—The behavior of the RuO_2 (100) electrodes is different from that of all other RuO_2 surfaces in that it does not show the same high degree of symmetry as they do. The fast scan CV characteristics are presented in Fig. 6. All curves are sloped and the anodic-cathodic charges do not compensate in any of the three potential regions discussed for other surfaces. The situation in the hydrogen adsorption region is more clearly shown in Fig. 7, where the potential scans are limited to

Fig. 4. CV characteristic for the face (101) of the RuO_2 single-crystal electrode in 0.5 mol/ dm^{-3} H_2SO_4 at $v = 500$ mV s^{-1} .

the range -550 to 800 mV (SCE). Two cathodic/anodic peaks at about 0 and -50 mV are initially observed at $v = 100$ mV/s. However, the cathodic peak splits into two peaks as the potential sweep speed is increased up to 1000 mV/s. These two peaks are labeled H'_{1C} and H'_{2C} in Fig. 7. At the same time, the anodic peak designated H'_{1A} remains without significant changes and the peak current follows linear dependence upon v , as also the cathodic peak currents do. The peak potentials for H'_{1A} and H'_{1C} do not change as v increases, while that for H'_{2C} shifts in cathodic direction increasing separation of the cathodic peaks. It is characteristic that asymmetry of CV curves for (100) face remains even at very slow scan rates. The voltammogram obtained at $v = 1$ mV/s is presented in Fig. 8. The cathodic and anodic peak potentials are -97 and -12 mV (SCE), respectively. Exact cathodic wave is seen at potentials lower than about 0 mV. The evolution of hydrogen bubbles at significant rate commences at $E = -700$ mV (SCE), as can be seen from Fig. 6.

The oxide rearrangement proceeds with the formation of one couple of anodic/cathodic peaks. In the oxygen adsorption region, a pair of peaks O'_{1A} and O'_{1C} can be re-

Fig. 5. Dependence of LSV characteristics for the RuO_2 (101) surface in 0.5 mol/ dm^{-3} H_2SO_4 upon the anodic inversion potential. The electrode was kept at E_r for 15 min before each run.

Fig. 6. CV characteristics for (100) face of RuO₂ single-crystal electrode in 0.5 mol/dm⁻³ H₂SO₄ solution for $\nu = 500 \text{ mV s}^{-1}$.

solved at 1000 mV (Fig. 6) and eventually the sloped part of CV curves can be ascribed to the reactions O''_{2A} and O''_{2C}.

Interpretation of Experimental Results

The aim of the present study of the electrochemical behavior of the RuO₂ single crystals is to find a correlation between the obtained voltammograms and the structure and composition of RuO₂ surfaces. The use of single crystals for this purpose gives the additional degree of freedom in looking for such correlations. These investigations were impossible earlier because of the unavailability of the RuO₂ single crystals.

The compositional and structural data for the ruthenium dioxide, crystallizing in the rutile-type structure, are

given in Table I. The sketch of ideal model surfaces (110), (001), (111), (101), and (100) of the RuO₂ single crystals is presented in Fig. 9. There are substantial differences in structure and composition of different crystallographic faces of the RuO₂ single crystals. While crystals with orientations (101), (111), and (100) have only ruthenium atoms present on the surface, both ruthenium and oxygen are present on the (110) and (001) faces. The plane lying below the top plane has only oxygen in the case of (110), (101), (100), and (111) orientations, while both ruthenium and oxygen are found in the (001) case. Also, the ruthenium and oxygen ions on each surface are not identical. The numbers of oxygen ions n_{ox} required by a particular kind of surface ruthenium ion to restore their octahedral coordination are given in Table I.

In further discussion, we use the term "oxygen-free surfaces" for the model, ideal surfaces (101), (111), and (100) and the term "(Ru,O)-composite surfaces" for the ideal crystallographic faces (110) and (001).

On the basis of a general consideration of the properties of the model RuO₂ crystal, we expect a great influence of the oxygen presence at the crystal surface on its electrochemical behavior. In the limiting case, adsorption of hydrogen can proceed on two different kinds of active surface sites, Ru and \bar{O} , and separate voltammetric peaks can appear. Then the following electroreduction reactions ought to be ascribed to the chemisorption of H⁺ on the \bar{Ru} sites

and on the \bar{O} sites

Fig. 7. CV for RuO₂ (100) surface in 0.5 mol/dm⁻³ H₂SO₄ in the hydrogen adsorption region ν [mV s⁻¹]: (1) 100, (2) 250, (3) 500, (4) 1000.

* After Ref. (23).

From the comparison of the experimental CV characteristics in the hydrogen adsorption region, we can see that only one pair of reduction/oxidation peaks appears in case of the oxygen-free surfaces [i.e., (101) and (111); about the (100) face, see below]. These peaks are situated at approximately -0.3V (vs. SCE). For the (Ru,O)-composite faces, we observe two pairs of adsorption/desorption peaks, the first at about 0 V (SCE) and the second at -0.3V. Hence, the peak at -0.3V, present on CV characteristics for all four faces (101), (111), (110), and (001), can be ascribed to the chemisorption of H⁺ on the Ru sites according to the reaction Eq. [1]. The peaks at 0 V appear only for the composite faces, so we ascribe them to H⁺ adsorption on the O sites (reaction [2]).

If the above hypothesis is correct, the adsorption energy for hydrogen chemisorbed on the $\bar{\text{O}}$ sites ($E_p \cong 0$) would be much more negative than that for the electroadsorption of H⁺ on Ru sites ($E_p \cong -0.3\text{V}$). The bond strength W for Ru · H⁺ and O · H⁺ can be estimated from the Pauling equation, which for these two cases can be written in the form

$$W(\bar{\text{Ru}} \cdot \text{H}) = \frac{1}{2} W(\bar{\text{Ru}} - \text{Ru}) + W(\text{H} - \text{H}) + 23.06 (\chi_{\text{Ru}} - \chi_{\text{H}})^2 \quad [3]$$

and

$$W(\bar{\text{O}} \cdot \text{H}) = \frac{1}{2} W(\bar{\text{O}} - \text{Ru}) + W(\text{H} - \text{H}) + 23.06 (\chi_{\text{O}} - \chi_{\text{H}})^2 \quad [4]$$

where χ is the electronegativities for isolated atoms. The term $W(\bar{\text{Ru}} - \text{Ru})$ is used in former equation because the adsorbed hydrogen is supposed to replace the Ru atom that would be the nearest neighbor of Ru if the crystal would not be terminated. The same applies to Eq. [4]. The use of the term $W(\bar{\text{O}} - \text{Ru})$ seems to be more adequate to the real system than use of the term $W(\bar{\text{O}} - \text{O})$ because the adsorbed hydrogen will act rather as an individual replacing Ru cations in the coordination shell of the $\bar{\text{O}}$ site. Both Eq. [3] and [4] should now be developed to account for the multiple broken bonds. In an elementary treatment, this leads to the expressions

$$W(\bar{\text{Ru}} \cdot \text{H}) = \frac{1}{n+1} n x W(\bar{\text{Ru}} - \text{Ru}) + W(\text{H} - \text{H}) + 23.06 (\chi_{\text{Ru}} - \chi_{\text{H}})^2 \quad [5]$$

$$W(\bar{\text{O}} \cdot \text{H}) = \frac{1}{m+1} m x W(\bar{\text{O}} - \text{Ru}) + W(\text{H} - \text{H}) + 23.06 (\chi_{\text{O}} - \chi_{\text{H}})^2 \quad [6]$$

where n and m stand for the number of broken bonds Ru-Ru and O-Ru, respectively. Despite the simplified treatment (not clear is especially the role of other broken bonds), Eq. [5] and [6] take into account different situations on different crystallographic planes of a single-crystal electrode. Although a detailed analysis of the bond energies is beyond the scope of this paper, we can state qualitatively that the bond strength $W(\bar{\text{O}} - \text{Ru})$ is certainly greater than $W(\bar{\text{Ru}} - \text{Ru})$. Similarly, the electronegativity differences between oxygen and hydrogen are greater than between ruthenium and hydrogen. Therefore, the binding energy for hydrogen adsorbed on the $\bar{\text{O}}$ site should be much greater than that for the surface dipole $\bar{\text{Ru}} \cdot \text{H}$. On the basis of Eq. [5], we can also expect that the differences in the bond strength $W(\bar{\text{Ru}} \cdot \text{H})$ for different crystallographic planes should influence the voltammetric behavior of the RuO₂ single crystals to much smaller extent than the difference between $W(\bar{\text{Ru}} \cdot \text{H})$ and $W(\bar{\text{O}} \cdot \text{H})$ does. All the above considerations justify our preference in assigning well-separated peaks H₁ and H₂ to the adsorption of hydrogen at "chemically" different kinds of active surface sites.

In support of our assumption that the energy interaction between H⁺ and $\bar{\text{Ru}}$ centers is not very different

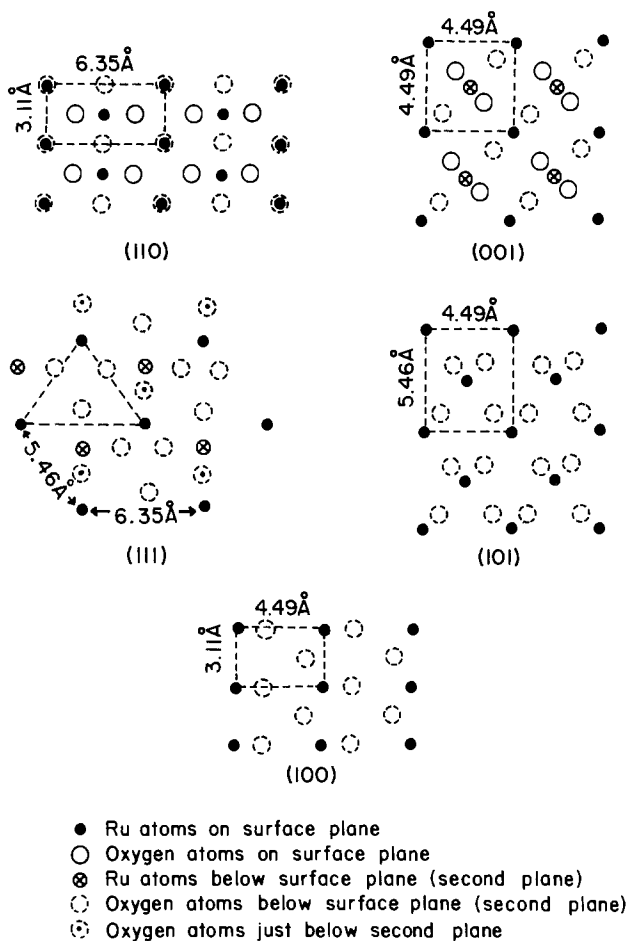

Fig. 9. Scheme of the atomic compositions of the ideal RuO₂ (110), (001), (111), (101), and (100) single-crystal surfaces. Broken lines denote unit cells.

among the four surfaces (110), (001), (101), and (111) causing only secondary effects in the peak structure of RuO₂ electrode in hydrogen adsorption region, come recent measurements of the PZC (23) for the oriented RuO₂ single crystals. It appears that within the experimental error the PZC, Φ , equals $-0.09 \pm 0.1V$ (SCE) for all surfaces (23). Following arguments of Kolb *et al.* (24) and Trasatti (25), who derived an expression for the underpotential deposition of metals, we can write for the hydrogen adsorption on Ru sites

$$\Delta E_{i_j}^{\text{UPD}} - \Delta E_{i_j}^{\text{UPD}} = e(\Phi_i - \Phi_j) \quad [7]$$

where ΔE^{UPD} is the potential shift for UPD and the indexes i, j stand for two different crystallographic faces. As the right-hand side of Eq. [7] approximates to zero, there should not be significant differences in peak potentials for H_{2C} reaction at various surfaces. The same should apply to the peak H_{1C}, and this is what we see experimentally.

Further proof for ascribing reaction [2] to peaks H_{1C} and H_{1A} comes from the consideration of the relative densities of different sites on the RuO₂ faces (110) and (001). On the former face, one oxygen atom falls per one ruthenium atom, while on the latter face, two oxygens are present on the surface per one ruthenium atom. Comparison of the CV curves for the faces (110) and (001) (Fig. 1 and 2) shows clearly relative increase of the peaks H_{1C} and H_{1A} with respect to H_{2C} and H_{2A} when going from (110) to (001). However, there is one apparent inconsistency. The surface densities of oxygen sites are the same on both surfaces (110) and (001) while that of Ru sites are 10×10^{14} and $5 \times 10^{14} \text{ cm}^{-2}$ for (110) and (001) surfaces, respectively. One could expect then that the peaks H_{2A} and H_{2C} ought to be higher for the (110) face than for the (001) face (if lateral interactions are the same, see below). But it is not the case. The peak current densities do not depend linearly upon the surface concentration of the Ru sites. And it applies not only to the above two surfaces. In Fig. 10, we present a correlation between the peak current densities and the surface density of ruthenium sites for all four faces (110), (001), (101), and (111).

The peak currents are not corrected for currents due to other than hydrogen adsorption reactions. It is seen from Fig. 10 that the whole effect of n_{Ru} on the peak currents for the reactions H₂ is removed far to lower values of n_{Ru} , below $3 \times 10^{14} \text{ cm}^{-2}$. Above this value, rather surprisingly, n_{Ru} has almost no influence on $i_{p,2}$. (Slightly higher values

of i_p for the reaction H_{2A} at surfaces (001) and (110) may be due to the shoulders of the peaks H_{1A}). However, the peaks H₁ appear only when the oxygen sites are available on the electrode surface, and there is no correlation between $i_{p,1}$ and n_{Ru} . The shape of the curves for $i_{p,1}$ has then no physical meaning. These curves were drawn to emphasize clearly our model of hydrogen adsorption based on reaction Eq. [1] and [2].

At the present stage of our knowledge, we cannot analyze fully all of the surface interactions associated with the hydrogen adsorption reactions. However, some temporary conclusions can be drawn. Despite the peaks H_{1C} and H_{2C} observed at (110) and (001) surfaces overlap (as also their anodic counterparts do), we can figure out that they differ significantly in the half-peak width $\Delta E_{1/2}$. In case of the Langmuirian adsorption isotherm

$$\frac{\theta}{1-\theta} = C \exp \{-(E - E_f^0)e/kT\} \quad [8]$$

(where θ is the surface coverage, C is the concentration of H₃O⁺ in solution, E_f^0 is the formal standard electrode potential for the reaction of hydrogen discharge, and other symbols have their usual meanings), the half-peak width is $\Delta E_{1/2} = 90.6 \text{ mV}$. This corresponds (26) to the absence of the lateral interactions (or the lack of induced heterogeneity). Both the peaks H₁ and H₂ have greater values of $\Delta E_{1/2}$. On the basis of the Frumkin electroadsorption isotherm

$$\frac{\theta}{1-\theta} = C \exp \{-g\theta\} \exp \{-(E - E_f^0)e/kT\} \quad [9]$$

greater values of $\Delta E_{1/2}$ than 90.6 mV can be attributed to the repulsion surface interactions associated with the coverage dependent heat of chemisorption $g\theta RT$. In order to estimate the interaction coefficient g , the following relation can be used

$$\Delta E_{1/2} = \frac{2RT}{F} \left[ga + \ln \frac{(0.5 + a)}{(0.5 - a)} \right] \quad [10]$$

where

$$a = 0.5 \sqrt{\frac{g+4}{g+8}} \quad [11]$$

It should be noted that $\Delta E_{1/2}$ is independent of the monolayer charge Q_0 , and the scan rate v . For the reactions pro-

Fig. 10. The correlation between the peak current densities i_p for the processes H_{2C}, H_{2A}, H_{1C}, and H_{1A} and the atomic surface density of the ruthenium sites at different crystallographic faces of the RuO₂ single-crystal electrode. The peaks H_{1C} and H_{1A} appear only when oxygen sites are present on a model, ideal surface. The shape of the curves H_{1C} and H_{1A} is thus arbitrary.

ceedings in the region of peaks H_{2C} and H_{2A} , we have estimated $g = 8.5 \pm 0.5$ for both (110) and (001) surfaces. It corresponds to the maximum (at $\theta = 1$), coverage-dependent heat of chemisorption ΔH_0^{\max} about 5 kcal/mol. The surface interaction coefficient is smaller for the reactions H_{1C} and H_{1A} (at the same surfaces) and is estimated to be $g = 5 \pm 1$, which gives $\Delta H_0^{\max} = 3$ kcal/mol. In conclusion, we can then state that the lateral repulsions between hydrogens adsorbed on oxygen sites are smaller than those between hydrogen atoms adsorbed on ruthenium sites. For the RuO_2 (111) surface which does not contain \bar{O} sites, the value of g is approximately 8, i.e., very close to g for the $\text{Ru} \cdot \text{H}$ surface dipoles at (110) and (001) faces. Probably a little smaller value of g can be ascribed for hydrogens adsorbed on the (101) surface, but here the H chemisorption peaks are not well separated from the gaseous hydrogen evolution wave and the correct value of g cannot be determined.

The voltammetric behavior of the RuO_2 (100) surface cannot be simply correlated with the properties of the ideal model (100) surface of the rutile structure. From the presence of only ruthenium atoms on the model surface (see Fig. 8), one might expect the occurrence of one pair of hydrogen adsorption/desorption peaks at a potential near -0.3V (SCE). However, the peak structure in the voltammograms (Fig. 6-8) for real (100) surfaces show rather complicated electrochemical behavior. It is evident from Fig. 7 that a pronounced kinetic effect is involved. The separation of cathodic peaks H'_{1C} and H'_{2C} with increasing potential scan rates is only possible when there is significant difference between the rate constants of these two processes. The reaction H'_{1C} is thus reversible (approximately no change of the peak potential with v), and the reaction H'_{2C} is irreversible, showing significant shift of E_p with v . The position of the first cathodic peak (H'_{1C}) might be ascribed to the hydrogen chemisorption on the oxygen sites rather than on the ruthenium sites if the adsorption energies would not change very much in comparison to those for the faces (110), (001), (111), and (101). However, the origin of the second peak H'_{2C} is not clear since the peak potential at slow potential scans is close to that for H'_{1C} . Besides, there is no desorption peak H'_{2A} corresponding to H'_{2C} (if it is assumed to be the adsorption process). In this situation, an attempt has been made to consider the possible effect of reconstruction of the model surface (100). In LEED experiments, it has been found that the RuO_2 (100) surface undergoes restructuring. Similar observations have been made for the rutile TiO_2 (100) surface (27). It has also been found that the RuO_2 (110) surface is unreconstructed (28), similar to the TiO_2 (110) surface (29, 30). The complex electrochemical behavior of the RuO_2 (100) surface may then be a natural consequence of the reconstruction effects. On the basis of data (29) obtained for TiO_2 we may also expect that the (001) surface of RuO_2 is unstable and faces to planes with higher coordination of Ru by oxygen. In case of (001) TiO_2 , the facets {011} and {114} have been observed (29). However, further discussion of the correlations between the reconstruction and faceting effects and the voltammetric behavior should await some more experimental data for RuO_2 , especially by LEED and XPS.

Conclusion

We have observed significant differences of the electrochemical behavior in the hydrogen adsorption region for single-crystal surfaces (110), (001), (111), (101), and (100) in 0.5M H_2SO_4 solution. For the former four faces, there is a strong correlation between the cyclic voltammograms and the composition and structure of the ideal, model surfaces of the RuO_2 rutile material. The cathodic/anodic pair of peaks appearing at approximately the same potential -0.3V (vs. SCE) for these planes can be ascribed to the adsorption of hydrogen on ruthenium sites, while the additional pair of peaks at 0V (vs. SCE) observed for the RuO_2 (110) and (001) surfaces can be attributed to the chemi-

sorption of hydrogen on the oxygen sites which are present only on these two model surfaces.

The cyclic voltammograms obtained for the RuO_2 (100) face are not readily correlated to the properties of the ideal (100) surface. We suggest that this may be due to the surface reconstruction effects observed by LEED for this face. The effect of slow electrochemical kinetics leading to the splitting of the cathodic peak at higher potential scan rates has been found. Further investigations are necessary to correlate the electrochemical and physical properties of the reconstructed (100) surface.

Thermoelectricity

VII. The Seebeck Quality Factor, Q_s , a Semiconductor Characterization Tool

Donald Tuomi*¹

Borg-Warner Corporation, Roy C. Ingersoll Research Center, Des Plaines, Illinois 60018

ABSTRACT

Through the electron mobility-effective mass product, $\mu_0 (m^*/m_0)^{3/2}$, used as a parameter in single-band theory description of electron transport in a degenerated semiconductor, a new variable Q_s , the Seebeck quality factor is proposed for characterizing the quality of electronic transport within doped semiconductor alloys. This empirically defined variable, based upon acoustic vibrational mode and alloy scattering of electrons, provides a useful route for correlating the electron transport variables of Seebeck coefficient and electrical conductivity to structural-chemical and process variables in bulk materials. The fundamental parameter of $\mu_0(m^*/m_0)^{3/2}$ is reserved to characterize only the highest quality materials.

Publication of A. F. Ioffe's "Energetic Principles of Semiconductor Thermoelectric Batteries," in 1949 (1), followed by "Semiconductor Thermoelements," in 1957 (2), touched off worldwide research programs on semiconductor alloys. The revolutionary goal was replacing conventional steam power generators and Freon refrigerators with solid-state thermoelectric systems (3, 4).

The key to progress was finding n- and p-type semiconductors with high figures of merit, Z , a measure of system efficiency. This is $Z = S^2\sigma/K$, where S is the Seebeck coefficient ($\mu V/K$), σ the electrical conductivity (mho/cm), and K the thermal conductivity (mW/cm K). Attainment of Z between 8 and $10 \times 10^{-3}/K$ promised revolutionary changes, while $4.5 \times 10^{-3}/K$ would create significant new business opportunities.

As work progressed, thousands of alloys were prepared and tested, but none were capable of contributing to the revolutionary changes. In fact, many became disillusioned, and hope for progress vanished. Few strove to build specialty businesses from the better material with figures of merit ranging from 1×10^{-3} to 2.5×10^{-3} , with $3 \times 10^{-3}/K$ being exceptional (5, 6).

The semiconductor materials screening work focused upon discovering high figure of merit alloys (7). Rigorous guiding frameworks for organizing information did not emerge (8). Elementary theories called for optimizing the Seebeck coefficient near 200 $\mu V/K$ while optimizing the σ/K ratio. The Price loop correlation of Seebeck coefficient and electrical conductivity (9) led to assuming that the key to progress resided in the K term of Z . The thermal conductivity consisted of (i) an electronic component, K_e , related to the electrical conductivity through the Wiedeman-Franz law, and (ii) a lattice component of thermal conductivity, K_L , related to structural-chemical details of the alloy. The challenge was thought to be the optimization of Z by reducing the lattice thermal conductivity component (10).

As silicon supplanted germanium as the key to electronics technology advances, and the III-V compounds proved recalcitrant to the development of production technology giving high quality materials, the interest in thermoelectric materials vanished in the western nations, with only a few exceptions.

The voluminous data on thermoelectric properties remained as bits in the literature relating to low figure of merit samples. The data has continued to be augmented by Russian investigators following the earlier practices of using Seebeck coefficient and electrical conductivity data as alloy-characterization tools. The exceptionally large value for $S^2\sigma$, the power coefficient, remains elusive, as does the exceptionally small lattice thermal conductivity necessary for large Z .

Theoretical Descriptions of Alloys

Early in the research and development effort, attention was given to technologies for measuring the parameters used to calculate figures of merit (1). Until Ioffe's studies, no one had simultaneously determined all three parameters S , σ , and K on a single semiconductor sample.

The evolution of the Harman Z meter (11, 12) provided a source for S , σ , and K data, as well as the engineering parameter Z . Frequently, the power coefficient, $S^2\sigma$, was optimized while reserving actual thermal conductivity measurements for the select samples having large values. The slowness of electrical and thermal data generation led to stringent *a priori* judgments on samples for complete characterization of Z .

From the beginning, solid-state band theory was viewed as a tool to provide guidance to the experimental work (1, 2). The earliest studies brought attention to the importance of the electron mobility-effective mass product, $\mu_0(m^*/m_0)^{3/2}$, to the thermoelectric properties. Difficulties in measuring the electron effective mass led to focusing upon the electron mobility as a critical variable.

The availability of Harman Z meter data, as well as the derived individual parameters, quickly identified how complex the experimentalist's routes were to optimize Z in any specific alloy. This created a need for estimating the probable performance of optimally doped alloy from limited data.

In 1959, Chasmar and Stratton (14) utilized a spherical energy band model for an extrinsic semiconductor to extend Ioffe's earlier descriptors (1, 2). The figure of merit \times temperature product, ZT , a measure of thermoelectric efficiency, was derived using the basic Fermi integral description for electronic transport in a semiconductor. The analysis identified a "materials factor," B , as a critical parameter

$$B = 0.8952 \times 10^{-5} \mu_0(m^*/m_0)^{3/2}(T/300)^{5/2}(1/K_L)$$

where μ_0 is the classical limiting electronic mobility, m^*/m_0 the electronic effective mass ratio, T the absolute temperature, and K_L the lattice thermal conductivity.

The maximum for the ZT product could be calculated using selected values of B in combination with values for ν , the electronic energy relaxation time exponential parameter. The Fermi level, η , was systematically varied to estimate simultaneously the optimum doping level and the maximum value of ZT with the relaxation time parameter varying from $-3/2$ to $+3/2$.

Practical applications required identifying for a particular alloy sample the applicable scattering parameter, ν ; the temperature, the $\mu_0(m^*/m_0)^{3/2}$ product, and the lattice thermal conductivity. Unfortunately, the fundamental parameters are not readily accessible, so a clear basis did not exist for extrapolating optimum properties.

The parameter, $\mu_0(m^*/m_0)^{3/2}$, directly related the Seebeck coefficient to the electrical conductivity along a characteristic theoretical curve for a given alloy. Thus an alloy

having, for example, a 200 ($\mu\text{V/K}$) Seebeck coefficient and a 1000 (mho/cm) electrical conductivity would be characterized by a mobility-effective mass product varying from 25 to 1050 $\text{cm}^2/\text{V-s}$, as shown in Fig. 1 for the assumed variations in scattering modes (13)

Scattering mode	Scattering parameter
(curve a) ionized impurity	3/2
(curve b) high temperature polar optical	1/2
(curve c) alloy and/or acoustic vibration	-1/2
(curve d) lead salt according to Ioffe (1)	-3/2

The illustration based upon an S, σ point set for a good alloy emphasizes the difficulties encountered in the interpolation or extrapolation of values far from optimum utilizing theoretical approaches in combination with points far from optimum.

Chasmar and Stratton stimulated a long series of studies (12-23) directed towards (i) identifying the variables interacting to limit the maximum attainable ZT , (ii) identifying optimum doping levels at the maximized figures of merit for experimental materials using the S, σ , and K data on one, two, or, at most, three specimens, and (iii) estimating reasonable limits to the attainable figures of merit using varied ranges of assumptions.

The analytical approaches did not give guidance on discovering or optimizing experimental alloys in a direct way. A feeling emerged that the dependence of the effective mass for electrons upon the reciprocal of the electron mobility removed the figure of merit dependence upon $\mu_0(m^*/m_0)^{3/2}$ so the only route to high Z lay in further decreasing the thermal conductivity of the lattice by alloying (10).

The Seebeck Quality Factor

Early in our materials work, we recognized the general inadequacy of figures of merit or power coefficients to characterize experimental samples. They were device-engineering variables rather than ones directly related to material characteristics. The question kept arising as to how to judge two different alloy samples as to excellence. An excellence ratio needed to be defined.

A likely candidate appeared to be the $\mu_0(m^*/m_0)^{3/2}$ parameter, but what relaxation time parameter for electron energies should be used? A series of figures were drawn of S vs. σ , using the $\mu_0(m^*/m_0)^{3/2}$ product as the variable parameter for $-3/2, -1/2, 1/2$, and $3/2$ values of the scattering parameter, ν . Experimental S, σ data from varied sources for different alloys were plotted on different copies of the master figures with the goal being to identify the best option for use in defining alloy excellence.

The fit of data for n-type doped $\text{Bi}_2\text{Te}_{2.1}\text{Se}_{0.9}$ compositions is shown in Fig. 2 for quenched and Bridgman grown rods with $\text{I}_2, \text{Cu}_2\text{Br}_2$, and BiI_3 dopants. The mobility effective mass product classifies the samples as 65, to 180, to 260 $\text{cm}^2/\text{V-s}$ class materials.

The $\mu_0(m^*/m_0)^{3/2}$ description of S, σ crystal anisotropy for the Bi_2Te_3 -class alloys is illustrated in Fig. 3 for direc-

Fig. 1. The characteristic mobility-effective mass parameter curves passing through the point 200 $\mu\text{V/K}$ and 1000 mho/cm for scattering parameter, ν . Variations: (curve a) $-3/2$ lead salt scattering, (curve b) $-1/2$, alloy and/or acoustic vibrational, (curve c) $+1/2$, high temperature polar optical, and (curve d) $+3/2$, ionized impurity mode.

Fig. 2. The experimental data fit of n-type $\text{Bi}_2\text{Te}_{2.1}\text{Se}_{0.9}$ quenched and Bridgman-grown rod alloys acoustic mode-alloy scattering, $\mu_0(m^*/m_0)^{3/2}$ parameter curves relating Seebeck coefficient to electrical conductivity by single-band theory.

tions perpendicular and parallel to cleavage plane of the layer lattice structure. The temperature-dependent data of Dennis (36) for p-type is characterized as 75 perpendicular to cleavage plane and 350 $\text{cm}^2/\text{V-s}$ parallel, while the n-type is 50 and 350 $\text{cm}^2/\text{V-s}$, respectively. The variability shown by the other specimens suggests variations in sample quality.

Similar categories of fits were encountered for extrinsic samples of $\text{Bi}_2\text{Te}_3\text{-Sb}_2\text{Te}_3$ and $\text{Bi}_2\text{Te}_3\text{-Bi}_2\text{-Se}_3$ alloys incorporating varying levels of doping, as well as in the temperature-dependent parameter studies when the S, σ experimental points were directly plotted as in Fig. 3.

The surprising feature emerging from the exercise was the variabilities encountered in $\mu_0(m^*/m_0)^{3/2}$ for different sample series (24). This fundamental parameter was proving to be a variable parameter of both chemical composition and processing condition. The acoustic mode-alloy scattering relaxation time, $\nu = -1/2$, curves for a S - σ correlation were providing simple $\mu_0(m^*/m_0)^{3/2}$ numbers which measured the alloy quality. This was an experimental variable of the alloys!

The Seebeck Quality Factor Curves

The work of Donohue *et al.* (25) suggested a general definition for the quality factor, as well as a presentation framework.

For Bi_2Te_3 alloys, they found that the electronic transport could be described using the single-band extrinsic semiconductor model with spherical constant energy surfaces and an acoustic vibrational mode relaxation time for the energy dependence of electron scattering. The electron transport equations became

$$S = (\pm) k/e (2F_{1(\eta)})/F_{0(\eta)} - \eta$$

$$\sigma = neu$$

$$\mu = [\pi^{1/2}/2] [F_{0(\eta)}/F_{1/2(\eta)}] \mu_0$$

$$n = (4/\pi^{1/2}) (2\pi m^* kT/h^2)^{3/2} F_{1/2(\eta)}$$

where the symbols are as follows

- S = Seebeck coefficient
- σ = electrical conductivity
- μ = carrier mobility
- μ_0 = nondegenerate carrier mobility
- m^* = density of states effective mass of charge carrier
- k = Boltzmann's constant
- n = number of charge carriers
- e = electronic charge
- F_n = Fermi integral of index N
- η = Fermi level
- T = absolute temperature
- h = Planck's constant

utilizing these equations, the Seebeck quality factor curves of constant $\mu_0(m^*/m_0)^{3/2}$ in $\text{cm}^2/\text{V-s}$ were constructed using a logarithmic electrical conductivity scale, as in Fig. 4, and a linear scale, as in Fig. 5.

The discovery of reasonably good fits for extrinsic samples of the Bi_2Te_3 - and PbTe -class alloys for either variable doping or for varying temperature dependence

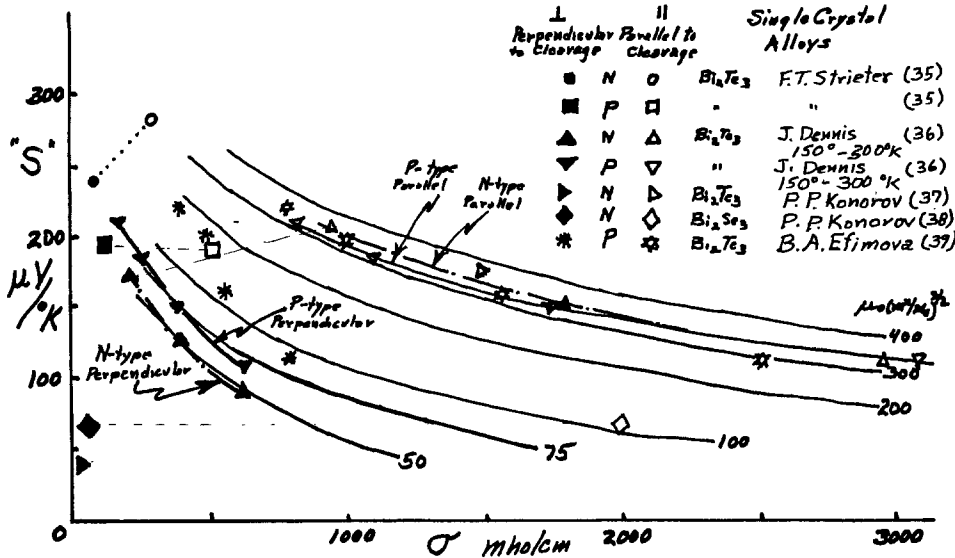

Fig. 3. The experimental data fits for the perpendicular and parallel to cleavage plane measurements of the Seebeck coefficients and electrical conductivity on single-crystal alloys of Bi₂Te₃ compared to the $\mu_0(m^*/m_0)^{3/2}$ parametric curves using acoustic mode-alloy scattering relaxation times in single-band theory.

led to ignoring the existence of a temperature-dependent effect on the mobility and effective mass of the carriers. Through the strategy of defining the curves as having characteristic values of

$$Q_s = \text{Seebeck quality factor}$$

an empirically useful tool for the materials scientist was created. The Q_s could be used to identify and to describe composition and process variable effects on a material parameter, which could be related to the device parameter in the later stage of material optimization through controlled doping at constant Q_s .

In Fig. 4, a set of reference curves for the S - σ relationship are shown with ν varying from $-3/2$ to $+3/2$. These were anticipated as a useful adjunct for identifying the critical scattering variables in different alloys as systematic changes in doping were undertaken. This has proven to be of limited value as increasingly sophisticated experiments identified the conditions giving the largest outlier Q_s for a particular composition using particular combinations of processing variables.

Applications of Q_s

Over the intervening years since the initial 1963 conceptualization, diverse applications of Q_s to data analysis, materials characterization, and materials optimization have all emphasized the utility of such zero or first-order quality characterizations of electronic transport processes in experimental materials.

A first illustration in Fig. 6 shows the surprisingly large Seebeck quality variation for p- and n-type bismuth telluride alloys, which were considered in the early 1960's to

Fig. 4. The semilogarithmic Seebeck quality factor curves relating Seebeck coefficients to electrical conductivities in extrinsic semiconductor alloys. Reference curves for ν , the scattering parameter of $-3/2$, $-1/2$, $1/2$, and $3/2$.

be superior or commercial-class materials. The large Q_s variations of nominally similar class figure of merit alloys suggests that either serious measurements errors confounded the results or the alloys had not been fully optimized. The implication continues to be true - best outlier figure of merit alloys of p- and n-type have not been made reproducibly for device use.

Subtle doping-variable-related effects have been noted in Fig. 2. Further evidence is provided in Beckman and Bergvall's studies on the n-type doping of Bi₂Te_{2.7}Se_{0.3} composition Bridgman-grown rods (26). The highest quality was found for copper doping (a 360 Q_s), lowest for BiI₃ (a 320 Q_s), and with Cu₂Br₂ or CuBr₂, an intermediate quality (340 Q_s).

Another illustration is the dramatic degradation of p-type Bi₂Te₃ by addition of no more than 0.5% Sn. The initially 350 Q_s p-type alloy precipitously decreased in Seebeck coefficient with only a slight increase in electrical conductivity, as shown in Fig. 7. The phenomena are related to polyphase, circulating current effects.

The bismuth telluride alloy data of Fig. 2 show the n-type-doped, quenched samples are in the 65 Q_s class, while the Bridgman-grown rods are 180-300 Q_s . All quenched alloys of the (Bi, Sb)₂(Te, Se)₃ system show below 100 Q_s alloy quality. Broad surveys of published S , σ data on varied alloys show this to be the rule for heavily doped semiconductors. Associated defects form during this processing which prove to be difficult to remove by annealing bulk alloy samples.

Telkes' early exploratory studies on power generator alloys (28) provides a further illustration of Q_s classification. The characteristics were as follows

Alloy	Q_s	Alloy	Q_s
n-PbS	80-190	p-Te	190
p-PbS	0.8-1.8	p-ZnSb	90-210
n-SnO ₂	2.1	p-Bi ₂ Te ₃	60-225
p-Cu ₂ S	17-27	n-Bi ₂ Te ₃	225

The existence of n and p lead sulfide near 200 Q_s (29) and Bi₂Te₃ alloys at 400 and higher Q_s (30) emphasizes the challenge present in alloy performance optimization (6).

Finally, a survey of the Si/Ge alloys utilized in power generators brings attention to a temperature-dependent behavior in Q_s . In Fig. 8, limited data for extrinsic behaving 80/20 Si/Ge alloys (30-32) show that Q_s increases with increasing temperature. At the high temperatures of the power generator environment (1200 K), the Seebeck qualities are in the 300 Q_s range, with n-type being superior to p-type. This behavior is crucial to the improvement in the figure of merit with increased temperature. By contrast, the Q_s of Gd₂Se₃, PbTe, and (Bi, Sb)₂(Te, Se)₃ extrinsic alloys are independent of temperature and, respectively, in the 100, 300, and above-400 Q_s classes.

Fig. 5. The Seebeck quality factor relationships of Seebeck coefficients and electrical conductivities for ranges relevant to thermoelectric alloy optimization.

Summary

Heavily doped semiconductors (33, 34) are the basis from which thermoelectric power generation and refrigeration will evolve into an increasingly sophisticated device technology. Theory and experiment will need to proceed hand in hand as the imperfection structures of nearly perfect crystals are brought under full structural-chemical control in an economically viable technology.

The phenomena degrading alloy performance need to be progressively minimized on the macro-, micro-, submicro-, and atomic-dimensional scales. A true materials science integration of chemists, physicists, and metallurgists' perspectives is necessary for systematic progress to take place.

A key factor in reaching the goals lies in being able and willing to make value judgments on the quality of alloys. The electronic transport phenomena related to the power coefficient numerator of the figure of merit are conveniently described by the Seebeck quality factor, Q_s , as an empirical materials-classification variable.

Though originally related to a simple single-band model of a semiconductor dominated by acoustic mode-

Fig. 7. The Q_s degradation of p-type Bi_2Te_3 through tin doping at 0% to 0.5% levels (27).

alloy scattering of electrons, the Q_s characteristics have proven experimentally to have rather universal utility to alloy-optimization research. With passage of time, the distinction between Q_s and $\mu_0(m^*/m_0)^{3/2}$ has become conceptually sharpened.

The defect structures modifying electron scattering in three-dimensional complex crystal lattices will also perturb the thermal conductivity. The electronic structures of the molecular orbital or band structure system create the three-dimensional structures of the x-ray crystallographer's electronic density maps. Within this electronic framework, the massive atomic nuclei oscillate in a quantum mechanically defined electric field space. This reality poses a "Catch-22" for modeling the ways to alter lattice and electronic components of thermal conductivity to optimize alloy performance.

Thus, a further conceptual evolution is needed, the defining of a thermal conductivity quality factor, Q_k , which facilitates alloy optimization as the $Q_s/Q_k = M$, materials parameter (40). The final stage of evolution is selecting the optimally doped alloy combinations of n- and p-type which provides the optimized performance in engineered devices.

The recommendation that Johann Seebeck be honored by adoption of Q_s , the Seebeck quality factor, as an experimentalist's approach to optimizing the electronic performance of semiconducting alloys is presented. Johann Seebeck was our first semiconducting alloy materials scientist working pragmatically on a significant exploratory research program.

Acknowledgments

This paper reflects over two decades of work in the heavily doped semiconductor area. Special acknowledgments need to be made to Stanley Cook and John Horwath at the Roy C. Ingersoll Research Center of Borg-

Magnetron-Sputtered SiO₂ Films in Hydrogen-Argon Mixtures

T. Serikawa and T. Yachi

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Midoricho, Musashino-shi, Tokyo 180, Japan

ABSTRACT

SiO₂ films are deposited from SiO₂ targets by RF planar magnetron sputtering in hydrogen-argon mixtures. Properties of the SiO₂ films are measured and compared with SiO₂ films deposited in only an argon mixture and thermally grown SiO₂ films. The following points are clarified by our experiments. The addition of hydrogen to the sputtering gas prevents the formation of film structures having microvoids, which appear when only argon is used. This results in film densification and a smooth surface texture. The addition of hydrogen greatly improves film property uniformities over the substrate. Infrared absorption spectra and Auger electron spectra show that the SiO₂ films sputtered in hydrogen-argon mixtures are indistinguishable in composition from the films by other methods.

SiO₂ films have played a major role in the development of silicon semiconductor devices (1, 2). The chemical vapor deposition method and the thermal oxidization of silicon in an oxygen ambient have been most widely used to deposit SiO₂ films in semiconductor device fabrication (1, 3). These methods, however, have a problem, in that they result in a high substrate temperature. Certain de-

vices or processing schemes require that the SiO₂ films be deposited at low temperatures.

Recently, a magnetron sputtering technique has been developed, which is a potentially attractive method for overcoming the above problem (4). Lower temperatures are obtained using this technique, even when the deposition rates are significantly high. Therefore, magnetron-

Fig. 1. The RF planar magnetron-sputtering apparatus

sputtered SiO_2 films are potentially useful, especially as an insulating material for aluminum multilevel interconnections in semiconductor devices (5-7).

The sputtered SiO_2 films are deposited as a result of the glow discharge of argon gas. However, films deposited in only argon suffer from the problem of a porous film structure (8). To overcome this problem, several sputterings, such as oxygen mixing and substrate biasing, have been studied (9, 10).

We have previously reported that the addition of hydrogen to the sputtering gas has the effect of improving SiO_2 film properties (11). The present study has been undertaken to further clarify the properties of SiO_2 films deposited by magnetron sputtering in hydrogen-argon mixtures.

Experimental

In our experiment, the SiO_2 films were deposited on a silicon substrate by the RF planar magnetron sputtering

Micrographs a (top left), b (top right), c (middle left), and d (middle right) correspond to hydrogen partial pressure of 0, 0.016, 0.1, and 0.6 Pa, respectively, where sputter depositions were carried out at 2.0 Pa pressure and at a 200°C substrate temperature. Micrograph e (left) corresponds to 1 μm thick thermally grown SiO_2 film.

Fig. 3. Effect of hydrogen partial pressure on etching rates for SiO₂ films deposited at 2.0 and 0.47 Pa. Substrate temperature was 200°C.

apparatus with two SiO₂ targets which is shown in Fig. 1 (11). The SiO₂ targets (99.99% pure) having an area of 5 × 15 in. and a thickness of 0.25 in. were mechanically clamped to water-cooled RF electrodes. The targets were covered with an adjustable shutter mounted approximately 25 mm in front of the targets. The substrates were put on a barrel-type rotatable substrate holder having a diameter of 500 mm and a height of 530 mm, which was electrically floated. Both the holder and shutter were made of titanium.

Before admitting the sputtering gas, the system was pumped to less than 4×10^{-4} Pa with a diffusion pump. The argon or hydrogen-argon mixtures were admitted to the sputtering system at a flow rate of 100 sccm. The sputtering power and rotation of the substrate holder were fixed at 2 kW per target and 10 rpm, respectively. Films having thickness of 0.1–2.5 μm were deposited on (100)-oriented, p-type, 10 Ω cm resistivity silicon substrate of 3 in. diam at various sputtering gas pressures and hydrogen partial pressures.

Properties of the SiO₂ films were evaluated by examining the etching rate, surface texture, film density, infrared absorption spectra, and Auger electron spectra.

Etching rates were calculated from the etched depth in a 30°C buffered hydrofluoric acid BHF [100 ml (50% HF) + 860 ml (40% NH₄F)] and from the etching time. The etched depths were measured by a roughness tester (Taly-Step™).

The surface textures of as-deposited films and slightly etched films in a 30°C BHF for 5s were observed using a transmission electron microscope of carbon replica.

Film densities were measured by a gravimetric technique.

Thermally grown SiO₂ films, on which most studies have been conducted, were also measured and used as a standard for comparison. These thermally grown SiO₂ films 1 μm thick were formed on (100)-oriented, p-type, silicon substrates in a 1000°C oxidization atmosphere.

Results and Discussion

Figures 2a to 2e show surface textures of SiO₂ films prepared at various hydrogen partial pressures, as well as the surface texture for thermally grown SiO₂ films. The SiO₂ films were etched for 5s in BHF at 30°C before looking at them. In the SiO₂ film deposited in only argon, shown in Fig. 2a, many microvoids of a few tens of nanometers in diameter are observed. As shown in Fig. 2b and 2c, at low hydrogen pressures, although microvoids formation is significantly decreased, microvoid marks still remain. However, as can be seen from Fig. 2d, high

hydrogen partial pressure completely removes microvoids. The SiO₂ film prepared at 0.6 Pa hydrogen partial pressure shown in Fig. 2d has a smooth surface texture, which is superior to that of the thermally grown film shown in Fig. 2e.

As a result of this decrease in microvoid formation achieved by introducing hydrogen into the sputtering gas mixture, the SiO₂ film is densified. This fact was experimentally demonstrated by the fact that the densities of the films sputtered at 2.0 Pa in only argon alone and in 0.6 Pa hydrogen partial pressure mixed gas, are 2.10 (g/cm³) and 2.33 (g/cm³), respectively. Moreover, the density of hydrogen partial pressure-sputtered SiO₂ film is slightly greater than the 2.30 (g/cm³) density of thermally grown SiO₂ films. This is inferred from the surface textures shown in Fig. 2d and 2e.

Fig. 4. Dependencies of etching rates in SiO₂ films deposited at various hydrogen partial pressures on substrate temperature. Sputtering gas pressure was 0.47 Pa.

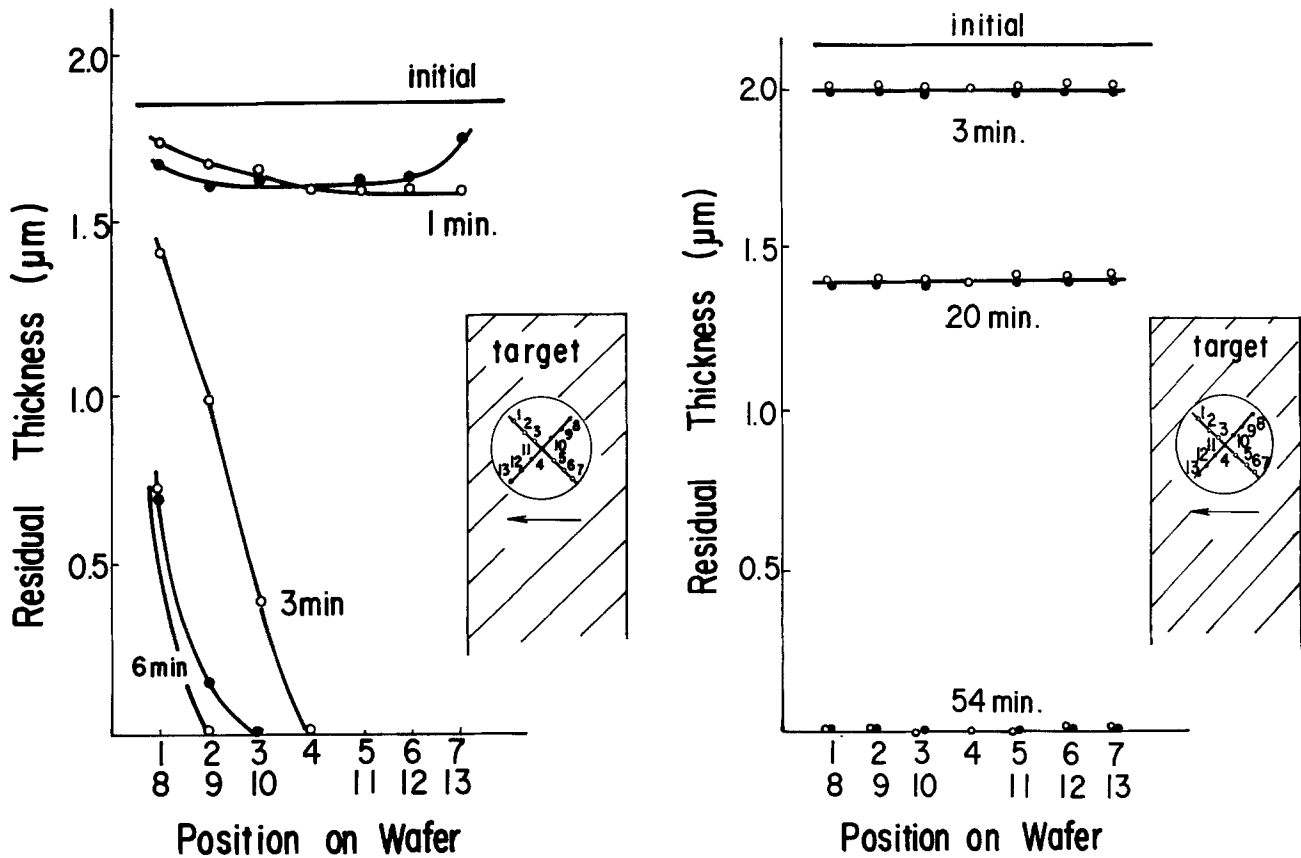

Fig. 5. Changes in residual thickness distributions of SiO_2 films over substrates as a function of etching time. The films were deposited in only argon (a, left), and 0.14 Pa hydrogen partial pressure mixture (b, right), where sputtering gas pressure and substrate temperature were 0.47 Pa and 200°C , respectively.

Changes in the etching rate as a function of hydrogen partial pressure at different sputtering gas pressures are shown in Fig. 3. Etching rates decrease proportionally with an increase in partial pressure. The films deposited at higher sputtering gas pressures have a higher rate, because of the formation of more microvoids (12, 13). Comparing Fig. 2a, 2b, 2c, and 2d, one sees that the etching rate decreases as the surface texture becomes smoother. That is, the removal of microvoids by intro-

Fig. 6. Infrared absorption spectra of SiO_2 films deposited by various methods. Sputtered films were deposited at 0.47 Pa and 200°C .

Fig. 7. Auger electron spectra of SiO_2 films deposited by sputtering in only argon (curve a), 0.14 Pa hydrogen partial pressure mixture (curve b), and thermal oxidation (curve c). Sputter conditions were the same as in Fig. 6.

ducing hydrogen lowers the etching rate. Moreover, under optimum hydrogen partial pressure, etching rates lower than the 70 nm/min are obtained. These etching rates are lower than thermally grown SiO₂ films.

In the case where only argon is used, the etching rate drops sharply with a rise in the substrate temperature, as shown in Fig. 4. By introducing a hydrogen partial pressure of higher than 2.4×10^{-2} Pa, this phenomenon disappears. Moreover, even at a low substrate temperature, low etching rate films can be deposited. Therefore, hydrogen mixing in sputtering gases is more effective in preventing microvoid formation than raising the substrate temperature.

In Fig. 5, distributions of residual thickness of SiO₂ films as a parameter of etching time are shown. The residual thickness was defined as SiO₂ film thickness after etching in a 30°C BHF. The insets in Fig. 5a and 5b indicate the relative configuration between the target and substrate, as well as the measurement positions on the substrate. The substrates move against the targets in the direction indicated by the arrows. In the case where only argon is used (Fig. 2a), the residual thickness distribution is nonuniform, especially over the upper part of the substrate. However, simply by introducing hydrogen, distribution uniformity is improved, as shown in Fig. 5b.

The properties of sputtered films are influenced by many factors, such as the energies and incident angle distributions of sputtered particles, substrate potential in relation to plasma, as well as the geometrical configuration of the system (4, 12, 13). These many factors are difficult to uniformly apply over the substrate. Therefore, film properties, such as the etching rate, become nonuniform despite a uniform deposition rate as shown in Fig. 5a. Hydrogen mixing in sputtering gas has the effect of decreasing microvoid formation, as shown in Fig. 2a to 2d. SiO₂ films are densified over the whole of the substrate, resulting in the uniform etching rate shown in Fig. 5b.

Figures 6 and 7 show the infrared absorption spectra and Auger electron spectra of sputtered SiO₂ films, compared with thermally grown SiO₂ films. Absorptions at 1100, 800, and 450 cm⁻¹, which are peculiar to silicon dioxide, are present in all the films shown in Fig. 6. No additional peaks were observed. In the Auger electron spectra, the peaks for silicon and oxygen appear at 78 and 500 eV, respectively. Therefore, it is concluded from Fig. 6 and 7 that the SiO₂ films in hydrogen-argon mixtures are similar in composition to the films sputtered in only argon or thermally grown SiO₂ films.

By increasing hydrogen partial pressure, the deposition rate decreases, as shown in Fig. 8. This figure also shows the deposition rate for sputtering in a 5% oxygen-95% argon mixture, which has been commonly used to improve SiO₂ film property. The decrease in the deposition rate due to the addition of hydrogen is the result of the large sputtering yield difference between argon and hydrogen (14, 15). The decrease for the hydrogen mixture is much smaller than that for the oxygen mixture.

As has been shown in Fig. 2 and 5, when only argon is used, the SiO₂ films exhibit film structures with many microvoids and the nonuniformity of film properties. The microvoids as well as this nonuniformity affect production yield and the long-term reliability of devices. However, the addition of hydrogen to the sputtering gas has the effect of preventing the formation of SiO₂ film with microvoids. Consequently, high density SiO₂ films can be uniformly deposited over the substrate even at low substrate temperatures. Moreover, this sputtering method is very simple and effective. Therefore, magnetron-sputtered SiO₂ films prepared in hydrogen-argon mixtures are very important in the fabrication of advanced devices.

Conclusion

It was experimentally demonstrated that magnetron sputtering in a hydrogen-argon mixture remarkably im-

Fig. 8. Changes in deposition rates as a function of partial pressure of hydrogen and oxygen. Sputter depositions were done at 0.47 Pa and 200°C.

proves SiO₂ film properties. Under proper hydrogen partial pressures, the SiO₂ films were found to be superior in film density and film surface texture to thermally grown SiO₂ films. Moreover, sputtering in a hydrogen-argon mixture eliminates property nonuniformity, which appears when only argon is used.

This sputtering in a hydrogen-argon mixture results in high density SiO₂ films even at low substrate temperatures. Moreover, this sputtering technique is simple. Therefore, it is very useful in the preparation of SiO₂ films for advanced devices.

ABSTRACT

This paper reports on silicon nitride formation by low energy implantation of nitrogen or ammonia into silicon. Extensive material investigation on nitrogen-implanted films using various analytical methods, including ellipsometry, chemical etching, transmission electron microscopy (TEM), x-ray photoelectron microscopy (XPS), infrared transmission spectroscopy (IR), and Rutherford backscattering spectroscopy (RBS) is discussed. A new technique to derive the film thickness, density, refractive index, and dielectric constant is developed. This method employs a combination of ellipsometry, capacitance measurement, and nitrogen areal density obtained by RBS. A major finding indicates that the implanted nitride films have a low density compared to CVD nitride. Other material properties are also summarized.

Thermal nitridation and nitridation of oxide have been shown to have certain advantages over thermal oxidation (1-3). The thin dielectric obtained is very uniform and exhibits high breakdown strength. In addition, the nitrided layer has a higher dielectric constant than oxide and is impervious to impurity diffusion. The film is also less susceptible to process-induced gate failures (3). With the scaling of the gate dielectric in VLSI, thin nitride is a potential candidate to be investigated.

We have shown that thin nitride can be formed by using low energy implantation of N_2 in an ion milling machine (4). Since the ion milling machine can deliver a high current density over a large area, the through-put of this process is comparable with single-wafer processing. The implantation of N_2 is accompanied by surface sputtering. The sputter-implantation process produces a very uniform layer. Rutherford backscattering spectroscopy (RBS) indicates that the total nitrogen incorporated into the Si surface is about $3.2 \sim 3.5 \times 10^{18} \text{ cm}^{-2}$ at 1.7 keV. The as-implanted layer has a N/Si ratio of 1. A damaged layer about 3 ~ 4 nm thick at the interface extending into the Si substrate is also present. After thermal treatment, the ratio approaches the stoichiometric nitride value of 1.3. The damage to the Si substrate is reduced but not totally removed after annealing at 900°C for 1/2h. A damaged layer about 0.8 nm thick remains. Transmission infrared spectroscopy shows the existence of N-Si bonding in both the as-implanted and the annealed samples. However, the transmission minimum shifts from about 850 to 800 cm^{-1} after heat-treatment.

Experiments

The substrates used in the studies were (100)-oriented silicon wafers. The native oxide is removed before loading into an ion milling machine (Veeco Microetch System). The system is first pumped down to below 2×10^{-6} torr and then the implantation is carried out with nitrogen or ammonia at a pressure of 8×10^{-5} torr. The total dose of the implant is always greater than 0.3 C/cm^2 . The samples are then annealed in dry nitrogen or oxidized in wet oxygen.

Results

Ellipsometry measurements.—Ellipsometry is often used to obtain the thickness and the refractive index of a dielectric layer independently. The calculation is based on the following assumptions: (i) the dielectric film is

lossless, (ii) the dielectric film is homogeneous, (iii) the dielectric-substrate interface is abrupt, and (iv) the substrate refractive index is known. For the study of very thin films, the ellipsometric parameter Δ is of special interest. In Fig. 1, we plot $\Delta_{\text{SI}}-\Delta$ vs. the product nd , where n is the refractive index and d is the dielectric thickness, for n between 1.4 and 1.7. A very good linear relationship is observed. This means that Δ can be used to determine the product of n and d .

All the above assumptions are questionable when the nitride in the as-implanted form is considered. However, the parameter still is a qualitative measurement of the film thickness, assuming the same refractive index. Information about the dependence of layer thickness on implant energy and the effects of annealing can be deduced using this method.

The data were taken using a He-Ne laser source (632.8 nm). The angle of incidence was 70°. Figure 2 shows the ellipsometric parameter Δ vs. the implantation energy. The results indicate that film thickness increases with higher implant voltages. Figure 3 shows Δ as a function of annealing time at a temperature of 950°C. The data indicate that the film reaches a steady-state condition in 5 min of heat-treatment. A difference in annealing transient between the N_2 implanted and the NH_3 implanted is observed. No nitridation due to the nitrogen annealing ambient is detected.

If the annealed film satisfies the condition for ellipsometric analysis, it is theoretically possible to derive the film thickness and the refractive index independently. In practice, the uncertainty in the data yields a thickness of 10 ± 3 nm and a refractive index between 1.4 and 1.6. However, the product of refractive index and dielectric thickness, nd , can be determined by Δ . For a 1.7 keV implant, n times d equals 14 nm.

Chemical etching.—Figure 4 shows the etching characteristics of the unannealed films. The etch rate is much higher for the ammonia-implanted layer than the nitrogen-implanted film. Figures 5 and 6 show the etching data for the annealed and oxidized films, respectively. The etching behavior becomes almost similar after heat-treatment, and the etch rate is retarded. For N_2 -annealed films, the nitride near the substrate-dielectric interface is more resistant to the HF etching than that in the middle of the film. In addition, the film appears to have a three-layer structure. The XPS result, which will be discussed later, shows that the top surface of the nitrogen annealed films is partially oxidized.

The etching study indicates that, prior to the heat-treatment, the films produced by the N_2 implant and NH_3

Fig. 1. The ellipsometric parameter, Δ vs. the product of n times d . The data show that for a thin film with low dielectric constant, Δ is almost linearly proportional to n times d . The cross indicated in the plot is the experimentally determined Δ for a 1.7 keV N_2 -implanted film after nitrogen annealing.

implant have very different chemical properties. However, the chemical properties become similar after annealing and are stabilized. Since one sample is prepared for each data point, the results indicate that the etching characteristics are very controllable.

X-ray photoelectron spectroscopy (XPS).—The XPS technique has been used for compositional analysis as well as chemical-state identification. Since chemical etching is well controlled, one can utilize this method to probe the film at the region of interest. To establish refer-

ences, measurement on three CVD nitride samples after a brief 20:1 HF etch were made. The average nitrogen to silicon atomic ratio (N/Si) is 1.39.

XPS analysis was also done on the N_2 -implanted samples. The nitrogen annealed film is found to be partially oxidized on the surface. During the compositional analysis, care is taken to etch through this oxynitride layer. Overetching to the point that the Si substrate contribution could significantly distort the N/Si ratio is also avoided. Therefore the measurement is confined between $171 > \Delta > 159$.

Four measurements on nitrogen-implanted layers were carried out on both unannealed and annealed film types. The data show that the N/Si ratio is 1.18 for the as-implanted layer and 1.26 for the annealed film. It should be noted that both ratios are lower than the CVD nitride standard. This result is consistent qualitatively with our RBS measurements (4). The as-implanted film is highly Si rich. After nitrogen annealing, the layer changes to a more stoichiometric ratio.

X-ray-induced Auger analysis.—The Si KLL Auger emission spectrum can offer further clues to the film

composition. The Si KLL peak is excited by the Bremsstrahlung portion of the incident x-ray.

It is possible that, during the annealing, excess Si precipitates. The elemental peak of the Si KLL Auger line is the sum of emission from the substrate and the precipitate. In Fig. 7, the Si KLL signal can be deconvolved and the contributions from the elemental Si and nitrogen

Fig. 7. The deconvolution of Si KLL Auger signal. We have indicated the deconvoluted signal for nitrogen-bonded Si and elemental Si. The original signal is larger than the sum of the two deconvoluted signals. This suggests that some of the Si atoms are in an incompletely bonded form.

bonded Si may be extracted. The ratios of nitrogen-bonded Si peak area to the elemental Si peak area, $I_{Si_3N_4}/I_{Si}$, are obtained. After the XPS analysis, the Δ of the samples are again measured.

Figure 8 is a theoretical calculation of $I_{Si_3N_4}/I_{Si}$ vs. the normalized film thickness, d/λ , where λ is the electron mean free path. The parameter R is the percentage ratio of precipitated Si to that of Si bonded to nitrogen. In the absence of experimental data, the mean free path in the implanted nitride and bulk Si is calculated based on Penn's model (5). They are 2.55 and 2.86 nm, respectively. In the calculation, we have also incorporated the appropriate implanted nitride density. The experimental data in Fig. 8 indicate that excess Si in the form of precipitation is less than 5%. However, excess Si may still exist in an incompletely bonded form.

Chemical state identification.—Table I lists the binding energy of N1s, Si2p peaks and the kinetic energy of N KLL and Si KLL peaks. Because of charging of the thick CVD nitride standard, modified Auger parameters, α^*_{N} and α^*_{Si} , are calculated for comparison (6). The modified Auger parameter is a sensitive measurement of the atomic chemical environment and is independent of charging. It is clear from Table I that the chemical state of

Fig. 8. The ratio of Si bonded to nitrogen to elemental Si, $I_{Si_3N_4}/I_{Si}$, vs. d/λ , the film thickness normalized by the electron mean free path. The parameter R is percent Si in the precipitated form. The filled squares are the measured data. The electron mean free path is calculated using Penn's model.

Table I. Binding energy, Auger electron energy, and Auger parameter (eV)

	N1s	N KLL	α^*_N	Si2p	Si KLL	α^*_{Si}
Standard	399.1	378.2	777.3	103.3	1610.9	1714.2
As-implanted	397.5	380.0	777.5	101.7	1612.6	1714.3
Annealed	397.5	379.6	777.1	101.7	1612.3	1714.0

the as-implanted and the annealed films are very close to that of standard CVD nitride. However, a difference of 0.3-0.4 eV in the Auger parameter between the as-implanted and the annealed samples is observed. The annealed film has a lower modified Auger parameter than the unannealed layer. The modified Auger parameter, α^* , is a measure of the extra-atomic relaxation energy, or, in other words, the polarization energy of the solid (7). A smaller α^* means that the compound is less polarizable.

To examine the sputter-implant process (4), a bare Si wafer was implanted in the XPS analysis chamber. In this experiment, we used a combined x-ray source of Au and Mg. Before the implant, the chamber was pumped down to below 10^{-9} torr. The high vacuum kept the contamination level to a minimum. Figure 9 shows the evolution of the Si KLL peak in various stages of the implant. Before the implant, the two peaks associated with the Si substrate; the native oxide are clearly resolvable and are indicated by arrows. Figure 10 shows the respective N_{1s} photoelectron lines.

Figure 9 indicates that as N_2 is implanted into the Si a new peak appears next to the elemental Si position and gradually shifts to the position expected of the nitride. The oxide peak decreases steadily and eventually disappears. However, the N_{1s} line remains fairly steady. The evolution of the Si KLL peaks suggests that the Si atoms are gradually being surrounded by nitrogen atoms. The nitrogen atoms react fully once they enter the substrate. This observation indicates that the film is likely to be Si rich. The disappearance of oxide is just due to the surface sputtering. These data are in agreement with our implant-sputter model (4) as well as the IR measurement.

Thickness, refractive index, dielectric constant, and density.—It is possible to determine the thickness, d , the dielectric constant, ϵ , the refractive index, n , and the density, ρ , based on the following assumptions: (i) the film is stoichiometric and homogeneous in composition, (ii) the chemical nature and the polarizability of the Si-N bond are the same as for CVD nitride, and (iii) the dielectric-bulk interface is abrupt.

Fig. 10. Evolution of N_{1s} photoelectron line. No apparent shift in energy peak is observed.

As shown in Fig. 1, Δ is related to nd

$$nd = \alpha(\Delta_{Si} - \Delta). \quad [1]$$

The accumulation capacitance relates the thickness and the dielectric constant, which is a function of refractive index

$$C = \frac{\epsilon}{d} \quad [2a]$$

$$\frac{n}{n_{CVD}} \approx \left(\frac{\epsilon}{\epsilon_{CVD}} \right)^{1/2} \quad [2b]$$

The total nitrogen content can be equated to the product of density and film thickness. The density is related to refractive index through the Lorenz-Lorentz relation

$$D_n = 4A\rho \frac{d}{M} \quad [3a]$$

$$k\rho = \frac{(n^2 + 1)}{(n^2 - 1)} \quad [3b]$$

The parameters, D_n , A , ρ , and M are the nitrogen areal density, Avogadro's number, the film density, and the molecular weight, respectively. The nitrogen areal density is obtained by RBS measurements. The k in the Lorenz-Lorentz relationship can be determined by the known data for CVD nitride. In the calculations above, the CVD nitride is assumed to have the following parameters, $n = 2.05$; $\rho = 3.1$, $\epsilon_{CVD} = 7.5$ (8).

The parameters, Δ , C , and D_n are directly measurable by ellipsometry, capacitance, and RBS, respectively. A refractive index-thickness curve can be obtained from each of the equation sets above and are plotted in Fig. 11. The

Fig. 9. Evolution of Si KLL Auger peaks as a function of implantation time. The implantation is done in the XPS analysis chamber. The long time span is due to the low beam current. Peak positions for oxide, nitride, and elemental Si are labeled.

Fig. 11. Determination of the refractive index and film thickness. The three curves are deduced from the measured quantities of total nitrogen areal density, the ellipsometry, and capacitance. The refractive index and the film thickness are obtained by the intersection of the three curves.

intersection of any two of the three curves determines the film thickness and refractive index. From these intersections, the physical parameters of the annealed film are fixed within the following ranges: d : 8.5-9 nm, ρ : 2.1- 2.2 g/cm³, n : 1.6-1.65, and ϵ : 4.6-4.9. The most surprising finding of the analysis is the film's exceptionally low density. This causes the other parameters to deviate from the accepted CVD nitride values. One can imagine that the violent implantation process produces a low density nitride film.

Transmission electron microscopy.—A direct measurement of the film thickness was done using TEM. Figure 12 is a cross-sectional picture of a 1.9 keV N₂-implanted film. A 9 ± 1 nm thick amorphous layer is formed. The film is apparently divided into two parts by a layer of features about 2 ~ 3 nm in size. The nature of these features is unknown at the present. It may be due to artifacts in sample preparation. However, one can firmly conclude that a 9 ± 1 nm layer has been formed, and it appears to be amorphous. The data agree with the thickness derived in the last section.

Summary and Discussion

Hezel *et al.* (9) and Thomas *et al.* (10) have also investigated low energy N₂ implantation into Si. They have employed sputter AES profiling as the composition analysis technique. Instead of detecting excess Si, they conclude

Fig. 12. The cross sectional TEM picture of the nitrogen implanted layer. The amorphous layer is found to be 9 ± 1 nm thick. (Courtesy of Dr. Ken Ritz, Signetic Company, and Dr. William Stacy of Philips Research Laboratories.)

that the as-implanted nitride has stoichiometric or near-stoichiometric composition. However, our measurements indicate that the film in the as-implanted form is Si rich. We feel that this is not a significant discrepancy due to the low resolution of AES composition analysis. The nitrogen atomic ratio in a stoichiometric nitride is 57%. It is too close to the atomic ratio of 50% in a film with N/Si = 1. As the resolution limit of AES improves, this discrepancy may be resolved.

The uniformity of the film composition in the as-implanted stage is indicated by all of our work. A layer of damaged Si, extending about 4 nm into the Si, is located at the film-substrate interface (4). The amount of damage observed here is less than reported by Thomas *et al.* After N₂ annealing, the composition approaches stoichiometric Si₃N₄. The damage is also reduced to a layer about 0.8 nm thick.

The chemical nature of the film has also been examined. It is investigated with wet etching, transmission infrared spectroscopy, and XPS. These studies indicate that a stabilization of chemical bonding occurs as result of N₂ heat-treatment. The stabilization exhibits itself in the compositional change, the reduction of etch rate, the shifting of transmission minimum in IR, and the decrease in the Si-N polarizability detected by XPS. It should be stressed that both IR and XPS investigations indicate that the chemical nature and the polarizability of the annealed film are very similar to CVD nitride films.

Another indication of the compositional change is the resistivity of the implanted layer. The as-implanted layer is highly conductive. After heat-treatment, the film is insulating. The lowering of conductivity is probably due to a reduction of excess Si. The resistivity increase also causes a decrease in the polarizability of the layer as measured by XPS. The XPS studies also reveal that, under N₂ bombardment, the Si substrate is gradually enriched with nitrogen until a steady state is reached. The nitrogen reacts fully once it enters the substrate. Si-N bonds exist in the as-implanted state.

To determine d , n , ϵ and ρ , we made three assumptions. First, the film is stoichiometric and homogeneous in composition. RBS, which is better for composition measurement, and AES profiling, which is the preferred profiling technique, indicate so. Second, the chemical nature and the polarizability of the Si-N bonds are the same as CVD nitride. This is indeed confirmed by our IR and XPS measurements. Third the dielectric-bulk interface is abrupt. TEM examination shows that this is a good assumption. The determination of d , n , ϵ , and ρ shows that the implanted film has very different physical parameters compared to CVD nitride. The low density is the cause of the low refractive index and dielectric constant. The low density is probably due to the sputter-implant process. The dielectric thickness of 8.5 ~ 9 nm is confirmed by direct TEM measurement. The data are also consistent with our ellipsometric measurements. It indicates that the annealed film has $d = 10 \pm 3$ nm and $1.4 \leq n \leq 1.6$.

Electrical studies have shown that, after annealing, the implanted nitride films contain a high density of positive fixed charge and trapping states. A full account of the electrical properties of the implanted nitride film will be

Table II. Material characteristics measured

Thermal Cleaning of InSb Surfaces in an Ultrahigh Vacuum

F. D. Auret

Department of Physics, University of Port Elizabeth, Port Elizabeth, Republic of South Africa

ABSTRACT

In and Sb surfaces of (111) InSb crystals were analyzed by Auger electron spectroscopy (AES) before, during, and after heating them in an ultrahigh vacuum system. Heating the samples to 450°C resulted in stoichiometric and oxygen-free surfaces. Sulfur due to chemical precleaning is removed at 470°C. Further, if the initial carbon concentration is low enough (< 10% surface coverage), then it can be almost totally removed by thermal cleaning at 450°C.

The degree of cleanliness of semiconductor surfaces is of the utmost importance during semiconductor device fabrication and has a pronounced influence on the characteristics and performance of these devices (1, 2). For GaAs, it was reported that the composition of the surface and the contaminants thereon could be related to the properties of Schottky barrier and ohmic contact devices formed on it (3, 4). Also, poor device characteristics in the case of InSb have been ascribed to nonstoichiometric surfaces caused by certain cleaning procedures prior to the metallization step (5). Auger electron spectroscopy (AES) studies of GaAs (3, 4, 6) and InSb (7) led to the optimization of cleaning procedures which yielded surfaces with a high degree of stoichiometry and with only small amounts of oxygen and carbon on them.

In order to further reduce the surface contaminants, several types of methods may be used. First, low energy sputter etching (8), plasma etching (9), or reactive ion etching (10) may be used to strip the surface of unwanted oxides and impurities. These techniques, however, cause a damage layer at the surface, consisting of, among others, positively charged donor states in the bandgap of the semiconductor (11-13). These defects change the effective barrier height of a Schottky barrier device, and can lead to very leaky devices on n-type substrates (8, 11, 12, 14). Second, *in situ* substrate heating may be used to clean the surface. The surfaces of GaAs substrates that were

heated to 550°C were completely stoichiometric and oxygen free, and contained only a small amount of carbon (6). The high degree of cleanliness, stoichiometry, and crystallographic order of these surfaces allowed gold films deposited on them to grow epitaxially (6).

It is the purpose of this paper to report on the results obtained when thermally cleaning InSb crystal surfaces by heating them in an ultrahigh vacuum (UHV). These results were obtained by using AES to monitor the surface stoichiometry and cleanliness as a function of substrate temperature.

Experimental Procedure

Three sets of samples, prepared from (111)-orientated n-type Te-doped ($4 \times 10^{15}/\text{cm}^3$) InSb crystals were studied. Each set consisted of two samples, of which the In and Sb surfaces were, respectively, investigated. Before inserting them into the Auger system, each set's samples were cleaned by different chemical procedure, as outlined in Table I. These three methods were selected because they yielded, respectively, high carbon, high oxygen, and high sulfur concentrations on the surface (7).

In the Auger system, samples were mounted on a heater block with their surface normals at an angle of 30° with respect to the incident electron beam and the analyzer axis. Auger measurements were obtained with a

Varian cylindrical mirror analyzer using a 3 keV electron beam. Analysis commenced after reaching a pressure of lower than 1×10^{-8} torr. This relatively high pressure was used because it is believed that the results thus obtained would still be valid in commercial metal deposition systems, where thermal substrate cleaning could be implemented.

After Auger analyzing the sample's surface at room temperature, its temperature was increased to 480°C at a rate of 0.1°C/s. At this rate, the sample, thermocouple, and heater block were always in thermal equilibrium. During heating, the Auger signals of the substrate as well as the contaminants were continuously monitored and recorded. Upon reaching the final temperature (480°C in most cases), the sample was kept at this temperature for about 5 min in order to ensure that its surface remains stoichiometric. Thereafter, the sample was cooled down to room temperature, at which stage a final Auger analysis was made.

The percentage surface coverage of each element is calculated from the simplified semiquantitative formalism, which requires only the Auger peak-to-peak heights and inverse sensitivity factors α_i of the surface elements (15). The α_i 's for In and Sb were experimentally determined for InSb (16), while those for carbon, oxygen, and sulfur were assumed equal to those for the GaAs matrix (17). This assumption is not completely valid for oxygen because most of it is present in the form of a surface oxide. However, it enables one to qualitatively compare the amounts of impurities obtained with different cleaning techniques.

Results and Discussion

Both the In and Sb surfaces exhibited the same thermal behavior; hence, only results of In sides are presented. Figure 1 is a typical temperature profile of a sample cleaned by method II (Table I). This profile may be divided into two regions. In region I, which extends from room temperature to 290°C, the concentrations of the substrate components and contaminants remain constant upon heating. The In/Sb ratio here is about 1.2. Region II, which extends from 290°C upwards, is characterized by a change in the In/Sb ratio and a decrease in the carbon and oxygen concentrations at the surface. The In/Sb ratio first increases to a maximum of 1.5 and then decreases to unity at 430°C. At about 400°C, the oxygen concentration starts to decrease sharply, and at 450°C it is completely absent from the surface. From 250°C upward, the carbon concentration also decreased from 8% surface coverage to 2% at 450°C. Upon further heating the sample to 480°C, the In/Sb ratio remains constant with 2% carbon as the only surface contaminant. In Fig. 2, the Auger surface scans of a sample cleaned by method II is shown. These scans were recorded before (Fig. 2a) and after heating (Fig. 2b).

The temperature profiles of samples cleaned by method I were similar to that described above for method II except for one difference. The initially high carbon concentration of 45% could not be reduced to below 35% even upon heating the substrate to 530°C.

Fig. 1. Temperature profile of a CP4A-etched InSb sample

Figure 3 displays the temperature profile of a sample cleaned by method III. The main difference between this method and method II is that, in this case, most of the usual surface oxide was replaced with sulfur during the Na₂S rinse. As before, the profile may be divided into two regions. In the first region (< 250°C), the concentrations of oxygen and sulfur are approximately constant, and the carbon concentration increases slightly; the In/Sb ratio is less than one and increases gradually to reach unity at 250°C. In region II above 250°C, this ratio increases further to a maximum at 360°C and then gradually decreases to unity at 430°C, where it remains constant upon further heating. At 350°C, the sulfur concentration starts increasing, reaches a maximum at 410°C, and then decreases to zero at 470°C. The oxygen disappeared from

Fig. 2. Auger surface scans obtained (a) before and (b) after heating a CP4A-etched InSb sample to 480°C.

Fig. 3. Temperature profile of an InSb sample that were CP4A etched followed by a $\text{Na}_2\text{S}(10^{-5}\text{M})$ rinse.

the surface at 450°C as before. For this cleaning method, the carbon was reduced to below 1% surface coverage at 450°C.

The results of surface analyses obtained before and after heat-treatment of the crystals are depicted in Table II for methods I-III. They show that for all three cleaning methods, an oxygen- and sulfur-free surface with a unity In/Sb ratio can be obtained by heating the samples to above 400°C. A further point of interest is that if the initial carbon concentration is low enough ($< 10\%$) (methods II and III), then it can be reduced to acceptably low levels ($< 2\%$) by heat-treatment. However, if the initial carbon concentration is too high (method I), then heat-treatment is not efficient in removing it.

Recently, Chang (18) has shown that residual carbon left on GaAs substrates after chemical cleaning could be removed by heating the substrates to temperatures of between 350° and 400°C. It was further observed that if these substrates are exposed to an Auger electron beam during heating, then subsequent removal of carbon above 350°C becomes very difficult because of a strengthening of the bonds between the surface carbon and the substrate. In contrast, we observed that, although surfaces with an initially low carbon concentration (methods II and III) were continuously exposed to the Auger electron beam during heating, all carbon except 1%-2% could be removed by heating to above 400°C. This small amount of residual carbon may be ascribed to electron beam stimulated carbon buildup (19) caused by the Auger electron beam. It thus seems that almost all the carbon observed on the InSb surface after cleaning by methods II and III is present as weakly bonded or "physisorp-like" bonded (18) carbon, and that its bonding to the surface does not become stronger when exposing the surface to the Auger electron beam during heating. However, we found that where carbon was initially present in large concentrations (method I), the thermal removal of only a fraction thereof was possible. We speculate that, after cleaning the substrates by method I, most of the carbon present was strongly bonded to the InSb surface and could thus not be removed thermally. This is likely because method I only removes carbon by "degreasing," whereas in methods II

Table II. Surface contamination and stoichiometry of InSb before and after heating to 480°C*

Contaminant/stoichiometry	Percentage surface coverage Chemical cleaning method number					
	I		II		III

and III carbon together with In and Sb is removed from the surface by etching.

Conclusions

We have demonstrated that it is possible to obtain oxygen- and sulfur-free surfaces with an In/Sb ratio of unity on InSb crystals by heating them to 470°C in a vacuum of less than 1×10^{-8} torr. The only contaminant present on the surface after heat-treatment is carbon, and its percentage surface coverage can be limited to below 2% by applying an appropriate chemical pre-cleaning before heat-treatment. This method should prove very valuable during device fabrication where an atomically clean and stoichiometric surface is of great importance.

Heating Effects in Reactive Etching of Nb and Nb₂O₅

Mao-Min Chen^{*,1} and Young H. Lee^{*}

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The reactive etching mechanism of Nb and Nb₂O₅ in CF₄/O₂ RF plasma has been studied in a flexible diode reactor, with special emphasis on a thin film heating effect. Etch rates of both materials during reactive ion etching are determined by a combination of the ion bombardment enhanced etching mechanism and the chemical etching mechanism. In niobium, the chemical etching always dominates over the ion enhanced etching. Etch rates in the plasma etching mode are primarily due to the chemical etching mechanism. The activation energy in the chemical etching is estimated to be 0.22 and 0.11 eV for Nb and Nb₂O₅, respectively. The Nb chemical reactivity (etch rate divided by a number density of the fluorine atoms) shows a substantial increase proportional to RF power and, surprisingly, to Nb film thickness. The thicker the film, the higher the etching rate observed during plasma etching. We argue that this is due to a temperature rise in a Nb film caused by the eddy current generated by the RF magnetic field (*i.e.*, the RF inductive heating).

The substrate temperature plays a very important role during plasma etching, because etching rates due to the chemical etching mechanism normally exhibit the Arrhenius-type dependence on wafer temperature (1-6). Reproducibility of the etching process not only depends on how tightly one can control plasma parameters such as gas pressure, flow rate, and RF power, but also how precisely one can control the wafer temperature during etching. Also, etching uniformity across a wafer or from wafer to wafer within a batch may be influenced by a nonuniform distribution of wafer temperature, if contribution from the chemical etching mechanism is large. In a RF parallel-plate reactive etching system, it is difficult to measure the wafer temperature accurately and routinely because of the RF interference as well as a poor thermal contact between a temperature probe and wafer surface. Several proposals have been suggested to solve this problem (7-9). In addition to this, it is also troublesome to implement a reliable heat-transferring technique, which can effectively and reproducibly remove the heat from the wafer surface to a temperature-controlled substrate table without causing any detrimental contamination problem to the wafer surface and to the plasma. Thus, it is important to know a temperature dependence of etching rate for a particular reactive etching process. Temperature dependence of the Si and SiO₂ etching rates has been studied in great detail for a fluorocarbon gas plasma (6). Temperature dependence of etching rate in various materials has been reviewed and summarized by Vossen and Kern (10). As usual, the activation energy of reactive plasma etching was measured from a slope of the Arrhenius plot of etching rate *vs.* temperature. We note that, even in silicon which has been studied extensively, the activation energy reported in the literature shows a wide variation depending on the etching conditions (1-6). In this paper, we will clarify the temperature effect of etching rates in Nb and Nb₂O₅ films by measuring the fluorine atom density and etching rates at various plasma etching conditions. Also, our result sheds a light on the reason why the activation energy for silicon etching, having been reported in the literature, appeared to vary with experimental conditions.

Niobium, a superconductor, is a very important material widely used for fabricating Josephson tunnel junctions for application to high speed digital circuits. Niobium can be used as an electrode of the tunnel junction and a wiring material of Josephson IC circuits. Therefore, reactive plasma etching of niobium and Nb₂O₅ becomes a crucial technique in fabrication of a potential VLSI-type Josephson device. Although the plasma etching process has been successfully utilized for Josephson device fabrication (11-15), much more effort is needed to fully understand the reactive etching mechanisms of Nb in various gas plasma and also to evaluate the impact of the etching process on the device characteristics.

In this paper, we present a temperature dependence of the etching rate for Nb and Nb₂O₅ and demonstrate the importance of an effective heat transferring technique between the wafer back-surface and the substrate table. We also show that the total etching rate of Nb and Nb₂O₅ in CF₄/O₂ plasma consists of contributions from the chemical etching mechanism and from the ion-bombardment-enhanced etching mechanism, as in the case of silicon etching. Such physical quantities as wafer temperature, activation energy, ion-bombardment energy, and fluorine density play a key role in determining etch rates and are invoked in explaining the RF power dependence and the loading effect (alteration of a cathode surface material from Al to Si) of etching rate observed for both Nb and Nb₂O₅. Results will be directly compared with undoped polysilicon results obtained under the identical plasma condition. Also, we will show the experimental evidence that good conductors, like niobium, receive additional heat from the RF inductive heating due to the eddy current generated within the film, which is absent in poor conducting films like Nb₂O₅ and undoped polysilicon.

Experimental

The plasma reactor used was a flexible diode system similar to the one described elsewhere (16), in which both the perforated aluminum top electrode (30.5 cm diam) and the water-cooled aluminum bottom electrode (30.5 cm diam) were separately powered by two Plasma-Therm RF generators (13.56 MHz) through automatic matching networks. The bottom electrode served as the substrate electrode. A temperature of the bottom electrode is maintained by a temperature controlled water circulation bath (Neslab RTB-8). It can regulate the electrode temperature between 8° and 90°C. The reactor chamber (50 cm diam) was pumped by a Balzer turbomolecular pump (500 liter/s) and backed by a Roots blower system. A multigas pressure/flow controller (MKS-245) was used to control a gas pressure (± 0.01 Pa) at a downstream position with an automatic throttle valve (15 cm diam) and also to regulate a gas flow rate (± 0.5 sccm) at an upstream position. Good etching uniformity is obtained by feeding the gas from the top of the chamber with a symmetric inlet configuration.

Reactive etching experiments were carried out with one of the electrodes powered by a RF generator, while the opposite electrode was always dc grounded. The plasma etching mode (PE) is defined as the situation where wafers lie on the bottom, grounded electrode and the RF power is fed to the top electrode. The reactive ion etching mode (RIE) is the case where wafers sit on the RF-powered bottom electrode while the top electrode is dc grounded. Niobium films are E-beam deposited onto thermally oxidized silicon wafers to a thickness of 230 to 1000 nm with a minimum residual resistance ratio of 5, which represents a high purity of Nb films. Niobium penta-oxide is a 220 nm thick film grown by partially anodizing 230 nm thick Nb film in a chemical solution of ammonium penta-borate and ethylene glycol. Etching

rates are determined by using either a Talystep, when samples are patterned by photoresist, or a He-Ne laser interference detector, when samples are blanket Nb₂O₅ and Nb films. Nominal sample size was about 3 cm². Samples are usually loaded on the aluminum bottom electrode without any further means of thermal bonding. To investigate the RF heating effect, a series of experiments were carried out with the sample thermally bonded to the bottom electrode by vacuum grease (Apiezon H). No obvious chemical effects due to the presence of the vacuum grease in the system was observed. This was checked out by loading two samples on the substrate electrode, in which one sample was bonded by vacuum grease and another free of it. The etching rate of Nb on the substrate without thermal bonding was the same as that obtained at the identical etching condition immediately before this control experiment. The companion sample which was thermally bonded to the water-cooled bottom electrode gave a Nb etching rate much lower than that without thermal bonding, presumably because of an effective cooling by vacuum grease. For cathode loading experiments, we loaded blanket silicon wafers (57 mm diam) so that 42% of the aluminum cathode surface area was covered by silicon wafers.

A PAR-1450 optical multichannel analyzer was installed so that the spectrometer entrance slit lies at a level of 1 cm above the substrate electrode. This monitors the emission spectra from a glow discharge through a quartz window mounted on the side wall. The spectra with wavelength range from 365 to 850 nm were acquired during etching. Argon actinometry (17) was employed to estimate the ground-state fluorine atom concentration.

Results and Discussion

Temperature effect.—The temperature sensitivity of Nb and Nb₂O₅ etching rates during plasma etching was measured by varying the temperature of the substrate electrode while holding other plasma etching conditions constant. The reason for using the plasma etching mode was to evaluate the temperature sensitivity of the chemical etching rate and to minimize any contribution arising from ion bombardment in a parallel-plate reactor. RF power was chosen to be 70W (0.1 W/cm²) in an effort to reduce any possible RF heating at a high power density. As we will show below, RF heating of Nb films was observed even at this power density. Figure 1 shows the temperature dependence of etching rate (ER) during plasma etching for both Nb and Nb₂O₅. Samples were loaded on the electrode without any means of thermal bonding between a sample and the temperature-controlled electrode. The activation energy estimated from the slope of log (ER) vs. 1/T plot are 0.22 eV for Nb and 0.11 eV for Nb₂O₅. The fluorine atom density, estimated by argon actinometry, remained the same as substrate temperature was increased.

Hence, the etching rate of Nb film is more sensitive to temperature variations than that of Nb₂O₅. For comparison, the activation energy of undoped poly-Si is also estimated to be 0.07 eV under identical experimental conditions in the same reactor, in reasonable agreement with some of the results reported in the literature (1, 4, 6). Note that a wide variation of the activation energy has been reported for Si etching in the fluorocarbon gas plasma. We will discuss the reason for this wide variation in activation energy below. The result in Fig. 1 also suggests that an etching rate (ER_{PE}) during plasma etching can be expressed by the equation

$$ER_{PE} = Kc \cdot N_f \cdot \exp(-\Delta E/kT) \quad [1]$$

where Kc is a rate constant which depends on the gas temperature, N_f the fluorine concentration, k the Boltzmann constant, T a wafer temperature, and ΔE the activation energy. From the process development point of view, it will be very helpful if one knows the activation energy of materials to be etched under the same plasma etching condition, because ΔE and Kc determine the etching rate selectivity of the materials involved.

Fig. 1. Temperature dependence of etch rates of Nb (●) and Nb₂O₅ (▲) measured during plasma etching. The activation energy which was calculated from the slope is 0.22 and 0.11 eV for Nb and Nb₂O₅, respectively. Temperature was measured at the water circulation bath, so that it may not be a "true" temperature of the sample surface.

There has been some experimental evidence (7) that wafer temperature increases rapidly with RF power during etching, if the wafer is not thermally bonded to the temperature controlled electrode. Figure 2 shows the effect of thermal bonding on the etching rate of Nb at various temperatures. Thermal bonding was achieved by applying vacuum grease (Apiezon H) to the back side of a sample. The solid line represents temperature dependence measured without thermal backing, and the dotted line is with thermal backing. Since solid and dotted lines in Fig. 2 are roughly parallel to each other, our estimate of the Nb activation energy in Fig. 1 should be correct, as long as the relative temperature was measured accurately. Also, we can estimate from Fig. 2 that the actual temperature of wafer without thermal bonding should be about 20° to 30°C higher than that with thermal bonding. Similar experiments were carried out also for Nb₂O₅ films and the results are shown in Fig. 3. The difference in the etching rates between bonded and nonbonded samples can hardly be observed. The temperature difference could be, at the worst, about 10°C or less. Since the heat removal rate should be about the same because a similar vertical structure was used for both samples, the amount of heat generated at the Nb surface may be larger than the heat generated on the Nb₂O₅ surface during RF plasma etching.

Power dependence.—The RF power dependence of etching rates was measured for Nb and Nb₂O₅ during both plasma etching and reactive ion etching, and the results are shown in Fig. 4. The fluorine population (a relative intensity of the FI emission line against the ArI line, I_F/I_{Ar}) was measured at the same time as a function of power and is illustrated in Fig. 4, also. At a fixed RF power, the fluorine density in the CF₄/O₂ plasma is more or less the same between plasma etching and reactive ion etching within our experimental error as long as the Al electrodes are not loaded with a fluorine consuming material (18). The power dependence of Nb₂O₅ etching rate is very similar to that of undoped polysilicon we reported

Fig. 2. Temperature dependence of the Nb etching rates in the plasma etching mode with (dotted line, ∇) and without (solid line, \bullet) thermal bonding between the substrate electrode and the back surface of a sample. A temperature at the Nb surface without thermal bonding is about 30°C higher than a temperature at the substrate electrode. The activation energy of Nb is 0.22 eV in both cases.

previously (18), but Nb etching rate appears to behave quite differently from undoped polysilicon.

Fig. 3. Temperature dependence of the Nb_2O_5 etching rates in the plasma etching mode with (dotted line, ∇) and without (solid line, \bullet) thermal bonding between the substrate electrode and a sample.

Fig. 4. Etch rate vs. RF power for Nb and Nb_2O_5 measured in the plasma etching mode (PE) and the reactive ion etching mode (RIE). The substrate electrode is made of Al, and etch rates were measured under no loaded condition. I_F/I_{Ar} , which represents a number density of the neutral fluorine atoms in the plasma, is almost equal between plasma etching and reactive ion etching.

In Fig. 5, we plot the chemical reactivity (etching rate divided by a F concentration or I_F/I_{Ar}) of Nb and Nb_2O_5 as a function of RF power during plasma etching. The chemical reactivity of Nb_2O_5 increases slightly as the power is increased, as in the case of polysilicon. However, niobium

Fig. 5. RF power dependence of the chemical reactivity of Nb and Nb_2O_5 measured in the plasma etching mode. The chemical reactivity, etch rate divided by a fluorine density, is the same, independent of a cathode loading.

exhibits a drastic increase in the chemical reactivity, proportional to RF power. The apparent chemical reactivity of Nb at a given power is relatively constant, regardless of a large change in the fluorine population, which may be achieved by varying a cathode loading condition or O₂% in CF₄/O₂ without changing the gas pressure, flow rate, and RF power. Therefore, we argue that a strong power dependence of the Nb chemical reactivity could be caused by any variation in wafer temperature due to RF power (see Eq. [1]). Also, the Nb activation energy, which is larger than that of both Nb₂O₅ and Si, should be to some extent responsible for a high sensitivity of the Nb etching rate contributed by the chemical etching mechanism. However, as we will describe later, there is some indication that the Nb wafer temperature increases with increasing the power density at a rate much faster than that of Nb₂O₅ and Si. A difference in wafer temperature between Nb and Nb₂O₅ becomes larger as the power density is increased. Because of higher temperature and activation energy, the Nb chemical reactivity (ER/N_r) increases with RF power much faster than those of Nb₂O₅ and Si, as shown in Fig. 5. Since the etching rate of Nb is more sensitive to the wafer temperature than that of Nb₂O₅ and Si, controlling the temperature during etching is critical, especially at high power density for Nb films. This may explain why Nb etching rates sometimes exhibit wide variations, particularly at high power, if heat transfer is poor.

We have shown previously (18) that the total etching rate in undoped Si during reactive ion etching contains contributions from the chemical etching mechanism as well as from the ion-bombardment-enhanced etching mechanism. Hence, etching rate due to the ion-enhanced etching mechanism alone can be estimated by subtracting the chemical etching component from the total etch rate. Under our unloaded condition where the fluorine population is the same between plasma etching and reactive ion etching (see Fig. 4), the chemical etching contribution should be almost equal in the two etching modes (RIE and PE). Thus, we subtract the etch rate in plasma etching from the total etch rate during reactive ion etching to obtain the ion-enhanced etching contribution. We find that, in the case of Nb, the etching rate contribution from the ion-enhanced etching mechanism is much smaller than that from chemical etching mechanism, especially at high power density, as shown in Fig. 4. Etch rates due to the ion enhanced etching mechanism follow the similar power law of the dc self-bias voltages (V) as we found in undoped polysilicon; that is

$$ER_i = K_1 V^n \quad [2]$$

We estimated $n = 3.1 (\pm 0.3)$ for Nb and $n = 2.2 (\pm 0.3)$ for Nb₂O₅ from the slope of a $\log (ER_i)$ vs. $\log (V)$ plot. K_1 is a constant. Thus, during the reactive ion etching mode, the total etching rate for both Nb and Nb₂O₅ can be expressed by

$$ER_T = K_c N_F \exp(-\Delta E/kT) + K_1 V^n \quad [3]$$

We note that the chemical etching component (the first term in Eq. [3]) results in the isotropic etching profile, and the ion-enhanced etching component (the second term in Eq. [3]) yields the directional etching profile parallel to the direction of impinging ions. If one uses the same plasma parameters as those specified in Fig. 4 and a nonerodible mask such as aluminum film, one would expect less undercutting in Si than in Nb. In other words, it is easier to produce vertical edge profiles for undoped poly-Si than for Nb in CF₄/O₂ plasma because the chemical etching component of Nb is substantially larger than the ion-enhanced etching contribution, but the relative magnitude of those two components is reversed in Si. Therefore, in order to achieve a vertical sidewall, the important consideration is to suppress the chemical etching by reducing a wafer temperature as well as fluorine population in plasma and to maximize the ion enhanced etching by increasing the self-bias voltage. This general rule has been verified in both Nb and undoped polysilicon

(20) and would apply to any material which can be etched by fluorine, unless polymerization comes into play.

Loading effect.—The cathode loading effect has been reported in reactive plasma etching for many materials, including Nb (15) and Si (3). Figure 6 presents the Nb etching rates during both reactive ion etching and plasma etching with 42% of the cathode area loaded with Si wafers. Using optical emission and argon actinometry, we have shown that the fluorine atom density decreases upon loading Si wafers due to a consumption of fluorines at the wafers (18). This reduction in a number density of the neutral fluorine atoms is primarily responsible for the decrease in etching rates due to silicon loading. The extent to which the Nb etching rate decreases upon Si loading is much larger during reactive ion etching than that during plasma etching. We observed that etch rates during reactive ion etching are always lower than those during plasma etching, independent of RF powers we studied. It is to be noted that, in the unloaded case, the reactive ion etching mode gives a higher etch rate than the plasma etching mode, as shown in Fig. 4. The reason for reversing the relative magnitude between the two etching modes (RIE vs. PE) upon silicon loading is simply due to the fact that the chemical etching predominates over the ion-enhanced etching in Nb. Since the fluorine atom density is about the same between the RIE and PE modes under the unloaded condition, the chemical etching component without Si loading should be almost equal between the RIE and PE modes, independent of RF power. Also, we know that the plasma potential was estimated to be relatively low and Nb is mostly etched through chemical reaction between Nb and F (19).

When silicon wafers are loaded onto the Al cathode, a fluorine density decreases in both RIE and PE modes but the amount of decrease is much higher during reactive ion etching (a factor of 2 to 5) than during plasma etching (30%). Because of a large difference in F depletion between the two etching modes, the chemical etching component decreases during RIE more than during PE. Hence, the total Nb etch rate during reactive ion etching becomes lower than that during plasma etching, even though a contribution from the ion-bombardment-enhanced etching mechanism certainly exists during reactive ion etching. Niobium is a typical example of the fact that ion-bombardment-enhanced etching does not necessarily dominate over chemical etching.

We note that the loading effect could introduce an error into the activation energy for the plasma etching process. The activation energy was normally estimated from the Arrhenius plot of etching rates against wafer temperatures. Although silicon etching by fluorine radicals has

Fig. 6. Niobium etch rate vs. RF power measured under a Si loaded condition. Etch rates in plasma etching (PE) is faster than etch rates in reactive ion etching (RIE).

been studied very extensively, the reported activation energy varies from 0.02 to 0.14 eV, depending on experimental conditions. A lower activation energy was obtained upon loading silicon wafers in the etching system. One would expect the activation energy to be a constant for a given set of radicals and materials, unless the loading effect alters chemistry of the etching process. When the cathode is loaded with a F consuming material, the fluorine density inside the reactor chamber could vary with the substrate temperature. This is expected because higher substrate temperature means higher etching rate, resulting in a smaller number of fluorines available in the plasma. Since the activation energy originates from the chemical etching mechanism which prevails during plasma etching, the activation energy must be derived from the plot of $\log(ER/N_F)$ vs. $1/T$, instead of $\log(ER)$ vs. $1/T$. Figure 7 illustrates the difference between these two methods of estimating the activation energy. When the Al electrode is not loaded, the fluorine population is constant, independent of the substrate temperature, and, consequently, there is no difference whether ER or ER/N_F is used. When the cathode is loaded with Si wafers, ER/N_F must be used to estimate the activation energy. In Fig. 7, the activation energy of Nb derived from ER/N_F is constant (0.22 eV), independent of whether the system is either unloaded or loaded with Si. However, if ER is used, it becomes 0.10 eV, a factor of 2 smaller than the true value. Therefore, the activation energy should be estimated under no cathode loading and requires not only etching rates and wafer temperatures, but also accurate measurement of the fluorine population.

Film thickness dependence.—We have mentioned above that Nb is heated more than Nb_2O_5 by the CF_4/O_2 RF plasma. Furthermore, the chemical reactivity of Nb appears to have a strong dependence on RF power (see Fig. 5), which differs from the results we observed in undoped silicon (18). Since the chemical reactivities of Nb, Nb_2O_5 , and Si were measured under the same plasma condition in the same reactor, the power dependence should be caused by the inherent characteristics of Nb rather than the chemical and physical properties of the CF_4/O_2 plasma. Also, Nb etching rates in the plasma etching

Fig. 7. Niobium etch rate vs. temperature, measured in the plasma etching mode with loading Si wafers which covers 42% of the Al electrode surface. The chemical reactivity (\square), measured under a Si-loaded condition, gives the same slope as Nb etch rate measured without loading Si wafers.

mode are predominantly due to the chemical etching mechanism, which does not require energetic ion bombardments (20).

The surface of a wafer could be heated by many different forms of energy present in RF plasma. The ambient temperature of RF glow discharge is proportional to power, and heat always flows from a volume of the intense glow to the surrounding walls, including the sample surface, by means of radiative conduction and, more effectively, through convection current of gas particles. In a parallel-plate reactor, an energetic particle such as ions and electrons impinges on a substrate surface and dissipates the kinetic energy to a substrate, consequently heating a wafer. Also, chemical reaction at a sample surface may accompany a heat release, if the reaction is exothermic or if excited species of radicals are involved. All the heat sources described above should affect both Nb and Nb_2O_5 equally. Another source of heat is the RF inductive heating (21) due to the eddy current which is normally generated in a highly conductive material by the ac magnetic field. Although the eddy current in a material such as insulator and semiconductor is negligible, the RF dielectric heating (21) due to the displacement current might become significant in plasma etching Si and Nb_2O_5 , if RF voltages were very large. Therefore, the RF inductive heating would play very important roles in the reactive etching process in RF plasma reactors, particularly in etching metal films and degenerate semiconductors (22) at a high RF power.

We measured Nb etch rates in the plasma etching mode for three different film thicknesses. The results are shown in Fig. 8 as a function of RF power. At a fixed power, the etch rate of a thicker Nb film is always higher than that of a thinner film. Moreover, etch rates of a thicker film increases with increasing RF power much faster than those of a thinner film. Thus, the difference in etch rate among different thickness films becomes more substantial at a higher RF power. N_F is fixed at a given power. The activation energy and the rate constant in Eq. [1] must be independent of the film thickness. Also, our Nb samples were prepared at a high 10^{-8} torr by E-beam evaporation, and exhibit the tensile stress of 0.8% ~ 0.9% and a fiber texture highly aligned along $\langle 110 \rangle$ direction, independent of a thickness within the range used in the present etching study (23). The residual resistance (a ratio of the sheet resistance at 300 K against that at 9.2 K, the superconductor critical temperature of Nb) is always higher than 5, which warrants the purity of our Nb films. Hence, neither film structure nor purity plays any role in the thickness dependence of Nb etch rates we have observed. We argue that the thickness dependence of Nb etch rates must arise from a difference in the temperature; that is, the thicker the film, the higher the substrate temperature is gained during RF plasma etching. Note that heating by radiation, gas convection, or

Fig. 8. RF power dependence of etch rate for three different thickness of Nb film. A thicker film yields a higher etching rate at a fixed RF power. Etch rates were measured in the plasma etching mode with the Al electrode (unloaded condition).

chemisorption should be independent of a film thickness; inductive heating is not. The eddy current flows below the surface to the effective skin depth, which depends on the electrical conductivity and electrical properties of the material to be etched. The depth of current penetration should be less than the depth of the heating zone, because thermal conduction pulls the heat in from the surface. The effective skin depth of Nb is roughly 50 μm at 13.56 MHz, much larger than Nb film thickness ($\leq 1 \mu\text{m}$) we studied. Thus, only a small portion of the input power can be dissipated at the Nb film, and the rest would be either reflected back or penetrate through. In any event, a RF power dissipation per unit area is approximately constant throughout the film, because Nb film thickness is less than 2% of the skin depth. We argue that the total heat quantity generated by RF dissipation per unit area would be directly proportional to a film thickness, resulting in a higher film temperature in a thicker film. At a fixed film thickness, substrate temperature increases with power. Therefore, we regard this thickness dependence of Nb etch rates as a strong experimental evidence that the RF inductive heating exists in metal films during RF plasma etching and this local heating effect enhances the contribution due to the chemical etching mechanism. We have observed a similar behavior in the heavily doped n-type silicon, suggesting that the doping effect in reactive etching would be caused by the RF inductive heating (22).

Summary

An efficient thermal contact between a substrate and the substrate electrode is essential to achieve good etching uniformity and reproducibility, especially in etching metal films like niobium. Reactive plasma etching of both Nb and Nb₂O₅ is contributed by chemical etching as well as ion-bombardment-enhanced etching, as in the case of silicon etching. The chemical etching mechanism predominates in plasma etching, but both chemical etching and ion-enhanced etching mechanisms are present in reactive ion etching. Competition between these two etching mechanisms determines the sidewall etch profile. The chemical reactivity of Nb exhibits a substantial increase proportional to RF power. This is attributed to the RF inductive heating due to the eddy current, which should be only effective in a highly conducting material such as metals, silicides, and heavily doped degenerate semiconductors. The RF inductive heating in Nb is so significant that Nb etching rates during plasma etching varies with a film thickness. The thicker the Nb film, the higher film temperature results from the inductive heating, leading to a higher etch rate.

High Frequency Capacitance Characteristics of the Thin-Based MOS Electrode

A. G. Anastopoulos, P. Nikitas, and D. A. Jannakoudakis

Laboratory of Physical Chemistry, University of Thessaloniki, Thessaloniki, Greece

ABSTRACT

The differential capacity characteristics of the MOS electrode with very thin ($< 0.4 \mu\text{m}$) semiconductor substrate are studied under high measurement frequencies. Model equations for the electric field, the differential space-charge capacitance, and the gate voltage are derived and numerically solved. The capacitance-voltage characteristics show that the formation of the depletion layer is limited by the thickness of the substrate. The absence of the contribution of minority carriers reveals the potential region corresponding to the formation of the depletion layer. The inversion and the depletion layers are found to coexist for a range of gate voltage values. Conclusions are drawn relative to the doping level, the oxide, and the substrate thickness for practical applications of the MOS electrode in electrochemical systems.

The study of the thin film metal-insulator-semiconductor (MIS) arrangements is currently dealing with the fabrication of the corresponding systems and the recording of their I-V characteristics (1-6). Special attention is paid to the nature of the dielectric layer which is deposited with various techniques on the semiconductor base (5-6).

The research work on the MIS structures has mainly advanced to the direction of the use of thin film metal-oxide-semiconductor (MOS) capacitors as variable reactors, but it has not dealt with the possibility of using such systems with a very thin semiconductor base ($< 0.4 \mu\text{m}$) in the form of electrodes in electrochemical cells. In our opinion, the use of such electrodes has a considerable interest in electrochemical applications, and this is supported by the findings of recent works on similar systems as oxide-electrolyte and metal-oxide-electrolyte systems (7-8).

A part of the research performed in our laboratory is directed towards the theoretical study of the thin-based ($< 0.4 \mu\text{m}$) MOS-electrolyte system under various conditions regarding the polarization, the semiconductor characteristics, and the chemical composition of the solution, etc.

In a preceding publication (9), we studied the C-V characteristics of a MOS system with a p-type thin ($< 0.4 \mu\text{m}$) base, under low measurement frequencies. However, due to the fact that a situation quite frequently encountered in practice in electrochemical applications of semiconductors is that of medium and high frequencies, we have attempted in this work to obtain model equations for the space-charge density, the differential capacitance, and the gate voltage of a thin-based MOS structure under these conditions. The equations derived are numerically solved for a series of base thicknesses ranging from 0.1 to 0.3 μm and for a set of physical simulation parameters. On the basis of the results obtained, we come to a series of practical conclusions which are outlined at the end of this work.

Derivation of a Model Equation for the Electric Field of the Very Thin-Based MOS Electrode under High Measurement Frequencies

The boundary conditions for a MOS structure (Fig. 1) with a very thin base ($x = d$) regardless of whether equilibrium conditions are established or not are the following (i) the potential is a function of distance $x: \Psi = f(x)$, (ii) at $x = 0$, $\Psi = \Psi_s$ (surface potential), (iii) at $x = d$, $\Psi = \Psi_0 \neq 0$ (back-side potential).

For reasons of convenience, a series of physical boundary conditions are also assumed. Thus, we do not account for the eventual existence of work function differences and surface states at either the front or the back surface.

Under high frequencies of measurement signals, we can assume that the minority carriers cannot follow the varia-

tions of the electric field, and thus they can be considered as being practically immobile.

We, therefore, expect that at potentials corresponding to depletion and accumulation, the majority carriers, which have very short equilibration times and are predominantly defining the capacitance characteristics of the MOS structure, will lead to capacitance values not differing from the low frequency case.

At potentials corresponding to inversion, the contribution of minority carriers practically vanishes under high frequencies. We assume that the dc gate bias at which measurements are carried out is varied slowly enough so that even at high measurement frequencies the charge distribution in the semiconductor can be adequately described by the equilibrium analysis. Therefore, at high frequencies and at thermodynamic equilibrium the expression for the charge density of a p-type nondegenerate substrate takes the following form

$$\rho = -qp_b(1 - e^{-\beta\psi'}) \quad [1]$$

where $\psi' = \Psi - \Psi_b$ and Ψ_b, p_b are the bulk values of Ψ and p . So, Poisson's equation take the following form

$$\frac{d^2\psi'}{dx^2} = -\frac{\rho}{\epsilon_s\epsilon_0} = \frac{q}{\epsilon_s\epsilon_0} [p_b(1 - e^{-\beta\psi'})] \quad [2]$$

where ϵ_s and ϵ_0 are the permittivities of the semiconductor and the free space, respectively.

On the basis of these assumptions, the integration of this equation from Ψ_0 to Ψ_s and from $x = 0$ to $x = d$ leads to the following expression for the electric field within the semiconductor crystal

$$E = \frac{1}{\beta L} \{[(\gamma + 1)(\beta\Psi_s + e^{-\beta\psi_s}) - \gamma] - [(\gamma + 1)(\beta\Psi_0 + e^{-\beta\psi_0})]^{1/2}\} \quad [3]$$

where

$$\gamma = \frac{M}{(M^2 + 4n_i^2)^{1/2}}$$

and $M = N_A - N_D$, the difference between the acceptor and donor concentrations, n_i is the concentration of the intrinsic carriers. In Eq. [3] we also have set

Fig. 1. The thin-based MOS structure

$$L = \frac{\epsilon_s \epsilon_0 kT}{q^2 (M^2 + 4n_i^2)^{1/2}} \quad \text{and} \quad \beta = q/kT$$

The ideal physical conditions assumed at either the front or the back surface (the back surface is assumed to be in contact with a homogeneous and isotropic medium, *i.e.*, an electrolyte solution) make Eq. [3] separable in two terms.

The first term results from the contribution of the surface potential, Ψ_s , while the second one comes out from the contribution of the potential at the back side, Ψ_0 .

The above contributions are provided in reduced form in Eq. [4] and [5], respectively

$$F_{HF}^2(\Psi_s) = [(\gamma + 1)(\beta\Psi_s + e^{-\beta\Psi_s}) - \gamma] \quad [4]$$

$$F_0^2 = F_{HF}^2(\Psi_0) = [(\gamma + 1)(\beta\Psi_0 + e^{-\beta\Psi_0}) - \gamma] \quad [5]$$

where

$$F(\Psi) = \beta LE \quad [5a]$$

is the reduced electric field.

Thus, from Eq. [3] with simple algebra, we can obtain an analytical expression for the space-charge differential capacitance of the MOS structure.

However, this equation cannot be used for calculation of the capacitance-voltage characteristics before an equation describing the dependence of the back-side potential Ψ_0 and the gate voltage is obtained.

This can be achieved by appropriately modifying Poisson's equation. Thus, since $E = d\Psi/dx$ by combination of Eq. [3] and [5], we obtain

$$\frac{dX}{[F_0^2 + (\gamma + 1)(X + e^{-X}) - \gamma]^{1/2}} = \frac{dx}{L} \quad [6]$$

where $X = \beta\Psi_s$ is the reduced surface potential.

If Eq. [6] is set in integral form, it can be solved numerically since analytical solution is impossible.

The limits of the integration are 0 and d for the substrate thickness x and accumulation to inversion voltage values for the reduced potential X .

High Frequency Space-Charge Differential Capacitance

Using the relation $Q_{sc} = \epsilon_s \epsilon_0 E_s$, we can obtain an expression for the charge of the thin-based device at high frequencies

$$Q_{sc} = \frac{\epsilon_s \epsilon_0}{\beta L} [F_0^2 + (\gamma + 1)(X + e^{-X}) - \gamma]^{1/2} \quad [7]$$

Therefore, since $C_{sc} = dQ_{sc}/dX$, we come to a model equation for the space-charge differential capacitance of the thin based MOS electrode under the above conditions

$$C_{sc} = \frac{\epsilon_s \epsilon_0}{\beta L} \cdot \frac{F_0 (dF_0/dX) + (\gamma + 1)(1 - e^{-X})}{[F_0^2 + (\gamma + 1)(X + e^{-X}) - \gamma]^{1/2}} \quad [8]$$

Finally, for the derivation of a model equation for the gate voltage we work as follows: the gate voltage Ψ_G divides between the oxide layer and the semiconductor base, *i.e.*

$$\Psi_G = \Psi_{ox} + \Psi_{base} \quad [9]$$

The potential drop Ψ_{base} across the semiconductor consists of two terms, one corresponding to the surface potential Ψ_s , and the other to the back-side potential Ψ_0 , arising from the charge distribution at the oxide-semiconductor and the semiconductor contacting homogeneous and isotropic medium interfaces, respectively. Thus

$$\Psi_G = \Psi_{ox} + \Psi_s + \Psi_0 \quad [10]$$

where $\Psi_s = X/\beta$ is the incremental surface potential relative to the back side and

$$\Psi_0 = xE_0 = \frac{x}{\beta L} F_0$$

For Ψ_{ox} it can be, similarly to a previous publication (9), shown that since $C_{ox} = \epsilon_{ox} \epsilon_0 / x_{ox}$, then $\Psi_{ox} \approx Q_{sc} / C_{ox} = Q_{sc} x_{ox} / \epsilon_{ox} \epsilon_0$ and therefore

$$\Psi_{ox} = \frac{\epsilon_s x_{ox}}{\beta L \epsilon_{ox}} [F_0^2 + (\gamma + 1)(X + e^{-X}) - \gamma]^{1/2}$$

where ϵ_{ox} and x_{ox} are the permittivity and the thickness of the oxide layer, respectively.

Thus, the expression for the gate voltage takes the following form

$$\Psi_G = \frac{1}{\beta} \left\{ X + \frac{X}{L} F_0 + \frac{\epsilon_s x_{ox}}{\beta L \epsilon_{ox}} [F_0^2 + (\gamma + 1)(X + e^{-X}) - \gamma]^{1/2} \right\} \quad [11]$$

Results and Discussion

The simultaneous computer solution of Eq. [6], [8], and [11] for a p-type substrate with doping levels equal to 1.50×10^{14} , 1.50×10^{16} , and $1.50 \times 10^{18} \text{ cm}^{-3}$, respectively, results in the curves of space charge capacitance *vs.* the gate voltage given in Fig. 2, 3, and 4. Calculations for Fig. 2, 3, and 4 use $x_{ox} = 0.2 \text{ } \mu\text{m}$, $T = 300 \text{ K}$, $n_i = 1.45 \times 10^{10} \text{ cm}^{-3}$, $C_{ox} = 1.73 \times 10^{-2} \text{ } \mu\text{F/cm}^2$, the Debye length $L = 3.34 \times 10^{-6} \text{ cm}$. The numerical solution of Eq. [6], after it was set in integral form, was performed by Romberg's integration method (IBM programming Handbook, 1974) and Gaussian quadrature integration method (ICL Technical Publications, 1974).

Both methods gave exactly the same set of x *vs.* F_0 data for each value of the base thickness. Those data sets were, in turn, fed into the computer programs used for the solution of Eq. [8] and [11], thus yielding C_{sc} against Ψ_G data, provided in Fig. 2, 3, and 4.

It is seen that for substrate thicknesses greater than $0.30 \text{ } \mu\text{m}$, the MOS structure falls into a thick-base device (infinite substrate thickness), and therefore for the typical thicknesses suggested in the literature (10), no thin-base behavior can be detected as it was also found under low measurement frequencies (9).

Fig. 2. Capacitance-voltage characteristics of a MOS structure with p-type substrate under high measurement frequencies. Doping level $M = 1.5 \times 10^{14} \text{ cm}^{-3}$. Base thickness (μm): (a) infinite, (b) 0.30, (c) 0.25, (d) 0.20, (e) 0.15, (f) 0.125, and (g) 0.10.

Fig. 3. Capacitance-voltage characteristics of a MOS structure with p-type substrate under high measurement frequencies. Doping level $M = 1.5 \times 10^{16} \text{ cm}^{-3}$. Base thickness (μm): (a) infinite, (b) 0.30, (c) 0.25, (d) 0.20, (e) 0.15, (f) 0.125, and (g) 0.10.

The C_{sc} vs. Ψ_G curves corresponding to infinite base thickness in Fig. 2-4 show that the behavior of the device when the contribution of the minority carriers is eliminated is not typically a high frequency one.

For the high frequency mode, it is known (11-12) that at voltages corresponding to inversion, the depletion region reaches to a limit, and therefore the capacitance becomes practically constant.

Instead of that, it is seen from Fig. 2-4 that with increasing bias beyond depletion, the capacitance of the infinite substrate (curves labeled a) keeps decreasing. This behavior of our model device denotes that, under increasing bias, the width of the depletion layer is continuously increasing. Phenomenologically, this is the case of rapidly changing bias voltage, *i.e.*, of transient conditions (13-14), which is not our case. This behavior of our model device is a result of completely ignoring the contribution of minority carriers. However, for substrate thicknesses equal to or less than $0.3 \mu\text{m}$, the device seems like switching from transient to high frequency response.

In this case, the acceptor ions in the crystal are totally exposed, *i.e.*, the substrate is completely depleted and thus the depletion layer does not increase any longer because it is limited by the width of the substrate itself.

A comparison between the corresponding low (9) and high frequency capacitance-voltage curves (Fig. 2-4) reveals some differences which go further than the expected ones. These differences include deviations between the low and high frequency curves at the potential range from accumulation to depletion. At this potential range, the C_{sc} high frequency values are somewhat lower than the low frequency ones, which were expected to practically coincide. Deviations are also observed at the potentials where the low frequency curves reach to a minimum. At this point, the high frequency curves keep decreasing down to a minimum value attained at large posi-

Fig. 4. Capacitance-voltage characteristics of a MOS structure with p-type substrate under high measurement frequencies. Doping level $M = 1.5 \times 10^{18} \text{ cm}^{-3}$. Base thickness (μm): (a) infinite, (b) 0.30, (c) 0.25, (d) 0.20, (e) 0.15.

tive potentials. The above deviations are made more clear through the plot of Fig. 5. In this figure, we provide the relative variation of the reduced quantities F_0 and X . The corresponding curves of Fig. 5 follow the same variation pattern. However, differences appear in what concerns the limiting values attained at inversion potentials and also the setting on potential of these limiting values.

Although, generally it is not quite reasonable to attach a physical interpretation to the behavior of a system when it is studied by means of model equations, the deviations observed call for such an interpretation.

Our opinion is that the deviations from the expected behavior pattern can be generally ascribed to the conditions assumed which imply the immobility of the minority carriers (17-18). However, under low measurement frequencies, the mobile minority carriers produce a series of screening effects.

For a p-type material at the potential region where the depletion layer is formed (small positive potentials), small amounts of electrons may be attracted to the surface. The electrons start to build up the inversion layer although the depletion layer is still developing. At these potentials when the contribution of electrons is ignored, deviations are produced between the low and high frequency curves.

For the interpretation of the continuous decrease of the nonequilibrium C_{sc} values beyond the minimum of the equilibrium curves—which formally is considered as the marking point (15-16) of the integration of the depletion layer—we have to recourse again to the role played by the minority carriers.

The continuous decrease of the C_{sc} values reveals that the depletion layer continues its development even at potentials corresponding to inversion.

This development for the very thin-based MOS electrode is limited by the physical dimensions of the substrate.

The above situation is also displayed in Fig. 5, where it is seen that $(F_0)_{LF} < (F_0)_{HF}$ and that the potentials at which

Fig. 5. Variation of the reduced back-side field against the reduced surface potential for a thin-based MOS structure. Doping levels: (—) 1.5×10^{14} , (—) 1.5×10^{16} , (---) $1.5 \times 10^{18} \text{ cm}^{-3}$. Capital letters represent low measurement frequencies. Base thicknesses (μm) for I: (a_1, A_1) 0.15, (b_1, B_1) 0.20, (c_1, C_1) 0.25, and (d_1, D_1) 0.30. Base thicknesses (μm) for II: (a_2, A_2) 0.10, (b_2, B_2) 0.125, (c_2, C_2) 0.15, (d_2, D_2) 0.20, (E_2) 0.25, and (F_2) 0.3. Base thicknesses (μm) for III: (A_3) 0.15, (B_3) 0.20.

the limiting value is reached, are always higher for high frequency than for low frequency curves.

The differences of the back-side field can be also seen from the point of view of the charge distribution under the inversion conditions given in Fig. 6.

Thus, the relation $(F_0)_{LF} < (F_0)_{HF}$ can be attributed to the assumption that the inversion layer is not formed under high frequencies. Under these conditions in the expression for the total charge within the MOS structure

$$Q_s = Q_n - qN_A d + Q_p$$

Fig. 6. Schematic representation of the charge distribution within the MOS structure under low (a) and high measurement (b) frequencies.

Fig. 7. The width of the depletion layer against the gate voltage. Doping levels: (\square) 1.5×10^{14} , (\odot) 1.5×10^{16} , (\triangle) $1.5 \times 10^{18} \text{ cm}^{-3}$. Points (\square) and (\odot) correspond to the upper division and points (\triangle) to the lower division of Ψ_G axis.

the term Q_n , which represents the charge of the inversion layer, vanishes.

Therefore, since Q_p (the positive charge accumulated at the back side under positive gate voltage) has a sign different than Q_n , Q_s increases under high measurement frequencies, thus leading to greater values of reduced back-side field.

The turning points of the curves of Fig. 5 denote the completion of the formation of the depletion layer. Therefore, the potentials corresponding to these points are the potentials at which the substrate is totally depleted. In Fig. 7, we provide the variation of these potentials against the corresponding base thickness. It is seen that the pattern of this variation is linear, which is typical (11) for the variation of the depletion layer width against the electrical variables of the system. It can be, therefore, concluded that the formation of the depletion and inversion layers seem to be to some extent a simultaneous process.

The immobility of the minority carriers reveals the limits of the development of the depletion layer. However, those limits must be applicable only in the transient case. Under equilibrium or quasi-equilibrium conditions, the formation of a strong inversion layer acts as a shield, preventing the further development of the depletion layer.

Summary

The work made up to this point has revealed the following practical conclusions relative to the use of the MOS electrode in electrochemical works (20-21).

1. The doping levels must be kept low or intermediate levels because otherwise the potential variation will override the limits of interfacial impedance studies.
2. The oxide thickness must be of the order of $0.2 \mu\text{m}$, because such a thickness insures good insulating properties and also prevents the contribution of C_{ox} to the total capacity to become excessive.
3. The substrate thickness used must lie between 0.2 and $0.3 \mu\text{m}$ because thinner substrates will produce back-side potentials inappropriate for interfacial impedance studies, while for base thicknesses greater than $0.3 \mu\text{m}$, a typical thick-base behavior is obtained.

On the Effect of Impurities on the Photovoltaic Behavior of Solar-Grade Silicon

I. The Role of Boron and Phosphorous Primary Impurities in p-type Single-Crystal Silicon

ABSTRACT

The electrical and photovoltaic properties of partially compensated p-type silicon samples have been investigated in order to understand the influence of the contemporaneous presence of donors and acceptors on the behavior of majority and minority carriers. It has been shown that the majority carrier properties are only slightly influenced by the presence of donors in p-type samples and that the minority carrier properties depend on the excess acceptor concentration up to an excess donor concentration close to 5×10^{16} at./cm³. A theoretical explanation of these features has been proposed, on the base of the Shockley-Read-Hall model of recombination at shallow traps and donor-acceptor pairs formation.

The need for a material considerably cheaper than the conventional electronic-grade silicon for terrestrial photovoltaic cells fabrication is still a mandatory issue, in spite of the substantial improvements recently achieved with the advanced Siemens processes (1). As it is consistently demonstrated that the balance of systems costs is heavily leveraged by cell efficiency, it appears, however, that a compromise between material cost and conversion efficiency must be pursued. This is particularly important in the case of MG silicon feedstocks, where the cascade process for impurity removal introduce additional costs in the material preparation route, which increase in a nonlinear fashion with the degree of upgrading required.

A considerable amount of knowledge on the effect of deep level impurities on the structural, electrical, and photovoltaic behavior of single-crystal silicon has been already obtained in the course of extensive investigation carried out at Dow Corning, Westinghouse, and Monsanto (2-3).

Less attention has been paid, however, to the behavior of electrically active impurities, such as boron and phosphorus, although the knowledge of their threshold concentration as single impurities or on the amount of tolerable compensation is of primary importance for the development of solar silicon as they represent, together with carbon, the least easily removable impurities from a MG silicon feedstock (1, 4, 5).

To the scope of providing the necessary information on this regard, systematic work has been carried out on p-type, n-type and p-type compensated samples, which concerned the preparation and the complete electrical characterization of the samples.

The results of this investigation are reported and discussed in this paper.

Experimental

Crystal growth, structural, and chemical characterization.—B-doped, p-doped, and partially compensated p-type <111> silicon ingots were grown using a Czochralski furnace. The charge consisted of 700g of EG polycrystalline silicon having a boron content less than 0.14 ppba and a donors content less than 0.35 ppba.

Boron doping was carried out using standard boron silicon alloys for samples which should contain less than 10^{16} at./cm³ or metallic boron for heavier doped samples. Phosphorous doping was carried out using standard phosphorous silicon alloys.

All the materials employed were furnished by Dynamit Nobel Silicon.

After completion of the growth (70% of the charge weight), the ingots were slowly cooled directly in the furnace chamber, and no further heat-treatment was thereafter applied.

The silicon ingots, after being sliced, were submitted to a complete chemical, structural, and electrical characterization.

* Electrochemical Society Active Member.

9	—	0.6 × 10 ¹⁸	—	1.4 × 10 ¹⁷
10	1.6 × 10 ¹⁸	0.9 × 10 ¹⁸	0.8 × 10 ¹⁷	2.6 × 10 ¹⁷
11	1.4 × 10 ¹⁸	1.0 × 10 ¹⁸	0.7 × 10 ¹⁷	—
12	1.7 × 10 ¹⁸	0.7 × 10 ¹⁸	1.3 × 10 ¹⁷	3.8 × 10 ¹⁷
13	1.7 × 10 ¹⁸	0.8 × 10 ¹⁸	0.8 × 10 ¹⁷	1.9 × 10 ¹⁷
15	1.2 × 10 ¹⁸	0.9 × 10 ¹⁸	0.5 × 10 ¹⁷	1.3 × 10 ¹⁷

FTIR spectroscopy was used for determining the interstitial oxygen and substitutional carbon content.

Spark source mass spectrometry has been used for the determination of P content, and neutron activation analysis was used for measuring the content of impurities not intentionally added but resulting from process contamination.

Results of chemical characterization are reported in Tables I and II, which show that the as-grown crystals present oxygen and carbon levels largely comparable with those of commercially available CZ silicon, while those of some deep level impurities, notably iron and nickel, are larger by about one order of magnitude than the corresponding quantities of commercially available EG CZ-grown silicon.

Dislocation density was systematically checked using standard etching procedures, while other structural imperfections were spot-wise determined by TEM and x-ray topography.

Samples were generally dislocation free; only on the most heavily compensated samples dislocation loops and locally stressed lattice regions were occasionally observed on the tag-end slices.

The radial distribution of the dopants was investigated using a collinear four-point probe.

The dopants were found to be homogeneously distributed within each single slice, being the resistivity fluctuation of the order of ± 20%, at the most, for the more heavily compensated samples.

Electrical characterization.—Hall effect measurements at 9 kG magnetic field strength were carried out on all the samples in order to determine the Hall mobility μ_H and the actual donors, acceptors, or excess acceptors concentration N_D , N_A , or $(N_A - N_D)$.

For p-type compensated samples, we applied the expression of the Hall coefficient for semiconductors having multiple energy minima in the conduction band (6) which could be written

$$R_H = - \frac{1}{e} \frac{r_e b^2 n - r_h p}{(bn + p)^2} \quad [1]$$

where

$$r_e = \frac{\mu_{H,e}}{\mu_{d,e}}, \quad r_h = \frac{\mu_{H,p}}{\mu_{d,p}}$$

$\mu_{H,e}$ and $\mu_{d,e}$ are the Hall and drift mobility for electrons, $\mu_{H,p}$ and $\mu_{d,p}$ the Hall and drift mobilities for holes, and

$b = \frac{\mu_{d,e}}{\mu_{d,p}}$ the drift mobility ratio and which reduces to

$$R_H = \frac{1}{e} \frac{1}{p - n} \quad [2]$$

at high magnetic field strength, thus permitting the determination of the excess acceptor concentration $(N_A - N_D)$ and, then, the Hall mobility $\mu_H = R_H \sigma$, where σ is the measured electrical conductivity.

Tables III and IV report the most relevant electrical parameters of the reference boron doped and phosphorous doped samples, while Table V reports the corresponding data for p-type compensated samples.

Instead of the Hall coefficient R_H , the Hall resistivity

$$\rho_H = \frac{R_H}{u_H}$$

is reported throughout.

From Tables III and IV, one can remark that the acceptor and donor concentrations, as determined by Hall-effect measurements, closely correspond to those calculated from the known B and P additions to the melt and effective segregation coefficients taken equal to 0.9 and 0.46, respectively.

From Fig. 1, one could remark that the Hall mobilities for electrons and holes in n-type and p-type samples significantly compare with the values of the corresponding drift mobilities calculated according the Caughly and Thomas relation (7)

$$\mu = \frac{\mu_{max} - \mu_{min}}{1 + (N/No)^a} + \mu_{min} \quad [3]$$

Table V. Summary of Hall and diffusion length measurements on compensated, p-type samples

electron	1330	65	0.72	8.5×10^{16}

being, however, the Hall mobilities for electrons systematically slightly in excess over their drift mobilities. This discrepancy could be explained, as remarked earlier by Mousty *et al.* (8), by considering that the Irvin curves (9) displaying the resistivity *vs.* dopant concentration relationships for n-type silicon (from which also the Caughly and Thomas relation is obtained) are interpolation of data referring to different donors, and that, at a given impurity concentration, the mobility is somewhat higher in the case of phosphorous doping.

As for the Hall mobilities of compensated samples, they fit instead quite well the Caughly and Thomas ones, when plotted as a function of the sole acceptors content up to about $2 \cdot 10^{17}$ at./cm³ thus indicating that the majority carriers' mobility does not depend very much on the compensation.

Diffusion length (L_D) measurements of the minority carriers were also systematically carried out on p-type compensated samples (see Table V), using the surface photovoltage method, in order to study the relationships between the diffusion length of electrons and the degree of compensation.

It is observed in Fig. 2 that the experimental L_D values reasonably fit the calculated values, if one calculates the L_D value as $\sqrt{\tau_n D_n}$, by assuming that L_D is function of the excess acceptors concentration ($N_A - N_D$), that the minority carrier diffusion constant

$$D_n = \frac{k}{e} \mu_n \quad [4]$$

could be calculated via the Caughly-Thomas equation (1) for the mobility of electrons which was already shown to

give a good fit of the experimental data for both p- and n-type samples, by using the excess acceptor concentration as a measure of the number of scattering centers and determining the lifetime τ_n of the electrons via the Fossum (10) equation

$$\tau_n = \frac{\tau_{no}}{1 + \frac{(N_A - N_D)}{6N_A}} \quad [5]$$

when using for the values of the constants the same value of $N_A = 7.7 \times 10^{15}$ at./cm³ used in Ref. (8) and a value of $\tau_{no} = 0.85 \times 10^{-5}$ s, which is a factor of two lower than that used by Fossum.

A slightly worse, although still satisfactory, fitting with the Fossum equation is observed when instead of the L_D values one displays in Fig. 3, directly the minority carriers lifetime τ , determined from the experimental values of L_D and the calculated values of D_n according to Eq. [4].

Solar cell fabrication and characterization.— 1×1 cm² diffuse junction solar cells were fabricated by conventional open-tube phosphorous diffusion at 900°C for 7 min using POCl₃ as the phosphorous source. The ohmic front grid collector was formed using photolithographically etched vacuum-deposited Ti/Ag contact, while Al was used for the back ohmic contact.

An 8000 nm thick, single SiO layer was used as the AR coating.

Reference cells for base-line determination were prepared using slices cut from a 2.4×10^{16} at./cm³ B-doped ingot, having an L_D value major than 150 μ m, which resulted to be 15% efficient using a water filtered 100 mW/cm² tungsten-halogen lamp.

The photovoltaic characteristics of the p-type compensated samples, measured under the same illumination conditions, as well as the base-minority carrier diffusion lengths and lifetime measured on the completed cells, are reported in Table VI.

Fig. 1. Hall mobility of the majority carriers in n- and p-type samples. ●: n-type samples. ○: p-type samples. □: compensated, p-type samples. Solid lines display the calculated dependence of the drift mobility.

Fig. 2. Experimental and calculated (solid line) dependence of the diffusion length on the excess acceptor concentration in p-type compensated samples.

One could remark that, apparently, only the samples 44 and 45 containing boron and phosphorous in excess of 10^{17} at./cm³ show a significant decrease of the normalized efficiency η/η_0 , which is accompanied by a small, but significant decrease of the diffusion length and lifetime values of the minority carriers, with respect to those of the unprocessed slices (see Table V).

Figure 4, which displays the excess acceptors concentration dependence of the normalized efficiency, shows that a threshold exists around $(N_A - N_D)$ values close to 5.5×10^{16} at./cm³.

Discussion

It is well known from the literature (11) that the minority carrier lifetimes in p-type and in n-type samples is supposed to be limited by a Shockley-Read-Hall-type mechanism (12) at dopant concentration lower than 2×10^{18} at./cm³, while Auger recombination dominates their behavior at higher concentrations. From the calculated capture sections of traps constituted by shallow donors or acceptors is also known that the dominant mechanism of carrier trapping into shallow impurity states is by phonon emission (12-14). It is, eventually, also known that on p-type base cells the efficiency is practically independent of the acceptor concentration up to $\approx 5 \times 10^{16}$ at./cm³ (1 ppm) (15) in good agreement with earlier findings (16).

From the results of this present investigation, it appears that the recombination mechanism and the photovoltaic properties thereafter are not significantly affected by the contemporaneous presence of acceptors and donors, provided the excess acceptor concentration is lower than $\approx 5 \times 10^{16}$ at./cm³ which is a figure very close to the threshold boron concentration tolerated in p-type samples.

Furthermore, it has been demonstrated that the minority carrier properties do depend only on the excess ac-

ceptor concentrations $N = N_A - N_D$ (see Fig. 2 and 3) and that their lifetime dependence on the traps concentration is well described by the Fossum equation, using as the traps concentration that of the excess acceptors.

These experimental results could be well understood when considering the following.

Fig. 3. Experimental and calculated (solid line) dependence of the lifetime on the excess acceptor concentration in p-type compensated samples.

Fig. 4. Experimental dependence of the normalized efficiency on the excess acceptor concentration in p-type compensated samples.

Table VI. Summary of photovoltaic parameters of solar cells prepared with compensated, p-type samples

Sample	L_D (μm)	τ^* (μs)	J_{sc} (mA/cm^2)	V_{oc} (mV)	FF	η (%)	η/η_0
41	83	2.7	33.9	590	0.75	15	1

44	22	0.25	26.6	585	0.71	11.1	74
45	13	0.21	22.9	511	0.74	9.7	64
56	60	1.3	32.1	585	0.75	14.6	97

* From experimental values of L_D and calculated D .

First, that in a compensated semiconductor for which $N_A > N_D$, $kT > \epsilon_D$, ϵ_A , and $kT \ll Eq$ (where ϵ_D and ϵ_A are the energy levels of the donor and acceptor states), a concentration N_D of acceptors is associated in (A^-D^+) pairs (17) as N_D acceptor levels are occupied by electrons from the N_D donor levels, so that the number of available holes in the valence band is

$$N = N_A - N_D$$

which is sufficiently large to recombine with electron trapped at the D^+ species in the (A^-D^+) pairs before being reemitted, which then behave like traps for minority carriers. The lifetime should then be given by Eq. 4, written as

$$\tau_n = \frac{\tau_{no}}{1 + \frac{N_D}{N_A^0}}$$

if we neglect the influence of the traps consisting of empty acceptor sites and recognize that a τ_{no} value different from that of pure p-type semiconductors should be used to account for the different trap nature.

Second, that in a sample close to being fully compensated ($N_A \geq N_D$), the concentration of holes in the valence band is not sufficiently large to recombine with electrons into the empty traps, within the donor-acceptor pairs. Only free acceptors whose concentration is $(N_A - N_D)$ should act as traps and

$$\tau_n = \frac{\tau_{no}}{1 + \frac{N_A - N_D}{N_A^0}}$$

We can therefore conclude that in p-type compensated samples and in the 10^{16} – 10^{17} at./cm³ range of both acceptors and donors it is the excess acceptor concentration which dominates the recombination mechanism while ionized donors in the pair behave like electrically inactive species.

A threshold for photovoltaic efficiency close to 5×10^{16} at./cm³ of excess acceptors like in pure p-type samples could be therefore justified in compensated p-type samples, as recombination at ionized donors in donor-acceptor pairs seem to play a negligible role.

Applications of Optical Properties of Sputtered-Chromium Thin Films in Photomask Making

L. C. Hsia*

IBM Corporation, General Technology Division, Hopewell Junction, New York 12533

ABSTRACT

Optical properties of thin $\text{Cr/Cr}_x\text{O}_y$ films sputtered on glass for photomask making are investigated using Auger spectroscopy, ellipsometry, and reflectometry techniques. The films selected for the study vary from very rich to very poor in oxygen. The complex indexes of refraction are derived from the ellipsometry data using metal film calculation. The reflectance is then calculated to compare with that directly measured. These comparisons are important in understanding the film properties and their application in microlithography. The optical properties are found to be closely related to the oxygen concentration and its profile in the film. Optical intensity profiles in the photoresist are calculated for various photoresist/ $\text{Cr/Cr}_x\text{O}_y$ systems, yielding optimal conditions for minimizing resist line-width variations. An experiment is also carried out to illustrate the main points predicted by the theory.

With integrated circuit complexity and the number of circuits per chip increasing continuously, it has become necessary to fabricate devices with very small geometries. These advances in device design have imposed stringent requirements on photomasks used for device fabrication. The chromium photomasks have been used in semiconductor industry for many years, and great progress has been made in photomask processing (1). However, the improved reliability, defect reduction, and image-size control depend heavily on a better understanding of the properties of $\text{Cr/Cr}_x\text{O}_y$ thin films on glass. In the chromium thin-film preparation, oxygen is often introduced to alter the film complex index of refraction (thus reducing the reflectivity), which is one of the key parameters in image-size control. The sputtered-Cr films grown under different conditions present a rather complex system for characterization and analysis; the atomic ratio of Cr to O can vary drastically in the films. However, the surface layer has the most important implication in photolithography.

Auger Analysis

In this study, three types of $\text{Cr/Cr}_x\text{O}_y$ thin films with oxygen content poor, medium, and rich are chosen (which will be referred to as type A, B, and C, respectively). These films were prepared by sputtering chromium onto borosilicate glass. Auger electron spectroscopy analysis was performed, and the results are reported in Fig. 1-3. In each figure, the peak-to-peak intensity, which is proportional to the atomic concentration of the elements under investigations is shown. In all Auger profiles, this is limited to carbon, chromium, and oxygen, listed along the ordinate. Type A was prepared by sputtering pure chromium onto the glass substrate in a helium gas environment. The film has a thickness 700\AA , which roughly corresponds to 30 min of sputtering time in Fig. 1. Beyond 30 min, a film/glass interface region is reached, and the tail of the profile is due to the glass material (SiO_2). It can be observed that this is quite a homogeneous film with an atomic ratio of Cr to O 4:1 across the film. The carbon component may be due to contamination.

In the preparation of type B film, oxygen was purposely introduced into the sputtering chamber such that, while the film was grown, oxidation took place and a Cr_2O_3 film was formed. The film thickness is about 1250\AA , which roughly corresponds to 37 min of sputtering time in Fig. 2. Apart from the surface layer (about 30\AA), the film is relatively homogeneous with an atomic ratio of Cr to O 3:2. Some carbon contamination was also detected.

In order to further increase the oxygen concentration while maintaining high optical density, type C film was prepared by first sputtering chromium in an environ-

ment similar to that of type A. Then, the oxygen content was increased in the chamber. As a result, a film with complicated profile was grown, as shown in Fig. 3. The film has a thickness of 1900\AA , which roughly corresponds to 50 min of sputtering time in Fig. 3. The atomic ratio varies tremendously across the film. The oxygen-rich surface layer, which itself has a complex profile, has a thickness of about 500\AA .

Optical Properties

The optical properties of a homogeneous, isotropic medium are completely describable in terms of index of refraction of $N = n - ik$, where the imaginary part, k , is the extinction coefficient. The k is due to the intensity attenuation of an electromagnetic wave traversing the medium, and thus closely related to the optical density. The n and k are wavelength dependent. The reflectance is determined by the complex index of refraction. The reflectance R is given by

$$R = [(1 - n)^2 + k^2] / [1 + n^2 + k^2] \quad [1]$$

At present, most 10:1 optical projection mask-making systems employ the near-UV region; while for wafer fab-

* Electrochemical Society Active Member.

Fig. 3. Auger profiles of type C chromium film. Thickness = 1900 Å

rication, medium UV or deep UV light is utilized. Thus, properties of photomask materials have to be investigated from the near-UV to the deep-UV region.

Figure 4 shows the reflectance for the three types of Cr/Cr₂O₃ films as a function of the wavelength. A reflectometer with variable wavelength feature was used for the measurement. It can be observed that although the reflectance varies from 60% for the oxygen poor to 10% for the oxygen rich, it remains relatively flat within the region of interest for all three types of films.

The complex indexes of refraction were calculated from ellipsometry measurements. The ψ and Δ were derived from intensity signals at prescribed conditions using a rotating element ellipsometer at $\lambda = 4880 \text{ \AA}$ (2). The index of refraction was calculated using a computer program developed for metal films. Table I contains the measured ω and Δ for each film. The reflectance can be calculated from Eq. [1]. A comparison between the directly measured and calculated values of these parameters offers a better understanding of the dependence of film properties on the oxygen concentration. Table II is a comparison of the calculated reflectance with that of the direct measurement. In general, good agreement between the calculated and the measured is observed. However, as the oxygen concentration increases, the difference between the two becomes larger. This may be caused by the fact that as the film resistivity increases, the condition deviates further away from the assumption of a conducting metal film. In particular, for type C, which is extremely inhomogeneous, the surface oxygen-rich layer plays a dominant role in determining the surface optical properties such as reflectance and polarization.

Calculation of Intensity Profile in Photoresists

For an optical projection mask making system, two of the major lithography-related parameters are the achievable image-size control and the practical resolution limit. Linewidth variations are principally caused by the standing wave effects (3) in mask fabrication, since the slope or bulk effect (4), which is important in wafer fabrication, is virtually nonexistent in mask making. The standing wave effects are determined by the optical properties of the

Cr/Cr₂O₃ thin film and photoresist absorption and thickness. Like other metal thin films encountered in wafer fabrication, lithography-related properties of Cr films are characterized by the complex indexes of refraction. This means a significant phase change of light occurring upon reflection and partial reflection has to be the standing wave effects, along with some simplifying assumptions, is used to illustrate the major points. The approximation of a weakly absorbing resist film on a partially reflecting substrate with monochromatic illumination is made. Although this is a special case, it does approximate optical mask making situations. In this work the wavelength of illumination is $\lambda = 4350 \text{ \AA}$.

The standing wave intensity in the resist film can be calculated using the concept of the complex amplitude and multiple reflection (5). The situation is illustrated in Fig. 5. The incident light is imaged normally into a weakly absorbing film of thickness d , coating a Cr/Cr₂O₃ film with the index of refraction $N_2 = n_2 - ik_2$. The intensity of each reflection, either from the Cr/resist or resist/air interface, can be expressed as

$$E_i = A_i E_0 e^{i(\omega t \pm r_i k)} \quad [2]$$

where

$$k = 2\pi N/\lambda$$

The total standing wave amplitude is given by summing up all the E_i 's.

$$E_s = \sum_{i=1}^{\infty} E_i = E_0 t_{ole} e^{i\omega t} (1 + f_{12} e^{2ik_1(x-d)}) \frac{e^{-ik_1 x}}{1 - f_{12} f_{10} e^{2idk_1}} \quad [3]$$

where

$$f_{12} = (N_1 - N_2)/(N_1 + N_2) \quad [4]$$

1.9466	2.0981	1.9384	2.0899	2.0452	2.1967

$$f_{10} = (N_1 - 1)/(N_1 + 1) \tag{5}$$

$$t_{01} = 2/(1 + N_1) \tag{6}$$

$$N_1 = n_1 - ik_1, \text{ resist index} \tag{7}$$

$$N_2 = n_2 - ik_2 \text{ Cr/Cr}_2\text{O}_3 \text{ index} \tag{8}$$

Only the relative intensity is meaningful, which is given by

$$RI = \frac{E_s^2}{E_0} \tag{9}$$

It is obvious from Eq. [3] that the amplitude of the standing wave $E(x, d)$ is dependent on thickness d . It can be readily shown that the maximum and minimum intensity envelopes are given, respectively, by

$$d_{\text{max}} = (\phi + 2m\pi) \lambda / 4n_1\pi \tag{10}$$

$$d_{\text{min}} = (\phi + (2m + 1)\pi) \lambda / 4n_1\pi \tag{11}$$

where ϕ is the phase change during the reflection and $m = 0, 1, 2, \dots$. The condition $k_1 \ll n_1$ has been used.

Table III contains the first few maxima and minima calculated for types A, B, and C films cannot determine these extrema. In fact, a commercially available mask blank has almost the same reflectance as type B (about 34%), but has very different index of refraction (1.78 - i 2.36). For wavelength = 4350Å, the correspondent minimum intensity envelope occurs at a thickness 5080Å instead of at 5598Å as for type B. This shows that the reflectance alone cannot determine the optimal thickness for minimizing the standing wave effects, which are crucial for the image-size control.

The standing wave intensities at thicknesses $d = 1.037\lambda$ and $d = 1.189\lambda$ are plotted for type A in Fig. 6. These two thicknesses correspond to Eq. [10] and [11] for a maximum and minimum, respectively. It is seen that for a highly reflecting surface such as type A, coated with a weakly absorbing film of resist, the film thickness d is a powerful variable in determining the intensity of the standing wave in the resist film. By choosing a resist film thickness corresponding to a minimum, better linewidth control can be achieved. Thus, for metal surfaces, such as Al, Pt, and Cr, resist film thicknesses must be carefully chosen. However, as shown in Fig. 7, the case

Fig. 6. Effect of thickness to produce maximum ($d = 1.037\lambda$) and minimum ($d = 1.188\lambda$) standing wave intensity envelopes for type A. (—): Max. (---): Min.

Fig. 7. Effect of thickness to produce maximum ($d = 1.36\lambda$) and minimum ($d = 1.188\lambda$) standing wave intensity envelopes for type C. (—): Max. (---): Min.

for type C, which has much smaller reflectance, this effect is much less conspicuous. It is, therefore, much more important to reduce film thickness variation for highly reflecting surfaces.

The standing wave intensities at $d = 5800\text{Å}$ for types A, B, and C are plotted in Fig. 8. This gives a ratio $d/\lambda = 1.33$. This thickness does not correspond to any extrema determined by Eq. [10] and [11]. However, this thickness is chosen for the experiment later. It is seen that there always exist underexposed layers which correspond to the nodes in Fig. 8, and the higher the reflectance, the more unexposed the nodal layers. However, by using an active developer, there is little difficulty in breaking through the underexposed layers and clearing resist from the resist-substrate interface for geometries layer than $1\ \mu\text{m}$; it will be shown later that for submicron geometries this is more difficult to achieve. In Fig. 9, the standing wave intensities at the photoresist/Cr-Cr₂O₃ interface as a function of film thickness are plotted. Since none of the substrates are perfectly reflecting, the phase change upon reflection is much less than π . These cause the first intensity minimum to be shifted from the interface as illustrated in Fig. 8, and a finite light intensity appears. It is also clear that the substrate with the highest index of refraction (type A) receives the smallest dose at the interface.

Finally, Fig. 10 shows the standing wave intensities at the thickness corresponding to the minimum ($d = 1.189$ for A, $d = 1.181$ for B, $d = 1.287$ for C).

The results of this section should serve as a guide for searching optimal conditions for minimizing standing wave intensities for metal surfaces.

Experimental Results and Discussion

The purpose of this experiment is to demonstrate a few important points shown in the last section. While the min-

imum standing wave intensity lengthens the exposure time, it is preferred for better image-size control. In particular, the exposure variations caused by small photoresist thickness variations can be minimized.

The 10:1 projection system used in this experiment has an exposure wavelength = 4350Å. Other wavelengths are all filtered out and can be totally ignored. The photoresist used is AZ1350J, which, when unexposed, has an index of refraction $N = 1.65 - i0.02$.

After the exposure, the inhibitor concentration is greatly reduced, and, therefore, for most of the exposure, the resist is quite transparent. The three types of substrates A, B, and C are first spin coated with resist having a thickness of 5800Å. The resist thickness is measured using an IBM thin film measurement system. After exposure, the patterns are then developed using an AZ developer. In order to have a truthful comparison, the process variation must be minimized. For this purpose, the three types of substrates are exposed one after the other, giving the same exposure time. A test pattern with various linewidths is used for patterning. The patterned masks are then developed together. The resist images are then measured. Table IV contains the results of the measurements. The 1.5 μm nominal lines or above are all well developed. It is seen that as the reflectance increases, so do the standing wave intensities in the films, the image size variations increase also. The large variation for 1.5 μm nominal lines for type C is mainly due to the limitations of the measurement tools. What is interesting in this experiment is that the image sizes for different substrates are found to be roughly proportional to their maximum standing wave intensities in the films. The maximum intensity ratios calculated from standing wave theory are: $E_B^2/E_A^2 = 0.71$ and $E_C^2/E_B^2 = 0.70$ for the three types of substrates under investigation. Good agreement is found when comparing these ratios with those in rows 4 and 9 calculated from the image sizes. These results are repeatable.

The lines with nominal under less than 1 μm were not developed out for type A. As shown in the micrographs in Fig. 11, resist is not completely cleared from the film substrate interface, while under the same conditions it is cleared for both types B and C, which have much lower reflection.

This observation is consistent with Fig. 9, where the intensities at the resist/substrate have been plotted. This indicates that for submicron geometries either longer exposure time or longer development time is required for type A, which is often not desirable. The standing wave effects can be clearly observed in Fig. 11. Figure 11a, which corresponds to type A, shows much more conspicuous standing wave effects than do Fig. 11b or 11c, as predicted by the theory.

Conclusion

For future photomask manufacturing using photolithography, it is necessary to control image sizes much closer than is done now. Optical properties of the chromium substrates must be made to suit the need for deep-UV lithography used in wafer fabrication. This work offers some understanding from both theoretical and experimental point of view, and the lithography-related parameters such as reflectance have been investigated. The index of refraction has been shown to be an extremely important parameter in metal film lithography because it determines the standing wave effects, which place a limitation on the resolution capability of conventional resists. The relationship between the resist absorption, film thickness, and index of refraction of Cr/Cr_xO_y system has been derived and discussed. An experiment has also been carried out to illustrate some features of standing wave effects and minimization.

Corner Undercutting in Anisotropically Etched Isolation Contours

M. M. Abu-Zeid*

Eindhoven University of Technology, 5600 MB Eindhoven, The Netherlands

ABSTRACT

Corner undercutting of mesa structures anisotropically etched in (100) silicon using ethylene diamine-water solution at 85°C is shown to be gradual with the prominent beveling facets on the {212} planes and ending with small ledges on {323} planes. Considering the undercutting to be a beveling on the {212} planes, relations are derived to calculate corner compensation masks of different shapes. It is further shown that when the mask edge is tilted with respect to the wafer flat, the etched mesa sidewall is formed by a striated sidewall plane running parallel to the mask edge and intersecting the corner beveling planes unsymmetrically. The conditions to obtain straight sidewall traces on the (100) surface at a certain etching height are given.

Convex corner cutting under the oxide mask of mesa structures anisotropically etched in (100) single-crystal silicon arises in the fabrication process of three-dimensional microstructures (1, 2). It is significant in dielectric isolation techniques of integrated circuits (3, 4), where it presents limitation to the useful surface area when deep etching is used. In this case, two methods are usually used to correct for corner undercutting (3): (i) the addition of compensation patterns to the mask corners and (ii) the tilting of the mask side with respect to the wafer flat by a small angle. However, controlled corner undercutting can be used as a micromachining process in rounding sharp corners in high voltage termination contours and channel structures (5).

In this paper, a detailed investigation is presented of the convex corner facets of anisotropically etched mesa structures using ethylene diamine-water etch solution at 85°C, complementing previously reported studies using KOH (3, 4) and hydrazine (8, 9) etch solutions. The corner profile was constructed from the measured etching parameters and then modeled by a single beveling plane. The simplified beveling model is used in calculating the dimensions of different compensation patterns. It is also used in investigating the shapes and textures of the etched mesa sidewalls and their traces on the (100) surface with different mask tilt angles and etching heights.

Experimental

The etch solution is a mixture of 55 volume percent (v/o) ethylene diamine in deionized water at 85°C (6, 7). Mesa structures were etched in (100) silicon using $100 \times 100 \mu\text{m}^2$ SiO₂ masks making successive angles with the (011) wafer flat ranging from 0° to 45° in steps of 5°. For each structure, corner and sidewall facets were examined at various etching heights using SEM and high resolution optical microscopes. The measured etch rates of the (100) and (111) planes are 0.5 and 0.018 $\mu\text{m}/\text{min}$, respectively.

When the mask edge is aligned with the wafer, flat corner undercutting starts from the (111) plane and increases gradually on various orientation planes as shown in Fig. 1 and Fig. 5. It is best represented by a {212} beveling plane intersecting the (100) surface at 48.2° and its trace making an angle $\alpha = 18.4^\circ$ with the (111) trace. The {212} beveling planes differ from the reported {331} planes using KOH-water-propanol etch solution (3, 4) and the {112} planes using hydrazine-water-isopropyl alcohol (8, 9). The top part of the undercut corner is in the form of a ledge that increases in width gradually from the (111) plane. The most prominent plane forming the lower side of the ledge was identified as (323), intersecting the (100) surface at 50.24°.

Figure 2 illustrates the case when the mask is rotated so that its edge is tilted with respect to the wafer flat by a small angle θ and the mesa is etched to a height H much smaller than the mask length L . The mesa corners continue to be bounded by the {212} beveling planes. A sidewall plane is formed whose trace on the (100) surface is parallel with the mask edge at a distance d_s and intersects

the traces of the beveling planes unsymmetrically. This plane coincides with the corresponding crystallographic plane. Its surface is striated and terminates on the (100) surface plane by a small ledge not shown in Fig. 2. The measured sidewall edge undercutting given by the normalized value $U_s = d_s/H$, and the sidewall plane slope ϕ varies with θ , as shown in Fig. 3 for $H/L = 0.24$. The effect of varying H/L and θ on the shapes of the etched mesa structures is given later.

Mesa Corners

A two-dimensional profile of the convex mesa corner undercuts on the (100) surface was constructed using a modified Wulff-type construction (10). For this procedure the lateral etch rate vectors on the (100) surface are represented by the experimentally determined values of U_s , and their polar diagram as a function of the crystallographic direction around the mask corner as origin is shown in Fig. 4. The corner undercutting profile is given by the envelope of the normals to the rate vectors. The diagram of one side of the constructed profile shown is bounded by many planes starting with the slowest etch rate (111) plane and ending with the medium-fast etch rate (313) plane, which touches the tip of the mesa corner and makes 26.57° with the mask edge. A large facet of the undercut corner within a radius making 30° from the mask diagonal is contributed by the (212) plane.

The constructed corner profile with the (323) top ledge is illustrated in Fig. 5. In section a-a, the relative thickness of the ledge at the mesa corner is $h/H = 0.052$. For the sake of clarity, the top ledge will not be considered in the following analysis, and the (212) beveling planes will be extrapolated to intersect the (100) surface. The extrapolated profile is shown with long dashed lines. The corner undercutting is measured by the conventional normalized factor $U_c = d_c/H$, where d_c is the perpendicular from the mask tip on to the trace of the (212) beveling plane on the

Fig. 2. Facets of a mesa sidewall etched using a mask edge tilted by $\theta = 5^\circ$ and $H/L = 0.24$. d_h and d_l are the perpendiculars from the beveled corner tips on to the mask edge.

(100) surface (8). With our etch solution $U_c = 0.5$ and is independent of the etch height, since d_c is proportional to H , in agreement with the reported results using KOH etch solution (1).

Mask Corner Compensation

Square patterns are usually added to the mask corners in order to correct for corner undercutting (1, 3). However, other geometrical patterns can be used when spac-

Fig. 3. Variation of the normalized edge undercutting $U_s = d_s/H$ and the sidewall plane slope Φ with the mask tilt angle θ for $H/L = 0.24$.

Fig. 4. Profile of a constructed undercut corner from the U_s vs. θ polar diagram.

ings between masks are limited. These are formed by superimposed rectangular stripes and square geometries. The criterion in calculating their dimensions is that the receding peaks of the convex corners under the compensating pattern have to reach the main mesa tip simultaneously when the specified etched height is reached. However, if etching continues, corner undercutting starts again.

Neglecting the sidewall undercutting of the {111} planes and assuming the receding convex corners to be bounded by the {212} planes only, a part of a compensating mask in the form of a long stripe having a small width W gives the successive etched shapes shown in Fig. 6a. After the two adjacent beveled planes meet at the mask edge, the tip recedes along the plane of symmetry as etching continues. At P , the two outer beveled planes meet, and at R , all the mesa surface disappears. The mesa height when its tip recedes from the mask edge by a distance d is given by

$$H = (0.5 W \sin \alpha + d \cos \alpha) / U_c \quad \text{for } d \leq 0.5W$$

and

$$H = (0.5 W \cos \alpha + d \sin \alpha) / U_c \quad \text{for } d \geq 0.5W$$

Etching follows the same pattern when a long rectangle having width of $0.5W$ is bounded by two orthogonal {111} planes, as shown in Fig. 6b.

These relations were used to calculate four patterns shown in Fig. 7 that give the same compensating results for a mesa height of $25.25 \mu\text{m}$. Even though the intersections of the mesa sidewalls on the (100) surface formed perfect squares when the specified etched height was reached, the sidewall intersections around the corners were surrounded by cones whose facets depend upon the geometrical shape of the compensating mask. Figure 8 shows a mesa corner etched out to the specified height using the mask with square compensating patterns. Even though there is no corner undercutting, the cones

Fig. 5. Facets of a beveled corner

surrounding the corner intersections give the mesa the shape of a tablecloth. This is due to the difference in the inclinations of the {111} and {212} planes, as illustrated in the plan view shown in Fig. 9. The facet planes forming the corner cone meet at the mesa tip O, and the projections of their lines of intersections equal the mesa height. The corner cones disappear and the {111} sidewall planes meet when the etching height is increased by 0.185 times the calculated value. Corner undercutting resumed when the etching height was further increased.

Fig. 6. Successive etching shapes with a long rectangular mask.

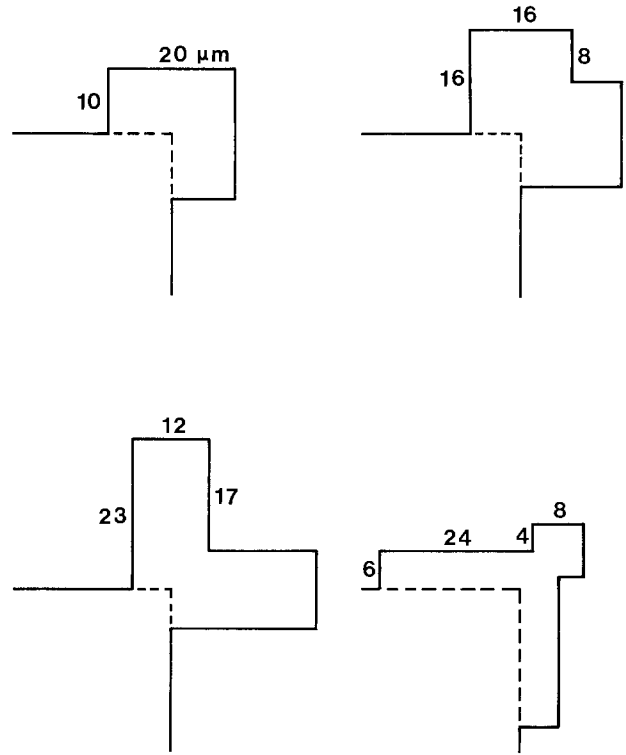

Fig. 7. Mask compensating patterns for a mesa height of 25.25 μm

Mesa Sidewalls with Tilted Masks

The etching shapes of the mesa sidewalls when the masks are tilted through successive angles depend on both the tilt angle θ and the ratio H/L . The H/L vs. θ plane shown in Fig. 10 is divided into five regions by curves A and B and line C, giving the boundary $\theta = \alpha$. In region 1, the sidewall plane intersects the two adjacent beveling planes unsymmetrically, as illustrated in Fig. 2. From the photomicrograph of this sidewall shown in Fig. 11, it is clear that the surface of the sidewall plane is striated, indicating that it is formed by more than one plane, in accordance with the ledge etching model proposed by Kendall (10). We also noticed that it is usually terminated at the (100) surface by a small top ledge, similar to that associated with an undercut corner. However, the following analysis does not take the top ledges into consideration. Detailed investigation using the ledge etching model to explain the variation of Φ and U_s with θ as shown in Fig. 3, together with the sidewall surface textures and etching mechanism, will be reported later. Region 1 is bounded

Fig. 8. Photomicrograph of a mesa sidewall etched with a mask having square compensating patterns.

Fig. 9. Plan view of a mesa corner etched with a mask having square compensating patterns.

by curves A and B. Curve A gives the boundaries where one of the beveling planes passes through the two adjacent mesa corners and is given by

$$H/L = [(1 + \cot \alpha) \sin(\alpha - \theta)]/2 U_c$$

Curve B gives the values of H/L vs. θ , where the undercutting produced by the beveling planes of two adjacent corners just exceeds the sidewall plane undercutting d_s . Referring to Fig. 2 and 5, this situation exists when

$$L = \sqrt{2} r_c \cos \theta + (d_h - d_s) \cot(\alpha - \theta) + (d_1 - d_s) \cot(\alpha + \theta)$$

giving

$$L/H = [2 \sin \alpha / (\sin^2 \alpha - \sin^2 \theta)] (U_c \cos \theta - U_s \cos \alpha) \text{ for } 0 < \theta < \theta_t$$

where θ_t is the transition angle when curves A and B intersect. it satisfies the relation

Fig. 10. H/L vs. mask tilt angle θ at the threshold of one beveling plane joining the two adjacent mesa tips (A) and sidewall planes disappear (B). $\theta_t = 10.4^\circ$.

Fig. 11. Photomicrograph of a mesa sidewall etched with a mask tilted 5° and $H/L = 0.2$.

$$U_s/U_c = \sin(45 - \theta) / \sin(45 + \alpha)$$

With $\theta > \theta_t$, one beveling plane extends along the whole sidewall and intersects those of the adjacent sidewalls at right angles. In this case

$$L = \sqrt{2} r_c \cos \theta + (d_h - d_s) \cot(\alpha - \theta) + (d_1 - d_s) \tan(\alpha - \theta)$$

giving

$$L/H = \frac{2}{\sin 2(\alpha - \theta)} \left[\frac{\cos \theta + \sin(2\alpha - \theta)}{\sin \alpha + \cos \alpha} U_c - U_s \right] \text{ for } \theta_t < \theta < \alpha$$

The mesa sidewall in region 2 is formed by two beveling planes making $180^\circ - 2\alpha$ with each other, and the sidewall plane disappears, as illustrated in Fig. 12a. In region 3, it is formed by one beveling plane making $\alpha - \theta$ with the mask edge and 90° with the beveling planes forming the adjacent sidewalls, as illustrated in Fig. 12b, and recedes parallel to itself when etching continues. In region 4, it consists of a sidewall plane and one beveling plane, as

Fig. 12. Etched shapes of mesa sidewalls that correspond to the regions shown in Fig. 10. a: $\theta = 5^\circ$, $H/L = 0.7$, region 2. b: $\theta = 5^\circ$, $H/L = 1.0$, region 3. c: $\theta = 15^\circ$, $H/L = 0.35$, region 4. d: $\theta = 20^\circ$, $H/L = 0.2$, region 5.

shown in Fig. 12c. In region 5, the sidewall plane is parallel with the mask edge and extends between the mesa tips without corner undercutting, as illustrated in Fig. 12d. However, corner undercutting starts when θ exceeds 35° .

The trace of the sidewall plane on the (100) surface becomes straight, without corner undercutting, in regions 3 and 5. However, in both regions, sidewall undercuttings occur. For equal mesa heights, the trace of the sidewall plane at the boundary of region 3 given by curve A, with a small tilt angle θ , is slightly longer than that at the boundary of region 5 with tilt angle α . The increase related to

the mask length L is given by

$$\Delta d / L = \sqrt{2} \sin (45 + \alpha - \theta) - 1$$

Conclusions

When ethylene diamine-water etch solution at 85°C is used to etch mesa structures, convex corner undercuttings start from the {111} planes and increase gradually on various orientation planes with the top parts covered with small ledges. The prominent facets contributing to the undercuttings coincide with the {212} planes. Various pattern geometries can be designed for mask corner compensation at a specified etched height. At that height, the corner intersections are surrounded by cones that disappear when the etched height is further increased by a small specified amount. Undercutting starts again when etching is further resumed.

When the mask edge is tilted with respect to the wafer flat, the sidewall consists of different facets depending on the tilt angle θ and the etched height H . There are two regions in the H/L vs. θ plane where the sidewall trace on the (100) surface is straight. In both regions the sidewall makes smaller angles than the (111) plane with the (100) surface and the compensation is independent of the etched height. However, the sidewall surfaces are usually striated with large edge undercuttings.

Grain Growth Studies in Polysilicon by Ar⁴⁰ Ion Implantation and Thermal Annealing

Anjan Bhattacharyya* and Kenneth N. Ritz*

Philips Research Laboratories Sunnyvale, Signetics Corporation, Sunnyvale, California 94086

ABSTRACT

We have used the technique of multiple ion implantations of Ar⁴⁰ in polycrystalline silicon films for amorphization and subsequent thermal annealing for recrystallization. We observe dendritic grain growth with grain sizes ($\approx 0.75 \mu\text{m}$) about ten times larger than in original polycrystalline silicon films. This ion implantation technique can be used to form a device quality polysilicon film with large grains on an amorphous substrate.

In recent years, there has been much interest to form a device-quality silicon film on an amorphous substrate (e.g., SiO₂). The most commonly used techniques are recrystallization by laser or strip-heater (1, 2). However, the main drawbacks of these techniques are the high temperature needed for melting the polysilicon layer and lack of good reproducibility. Also, the melting cannot be always limited to the polysilicon layer and disturbs the material underlying the oxide.

It would be better to induce grain growth in polysilicon at comparatively lower temperatures ($<900^\circ\text{C}$) by a reproducible alternative process. Such a technique then could be used for the fabrication of stacked CMOS or multi-layered SOI devices and circuits (3).

In this investigation, we have determined a well-controlled processing condition, i.e., ion implantation, with a species (Ar⁴⁰) of dose compatible with current implanter capabilities which does amorphize the polysilicon and leads to grain growth after thermal annealing. The technique of ion implantation is a reproducible and controlled way to amorphize polysilicon or single-crystal silicon. The strain energy stored in the polysilicon due to the implanted ions could lead to a strain-induced recrystallization mechanism.

Also, the electrical properties of polysilicon such as the electrical conductivity (4) and excess carrier lifetime (5) depend on the grain size. The present technique of grain size growth can also have potential for solar cell applications.

Ion Implantation Conditions

We have to choose the implant conditions (energy, dose) for a particular ion (e.g., Ar⁴⁰) in polysilicon film which would produce amorphization. Such a process would totally destroy the grain boundary structure and could promote recrystallization of the amorphous state to a new structure, different from the original one. If the implant conditions do not produce amorphization, then there will be no major change in grain size and the grain structure will be morphologically similar to the original film.

To produce "uniform amorphization" of the polysilicon film, we have used three successive implants each with a dose of $2 \times 10^{15}/\text{cm}^2$ with projected ranges such that the superposition of three Gaussian implant profiles would give us a square profile. We have used the following implantation energies in sequence, with the projected ranges as shown

Energy (keV)	Projected Range (Å)
50	500
110	1092
180	1816

The energies are chosen in such a fashion that we would "uniformly amorphize" the polysilicon film of thickness 2500Å.

Sample Preparation

We have prepared samples with implantation doses less than and greater than the critical dose of $2 \times 10^{15}/\text{cm}^2$. All the samples were implanted sequentially at three different implantation energies, as described before.

The polysilicon films of thickness 2500Å were prepared by LPCVD ($\approx 620^\circ\text{C}$) onto a 650Å thick layer of SiO₂ grown at 950°C by oxidation of p-type $<100>$ Si wafers of resistivity 5-20 Ω-cm.

We used four different implantation doses (Ar⁴⁰) ($1 \times 10^{14}/\text{cm}^2$, $1 \times 10^{15}/\text{cm}^2$, $2 \times 10^{15}/\text{cm}^2$, and $4 \times 10^{15}/\text{cm}^2$) to study the dependence of grain growth on implantation dose. In each case, the samples were implanted three times with a particular dose at energies as shown above. After implantation the samples were annealed for 30 min in dry N₂. For comparison purposes, as-deposited polysilicon samples were also annealed in dry N₂.

Samples with all the various doses were annealed at 900°C. We have studied in detail the samples implanted with a dose of $2 \times 10^{15}/\text{cm}^2$ by annealing at 700°, 800°, 900°, 1000°, and 1100°C.

The samples were then prepared for planar TEM section studies to study the polysilicon grain size. Electron

Fig. 1. As-received polycrystalline silicon sample, selected area diffraction pattern.

* Electrochemical Society Active Member.

diffraction patterns were also obtained to study the "amorphous" to "crystalline" phase change.

Large area electron transparent TEM samples were prepared using a thinning technique similar to that used by Kolbesen *et al.* (6), wherein the samples are etched from the back surface with a 5:1:1 mixture of nitric, hydrofluoric, and acetic acids.

Results and Discussion

Figure 1 shows a TEM micrograph and a selected area electron diffraction pattern for the as-deposited polysilicon film. We note that the grain size is in the range 0.04-0.1 μm . The grain size of the polysilicon after annealing at 900°C for 30 min in N_2 increases to 0.05-0.15 μm .

Now, let us consider a sample which was implanted with a dose of $2 \times 10^{14}/\text{cm}^2$, which is less than the critical dose for amorphization. We found from TEM micrographs that there are some grains with size 0.25 μm , but no evidence of any dendritic grain growth or grains with large diameters. The recrystallization produced a structure which was morphologically similar to the original polycrystalline film.

We now consider samples implanted with a dose of $1 \times 10^{15}/\text{cm}^2$, which is comparable to the dose of ($2 \times 10^{15}/\text{cm}^2$) required for amorphization. From the TEM micrograph as shown in Fig. 2, we see that the original polysilicon grain structure has been completely destroyed and the polysilicon film has been transformed to an amorphous structure. The detailed features in the TEM micrograph is possibly due to contamination by organic solvents during TEM sample preparation. Figure 2 also shows the typical diffuse diffraction ring images which are characteristic of amorphous silicon.

We have examined closely the grain in samples implanted with the dose of $2 \times 10^{15}/\text{cm}^2$ by annealing them in dry N_2 for 30 min at different temperatures to determine the minimum processing temperature at which the grain growth is almost complete.

Figure 3 shows a TEM micrograph and an electron diffraction pattern of samples implanted with a dose of $2 \times 10^{15}/\text{cm}^2$ and annealed at 900°C.

Fig. 2. Polysilicon sample implanted with a dose of $1 \times 10^{15}/\text{cm}^2$, selected area diffraction showing diffuse rings only.

Fig. 3. Polysilicon sample implanted with a dose of $2 \times 10^{15}/\text{cm}^2$ and annealed at 900°C for 30 min in dry N_2 , selected area diffraction pattern showing growth of large dendritic grains.

If we examine the TEM micrograph the sample annealed at 900°C, we note that the recrystallized polysilicon has a structure totally different from the original polycrystalline form. We observe appearance of a dendritic structure. The average size of the dendritic grain is $\approx 0.75 \mu\text{m}$, which is remarkably larger than the grain size (0.04-0.1 μm) of as-deposited polysilicon. The electron diffraction pattern is clearly more discrete than obtained from the original polycrystalline film.

The TEM micrographs of the samples annealed at 700°, 800°, and 1100°C also show similar dendritic grains. Any increase in annealing temperature beyond 900°C does not substantially increase the grain size.

For the samples implanted with a higher dose of $4 \times 10^{15}/\text{cm}^2$ and annealed at 900°C for 30 min, we did not observe any further increase in grain size.

Figure 4 shows a plot of the average dendritic grain size in micrometers *vs.* annealing temperature. The samples implanted with $2 \times 10^{15}/\text{cm}^2$ showed dendritic grains after annealing at 700°C. We note that with increase in the annealing temperature, the average dendritic grain size increases to 0.75 μm at 900°C. Beyond 900°C, we did not observe any further increase in grain size. Also shown in the graph are average grain sizes for samples implanted with a dose of 1×10^{14} , 1×10^{15} , and $4 \times 10^{15}/\text{cm}^2$ and annealed at 900°C in dry N_2 for 30 min.

Polysilicon films deposited in a Tempress (Unicorp) LPCVD reactor over the temperature range 580°-640°C have been studied by Kamins *et al.* (7). In particular, the films deposited at 580°C were amorphous and showed marked change in structure after thermal annealing at 800°-1200°C. However, the particular condition of deposition of amorphous films, *e.g.*, by evaporation (8) or by atmospheric pressure CVD in a nitrogen ambient (9) determines the structure of the films after thermal annealing. The amorphous films deposited (7) at 580°C and annealed at 800°C showed a definite structure, but films with better defined larger grains did not appear until the anneal temperature was increased to 1200°C.

Fig. 4. Average dendritic grain size in micrometers vs. annealing temperature. *: Dose of $2 \times 10^{15}/\text{cm}^2$, various anneal temperatures. O: $1 \times 10^{15}/\text{cm}^2$, 900°C anneal. +: $1 \times 10^{14}/\text{cm}^2$, 900°C anneal.

The present technique of amorphization of polysilicon films by ion implantation is a reproducible and controlled mechanism and is not strongly dependent on processing conditions as in the different alternatives in depositing amorphous films (7-9). The grain growth for the samples implanted with a dose of $2 \times 10^{15}/\text{cm}^2$ was complete after annealing at 900°C with no significant increase in grain size when the annealing temperature was increased to 1100°C . Such a process has the potential of application in processing sequences where the maximum temperature is limited to 1000°C or less.

Conclusions

The present unique technique produces a significant grain growth in polysilicon film. The implantation dose of $2 \times 10^{15}/\text{cm}^2$ and annealing temperature of 900°C produces the optimum conditions for dendritic grain growth. The implantation conditions have to be such that the polycrystalline film is amorphized, and such that it loses its past history of grain size and grain boundaries. This technique could have significant application to produce large grain polysilicon film on amorphous substrates as required in silicon-on-insulator technology.

Photo-CVD for VLSI Isolation

ABSTRACT

This paper reviews the technique of photochemical-assisted vapor deposition (photo-CVD), and its applications in silicon IC processing. The photo-CVD process deposits SiO₂ films (PHOTOX™) at temperatures as low as 50°C. The deposition process, the resulting film properties, and the use of PHOTOX SiO₂ for lateral isolation among transistors and vertical isolation between two-level interconnects are discussed. A novel process employing PHOTOX deposition in conjunction with a photoresist liftoff can be used to achieve totally isoplanar isolation. Photo-CVD can also be extended to produce other dielectrics such as silicon nitride and aluminum oxide.

In fabricating VLSI circuits, low temperature processing may be one of the most important techniques for achieving the precise control required for device structures, isolation, and interconnection (1). Specific effects that may be minimized include wafer warpage, defect generation, Al hillock formation, Al/Si interface degradation, and dopant diffusion. However, the needs of the IC industry for high quality, uniform, pinhole-free dielectrics have always resulted in some high temperature steps in the process: thermal oxides obtained at > 900°C in the most demanding situations, or CVD films at > 300°C. Consequently, the need exists for a low temperature insulator deposition process that results in high quality oxide or nitride films.

Consider the electrical isolation between active devices on an IC chip. The degree of isolation required is extreme in order to obtain several thousand integrated devices without cross-talk between them (2). For MOS IC's, this isolation is generally achieved with a thick oxide (field oxide) between transistor areas. One well-known technique for defining the field oxide patterns is known as LOCOS (3), in which a nitride film is masked and etched to form the desired pattern followed by a high temperature oxidation. The nitride pattern prevents oxide growth within the area that becomes the transistor region. The long high-temperature process in the LOCOS process can generate defects in the silicon substrate. Moreover, the periphery of the transistor area is overtaken by oxide encroachment beneath the nitride edges, resulting in a bird's beak structure which can reduce the yield of gate-lines crossing it. Encroachment also results in a narrower MOSFET channel, thereby reducing the current driving capacity, and hence the ultimate speed of the IC's. Several approaches have been developed to reduce the bird's beak phenomena (4, 5), at the expense of complicating the processing, and without solving the problem of thermally induced defects. Moreover, non-LOCOS techniques have similar problems. For example, etching the desired field pattern in a uniform oxide (6-9) leaves sharp steps at the window edges.

Vertical isolation between two levels of metalization is another area of IC processing that could effectively employ insulators formed in low temperatures. The insulator separating the Al or Al alloy interconnection structures must have low pinhole density, low stress, a smooth surface morphology, high breakdown voltage, low dielectric constant, and high resistivity. With the conventional method of depositing SiO₂ by low pressure CVD (LPCVD), Al and Si interdiffuse at the deposition temperature (≤ 400°C), which can cause leakage (10, 11). Moreover, at 400°C, hillocks form on the Al surfaces which result in reduced breakdown voltages or electrical shorts (12) in the insulators that cover them. It is therefore desirable to deposit an insulator at temperatures much lower than 400°C.

A unique new approach to obtaining insulator films at low temperature is to use UV irradiation to form vapor-phase reactants that enhance the desired reaction (12-15). Silicon oxides and nitrides, as well as alumina, have been deposited by these techniques. This photochemical-assisted CVD process (photo-CVD) has already been employed successfully to deposit the insulator between two levels of Al metalization (12, 13). It has also been used for isolation (16) by masking the transistor areas with photoresist, etching the field region, and then refilling the etching region with a photo-CVD oxide. Excess oxide is later lifted off to form an isoplanar structure. With this lift-off technique, one avoids the defects and the bird's beak formation. The low temperature photo-CVD process (~100°C) permits lift-off with a photoresist medium which would degrade at higher temperatures. The resulting isolation structure is fully recessed, isoplanar, and much simpler to implement than earlier attempts using Al (17) or Mo (18) to lift off SiO₂ deposited at ~300°C by plasma-CVD.

The remainder of this paper describes methods of photo-CVD, characterization of the resulting SiO₂ films, applications to Si device technology, and extensions to other semiconductor technologies.

Methods of Photo-CVD

There are two basic photo-CVD mechanisms: Hg-sensitized photolysis and direct photolysis (14, 15). A new technique of laser photolysis is a promising extension of direct photolysis.

The reactor system for the Hg-sensitized photo-CVD is similar to other low pressure CVD systems. The difference is the source of excitation. The reaction chamber employs a UV-grade quartz window above a heated substrate platform, and low pressure Hg lamps provide UV illumination on the substrate. Figure 1 is a schematic of such a reactor system. Note that the Hg reservoir in the gas inlet manifold provides minute quantities of Hg vapor to the reactant stream. During photo-CVD, Hg vapor resonantly absorbs UV radiation at a wavelength of 2537Å and catalytically transfers energy to the reactant gases via the reaction

In Hg-sensitized photo-CVD, N₂O is typically the oxygen source because it readily reacts with excited Hg atoms and yields neutral atomic oxygen in the ground state

The ground-state oxygen atom can convert many reactant gases to their respective oxides. For example, SiH₄ reacts spontaneously with atomic oxygen to form the monoxide or dioxide

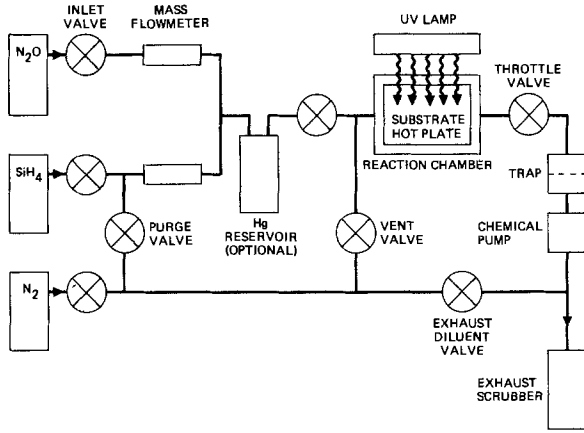

Fig. 1. Schematic of PHOTOX reactor system

SiH_4 can also react with excited Hg atoms to form an amorphous silicon (19)

It is possible to deposit films of the desired O to Si stoichiometry (SiO_x , $0 \leq x \leq 2$) by varying the SiH_4 -to- N_2O flow ratio. At one extreme (low $\text{SiH}_4/\text{N}_2\text{O}$), SiO_2 forms; at the other extreme (pure SiH_4), a-Si:H forms; and at intermediate ratios, SiO_x forms. SiO and SiO_2 have indexes near 2.0 and 1.45, respectively, and different mixtures have different indexes between these limits. Figure 2 shows a linear relation of film refractive index to the $\text{SiH}_4/\text{N}_2\text{O}$ flow ratio.

The deposition rate depends primarily on UV intensity and weakly on substrate temperature (temperature affects film density and etch rate). The deposition rate, along with stoichiometry and uniformity, also depends on the reaction chamber geometry, chamber pressure, and pumping speed. A rate of $\sim 150 \text{ \AA}/\text{min}$, spread uniformly over an area of $\sim 150 \text{ cm}^2$, is routinely achieved in a square reaction chamber with a window area of $\sim 650 \text{ cm}^2$.

Photo-CVD is not limited to silicon oxides and amorphous silicon. Photo-CVD of P-doped SiO_2 and SiO_xN_y films can be accomplished with the addition of the reactant gases PH_3 and NH_3 , respectively (14, 20). Photo-CVD of alumina can also be accomplished by replacing SiH_4 with $\text{Al}(\text{CH}_3)_3$ (21).

An alternative to the Hg-sensitized method is direct photolysis employing UV excitation of reactant gases. The reactor system is the same as shown in Fig. 1, but without the Hg reservoir. UV radiation at a high enough

Fig. 2. PHOTOX- SiO_x (100°C) refractive index vs. reactant gas ratio

energy splits N_2O directly and produces oxygen in an excited state

Upon collisional relaxation of the $\text{O}(^1\text{D})$ to the ground state, deposition proceeds according to Eq. [3]. A good choice of wavelength is 1849 \AA because it is readily obtainable from low pressure Hg lamps, and because SiH_4 is nearly transparent in this region of the spectrum.

The deposition rate of direct photolysis, however, is lower than with the Hg-sensitized process by about an order of magnitude. This is thought to be primarily a result of lower intensity at the required wavelength and inefficiency in Eq. [3]. Where no Hg contamination can be tolerated, there may be an advantage to using the direct photolytic method over the Hg-sensitized method. However, no detrimental effects with MOS devices have yet been ascribed to Hg contamination. Trace analyses for Hg content will be discussed in the next section.

A new direct photolytic method using an ArF laser with a wavelength of 1930 \AA , was recently described (22, 23). In this method, the laser beam (a much more powerful UV source) passes about $\sim 1 \text{ mm}$ parallel to the substrate surface, and deposition proceeds at rates up to $\sim 3000 \text{ \AA}/\text{min}$. Uniform deposition has occurred over a rectangular area $\sim 1 \text{ cm}$ wide, the width of the beam. This laser-CVD is very promising for many applications which require a very high deposition rate.

Properties of PHOTOX SiO_2

Table I lists a number of optical, electrical, physical, and chemical properties of PHOTOX- SiO_2 films and those of thermal- SiO_2 films (24). PHOTOX SiO_2 deposited at 200°C is quite similar to thermal SiO_2 grown at $>900^\circ\text{C}$. Upon annealing for short periods, the etch rates of PHOTOX SiO_2 approach those of thermal SiO_2 .

Excellent adhesion has been observed for PHOTOX SiO_2 on Si substrate. As shown in Table I, adhesive strength as high as $69 \times 10^6 \text{ Pa}$ was obtained from PHOTOX SiO_2 film. Film adhesion was measured by pulling tensile specimens, which were formed by cementing metal studs to a film on Si substrate. The adhesive strength for PHOTOX SiO_2 on Si substrate, however, is less than the PHOTOX SiO_2 adhesion by about an order of magnitude (25).

Figure 3 compares the infrared spectrum of a 4600 \AA thick film of PHOTOX SiO_2 produced at 200°C with the spectrum of a 4000 \AA thick film of thermal SiO_2 produced at 925°C . These spectra were obtained using Fourier transform techniques and subtracting the absorption of bare substrates (wafers of intrinsic Si, resistivity $> 10^4$

Fig. 3. IR spectra of 4600Å thick PHOTOX-SiO₂ (200°C) and 4000Å thick thermal SiO₂.

Ω-cm). The absorbance levels for both spectra were identical. The PHOTOX spectra was offset for clarity. The spectra are quite similar in all the absorption peaks (peak 3-6), except for small OH stretch mode (shown as peak 1 and 2) in PHOTOX SiO₂. Using calibrated formulas, analysis of this spectral structure gives a water content of ~2% by weight in the PHOTOX SiO₂.

Hydroxyl ions and water molecules are common in SiO₂ films deposited at low temperatures, and the water content may be as much as 5% by weight if they are not annealed above 800°C (26).

Auger electron spectroscopy (AES), electron spectroscopy for chemical analysis (ESCA), and Rutherford backscattering spectroscopy (RBS) have all been used to characterize PHOTOX SiO₂ deposited on Si. Figure 4 shows the peak-to-peak AES signals for O, Si, P, and C vs. etch time for a 1000Å PHOTOX film. On the same sample, ESCA data were obtained after removing 200Å. The elemental percentages determined are shown in Table II. For comparison, Table II also lists the elemental percentages of control samples of thermal SiO₂, P-doped PHOTOX SiO₂, and a PHOTOX SiO_xN_y sample. Within background experimental errors (~5%), PHOTOX SiO₂ has the 2:1 O:Si ratio expected for SiO₂. RBS experiments were unable to detect Hg in Hg-sensitized photolysis (limit ~100 ppm).

Figure 5 displays capacitance-voltage (C-V) behavior at 1 MHz of a MOS device before and after bias-temperature stressing (10V on gate for 5 min at 200°C). The metal is Al, the dielectric is 1000Å of PHOTOX SiO₂ produced at 200°C, and the semiconductor is ~5 Ω-cm n-type. These C-V curves show well-behaved MOS characteristics with

a flatband voltage shift (ΔV_{FB}) of $-0.3V$, yielding a mobile-ion surface density of $8 \times 10^{10} \text{ cm}^{-2}$. This quantity is not excessive, but it is higher than the $\sim 1 \times 10^{10} \text{ cm}^{-2}$ produced by well-established thermal oxidation processes.

To summarize, PHOTOX SiO₂ has properties and characteristics that are comparable with thermal SiO₂ produced at much higher temperatures. This suggests the compatibility of PHOTOX SiO₂ for insertion into Si device technology.

Applications to Si Technology

Low temperature photo-CVD may be useful in many processing steps of MOS IC fabrication where high temperature thermal oxidation and conventional CVD may induce problems. Table III lists the sequence of a basic MOS fabrication process and the steps where photo-CVD technology may be considered to replace the conventional technique. Figure 6 shows a cross section of the corresponding MOSFET device. Of the five different insulating films that might be provided by photo-CVD, different requirements lead to separate evaluations of each case. This section primarily discusses application to lateral isolation and interlevel isolation, and briefly summarizes other applications.

Lateral isolation.— In standard IC's, a relatively thick ($\geq 0.4 \mu\text{m}$) field insulator provides a high field inversion voltage for electrical isolation between transistors. The pinhole density of the material used for the field insulator must be low, and the residual charge density must be minimal in order to avoid leakage and field inversion. It must also be compatible with standard MOS IC processing steps such as etching and various anneals.

NMOS transistors have been made with a $0.4 \mu\text{m}$ thick PHOTOX SiO₂ as the field insulator in a process using conventional window isolation. The standard process takes several hours at 925°C to grow a $0.4 \mu\text{m}$ thick thermal oxide, but with photo-CVD at 100°–200°C, it takes less than 30 min. It is difficult to transfer a precise IC pattern into the as-deposited PHOTOX SiO₂ because of its high etch rate. However, PHOTOX SiO₂ densified at 925°C for 15 min etches at nearly the same rate as that of a

thermal-SiO₂ film (Table I). Figure 7 compares an IC test pattern etched into various 0.4 μm thick SiO₂ films using a buffered HF etchant. Notice that the pattern is well defined in densified PHOTOX SiO₂. In addition, PHOTOX-SiO₂ films do not exhibit stress or adhesion problems after the thermal cycling. Films subjected to the entire IC process show no degradation in integrity.

The most important requirement of PHOTOX SiO₂ in this isolation application is low leakage current (< 1 pA) between transistors with a common gate. Figure 8 shows the leakage current for a PHOTOX SiO₂ isolation oxide with a spacing of 1.6 μm between two transistors. Leakage is < 1 pA for a gate voltage of ~14V, and the corresponding field inversion voltage (typically defined as the gate voltage at a leakage of 1 μA) is ~20V. These characteristics provide a sufficient margin of isolation among MOS transistors operated with a standard 5V power supply.

Because of the unique capability of depositing high quality SiO₂ at a low temperature, PHOTOX can be used to achieve a novel isoplanar isolation (16). In this technique, a photoresist pattern is used to mask the transistor areas on a bare Si wafer while the field region is etched to a depth of 0.4 μm. PHOTOX SiO₂ is then deposited uniformly to a thickness of 0.4 μm. Finally, the photoresist is lifted off with an ultrasonic solvent bath to remove the excess PHOTOX SiO₂ and expose the active areas for subsequent processing. Although more work is needed to establish a reproducible lift-off technique that is suitable

Fig. 8. Subthreshold leakage current under the field insulator formed by PHOTOX-SiO₂.

for high yield IC processing, this simple technique provides a fully recessed, isoplanar structure, as shown in Fig. 9.

With this isoplanar isolation structure, field oxide encroachment (the "bird's beak") is completely eliminated, and thermally induced defects are avoided. MOSFET's with excellent device characteristics have been fabricated, and narrow channel effects have been virtually eliminated, as shown in Fig. 10. Here, identical MOSFET threshold voltages were found with varying channel widths down to 1.6 μm, the narrowest width attempted. Figure 11 shows the gain of these MOSFET's improves dramatically over MOSFET's fabricated with the nonplanar window isolation method. The result of modeling studies of these two structures, have shown that with the isoplanar structure, field pinching in the channel is minimal, resulting in the absence of narrow channel effects (16).

Interlevel isolation.—The use of PHOTOX SiO₂ between two levels of Al metalization has been studied as a replacement for conventional CVD processes (12). A test chip was fabricated containing a large area capacitor, several via chains with 100 vias/chain, and a serpentine capacitor with a total of 1200 perpendicular crossovers. Figure 12 shows the serpentine capacitor with two perpendicularly crossing levels of Al metalization isolated by PHOTOX-SiO₂. Several wafer lots were prepared using 1 μm thick PHOTOX-SiO₂ films deposited at 200°C. Excellent mechanical properties, such as conformal coating, smooth surface morphology, low defect density, and

Fig. 9. SEM micrograph of an isoplanar structure produced by photoresist lift-off of PHOTOX-SiO₂.

Fig. 10. I-V measurements for N-MOSFET threshold voltage (plotted in insert) as a function of channel width.

good adhesion, were obtained with the PHOTOX-SiO₂ films. The 1 μm thick films deposited on Al substrates showed pinhole densities of < 3-7 cm⁻² and dielectric strengths of > 3 × 10⁶ V/cm. Electrically active defect densities were estimated by the Poisson relation ($Y = e^{-DA}$), where Y is the capacitor yield, D is the defect density, and A is the capacitor area. Table IV shows the experimental yield obtained from three different wafer lots. The absence of Al hillock formation in PHOTOX-SiO₂ is believed to be a major reason for the high yields shown.

Other applications.—As a gate insulator, PHOTOX-SiO₂ must demonstrate low leakage, high dielectric strength,

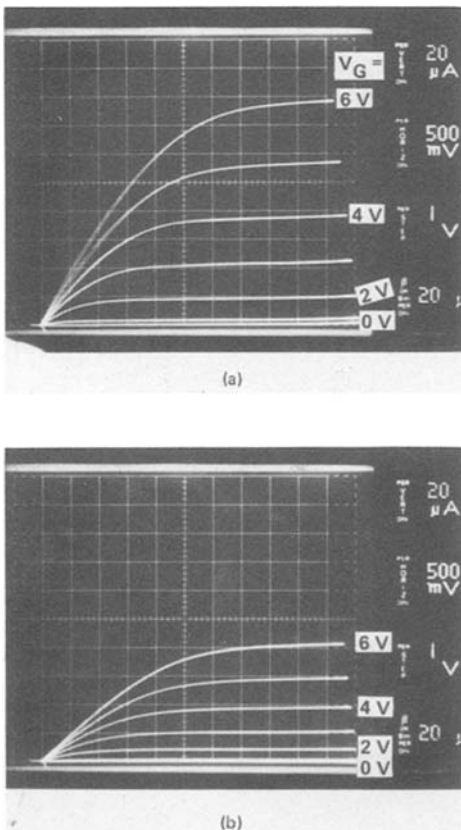

Fig. 11. I-V curves of narrow-channel MOSFET's fabricated by (a) isoplanar PHOTOX and (b) nonplanar technique. Channel widths are 1.5 μm for both cases.

Fig. 12. SEM micrographs of double-level Al isolated by PHOTOX-SiO₂.

low mobile-ion density, and a low interface density of states. For insertion into Si technology, it should be better than standard thermal oxides, which are usually produced in a short period (<30 min) at temperatures of 800°–1000°C. Although the mobile ion density in PHOTOX-SiO₂ is not excessive (see the “Properties” section, above) it cannot compete with the excellent interface properties of thermal SiO₂. PHOTOX-SiO₂ may be employed, however, with semiconductors that do not have a good native oxide or that are temperature sensitive. For example, SiO₂ deposited by photo-CVD at 100°C has demonstrated good passivation characteristics of HgCdTe (27) operated at 77 K. PHOTOX-SiO₂ has also been used to passivate InP devices operated at room temperature (14). Another promising gate insulator material is PHOTOX-Al₂O₃ (21).

Another application of PHOTOX-SiO₂ is P-doped SiO₂, which reflows at a temperature low enough (~950°C) to avoid significant amount of dopant diffusion in the silicon substrate. Such a reflow provides sloped and smooth oxide contours over relatively sharp poly-Si corners. P-doped SiO₂ may also be useful as a barrier against mobile ions. P-doped PHOTOX-SiO₂ has been demonstrated, but significant characterization data are not yet available.

PHOTOX-SiO_xN_y has been employed as a final passivation to coat fully wire bonded lead-frame assemblies (20). It was found that this material was compatible with the assemblies and could protect devices from metallic particles. It was also found that the PHOTOX-SiO_xN_y was comparable to the nitride produced by plasma-CVD (28). (Nitride films are preferred for their barrier resistance to moisture and mobile ions.) Another promising material with high barrier resistance is PHOTOX-Al₂O₃, which has also been deposited with photo-CVD.

Summary

Isolation is critical for achieving high density circuits in VLSI. Furthermore, avoiding high temperatures during fabrication of small device structures is desirable because it reduces dopant redistribution, defect generation, and Al/Si degradation. Low temperature processes could be employed in VLSI fabrication for lateral isolation among

Table IV. Evaluation of PHOTOX-SiO₂ (200°C) for interlevel insulator

active devices, and vertical isolation among multilevel metalizations.

The low temperature (50°–200°C) process of photochemical-assisted chemical vapor deposition (photo-CVD) meets these demands. Photo-CVD involves the discrete absorption of energy from UV radiation to initiate deposition. This process depends primarily on UV intensity and only weakly on substrate temperature, and it thus avoids the high temperatures and energies of thermal-CVD and plasma-CVD.

Photo-CVD SiO₂ (PHOTOX) has demonstrated excellent mechanical and electrical properties for isolation between two levels of Al metalization. This interlevel insulator provides low pinhole density ($\leq 3\text{--}7\text{ cm}^{-2}$), high breakdown strength ($\geq 3\text{ MV/cm}$), and good uniformity ($> 3\%$ across a 4 in. wafer). Furthermore, the low temperature processing minimizes Al/Si interdiffusion and Al hillock formation, which occur at higher temperatures.

Photo-CVD at temperatures ($\sim 100^\circ\text{C}$) permits a simple lift-off technique for achieving a fully recessed, isoplanar field isolation. Narrow channel MOSFET's fabricated with this technique escape the "bird's beak" formation that accompanies high temperature oxidation, achieve much larger gain, and do not have narrow channel effects.

One major concern in applying Hg-sensitized PHOTOX films in Si processing is Hg contamination. Although RBS measurements did not detect Hg in these films, the detection sensitivity ($\sim 100\text{ ppm}$) is not high enough. Hg contamination as high as 10^{18} cm^{-3} could be present in these films. The Hg impurities which may not have deleterious effect in MOS devices can be detrimental to minority-carrier devices such as bipolar transistors. More analyses are needed to determine the actual concentration of Hg atoms in the Hg-sensitized PHOTOX films. Although one can apply PHOTOX films by direct photolysis, the deposition process is very slow ($15\text{--}30\text{ \AA}/\text{min}$). Even with Hg-sensitized process, we can only obtain a rate of $150\text{ \AA}/\text{min}$, whereas laser-CVD can provide deposition rate up to $\sim 3000\text{ \AA}/\text{min}$. The low PHOTOX deposition rate has been a limitation in the application of PHOTOX to Si production process. Furthermore, the uniformity of film thickness can also limit wafer production. Although the uniformity over a 4 in. wafer is better than 3%, the uniformity across the entire substrate heater (which holds five 4 in. wafers) is $\sim \pm 10\%$ (25). At present, wafer throughput is limited due to the low deposition rate and nonuniformity among wafers.

Applications of photo-CVD extend beyond isolation in Si technology. The benign nature of photo-CVD permits processing on sensitive substrates such as InP and other temperature-sensitive compound semiconductors. Finally, photo-CVD is not limited to SiO₂; PHOTOX-SiO_xN_y and PHOTOX-Al₂O₃ have been demonstrated for high quality dielectrics.

Ion Beam Exposure of Polymer Resist PMMA

N. Chan Tung

Centre National d'Etudes des Télécommunications, B. P. 98, 38243 Meylan, France

ABSTRACT

Ion beam exposure characteristics of a positive polymer resist, polymethylmetacrylate (PMMA) have been investigated. The samples were irradiated with B^+ ions in the energy range of 20–160 keV, the ion dose varying between 8×10^{11} and $5 \times 10^{13} \text{ cm}^{-2}$. In the energy range considered, beam sensitivity and resist contrast were found to be between $4.5 \times 10^{12} \text{ cm}^{-2}$ and 2.3–2.5, respectively. An empirical formula is proposed to approximate the characteristic dissolution curves (thickness removed *vs.* dissolution time). The empirical values agree with the experimental results within an accuracy better than 12%. A procedure is described whereby the total number of scission chain fragments as a function of resist depth may be extracted from the experimental curves.

Ion beam lithography is a novel technique which bypasses some of the drawbacks of electron beam lithography. In general, resists are more sensitive to ions than to electrons. This is due to a greater energy deposition per unit volume. Another advantage in ion beam lithography is its feeble lateral spread (100Å) for heavy ions. Ion beams, as compared to electron beams, produce low energy electrons and negligible amount of high energy backscattered electrons. In the case of direct writing using an ion beam, pattern dimensions are limited only by the beam size. Indeed, pattern dimensions inferior to 1000Å (1, 2) have been obtained with a liquid-metal gallium ion source.

Ion lithography can be carried out in two different ways: through direct writing and through the ion projection exposure technique as developed by Sacher Technik Wien (3). A liquid metal ion source (4–8) can be used for direct writing, as in electron beam lithography, but with reduced computing time owing to the absence of proximity effects and enhanced ion sensitivity. Another method of transferring patterns to resists is through direct contact masking of the resist; channeling (9) may also be used; typical mask to resist distances are 20 μm .

Komuro *et al.* (10) have investigated the ion beam sensitivity of positive PMMA and negative PDMS (polydimethylsiloxane) using He^+ ions (60 and 200 keV) and Ar^+ ions (150 and 250 keV). According to their measurements, the calculated Gel and Gn values are 1.7 and 0.9, respectively, for PMMA whose average molecular weight is 1.85×10^5 . Gel and Gn are the radiation yields per 100 eV absorbed for main chain scission brought about by electronic and nuclear collisions, respectively. Hall *et al.* (11) have studied the behavior of positive and negative resists using high energy ions: hydrogen, helium, and oxygen at 1.5 MeV. They proposed a model to account for the variation of the energy distribution around the particle track in terms of the number of sites required for exposure. Ryssel *et al.* (12) presented the dissolution characteristics of both positive and negative resists exposed to argon, gallium, hydrogen, and helium ions.

Karapiperis *et al.* (13) have used Monte Carlo computer simulations to calculate the electronic and nuclear energy losses of 60 keV H^+ ions in PMMA. For these ions, electronic energy losses per unit length predominate. The electronic energy loss *vs.* resist depth is initially a slowly decreasing curve, which then falls rapidly.

At the resist surface the energy loss value is 1.14×10^9 eV/cm/particle. Gel permeation chromatography (GPC) measurements reveal that Gel = 0.7 for 100 keV H^+ ions (14). Dissolution characteristics were carried out for 50 keV H^+ ions for an ion dose varying between 9×10^{12} and $2 \times 10^{13} \text{ cm}^{-2}$. Maximum removed thickness measurements were also carried out by Adesida (14) for H^+ ions (40–300 keV) and for B^+ ions (50–300 keV). To our knowledge, no dissolution characteristics (developed depth *vs.* time curves) for these H^+ ions, with the exception of those for 50 keV, nor for B^+ ions have been published by Adesida; only maximum removed thickness measurements have been presented.

In this work, the dissolution characteristics of PMMA. (Elvacite 2041) are presented. The resist was irradiated with B^+ ions whose energy varies between 20 and 120 keV. An empirical formula is proposed to approximate the dissolution curves. Using these data, and applying Greeneich's model (15) modified by Komuro to 160 keV ions, the total number of scission fragments *vs.* resist depth is extracted for 20, 40, and 80 keV B^+ ions.

Experimental Procedure

The PMMA used for our experiments has an average number molecular weight of 1.93×10^5 (value given by du Pont). The resist was dissolved in trichloroethylene, the concentration of the solution depending upon the desired thickness. Different resist thicknesses ranging from 0.2 to 0.9 μm were spin-coated onto clean silicon wafers; the thickness chosen depended upon the energy of the impinging ions.

The coated wafers were prebaked for 30 min at 160°C. After exposure to the ion beam, the wafer was cleaved into samples, and its thickness measured by a commercially available Rudolf ellipsometer ($\lambda = 632.8 \text{ nm}$). For each cleaved piece, the thickness was measured at five different points in a cross-like manner near the center. The mean value of the measurements was considered as the initial resist thickness. In all our measurements, the refractive index of the resist was fixed to 1.488.

Each sample was then developed in a solution of methyl isobutyl ketone (MIBK) and iso-propyl alcohol (IPA) in the proportion of 1:2. The development varied from 6s to 20 min; the temperature of the developer was between 18° and 21°C. The sample was rinsed in an IPA bath stirred by a magnetic agitator and blown dry with nitrogen.

The resist was then postbaked for 30 min at 160°C. Final thickness measurements were then carried out as described above, by ellipsometry. Repetitive ellipsometric thickness measurements made at the same point (without moving the sample), differed only by a few angstroms from run to run. The difference between the initial and final values gave the removed resist thickness. The removed thickness measurements as performed by ellipsometry were compared to those done using a Talystep (before and after development). For B^+ 40 keV ions (doses = 3×10^{12} and $7 \times 10^{12} \text{ cm}^{-2}$), the removed thickness (as measured by the two different methods) differ from one another by about 80Å.

Results and Discussion

Dissolution characteristics.—The dissolution characteristics of PMMA exposed with B^+ ions of 20, 40, and 80 keV are shown in Fig. 1, 2, and 3, respectively, the irradiation dose ranging between 8×10^{11} and $5 \times 10^{13} \text{ cm}^{-2}$. Based on these curves, the following remarks can be made: first, for a given ion energy, the saturation value of the removed thickness rises slowly with increasing ion dose. For 40 keV ions, the saturation thickness increases from 2340 to 2700Å when the dose is increased from 7×10^{12} to $5 \times 10^{13} \text{ cm}^{-2}$. This slow saturation thickness increase

Fig. 1. Characteristic dissolution curves of 20 keV B⁺ ions.

may be due to the fact that towards the end of the ion range, an increase in the ion dose does not bring about any substantial increase in the number of chain scission fragments per unit volume. This can be interpreted in terms of absorbed energy density threshold. Saturated removed resist thickness have also been observed by Ryssel (12) for other ions. Second, for the removal of a given nonsaturated resist thickness, the necessary dissolution time decreases for increasing ion doses. An ion dose increase means an augmentation of the energy deposited per unit volume. This in turn leads to an increase in the number of chain scissions per unit volume and, thus, an increase of the dissolution speed. Finally, the saturated removed thickness increases with ion energy. This is attributed to a greater ion range within the resist for increasing energy. As has been explained elsewhere (14), the saturated developed depth can be taken as the mean path length in PMMA for light ions.

For the highest dose used (i.e., $5 \times 10^{13} \text{ cm}^{-2}$), the maximum removed thicknesses are, respectively: 1550, 2700,

and 4500 Å for 20, 40, and 80 keV ions. The experimental values of the dissolution curves are shown Fig. 1-3.

Proposed empirical formula.—The experimental data can be approximated by means of an empirical formula of the form

$$z(t) = a(1 - \exp^{-bt}) + c \cdot t^d$$

where: z is the removed thickness, t the dissolution time, and a , b , c , and d adjustable parameters. The overall calculated values (solid lines, Fig. 1-3) agree with the experimental results within 12%. For a development time greater than 3 min, the agreement falls within 6%. The parameters are adjusted in order to minimize the difference between observed and calculated curves over the dissolution time range. Table I shows the values of the constants a , b , c , and d used for 40 keV B⁺ ions and the maximum percentage difference between the calculated and the experimental data over the considered dissolution time. The empirical formula allows calculation of the dissolution speed (dz/dt) of the resist for a given depth.

Fig. 2. Characteristic dissolution curves of 40 keV B⁺ ions.

Fig. 3. Characteristic dissolution curves of 80 keV B⁺ ions.

Fig. 4. Characteristic dissolution curves of 160 keV B⁺ ions and comparison with Komuro's model.

The value of *a* (except for $1 \times 10^{13} \text{ cm}^{-2}$), *b* (except for $3 \times 10^{12} \text{ cm}^{-2}$), and *c* increase with the ion dose since an increase in the dose brings about an increase in the removed thickness for a given time *t*. For the 40 keV ions, the maximum percentage difference between calculated and experimental results is 11.7%.

Table I. Values of adjusted parameters *a*, *b*, *c*, and *d* used for B⁺ 40 keV ions and maximum percentage difference between empirical and experimental results

Ion dose (cm ⁻²)	Values of the adjusted constants for B ⁺ 40 keV ions				Maximum percentage difference between empirical and calculated values
	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	
2×10^{12}	200	0.3	60	0.9	7.5
3×10^{12}	900	0.2	100	0.6	9.3
4×10^{12}	1400	0.6	100	0.6	11.7
5×10^{12}	1500	0.6	200	0.4	10.7
7×10^{12}	2100	1.6	200	0.1	8.9
1×10^{13}	1300	3.1	900	0.1	11.7

The dissolution characteristics for B⁺ 160 keV ions are shown in Fig. 4. No dissolution time lag has been observed in these curves (Fig. 1-4). The same observation has been made by Hoffmann *et al.* (16). It must, however, be noted that time-lag phenomena have been observed by Komuro. Owing to lack of experimental data, this point is still not clear.

Total number of chain scission vs. resist depth.—The calculations performed to extract the total number of chain scissions vs. resist depth are as follows.

Table II. Comparison of ion sensitivity and contrast of B⁺ ions (20-160 keV) to 20 keV electrons

Type	Ion energy (keV)				Electron energy (keV)
	20	40	80	160	
Sensitivity (cm ⁻²)	5×10^{12}	4.1×10^{12}	4.4×10^{12}	5×10^{12}	$2.5-5 \times 10^{14}$
Contrast	2.3	2.4	2.5	2.5	2-3

Fig. 5. Total number of chain scissions vs. resist depth for 20 keV B⁺ ions (a), for 40 keV B⁺ ions (b), and for 80 keV B⁺ ions (c).

For a given depth z , the development speed is given by the Greenich (15) formula

$$\frac{dz}{dt} = R_0 + \frac{\beta}{M_f^\alpha} \quad [1]$$

where R_0 , β , and α are fitted constants, and M_f is the fragmented average molecular weight after energy exposure. M_f is related to M_n (initial number average molecular weight) by

$$\frac{1}{M_f} = \frac{1}{M_n} + \text{Dose} \left\{ \frac{\text{Gel Sel}(z) + \text{Gn Sn}(z)}{\rho N_a 100} \right\} \quad [2]$$

where ρ is the resist density, N_a Avogadro's number, Gel, Gn the radiation yields for main chain scission caused by electronic and nuclear collisions respectively (events/100 eV) and Sel(z) and Sn(z) the energy deposition rates of the ion beam resulting from electronic and nuclear collisions (eV/cm). ρ is taken to be 1.2. The parameter [Gel Sel(z) + Gn Sn(z)]/100 denoted by $G S(z)/100$ represents the total number of chain scissions (nuclear + electronic)/unit length/particle brought about by ion exposure. Combining Eq. [1] and [2], the development speed (from Greenich's model modified by Komuro) is given by

$$\frac{dz}{dt} = R_0 + \beta \left[\frac{1}{M_n} + \frac{\text{Dose} \{ \text{Gel Sel}(z) + \text{Gn Sn}(z) \}}{N_a \rho 100} \right] \quad [3]$$

The left-hand side of Eq. [3] is calculated from the empirical formula approximation described above. The values of M_n , dose, ρ , and N_a are known.

For 160 keV B^+ ions, the values of R_0 , β , and α are chosen such that for the various ion doses $1 \times 10^{12} - 5 \times 10^{12} \text{ cm}^{-2}$, the $G.S(z)/100$ values vs. resist depth form a quasi-unique curve, similar in shape to Fig. 5a, 5b, and 5c. For a given ion energy, the $G.S(z)/100$ curve is independent of the ion dose since we are comparing chain scission numbers for one particle.

The values of the constants are: $R_0 = 0 \text{ \AA}/\text{min}$, $\beta = 4 \times 10^{18} \text{ \AA}/\text{min}$, and $\alpha = 4$. In order to test the validity of the values of R_0 , β , and α , the removed thickness d is calculated by

$$T = \int_0^d \frac{dz}{R_0 + \beta \left\{ \frac{1}{M_n} + \frac{\text{Dose} G.S(z)}{\rho N_a 100} \right\}^\alpha} \quad [4]$$

where T is the dissolution time.

The calculated curves (solid lines in Fig. 4) agree with the experimental measurements. Using the procedure described above, the total number of chain scissions for 20, 40, and 80 keV ions are shown in Fig. 5a, 5b, and 5c, respectively, the ion doses varying between 3×10^{12} and $1 \times 10^{13} \text{ cm}^{-2}$. The values of R_0 , β , and α are those reported above. These curves give rise to the following remarks.

1. The shape of the extracted curves (chain scission numbers vs. resist depth) is similar to that calculated directly by both Karapiperis (H^+ 60 keV) and Komuro (electronic energy loss vs. resist depth calculations). That is, the typical curve is initially a slowly decreasing curve which decreases rapidly. Our extracted curves can be compared to those calculated by these authors as only a proportionality factor separates them.

2. For a given ion energy, the $G.S(z)/100$ curve is independent of the ion dose. This is as expected since we are comparing chain scission numbers for one particle; otherwise, the parameters R_0 , β , and α would be incorrect.

3. At the origin ($z = 0$), $G.S(z)/100 \sim 10^7/\text{cm}/\text{particle}$. This result is compatible with that calculated by Karapiperis (13), who obtained $\sim 8 \times 10^6/\text{cm}/\text{particle}$ for H^+ 60 keV (Sel $\sim 1.4 \times 10^9 \text{ eV}/\text{cm}$; Gel = 0.7) (13).

4. The number of chain scissions $G.S(z)/100$ increases with ion energy; this is due to an increase in the deposited energy.

Resist sensitivity and contrast.—Irradiated resists are commonly characterized by their sensitivity and contrast.

Fig. 6. Comparison of our maximum removed thickness measurements with Adesida's.

Sensitivity is defined as the fluence required to remove 50% of the resist thickness. Table II compares our results for B^+ ions (20-160 keV) to those published by Ryssel (12) for 20 keV electrons. In our case, the development time was fixed to 3 min. The resist is 60-100 times more sensitive to B^+ ions than to 20 keV electrons. From the point of view of contrast, ions are comparable to electrons. A resist sensitivity of $5 \times 10^{12} \text{ cm}^{-2}$ is amply sufficient for technological applications. To our knowledge, no PMMA Elvacite 2041 resist sensitivity and contrast results have been published in the literature for B^+ ions.

Figure 6 compares our maximum removed thickness for B^+ ions (20-160 keV) to those measured by Adesida for the same ions at an energy of 50-300 keV. Our experimental results are in good agreement.

Conclusion

An empirical formula has been proposed to approximate the characteristic dissolution curves of B^+ ions in the energy range of 20-160 keV. The calculated values agree with the experimental results within an accuracy of, or better than, 12%. This formula may be extended to the dissolution curves of other charged particles. Our maximum removed thickness measurements are in good agreement with the results of Adesida for the same ions. A resist sensitivity of $4.5 \times 10^{12} \text{ cm}^{-2}$ is obtained for B^+ ions (20-160 keV); this is sufficient from the point of view of technological applications. Comparison of B^+ ion sensitivity to that of 20 keV electrons shows an enhancement factor of 60 to 100 for the ion beam with respect to the electron beam (in terms of particle fluence).

A procedure is described wherein the total number of chain scission fragments as a function of resist depth may be extracted from experimental dissolution curves. These extracted curves are comparable to those calculated directly by means of computer simulations by others. This procedure has the advantage of saving time, since it is relatively easy to put into practice.

Acknowledgments

The author wishes to thank the Polymer Group for their help in resist-coating, J. P. Dœuvre and A. Brun for the ion implantation, and A. Golanski and J. L. Buevoz for discussions and interest shown in this work. Our thanks are also extended to L. Karapiperis for the review of this paper and to J. Dargent for the linguistic corrections.

Thermodynamics and Phase Diagram of Pseudobinary ZnTe-CdTe System

L. A. Zabdyr

Institute for Metal Research, Polish Academy of Sciences, 30-059 Kraków, Poland

ABSTRACT

The thermodynamic properties of solid ZnTe and CdTe as well as of pseudobinary ZnTe-CdTe solid solutions have been determined by means of EMF technique. Results for ZnTe-CdTe solid solutions have been interpreted by regular solution model with the parameter $\alpha^s = -80$ cal. Based on the solidus and liquidus data of Steininger, Strauss, and Brebrick and assuming liquid solution to be regular, the solution parameter $\alpha^l = +50$ cal has been calculated. Finally, phase diagram calculations have been performed using the parameters mentioned above. The results seem to fit experimental solidus and liquidus data excellently.

The development of crystal-growth technique from the melt has created a need for accurate thermodynamic data and a knowledge of the phase equilibria in semiconductor alloy systems. A strong interest exists, especially in systems forming pseudobinary solid solutions. The ability for variation of electron properties with composition makes them very useful in semiconductor industry.

The pseudobinary ZnTe-CdTe system forms a complete series of solid solutions with lattice parameter following Vegard's rule. This has been first confirmed by Goryunova and Fedorova (1). Gromakov *et al.* (2) have performed thermal analysis study to determine ZnTe-CdTe phase diagram, but their results were more than 40 K lower than the most recent data, even for pure compounds. Steininger *et al.* (3) have carried out extensive studies on ternary Zn-Cd-Te and pseudobinary ZnTe-CdTe systems by means of thermal analysis. Their liquidus data combined with ideal solution model for both solid and liquid phases resulted in pseudobinary phase diagram. Laugier (4) obtained solid solution parameter $\alpha^s = 1340$ cal assuming ideal liquid and regular solid solution by fitting experimental data of Steininger *et al.* (3). His phase diagram differed slightly from that of Steininger *et al.*, but in both cases agreement with experimental data was satisfactory. A regular solution model for both solid and liquid phases and the experimental data of Steininger have been combined by Ilegems and Pearson (5) to adjust solid and liquid solution parameters, $\alpha^s = 100$ cal and $\alpha^l = -1300$ cal, respectively. The phase diagram calculated under those conditions was close to those given by Steininger and Laugier. Different best fit values of α parameters obtained from the same set of experimental data demonstrate that results for α^l depend on choice of α^s and vice versa.

In this situation, it seemed desirable to find the experimental value of at least one of solution parameters, and this was the main aim of this study. Having a well-developed EMF technique, it was decided to apply it for determination of thermodynamic properties of solid ZnTe-CdTe solutions.

Experimental

Two kinds of galvanic cells were used: cells of formation and concentration cells, both with liquid salt electrolyte. Formation cells of the type

were applied for redetermination of the formation properties for solid compounds ZnTe and CdTe. Formation cells of the type

were used to get free energy of formation of solid $\text{Zn}_x\text{Cd}_{1-x}\text{Te}$ compounds for a few x values. Finally, concentration cells

were employed for determination of activity of ZnTe in ZnTe-CdTe solid solution.

Electrode materials.—Zinc and cadmium of 5N purity were supplied by Zakład Doświadczalny at Skawina, Poland, and tellurium 99.99% was obtained from ASARCO, USA.

Alloy electrodes were prepared as follows: appropriate amounts of constituents were melted together in evacuated silica capsules, equilibrated at least 24h at about 50 K above liquidus and then rapidly cooled to the room temperature. Next, they were annealed for a long period at about 50 K below solidus. Samples prepared in this way were checked metallographically and x-ray analysis gave lattice parameters in accord with literature data.

Electrolyte constituents were obtained from several sources: KCl from POCH, Poland; LiCl from CHEMAPOL, Czechoslovakia; anhydrous ZnCl_2 and CdCl_2 from FLUKA AG, Germany and UCB, Belgium, respectively. Electrolyte compositions were as follows: 70 weight percent (w/o) ZnCl_2 , 18 w/o KCl, 12 w/o NaCl for the ZnTe version of cell [I]; 65 w/o ZnCl_2 , 8 w/o CdCl_2 , 18 w/o

KCl, 9 w/o NaCl for both the CdTe version of cell [I] and cell [II], and 43 w/o LiCl, 52 w/o KCl, and 5 w/o ZnCl₂ for cell [III]. Molybdenum wires sheathed by high melting glass tubes served as current leads. Cell assembly and experimental procedure were similar to those applied in one of previous works (6). Temperature was controlled by Pt-PtRh10 thermocouple and EMF readings were taken by a V 534 ELWRO, Poland, high resistance digital voltmeter from both heating and cooling cycles. Since solid-state reactions were involved, it took a long time to reach equilibrium at a certain temperature. In case of cell [III], it was at least 12h for a single measurement.

Results

Zinc-tellurium.—Alloys of eight compositions ranging from 90 to 98 atom percent (a/o) of Te were investigated at temperatures between 503 and 692 K, and linear dependence of EMF on temperature was found from 150 experimental points as follows

$$E(\pm 1.5) = 609.5(\pm 1.3) - 0.057(\pm 0.002)T \text{ (mV)}$$

Using the well-known relation: $\Delta G = -nFE$, the free energy of formation was calculated due to reaction

and

$$\Delta G_1(\pm 69) = -28117(\pm 137) + 2.63(\pm 0.21)T \text{ cal/mol} \quad [2]$$

Heat capacity data taken for ZnTe from Mills (7) enabled the calculation of the standard heat of formation, ΔH_{298}° and standard entropy S_{298}° for the solid zinc telluride. Numerical data are presented below.

Cadmium-tellurium.—Alloys of five compositions ranging from 80 to 97 a/o Te were investigated at temperatures between 619 and 719 K. Linear dependence of EMF on temperature was found as well from 84 experimental points

$$E(\pm 1.02) = 559.1(\pm 2.6) - 0.089(\pm 0.0039)T \text{ (mV)}$$

and free energy of formation of cadmium telluride was calculated as above due to reaction

and

$$\Delta G_3(\pm 47) = -25,792(\pm 120) + 4.11(\pm 0.18)T \text{ cal/mol} \quad [4]$$

Standard thermodynamic functions were calculated and presented as those for ZnTe compound.

Zinc-cadmium-tellurium.—Formation cells [II] were not as convenient in operation as cells [I] and gave considerable experimental errors. Results of only two out of eight compositions, *i.e.*, $x = 0.6$ and 0.3 , proved to be of the satisfactory accuracy. Reasons for that will be discussed later. An EMF *vs.* temperature plot for $x = 0.6$ is shown in Fig. 1 as an example. The overall cell [II] reaction

combined with fusion data for tellurium (8) and with mixing data for Zn-Cd liquid alloys (9) gave the free energy of formation of solid $\text{Zn}_x\text{Cd}_{1-x}\text{Te}$ compound from liquid constituents due to the reaction

and

$$\Delta G_5(x = 0.6) = -33,600 + 9.7T \text{ cal/mol} \quad [6]$$

$$\Delta G_5(x = 0.3) = -35,800 + 14.3T \text{ cal/mol} \quad [7]$$

Combining reactions [5], [1], and [3] with fusion data from zinc and tellurium (8), one may obtain the following reaction

Fig. 1. Plot of experimental EMF values on temperature for cell [II] at $x = 0.6$. Open and closed points represent results of different runs.

Fig. 2. Plot of experimental EMF values on temperature for cells [III] at x ranging from 0.1 to 0.8. Open and closed points represent results of different runs.

from ideality. To have more accurate values of ΔG^M , concentration cells [III] have been employed to realize reaction [8].

Preliminary experiments showed that high accuracy of EMF measurements is required, especially for high x values, to obtain reliable ΔG^E data.

Careful electrode and electrolyte preparation and many times repeated measurements resulted in EMF accuracy of order of 0.05 – 0.10 mV.

Twenty-four alloy compositions have been investigated with X_{ZnTe} ranging from 0.1 to 0.8 and with excess of tellurium of 60, 70, and 80 a/o, respectively, for each X_{ZnTe} value. EMF readings were taken at temperatures between 732 and 901 K, and a linear dependence on temperature was observed in all cases (Fig. 2). Partial free energy of mixing of ZnTe was calculated from experimental data using well-known relationship

$$\Delta\bar{G}_{\text{ZnTe}} = -nF E_{\text{III}}$$

with $n = 2$ and $F = 23.066$ cal/mV · mol.

Fig. 5. Pseudobinary ZnTe-CdTe phase diagram calculated for $\alpha^s = -80$ cal and $\alpha^l = +50$ cal (solid line). Dashed lines represent phase diagram after Steininger et al. (3), with their DTA data shown as points.

Table III. Comparison of thermodynamic properties of ZnTe and CdTe obtained in this work with respective data selected by Mills (7)

Thermodynamic function	Zinc telluride This work	Mills	Cadmium telluride This work	Mills
$-\Delta H_{298}^{\circ}$ (cal/mol)	27.87 ± 0.14	28.5 ± 0.1	24.09 ± 0.12	24.1 ± 0.2
S_{298}° (cal/mol · K)	19.68 ± 0.31	18.6 ± 0.5	23.04 ± 0.28	22.8 ± 0.5

Experimental data and calculated $\Delta\bar{G}_{\text{ZnTe}}^{\circ}$ and $\Delta G_{\text{ZnTe}}^{\text{E}}$ are listed in Table I. Analysis of last two columns of Table I leads to the conclusion that, within estimated error limits ranging from ± 2.3 to ± 4.6 cal, $\Delta G_{\text{ZnTe}}^{\text{E}}$ may be assumed to be independent of temperature and may be described by the regular solution model

$$\Delta G_{\text{ZnTe}}^{\text{E}} = \alpha^{\text{s}}(1 - X_{\text{ZnTe}})^2 \quad [9]$$

with solution parameter $\alpha^{\text{s}} = -80$ cal. Thus, other thermodynamic functions for pseudobinary solid solutions ZnTe-CdTe are as follows

$$\Delta G_{\text{CdTe}}^{\text{E}} = \alpha^{\text{s}}X_{\text{ZnTe}}^2 \quad [10]$$

and

$$\Delta G^{\text{E}} = \Delta H^{\text{M}} = \alpha^{\text{s}}(1 - X_{\text{ZnTe}})X_{\text{ZnTe}} \quad [11]$$

Plots of $\Delta G_{\text{ZnTe}}^{\text{E}}$ and ΔG^{E} vs. composition, calculated from [9] and [11], are presented in Fig. 3. As can be seen, relations [9] and [11] describe satisfactorily experimental data.

The free energy change for reaction [5], ΔG_{s} , may be calculated again from ΔG^{E} using Eq. [11] and a combination of ΔG_{s} and ΔG_{s} with the fusion data for zinc and tellurium. Results of such a calculation at 750 K are shown in Fig. 4. Finally, calculations were carried out to match regular solution model for the liquid phase with solidus-liquidus data of Steininger *et al.* (3) and experimentally determined parameter $\alpha^{\text{l}} = -80$ cal for the regular solid solution. The best fit value for the liquid solution parameter is $\alpha^{\text{l}} = +50$ cal.

Using fusion data for both compounds taken from Kulwicki (10) and the parameters derived above, phase diagram calculation has been performed, and the results are shown in Fig. 5 and listed in Table II.

Discussion

The values of standard thermodynamic functions for ZnTe and CdTe obtained in this work are compared with respective data selected by Mills (7) in Table III.

As can be seen, agreement is excellent, especially for cadmium compound.

In the case of cells [II], low melting electrolyte has been used containing ZnCl_2 and CdCl_2 . Since both zinc and cadmium ions present in the melt were in contact with liquid Zn-Cd electrode, a side reaction might occur

If reaction [12] goes to the right, it should decrease zinc content in liquid ZnCd electrode and move the points shown in Fig. 4 to the left.

On the other hand, a high concentration of ZnCl_2 in electrolyte might shift equilibrium of reaction [12] to the left.

To solve this problem exactly, thermodynamic data are needed for four-component system ZnCl_2 - CdCl_2 - KCl - LiCl and the knowledge of kinetics of possible reactions with metallic phase involved. Thus, free energy values calculated from [6] and [7] are of the qualitative character.

High accuracy EMF measurements from cells [III] enabled confirmation of slightly negative deviation of pseudobinary solid solution from ideality and description of its thermodynamic properties by regular solution model.

Moreover, one can calculate free energy of formation of ternary $\text{Zn}_x\text{Cd}_{1-x}\text{Te}$ compounds from their constituents along pseudobinary line.

Finally, calculated phase diagram seems to fit excellently both solidus and liquidus experimental data.

All mentioned error limits were calculated for 90% confidence level.

Heat Effects in Zircaloy Oxidation by Steam

Donald R. Olander

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Nuclear Engineering, University of California, Berkeley, California 94720

ABSTRACT

Partitioning of the heat of combustion during Zircaloy oxidation between the gas-oxide and oxide-metal interfaces was determined. The spatial distribution of the heat release is very sensitive to the poorly known partial molar enthalpy of oxygen dissolution in ZrO_2 . This uncertainty is of minor consequence in the thermal analysis, however, because temperature gradients in the specimen due to the heat released by oxidation are very small. The temperature is mainly a function only of time. A simple lumped-capacity thermal analysis suffices to describe the temperature transient initiated by the corrosion process. A method of coupling the temperature rise due to the heat release to the corrosion kinetics was developed.

Although oxidation of a metal is accompanied by considerable release of heat, most analyses of this process assume that the temperature of the reacting solid is specified by the external environment. However, when external heat removal rates are low, the heat of combustion can be a significant heat source, as was dramatically illustrated by the accident at the Three Mile Island nuclear reactor. In this case, the energy released by oxidation of the Zircaloy cladding exceeded that provided by decay of the fission products in the fuel contained by the cladding tubes. In laboratory experiments in which a specimen is held in a furnace or heated by induction or by resistance, rapid oxidation can provide a heat source comparable in magnitude to that supplied by the applied heating method. The localized nature of the heat release by oxidation can cause temperature nonuniformities in the reacting metal which must be understood quantitatively if the corrosion process is to be properly modeled.

In this work, oxidation of zirconium¹ is analyzed with reaction heating considered. Zirconium oxidizes by formation of a coherent oxide scale through which oxygen is transported by ionic diffusion from the gas to the metal. At the oxide-metal boundary, the incoming oxygen either converts some of the metal to oxide or dissolves into the metal and continues to penetrate by interstitial diffusion. At high temperature, the metal phase consists of a α -zirconium and β -zirconium components, but, for the present study, the distinction between the two is not important.

In the following section, the heat of combustion of zirconium is broken down into three parts. First, addition of oxygen to the initially pure metal produces α -Zr saturated with oxygen. Second, sufficient additional oxygen is supplied to convert the saturated metal to zirconia at the lower phase boundary. Finally, the hypostoichiometric oxide is saturated with oxygen to achieve ZrO_2 .

In a slab of metal exposed to steam, these steps occur simultaneously but at different locations in the specimen, rather than sequentially in time but uniformly throughout the solid. In addition, water vapor must be decomposed to produce the oxygen which enters the solid and the reaction product hydrogen which returns to the gas phase. Application of the three-step oxidation process to this case permits determination of the heat releases at various positions in the corroding specimen, particularly at the gas-oxide and the oxide-metal interfaces. This analysis is presented in the "Heat Release" section.

In the succeeding sections, the effect of the heat released during the corrosion process on the temperature distribution within the specimen and on the kinetics of scaling are considered. To this end, a simplified problem is analyzed. The system considered closely resembles the method by which corrosion kinetics are studied in laboratory tests, but the general features of the analysis are also applicable to nuclear fuel elements, wherein oxidation of

¹Nuclear reactor fuel cladding is fabricated from the zirconium-based alloy Zircaloy, which contains 1.5% tin and smaller amounts of iron and chromium. This alloy is superior to pure zirconium for normal reactor use, but the high-temperature oxidation characteristics of the two are very similar.

the cladding proceeds from the surface exposed to the coolant toward the inner surface adjacent to the fuel. The system consists of a slab specimen initially placed in an inert environment at temperature T_0 . In the absence of chemical reaction, the specimen acquires the temperature of its surroundings, which is maintained constant at T_0 at all times. Steam at temperature T_0 is admitted at time zero and proceeds to oxidize the slab from both sides. Thus, the midplane of the specimen is adiabatic for heat-transfer purposes. The half-thickness of the specimen is assumed to be sufficiently large so that the oxygen diffusion process occurs as in an infinite medium. Heat-transfer between the enclosure and the specimen, whether by radiation to the walls or by convection to the steam, is characterized by a heat-transfer coefficient h .

In the "Temperature Distribution" section, the problem described above is analyzed without considering coupling of the heat release and oxidation kinetics. In the following section, a commonly used approximate coupling scheme is analyzed. Finally, rigorous linkage of the heat- and mass-transfer processes is developed.

Components of the Heat of Combustion of Zirconium

The heat of formation of ZrO_2 , $\Delta H_{ZrO_2}^0$, is the enthalpy change of the reaction

where the zirconium reactant is initially free of oxygen and the oxide product is stoichiometric (*i.e.*, with O/Zr ratio of 2). The heat of formation of zirconium dioxide at 298 K is given in Ref. (1). Extrapolating to temperatures of interest here (1200°-1600°C) and taking into account the difference in heat capacities of products and reactants [also given in Ref. (1)] gives $\Delta H_{ZrO_2}^0 = -1088$ kJ/mol.

With reference to the isotherm on the phase diagram of Fig. 1, the heat of formation of ZrO_2 corresponds to the difference in enthalpy between points a and d. This difference can be divided into three parts.

a-b.—Addition of $\frac{1}{2} y$ mol of gaseous oxygen to 1 g atom of pure zirconium to produce the saturated metal (O/Zr = y) can be written as

and the heat release is

$$Q_{a-b} = -\frac{1}{2} \int_0^y \overline{\Delta H}_M dy' \approx -\frac{1}{2} \overline{\Delta H}_M y \quad [3]$$

where $\overline{\Delta H}_M$ is the partial molar enthalpy of oxygen in the metal. Komarek and Silver (2) measured the oxygen pressures in equilibrium with solutions of oxygen in α -Zr. Their data yield a heat of solution $\overline{\Delta H}_M = -1138$ kJ/mol at 10-15 atom percent (a/o) oxygen and a variation of ~ 54 kJ/mol between infinite dilution and saturation. The latter variation is neglected, and the heat of solution is as-

Fig. 1. Zr-O equilibrium phase diagram from Ref. (18) with isotherm at 1300°C.

sumed to be independent of composition. In addition, as explained earlier, it is assumed to be the same for the α and β modifications of zirconium.

b-c.—Addition of oxygen to the oxygen-saturated metal to produce 1 mol of the oxide at the lower phase boundary ($O/Zr = 2 - x$). This reaction can be written as

The heat released by this equilibrium reaction is

$$Q_{b-c} = -\Delta H_R \quad [5]$$

where ΔH_R is the standard enthalpy change of reaction [4].

c-d.—Dissolution of oxygen in the hypostoichiometric oxide to produce perfect stoichiometry corresponds to the reaction

and the heat release for this step is given by

$$Q_{c-d} = -\frac{1}{2} \int_0^x \overline{\Delta H}_{\text{ox}} dx' \quad [7]$$

where $\overline{\Delta H}_{\text{ox}}$ is the partial molar enthalpy of oxygen in ZrO_{2-x} , which is a function of the O/Zr ratio.² The only work that provides some information on the partial molar enthalpy of solution of oxygen in ZrO_2 is that of Aronson [3]. Unfortunately, the oxygen potential he obtained changes temperature dependence across the ZrO_{2-x} phase field in a manner which implies changes in the signs of $\overline{\Delta H}_{\text{ox}}$ and the partial molar entropy of solution, $\overline{\Delta S}_{\text{ox}}$. This unusual behavior may be due to the fact that the temperature range of his experiments (900°-1100°C) spanned the monoclinic-tetragonal transition temperature of zirconia (1000°C). Rather than accept the odd variation of $\overline{\Delta H}_{\text{ox}}$

²The oxygen solution reaction given by Eq. [6] need not imply that this element enters the oxide lattice as interstitial neutral atoms, as it does in the metal. Rather, the final state of oxygen entering the oxide is the substitutional ion O^{2-} , achieved by addition of two oxygen atoms to vacant anion lattice sites and acquisition of two electrons from the solid. The experimental enthalpy of solution, $\overline{\Delta H}_{\text{ox}}$, reflects this charge-exchange step.

with O/Zr implied by these data, we use only the measured oxygen potentials at 1100°C, which apply to tetragonal zirconia. These data, in conjunction with a theoretical estimate of $\overline{\Delta S}_{\text{ox}}$, determine $\overline{\Delta H}_{\text{ox}}$ by

$$\overline{\Delta H}_{\text{ox}} = \overline{\Delta G}_{\text{ox}} + T\overline{\Delta S}_{\text{ox}} \quad [8]$$

The partial molar entropy of solution is given by

$$\overline{\Delta S}_{\text{ox}} = 2\overline{S}_0 - S^{\circ}_{\text{O}_2} \quad [9]$$

where $S^{\circ}_{\text{O}_2}$ is the entropy of molecular oxygen and \overline{S}_0 is the partial molar entropy of oxygen ions in ZrO_{2-x} . The former consists primarily of a translational entropy contribution with a smaller contribution from rotation. At temperatures above 1200°C, the methods described in Ref. (4) give the value $S^{\circ}_{\text{O}_2} \approx 210 \text{ J/mol}\cdot\text{K}$.

The tetragonal structure of zirconia is simply a distorted fluorite lattice (5), and the dominant point defects in the nonstoichiometric compound are oxygen vacancies. Consequently, $\overline{\Delta S}_{\text{ox}}$ of ZrO_{2-x} should behave in a manner similar to other oxygen-deficient oxides with the fluorite structure, such as $(\text{U},\text{M})\text{O}_{2-x}$ where M is another cation. Wadier (6) has shown that \overline{S}_0 for the hypostoichiometric mixed uranium-neodymium oxide can be satisfactorily represented by a simple model which assumes a perfect cation sublattice and isolated vacancies on the anion sublattice. His result, which is applicable to zirconia as well, is

$$\overline{S}_0 = -R \ln \left(\frac{2-x}{x} \right) \quad [10]$$

Using this estimate of $\overline{\Delta S}_{\text{ox}}$ and Aronson's values of $\overline{\Delta G}_{\text{ox}}$ at 1100°C in Eq. [8] yields the partial molar enthalpy of solution shown in Fig. 2. Although there is no way of accurately estimating $\overline{\Delta H}_{\text{ox}}$ at exact stoichiometry (because of the mathematical form of Eq. [10]), the shape and magnitude of the curve in Fig. 2 are consistent with those observed for $(\text{U},\text{Pu})\text{O}_{2-x}$ (7).

The sum of the heat releases in the three steps is equal to the negative of the heat of combustion of pure zirconium

$$\Delta H^{\circ}_{\text{ZrO}_2} = \frac{1}{2} \overline{\Delta H}_{\text{M}y} + \Delta H_R + \frac{1}{2} \int_0^x \overline{\Delta H}_{\text{ox}} dx' \quad [11]$$

Estimates of the oxide-metal interface compositions x and y can be obtained from the Zr-O phase diagram. The solubility limit of oxygen in α -Zr is nearly temperature independent, but the lower phase boundary of ZrO_{2-x} is slightly temperature sensitive (8).

Heat Release during Zircaloy Oxidation

Corrosion kinetics are customarily expressed as the rate of weight gain and the rate of growth of the oxide scale. In the case of zirconium oxidation, a layer of oxygen-

Fig. 2. Composition dependence of the partial molar enthalpy of solution of oxygen in zirconia.

stabilized α -Zr forms between the oxide scale and the substrate. In the present analysis, the α -Zr layer is not distinguished from the remaining β -Zr because the two phases are assumed to have similar thermal properties. Figure 3 shows typical scale formation on zirconium. The points labeled a, b, c, and d correspond to those in Fig. 1. Because the change in O/Zr ratio across the oxide phase is small, the segment d-c of the oxygen distribution is assumed to be a straight line. If the initial thickness of the oxygen-free zirconium slab is L_{M0} , and L_M and L_{ox} denote the thickness of metal ($\alpha + \beta$) and oxide at time t , conservation of zirconium leads to

$$\rho_M(L_{M0} - L_M) = \rho_{ox}L_{ox} \quad [12]$$

where ρ_M and ρ_{ox} are numbers of gram atoms of zirconium per unit volume of metal and oxide, respectively.

In a time interval Δt the result of oxidation is $\Delta N_T =$ total uptake of oxygen (g atoms/cm²) and $\Delta L_{ox} =$ increase in oxide layer thickness.

The number of gram atoms of zirconium contained in a unit area of oxide scale is $\rho_{ox}L_{ox}$, and the average O/Zr ratio of the scale is at all times equal to $2 - \frac{1}{2}x$. Therefore, the change in the amount of oxygen bound in the oxide scale as a result of the increase of ΔL_{ox} in thickness is $(2 - \frac{1}{2}x)\rho_{ox}\Delta L_{ox}$. However, the oxide scale grows by converting $\rho_{ox}\Delta L_{ox}$ g atoms per cm² of adjacent zirconium metal which is saturated with oxygen. Thus, of the change in the amount of oxygen in the scale, an amount $y\rho_{ox}\Delta L_{ox}$ is supplied by the converted metal, with the remainder being supplied from the total uptake from the oxidizing gas. The difference

$$\Delta N_M = \Delta N_T - (2 - \frac{1}{2}x - y)\rho_{ox}\Delta L_{ox} \quad [13]$$

is the quantity of oxygen which enters the metal phase.

As a first approximation determining the heat release, the partial molar heats of solution of oxygen in the metal and in the oxide are considered to be independent of composition. The consequence of this assumed behavior is the absence of heat release in the bulk oxide and metal phases due to oxygen diffusion down concentration gradients. The heat effects of corrosion are localized at the interfaces between the gas and the oxide and between the oxide and the metal.

For oxidation in steam, the heat released at the gas-oxide interface consists of two components. The oxygen entering the specimen must first be produced by decomposing water

for which the heat release is the standard heat of formation of water, $\Delta H^0_{fH_2O}$. The oxygen gas is dissolved in the surface of the oxide according to Eq. [6]. The heat release per gram atom of oxygen absorbed at the gas-oxide surface is

$$Q_{g-ox} = -\frac{1}{2} \overline{\Delta H}_{ox} + \Delta H^0_{fH_2O} \quad [15]$$

Fig. 3. Oxide scale growth and oxygen concentration distribution during steam oxidation of Zircaloy.

The ΔN_T g atoms of oxygen entering the surface ultimately appear in one of three locations. An amount ΔN_M enters the metal at the oxide-metal interface where the heat released is $(\frac{1}{2}\overline{\Delta H}_{ox} - \frac{1}{2}\overline{\Delta H}_M)\Delta N_M$. A portion $(2 - x - y)\rho_{ox} \Delta L_{ox}$ reacts with the metal at the oxide-metal interface to produce ZrO_{2-x} . The heat released at this interface by this process is $(2 - x - y)\rho_{ox} \Delta L_{ox}(\frac{1}{2}\overline{\Delta H}_{ox}) - \Delta H_R\rho_{ox}\Delta L_{ox}$. The remaining $\frac{1}{2}x\rho_{ox}\Delta L_{ox}$ g atoms of oxygen stay in the oxide but contribute nothing to the heat release because in the present approximation, $\overline{\Delta H}_{ox}$ is composition independent. Adding these contributions, eliminating ΔN_M by using Eq. [13], and ΔH_R by Eq. [11] (with $\overline{\Delta H}_{ox}$ a constant for this approximation), yields the heat release at the oxide-metal interface per gram atom of oxygen absorbed by the specimen

$$Q_{ox-M} = \frac{1}{2} \overline{\Delta H}_{ox} - \frac{1}{2} \Delta H_M - \left[\Delta H^0_{fZrO_2} - \frac{1}{4}x\overline{\Delta H}_{ox} - \left(2 - \frac{1}{2}x\right) \left(\frac{1}{2} \overline{\Delta H}_M\right) \right] \rho_{ox} \frac{\Delta L_{ox}}{\Delta N_T} \quad [16]$$

Current analyses which attempt to account for the heat effect of the metal-water reaction assume that the thermal source term is equal to the negative of the integral heat of the reaction

which is

$$\Delta H^0 = \frac{1}{2}\Delta H^0_{fZrO_2} - \Delta H^0_{fH_2O} \quad [18]$$

However, during the corrosion process, the appropriate source term is the differential heat of reaction

$$Q = Q_{g-ox} + Q_{ox-M} \quad [19]$$

This quantity is obtained from Eq. [15] and [16] as

$$Q = \Delta H^0_{fH_2O} - \frac{1}{2}\overline{\Delta H}_M - \left[\Delta H^0_{fZrO_2} - \frac{1}{4}x\overline{\Delta H}_{ox} - \frac{1}{2}(2 - \frac{1}{2}x)\overline{\Delta H}_M \right] \rho_{ox}\Delta L_{ox}/\Delta N_T \quad [20]$$

The following argument demonstrates that Eq. [18] and [20] are self-consistent. Complete oxidation by steam contacting one face of a slab which contains $\frac{1}{2}$ g-atom Zr is accomplished in two steps. In the first step, sufficient oxygen is added to convert all of the metal to an oxide which has an O/Zr ratio of 2 on the steam side and $2 - x$ on the opposite side, with a linear variation between the two faces. The average O/Zr ratio of the nearly fully oxidized slab is thus $2 - \frac{1}{2}x$. Using Eq. [12] with $L_M = 0$, $\rho_M L_{M0} = \frac{1}{2}$, the term $\rho_{ox}\Delta L_{ox}$ in Eq. [20] is seen to be $\frac{1}{2}$. The quantity of oxygen added to the slab in step 1 (ΔN_T in Eq. [20]) is $\frac{1}{2}(2 - \frac{1}{2}x)$ g atoms and the heat release for this step is

$$Q_1 = \frac{1}{2}(2 - \frac{1}{2}x)Q \quad [21]$$

where Q is given by Eq. [20] with the values of $\rho_{ox}\Delta L_{ox}$ and ΔN_T determined above. The second step is the addition of $\frac{1}{2}x$ g atoms of oxygen to bring the slab to exact stoichiometry, for which the enthalpy change is

$$Q_2 = \frac{1}{2}xQ_{g-ox} \quad [22]$$

where Q_{g-ox} is given by Eq. [15]. Adding the contributions of the two steps shows that

$$Q_1 + Q_2 = -\frac{1}{2}\Delta H^0_{fZrO_2} + \Delta H^0_{fH_2O} \quad [23]$$

which is exactly the negative of the integral enthalpy of reaction given by Eq. [18].

Thus, although the heat released by complete oxidation of zirconium is given by the overall thermochemistry of reaction [17], the heat effect during oxidation (i.e., while some metal is still present) is determined by the differential heat of reaction of Eq. [20]. This heat effect is not a purely thermodynamic quantity, because it depends upon the ratio of increments of oxide layer growth ΔL_{ox} to total oxygen absorbed, ΔN_T , which depends on the details of the corrosion process. In order to evaluate Q ,

specification of the kinetics of corrosion is required. For isothermal oxidation in an infinite-medium specimen, parabolic kinetics prevails and Q can be computed. We will perform this computation, but its restrictions to the isothermal, infinite medium case should be kept in mind. When we deal with the transient situation in the following sections or with an isothermal reaction in a finite slab, the appropriate expression for $\Delta L_{ox}/\Delta N_T$ must be used in Eq. [20].

For parabolic scaling, we may write

$$\frac{dL_{ox}}{dt} = \frac{k_{ox}}{\sqrt{t}} \quad [24]$$

$$J = \frac{dN_T}{dt} = \frac{k_T}{\sqrt{t}} \quad [25]$$

Where J is the oxygen uptake rate and k_{ox} and k_T are the scaling constants for oxide layer growth and total oxygen uptake, respectively. Using Eq. [24] and [25] in Eq. [20] yields the appropriate thermal source term during parabolic scaling of zirconium in steam

$$Q(\text{parabolic}) = \Delta H^{\circ}_{H_2O} - \frac{1}{2}\Delta H_M - [\Delta H^{\circ}_{ZrO_2} - \frac{1}{4}x\overline{\Delta H}_{ox} - \frac{1}{2}(2 - \frac{1}{2}x)\overline{\Delta H}_{ox}] \frac{\rho_{ox}k_{ox}}{k_T} \quad [26]$$

The preceding analysis was also based upon the assumption that the enthalpy of solution of oxygen in zirconia was independent of composition. A more accurate analysis allows for the composition-variation of $\overline{\Delta H}_{ox}$ given in Fig. 2. This curve can be fitted to the quadratic formula

$$\overline{\Delta H}_{ox} = (\overline{\Delta H}_{ox})_0 + ax + bx^2 \quad [27]$$

Repeating the analysis developed above for $\overline{\Delta H}_{ox} = \text{constant}$, the heat sources in the solid for the variable $\overline{\Delta H}_{ox}$ case are found to be

$$Q_{g-ox} = -\frac{1}{2}(\overline{\Delta H}_{ox})_0 + \Delta H^{\circ}_{H_2O} \quad [28]$$

$$Q_{ox-M} = \frac{1}{2}(\overline{\Delta H}_{ox})_0 - \frac{1}{2}\overline{\Delta H}_M - \left[\Delta H^{\circ}_{ZrO_2} - \frac{1}{4}x(\overline{\Delta H}_{ox})_0 - \frac{1}{4}ax^2 - \frac{1}{6}bx^3 - \frac{1}{2}(2 - \frac{1}{2}x)\overline{\Delta H}_M \right] \frac{\rho_{ox}\Delta L_{ox}}{\Delta N_T} \quad [29]$$

In addition, there is a bulk heat release in the oxide scale due to the change in $\overline{\Delta H}_{ox}$ as oxygen diffuses from the gas-oxide interface to the metal-oxide interface. This contribution can be shown to be given by

$$Q_{ox} = -\frac{1}{2}x^2 \left(\frac{1}{3}a + \frac{1}{4}bx \right) \frac{\rho_{ox}\Delta L_{ox}}{\Delta N_T} \quad [30]$$

The total heat release per gram atom of oxygen absorbed by the specimen for this case is given by

$$Q = Q_{g-ox} + Q_{ox} + Q_{ox-M} \quad [31]$$

Table I shows the contributions of the various heat sources calculated in this section. The data used in the computations are collected in the first part of Table I. Parabolic oxidation kinetics are assumed, so that the term $\Delta L_{ox}/\Delta N_T$ is the ratio of the parabolic scaling constants k_{ox}/k_T . The total heat releases according to Eq. [26] and [31] are given as functions of temperature between 1500 and 1900 K. The heat releases per gram atom of oxygen absorbed by the specimen are quite insensitive to temperature in this range and to the assumption concerning the composition dependence of $\overline{\Delta H}_{ox}$. However, the average value of $Q \approx 307$ kJ/g-atom O is $\sim 3\%$ larger than the integral heat of reaction, given by Eq. [18] and the data in Table I as $\Delta H^{\circ} = 297$ kJ/g-atom O. This slight increase in the heat release may be significant in analysis of the chemical heat effect in severe fuel damage codes for nuclear reactors.

The last part of Table I shows the way that the reaction heat is partitioned in the solid. Here the concentration effect on the heat of solution of oxygen in zirconia has a

profound effect. If $\overline{\Delta H}_{ox}$ is taken to be a constant equal to the average value given in the top of Table I, 90% of the reaction heat appears at the gas-oxide interface. However, if the composition-dependence shown in Fig. 2 is adopted, only 30% of the reaction heat appears at the surface. However, in both cases, despite the endothermicity of reaction [14], the large energy release upon incorporation of gaseous oxygen in the oxide makes the overall surface reaction exothermic. This result is just the opposite of the conclusion recently reached by Cubicciotti (10). The bulk heating of the oxide layer is relatively minor.

Effect of the Heat of Reaction on the Temperature Distribution

All experimental studies of Zircaloy corrosion by steam assume a uniform temperature distribution within the reacting sample. However, temperature nonuniformities may result from the partitioning of the heat release between the gas-oxide and oxide-metal interfaces. The location as well as the magnitude of the heat release due to oxidation may have a significant effect on calculation of cladding temperatures in a reactor accident situation which involves oxidation of Zircaloy.

To assess the importance of the heat-source location on the temperature distribution, the idealized situation described above is analyzed. For the present, we assume that the oxidation kinetics are those for parabolic scaling at the constant base temperature T_0 ; acceleration of the corrosion rate by the heat release is neglected. Our object here is to obtain estimates of the temperature nonuniformities caused by discrete heat sources in the slab.

With this restriction, the growth rate of the oxide scale and the flux of oxygen into the specimen are given by Eq. [24] and [25], respectively, with the scaling constants k_{ox} and k_T those at the base temperature T_0 . The planar heat sources at the gas-oxide and metal-oxide interfaces are equal to $Q_{g-ox}J$ and $Q_{ox-M}J$, respectively, where Q_{g-ox} and Q_{ox-M} are given by Eq. [15] and [16], respectively.

The heat balance at the specimen surface includes the radiative-convective loss to the environment, the heat

conducted to the specimen from the interior (given by the product of the oxide thermal conductivity and the temperature gradient in the oxide), and the heat source $Q_{g-ox}J$. The balance consists of equating the difference in the first two terms to the last.

The thermal response time of the oxide layer is L_{M0}^2/α_{ox} , where α_{ox} is the thermal diffusivity of ZrO_2 . The characteristic scale growth time is equal to L_{M0}^2/k_{ox}^2 . Because the latter is very much larger than the former (by a factor of $\sim 10^5$ at 1300°C), quasisteady-state heat conduction applies to the oxide layer, or the temperature distribution in this phase is linear at all times.

In addition, because the thermal conductivity of the metal is very large compared to that of the oxide, the thermal response of the metal phase can be treated as a lumped capacity and temperature gradients neglected here. Consequently, the transient heat-conduction equation in the metal portion of the specimen can be replaced by an energy balance which equates the time rate of change of the heat content of the metal phase to the difference between the reaction heat source at the oxide-metal interface, $Q_{ox-M}J$, and the heat transferred away from this interface by conduction into the oxide.

Elaboration of this model in Ref. (11) leads to equations giving the time variations of the metal phase and oxide surface temperatures following introduction of steam into the system. Calculations were performed for a variety of external heat transfer coefficients (h) ranging from that for pure radiation from the surface to a medium at constant temperature to smaller values intended to represent convection to slowly flowing steam that might be encountered in a core-uncovery situation in a nuclear reactor accident. In all cases, the calculations showed that despite the low thermal conductivity of ZrO_2 , temperature gradients over the oxide scale were negligible at all but the very earliest times during the transient. The reason for this result is Biot number, hL_{M0}/κ_{ox} , where κ_{ox} is the thermal conductivity of ZrO_2 , is very much less than unity. This condition is encountered in other solid-fluid heat-transfer situations (12), and simply reflects the fact that in such cases external heat-transfer provides the major thermal resistance in the system. The same conclusion has been reached by use of the detailed thermal analysis modules in the nuclear reactor severe fuel damage codes SCDAP (13) and PWR HEATUP (14).

The consequences of this behavior are twofold. First, the thermal response of the oxidizing metal is independent of the manner in which the heat of the chemical reaction is partitioned between the gas-oxide and metal-oxide interfaces and depends only upon the total heat release given by Eq. [20]. Second, the entire specimen can be characterized by a spatially uniform temperature whose time dependence is given by a lumped-capacity energy balance. This balance takes on the following simple but accurate form if the change in the solid heat capacity due to oxidation is neglected

$$\rho_M C_{PM} L_{M0} \frac{d}{dt} (T - T_0) = QJ - h(T - T_0) \quad [32]$$

where ρ_M and C_{PM} are the density and heat capacity of the metal, respectively. The temperature of the environment (T_0), representing the enclosure surfaces for radiation and steam temperature for convection, can be time dependent. The heat release due to reaction (Q) is given by Eq. [20], and the oxygen uptake rate (J) is described by the appropriate corrosion kinetics (which need not be those of parabolic scaling). Although the form of Eq. [32] was obtained without considering the temperature dependence of J , the simple lumped-capacity heat balance can be employed with models that account for coupling of J to the temperature transient.

Approximate Coupling of Corrosion Kinetics and Thermal Response

The approximate coupling method adopted by Markworth (15) and used in severe fuel damage codes (13, 14)

consists of assuming that the basic parabolic scaling laws apply in a temperature transient but the scaling coefficients are thermally activated. According to this prescription, the oxygen uptake rate given by Eq. [25] is replaced by

$$J = \frac{dN_T}{dt} = \frac{k_{T_0}}{\sqrt{t}} \exp \left[-\frac{E_T}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad [33]$$

where k_{T_0} is the parabolic rate constant at temperature T_0 and E_T is the activation energy for the total oxygen uptake determined by isothermal corrosion experiments at various temperatures.

Similarly, Eq. [24] is generalized to

$$\frac{dL_{ox}}{dt} = \frac{k_{ox0}}{\sqrt{t}} \exp \left[-\frac{E_{ox}}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad [34]$$

where k_{ox0} is the parabolic rate constant for oxide scale growth at T_0 and E_{ox} is its activation energy.

The heat of reaction Q is obtained by substituting Eq. [33] and [34] into Eq. [20] in order to eliminate $\Delta L_{ox}/\Delta N_T$. The result is multiplied by Eq. [33] to obtain the heat source QJ . Using this result in Eq. [32] gives

$$C_1 \frac{d\theta}{dt} = \frac{A_1 \exp(E_1\theta)}{\sqrt{t}} - \frac{A_2 \exp(E_2\theta)}{\sqrt{t}} - C_2\theta \quad [35]$$

where

$$C_1 = \rho_M C_{PM} L_{M0} T_0$$

$$C_2 = hT_0$$

$$A_1 = (\Delta H_{H_2O}^0 - \frac{1}{2} \Delta \bar{H}_M) k_{T_0}$$

$$A_2 = [\Delta H_{ZrO_2}^0 - \frac{1}{4} x \Delta \bar{H}_{ox} - \frac{1}{2} (2 - \frac{1}{2} x) \Delta \bar{H}_M] \rho_{ox} k_{ox0}$$

$$E_1 = E_T/RT_0$$

$$E_2 = E_{ox}/RT_0$$

and

$$\theta = (T - T_0)/T_0 \quad [36]$$

is the dimensionless temperature of the specimen.

Equation [35] can be solved numerically using the initial condition $\theta(0) = 0$ to yield the temperature variation during the transient initiated by introduction of steam at time zero. Using this result in Eq. [33] and [34] permits the corrosion rate to be determined.

The above formulation assumes a constant heat of solution $\Delta \bar{H}_{ox}$. If the more accurate representation of this quantity according to Eq. [27] is employed, Eq. [31] is used for Q and different coefficients A_1 and A_2 , obtained from Eq. [28]-[30], result. Both cases apply only to oxidation of a semi-infinite solid, however.

Accurate Coupling of Heat and Mass Transport during Corrosion

The major shortcoming of the coupling method described in the previous section is the description of the corrosion process by parabolic kinetics in a temperature transient. This is, in principle, wrong, because parabolic kinetics requires time-independent parameters such as oxygen diffusion coefficients and interface concentrations. Thus, application of Eq. [33] and [34] to situations with time-dependent temperatures is open to question. This deficiency can be eliminated by analyzing the corrosion process from the same basic principles that have been applied to isothermal corrosion kinetics. The material properties are permitted to be time dependent, but the temperature is assumed to be spatially independent because the demonstration of this property in the "Temperature Distribution" section remains valid.

The kinetics of oxidation are determined by solving the oxygen diffusion equations in the oxide and metal zones of the specimen and matching fluxes and concentrations at the metal-oxide interface. This technique has been used by Paweł (16) to analyze isothermal oxidation of Zir-

caloy. We apply the same type of analysis to the present transient problem with the aid of the following simplifications: (i) the oxygen concentration profile in the oxide layer is assumed to be a linear function of distance, (ii) the distinction between α -Zr and β -Zr is neglected, and (iii) the system is semi-infinite insofar as oxygen penetration is concerned.

The system is depicted in Fig. 3. Because of the volume change upon oxidation, the metal lattice moves away from the gas-oxide interface with a velocity denoted by v_{zr} . From Fig. 3

$$v_{zr} = \frac{d}{dt} (L_{ox} + L_M)$$

This motion can be related to the velocity of the oxide-metal interface by using the zirconium balance given by Eq. [12]

$$\frac{dL_M}{dt} = -\frac{\rho_{ox}}{\rho_M} \frac{dL_{ox}}{dt} = -\frac{1}{B} \frac{dL_{ox}}{dt}$$

where B is the ratio of the zirconium atom densities in the metal and oxide phases (the Pilling-Bedworth ratio). Combining these two equations and noting that $dL_{ox}/dt = v$ yields

$$v_{zr} = \left(\frac{B-1}{B}\right) v \quad [37]$$

Because the oxygen distribution in the oxide layer has been assumed to be linear, we may write

$$\frac{C_d - C_{ox}}{C_d - C_c} = \frac{z}{L_{ox}} \quad [38]$$

where C_{ox} is the oxygen concentration at location z in the oxide layer and C_d and C_c are the boundary concentrations of oxygen at points d and c in Fig. 3, respectively. These correspond to stoichiometric zirconia and to substoichiometric zirconia at the lower phase boundary.

In the metal phase the oxygen conservation equation is

$$\frac{\partial C_M}{\partial t} = \frac{\partial J'}{\partial z'} \quad [39]$$

where C_M is the oxygen concentration in the metal and J' is the oxygen flux in the metal phase with respect to the coordinate origin of z' , which is chosen as the moving oxide-metal interface. This flux consists of two terms, a Fick's law component representing oxygen diffusion relative to the zirconium lattice and a convection term reflecting movement of the zirconium lattice with respect to the oxide-metal interface. The convective velocity is the difference between the lattice velocity with respect to the fixed gas-oxide interface and the velocity of the oxide-metal interface with respect to the same plane

$$v_M = v_{zr} - v = -v/B \quad [40]$$

The oxygen flux in the metal is

$$J' = -D_M \frac{\partial C_M}{\partial z'} + v_M C_M \quad [41]$$

where D_M is the diffusion coefficient of oxygen in the metal. Combining Eq. [39]-[41] gives the oxygen diffusion equation in the metal phase

$$\frac{\partial C_M}{\partial t} - \frac{v}{B} \frac{\partial C_M}{\partial z'} = D_M \frac{\partial^2 C_M}{\partial z'^2} \quad [42]$$

The initial and boundary conditions are

$$C_M(z', 0) = 0 \quad [43]$$

$$C_M(0, t) = C_b \quad [44]$$

$$C_M(\infty, t) = 0$$

where C_b is the saturation concentration of oxygen in α -Zr. The last condition embodies the semi-infinite medium condition and neglects the transformation from α -Zr to β -Zr.

Equality of oxygen fluxes in the oxide and metal phases at the interface is expressed by

$$-D_{ox} \left(\frac{\partial C_{ox}}{\partial z} \right)_{L_{ox}} - v C_c = -D_M \left(\frac{\partial C_M}{\partial z'} \right)_0 - \frac{v}{B} C_b \quad [45]$$

where D_{ox} is the oxygen diffusivity in ZrO_2 .

Isothermal solution.—If the diffusion coefficient and the boundary concentrations are all constant, the velocity in Eq. [42] is $v = k_{ox}/\sqrt{t}$, where k_{ox} is the parabolic scaling constant, and the solution to Eq. [42] is

$$\frac{C_M}{C_b} = \frac{\operatorname{erfc} \left(\frac{z'}{2\sqrt{D_M t}} + \frac{k_{ox}}{B\sqrt{D_M}} \right)}{\operatorname{erfc} \left(\frac{k_{ox}}{B\sqrt{D_M}} \right)} \quad [46]$$

Substituting Eq. [38] and [46] into Eq. [45] and noting that $L_{ox} = 2k_{ox}\sqrt{t}$ yields

$$\begin{aligned} & \frac{D_{ox}(C_d - C_c)}{2k_{ox}} - k_{ox}(C_c - C_b/B) \\ &= C_b \left(\frac{D_M}{\pi} \right)^{\frac{1}{2}} \frac{\exp \left[-\left(\frac{k_{ox}}{B\sqrt{D_M}} \right)^2 \right]}{\operatorname{erfc} \left(\frac{k_{ox}}{B\sqrt{D_M}} \right)} \end{aligned} \quad [47]$$

The kinetic equation for the rate of oxygen uptake is obtained from

$$\frac{dN_T}{dt} = -D_{ox} \left(\frac{\partial C_{ox}}{\partial z'} \right)_0 = \frac{k_T}{\sqrt{t}}$$

or

$$k_T = \frac{D_{ox}(C_d - C_c)}{2k_{ox}} \quad [48]$$

The isothermal rate constants k_{ox} and k_T can be determined by using the oxygen diffusion coefficients and interface concentrations in Eq. [47] and [48]. Using the following data given in Ref. (16) for 1300°C

$$C_d = 2\rho_{ox} = 0.094 \text{ g atom oxygen/cm}^3$$

$$C_c/C_d = 1.84/2 = 0.092$$

$$C_b/C_d = 0.31$$

$$D_{ox} = 2.0 \times 10^{-6} \text{ cm}^2/\text{s}$$

$$D_M = 3.2 \times 10^{-7} \text{ cm}^2/\text{s (for } \alpha\text{-Zr)}$$

$$B = \rho_M/\rho_{ox} = 1.5$$

Equation [47] gives $k_{ox} = 2.5 \times 10^{-4} \text{ cm/s}^{1/2}$ and Eq. [48] yields $k_T = 3.5 \times 10^{-5} \text{ g atom oxygen/cm}^2 \cdot \text{s}^{1/2}$. These results are in excellent agreement with the measured scaling constants (see Table I), which is not surprising since these data were used by Pawel (16) to determine D_{ox} and D_M . All that we have done is to reverse this process. However, the comparison does demonstrate that assumptions (i) and (ii) given at the beginning of this section are adequate for the corrosion analysis, and will be retained in analyzing the transient case.

Nonisothermal solution.—Analysis of diffusive transport during a transient is simplified by the spatial uniformity of the temperature. Because of this feature, the diffusion coefficients, which are functions of temperature, depend on time but not on position. As a consequence, the oxygen concentration distribution in the oxide and metal phases is still determined by Eq. [38] and [42], respectively, and the oxygen flux match at the oxide-metal interface is correctly expressed by Eq. [45]. What is inapplicable in the case of time-dependent diffusion coefficients is the assumption of parabolic scaling expressed by the relationship $v = k_{ox}/\sqrt{t}$.

The diffusivity of oxygen in zirconium metal can be considered as a function of time via the temperature

$$D_M = D_{M_0} f \quad [49]$$

where D_{M_0} is the diffusion coefficient at temperature T_0 and the factor f is given by

$$f = \exp \left[-\frac{E_{DM}}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] = e^{16.3\theta} \quad [50]$$

where $E_{DM} = 213$ kJ/mol is the activation energy of oxygen diffusion in α -Zr [Ref. (16)] and θ is dimensionless temperature defined by Eq. [36].

The only other quantity with a significant temperature dependence is the product of the oxygen diffusivity in the oxide and the oxygen concentration driving force across the oxide layer. The former exhibits Arrhenius behavior, but the difference in O/Zr ratio between stoichiometric zirconia and the reduced oxide at the lower phase boundary is approximately proportional to the absolute temperature (x in Table I). However, the temperature dependence of this product can be expressed in Arrhenius form with an activation energy slightly larger than that which characterize the diffusion coefficient in the oxide. Thus

$$D_{ox}(C_d - C_c) = [D_{ox}(C_d - C_c)]_0 g \quad [51]$$

where the bracketed coefficient with the zero subscript is the diffusivity-driving force product at temperature T_0 and the factor g is

$$g = \left(\frac{T}{T_0} \right) \exp \left[-\frac{E_{Dox}}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] = e^{12.1\theta} \quad [52]$$

where $E_{Dox} = 144$ kJ/mol is the activation energy of oxygen diffusion in the oxide phase (16).

Equation [49] is substituted into Eq. [42], and a new time variable is defined by

$$u = \int_0^t f dt' \quad [53]$$

The result is

$$\frac{\partial C_M}{\partial u} - \frac{v}{Bf} \frac{\partial C_M}{\partial z'} = D_{M_0} \frac{\partial^2 C_M}{\partial z'^2} \quad [54]$$

In analogous fashion, the derivative on the left-hand side of Eq. [45] is evaluated from Eq. [38] along with Eq. [51]. Using Eq. [49] for D_n transforms the oxygen flux match to

$$\frac{[D_{ox}(C_d - C_c)]_0 g}{f L_{ox}} - \frac{v}{f} \left(C_c - \frac{C_b}{B} \right) = -D_{M_0} \left(\frac{\partial C_M}{\partial z'} \right)_0 \quad [55]$$

The temperature dependence of the difference $(C_c - C_b/B)$ is small, and so this quantity is evaluated at T_0 .

There is no exact analytical solution to Eq. [54] and [55] when f and g are arbitrary functions of the time variable u . However, an approximately analytical solution can be obtained by assuming that the ratio v/f is inversely proportional to \sqrt{u}

$$\frac{v}{f} = \frac{k}{\sqrt{u}} \quad [56]$$

where k is a constant which replaces the scaling constant k_{ox} of the isothermal case.

The oxide scale thickness in the first term of Eq. [55] is determined by

$$L_{ox} = \int_0^t v dt' = k \int_0^t \frac{f(t') dt'}{\sqrt{u(t')}} = 2k\sqrt{u} \quad [57]$$

where Eq. [53] has been used.

Substituting Eq. [56] into Eq. [54] produces an equation whose form is identical to that for the isothermal situation. The solution for the transient temperature process is thus given by Eq. [46] with k_{ox} replaced by k , t by u , and D_M by D_{M_0} . This solution is used to evaluate the derivative on the right-hand side of Eq. [55]. With v and L_{ox} on the left-hand side given by Eq. [56] and [57], Eq. [55] becomes

$$\begin{aligned} & \frac{[D_{ox}(C_d - C_c)]_0 g}{2k} \frac{1}{f} - k \left(C_c - \frac{C_b}{B} \right) \\ &= \left(\frac{D_{M_0}}{\pi} \right)^{1/2} C_b \frac{\exp \left[-\left(\frac{k}{B\sqrt{D_{M_0}}} \right)^2 \right]}{\operatorname{erfc} \left(\frac{k}{B\sqrt{D_{M_0}}} \right)} \end{aligned} \quad [58]$$

Except for the ratio g/f in the first term on the left-hand side, this equation is identical to its isothermal counterpart, Eq. [47]. Although the activation energies of the factors g and f are large, the ratio g/f is only slightly temperature dependent because the activation energies of D_M and D_{ox} are comparable and the temperature dependencies of g and f approximately cancel. Consequently, the approximation $g/f = 1$ in Eq. [58] is acceptable, from which there follows

$$k = k_{ox_0}$$

where k_{ox_0} is the parabolic scaling constant at T_0 .

The temperature function $\theta(t)$ is determined by solution of Eq. [32], wherein the heat source Q is the sum of the gas-oxide and oxide-metal components given by Eq. [15] and [16], respectively. These in turn depend upon the corrosion kinetics through the quantities dN_T/dt and dL_{ox}/dt . The rate of weight gain is equal to the flux of oxygen across the oxide layer

$$\frac{dN_T}{dt} = \frac{D_{ox}(C_d - C_c)}{L_{ox}} = \frac{[D_{ox}(C_d - C_c)]_0 g}{2k_{ox_0}} \frac{1}{\sqrt{u}} = k_{T_0} \frac{g}{\sqrt{u}} \quad [59]$$

Similarly, Eq. [56] yields

$$v = \frac{dL_{ox}}{dt} = \frac{k_{ox_0} f}{\sqrt{u}} \quad [60]$$

The heat source in Eq. [32] is obtained as follows. The term Q is the sum of the components given by Eq. [15] and [16]. The ratio $\Delta L_{ox}/\Delta N_T$ in the latter is obtained from Eq. [59] and [60] as $k_{ox_0} f/k_{T_0} g$. When this value of Q is multiplied by the oxygen flux J given by Eq. [59], the result is

$$QJ = 10.1 \frac{g}{\sqrt{u}} - 0.5 \frac{f}{\sqrt{u}}, \text{ W/cm}^2 \quad [61]$$

The solution is accomplished by iteration. An initial guess of $\theta(t)$ is obtained, either from the no coupling solution described in the "Temperature Distribution" section or from the approximate coupling method of the "Coupling" section. This guess determines the first estimate of the time-dependent functions f and g from Eq. [50] and [52]. The new time variable u is computed from Eq. [53] and Eq. [61], then provides the oxidation heat source for the next iteration. The new temperature function is obtained by solving Eq. [32], with QJ given by Eq. [61], and the iteration process continues until the solution has converged. The growth of the oxide scale as a function of time is calculated from Eq. [57].

Results and Discussion

Figures 4 and 5 show the results of the thermal and corrosion kinetic analyses for a 1 mm thick slab of Zircaloy oxidized on both sides by steam at 1300°C.

Figure 4 shows the temperature transient calculated by the three methods described in previous sections: no coupling of heat and chemical reaction, approximate coupling by application of Arrhenius-type temperature dependences to the parabolic scaling constants, and the accurate coupling method, wherein temperature influences the basic thermodynamic and transport properties of the reacting solid. The results in Fig. 4 and 5 show that the approximate method of coupling produces poorer predictions than ignoring coupling entirely. The curves labeled "accurate coupling" were obtained by iteration starting either from the no coupling or approximate coupling initial guesses.

A substantial temperature perturbation occurs at the start of the oxidation process when the rates of oxygen

Fig. 4. Temperature perturbation due to inability to rapidly remove reaction heat during oxidation of Zircaloy at 1300°C. Heat removal parameter $C_2 = hT_0 = 100 \text{ W/cm}^2$. Specimen heat capacity parameter $C_1 = \rho_M C_{pM} L_{M_0} T_0 = 194 \text{ J/cm}^2$. Three methods of calculating the temperature transient are represented.

uptake by the solid is highest, but the temperature eventually approaches the ambient value because the thick oxide scale considerably reduces the rate of corrosion and hence the strength of the heat source inside or on the surface of the specimen. Figure 5 shows that correct simultaneous solution of the heat- and mass-transport equations in the solid predicts a scale thickness which is $\sim 7 \mu\text{m}$ larger than that given by the theory of isothermal scaling. The approximate coupling analysis overestimates the extent of oxygen absorption.

The results are sensitive to the heat removal rates from the specimen. This factor is contained in the external heat-transfer parameter hT_0 , which was chosen as 100 W/cm^2 for preparing the curves of Fig. 4 and 5. When more effective heat-transfer to the surroundings is simulated by increasing hT_0 to 150 W/cm^2 , the peak temperatures shown in Fig. 4 are reduced by 50°C and the oxide layer thicknesses are several percent less than those shown by the solid curve in Fig. 5.

Although radiation cooling provides a lower limit to the heat-transfer coefficient in the case of a single tubular specimen in a laboratory test, comparable minimum heat removal capability is not assured in a bundle of tubes as in a nuclear reactor fuel assembly. Because each cladding tube is surrounded by other tubes which are undergoing comparable oxidation, radiant interchange between one tube and its environment is drastically reduced. Only con-

Fig. 5. Oxide scale growth during reaction in the temperature transient displayed in Fig. 4. The results of three methods of coupling the heat- and mass-transport processes are shown.

vective heat-transfer to the flowing steam remains as a mechanism of removing the heat oxidation. In this case, the heat removal parameter hT_0 could be considerably smaller than the value of 100 W/cm^2 used in the sample calculations presented here and the temperature spike larger than that shown in Fig. 4.

The temperature excursion shown in Fig. 4 is qualitatively very similar to that observed by Hagen (17) in a fuel rod simulation test. In this configuration, heat was supplied from a central tungsten rod inside an annular fuel stack clad in Zircaloy. A Zircaloy shroud was placed around the specimen to simulate the presence of surrounding fuel pins. Initially, argon flowed in the annular gap between rod and shroud. Upon adding steam to the argon flow, the Zircaloy temperatures rose from the steady pretest value of 1700° to 2200°C and returned to less than 1700°C in less than 1 min. The time scale of the transient was thus very close to that shown in Fig. 4, in which the comparable duration is $\sim 1/2$ min. However, the amplitude of the experimental transient (500°C) was much larger than the one represented in Fig. 4 (125°C). Moreover, in Hagen's experiment, the surface temperature following the transient was lower than it was prior to addition of steam.

The reason for the latter observation is the dominance of convection rather than radiation cooling in Hagen's test; radiative heat transfer was effectively reduced by the surrounding shroud, which reacted in much the same way as the cladding and thus did not provide a radiation heat sink. Addition of steam to the argon flow sufficiently increased the convective heat-transfer coefficient to give temperatures lower than prereaction values when the Zircaloy had become oxidized to an extent that heat release by residual corrosion was small.

The larger amplitude of the temperature transient reported by Hagen compared to the one analyzed in this work is probably due to the higher initial temperature in the former. Since the scaling constants are thermally activated, the magnitude of the transient should be greater at higher temperatures. Moreover, the calculations were based on rate constants appropriate to a tetragonal zirconia scale, while the experimental temperatures probably resulted in a cubic zirconia layer and, at least during part of the excursion, in liquid zirconium.

Conclusions

1. The energy released during oxidation of Zircaloy by steam appears as planar sources of heat at the gas-oxide and oxide-metal interfaces. The sum of the heat releases at these two locations is approximately 3% larger than the integral heat of reaction of water vapor with Zircaloy to produce hydrogen gas and zirconium dioxide. The portion released at the gas-oxide interface is equal to the part molar enthalpy of oxygen solution in ZrO_2 less the heat of formation of water, and is always exothermic. The principal difficulty in accurately assessing the partitioning of the heat release between the two interfaces is lack of reliable information on the partial molar enthalpy of solution of oxygen in ZrO_2 .

2. The thermal response of the oxidizing metal to the heat released by the reaction is practically independent of the details of the location of the heat sources inside the specimen. Despite the low thermal conductivity of the ZrO_2 scale, spatial variations of temperature in the oxide and the metal phases are negligible. The temperature of the specimen as a function of time is determined by a lumped-capacity heat balance, which divides the reaction enthalpy into heat removal by external cooling or increase in specimen temperature.

3. The method of coupling the heat-transfer problem with scale formation kinetics is critical to accurate modeling. The conventional technique of assuming Arrhenius temperature dependences of the parabolic scaling constants (which were determined by isothermal experiments at different temperatures) is in principle incorrect and in practice inaccurate. Linkage of heat and mass transfer must be performed by according the appropriate

temperature dependences to the basic properties which enter the conservation laws: namely, the equilibrium interface concentrations and the oxygen diffusion coefficients. An analytical solution based on the near equality of the activation energies of oxygen diffusion in the oxide and in the metal is proposed.

Ames Laboratory, USDOE, Iowa State University, Ames, Iowa 50011

ABSTRACT

The electric mobilities, diffusivities, and effective valences were determined for molybdenum, rhenium, tungsten, and zirconium in β -thorium. All four solutes migrated in the same direction as the electron flow. Rhenium and molybdenum were found to be very mobile, with tungsten somewhat slower. Zirconium was found to move at a rate near that of the self-diffusion of β -thorium, *viz.*, about 10^{-11} m²/s at 1500°C. The electromigration velocities showed a similar trend. A comparison was made between experimental data obtained by scanning laser mass spectrometry and theoretical transport equations for two purification experiments. Good agreement was obtained with both the concentration profile predicted by DeGroot and the purification ratio predicted by Verhoeven.

One of the most effective methods of purifying refractory metals of undesirable solutes is by electrotransport at high temperatures. In this process, a constant voltage is applied across the metal sample which yields an internal electric field and a constant current, which heats the sample. The solutes are stimulated by the charge carriers to move toward one of the ends of the sample, thereby leaving a major portion of the sample virtually free of impurities.

The migration of solutes in solid metals under the influence of a direct current has been known since 1928, when Coehn and Specht (1) observed hydrogen transport in palladium. Many of the earlier investigators of electrotransport of interstitial solutes interpreted the direction and velocity of migration on the basis of a charge on the solute particle. In 1953, Seith and Wever (2) showed this interpretation to be incomplete to the extent that one cannot separate the contributions to the force moving the solute which arise from the charge on the solute in an electric field and the momentum transfer from the scattering of electrons or holes. Reviews by Heuman (3), Verhoeven (4), Huntington (5), and Pratt and Sellors (6) consider both the electrostatic force and the force resulting from moving electrons being scattered by the solute. The potential for applying electrotransport to the ultrapurification of

metals has been described by Verhoeven (7) and Peterson (8).

The purpose of this investigation is to continue our study of the electrotransport behavior of metallic solutes in refractory metals. In our previous work concerning the electrotransport purification of thorium (9), we found that not only the interstitial solutes carbon, nitrogen, and oxygen migrated in thorium when under the influence of the electric field but that several nonvolatile metallic solutes also moved. In our present work, we determined the electrotransport parameters of molybdenum, rhenium, tungsten, and zirconium since these metals are common impurities in thorium and are very difficult to remove by volatilization due to their low vapor pressures. The development of the scanning laser mass spectrometric (SLMS) technique (10) as a quantitative method of determining the concentration profile of a sample containing these solutes enables us to compare our experimental data with the concentration profile predicted from equations developed by DeGroot (11) and by Verhoeven (7).

Conceptual Approach

Determination of electrotransport parameters.—A current theoretical model of the electrotransport process as developed by Verhoeven (7) considers a force to be ex-

erted on the diffusing species by the applied electric field. This force contributes to the diffusing flux J such that

$$J = -D \frac{dc}{dx} \pm UEc \quad [1]$$

where D is the diffusion coefficient, dc/dx is the gradient of the concentration c with respect to distance, x , U is the electromigration mobility, and E is the applied electric field. The product UE is a velocity imparted to the diffusing species by the field E . The divergence of the total atom flux gives rise to the time rate of change of the concentration in the form of Fick's second law of diffusion, viz.

$$\frac{\partial c}{\partial t} = -\frac{\partial J}{\partial x} = D \frac{\partial^2 c}{\partial x^2} \pm UE \frac{\partial c}{\partial x} \quad [2]$$

This relation assumes D is independent of concentration and position, i.e., allowing no thermal gradients as D is a strong function of temperature. Equation [2] also assumes U and E are independent of position.

For short-time experiments using a sample with a step in the central portion of the concentration profile, the diffusion is confined to the central portion of the sample. A simple solution of Eq. [2] for these experiments can be expressed in terms of the error function

$$c(x,t) = c_1 + \frac{c_2 - c_1}{2} \left[1 + \operatorname{erf} \left(\frac{x \pm UEt}{\sqrt{4Dt}} \right) \right] \quad [3]$$

where x is measured from the initial position of the step, c_1 and c_2 are the initial solute atom concentrations below and above the step, respectively, and

$$\operatorname{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z e^{-s^2} ds \quad [4]$$

By rewriting Eq. [3] in the form

$$\left[2 \left(\frac{c(x,t) - c_1}{c_2 - c_1} \right) - 1 \right] = \operatorname{erf} \left(\frac{x \pm UEt}{\sqrt{4Dt}} \right) \quad [5]$$

the inverse error function can be expressed as

$$\operatorname{erf}^{-1} \left[2 \left(\frac{c(x,t) - c_1}{c_2 - c_1} \right) - 1 \right] = \frac{x \pm UEt}{\sqrt{4Dt}} \quad [6]$$

In the diffusion zone, Eq. [6] is a function linear in x with slope $1/\sqrt{4Dt}$ from which the diffusion coefficient can be obtained. If the origin is located at the initial position of the step, the point x at which $c(x) = (c_2 + c_1)/2$ may be used to determine the electromigration mobility according to $\Delta x = UEt$. This displacement is illustrated schematically in Fig. 1. Thus, by interpreting the solute atom concentration profile in terms of Eq. [3], values of the parameters D and U can readily be obtained.

An effective valence for the migrating solute may be obtained from the relation

$$Z^* = \frac{UkT}{De} = \frac{\Delta x kT}{EtDe} \quad [7]$$

where k is Boltzmann's constant, e the unit electric charge, and T the absolute temperature. Z^* is a measure of the interaction strength between the electromigrating species and the applied electric field.

The diffusion coefficient, D , is usually considered to have a temperature dependence of the form

$$D = D_0 \exp \left(-\frac{Q}{kT} \right) \quad [8]$$

where D_0 is a constant and Q is the activation energy for the diffusion process. By performing the electrotransport experiments at several different temperatures, the parameters in Eq. [8] can be determined.

Fig. 1. Schematic illustration of the solute concentration profile before (dashed line) and after (solid line) electrotransport showing resulting displacement, Δx .

Purification of metals by electrotransport processing.—The purification of metals by electrotransport as described by Verhoeven (4), for the case of a metal having an initial impurity concentration of C_0 , requires continuing the electrotransport operation until near steady state is achieved. In terms of the above model, this requires solving Eq. [2] as a boundary-value problem; the boundary conditions being that no flux enters the sample through the ends or from the environment. Verhoeven obtained this solution and expressed it in terms of the mean concentration in the purified half of the rod, $C_m(t)$. Normalized to the original concentration of the rod C_0 , this solution is of the form

$$\frac{C_m(t)}{C_0} = 2 \left[\frac{1 - e^{-S/2}}{1 - e^{-S}} - \sum_{n=1}^{\infty} C_n e^{-S/4} \sin \left(\frac{n\pi}{2} \right) e^{-\lambda_n t} \right] \quad [9]$$

where

$$C_n = \frac{32n\pi S [1 - (-1)^n e^{S/2}]}{(S^2 + 4n^2\pi^2)^2}$$

$$\lambda_n = \left(n^2\pi^2 + \frac{S^2}{4} \right) \frac{D}{l^2}$$

$$S = -\frac{U}{D} El$$

and l is the length of the sample. This equation should hold, assuming that U , D , and the electric field, E , are independent of position along the sample and that there is no external source of contamination.

An earlier solution of Eq. [2] as derived by DeGroot (11) for the same boundary conditions and assumptions has the form

$$\frac{C(x,t)}{C_0} = \frac{Se^{-Sx}}{1 - e^{-S}} + \sum_{n=1}^{\infty} C_n e^{-Sx/2} \left(\sin n\pi X - \frac{2n\pi}{S} \cos n\pi X \right) e^{-\lambda_n t} \quad [10]$$

where

$$C_n = \frac{16\pi n S^2 [1 - (-1)^n e^{S/2}]}{(S^2 + 4n^2\pi^2)^2}$$

$$S = \frac{U}{D} El$$

$$X = x/l$$

$$\lambda_n = \left(n^2\pi^2 + \frac{S^2}{4} \right) \frac{D}{l^2}$$

DeGroot's solution expresses the ratio of the solute concentration $C(x,t)$ to the initial concentration C_0 , at any point x , where $x = 0$ at the end of the sample to be puri-

fied, and at any time t . Solution of DeGroot's equation will, therefore, allow the calculation of the entire solute concentration profile at any time up to and including steady state.

Experimental

The experimental method used in this investigation to measure the transport properties of molybdenum, rhenium, tungsten, and zirconium in β -thorium was similar to that described by Peterson *et al.* (9). In this work, rods having a sharp concentration gradient of the solute were joule heated with a dc current under vacuum for various times at various temperatures. The displacement of the center of this diffusion couple from the original weld interface was used to measure the electrotransport mobility of a solute in a metal. The net effect of the electric field is a displacement Δx of the concentration profile by an amount, $\Delta x = UEt$, where U is the mobility, E the electric field, and t the time. Times were chosen at each temperature to give a reasonable smoothing by diffusion of the step-like concentration profile and a measurable displacement of the mean concentration from the weld interface. Pressures $< 2.6 \times 10^{-5}$ Pa were generally achieved during each experiment.

The diffusion coefficient, D , was calculated from the concentration profiles by the Grube method (12), taking the midpoint at a distance Δx from the weld interface. The values were obtained using the inverse error function, and a least squares analysis was used to estimate the slope from which a value of D was obtained. The effective valence, Z^* , was calculated from the mobility and diffusion coefficient using Eq. [7].

Materials.—The high purity thorium used in this work was prepared by the magnesium intermediate alloy process developed by Peterson *et al.* (13). This material had been triple electron-beam melted and contained less than 230 weight parts per million (wt ppm) total impurity. The major impurities were carbon 50 wt ppm, nitrogen 45 wt ppm, oxygen 25 wt ppm, and less than 100 wt ppm of total metallic impurities.

The molybdenum, rhenium, tungsten, and zirconium used as alloy additions were cut from electron-beam-melted ingots of the respective metals and were obtained from commercial sources. These metals were of 99.95 weight percent (w/o) or greater purity. The tantalum metal used as adapters for the thorium samples was of 99.95 w/o purity. It was also electron-beam melted for further purification before it was fabricated into the desired parts.

Sample preparation.—The binary alloys were made by separately arc melting nominal amounts of the high purity solute material with 50g of the high purity thorium metal. The nominal alloy concentrations were typically 80-90 wt ppm, low enough to be in solid solution, yet high enough to be detected by mass spectrometric analysis. The arc-cast alloys were fabricated by rolling and subsequent swaging into rods of 0.00254m diam.

The specimens used in the electrotransport mobility measurements were rods 0.066m long and of 0.0025m diam. One third of the rod consisted of pure thorium, and the remainder consisted of the thorium containing solute additions of molybdenum, rhenium, tungsten, or zirconium. Prior to butt welding these segments together in an inert atmosphere, they were surface cleaned by electropolishing in a chilled methanol-perchloric acid bath (14). The composite sample thus contained a sharp step in the solute concentration profile at the weld interface similar to that shown in Fig. 1.

Apparatus.—The apparatus used to contain the electrotransport specimens during processing consists of a stainless steel sample chamber equipped with two electrodes, a sight glass for viewing the sample and to optically monitor its temperature, and a vacuum system capable of obtaining a pressure of $< 10^{-5}$ Pa. The composite thorium specimen was threaded onto high purity tantalum U-shaped adapters and inserted between the two elec-

trodes; the pure thorium end of the specimen being connected to the cathode of the power supply. A regulated direct current power supply with voltage and current mode control was used to joule heat the sample to the desired temperature. The temperature of the sample was measured with an optical pyrometer and the observed temperature was corrected according to the equation

$$\text{True temp} = 1.167 (\text{observed temp}) - 97.23 \quad [11]$$

This equation was obtained from data of a separate experiment in which several observed surface temperatures were compared to temperatures of adjacent black-body holes in the electropolished thorium specimen. An additional 15° - 25° C was added to compensate for loss due to absorption by the viewing window. The viewing window correction was determined after each experiment using a tungsten lamp. The temperature at any point along the specimen was constant to within 10° C during an experiment. The center of the sample was about 25° C hotter than the ends because the tantalum adapters were somewhat cooler than the specimen.

Analysis.—After the specimens were heated for a specific time and temperature, their concentration profiles were obtained using a scanning laser mass spectrometric technique (15). The rod specimens were ground flat on two sides and electropolished to provide a flat longitudinal surface along which to measure the concentration profile. The mass spectrographic technique utilizes a vacuum system in which a pulsed laser beam is rastered across the sample while making a continuous scan longitudinally along the sample. The scanning laser beam vaporizes and ionizes a small amount of the specimen, and these ions are collected and sorted by the mass spectrometer, permitting the intensity of a single ion to be monitored. These solute atom ion signals are normalized to the total ion beam signal by taking the ratio of this solute atom ion current to the ion beam current from the thorium ions ($^{232}\text{Th}^{+}$). Since the number of thorium ions remains essentially constant along the sample, the ratio gives a relative intensity of the solute atoms present. By selecting an ion of a solute atom and plotting its relative intensity while the laser longitudinally scans the sample, an intensity profile proportional to the solute atom concentration is obtained as a function of distance along the sample. The isotopes monitored during the individual mass spectroscopic concentration profile measurements were ^{99}Mo , ^{187}Re , ^{184}W , and ^{90}Zr . During the scan, the laser is extinguished periodically, leaving blank spaces on the sample and on the intensity graph. These spaces are used for a precise spatial correlation between the graph and the sample. This correlation is necessary to locate the position of the initial weld interface on the intensity profile from which the distance of electromigration, Δx , is measured. The measurement of the distance of these spaces

Fig. 2. A ^{99}Mo intensity graph showing the solute atom concentration profile in thorium following electrotransport for 3h at 1530°C .

Table I. Electrotransport mobilities, diffusion coefficients, and effective valences for molybdenum, rhenium, tungsten, and zirconium in β -thorium

Solute	Temp (°C)	$\Delta x \times 10^2$ (m)	t (h)	$E \times 10^2$ (V/m)	$U \times 10^9$ (m ² /V s)	$D \times 10^{10}$ (m ² /s)	Z^*

	1500	0.62	11	0.153	10.2	1.73	-9.0
	1460	0.50	11	0.149	8.82	1.78	-7.4
	1410	0.41	12	0.133	7.16	1.17	-8.9
Zirconium	1600	0.30	104	0.184	0.428	0.356	-1.9
	1500	0.13	125	0.160	0.174	0.089	-3.0

from the weld interface was accomplished using a precision microscope equipped with a vernier eyepiece. Figure 2 shows a composition profile in which the relative solute intensity is plotted as a function of the relative distance for the ⁹⁹Mo³⁺ ion in a composite thorium/thorium-molybdenum sample which was run for 3h at 1530°C. The position of the weld interface is shown and the shift of the solute concentration from its initial step-shape can be seen.

Analysis of the solute atom concentration profile graphs was performed statistically, data points having been taken off the intensity graphs as functions of arbitrarily scaled abscissas. From the corresponding blanks on each sample and graph, a scale factor was determined to correlate the graph abscissa with the sample. From each graph, upper and lower concentration levels were determined for c_2 and c_1 , respectively, and the data were normalized and transformed as in Eq. [6]. A linear least squares analysis was used to calculate values of the slope and of the intercept of the straight line with the abscissa. Values of D and U were then calculated.

In order to test the purification equations, Eq. [9] and [10], composite samples were prepared consisting of a 0.025m length of the pure thorium and a 0.137m length of thorium containing 100 wt ppm molybdenum. These samples were then heated with a direct current for 30h at a pressure of about 1×10^{-6} Pa. The center of each of the samples was maintained at a temperature of about 1500°C. After several hours of heating considerable sagging in the center section was observed. A 0.015m long section on either end of the sample was too cool to creep and deform under the pull of gravity, and remained straight. The use of the pure thorium section at the cathode end eliminated any effect of a temperature gradient. After each experiment, the entire rod was cut into sections and analyzed with the mass spectrometer to obtain the complete profile of the sample.

Results and Discussion

The electrotransport parameters for thorium composite samples consisting of a dilute binary alloy of molybdenum, rhenium, tungsten, or zirconium and a segment of pure thorium were determined between 1390° and 1670°C, as shown in Table I. All four solutes move toward the anode, *i.e.*, in the direction of the electron flow during electrotransport. The electrotransport parameters follow a regular variation with temperature except for the effective valence, Z^* , which shows considerable scatter. Verhoeven (7) has stated that Eq. [7] for the calculation of Z^* should include the correlation factor, f , for movement by a substitutional solute-vacancy mechanism. Since the mechanism of diffusion for molybdenum and rhenium and possibly tungsten is uncertain, however, the correlation factor was not included in any of the calculations.

From the data in Table I, it is seen that molybdenum and rhenium exhibit considerably higher electric mobilities and diffusivities than either tungsten or zirconium at all temperatures studied. These values for molybdenum and rhenium are about two orders of magnitude greater

than those for zirconium at comparable temperatures with tungsten lying somewhere between. This can be seen from Fig. 3, which is an Arrhenius-type plot of $\ln V/j$ vs. $1/T$ for the four solutes, where V is the migration velocity in cm/s and j is the current density. Huntington and Grone (16) used a similar plot to obtain a "pseudo-activation" energy of electrotransport, Q_E . They found that this value for gold was about 20% lower than the activation energy for self-diffusion for the same metal. Values of Q_E were obtained for each of the solutes from least squares best-fit straight lines. These values are listed in Table II.

Figure 4 shows similar Arrhenius-type plots of the diffusion coefficients vs. reciprocal temperature for the four solutes. The slope of the least squares best-fit straight line in Fig. 4 is the activation energy, Q_D , in Eq. [8], and the intercept gives the pre-exponential, D_0 . These values are also given for each of the solute atoms in Table II. The activation energies for electrotransport and diffusion, Q_E and Q_D , respectively, shown in Table II exhibit differences of from 18% for rhenium to 33% for zirconium, with Q_E in every instance being smaller than Q_D . Similar differences have been reported in Q_E and Q_D for self-transport of aluminum and silver (17) and for vanadium, niobium, and tantalum solutes in β -thorium (18).

Generally, these solute atoms could be considered to be substitutional impurities in thorium. Their diffusive movement would thus be determined by a vacancy mechanism similar to self-diffusion. The variability in both the electric mobility and diffusion rates, however, indicates the possibility of some other transport mechanism as the faster moving solutes have electric mobilities and diffusivities in the range of those observed for interstitial solutes in thorium. The atom sizes, for instance, appear to have some significance. Upon considering the atomic radii of these solute atoms, rhenium is the smallest of the four, followed by molybdenum, tungsten, and zirconium. The electric mobilities and diffusivities of these atoms in β -thorium show decreasing magnitudes in the same order. Thus, one might conclude that there is a simple size dependence for solute atom migration in β -thorium. Consideration of the behavior of other solute atoms, however, shows that this is not a completely reliable indicator of the magnitude of the mobility or diffusivity.

The results obtained in this investigation compare favorably with the diffusivities obtained for vanadium, niobium, and tantalum (20) and iron, cobalt, and nickel (18) in β -thorium, as can be seen from Fig. 5. Earlier studies (18) have shown that iron, cobalt, and nickel are fast dif-

Table II. Electrotransport and diffusion parameters for molybdenum, rhenium, tungsten, and zirconium in thorium

Solute	Q_E (kJ/mol)	Q_D (kJ/mol)	D_0 (m ² /s)
Molybdenum	173	216	1.51×10^{-3}
Rhenium	66	84	4.04×10^{-7}
Tungsten	131	160	1.03×10^{-5}
Zirconium	257	384	1.73

Fig. 3. Arrhenius-type plot of $\ln V/i$ vs. reciprocal temperature for rhenium, molybdenum, tungsten, and zirconium in β -thorium.

fusing solutes in α - and β -thorium. The diffusivity of cobalt is similar in magnitude to that of rhenium ($D > 10^{-9}$ m²/s, $T > 1400^\circ\text{C}$), with iron and nickel being slightly higher. Molybdenum exhibits diffusivities equal to or greater than rhenium at temperatures above about 1600°C , as is seen from Fig. 5. Its atomic radius is about the same as that of rhenium. Both rhenium and molybdenum, however, have atomic radii considerably larger than iron, cobalt, or nickel, the latter three atoms being very similar in size.

Vanadium is anomalous since it has an atomic radius smaller than molybdenum and rhenium but diffuses slower than either. Tungsten, niobium, tantalum, and zirconium all diffuse at rates slower than vanadium; their magnitudes decreasing in the order listed and their

Fig. 4. Arrhenius-type plots for diffusivity of rhenium, molybdenum, tungsten, and zirconium in β -thorium.

Fig. 5. Arrhenius-type plot for diffusivity of oxygen, nitrogen, carbon (20), iron, cobalt, nickel, niobium, tantalum, vanadium, rhenium, molybdenum, tungsten, and zirconium in β -thorium.

atomic radii increasing in the same order. The diffusivity of zirconium is of the same order as that for self-diffusion in β -thorium, *i.e.*, about 10^{-11} m²/s at 1500°C (21). Thus, those solutes in Fig. 5 that diffuse slower than tungsten appear to follow a size-dependent behavior. The fast diffusing solutes in β -thorium, namely, iron, cobalt, nickel, and rhenium, exhibit a more complicated diffusivity behavior.

Two purification runs were made using molybdenum as the solute. Molybdenum was chosen since it has a relatively high solubility and mobility in thorium at the temperatures of interest. It was also important that the experiments be performed in a molybdenum-free system to eliminate any possibility of external contamination. In order to obtain a valid test of the theoretical transport equations, it was necessary to perform the purification runs at a temperature and for a length of time such that the solute concentration would be above the detection limit (1 wt ppm) of the SLMS apparatus in at least 75% of the rod. A temperature of 1500°C was chosen. According to previous results at this temperature, the diffusivity, D , equals 6.8×10^{-10} m²/s, and the electromigration velocity, V , equals 0.002 m/h. By the solution of Eq. [9] using these values and a sample length, l , equal to 0.137m, a purification ratio, C_m/C_o , equal to 0.15 was calculated for a time of 30h at 1500°C . Since $C_o = 100$ wt ppm, this ratio predicts an average concentration of 15 wt ppm in the purer half of the rod.

The experimental molybdenum concentration as a function of distance after purification at 1500°C is shown in Fig. 6. Also shown for comparison are two theoretical concentration profiles calculated from Eq. [10] for 30h at 1465°C and 1500°C . As can be seen from Fig. 6, the best agreement was obtained between the experimental curve and the theoretical curve calculated at 1465°C . This difference may in part be due to uncertainties in the experimental temperature. From this plot, a C_m value of 28 wt ppm was obtained for the experiment, which is in reasonably good agreement with the predicted value of 15 wt ppm. There is a significant deviation between theory and experiment, however, in the high concentration end of the rod. A second purification experiment was made as a check on the data from the first run. The data from the two experiments agreed within a few percent throughout

Fig. 6. Comparison of experimental and theoretical molybdenum concentration in thorium rod as a function of distance after heating for 30h.

the length of the two samples, with both experiments showing the same deviation from the theoretical prediction.

Summary

The electric mobilities, diffusivities, and effective valences of the metallic solutes, molybdenum, rhenium, tungsten, and zirconium in β -thorium were determined. All four solutes migrate in the same direction as the electron flow. Rhenium and molybdenum exhibit high electric mobilities in thorium, whereas zirconium was found to be extremely slow, with tungsten lying somewhere between. The "pseudo-activation" energy for electrotransport, Q_e , of rhenium in β -thorium is quite low at 66 kJ/mol, with molybdenum and tungsten having energies of 173 and 131 kJ/mol, respectively, and zirconium having a high activation energy of electrotransport of 257 kJ/mol.

The diffusion parameters, Q_D and D_0 , for the four solutes in β -thorium were also determined. The diffusivities range from those of fast diffusing solutes to those observed for vacancy-controlled diffusion, *i.e.*, from rhenium with $D(1500^\circ\text{C}) \sim 2 \times 10^{-9} \text{ m}^2/\text{s}$ to zirconium with $D(1500^\circ\text{C}) \sim 9 \times 10^{-12} \text{ m}^2/\text{s}$. The values obtained for Q_e are considerably lower than those observed for Q_D , with the differences ranging from only 18% for rhenium to 33% for zirconium. The magnitude of the diffusion constants, D_0 , for rhenium, molybdenum, and tungsten are reasonable for metallic solutes, but that for zirconium is excessively large. However, it is based on only two points and could have a large error. The observed electrotransport behavior of the slower diffusing solutes in β -thorium, tungsten, and zirconium, is consistent with our previous conclusion that a correlation exists between the electric mobility or diffusivity and the relative atomic sizes of the solute and host metals. For the faster diffusing solutes, this correlation is not apparent, and a more complicated relationship must exist.

Two purification-type experiments were performed to provide data for comparison with theoretical predictions. Good agreement between theory and experiment was

found for the purified portion of the rods, but a significant deviation from theory was noted in the high concentration end.

Characterization of LPCVD Aluminum for VLSI Processing

R. A. Levy,* M. L. Green,* and P. K. Gallagher

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Aluminum and aluminum alloys are widely used for metallizing devices in VLSI processing. Such films can be deposited by a variety of techniques, which all presently suffer from inadequate step coverage. In this paper, we discuss the properties of aluminum films deposited by a low pressure chemical vapor deposition process using tri-isobutyl aluminum as a source. Results of this work demonstrate that this process provides conformal step coverage, introduces no surface states, and promises to yield high wafer throughput. Films deposited on oxidized silicon monitors exhibit excellent properties in terms of chemical purity, adhesion, and electrical resistivity. Films deposited on device wafers prove to be compatible with current VLSI processing in terms of patterning, dry etching, and bondability and appear to have no effect on overall device performance. However, drawbacks of LPCVD aluminum appear to be in its structure-related properties: namely, electromigration resistance and Al-Si interdiffusion. These problems and potential solutions are addressed.

Aluminum and aluminum-silicon-copper alloy films are widely used for metallizing devices in VLSI processing. Such films have normally been deposited by electron-beam (E-Gun[®]) or RF induction-source (In-Source[®]) evaporation, although more recently sputtering has become prominent. All these line-of-sight deposition techniques suffer, however, from inadequate step coverage, which often results in the formation of microcracks and discontinuities at corners of deep steps. With the expected increase in the use of multilevel metallization for vertical integration, coupled with the expected increase in packing density of devices with horizontally reduced dimensions, the development of a deposition technique which provides conformal step coverage becomes essential. In this paper, we will discuss the properties of aluminum films deposited on both oxidized silicon monitors and device wafers by a low pressure chemical vapor deposition (LPCVD) process using tri-isobutyl aluminum (TIBAL) as a source. Little has been published regarding LPCVD aluminum or its alloys because of the lack of suitable sources dissociating below the melting point of the metal (660°C) and the well-known chemical activity of aluminum with residual oxygen and water. Results of this work will establish a basic understanding of the properties of these LPCVD aluminum films, and their suitability for current VLSI processing.

Properties and Plating Chemistry of TIBAL

TIBAL (1) used in the present investigation, is a clear liquid with a density of 0.8 g/cm³. It has a melting point of -6°C and a boiling point of 40°C at 0.1 torr of Hg. It is pyrophoric, mildly toxic, and explosive in contact with water. Hence, extreme care should be exercised in the handling and disposing of the source liquid and the unreacted product of the dissociation.

The following chemical reactions occur during thermal decomposition (2)

Reaction [1] occurs from 50° to 150°C. During this step, TIBAL decomposes to di-isobutyl aluminum hydride by releasing isobutylene gas. At about 220°C, reaction [2] occurs, during which the di-isobutyl aluminum hydride thermally dissociates to pure Al by releasing both H₂ and isobutylene gas. Reaction [1] is reversible, and the formation of di-isobutyl aluminum hydride can be suppressed by adding excess isobutylene gas. Reaction [2] is not reversible and is known to proceed only over a narrow temperature range (220°-300°C) which, unfortunately, precludes in this process the simultaneous dissociation of SiH₄ (~450°C) and codeposition of Si in these films.

*Electrochemical Society Active Member.

Deposition Procedure

LPCVD Al films are becoming commercially available. The films, under present investigation, were deposited by ASM America, Incorporated, in an experimental LPCVD reactor shown in Fig. 1. Details on the design of the reactor as well as the process used by the vendor have been previously reported (3). The TIBAL liquid was evaporated at 45°C with the vapor flowing down a 1200 mm long, 150 mm diam stainless steel reactor tube. The reactor tube was loaded with as many as fifty 75 mm wafers within a three-zone furnace and pumped down with the aid of a liquid nitrogen cold trap and a Roots rotary pump combination. At the start of the operation, the LPCVD reactor was evacuated and purged with hydrogen at 450°C to reduce adsorbed air and moisture and the temperature in the center zone ramped down to ~260°C. The wafers were then exposed to TiCl₄ vapor, at a pressure of 0.5 torr, to "activate" the substrate surface prior to deposition. Without TiCl₄ acting as a nucleation catalyst, the aluminum is known to nucleate randomly on the surface, causing the growth of large individual crystallites. Following pumpdown of the TiCl₄ vapor, the dissociation reaction of TIBAL proceeded, at the previously fixed conditions of temperature and pressure, yielding a deposition rate of ~300 Å/min. At the end of the operation, the reactor went through a final pumpdown and was backfilled with nitrogen to atmospheric pressure. Table I details the process sequence used and the operating time for each step.

Physical Properties of LPCVD Aluminum

The chemical composition and adhesion, as well as the electrical, structural, and optical properties of LPCVD aluminum have been characterized by investigating films deposited on thermally oxidized monitors. Each of these properties will now be described.

Chemical composition.—One of our primary concerns in the use of TIBAL was the possible inclusion of carbon in the films. To check that possibility, Auger spectra were

gathered both on the surface and at a depth of 1000Å. Figure 2 shows an elemental survey of the surface which indicates the presence of aluminum, oxygen, carbon, and sulfur. The tendency of aluminum to react readily with the ambient to form a thin corrosion-resistant film of Al₂O₃ accounts for the presence of the oxygen. The carbon and sulfur are considered, here, to be normal surface contaminants. A second elemental survey, shown in Fig. 3, taken after ion milling with neon to a depth of 1000Å, exhibits the aluminum peaks but fails to reveal, at this magnification, observable contaminants beyond the expected neon signal. An expansion of the spectrum in the vicinity of the carbon signal, shown in Fig. 4, reveals an estimated carbon content in the film of $\approx 0.3\%$. Mass spectrometric gas evolution analysis performed on part of a monitor wafer over a temperature range extending from 27° to 700°C failed to reveal significant evolution of carbonous material beyond that in the background of the system. This data coupled with the Auger analysis sets the purity of these films to better than 99.7%.

Adhesion.—A segment of Scotch tape applied and peeled off the surface of the aluminum film failed, under repeated testing, to show signs of flaking. This test, however rudimentary, illustrates the degree of adherence of the LPCVD aluminum film to the underlying thermal oxide.

Electrical properties.—In order to evaluate the electrical properties of these films, the resistivity and electromigration resistance were determined. The resistivity was determined using two different methods. In one case, both the sheet resistance and thickness were measured over several areas of the film using a four point probe and Dektak® stylus. By combination of the average of these two parameters, a value for the resistivity of the LPCVD aluminum film was calculated to be $3.36 (\pm 0.24) \times 10^{-6} \Omega\text{-cm}$. In the other case, an electromigration meander tester was used, where the track was 1 cm long and had a deposited film thickness of $7774 \pm 303 \text{Å}$ and a patterned linewidth of $2.30 \pm 0.07 \mu\text{m}$. The resistance of the line was measured with a digital multimeter. From known values of resistance, length, and cross-sectional area, the resistiv-

Fig. 2. Auger elemental survey of LPCVD aluminum surface

Fig. 3. Auger elemental survey of LPVCD aluminum at 1000Å depth

ity was calculated to be $3.42 (\pm 0.17) \times 10^{-6} \Omega\text{-cm}$. Both these measuring techniques yielded values of resistivity $\sim 10\%$ higher than those reported for typical aluminum films (4).

The electromigration measurements were carried out on a group of typically 12 packaged testers with $2.25 \mu\text{m}$ wide aluminum meander lines under accelerated conditions of temperature (T) set at 192°, 214°, and 270°C and current density (J) set at $1.85 \times 10^6 \text{ A/cm}^2$. All films which underwent this test were reactive ion etched and sintered at 300°C/30 min/H₂. From a plot of the measured values of the median time-to-failure, MTF, vs. $1/T$, shown in Fig. 5, an activation energy, Q , of 0.51 eV was calculated. This is in excellent agreement with values reported for fine-grained In-Source aluminum films (5). Using the present value of Q , the median time-to-failure (MTF) extrapolated to 80°C and $1 \times 10^5 \text{ A/cm}^2$, was calculated with the use of the relationship $\text{MTF} = AJ^{-2} \exp [Q/kT]$, to be equal to $9.1 \times 10^4 \text{ h}$. This value compares well with the reported value of $7.6 \times 10^4 \text{ h}$ for the $2.9 \mu\text{m}$ wide meander lines of In-Source Al-0.5%Cu similarly deposited at a rate of 300 Å/min and sintered at 300°C/30 min/H₂ (6). However, it is significantly lower than the value of $5.3 \times 10^6 \text{ h}$ observed by the authors for In-Source Al-0.5%Cu deposited at 300°C at a rate of 140 Å/s and sintered at 300°C/30 min/H₂. This difference is believed to be primarily due to the copper contribution as well as structural differences. As will be described further in this report, LPCVD aluminum films exhibit grains that are small in size; a fact that has been shown to adversely affect both Q and MTF (7). Furthermore, the nonuniform thickness observed across the film is expected to modulate the magnitude of the current density, thereby enhancing the electromigration failure in the thinner cross-sectional areas. Electromigra-

Fig. 5. Median time to failure vs. reciprocal temperature at an accelerated current density. (—): Sintered at 300°C/30 min/H₂. (---): Sintered at 300°C/30 min/H₂ with 1.4 μm plasma SiN.

tion data were also gathered on 1.34 μm wide meander lines, subjected to an accelerated temperature of 186°C and a current density of 1.85×10^6 A/cm². The extrapolated value (80°C, 1×10^5 A/cm²) for MTF, using $Q = 0.51$ eV was calculated to be 1.1×10^5 h, showing little variation, in this case, with narrower linewidths.

In order to examine the effect of capping the LPCVD aluminum with plasma SiN, groups of typically 18 meanders with 1.83 μm linewidth were tested, under accelerated conditions, at temperatures of 162°, 187°, and 212°C and at a constant current density of 1.85×10^6 A/cm². The 1.4 μm plasma SiN cap layer was deposited at ~300°C for 110 min on the entire wafer and subsequently patterned and plasma etched to expose the aluminum pads for wire bonding. A plot of MTF vs. $1/T$ yielded a value of 0.67 eV, possibly reflecting the increase in aluminum grain growth with additional heat-treatment. The extrapolated value of MTF (80°C, 1×10^5 A/cm²) was calculated to be 4.5×10^5 h with the increase, as shown in Fig. 5, resulting from the higher activation energy.

Structural properties.—One of the most prominent features of LPCVD aluminum is its surface topography. Under visual examination, the films have a distinctive non-specular, cloudy appearance. At 1100× magnification, a rough grainy structure becomes evident. At still higher magnification, with the aid of a scanning electron microscope (SEM), the steep peaks and valleys, which account for the poor reflectance of the surface, could be readily seen (Fig. 6). This surface roughness is believed to be directly related to the deposition process which governs the nucleation and growth mechanism of aluminum. In the present LPCVD process, we postulate that the aluminum atoms, after decomposition of the adsorbed alkyl molecules, stick to the substrate without significant surface diffusion. In an improperly activated substrate surface, nucleating sites are few and randomly distributed across

Fig. 6. SEM micrograph illustrating surface topography of LPCVD aluminum.

the surface. The growth of nuclei is believed to be three dimensional, but anisotropic with preferred growth occurring normal to the surface. During the growth process, these nuclei coalesce and form crystallographically shaped islands. As deposition continues, secondary nucleation occurs in open areas, and these nuclei in turn grow and coalesce to form new islands which eventually merge with the older ones to form a coherent film. Depending, therefore, on the time lag between primary and secondary nucleation and the growth kinetics of these nuclei, a wide range of topography may be expected. Figure 7 shows a transmission electron micrograph of a thin vertical cross section of an LPCVD aluminum film. The average film thickness, in this case, is ~6000Å with a maximum peak to valley height of ~2500Å. These variations from the average film thickness are expected to further increase with thicker films. Figure 8 shows a transmission electron micrograph of a thin horizontal cross section of an LPCVD aluminum film subjected to a 300°C/30 min/H₂ sinter. The grain-size distribution is observed to be wide, ranging from 1 to 4 μm. Using the conventional line intersection technique, a value for the average grain size was measured to be 1.4 ± 0.3 μm. Both the grain size and grain size distribution appear to be significantly different from those of In-Source Al-0.5%Cu deposited at 300°C, at a rate of 140 Å/s and sintered at 300°C/30 min/H₂. Such a film, shown in Fig. 9, has a distribution of grain sizes ranging from 1 to 6 μm with an average grain size of 1.8 ± 0.4 μm.

X-ray diffraction data taken with CuKα radiation at 45 kV and 30 mA, on both as-deposited LPCVD aluminum and In-Source Al-0.5%Cu deposited at ~220°C and at a rate of ~60 Å/s, reveal significant differences. Besides reflections parallel to the <100> Si substrate, which were common in both samples, the comparative spectra, shown in Fig. 10, exhibit, in the case of the LPCVD alu-

Fig. 7. TEM vertical cross-section micrograph of LPCVD aluminum

Fig. 8. TEM horizontal cross-section micrograph of LPCVD aluminum

Fig. 9. TEM horizontal cross-section of In-Source Al-0.5%Cu

minum, a highly textured $\langle 111 \rangle$ structure. This is evident from the intensity ratio (I_{111}/I_{200}), which has been calculated to be (100/2) compared to the (100/47) expected of polycrystalline aluminum with random orientation. Although reflections from the $\langle 311 \rangle$ and $\langle 222 \rangle$ planes were evident, the $\langle 220 \rangle$ diffraction peak was absent from this x-ray pattern. The In-Source Al-0.5%Cu spectrum, on the other hand, reveals a lower degree of $\langle 111 \rangle$ texture as indicated by the calculated (I_{111}/I_{200}) intensity ratio of (100/6), the weaker reflections of the $\langle 222 \rangle$ planes and the emergence of the $\langle 220 \rangle$ diffraction peak.

Optical properties.—In order to investigate the optical properties of LPCVD aluminum, reflectance measurements were gathered over the optical wavelength scan of 0.20 to 0.90 μm using a Perkin-Elmer (Coleman 575) spectrophotometer. Figure 11 shows the percentage of reflectance of a 0.5 μm thick Al film relative to that of a 1 μm thick In-Source Al-0.5% Cu film in the wavelength range where photolithographic processing is prevalent. The data indicate a broad minimum with a 5% reflectance ratio centered around the 0.35 μm wavelength. Below this minimum, a 14% reflectance ratio is reached at the lowest investigated wavelength of 0.20 μm , and a 40%

Fig. 10. Comparative x-ray spectra of LPCVD Al and In-Source Al-0.5%Cu.

Fig. 11. Percentage of reflectance of LPCVD aluminum relative to In-Source Al-0.5% Cu vs. wavelength.

reflectance ratio at the highest investigated wavelength of 0.90 μm . The poor reflectance of LPCVD aluminum, which may prove to be beneficial in photolithographic processing, is directly related to the surface roughness of the film. A reflected beam is known to form only if the average depth of the surface irregularities of the reflector is substantially less than the wavelength of the incident light. In the present case, where our surface irregularities are of the order of $\sim 2500\text{\AA}$, enhancement of the reflectance occurs, as, indeed, observed in Fig. 11, at longer wavelengths.

Suitability of LPCVD Aluminum to VLSI Processing

The suitability of LPCVD aluminum to current VLSI processing was investigated with the use of 75 mm device wafers fabricated in accordance with the 2.5 μm Twin-Tub CMOS process (with TaSi_2) (8). The processed wafers included IGFET, contact resistance, van der Pauw, and MOS testers which were automatically probed, after aluminum patterning, at four sites across each wafer. All wafers received a preclean ($\text{H}_2\text{SO}_4/\text{H}_2\text{O}_2$) and an HF etch prior to insertion into the LPCVD reactor. For correlation purposes, device wafers metallized with sputtered Al as well as In-Source Al-0.5% Cu were processed with the experimental batch. The etching profile, step coverage, spiking, bondability, and effect on device performance of LPCVD aluminum will now be considered.

Etching profile.—Following photolithography, the aluminum was reactive sputter etched in a HEX reactor using a chlorine-based gas mixture. Figure 12 illustrates the quality of the etch in various parts of a wafer. Examination of the photographs reveals no residue between the

Fig. 12. Etching profile across device wafer for LPCVD aluminum

delineated patterns, no signs of undercutting, and no Al wall erosion or severe linewidth loss.

Step coverage.—The possibility of achieving conformal step coverage has been the primary objective in the development of LPCVD aluminum. Evaporation and sputtering techniques have been known to produce films that thinned down considerably along window walls and bulged upward at the bottom of the window. Although considerable effort was directed toward improvement of step coverage by adopting higher deposition temperatures to enhance surface mobility or optimizing the planetary motion to improve uniformity, fundamental limits restricted further improvements. Figure 13 shows a series of SEM cross-sectional photographs illustrating the quality of step coverage for LPCVD aluminum deposited over contact windows to silicon and polycide. Measurements of the film thickness along the window sidewalls and along the top or bottom regions of the window yield identical values everywhere, confirming the conformal step coverage of this process. An increase in the aluminum film thickness to $\sim 1.3 \mu\text{m}$ is expected, in the present $2.5 \mu\text{m}$ design pattern, to totally plug the windows and establish a markedly reduced topography. This can be seen in Fig. 14, where Al appears to have filled the cavities in the P-glass between polycide runners. The plasma SiN used for capping devices appears, as shown in Fig. 15A, to replicate the conformal CVD coverage of the underlying aluminum and P-glass structures while exhibiting, as seen in Fig. 15B, its characteristic surface morphology.

Fig. 15. (A) Overall step coverage of plasma SiN cap, LPCVD aluminum and P-glass. (B) Surface topography of plasma SiN cap. Magnification bar is $4 \mu\text{m}$.

Junction spiking.—Prior to LPCVD aluminum deposition, all wafers in the present investigation were preheated at $\sim 450^\circ\text{C}$ in H_2 to reduce air and moisture in the reactor. The temperature was then ramped down to $\sim 260^\circ\text{C}$ to activate the substrate surface with TiCl_4 and dissociate the TIBAL. Following aluminum patterning, a group of device wafers was sintered at $300^\circ\text{C}/30 \text{ min}/\text{H}_2$. Part of that group received a $1 \mu\text{m}$ thick plasma SiN cap film deposited at 300°C for 95 min, with one wafer getting an additional $450^\circ\text{C}/30 \text{ min}/\text{H}_2$ sinter. Figure 16 shows SEM cross-sectional micrographs of contact windows to silicon and polycide taken after stripping the aluminum and prior to the $300^\circ\text{C}/30 \text{ min}/\text{H}_2$ sintering step. These micrographs indicate that, although the contact window to polycide remained intact after the $\sim 260^\circ\text{C}$ aluminum deposition (Fig. 16B), the contact window to silicon has been significantly eroded. Measurements of the depth of this pit at several points below the Si surface yielded values as high as $\sim 2000\text{\AA}$. We believe that this interdiffusion occurred, at these relatively low deposition temperatures ($\sim 260^\circ\text{C}$), in a continuous fashion across the interface due to the etching of the native oxide during the pretreatment process. In the presence of an imperfect native oxide, the interdiffusion as observed for evaporated or sputtered aluminum has been reported (9) to proceed through pinholes in the oxide, causing preferential spiking along $\langle 111 \rangle$ crystallographic planes. Further evidence for this native oxide etch, to be discussed further below, is provided by the remarkably low values for aluminum contact resistance to N^+ silicon. Figure 17 is a SEM micrograph taken after stripping the aluminum from contact windows to silicon and polycide. The surface morphology of

Fig. 16. SEM cross-sections of contact windows to (A) silicon and (B) polycide, after aluminum removal.

the silicon window appears quite rough. For shallow junction devices ($<0.25 \mu\text{m}$) this interdiffusion is a significant problem, which can be resolved by further reduction of the aluminum deposition temperature and that of subsequent processing, or by the use of a diffusion barrier. Ongoing efforts are addressing these possibilities. Figure 18 shows SEM cross-sectional micrographs of stripped contact windows to silicon and polycide following the $300^\circ\text{C}/30 \text{ min}/\text{H}_2$ sinter. The interdiffusion of silicon and aluminum is seen to have extended over a maximum depth of 4000\AA below the Si surface. This temperature-dependent erosion of the interface provides supporting evidence that our observations are consistent with a thermally activated interdiffusion phenomenon. Additional thermal processing caused by plasma SiN capping of the devices at 300°C for 95 min, and a supplemental $450^\circ\text{C}/30 \text{ min}/\text{H}_2$ sinter was observed to further enhance interdiffusion of silicon and aluminum down to a depth of $\sim 6000\text{\AA}$.

It is interesting to note that a series of highly oriented crystallographic precipitates of silicon, as determined by x-ray energy dispersive analysis, was observed on a few of the contact windows to polycide for samples which had received the $300^\circ\text{C}/30 \text{ min}/\text{H}_2$ sinter. The presence of these faceted crystals, shown in Fig. 19, is quite surprising in view of the fact that the TaSi_2 substrate is

polycrystalline, and tends to indicate that silicon diffusion from or through the TaSi₂ is possible. In such cases, the use of a barrier becomes necessary not only to prevent reaction with aluminum at silicon junctions but also diffusion at polycide gates.

Bondability.—The ability to wire bond to LPCVD aluminum films was investigated with the use of several electromigration tester chips which had been eutectically bonded to 40 pin dual-in-line packages. Both Au and Al-1%Mg wires 25 μm thick were wire bonded to aluminum pads on the chip side and gold pads on the package side. The gold wires were drawn automatically out of a spool, with the package heated at 150°C, to ultrasonically form a ball bond on the aluminum pad and a wedge bond on the gold pad. The aluminum wires were wedge-wedge bonded ultrasonically, at room temperature, to both the aluminum and gold pads. Figure 20 shows SEM micrographs illustrating the quality of these ball-wedge and wedge-wedge wire bonds. Aluminum wire bonds which subsequently underwent high temperature treatments (180°C) for ~17h during electromigration testing remained intact in all cases.

Effect on device performance.—The effect of LPCVD aluminum on device performance was evaluated by automatically probing the IGFET, van der Pauw, contact resistance, and MOS testers present at four sites across each of three device wafers fabricated in accordance with the 2.5 μm Twin-Tub CMOS process (8). Table II offers a comparison of the CMOS parametric data for the nonsintered LPCVD, In-Source, and sputtered aluminum films. An examination of those data reveals insignificant differ-

ences in the characteristics of the square transistor for all three types of aluminum as determined by values of threshold voltage and beta per square. However, slight variations in the values of beta for the nominal transistors are observed in a comparison among these three deposition processes. These variations appear to be related to corresponding changes in channel length believed to be caused by gate definition. The van der Pauw data, similarly, reveal little variation in the values of leakage current among the three types of aluminum. The most striking difference characterizing the LPCVD aluminum films is found in the values of the contact resistance to N⁺ and P⁺ source/drain regions. For the 2.5 × 2.5 μm contact windows, the value of contact resistance to N⁺ is a factor of ~30 less than that of In-Source aluminum and a factor of ~10 less than that of sputtered aluminum. The value of contact resistance to P⁺, however, is identical to that of N⁺, but is still significantly lower than the corresponding values for In-Source and sputtered aluminum. We postulate that this unusually low value of contact resistance to N⁺ is related to the effect of the TiCl₄ pretreatment, which results in the etching of the native oxide as well as part of the underlying Si surface. The fact that In-Source aluminum deposited at ~220°C exhibits a significantly higher contact resistance to N⁺ than that of sputtered aluminum deposited at ~300°C is consistent with the presence of an interfacial oxide barrier which is easier to reduce at higher deposition temperatures. The contact resistance of aluminum to TaSi₂ appears to be unusually high in all three cases. This is believed to be a result of properties related to the TaSi₂ rather than those of LPCVD aluminum.

Table III draws a comparison of the CMOS parametric data at various steps in the process following LPCVD aluminum deposition. The data reveal little change in any of the device characteristics following the 300°C/30 min/H₂ sinter. However, after SiN capping two of the device wafers at 300°C for 95 min, a significant change in the values of the threshold voltage for both N- and P-channel transistors was observed. An additional 450°C/30 min/H₂ treatment is shown in Table III to restore the threshold voltages back to their values prior to SiN capping. However, that additional heating step is also seen to generate large leakage currents in the N⁺/P Tub contact resistance tester caused by the severe junction spiking occurring at these relatively high temperatures.

Conclusion

Our results have established that LPCVD aluminum is close to being a viable VLSI technology. It provides 100% conformal step coverage, introduces no surface states, and promises to yield high wafer throughput. The LPCVD aluminum films have been shown to exhibit excellent properties in terms of chemical purity, adhesion, electrical resistivity, and contact resistance. The films have also been proven to be suitable for VLSI processing in terms of patterning, dry etching, and bondability and appear to have no effect on overall device performance. One of the drawbacks of LPCVD aluminum has been shown to be its structure-dependent properties: namely, electromigration resistance and Al-Si interdiffusion. We believe that both these problems can be resolved with a proper diffusion barrier, which would not only eliminate junction spiking but also allow for higher sintering temperatures that in turn should enhance crystal growth and electromigration resistance. The remaining concern at the present is the hazard associated with the handling of TIBAL, which can possibly be overcome by the adoption of strict safety procedures during operation or the devel-

opment of an alternatively safer LPCVD aluminum transport process. Both these options are under present investigation.

Acknowledgments

The authors wish to thank R. S. Rosler at ASM America Incorporated for depositing the aluminum, W. Y. C. Lai for providing us with the device wafers, C. C. Chang for gathering the Auger data, R. V. Knoell for the transmission electron microscopy work, T. E. McGahan for the SEM micrographs, L. J. Lecheler for assisting in various tasks of this project, and L. C. Parrillo as well as J. T. Clemens for many fruitful discussions.

Poly Solar Incorporated, Garland, Texas 75041

ABSTRACT

Large grain thin films of copper indium diselenide with a preferred {112} orientation have been prepared by (i) the deposition of nearly stoichiometric films of copper and indium on suitable substrates using vacuum evaporation or electrodeposition, and (ii) the heat-treatment of Cu-In films in a hydrogen-selenium atmosphere at temperatures above 630°C. The compositional, structural, and electrical properties of the films have been evaluated. In an alternate approach, a copper film on a substrate was first converted into cuprous selenide, followed by the deposition of indium and selenization. The resulting CuInSe₂ films have the same properties as those from the selenization of Cu-In films.

Copper indium diselenide, CuInSe₂, a direct gap semiconductor with a room temperature energy gap of about 1 eV, has very large optical absorption coefficients at the bandedge and beyond (1), and the minority carrier diffusion length becomes relatively unimportant in the operation of photovoltaic devices. Thus, CuInSe₂ is particularly suited for thin film devices. Since the first report of a single-crystalline n-CdS/p-CuInSe₂ heterojunction device with a conversion efficiency of 12% (2), considerable efforts have been directed to the fabrication and characterization of thin film devices of the same configuration (3). The deposition of CuInSe₂ films on foreign substrates was carried out, in most cases, by vacuum techniques such as evaporation and sputtering, and the

* Electrochemical Society Active Member.

accurate control of the copper and indium fluxes at the substrate surface is essential for obtaining stoichiometric CuInSe₂ films. In spite of the small grain size (about 1 μm) in films deposited by vacuum techniques, short-circuit current densities similar to those reported for single crystalline devices (40 mA/cm²) have been obtained, and heterojunction solar cells with AM1 efficiencies of near 11% have been reported (4).

In this work, CuInSe₂ films have been prepared by two chemical approaches: (i) the deposition of Cu and In films on a suitable substrate by vacuum evaporation or electrodeposition followed by the treatment of Cu-In film with selenium vapor at high temperatures, and (ii) the formation of Cu₂Se film on a suitable substrate by the selenization of Cu film, followed by the deposition of In

film and selenium treatment. The use of electroplating and selenization processes has distinct cost advantages as compared with the current technology. The compositional, structural, and electrical properties of deposited films have been investigated. The experimental procedures and results are summarized in this paper.

Experimental

The important process parameters in the preparation of CuInSe_2 films by the selenization of Cu-In films are: (i) the stoichiometry of the Cu-In film, (ii) the temperature of selenium treatment, and (iii) the partial pressure of selenium and the duration of selenium treatment. The Cu-In phase diagram indicates that the 1:1 Cu-In alloy melts at about 630°C (5). Thus, the selenium treatment of Cu-In films at 630°C or above involves gas-liquid reactions, while that at lower temperatures involves gas-solid reactions. For low temperature selenium treatment, nearly any inert substrates, such as graphite, may be used. When selenium treatment is carried out at high temperatures, the uniform wetting of the substrate surface by the liquid Cu-In film is essential for obtaining uniform CuInSe_2 films. Tungsten-coated graphite, prepared by the thermal reduction of tungsten hexafluoride with hydrogen on the surface of graphite at 500°C - 600°C , was found to be suitable.

The Cu-In films were deposited on the substrate surface by vacuum evaporation or by electroplating. Evaporation was carried out in the conventional manner under a pressure of 10^{-6} torr or less using elements of 99.999 + % purity, and the substrate-source was arranged to yield large area films with thickness variations less than 3%. In the evaporation process, the order of depositing Cu and In films is not important, while Cu must be electroplated before In because of the reaction of In with the Cu plating solution. The electroplating of Cu was carried out from a sulfuric acid solution of copper sulfate at a current density of 50-75 mA/cm²; the deposition rate was determined to be 1.1 $\mu\text{m}/\text{min}$ at 50 mA/cm². The electroplating of In was carried out from a sulfuric acid solution of indium sulfamate and sodium sulfamate (pH = 1.5-2) at a current density of 10-20 mA/cm² (6); the deposition rate was determined to be 0.19 $\mu\text{m}/\text{min}$ at 20 mA/cm². The samples were thoroughly cleaned before and after the plating process. On the basis of the densities of Cu, In, and CuInSe_2 , the use of 2.21 μm of In film and 1.0 μm of Cu film should yield 5 μm of CuInSe_2 film after selenium treatment.

The selenium treatment of Cu on Cu-In films was carried out in a hydrogen atmosphere using the apparatus shown schematically in Fig. 1. Hydrogen was purified by diffusion through palladium-silver alloy. A selenium container and the samples to be selenized were placed in a fused silica reaction tube of 59 mm od, and the tube was heated in a two-temperature zone furnace with each zone separately heated and controlled. The selenium was of 99.999 + % purity, and the selenium container was maintained at 440°C (vapor pressure of $\text{Se}_2 = 10$ torr). The partial pressure of selenium in the reaction tube was controlled by adjusting the flow rates of hydrogen through the selenium container and through the reaction tube. The temperature of Cu and Cu-In films was varied over a wide range, 300°C - 750°C . The duration of selenization was determined from the selenium content of the reaction mixture and the substrate temperature, usually 2-6h.

In the second approach, a Cu film on graphite was first selenized at 600°C to yield Cu_2Se films, and indium was deposited followed by selenium treatment at 550°C - 600°C .

Fig. 1. Schematic diagram of the apparatus for the treatment of Cu or Cu-In films with selenium.

Fig. 2. Scanning electron micrographs of the surface of and vertical cross section of a CuInSe_2 film prepared by the selenium treatment of a Cu-In film on a W/graphite substrate at 650°C .

Results and Discussion

All Cu-In films used for selenium treatment consist of 2.21 μm of In and 1.0 μm of Cu. The selenization of Cu-In/W/graphite structures was carried out over the temperature range 300°C - 750°C . The use of high temperatures, such as 650°C or above, yields films with large grains, several millimeters in size. Figure 2 shows scanning electron micrographs of the surface of a typical film at two magnifications and the vertical cross section of the sample. The cross-sectional photograph indicates that the film is about 5 μm thick, as expected. The low magnification photograph of the surface shows only several grain boundaries, and the higher magnification photograph shows a large number of isosceles triangles of the same orientation, indicating that this crystallite has a two-fold symmetry. The formation of the large grain films is due apparently to the gas-liquid reaction, where the surface of liquid Cu-In film first reacted with selenium to form CuInSe_2 , and the subsequent diffusion of selenium through the surface film completes the transformation of Cu-In into CuInSe_2 . The composition of the large grain films was analyzed by the electron microprobe technique using a 10 keV, 25 nA beam on 60 spots of a specimen; the results including the standard deviations shown in Table I (sample no. 1) indicate that the large grain films are essentially stoichiometric CuInSe_2 .

The crystallographic properties of large grain CuInSe_2 films were determined by the x-ray diffraction technique. CuInSe_2 crystallizes in the chalcopyrite structure, and polycrystalline CuInSe_2 powder of random orientation is known to show three strong diffraction peaks associated with {112}, {204} and {220}, and {116} and {312} reflections with 2θ values of 26.66° , 44.36° , and 52.45° , and relative intensities of 70, 100, and 85, respectively. The diffraction spectra of large grain CuInSe_2 films were obtained by scanning 2θ in the range of 20° - 60° . An example

Table I. Composition of three copper indium selenide films by electron microprobe analysis

Sam- ple no.	a/o Cu (1σ)	a/o In (1σ)	a/o Se (1σ)
1	24.67 \pm 0.3 (0.35)	25.96 \pm 0.31 (0.40)	49.40 \pm 0.59 (0.67)
2	25.43 \pm 0.65 (1.13)	25.11 \pm 0.64 (0.76)	49.43 \pm 1.26 (1.52)
3	25.58 \pm 1.02 (0.74)	25.6 \pm 1.02 (0.67)	48.79 \pm 1.59 (0.59)

is shown in Fig. 3, where only the diffraction peak with 2θ value of about 26.70 is present, indicating that the large grain films are of {112} orientation.

The electrical resistivity of large grain CuInSe_2 films was measured by evaporating gold ohmic contacts on the surface and measuring the resistance through the thickness of the specimen. The Au- CuInSe_2 contact resistance was determined by the potential probe measurements, and the CuInSe_2 -substrate contact resistance was found to be negligible (less than $0.1 \Omega\text{-cm}^2$). The conductivity type and electrical resistivity of CuInSe_2 films were found to depend on the partial pressure of selenium, the flow rate of the reaction mixture, and the duration of selenium treatment. Qualitatively, when a less than stoichiometric amount of selenium was used, the resulting film was always n-type. On further treatment with selenium, the film became p-type, and its resistivity decreased with increasing duration of selenium treatment. No systematic work on the dependence of the resistivity of CuInSe_2 films on the selenization parameters was carried out. However, by controlling the process parameters to introduce an excess (0.1–0.6%) of selenium into the reaction tube, electrical resistivities in the range of 1 to $20 \Omega\text{-cm}$ have been obtained.

When the selenization of Cu-In films was carried out at temperatures below the melting point of Cu-In alloy, such as 500°C , the resulting films consisted of small grains, 2–3 μm in size. Figure 4 shows scanning electron micrographs of the surface and vertical cross section of a CuInSe_2 film prepared by the selenium treatment of a Cu-In film at 500°C . The film appears to be loosely packed. The thickness of the film measured from the vertical cross section is considerably larger than $5 \mu\text{m}$, indicating high porosity in the film. The porosity is apparently the result of the gas-solid reaction and is not readily controlled. However, the electron microprobe analysis (Table I, sample no. 2)

Fig. 3. X-ray diffraction spectrum of a large grain CuInSe_2 film on a W/graphite substrate.

Fig. 4. Scanning electron micrographs of the surface and vertical cross section of a CuInSe_2 film prepared by the selenium treatment of a Cu-In film on a W/graphite substrate at 500°C .

indicates that the films are essentially stoichiometric in composition. X-ray diffraction spectrum showed the presence of all three diffraction peaks with 2θ values of 26.7° , 44.4° , and 52.5° . As the temperature of selenization was further reduced (to 350°C , for example), multiple-phase material was obtained; selenides of copper and indium

Fig. 5. X-ray diffraction spectrum of a typical cuprous selenide film on a graphite substrate.

were present in addition to CuInSe₂. While Cu forms only Cu₂Se, In forms four selenides: In₂Se, InSe, In₃Se₆, and In₇Se₃.

The conversion of Cu-films on graphite substrates to cuprous selenide takes place readily at 600°C. The selenization product was found to be Cu₂Se or a mixture of Cu₂Se and Cu_{2-x}Se, depending on the extent of selenization. The strong diffractions in polycrystalline Cu₂Se are associated with {111}, {220}, and {311} reflections with 2θ values of 26.34, 43.69, and 51.91 and relative intensities of 80, 100, and 80, respectively. The strong diffractions in polycrystalline Cu_{2-x}Se ($x \sim 0.15$) are associated with {111}, {220}, and {311} reflections with 2θ values of 26.75, 44.83, and 52.91 and relative intensities of 90, 100, and 80, respectively. Figure 5 shows a typical diffraction spectrum of a cuprous selenide film. The deposition of In followed by selenium treatment at 600°-650°C produced large grain CuInSe₂ films as identified by electron microprobe (Table I, sample no. 3) and x-ray diffraction. These films have essentially the same properties as those obtained by the high temperature selenium treatment of a Cu-In/W/graphite structure.

Summary

The heat-treatment of Cu-In films in a hydrogen-selenium atmosphere has been used for the preparation of CuInSe₂ films. The most important process parameter affecting the microstructure of CuInSe₂ is the temperature of the Cu-In film. Using liquid Cu-In films on a suitable substrate, the gas-liquid reaction yields single-phase, large grain, essentially stoichiometric CuInSe₂ films with a preferred {112} orientation, as shown by compositional analysis and x-ray diffraction. The electrical resistivity of

CuInSe₂ films can be controlled by the duration of selenization; the use of a large excess of selenium yields low resistivity p-type films. At Cu-In film temperatures below 600°C, the selenization process involves gas-solid reactions, and the resulting films consisted of loosely packed small grains and are porous in structure. Large grain CuInSe₂ films can also be prepared by the deposition and selenization of copper, followed by the deposition of indium and the selenization of cuprous selenide-indium structures.

Photoelectrochemical Imaging

M. A. Butler*

Sandia National Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

A device is described for producing video images from localized photocurrent measurements on electrode surfaces. Images generated from photoinduced electron-hole pair currents in passivating oxide layers on polycrystalline titanium and high resistance polycrystalline GaP photoelectrodes are shown as examples. The applicability of this device for producing images from other optically induced effects is also discussed. It is proposed that the localized heating from a focused laser beam can be used to image the current distribution on metal electrodes.

In a recent paper (1), localized photoelectrochemical measurements were used to study the properties of a 100Å thick oxide layer on polycrystalline titanium metal. Using a computer-controlled X-Y stage, crude line images, or maps of the photocurrent response of this sample were produced. Since that time, we have improved the equipment to the point where real video images can be made from the localized photocurrent measurements. The purpose of this paper is to describe the new apparatus, demonstrate the kind of images it can produce, and discuss possible applications to other situations.

Photocurrent generated by a focused light beam or electron beam has been used to produce images for some time in solid-state devices (2-4). The response time of such devices is rapid enough to allow generation of a whole image in a fraction of a second. Thus, the image can be displayed on a conventional cathode ray tube and periodically refreshed just as with conventional television images. For a semiconductor-electrolyte junction, however, the large interfacial capacitance limits the response time and requires that the image be built up slowly (5). This suggests outputting each piece of the picture as it is

formed, as with the line scans (5), or storing the information in a memory until the complete image is produced. The latter approach is the one we have taken with the present device.

Experimental

A schematic of the laser scanning system as it is presently configured is shown in Fig. 1. The laser is a Coherent Model CR-750k krypton laser with lines available from 800 to 351 nm. The beam is chopped at an appropriate frequency, usually 15.6 Hz, and focused onto the electrochemical cell. The cell is mounted on a computer controlled X-Y table, Klinger Model MT-160. The cell uses a quartz window with a thin (3 mm) electrolyte layer to minimize distortions of the laser beam. A conventional saturated calomel reference electrode is used. The cell is operated under potentiostatic control with lock-in detection of the photocurrents.

All measurements are made under active control of the computer which, through the Klinger controller, tells the table when to move, the direction, and step size. The individual localized photocurrent measurements are stored in the Colorado Video video expander, Model CV-275. This device contains a 256 × 256 digital memory array and

*Electrochemical Society Active Member.

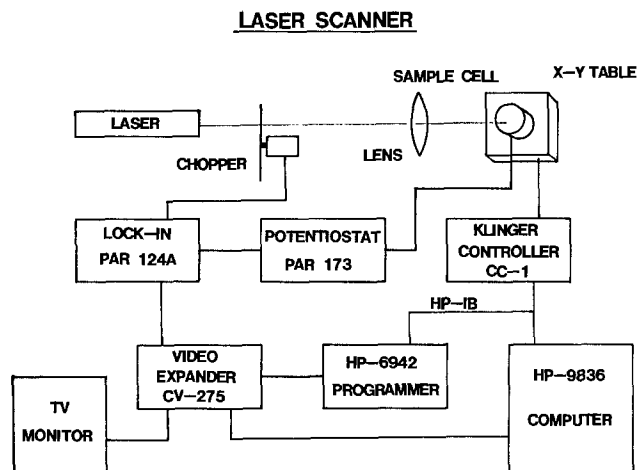

Fig. 1. Laser scanning system. Details of the operation are given in the text.

video signal generating circuitry which scans this memory 30 times a second to produce the video signal. The programmer, Model HP-6942, generates timing pulses at the command of the computer to digitize the incoming analog signal from the lock-in amplifier and to determine the memory location in which the digitized signal is stored. Thus the measurement sequence involves several steps. The computer tells the X-Y table to move to some position and wait for a given period of time. The computer then tells the video expander to digitize the analog signal from the lock-in amplifier and store it in a location corresponding to the position of the table. This process is then repeated until the complete image is produced. During this time, the contents of the memory are visible on the TV monitor so that the slow buildup of the image can be observed.

The computer also has direct access to the memory array in the video expander. This allows complete images to be entered into the computer for image processing or storage on disk files. In addition, the computer can write directly into the image memory array. This is useful for putting scale factors or additional information directly on the monitor screen and to display previously stored images.

This system with direct computer control of the measurement process provides considerable flexibility because many factors are controlled by the software. For example, the dwell time of each point is set by typing it into the computer. Since the image always consists of an array of 256×256 data points, the resolution of any image is one step. Since the step size is entered into the computer, the resolution and the magnification of the image may be easily changed at the computer keyboard. The smallest step size with these tables is $1 \mu\text{m}$. Thus the maximum magnification will be an image $256 \times 256 \mu\text{m}$.

A number of other factors are important in determining the resolution besides the minimum step size of $1 \mu\text{m}$. The focused laser spot is ultimately limited by diffraction effects to

$$\Delta \approx 2\lambda \frac{F}{d} \quad [1]$$

where λ is the wavelength of light, and F the focal length of the lens and d the laser beam diameter. One also has to worry about vibration, and a good optical table is important if one is trying to approach the diffraction limit. Another problem is damage to the sample. 1 mW of power focused onto $10 \mu\text{m}^2$ gives a power density of 10 kW/cm^2 . This can have drastic consequences for the surface, particularly at the solid-liquid interface. Finally, we must be concerned with the effects of scattered light as the whole electrode surface is photosensitive rather than just the spot on which the laser is focused. For short focal length lenses necessary to achieve small spot sizes, scattering

within the lens system and from the sample surface and back off the lens can illuminate a considerable area of the surface. Since the scattered light illuminates a much larger area, relatively weak scattered light can cause a signal comparable to that arising from the focused laser beam. All of these factors conspire to limit the resolution of the laser scanning system. The best we have observed, without a floated optical table, is $3 \mu\text{m}$.

Results

The kind of photoelectrochemical image that this system can produce is illustrated in Fig. 2. This is an image of high resistance polycrystalline GaP. The step size is $6 \mu\text{m}$ in the Y direction and $8 \mu\text{m}$ in the X direction. Different step sizes in different directions are necessary so as to not distort the image. The memory is a 256×256 square array while all video displays have a 4×3 relationship between X and Y axes. This modification was made by simply changing the program. Typical photocurrents are $0.1\text{--}1 \mu\text{A}$. At the exciting wavelength, 476 nm , the optical absorptions depth is $5\text{--}10 \mu\text{m}$.

A number of interesting features are immediately obvious. It seems that the grain boundaries are brighter (more photocurrent) than the exposed faces of the grains. This is in contrast with images of polycrystalline silicon solar cells, where grain boundaries show up dark because of enhanced recombination at the grain boundaries (6). Comparison of the photocurrent image with a photograph of the surface, shown in Fig. 3, indeed shows that the bright lines correspond to grain boundaries. However, not all grain boundaries result in significantly increased photocurrents. Apparently, some other factor is necessary for the boundaries to show up bright in the photocurrent image. One explanation might be that for these highly resistive samples the electrically active grain boundaries act as conductive regions and collect minority carriers from surrounding grains while most of the carriers recombine at defects and impurities. Thus, only the electrically active boundaries would show up bright in the photoelectrochemical image. These are the boundaries with large lattice mismatch and thus high densities of states.

Another interesting feature is the dark streaks, which are not localized to individual grains. These also appear on the photograph (Fig. 3), and they are probably scratches left over from the polishing of the sample. Apparently, mechanical polishing of GaP introduces recombination centers in the material to a considerable depth (7). There are also other dark patches, which are surface effects. Etching and Ru ion treatment of the surface produces marked changes in these features of the image.

Another interesting photocurrent image is shown in Fig. 4. The photoresponse from the $\sim 100\text{\AA}$ thick TiO_2 layer on polycrystalline titanium clearly shows evidence of the underlying metal grain structure. This may be compared with a photograph of the same region of the sample shown in Fig. 5. Apparently, the properties of the oxide depend on the underlying crystallographic face on which it grows.

The photoresponse of the passivating layer also depends on the growth conditions for the oxide and its history with respect to exposure to bandgap light. We find that the grain structure is only weakly visible for oxide grown in $0.2N \text{ Na}_2\text{SO}_4$ under potentiostatic control by slowly increasing the applied potential to $+2.0V(\text{SCE})$ while keeping the current density below $3 \mu\text{A/cm}^2$. However, flooding the surface with 30 mW/cm^2 of 351 nm light for 2 min makes the grain structure clearly visible. This is illustrated in Fig. 6 for identical measurement conditions. One possible explanation is the filling of electronic traps in the oxide by the bandgap light, which then distorts the electric field in the oxide layers and, thus, changes the photoresponse (1). The variations from grain to grain would then come from differing trap densities. Such an interpretation suggests that the contrast could be removed by emptying the traps. We tried to do this by flooding the surface with red (647 nm) light at 1 W/cm^2 for 20 min and by leaving the cell under open-circuit con-

Fig. 2. Photoelectrochemical image of polycrystalline GaP photoelectrode in 0.1M HClO₄ at -1.0V (SCE). Dwell time at each point is 0.15s. Light source is 476 nm line of an argon ion laser with 1 mW incident power.

ditions overnight. Neither experiment had a significant effect on the visibility of the grain structure.

Growth of the oxide layer on the polycrystalline titanium under potentiostatic control by stepping the potential to +2V(SCE) results in a uniform photoresponse with no grain structure visible. Furthermore, flooding with bandgap light reduces the overall photoresponse but does not make the grain structure visible. Thus, the probable different morphology of the film with different growth rates modifies the photoresponse of the passive film on

a polycrystalline surface. We speculate that the optical activation necessary to see the grain structure comes from charging of trap states associated with defects. These defects then move under the influence of the large electric field in the film (10^6 V/cm) and are trapped at one of the two interfaces. This is why the effect is not easily reversible. The density of available defects depends on the underlying metal crystallographic face, and this explains the variations in photocurrent from grain to grain. In the more rapidly grown film, the growth rate is such as to

Fig. 3. Photograph of the polycrystalline GaP photoelectrode used to produce the photocurrent image.

Fig. 4. Photoelectrochemical image of 100Å thick oxide layer on polycrystalline titanium. The electrolyte is 0.2N Na₂SO₄, and the potential is +2.0V (SCE). Light source is the 351 nm line of a krypton laser with incident power of 300 μW. The dwell time at each point is 0.1s. Typical photocurrents are a few tenths of a microampere.

produce a uniform density of defects, which results in a uniform photoresponse.

Clearly, the above interpretation is very speculative, and further experiments are needed to find out what is really happening. However, these results clearly show that photoelectrochemical images of passive films on titanium can give valuable information about the detailed structure of the oxide.

Discussion

While this paper is principally concerned with photoelectrochemical imaging of solid-liquid interfaces, it is worthwhile to spend some time to point out the versatility of this imaging system. Images can be produced using any optically stimulated effect that can be quantitatively measured. Previously, we have produced line images from measured variations in optical absorption in a thin sample of polycrystalline GaP (8) and from the photoluminescence of GaAs, ZnSe, and GaAsP (9). Images could also be made with reflectivity, electroreflectance, Raman, and ellipsometric measurements.

There is one other aspect of optically stimulated effects that is worth exploring in some detail. In addition to inducing effects directly related to light absorption such as photocurrent, the absorbed light can be degraded to produce local heating of the interface. Thus, we should expect that thermally induced effects can be used to produce images. In particular, we should be able to modulate locally the current density at any electrode on which an electrochemical reaction is occurring. As we will show, this allows the mapping of the current density of a reaction on an electrode. You should be able to study, for example, the relative current densities on crystalline faces and grain boundaries in polycrystalline metal electrodes.

In order to explore this idea, let us consider a simple model. This model is undoubtedly lacking in many respects, but perhaps contains enough factors to realistically display the effect of interest. We will only consider the measurements in the Tafel region, where the current density is assumed to have the following simple form

$$j = j_0 \exp\left(\frac{\alpha\eta}{kT}\right) \quad [2]$$

where α is a parameter between 0 and 1, η is the overpotential, k Boltzmann's constant, T is the absolute temperature, and j_0 the exchange current density. Normally we think of the exchange current density as having a temperature dependence of the form (10)

$$j_0 = A \exp(+\phi/kT) \quad [3]$$

where any weak temperature dependence to A will be ignored. We also assume that current density may be position dependent. Thus the total current is given by

$$J = \sum_k j_k \quad [4]$$

The area of each element k is small compared to the total area of the electrode and for simplicity is taken as equal to the illuminated area. Similarly we assume a uniform temperature T for the electrode surface except for the illuminated element which has a temperature $T + \Delta T$. This approximation implies similar optical absorption and loss mechanisms across the whole surface. Otherwise ΔT may be position dependent. It also implies poor thermal conduction in the plane of the interface. Finally, we assume a single overpotential between electrode and electrolyte. This is appropriate in the limit of infinitely conductive electrodes and electrolytes; otherwise, nonuniform overpotentials would result in sustained charge flows parallel to the interface.

Within the limits of this simple model, we can now explore the effects of illuminating a small area of an electrode at which a simple electrochemical reaction is taking place. Since measurements may be made galvanostatically or potentiostatically, we will consider these two possibilities in this order. For the galvanostatic case with no light, the current is given by

$$J = \sum_k j_k = \sum_k A_k \exp\left(\frac{\alpha\eta + \phi}{kT}\right) \quad [5]$$

Fig. 5. Photograph of polycrystalline titanium electrode surface showing the same region as in Fig. 4.

When the area of element m of the electrode surface is illuminated, the total current is given by

$$J = \sum_k A_k \exp\left(\frac{\alpha[\eta + \Delta\eta] + \phi}{kT}\right) + A_m \exp\left(\frac{\alpha[\eta + \Delta\eta] + \phi}{k[T + \Delta T]}\right) - A_m \exp\left(\frac{\alpha[\eta + \Delta\eta] + \phi}{kT}\right) \quad [6]$$

In the limit of very small thermal modulation, we can expand the exponentials and only keep terms to first order in $\Delta\eta$ and ΔT . Then, solving for $\Delta\eta$, we find

$$\Delta\eta = \left(\frac{\Delta T}{T}\right) \left(\eta + \frac{\phi}{\alpha}\right) \frac{A_m}{\sum_k A_k} \quad [7]$$

A much simpler argument can be made for the potentiostatic case. Since η is held fixed and the temperature

Fig. 6. Photocurrent image of passive film on polycrystalline titanium surface under the same conditions as in Fig. 4. The left side is freshly grown oxide, while the right side is after flooding the surface with 351 nm light, as discussed in the text.

only changes for the illuminated element m , the only change in current will be for element m . Taking the current expression for this element only

$$j_k = A_k \exp\left(\frac{\alpha\eta + \phi}{kT}\right) \quad [8]$$

and differentiating with respect to T , we find

$$\Delta j_m = -j_m \left(\frac{\Delta T}{T}\right) \left(\frac{\alpha\eta + \phi}{kT}\right) \quad [9]$$

Thus it appears that, within the limits of the simple model, an effect should be observed both under galvanostatic and potentiostatic control. It is of interest to explore the size of the effects expected from thermal modulation of the electrochemical reaction. Two papers (11, 12) have recently appeared which utilize thermal modulation with no spatial resolution to study the electrochemical kinetics. The importance of these papers is that they demonstrate the effect. The only extension required here is localization of the heat input to produce images. Miller (11) observes a ratio $\Delta j/j \sim 1$ with a power density of ~ 10 W/cm² incident upon a strongly absorbing surface. By focusing the light, the size of the effect decreases by the ratio of the areas. However, the incident power and thus the term $\Delta T/T$ should increase correspondingly. This all suggests that the effect will be large enough to observe if the electrochemical reaction is carefully chosen.

Preliminary experiments have been performed using the old version of the laser scanner which only produced line maps (1). Effects were observed using Cu electrodes in CuSO₄/H₂SO₄ electrolytes. The electrode was biased so as to decrease the likelihood of the existence of copper oxide. However, lack of reproducibility and concerns about a photoelectrochemical response from possible copper oxide do not allow the results to be convincing evidence of the effect. It is hoped that others will pursue this avenue of research and produce convincing evidence for thermal imaging of electrochemical reactions.

Conclusions

The device described in this paper is a useful tool for studying the solid-liquid interface. Images convey infor-

mation in a manner that humans can easily assimilate. Furthermore, the spatial resolution gives insight into the role of grain boundaries and defects. This device can also be used to examine other surfaces and to form images from photoinduced effects other than the photocurrent. It appears that using the focused laser to locally heat an electrode surface will allow imaging of electrochemical reactions by thermal modulation of the reaction kinetics. This kind of effect would be very useful for studying the role of grain boundaries on polycrystalline metal electrodes.

Viscosity Points and OH Absorption Removal for ZnO-B₂O₃-PbO-SiO₂ Passivation Glasses

Keiji Kobayashi

Toshiba Corporation, Toshiba Research and Development Center, Kawasaki, Japan

Low flow point (1), low polarization (2), and OH-free highly purified glasses have recently been needed for semiconductor device passivations. Additionally, high water durability, high electrical resistivity, and noncrystallizable glass properties are also indispensable to assure the reliability of the devices. Passivation glasses filled under several conditions described herein can be obtained from the compositional improvement of glasses (3, 4). Glass compositions including fluoride containing ZnO-B₂O₃-PbO-SiO₂ systems have been formulated and investigated. It is generally known that the flow point or softening point of such glasses can be lowered by increasing B³⁺ and Pb²⁺ contents, and that the durability of glasses to water can be enhanced by raising Si⁴⁺ and Zn²⁺ contents. Also, the polarizability of the glasses can be reduced by increasing the B³⁺ content in glass compositions (5). Batch compositions were melted at 1350°C for 3h in a Pt crucible using an electric furnace. After melting, molten glass was poured on a stainless steel plate and annealed. Glass was shaped into a 10 × 20 × 2 mm plate by grinding for infrared transmission measurement. Infrared absorption spectra were measured by the use of a Hitachi spectrophotometer. The OH radicals removal is represented in the following reaction

In addition, dry air bubbling technique is effective for the complete removal of OH to prevent near-infrared OH absorption. This technique involves blowing dry air

through the molten glass liquid during melting. This paper discusses variations in viscosity points, including the flow point, with chemical compositions and the removal of the near infrared OH absorption band for a typical passivation glass. Chemical compositions of ZnO-B₂O₃-PbO-SiO₂ glass systems are represented in Table I. Differential thermal analysis (DTA) curves for them, measured

(5)	535	565	—	610	675

Fig. 1. DTA curves for ZnO-B₂O₃-PbO-SiO₂ passivation glasses

using the Rigaku DTA system, are given in Fig. 1, where T_g is glass transition point ($\log \eta = 13.3$), M_g is deformation point ($\log \eta = 11.0$), T_s is softening point ($\log \eta = 7.6$), T_{sint} is sintering point ($\log \eta = 6.0$), and T_f is flow point ($\log \eta = 5.0$). The heating rate for measuring DTA curves was 10°C/min. As listed in Table II, T_g , T_s , T_f , and the other points are raised with an increase in SiO₂ and a decrease in B₂O₃, regardless of the amount of ZnO and PbO. As the Al₂O₃, P₂O₅, and ZnF₂ contents are small, it seems likely that they do not affect the variations in glass viscosity points. Typical infrared absorption spectra are represented in Fig. 2, which exhibit sharp absorption bands nearly at 2.7 μ m, caused by OH stretching vibration. Compared with the spectrum for an untreated glass without fluoride, the OH absorption band removal was carried out completely by dry air bubbling treatment for a fluoride containing molten glass. Low flow point and OH-free glasses are suitable for semiconductor device passivations, because they are not harmful to the reliability and I-V curves of passivated devices.

Corrosion of FeCrAl, FeCrAlY, and FeCrAlHf Alloys in High Temperature H₂-H₂O-H₂S Environments

T. T. Huang,* Y. C. Lin, D. A. Shores,* and E. Pfender

Corrosion Research Center, University of Minnesota, Minneapolis, Minnesota 55455

High temperature corrosion plays an important role in the development of many combustion and coal gasification processes. In gasification processes, various grades of fuel gas are produced by the reaction of coal with steam and oxygen at high temperatures. The resulting gas contains hydrogen, steam, carbon dioxide, carbon monoxide, and some methane. It also contains low levels of hydrogen sulfide and other impurities derived from the coal. Reaction of such impurities with alloys is a common cause of corrosion. For example, sulfidation has been shown to have a devastating effect on many metallic structural components in coal gasification environments (1-3).

*Electrochemical Society Active Member.

In a typical coal gasification process, the atmosphere has a low oxygen activity, but relatively high activities of sulfur, carbon, hydrogen, and nitrogen (1). It is becoming increasingly apparent that available stainless steels and superalloys do not have adequate corrosion resistance in such environments (3, 4). To survive, an alloy must form a compact, protective scale, which acts as a barrier to the penetration of sulfur or carbon to the metal. All stainless steels and superalloys form oxide scales in these environments, but the scales offer widely differing degrees of protection. Many factors may contribute to the less-than-optimum performance of the oxide scales. Much previous work has been carried out to evaluate the performance of alloys in environments that simulate to varying degrees the expected exposure conditions in coal gasifiers.

Recently, several studies have addressed mechanistic questions concerning the protection offered by oxide scales to environments containing H_2S (5-9). Most studies found that the resulting kinetics of attack and the morphology of the scale depend upon the initial exposure conditions. If the alloys were exposed to oxidation/sulfidation conditions from the start, the scale typically would be composed of both oxides and sulfides, and the rate of attack would be fairly fast (5-9). If the alloys were preoxidized, then the environment switched to oxidation/sulfidation conditions without cooling the specimen, these oxide scales were found to be protective in some cases; however, the details differ among investigators. Rao *et al.* (5) found preoxidation of 310 stainless steel at 877°C in low oxygen potentials to be beneficial. Loudjani *et al.* (7) also found preoxidation of Fe-Cr-Al, Fe-Ni-Al, and Fe-Ni-Cr-Al at quite a high temperature (1200°C) to be beneficial, and concluded that Al_2O_3 scales were more effective barriers than Cr_2O_3 scales. However, Mari *et al.* (8) found the preoxide scale formed on Fe-Cr-Al at 1000°C to be an effective barrier to sulfur vapor, but to eventually breakdown in H_2 - H_2S environments. The time to breakdown increased as the preoxidation time, and hence the scale thickness, increased. The question of whether the sulfur penetrates the scale by solid-state diffusion or by permeation down cracks and pores is not universally resolved. Indeed, a variety of behavior may be observed, depending on the morphology of the oxide scale, which in turn depends on the alloy system, the temperature, and the environment in which it was grown.

In this work, the protection provided by an Al_2O_3 scale in a simple simulation of a coal gasification environment has been studied. Particular attention has been paid to the effect of the addition of a reactive element, Y or Hf, on sulfidation resistance. These elements are known to enhance oxidation resistance by promoting scale adherence (10, 11).

Experimental Procedure

The alloys which have been studied are Fe-18%Cr-6%Al, Fe-18%Cr-6%Al-0.3%Y, and Fe-18%Cr-6%Al-1%Hf (weight percent). Samples of these alloys were obtained from ingots that had been tungsten arc melted several times in an argon atmosphere, then drop-cast into a water-cooled copper mold. The ingots were subsequently homogenized at 1050°C for 10h in sealed quartz capsules. Small coupons from the ingots were polished through 600 grit SiC paper, followed by thorough cleaning and degreasing.

Gaseous environments containing H_2 and H_2O or H_2 - H_2O - H_2S were prepared by passing carefully metered flow rates of H_2 through a water saturation column held at a controlled temperature. In cases "C" to "E," a H_2/H_2S mixture was blended with the H_2/H_2O flow. Five different gas mixtures were prepared; their compositions and the equilibrium activities of oxygen and sulfur at 900°C are listed in Table I.

Coupons were exposed under two different conditions: some were exposed directly to gases "C," "D," or "E"; others were first preoxidized in "A" (various times at 900°C) or in "B" (10h at 1100°C), then the gas was changed to one of the sulfur bearing gases. Only FeCrAl specimens were preoxidized at 1100°C; they were slowly cooled to 900°C, then exposed to gas "E." The compositions of gases "C," "D," and "E" are indicated on the Ellingham plot of $\log(p_{S_2})$ vs. $\log(p_{O_2})$ shown in Fig. 1. After expo-

Fig. 1. Ellingham diagram for the systems Al-S-O, Cr-S-O, and Fe-S-O at 900°C. The triangles labeled "C," "D," and "E" are experimental gas compositions (see Table I).

sure, the coupons were examined metallographically and by scanning electron microscopy. Auger electron spectra (AES) were obtained from some of the specimens.

An acoustic emission technique was developed to determine whether oxide scales cracked during preoxidation. A schematic diagram of the experimental setup is shown in Fig. 2. The specimen was suspended directly on an Al_2O_3 rod in the center of a high temperature resistance furnace. The temperature of the specimen was measured with a thermocouple. The Al_2O_3 rod, which served as the waveguide, was clamped cantilever-fashion to a piezoelectric transducer outside the furnace. The specimen and transducer were inside a quartz tube, through which the gas mixtures were passed. When cracks occurred, the elastic energy released traveled to the transducer, which produced an electrical signal. The transducer was sensitive to a wide range of frequencies, but the output was filtered to a range of 150-250 kHz. The signal from the transducer was amplified, filtered, then amplified again, and passed to a digital counter. The total amplification was 97 dB. The counter summed the number of signals above a preset threshold. A practical threshold setting was determined with the sample in place and gas flowing but with the furnace cold; the gain was slowly increased until the background noise began to be counted, then the setting was backed off slightly. An analog voltage proportional to the count summation was plotted vs. time (using a ramp generator) on an X-Y plotter. It is well known from acoustic emission studies of cracking in metals that a single cracking event can produce a burst of several elastic waves, and hence the num-

ber of counts will usually far exceed the number of individual cracks. In the present work, bursts of acoustic signals were widely separated in time, usually minutes apart to even hours apart. For the present purposes, it was not necessary to determine if a burst corresponded to several closely spaced, sequential cracks or to a single crack giving multiple counts; the different alloys behaved very differently, and the conclusions are clear without a detailed analysis of the individual signals. Clearly, a detailed signal analysis would be desirable, and work along that avenue has begun.

Results

Oxidation/sulfidation experiments.—Coupons of FeCrAl, FeCrAlY, and FeCrAlHf alloys were exposed to gas mixtures "C," "D," and "E" at 900°C. The activities of sulfur and oxygen in the gas were within the phase stability regions of Al_2O_3 , Cr_2O_3 , and FeS, as shown in Fig. 1 on the Ellingham diagram for the superimposed systems Fe-S-O, Cr-S-O, and Al-S-O (13). The results on the FeCrAl alloy are illustrated in Fig. 3-6. AES from the surface of the specimens after reaction are shown in Fig. 3a-3c. These data show that only Al_2O_3 formed on the surface of this alloy after exposure to gas "C." At a higher sulfur activity, gas "D," (but at the same oxygen activity of 10^{-16} atm) a small amount of Cr_2O_3 appeared on the surface along with the predominant Al_2O_3 (Fig. 3b). At a still higher sulfur activity, gas "E," the scale was largely sulfide (predominantly FeS).

A scanning electron micrograph (SEM) of the surface of the sulfide scale is shown in Fig. 4 for FeCrAl. An enlarged view is shown in Fig. 5a, where the brighter area represents the sidewall of a sulfide block and the darker area is the top. Figure 5 also includes the corresponding AES mapping for S, Fe, O, and Cr for the same area. It is apparent that the sidewall is rich in Al and O (Al_2O_3) and the top is rich in Fe and S (FeS). Using Ar ion sputtering to remove successive layers from the surface at points "1" and "2" (as indicated on Fig. 5a), the chemical composition at different depths in the scale can be revealed. The results, shown in Fig. 6a and 6b, indicate that each block is essentially FeS containing some Cr and a small amount of Al, with a thin layer of Al_2O_3 at the surface of each block. These results suggest that Al can diffuse through FeS to the surface of the blocks, where it is oxidized. A cross section (fracture surface) of the sulfide scale is shown in Fig. 7. The outer layer is FeS; the inner scale is largely Al_2S_3 with an iron-chromium sulfide spinel intermediate layer (as determined by x-ray diffraction analysis).

Exposure of FeCrAlY and FeCrAlHf coupons to gases "C," "D," and "E" produced results very similar to those described above for FeCrAl. Since these tests were isothermal, the beneficial effect of the reactive elements on scale adherence was of little advantage. In particular, these alloys also formed sulfide scales in gas "E." It has been suggested that Hf and Y promote nucleation and formation of oxide scales and, therefore, enhance sulfidation resistance (14). However, our experience with the experimental procedure outlined above does not support a view that Hf or Y are inherently beneficial. As will be shown later, the physical integrity of the scale is critical. Under exposure conditions such as thermal cycling, where scale adherence is poor without Hf or Y, these elements could well be beneficial to sulfidation resistance.

Preoxidation followed by sulfidation.—In the previously described experiments, sulfur was available in the gas to react directly with the alloy during the transient oxidation stage. Because of their fast growth rates, sulfides formed during transient scaling might be able to persist even though in the normal evolution of scale structures a protective Al_2O_3 would be expected to develop eventually. Therefore, to avoid the effects of transient scaling structures, the alloys described above were first preoxidized for various times, then, without changing temperature, the specimens were exposed to oxidiz-

Fig. 3. Auger electron spectra from the surface of FeCrAl alloys exposed to oxidation/sulfidation at 900°C for 24h. a: gas "C." b: gas "D." c: gas "E."

ing/sulfidizing environments. Preoxidation was carried out for 1, 24, 65, and 105h in gas "A" at 900°C. Sulfur can attack the underlying alloy by either chemical diffusion through the preformed Al_2O_3 scale or by permeation through microcracks and pores.

No sulfide was found on the scale surface or at the scale/metal interface of the specimens that had been preoxidized for 1 or 24h. However, when the preoxidation time was 65h, the Al_2O_3 scale on the FeCrAl alloy became less protective against sulfur attack, as illustrated in Fig. 8. Small sulfide particles (chromium sulfides) were found on the bare metal surface beneath the oxide scale in areas where the scale had become detached. When the preoxidation time was increased to 105h, sulfur was able to pass through the scale on both FeCrAl and FeCrAlY, as illustrated in Fig. 8b and 8c. The sulfides formed on the FeCrAlY were found to be concentrated in regions overlying the boundaries of dendrites in the alloy, as shown in

Fig. 4. SEM micrograph of the surface of FeCrAl exposed to gas "E" for 24h at 900°C. The platelets are largely iron sulfide.

Fig. 9. These boundaries contain precipitates which are rich in Y as a result of segregation during solidification. Figures 9a and 9b show sulfide particles emerging through cracks in the Al_2O_3 scale. The metal surface, where scale spalled during cooling, is shown in Fig. 9c and 9d. The particle in Fig. 9d is a Y-rich oxide in a dendrite boundary; the sulfides at the gas/scale surface (Fig. 9a and 9b) were iron- and chromium-rich. Examination of the Al_2O_3 scale on FeCrAlY formed during preoxidation of 105h showed that the scale had cracked primarily in the area of the Y-rich precipitates, as shown in Fig. 8c. In contrast to this behavior, the FeCrAlHf maintained the integrity of the scale throughout the preoxidation and the sulfidation exposures, and as a result suffered no sulfidation in these tests.

The results of the preoxidation/sulfidation tests run counter to what might be expected from the simple idea that thicker Al_2O_3 scales, formed by longer preoxidation,

Fig. 5. Scanning Auger elemental maps of part of a single platelet on the specimen shown in Fig. 4. On the image in a (top left), the top of the platelet is labeled "2," and the side or wall is "1." The elemental maps for S, Fe, O, Cr, and Al indicate that the top of the platelet is rich in Fe and S (FeS) and the sidewall is rich in Al and O (Al_2O_3).

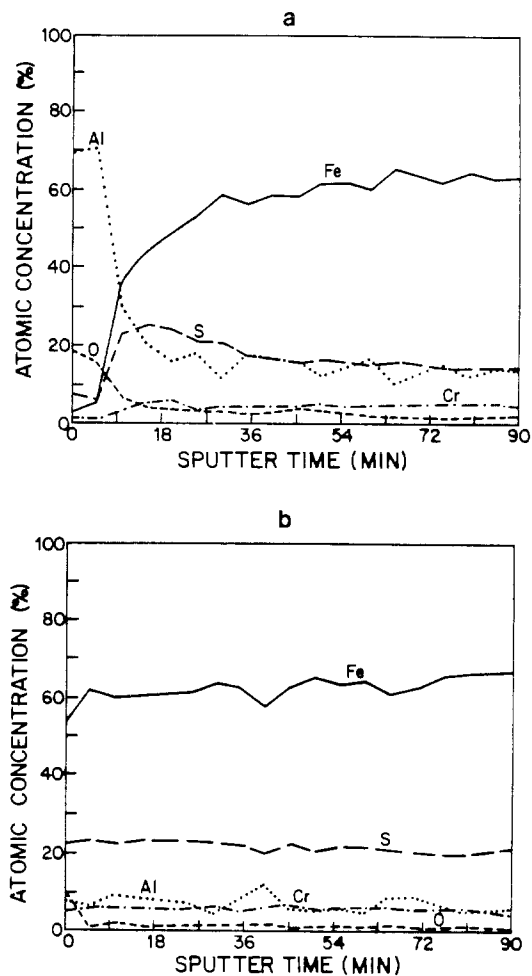

Fig. 6. Composition as a function of depth into the platelet determined by Auger analysis after argon ion sputtering. a (top): location "1" on Fig. 3a. b (bottom): location "2" on Fig. 3a.

ought to be more effective barriers to sulfur penetration. Indeed, the thicker scales were less effective on FeCrAl and FeCrAlY. This implies that lattice diffusion of sulfur through the oxide was not an important step in these experiments. The results also suggest that Al_2O_3 scales on these alloys crack as they grow isothermally, although less so on FeCrAlY than on FeCrAl. It is proposed that sulfur, as H_2S gas, permeates down the cracks to react with the underlying alloy, forming sulfides. From this perspective, Hf has an advantage over Y as an additive in that the Al_2O_3 scales on FeCrAlHf cracked far less exten-

Fig. 8. SEM micrographs of Cr_2S particles (located by arrows) at the metal/scale interface on alloys preoxidized in gas "A," then sulfidized for 24h in gas "E." a (top left): FeCrAl preoxidized 64h. b (top right): FeCrAl preoxidized 105h. c (bottom): FeCrAlY preoxidized 105h.

sively. It is noted that Hf is more soluble in the alloy, and therefore more dispersed, than Y, which is present largely as precipitates.

Acoustic emission tests.—In order to help verify the proposed mechanism that sulfur attacks the metal through microcracks in the scale, an acoustic emission technique was used to monitor oxide cracking during oxidation. When the oxide cracks, a transient elastic wave is generated, which propagates through the specimen. The acoustic emission technique has been used extensively to study cracking during metal fracture, but its application to oxidation studies is relatively new (15, 16).

A summary of some preliminary results is shown in Fig. 10 as a plot of accumulated counts vs. time for three alloys during oxidation at 900°C. The FeCrAl alloy generated "counts" more or less continuously during isothermal oxidation, whereas FeCrAlY generated a few widely spaced "bursts of counts" during the same time. Even fewer counts were recorded for FeCrAlHf. All the tests were conducted at the same sensitivity threshold. We interpret these data as indicating that the Al_2O_3 scale on FeCrAl cracks continuously during isothermal exposure,

Fig. 9. SEM micrographs of preoxidized (105h) and sulfidized FeCrAlY. a (top left): surface of the oxide scale showing Cr_2S emerging through the Al_2O_3 in a pattern corresponding to metal grain boundaries. b (top right): enlarged view of Cr_2S from a. c (bottom left): metal surface beneath spalled scale showing grain boundaries delineated by Y-rich compound. d (bottom right): enlargement of a Y-rich segregate from c.

Fig. 10. A plot of the accumulated acoustic emission events as a function of time during oxidation of FeCrAl, FeCrAlY, and FeCrAlHf at 900°C and FeCrAl at 1100°C. Specimen temperatures are superimposed on the plot.

but much less so on FeCrAlY and even less so on FeCrAlHf. Although the details of the cracking mechanism are not known, it is clear even with this qualitative interpretation that the acoustic emission technique is capable of monitoring scale cracking. Upon cooling to room temperature after about 100h exposure, as indicated by the superimposed temperature plot in Fig. 10, FeCrAl and FeCrAlY (but not FeCrAlHf) suffered further cracking owing to the thermally generated stresses. A few samples of FeCrAl were preoxidized in "B" at 1100°C for a shorter time calculated to produce the same thickness of oxide as 100h at 900°C. These samples did not generate acoustic counts at 1100°C, as shown in Fig. 10, possibly because the greater plasticity of the oxide scale or of the underlying alloy kept the growth stresses below the fracture limit. When cooled to room temperature, these samples did emit counts, and cracks were evident in the scale. However, samples could be cooled slowly to 900°C without cracking, as monitored by acoustic emission. When the slowly cooled samples were exposed to H_2 - H_2O - H_2S at 900°C, they did not suffer sulfidation.

These acoustic emission data are qualitative at this time and must be interpreted cautiously since the technique is not well established for this application. Nevertheless, these results are strikingly in accord with the proposal that the superior resistance of Al_2O_3 scales on FeCrAlHf is due to their physical integrity, and that the relatively poorer performance of FeCrAl (at 900°C) and FeCrAlY results from scale cracking. This is further supported by the observation that Al_2O_3 scales on FeCrAl, grown free of cracks at 1100°C, were impervious to sulfidation under conditions that caused severe sulfidation to samples preoxidized at 900°C.

Summary and Conclusions

FeCrAl, FeCrAlY, and FeCrAlHf alloys, which form Al_2O_3 scales, have been exposed to oxidizing/sulfidizing environments at 900°C. Two different exposure sequences were used: in the first, samples were exposed directly to H_2 - H_2O - H_2S mixtures in which the activity of sulfur varied from 10^{-6} to 10^{-10} atm; in the second, samples were preoxidized for various times in H_2 - H_2O , then exposed to H_2 - H_2O - H_2S mixtures as above. In the latter sequence, the samples were not cooled between the preoxidation and the oxidation/sulfidation exposures. Auger electron spectroscopy was used extensively to analyze the corrosion products.

Upon direct exposure to an oxidizing/sulfidizing gas, the alloys formed predominately an Al_2O_3 scale at low sulfur activities, but at high activities, the scale was predominately FeS. Preoxidation to form a barrier layer of Al_2O_3 to prevent the formation of FeS was successful if the preoxidation times were short. However, thicker oxide scales, formed by longer preoxidation times, were less

effective. This suggests that sulfur penetration by lattice or grain boundary diffusion was unlikely to be important. FeCrAlHf was the most resistant to sulfide formation after preoxidation, FeCrAlY less so, and FeCrAl the least resistant. Some preliminary experiments with an acoustic emission technique indicated that the Al_2O_3 scales crack even during isothermal oxidation at 900°C. The order of resistance to cracking (FeCrAlHf >> FeCrAlY > FeCrAl) paralleled the order of resistance to sulfidation attack after preoxidation. Crack-free Al_2O_3 could be grown on FeCrAl at 1100°C, and these scales were impervious to subsequent sulfur penetration at 900°C under the test conditions used here. The evidence supports the proposal that sulfidation under these conditions was initiated by permeation of gaseous H_2S through cracks in the oxide scale. Once formed at crack sites, sulfide phases provide paths of fast mass transport and lead to rapid attack. The ability of the scale to resist cracking is crucial to corrosion resistance, since healing of the cracks apparently is prevented in sulfidizing environments.

Long Cycle-Life Secondary Lithium Cells Utilizing Tetrahydrofuran

K. M. Abraham,* J. S. Foos,* and J. L. Goldman*

EIC Laboratories, Incorporated, Norwood, Massachusetts 02062

The tetrahydrofuran (THF)/LiAsF₆ electrolyte solution, except for its high reactivity with Li (1), is highly desirable for use in ambient temperature rechargeable Li cells (2). In a recent patent application (3), we have disclosed that the use of unsaturated organic additives such as 2-methyl-furan (2Me-F) enables high efficiency Li cycling in THF/LiAsF₆. A most important consequence of this discovery has turned out to be the utility of the high rate, low temperature mixed solution, 50:50 THF:2Me-THF/LiAsF₆(1.5M) (2,4,5), in 5 A-hr Li/TiS₂ cells to achieve, for the first time, more than 200 cycles of 60% depth-of-discharge (d.o.d). The Li anode cycling efficiency in these 5 A-hr cells exceeded 97%. We now believe that this mixed electrolyte is significantly better than 2Me-THF/LiAsF₆ for use in ambient temperature secondary Li cells. The relevant data are reported in this communication.

In prior publications (6-8), we have reported on the superior ability of the 2Me-THF/LiAsF₆ solution to cycle Li with high efficiencies which span the range of 96-97.5% (Figure of Merit, F.O.M._{Li} = 25-40) for Li charge densities of 7-10 mA-hr/cm². A persistent impurity in distilled 2Me-THF is 0.2-0.4 volume-percent (v/o) of 2Me-F (4,7,9), the unsaturated analog of 2Me-THF (see Table II. for structural formulas). In fact, most of the published results discussing the use of 2Me-THF/LiAsF₆ in rechargeable Li cells have dealt with an electrolyte solution containing ~0.2-0.4 v/o 2Me-F. This has come about because of the difficulty of removing the 2Me-F by fractional distillation of the solvent.

Recently we have found that this 2Me-F can be completely converted into 2Me-THF by hydrogenating the "impure solvent" over a Pt catalyst at ambient temperature and pressure (3). Li/TiS₂ laboratory cells using the 2Me-F-free-2Me-THF/LiAsF₆ solution, to our surprise, have

exhibited inferior cycle lives; typically, about half of that of cells utilizing the "regular electrolyte" with 0.2-0.4% 2Me-F. The cycle tests at 1 mA/cm² and 7 mA-hr/cm² were performed in 0.68 A-hr Li/TiS₂ laboratory test cells, identical to those we have previously described in ref. 7. Indeed, the cycle numbers for the various cells reported in Table I are directly comparable to those presented in Figures 4 and 5 of ref. 7. It should be noted that all cell capacities mentioned in this paper are based on 1e⁻/TiS₂. As discussed in ref. 7, the theoretical Li capacity in a cell is much larger than the TiS₂ capacity. Following the surprise with the 2Me-F-free-electrolyte, we deliberately prepared 2Me-F-containing solutions by adding 0.3, 0.6 or 1.2 v/o of 2Me-F into the solution in neat 2Me-THF, obtained via the hydrogenation procedure. Performance of laboratory Li/TiS₂ cells employing these solutions is summarized in Table I. It is clear that 0.3 to 0.6 v/o of 2Me-F doubles the cycle life of 2Me-THF/LiAsF₆-based cells.

Table I. Effect of 2-Methyl-furan (2Me-F) on the Cycle Life of Li/TiS₂ Laboratory Cells^(a)

Cell No.	Electrolyte	Amount of 2Me-F v/o	Number of Cycles ^(b)
98-18	2Me-THF ^(c) /LiAsF ₆ (1.4M)	0.0	96
98-07		0.3	150
98-26		0.6	177
98-29		1.2	198
140-19	THF/LiAsF ₆ (1.5M)	0.0	7
35-10		0.5	111
35-32 ^(d)		0.5	92
98-06		1.0	96
98-11		1.5	110
98-15		2.0	105
101	2Me-THF (50 v/o): THF (50 v/o)/LiAsF ₆ (1.5M)	0.5 ^(e)	145
102	2Me-THF (50 v/o): THF (50 v/o)/LiAsF ₆ (1.5M)	1.0	140

(a) Each type of cell has been cycled at least in duplicate. Temperature, 25°C.

(b) Obtained at 1 mA/cm² for 7 mA-hr/cm²; compare Fig. 5 in Ref. 7.

(c) Obtained by hydrogenating distilled 2Me-THF containing 0.2-0.4 v/o 2Me-F over Pt catalyst and subsequently preparing the LiAsF₆ solution.

(d) Stored 14 days at 50°C prior to cycling.

(e) Stored for 1 month at 50°C prior to cycling. Unstored cells gave ~10 cycles less.

*Electrochemical Society Active Member
Key Words: Li Battery, Electrolytes

An obvious question is whether 2Me-THF/LiAsF₆ is less reactive in secondary Li cells than THF/LiAsF₆, as previously claimed (8). The answer is yes, although about half of the cycles of the cell presented in Figure 5 of ref. 7 appears to be due to the effect of 2Me-F.

We have also found 2Me-F to improve substantially the cycle life of cells utilizing THF/LiAsF₆. Some relevant data are given in Table I. Cells utilizing THF/LiAsF₆ plus 0.5 v/o 2Me-F exhibit about 100 cycles as opposed to 7 in 2Me-F-free cells. Interestingly enough, a significant increase in cycles is not seen at the higher 2Me-F concentrations of 1, 1.5 and 2 v/o. It appears from the data obtained from both THF and 2Me-THF cells, that there is a stoichiometric relationship between the amount of effective 2Me-F and the Li being electrochemically cycled. Our present data indicate that about 0.4 mmoles of 2Me-F is required per 1 A-hr of Li for the manifestation of an optimum additive effect in THF/LiAsF₆. This Li-to-additive mole ratio has been satisfactorily tested in 5 A-hr prismatic Li/TiS₂ cells (vide infra). The practical significance of this discovery is very clear. For the first time, high rate, low temperature discharge and long cycle life have all been achieved in the same electrolytes, namely THF/LiAsF₆ and its blends.

We believe that 2Me-F is effective as a cycle life enhancing additive because it forms a protective film on the Li surface. The film may be of the solid electrolyte (10) or of the polymer electrolyte (11) type, enabling Li discharge and charge, while preventing or significantly slowing down direct chemical reactions at the Li surface. Further studies to fully elucidate the chemistry of the additive effect are in progress.

In laboratory test cells, the 50:50 THF:2Me-THF/LiAsF₆(1.5M) electrolyte solution with 0.5 v/o 2Me-F has given cycle lives mid-way between those given by cells containing the parent solutions plus the additive (see Table I). However, in 5 A-hr prismatic Li/TiS₂ cells this order of additive effects changes. In these larger cells, employing a practical Li-to-electrolyte ratio, the mixed THF:2Me-THF solution plus 2Me-F has produced the longest cycle life. Thus a 5 A-hr Li/TiS₂ cell (12) utilizing a solution of the composition, THF (48.3 v/o):2Me-THF(48.3 v/o):2Me-F(3.4 v/o)/LiAsF₆ (1.5M), has given more than 225 cycles when cycled at a d.o.d. of 60% (Figure 1). As indicated earlier, the amount of the additive required is determined by the total Li in the cell, and the larger additive concentration in

these cells is due to the larger Li to electrolyte ratio. Under similar cycling regimes, 2Me-THF/LiAsF₆ cells gave 125 cycles and the THF/LiAsF₆ cells 120 cycles. In all cases, cell failure occurred due to increased impedance and dendrite shorting. The blended solution, in addition, has exhibited relatively good thermal stability (see Table I) and its low temperature performance is superior to that of the parent solutions. A 5 A-hr Li/TiS₂ cell employing the blended solution has yielded ~2.5 Ahr at -20°C at 2mA/cm² (2,4,5). For the same temperature and current density, capacities were non-existent in the cells utilizing the parent solutions. The superior -20°C performance of the mixed solution over THF/LiAsF₆, despite the higher conductivity of the latter (2), may be related to the more desirable Li⁺-solvates in the blend, permitting better Li⁺ diffusivities and a consequently high rate capability. The 2Me-THF system is impractical below 0°C because of the formation of sparingly soluble Li⁺-solvates (2,7).

In exploring the field, we have discovered other additives as well suitable for improving the cycle life of THF/LiAsF₆-based secondary Li cells. Some examples are given in Table II. To date 2Me-F appears to be the most effective. Detailed studies of the various additives are in progress.

ACKNOWLEDGEMENT

This work was supported by the Office of Naval Research. We appreciate discussions with Dr. S. B. Brummer.

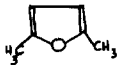

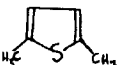

Figure 1. Typical cycles of a 5 A-hr theoretical capacity Li/TiS₂ cell utilizing THF (48.3 v/o):2Me-THF(48.3 v/o):2Me-F(3.4 v/o)/LiAsF₆(1.5M). Current: Cycles 1 and 100, $i_d = 0.5A$, $i_c = 0.25A$; Cycles 160 and 203, $i_d = i_c = 0.25A$. All cycling was performed to a depth-of-discharge of 60% (3A-hr).

In Situ Measurement of Resist Dissolution with a Psi-Meter

Warren W. Flack,* James S. Papanu, Dennis W. Hess,* David S. Soong, and Alexis T. Bell

Department of Chemical Engineering, University of California, Berkeley, California 94720

INTRODUCTION

The dissolution of exposed resists in developer solutions is a critical step in the fabrication of microelectronic devices. A number of process parameters, e.g. developer strength, temperature, and molecular weights in the exposed and unexposed regions, significantly affect the outcome of the process. Fundamental studies of the complex dependence of resist development on these process variables will greatly facilitate process design and optimization.

Critical information needed for fundamental understanding and mathematical modeling of the resist development process entails determination of resist film thickness as a function of time in the developer solution. Traditional procedures rely on repeated development of a resist for various predetermined times, followed by quenching in a nonsolvent and baking to drive off the developer before measuring the remaining film thickness (1,2). This technique is prone to errors due to the presence of induction periods and failure to stop dissolution immediately when desired.

Recently, several in-situ thickness-monitoring techniques for photoresist development have been reported. Konnerth and Dill (3) used a computer controlled spectrophotometer to measure the relative reflectivity of the resist sample as a function of wavelength. Film optical properties and a complex method for converting relative to absolute reflectivity were necessary to determine film thickness. A laser endpoint detection system based on interferometry principles was developed by Willson (4). This device provides data to within an integer multiple of one-half a wavelength. Thus, the resolution is not sufficient for detailed kinetic studies. Oldham (5) has developed a technique for measuring the capacitance between conductive developer solutions and substrates. Here, use is made

*Electrochemical Society Active Member.

of the fact that the total thickness of dielectric is related to the capacitance.

In this communication, we report the development and successful application of a simplified ellipsometer (psi-meter) (6) for the in-situ measurement of resist film thickness in developer solutions. Preliminary data suggesting the formation of a gel layer over the remaining glassy film will be discussed.

EXPERIMENTAL

Figure 1 shows a block diagram of our experimental arrangement. The psi-meter consists of a 2 mW helium-neon polarized laser source, a quarter-wave retardation plate to generate circularly polarized light, and a synchronously rotating polarizer to convert the beam to linearly polarized light with time-dependent orientation. Light reflected from the wafer placed in the optical cell enters a photodetector. The signal from the detector is split into AC and DC components by a ratiometer. Final data acquisition and storage are achieved with a dedicated Commodore PET 2001 computer. The amplitude ratio of the AC to DC components is equal to $-\cos(2\psi)$, where ψ is related to the optical constants of the substrate, film, and ambient, the wavelength of the light, the angle of incidence and the film thickness through the Drude equation (7). Since only ψ is determined by this apparatus (Δ , characterizing the change in phase upon reflection, is not measured), the refractive index of the film must be known a priori to calculate the film thickness.

Our experimental conditions were as follows. Silicon wafers were coated with approximately 700 nm of PMMA resist and prebaked at 160°C for one hour. Film dissolution took place in the optical cell, where a developer solution at room temperature was circulated at 100 ml per minute. The optical cell has a volume of 250 ml.

The motor-driven polarizer was adjusted to a rotation frequency of 100 Hz. An incident angle of 75° was chosen to give a high sensitivity. The wavelength was 632.8 nm. Data were collected at a rate of one point per second, allowing detailed delineation of the dissolution phenomenon.

RESULTS AND DISCUSSION

Figure 2 shows plots of AC/DC amplitude ratios as a function of dissolution time for wafers immersed in developer solutions of methyl ethyl ketone (MEK) and isopropanol (IPA) with compositions of 3:2 and 1:1 volume ratios of the two components. Appreciably different time scales are used to display the amplitude ratio variation, suggesting different rates of developer penetration and film dissolution. The AC/DC curves can be related to the variation of film thickness through a program developed by McCrakin (8) based on the Drude equation. The curve for the stronger solution (3:2) indicates a linear decrease in film thickness with time, with no apparent induction period and no distinct multiple layer formation. An extra maximum emerges at short times when the strength of the solution is reduced to 1:1.

We speculate that this extra maximum is associated with the formation of a gel layer at the solution-resist interface (9). Polymer dissolution involves both solvent penetration into the glassy matrix, converting it into a rubbery gel phase, and detachment of chain molecules from the entangled gel network into the solution. Different physical phenomena govern the rates of the two processes. The former is influenced by the mobility of small solvent molecules penetrating the glassy phase, whereas the latter is affected by chain diffusion. Thermodynamic compatibility of the developer and the resist also plays an important role in the development process. A thorough analysis of the resist dissolution kinetics will further elucidate the underlying physics. Detailed modeling is underway, and a systematic experimental program is currently being pursued.

Process Characterization of PSG and BPSG Plasma Deposition

S. Shanfield* and S. Bay

LFE Corporation, Clinton, Massachusetts 01510

A concern in the fabrication of high density integrated circuitry is the topography of interlayer dielectric steps over which metal conductor lines will pass. These steps, occurring as a result of underlying topography or via etching, should be gradually tapered to ensure continuity in subsequently deposited metal interconnect lines. Tapered steps can be achieved by reflow of phosphosilicate (PSG) or borophosphosilicate glass (BPSG) interlayer dielectric at device-compatible temperatures. PSG and BPSG deposition has been demonstrated using atmospheric-CVD(1), low-pressure-CVD(2), and recently, using plasma enhanced CVD in tube-type systems (3-5). In this communication, we report on process characterization of plasma-enhanced deposition of PSG and BPSG. A parallel-plate cold wall plasma deposition system was used.

Description

Dilute silane (2%-5% in Ar), nitrous oxide, dilute phosphine (5% in Ar), and dilute diborane (5% in Ar) are mixed in a manifold and admitted into the deposition chamber through five in-line showerhead electrodes (6). Gases exiting the reactor pass through a pressure-controlling throttle valve into a two stage mechanical pump. The plasma discharge is maintained by RF power (13.56 MHz) applied to the showerheads. Spacing between the 14 cm diameter showerheads and track was set at 1.4 cm. Wafers are automatically placed on the heated track beneath the showerheads. In normal operation, wafers receive one-fifth of the required deposition thickness under each showerhead.

Procedure

Thin films of PSG and BPSG were deposited on bare silicon wafers and as interlayer dielectric in MOS device structures. PSG and BPSG films on bare silicon were characterized for thickness and thickness uniformity using a Nanometrics Nanospec™ AFT, and index of refraction was measured with an ellipsometer. Dopant content (in weight percent phosphorous or boron) was measured by electron microprobe, and depth profiles of phosphorous content were obtained by Auger analysis. Etch rate and etch rate uniformity of films in buffered oxide etch were also measured. The degree of film particulate contamination was determined using a Tencor Surfscan™ 200 set to detect one micron or larger particles. SEM sections were used to characterize the profile of reflowed BPSG film over MOS device topography.

All depositions were performed with a substrate temperature of 340°C. Nitrous oxide flow was fixed at 1700 cc/min. while silane flow was varied between 20 and 60 cc/min. Chamber pressure during deposition was set at 2.35 torr. The phosphine-to-silane flow ratio ranged between 0 and 0.3 while the diborane-to-silane flow ratio ranged between 0 and 0.7.

Results

Films characterized were nominally 10,000 Å thick with typical across-wafer uniformity of ±2%. The index of refraction ($\lambda = 6328 \text{ \AA}$) for films with 0-11 weight percent phosphorous and 0-6 weight percent boron fell in the range of 1.46-1.47. Dopant level uniformity was typically ±0.1 weight percent across-wafer. Depth profile measurements in PSG films indicated ±0.5 weight percent variation in phosphorous content through 90% of the film thickness. Particulate levels in deposited films were in the range of 0.06-0.12 particles per cm². No evidence of homogeneous nucleation was observed, and the particulate levels were primarily a

function of walls, load lock, and track cleanliness.

Fig. 1 shows the theoretical relationship between silane flow and the maximum obtainable deposition rate of undoped silicon dioxide (solid line). The maximum obtainable deposition rate, $(dh/dt)_{\text{max}}$, is derived under the assumption that all of the silicon in the silane flow is converted to silicon dioxide in the film. This condition corresponds to silicon material utilization, U_m , equal to one in the equation below:

$$\frac{dh}{dt} = \frac{W_{\text{SiO}_2}}{W_{\text{SiH}_4}} \cdot \frac{\rho_{\text{SiH}_4}}{\rho_{\text{SiO}_2}} \cdot \frac{F_{\text{SiH}_4}}{A_d} \cdot U_m \quad (1)$$

where

W_x = atomic weight, gm/mole

ρ_x = density, gm/cm³

F_{SiH_4} = volumetric flow rate of silane, cm³/min.

A_d = deposition area, cm²

U_m = silicon material utilization

($0 \leq U_m \leq 1$)

By adjusting the silicon material utilization (U_m) or the silane flow (F_{SiH_4}), a range of deposition rates could be obtained. Experimental silane flow rates and the corresponding deposition rates used in this study are also shown in Fig. 1. For silane flows used in the study, silicon utilization, U_m , was fixed at about 75% by adjusting the RF power. At a silane flow of 20 cc/min., 75% silicon utilization was obtained with forward RF power set at 20 watts per electrode (0.13 w/cm²). The undoped oxide deposition rate under these conditions was about 1500 Å/min. Using a silane flow of 60 cc/min, forward RF power was set at 45 watts per electrode (0.30 w/cm²) to maintain 75% utilization. In this case, the undoped oxide deposition rate was about 3800 Å/min. With silane flow and RF power established, the relation between flows of dopant gases and the level of doping in the films was investigated.

Fig. 2 compares the theoretical and experimental relationships between weight percent phosphorous in BPSG films and the phosphine-to-silane flow ratio used in depositing the film. The theoretical relationship is derived by assuming that all phosphorous in the flow is incorporated as phosphorous in the films (i.e. 100% phosphorous utilization). The experimental points correspond to films with varying phosphorous content and a range of boron content between 0 and 7 weight percent. Fig. 2 indicates that the experimental relationship between phosphorous content and the phosphine-to-silane flow is approximately linear and, that the plasma deposition process utilized a large percentage of the phosphorous available. In addition, the data in Fig. 2 suggests that the level of diborane in the flow does not affect the phosphorous utilization.

Fig. 3 shows a comparison of the theoretical and experimental relationship between boron content in BPSG films and the diborane-to-silane flow ratio used during deposition. In this figure, the theoretical relationship is derived by assuming that all of the available boron in the flow ends up as boron in the films (similar to the assumption in Fig. 2). The experimental points correspond to films with varying boron content and a range of phosphorous content between 0 and 11 weight percent. Within experimental error, the relationship between boron content and the diborane-to-silane flow ratio is linear and the

boron content is independent of the level of phosphine flow. The plasma deposition process appears to use approximately one-half of the available boron in the diborane flow.

Fig. 4 plots the ratio of weight percent phosphorous to weight percent boron in deposited films as a function of the ratio of volumetric flow of phosphine to the volumetric flow of diborane used to deposit these films. A theoretical prediction of the relationship between these ratios advanced by Ramiller and Yau (3) is shown as a broken line in Fig. 4. An alternate prediction, derived by using the ratio of the theoretical relationships in Figs. 2 and 3, is shown as a solid line. This theoretical relationship, which appears to agree with experimental points plotted in Fig. 4, is given by

$$\text{wt. \% P/wt. \% B} = 2.8 \text{ PH}_3/\text{SiH}_4 \quad (2)$$

Eqn. 2 is based on the assumption of an independent level of utilization associated with each dopant. In contrast, the relationship derived by Ramiller and Yau assumes competition in the incorporation of phosphorous and boron in the film, as occurs in a thermally activated process. The assumption of independent dopant utilization (Eqn. 2) may be applicable under the conditions where the deposition is primarily plasma-activated (i.e. not thermally activated).

Fig. 5 shows an example of plasma deposited BPSG (5 weight percent P and 3 weight percent B) reflowed over a MOS device structure. The film was first densified at 800°C in dry nitrogen for 30 minutes. The temperature was then raised to 920°C for 30 minutes to accomplish the reflow shown. Reflow of 4 weight percent P and 4 weight percent B BPSG in dry nitrogen has been observed to occur between 825°C and 850°C. No evidence of cracking or bubbling was observed in any of the reflowed PECVD BPSG samples.

Conclusion

We have reported on process characterization of PSG and

BPSG film deposition using a parallel plate PECVD system. The films obtained were uniform in both thickness and dopant content. Deposition conditions were established by maintaining a fixed level of silicon material utilization. The amount, in weight percent, of phosphorous incorporated in BPSG films was found to be proportional to the phosphine-to-silane gas flow ratio. Similarly, the level of boron incorporation was found to be proportional to the diborane-to-silane gas flow ratio. The experimental relationship between the phosphine-to-diborane gas flow ratio and the weight percent phosphorous-to-weight percent boron ratio in deposited films suggests that the deposition process was primarily plasma-activated. Independent variation of phosphine and diborane gas flow rates in a plasma-assisted reaction allows correspondingly independent phosphorous and boron incorporation rates. For this reason, plasma-assisted deposition of doped silicon dioxides is expected to be easier to characterize and provide a more repeatable process in a device fabrication environment.

Electroluminescence of Polycrystalline CdSe Thin Film Photoelectrodes: A Sensitive Probe for Surface Recombination

N. Müller, M. Abramovich,* F. Decker,* F. Iikawa, and P. Motisuke

Instituto de Física, UNICAMP, 13.100 Campinas, SP, Brasil

Photoluminescence (PL) and Electroluminescence (EL) measurements have been used to characterize the excited state properties of Cd-chalcogenide single crystal electrodes in photoelectrochemical solar cells (PEC's) (1). Polycrystalline thin film electrodes of these materials, which are promising candidates for the efficient photoelectrochemical solar energy conversion, have been studied only very recently using PL (3). As EL originates more close to the surface of the electrodes, it is considered a probe of recombination more sensitive than PL to the surface conditions of the sample (1). We report the first EL measurements with electrodeposited thin film CdSe electrodes and the enhancement of EL efficiency upon photoetching (4).

CdSe thin film electrodes were prepared onto Ti substrates by electroplating according to literature procedures (2a). The electrodes were annealed at 600°C in N₂ and photoetched in a (0.3:9.7:90) HNO₃:HCl:H₂O solution under white light illumination shortening the photoelectrode to a carbon counterelectrode. Room temperature luminescence spectra were taken with a 0.5m SPEX monochromator and a cooled S-1 EMI photomultiplier. The 5145 Å line of a Coherent Radiation model 52 Ar⁺ ion laser was used to excite PL. The laser beam was expanded, having an intensity of about 100mW/cm² at the sample. During PL the sample was kept in air. EL measurements were performed in a N₂ purged 0.1 M Na₂S₂O₈ + 2.5 M KOH electrolyte. The electrode potential was pulsed between 0 V (SCE) (10 s) and -1.5 V (SCE) (1 s) while scanning the monochromator at 5Å/s. A specially constructed electrode holder enabled us to mount the electrodes in a reproducible way for taking the spectra.

Fig. 1 shows the PL and EL spectra of an electrodeposited CdSe thin film electrode at 295°K. In contrast to spectra measured earlier with CdSe single crystal electrodes (1), a broad subbandgap band dominates the PL spectra of our samples. Red luminescence corresponding to the bandgap peak can be observed with the dark adapted eye. The relative heights of the

bandgap and subbandgap peaks vary drastically with the electrode annealing conditions (5). The bandgap peak at 720 nm and the subbandgap peak at 1060 nm appear at the same position in PL and EL. A second subbandgap structure appears at 945 nm in EL, which has no counterpart in the PL spectrum. A similar phenomenon was reported in the literature (6). Direct hole injection from the SO₄⁻ radical ion into intermediate surface ⁴ states might be responsible for this additional peak.

Usually the subbandgap intensity in the PL spectra is an order of magnitude larger than the bandgap one. The origin of the subbandgap band is either a high density of structural defects or impurities in the electrodeposited samples. The PL of pasted CdSe thin film electrodes (7) shows a pronounced subbandgap band as well, though high purity starting material was used to prepare the samples (5). Irrespective of the kind of lattice defects responsible for this subbandgap luminescence, these defects probably decrease the solar-to-electric conversion efficiency in a PEC cell with such electrodes. Optimal results for CdSe thin film electrodes are obtained with a photoelectrochemical etching procedure, which increases the real surface area of the electrode (4). There are indications that as a simultaneous effect the photoetch also removes surface recombination centers (4b, 4c). EL being a sensitive probe of surface recombination should indicate whether a removal of surface recombination centers indeed contributes to the effect of photoetch.

Fig. 2 shows the EL spectra of an electrodeposited CdSe electrode before and after photoetching. While the height of the subbandgap peak remains almost unchanged, the bandgap peak has increased nearly 100% after the photoetch. Probably nonradiative surface recombination is reduced by the photoetch thereby increasing the radiative bandgap recombination as well as the photocurrent of the electrode in a PEC. Though the amount of the increase in EL intensity induced by photoetching varies from electrode to electrode, a large increase

*Electrochemical Society Active Member.

in the bandgap luminescence has been found with every electroplated electrode that has been tested. Since the electrode current during EL is not affected by the photoetch, the observed enhancement of EL cannot be related simply to the increase of the electrode surface areas. Therefore, we consider EL of polycrystalline thin film semiconductor electrodes as an useful probe for analyzing the effect of surface treatment which do change the density of surface recombination centers.

The effect of photoetching on the PL spectra of our samples is found to be very small, sometimes even a slight decrease in intensity of the bandgap peak is found. As EL originates more close to the surface of the electrode, it is able to monitor surface recombination properties more sensitively than PL. A more detailed study of EL and PL properties of electrodeposited and painted CdSe electrodes is under work, testing the effect of electrode annealing conditions on EL, PL and x-rays diffraction patterns as well as the electrode power output in the PEC cells (5).

Ceramic Membranes for Precise pH Measurements in High Temperature Aqueous Environments

S. Hettiarachchi* and D. D. Macdonald**

Fontana Corrosion Center, Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

Recently, Niedrach (1,2) and Macdonald and Tsuruta (3) described the use of yttria-stabilized zirconia (YSZ) membranes for the measurement of pH of aqueous solutions at temperatures as high as 300°C. In these studies, membrane electrodes with both aqueous and Cu/Cu₂O internal elements were used. This membrane electrode has been found to exhibit a nearly-Nernstian pH-response at elevated temperatures, and appears to be ideally suited for the measurement of pH of a wide variety of aqueous systems.

Although the preliminary studies demonstrated the potential use of YSZ membranes as pH sensors, its apparent lack of high precision as demanded by many research and control applications of high temperature technology, has led us to investigate the possible use of Hg/HgO as an internal reference (4). We have also attempted to eliminate the use of calculated pH values in evaluating the performance of these membrane electrodes. In order to achieve this second objective, the potential of the sensor and the potential of a hydrogen reference electrode were measured against a pressure balanced Ag/AgCl, 0.1M KCl reference electrode in systems containing known amounts of dissolved hydrogen. The excellent one-to-one correlation obtained between these measurements, as reported in this paper,

proves beyond any doubt that the Nernstian behavior expected of the hydrogen electrode with respect to the hydrogen ion is exactly followed by the zirconia (9%Y₂O₃) pH-sensors constructed by us (4).

All potentials were measured using a Keithley 614 electrometer having an input impedance of $5 \times 10^{13} \Omega$. Measured potentials were corrected for liquid junction potentials. Experiments were performed in the temperature range 175°C–275°C at 25°C intervals. Since the system was found to be sensitive to static charge, all measuring cables and electrode assemblies were placed in a Faraday cage.

Figure 1 shows the response of the pH-sensor and an internal reference hydrogen electrode (H₂, Pt/H⁺), both measured against a Ag/AgCl, 0.1M KCl reference electrode at various temperatures. The perfect one-to-one correlation obtained in these plots resulting in a regression coefficient of almost unity (Table I), proves that the pH-sensor behaves in a Nernstian manner, thus enabling us to estimate the pH of high temperature aqueous solutions to a high degree of precision. Furthermore, these findings also show that the lack of such high precision in previous studies is certainly not due to a fault of the pH-sensor, but can be traced to uncertainty in the calculated pH values of the buffer solutions used for the calibration.

The ability to measure pH to such a high degree of accuracy in aqueous systems at elevated temperatures opens up a whole new area of solution chemistry, since we are now in a position to study hydrolysis reactions and to determine activity coefficients for ions more accurately. This is an area which has only been briefly investigated by solution chemists.

The pH-sensor electrode is capable of withstanding high temperatures and

pressures and showed good long term stability, and is not affected by H_2 , O_2 or chloride ions in solution. These findings and the calibration procedure for precision high temperature pH measurements will be communicated shortly. (4).

Electrically conducting polymers have recently been the subject of intense interest. Polyacetylene has been widely studied as an electronic conductor. Ionic conductors include poly(ethylene oxide) (1), poly(propylene oxide) (2), polyacrylonitrile (3), poly(vinylidene fluoride) (3), poly(tetramethylene oxide) (4) and poly(ethylene succinate) (5). In the present note, the observation of electrically conducting poly(vinyl acetate) (PVAc) is reported. Ionic conduction is inferred from the data.

PVAc (MW 1.5×10^6) was obtained from Polysciences, Inc. PVAc and LiClO_4 in the ratio 8:1 were dissolved in methanol then dried in air on a teflon plate at about 55°C . The result was a brittle, clear solid at room temperature. Pure PVAc was prepared by the same method for comparison. Aluminum electrodes were then evaporated onto the faces of several samples and audio frequency complex impedance measurements were performed in a vacuum at temperatures from 5.5 K to 380 K using techniques described elsewhere (6). The results for one frequency (100 Hz) are shown in figure 1. Four other frequencies from 100 – 10^4 Hz gave similar results and are omitted for clarity. It is seen that the d.c. conductivity of the LiClO_4 complexed material at 100°C is about three orders of magnitude larger than that of the pure material and increases exponentially with an activation energy of about 2.1 eV. However, at about 50°C the a.c. conductivity of the pure material (a.c. loss due to the relaxation peak associated with the glass transition) is slightly greater than that for the complexed material at the same temperature. The glass transition in the complexed material is shifted to higher temperatures where it is probably masked by the d.c. conductivity. This temperature shift is confirmed by differential scanning calorimetry (DSC) studies. The DSC results together with further electrical relaxation studies will be presented elsewhere.

In order to gain further information concerning this material, ^7Li NMR linewidth and spin-lattice relaxation T_1 measurements were conducted at 155 MHz with a JEOL GX400 NMR spectrometer, after sealing the sample in an evacuated quartz tube. Over the temperature range studied, the ^7Li spectra exhibit a single absorption with no apparent quadrupolar broadening (as deduced by the appropriate $\pi/2$ pulsewidth condition). The temperature dependence of the full-width-at-half-maximum (FWHM) linewidth is shown in figure 2 (triangles). The T_1 -recovery process was found to be slightly non-exponential, which may indicate the presence of more than one relaxation time. However, no significant temperature dependence of the recovery profile was observed, which allowed the use of an "effective T_1 ," defined as the time required for the magnetization to recover 63% of its maximum value. A plot of T_1 (effective) vs. $1000/T$ also appears in Figure 2 (squares). The value of the "rigid linewidth" (4.4 kHz), which occurs below about 220K and the observed motional narrowing behavior bear a close similarity to results reported for PEO-Li⁺-based materials,^{7,8} which suggests a comparable degree of Li⁺ and/or polymer chain motion in PVAcg-LiClO₄. There are, unfortunately, no T_1 measurements above 383K at present, but it is likely that a T_1 minimum would occur at or near the melting point of the complex. T_1 does, however, exhibit Arrhenius behavior throughout the motional narrowing region (above room temperature) with an activation energy of 0.14 ± 0.03 eV. This small value presumably reflects localized motion with a correspondingly small potential energy barrier. The relation between the apparent localized process and motion resulting in long-range transport is not clear at the present time.

Finally, the following cell was constructed: $\text{Li/PVAcg-LiClO}_4/\text{MnO}_2\text{-C-PVF}_2$. The composition of the cathode was about 82% MnO_2 , 9.6% C and 8.4% PVF_2 by weight. The materials were hot-pressed at about 205°C to form a conducting disk about 2.54 cm in diameter and 1 mm thick. The polymer film was about 0.4 mm thick and 2 cm in diameter, while the lithium electrode was about 1 mm thick with a diameter of about

Fig. 1. $\text{Log}(\sigma(\text{A-cm})^{-1})$ vs. $1000/T$ for pure PVAc (x) and PVAc₈-LiClO₄ (□) at 100 Hz

Fig. 3. Voltage (V) vs. $J(\mu\text{A}/\text{cm}^2)$ for the cell Li/PVAc₈-LiClO₄/MnO₂-C-PVF₂ at 125°C

1.2 cm. The three disks were spring loaded into a cell under an argon atmosphere. The cell was not hermetically sealed. Although the present data were obtained with the cell in air, similar results were obtained when the experiment was carried out under vacuum. The discharge characteristics are shown in figure 3. Further tests showed that with a 100kΩ load, the voltage decreased gradually from 1.8V to 0.9V over a period of 16 hours. The cell failed at that time. While the discharge characteristics of the present cell are not particularly impressive, it should be emphasized that no attempt was made to optimize the performance of the cell. The construction of the cell was rather primitive and, for example, a higher operating temperature or thinner polymer would decrease the internal resistance of the cell. The "open circuit" voltage (the resistance of the Keithley 195 DMM is about 10⁶ ohms) is about 3.04 volts, which is not unreasonable for a cell of this type. Further, the initial internal resistance of the cell, was about 93 kΩ and was about 85 times larger than the resistance predicted from the a.c. conductivity measurements described above. While there is considerable uncertainty in the latter value due to the ambiguities in the geometry of the cell, it is clear that the internal resistance of the cell is larger than the a.c. resistance of the bulk polymer material. This is not surprising since, for example, anions as well as cations may be contributing to the a.c. conductivity, thus giving rise to a lower a.c. resistance. Finally, a similar cell was constructed using a pure PVAc film in place of the PVAc₈-LiClO₄. No voltage was detected for this cell.

All results are consistent with ion transport.

Electrochemistry of Carbonaceous Materials and Coal

Su-Moon Park*

Department of Chemistry, University of New Mexico, Albuquerque, New Mexico 87131

ABSTRACT

Electrochemistry of carbonaceous material and coal is reviewed comprehensively. The subject is divided into five categories: electrochemistry of various forms of carbon, chemical oxidation and reduction of coal, electrochemical oxidation and reduction of coal, photoelectrochemistry of coal, and direct power generation from coal burning fuel cells. Oxidation of coal by air or oxygen and reduction through hydrogenation reactions are not included in this review. Only reports relevant to solution chemistry are included. Characterization and derivatization of coal and carbonaceous material employing the above electrochemical reactions are discussed in each section.

Since comprehensive reviews of electrochemistry of inorganic (1) or organic (2) derivatives of carbon compounds have been compiled in the literature, we will limit this review to the electrochemistry of carbonaceous materials relevant to coal. In reviewing the subject, we classify it into several categories: (i) electrochemistry of various forms of carbon, (ii) chemical oxidation and reduction of coal, (iii) electrochemical oxidation and reduction of coal, (iv) photoelectrochemistry of coal and carbons, and (v) direct power generation from coal burning fuel cells.

Electrochemistry of Various Forms of Carbon

The oxidation of carbonaceous materials has been studied mainly for two purposes: to characterize surfaces of various carbons and to characterize carbon as an electrode material. We will review these two subjects in this section.

Surfaces of carbon black particles were characterized electrochemically by subjecting them to a polarographic experiment as a suspension in *N,N'*-dimethylformamide (DMF) as a solvent with, *e.g.*, 0.1M tetra-*n*-butylammonium perchlorate (TBAP) as a supporting electrolyte (3). A limiting current was observed with the half-wave potential ($E_{1/2}$) in the range $-0.58 \sim -0.78V$ (*vs.* Hg pool) depending on the supporting electrolyte used. When carbon black was treated by strong reducing agents such as lithium aluminum hydride, the polarographic wave was no longer observed. This treated sample, however, gave an anodic wave at about $+1.0V$ (*vs.* Hg pool), indicating that oxidizable surface species have been produced upon treatment. This anodic wave disappeared when the sample was treated with oxidants such as hydrogen peroxide (H_2O_2). From these electrochemical results along with infrared (IR) spectroscopic results, Hallum and Drushel suggested that benzoquinone-like surface groups are responsible for the reduction current. Later, these authors (4) estimated the amount of quinone oxygen and hydroquinone hydroxyl groups on the surface of carbon blacks by controlled potential coulometric reduction or oxidation. The benzoquinone content ranged from 0.002% to $\sim 0.26\%$; the hydroquinone content was 0.016% – $\sim 0.47\%$, depending on the sample. These observations were later substantiated by Jones and Kay (5), who used polarographic methods with a stirred aqueous suspension of activated charcoal.

Mamantov *et al.* (6) have shown that electrochemical

* Electrochemical Society Active Member.

anodization or chemical oxidation with strong oxidants such as Ce(IV) results in the formation of a film on the surface of pyrolytic graphite. The anodized sample gave a broad cathodic voltammetric peak at about $+0.5V$ *vs.* SCE ($E_{p/2} = +0.48V$ *vs.* SCE), whereas a sharp reduction peak was observed at approximately $+0.5V$ *vs.* SCE, which was followed by a broad peak at $\sim 0V$. The authors suggested electrolytic lamellar compounds of graphite as a possibility. In this study and the ones described below, the carbonaceous material was used as an electrode as opposed to the previously described studies, in which a mercury electrode was used in a suspended solution of the carbon.

Kinoshita and Bett (7) employed the cyclic voltammetric method to detect surface oxides on carbon black (Vulcan XC-72) which had been subjected to heat-treatment, electrochemical and chemical oxidation, and also gas-phase oxidation. These investigators used a carbon black with a surface area of $220 \text{ m}^2/\text{g}$, which was fabricated into an electrode using small quantities of Teflon (du Pont), $\sim 10\%$ by weight. The cyclic voltammetric test was made after the carbon black was oxidized or heat-treated under various conditions. The quinone-hydroquinone redox reaction was observed in the potential range of $0.05 \sim 1.28V$ *vs.* NHE. Surface concentrations of $10^{-10} \sim 10^{-11} \text{ mol}/\text{cm}^2$ of quinone oxides were estimated. The results indicate that various oxidation procedures increase the amount of surface oxides, whereas heat-treatment at 2000° and 2700°C decreases the amount of surface oxides. This is because the oxides desorb as CO from the surface upon heat-treatment. Blurton (8) reported similar but much better defined voltammetric peaks using graphite electrodes in $1N \text{ H}_2\text{SO}_4$ solution. A maximum of three anodic and three cathodic peak currents were observed depending on the experimental conditions. Two peaks at lower potentials showed reversibility at slow scan rates up to about $10 \text{ mV}/\text{s}$, while the peak separation became larger at higher scan rates, indicating a sluggish electron transfer. This author attributed anodic currents to the oxidation of hydroquinone-like surface species and cathodic currents to the reduction of quinone-like groups in different environments.

The above observations may be summarized as follows: (i) carbon surfaces are covered with quinone-like and hydroquinone-like functional groups, which are electroactive and thus give polarographic or voltammetric currents, (ii) concentrations of these groups are estimated to be $10^{-10} \sim 10^{-11} \text{ mol}/\text{cm}^2$ or up to 0.26% benzoquinone and

0.47% hydroquinone by electrochemical methods, (iii) the surface concentrations of these groups are increased upon mild anodic, chemical, or air oxidations, and (iv) these groups desorb as carbon oxides upon heat-treatment. This information, as will be discussed below, gives an insight into the oxidation mechanism of carbons and graphites.

Probably the most comprehensive study on the anodic oxidation of various carbons, including graphitized active carbon, charcoal, soot, and graphite, was carried out by Binder *et al.* (9). They employed the current-potential curves, chronopotentiometric measurements, volumetric determination of the product CO₂, chemical analysis, x-ray analysis, and electrical resistance measurements as their techniques while the electrode was polarized. From these studies, they concluded that when the electrode potential was lower than the oxygen equilibrium potential, about 80% of the charge was used for oxidation of the carbon electrode to CO₂ and about 20% for the surface oxide formation. They ran these experiments in H₂SO₄ or H₃PO₄ medium, and the results appeared to be relatively independent of the medium and temperature.

Several other groups of investigators reported the chronopotentiometric (galvanostatic) behavior of various carbon electrodes (10-12). These investigators report that the electrode potentials level off at several values before they reach the sharply increasing potentials upon application of constant anodic currents. These results indicate that the carbon surface becomes oxidized at several different potentials to different surface species; the findings are consistent with previously reviewed reports (above) in which mainly the surface characterization has been made.

Kokhanov and Milova (13) reported the product distribution of oxidations of graphite electrodes in phosphate buffer solutions as a function of pH. These investigators employed a current density of 3.7 mA/cm² and monitored the electrode potential as well as the product gas composition. At pH lower than 6.7, a current efficiency (CE) for CO₂ production was ~91% with about 6% for CO and 3% for O₂. When the pH was increased from 6.7 to 13.0 the CO₂ content gradually decreased down to 5%; oxygen production increased to 95%. The CO product went down almost to nil. At pH higher than 13, the gas composition remained almost the same.

This observation was substantiated by another group of investigators employing polyethylene-impregnated graphite electrodes (14). These investigators performed quite comprehensive studies employing different current densities. Using log of current densities of -1.5, -2.0, -3.0, -4.0, and -5.0 (unit = mA/cm²), they classified three potential-pH domains and four regions for different types of oxide surface production.

The electrochemical oxidation of a high surface area carbon black (1000 m²/g) in 96% H₃PO₄ at 135°C was investigated by Kinoshita and Bett (15). The total anodic current, amount of CO₂ evolved, and oxygen content at the carbon surface were measured as a function of time and potential. Their results indicate that two anodic processes occur: the formation of a surface oxide, and the evolution of CO₂. The rates of both processes decrease with time but at different rates, so that the CO₂ evolution becomes the major reaction in later stages of electrolysis. The current efficiency (CE) for the CO₂ evolution can be expressed by an equation

$$CE = \frac{1}{1 + Q_{ox}/Q_{CO_2}} \quad [1]$$

where Q_{ox} is the charge used for the surface oxide formation and Q_{CO_2} is for the CO₂ evolution. The charge for the CO₂ evolution was measured by determining the amount of CO₂ assuming that CO₂ production requires a four electron process.

At all potentials the formation of surface oxides is the predominant process at the beginning of the electrolysis, whereas CO₂ formation predominates in later stages of electrolysis. Thus, the current efficiency for CO₂ produc-

tion approaches unity as the ratio Q_{ox}/Q_{CO_2} approaches zero. The current efficiency for CO₂ production approaches unity more rapidly at higher applied potentials at the anode. These investigators summarized their observations as follows.

1. Two processes occur initially: surface oxide formation and CO₂ evolution. As the rate of surface oxide formation decreases, CO₂ evolution becomes the major anodic process.

2. The two processes are independent. The surface oxide does not inhibit CO₂ formation.

3. The surface oxide coverage approaches, but is less than, a monolayer, and continues to grow even after CO₂ is the major product.

4. The dissolution rates of carbon black electrodes are independent of water concentration or CO₂ pressure.

The electrode kinetic parameters were studied by several groups of investigators by following Tafel relationship between current density and potential (14, 16-18). In general, Tafel slopes are dependent on the pH of the medium, indicating different mechanisms for the oxidation reactions. Most of these investigators used galvanostatic measurements for investigations of the oxidation reactions of the various carbon electrodes.

Not much attention has been paid to the mechanism of CO production from carbon oxidation, mainly because of its lower fraction in the product composition. It appears that the desorption of oxides occurs in the form of CO in gaseous state under vacuum (7). In aqueous solution, CO₂ appears to be a major product with a few percent of CO detected (10). When the amount of CO₂ produced becomes sizable, the Boudouard reaction in pores behind the electrode surface

may occur producing a small amount of CO as a product (19). Thus, CO may be produced only if a large electrolysis current is passed.

Studies reviewed thus far were concerned with the electrochemical behavior of carbonaceous material either in suspension at Hg electrodes or as an electrode in a buffered solution that is not electroactive itself. Many investigators, however, studied electrochemical corrosion of graphite anodes in aqueous chloride electrolytes (20-22) or while electrowinning aluminum (19). The basic processes occurring under these environments are similar, but reaction mechanisms are more complicated due to the generation of oxidants such as OCl⁻, ClO₃⁻, etc. The readers may consult the references cited for these studies.

Summarizing this section, we may conclude that oxidation of various carbons occurs through two pathways: formation of surface oxides and CO₂ evolution. These two reaction pathways were claimed to be independent of each other by Kinoshita and Bett (15). It appears, however, that this may not be the case. Although not proved, it is reasonable to suggest that the formation of surface oxide precedes the CO₂ evolution reaction. When all the surface is covered with oxide film, the oxide desorbs as CO under vacuum and as CO₂ as electrolysis goes on. This is evident even in Kinoshita and Bett's data; the current efficiency for CO₂ evolution increases with electrolysis time.

Although the mechanism for carbon oxidation is not well understood, one can readily conclude that the electron transfer reaction does not include the water molecule, proton, or hydroxide ion. If the stoichiometry

correctly represents the carbon oxidation, the electrode potential would be pH dependent and thus, the product distribution should remain independent of pH. Actually, the oxygen evolution

becomes predominant at higher pH, indicating that the type of electrochemical reaction is different at low and

high pH. Potentials monitored during the galvanostatic electrolysis of polyethylene-impregnated graphite decreased from about +1.6V at pH = 1.0 to about 0.70V at pH = 14.5 (13). Thus, the electrode potential is controlled by carbon oxidation at low pH where oxygen overvoltages are high; the oxygen evolution reaction determines the electrode potential in higher pH regions.

Chemical Oxidation and Reduction of Coal

In reviewing this subject, the scope will be limited to the ones pertinent to the electrochemical reactions. Hence, only wet chemical oxidations or reductions in both aqueous and nonaqueous media will be considered. Oxidations with gaseous oxygen, metal oxides, etc. in the mixed solid form will be excluded, since these reactions do not have direct relevance to the understanding of the electrochemical behavior of coals. The subject will be divided into two categories: oxidations and reductions.

Oxidation reactions.—Chemical oxidation of coals has been carried out mostly as a tool to probe the structure of coal, mainly from product analysis. Oxidations were carried out using oxidants such as HNO₃, permanganate, and hypohalite in aqueous alkali media. Generally, oxidations in alkaline media were preferred because the oxidation products are easily solubilized due to carboxylic or phenolic groups found in the products. The product acids are usually not soluble in acidic solutions. The ultimate oxidation products of coal are carbonic acid, carboxylic acids, and phenols. Early studies on this area were reviewed by Howard in 1945 (24); most recent work on oxidation of coal was reviewed comprehensively by Hayatsu *et al.* (25).

Francis (26) was the first to propose that oxidation of coal occurs in three stages. According to him, coal undergoes stepwise oxidation reactions: the formation of surface oxides, followed by the formation of humic acid, and eventually of small aromatic as well as aliphatic acids.

Surface oxides formed may be desorbed as CO₂ or CO upon raising the temperature or as oxidation is prolonged. Coal thus oxidized shows little change in its gross property, but has more acidic properties at its surface. If oxidation is continued, products called "regenerated humic acids" form. These acids are soluble in alkaline medium, but form precipitates similar to Fe(OH)₃ in acidic medium. The rate of humic acid formation in 1N HNO₃ is coal-rank dependent (27). Low rank coals rapidly oxidized to humic acids, while high-rank Pocahontas coal display an induction period. Low rank (Illinois no. 6) coal pass through a period with a maximum yield of humic acid formation, which then decreases due to further oxidation to lower molecular weight acids. Humic acids produced from Pittsburgh seam coal (28) had average molecular weights of 193-242 and average equivalent weights (carboxylic acids) of 192-244. However, these properties vary widely. Oden (29), for example, reports the estimated molecular weight of 1000 ~ 1350 with an equivalent weight of about 340 for humic acids produced from peat. In general, the molecular weight of humic acids is approximately 1000 with three or four acidic (either carboxylic or hydroxyl) groups.

If the oxidation process is continued, humic acids are eventually broken down into smaller organic acids. Oxidizing agents such as HNO₃, MnO₄⁻, H₂SO₄, or peroxides were used in aqueous acidic media at elevated temperatures. In general, oxidation in the acidic medium produces poor yields of simple, soluble organic acids and carbonic acid. Product acids detected in earlier studies included pyromellitic acid and other benzene carboxylic acids (30), oxalic acid (31), trinitro-resorcinol (31), mellitic acid (32), and acetic, succinic, and picric acids (33), depending on the type of coal, reaction conditions, and reactants.

Carbonic, acetic, oxalic, and several different benzene-carboxylic acids were produced when various types of coals were oxidized by alkaline permanganate solution (34). Oxidation of a Pittsburgh seam bituminous coal with

alkaline permanganate gave a carbon distribution of 45.0% carbonate, 2.2% acetate, 15.0% oxalate, and 30.8% aromatic acids, totaling 93.0% of carbonate recovered as alkali salts (35). Usually, 50 ~ 60% of the nonvolatile acids produced by alkaline permanganate oxidation were aromatic. Typically, aromatic acids were in the form of mellitic, benzenepentacarboxylic, and terephthalic acids. Howard (24) speculates that mellitic acid can be formed only by oxidation of condensed carboxylic hydrocarbons, of which the simplest form could be

triphenylene

or of a benzene ring completely alkylated, such as

hexamethylbenzene

or mixtures of these two types. Actually, the yield of mellitic acid from triphenylene was 44.8% of the theoretically expected amount, while hexamethylbenzene produced CO₂ almost exclusively when the same oxidation procedure was used (24). Oxidation of an Australian coal by the same procedure produced about 1.1% oxalic, 0.3% succinic, 5.0% benzenedicarboxylic (o-, m-, and p-phthalic acids), 17.4% benzenetricarboxylic (both 1,2,3- and 1,2,4-), 21.7% benzenetetracarboxylic (1,2,3,4-, 1,2,3,5-, and 1,2,4,5-), 41.1% benzenepentacarboxylic, and 13.4% benzenehexacarboxylic (mellitic) acids of the soluble acid products (36). Aliphatic acids such as acetic, propionic, butyric, pentanoic, and heptanoic acids were also found in small amounts from the basic permanganate oxidation of coal (37). Acids above pentanoic were isolated only from the lower rank coals; none above propionic was isolated from the low-volatile coal.

Perhaps the most extensive studies on the oxidation of coal are those reported by Yokakawa *et al.* (38, 39). These investigators employed either boiling 1N HNO₃ or alkaline permanganate as an oxidant for the oxidation of humic acids and 30 model compounds. Results indicate that the most vulnerable structure destroyed in the first stage of humic acid oxidation was alicyclic or hydroaromatic, and that in the second stage various structures were destroyed unselectively with some differences in reaction rates. From this study, they reached the conclusion that a molecule of coal consists of two parts: alicyclic or hydroaromatic structures, which are vulnerable to oxidations, and condensed aromatic structures, which are more resistant to oxidations. They pointed out from their data that (i) the high reactivity and the lack of selectivity in oxidation reactions of low rank coal are due to the hydroxyl groups in the aromatic structure part, the basic structural unit of bituminous coal, and (ii) the degree of condensation of the aromatic structure is rather small. Phenolic hydroxyl groups were found to degrade to CO₂ and oxalic acid rather quickly upon oxidation. Later, these investigators (39) extended their work to "artificial" coals, which were prepared from cellulose and lignin, and they obtained similar results.

Concentrated nitric acid is not only a powerful oxidant, but also is a nitrating agent. This is somewhat disadvantageous for derivatization of coal, since the nitration reac-

tion introduces additional nitrogen. Recently, Hayatsu *et al.* (25) reported that aliphatic-rich macromolecules in coal are oxidized by concentrated HNO_3 without extensive degradation of aromatic rings. From the oxidation of methylated cannel-like high volatile A bituminous coal (Ohio PSOC 297) with 70% HNO_3 at 110°C for 48h, organic acids (31 weight percent [w/o] of the substrate), and regenerated humic acids (58.25%) were recovered; approximately 47% of the organic acids were found to consist of aliphatic unbranched dicarboxylic acids ranging from C_4 to C_{14} . Deno *et al.* (40) reported similar results from oxidation of various coals with 40% HNO_3 at 60°C.

The kinetics of alkaline permanganate oxidation of coal was studied by Smith and Mapstone (41) by monitoring the amount of permanganate consumed as a function of time. The rate of oxidation of several different coals was expressed by the equation

$$Q = (a - X_0) + X_0(1 - e^{-k_1 t}) + k_2 t \quad [5]$$

where Q represents the quantity of permanganate decomposed at time t (as milliliters of 1.0N), a is the amount of MnO_4^- that would have decomposed at $t = 0$ for the third stage of the reaction, X_0 is the amount of MnO_4^- decomposed for the second stage (first-order) reaction at $t = 0$, k_1 is the rate constant of the second stage (first-order) decomposition reaction, and k_2 is the slope of the linear plot for the last stage of the decomposition reaction. Thus, $(a - X_0)$ represents a rapid initial reaction, $X_0(1 - e^{-k_1 t})$ a further first-order reaction in which k_1 is possibly constant for all coals, and $k_2 t$ a 0th-order decomposition of permanganate continuing to extended reaction times. Correlation between particular terms in the above equation and various coal ranks was not satisfactory; only general trends were observed between the two. The general sequence of the coal oxidation kinetics is consistent with Francis' three-stage mechanism (26).

The action of oxygen at elevated temperatures and pressures on aqueous alkaline suspensions of coals has been studied (42-44). Typical reaction conditions were at 100° ~ 300°C and under up to 75 kg/cm² of pressures. One advantage of this method is that the oxidation reaction may be driven to CO_2 completely and water or to any desired stage. When "appropriately" oxidized, products included CO_2 , oxalic acid, and benzene carboxylic acids. Various U.S. (42), Japanese (43), and Chinese (44) coals were studied by this method.

In more recent studies, instrumental methods such as a nuclear magnetic resonance (NMR) (45), or infrared (IR) spectroscopies (46) were used for identification of oxidation products. Results reported from these studies are consistent with the previous findings.

A controversy started when Chakrabarty *et al.* published a series of papers (47) in which they claimed from their oxidation studies using basic hypochlorite as an oxidant that about 55%-60% of the total carbon in coal exists in the sp^3 valence state. They further stated that coal structures are made of modified bridged tricycloalkane systems or polyamantanes. This is a rather surprising statement, since the current understanding of the coal structural model is that coal has predominantly aromatic, with some hydroaromatic, structures. According to these investigators, hypochlorite (OCl^-) is a relatively mild and highly specific oxidant for coal. The specificity of this reagent can be shown by reactions such as

and

where X is a halogen, R a properly oriented activating group (e.g., acetyl or β -keto function), and R' a hydrogen, alkyl, or aryl group with or without activating influence. They showed from their experiments using

appropriate model compounds that hypochlorite oxidation will occur only when a carbanion can form at the methylene or methyl site and then stabilize itself on the substrate molecule. Thus, the oxidation can only cleave the sp^3 carbon but not the aromatic rings. Oxidation of an activated alicyclic compound containing a tertiary sp^3 carbon system may result in loss of one, two, or three carbon atoms as CO_2 or CHCl_3 via 1,3- and 1,4-halogenation steps. To obtain the reaction specificity, one has to control the pH of the medium at higher than 12.

Based on the above control experiments and other oxidation experiments on coal samples using basic hypochlorite as an oxidant, these investigators reached the conclusions listed below.

1. A minimum of 3%-5% of the total carbon in any coal exists as n-propyl groups, while n-butyl groups account for less than 1% of the total carbon in low-rank coals and about 2% in high-rank ones (47a).

2. In low-rank coals, at least 17% of the total carbon is present in the form of activated $-\text{CH}_2-$ and/or $-\text{CH}_3$. Detection of formic acid in the oxidation products indicates the presence of similarly activated $-\text{C}_2\text{H}_5$ groups.

3. Even in 500°C chars, at least 14% of the total carbon is nonaromatic ($-\text{CH}_2-$), and 3%-4% are contributed by n-propyl and/or n-butyl groups, not the corresponding alkanes.

4. It is estimated that between 55% and 60% of the total carbon in coal exists in the sp^3 valence state, which is much higher than the accepted hydroaromaticity of coals. These structures are modified bridged tricycloalkane systems or polyamantanes.

The above conclusions on coal structures were strongly disputed in the coal research community by other investigators (48-53). To argue against the oxidation mechanism of Chakrabarty *et al.*, these investigators used model compounds such as phenol (48, 51), naphthol-formaldehyde polymer (49), fluorescein (44), 2-naphthol (48, 51), 2-naphthoic acid (48, 53), 1-naphthol (51), 2,3-naphthalenedicarboxylic acid (51), 1-hydroxyanthracene (51), naphthalene (52), and 2-methylnaphthalene (52) for the hypochlorite oxidation under similar or the same experimental conditions. Results indicate that these aromatic compounds undergo oxidation reactions to end products including phthalic acid and CO_2 , invalidating some conclusions made by Chakrabarty. Aczel *et al.* (50) employed liquefaction experiments and showed that adamantane was extremely stable under the conditions in which more than 60% of Illinois no. 6 coal was converted to cyclohexane soluble liquids. Chakrabarty and Berkowitz (54) later pointed out that adamantane would be different from polyamantanes.

Mayo and Kirshen (53) ran extensive experiments using various coals and showed that the product composition depends mostly on pH during oxidation and on the state of subdivision of the coal. There appear to be two mechanisms of oxidations by aqueous NaOCl , a mechanism at $\text{pH} > 11$ and a second mechanism operative at $\text{pH} < 10$. The former mechanism is specific to enolizable compounds and some other compounds having acidic hydrogen atoms, as was shown by Chakrabarty and Kretschmer, whereas the latter may involve many more, perhaps most, organic compounds whether or not they react by the first mechanism. Thus, aqueous NaOCl would oxidize most organic, both aromatic and aliphatic, compounds indiscriminately by the second mechanism. The reaction path and the intermediate for the second mechanism are not known. For the oxidation of coal, high fractions of carbon appear in the soluble form of acids with only about 13% as CO_2 in the oxidation product at $\text{pH} = 13$, while the yields of soluble acids are lower and CO_2 higher at $\text{pH} 9-11$. These results as well as those of Landolt *et al.* (51) point to the fact that phenols are the most reactive groups in coal at high pH. Although the high pH mechanism of Mayo and Kirshen (53) agrees with that of Chakrabarty *et al.* (47), Mayo and Kirshen concluded from the (H + C)/C ratios and carbon and oxygen distributions in the oxidation products of coal that

CO₂ during high pH oxidation must arise from the aromatic compounds, probably hydroxylated rings. These results are consistent with the structure of bituminous coal in which aggregates of condensed aromatic, hydroaromatic, and bridged alicyclic rings held together by ether (or sulfide), methylene or polyethylene links, or combinations of these, are crosslinked in a three-dimensional fashion. Conventional oxidations break mostly aliphatic and ethereal bonds producing aromatic acids, but NaOCl apparently produces a different group of acids by cleaving some of the aromatic rings. Obviously, more characterizations must be done with respect to the hypochlorite oxidations.

More recently, sodium dichromate (55, 56), alkaline cupric oxide (57-59), hydrogen peroxide in acetic acid (peracetic acid; 60, 61), and pertrifluoroacetic acid (62, 63) were used to oxidize coal. Dichromate showed different degrees of oxidative power depending on pH of the medium. At lower pH, ring degradation occurred readily, but dichromate behaved as a mild oxidant. Peracetic acid (CH₃COOOH) led to the oxidative degradation of aromatic rings and the formation of dibasic acids. Pertrifluoroacetic acid (CF₃COOOH) behaved similarly, with the production of aliphatic acids as degradation products of alkyl aromatics. This acid might be a good reagent for studying the aliphatic structure in coals. Trifluoroacetic acid oxidation appeared to preserve aromatic rings containing nitrogen or sulfur heterocyclics (64, 65).

In summary, the oxidation of coal by chemical oxidants is accomplished in three stages: surface oxide formation, oxidation to humic acids, and final oxidation to end products including smaller aliphatic and aromatic acids and CO₂. Low-rank coals appear to produce higher yields of aliphatic acids compared to high-rank coal, whereas the inverse can be stated for the mellitic acid in oxidation products. This indicates that low-rank coals consist of more branched hydrocarbons, while high-rank coals approach a highly aromatic structure as in graphite. Finally, the hypochlorite oxidation apparently cleaves aromatic rings, producing different oxidation products compared to the conventional oxidants. Investigations of oxidation reactions provide the method of probing coal structures as well as of producing coal-derived chemicals, such as many organic acids.

Reduction reactions.—As already mentioned, chemical reductions of coal pertinent to electrochemical reactions will be reviewed in this section. Coal reduction by hydrogenation is reviewed elsewhere (65). Reductions of various coals can be accomplished by an electron transfer reaction from alkali metals such as Li (66-71, 73), Na (72, 73), K (73-77), LiAlH₄ (71), or Na-K alloy (77) in various organic solvents, including ethylene diamine (66-71), benzene (71), liquid NH₃ (72), tetrahydrofuran (THF) (73, 74), and a mixture of several ethers (76, 77). A variety of different ranks of coals (66-68, 70, 72-77) as well as some cokes and chars (69) and asphaltenes (71) have been studied by this method. In most cases, solvents behave as proton donors for the reduced coal, but some investigators used isopropyl alcohol as a proton donor. Many of these studies have been performed in either or both of two perspectives: to characterize coal structures and/or to prepare coal derived chemicals.

Reggel *et al.* (68) added to a vitrain of 90% carbon as many as 55 atoms of hydrogen per 100 carbon atoms using lithium as a reductant in ethylene diamine. Later Niemann and Homback (77) reported that they added up to 87 hydrogen atoms per 100 carbon atoms to a medium volatile bituminous coal by repeated reductions with potassium or sodium-potassium (1:1) alloy as reductants and isopropylalcohol as a proton donor. Brooks and Silverman (69) employed the reduction reaction to study some cokes and chars and suggested that the low reducibility and the low hydrogen content of the 900°C coke are due to the presence of carbon atoms predominantly in a divalent state. Sawatzky and Montgomery (71) studied asphaltenes using lithium in ethylenediamine and report

that considerable amounts of hydrogen have been added to asphaltenes and most of the sulfur has been removed. They noticed the reduction in molecular weight due to the cleavage of ethereal bonds and thioethers. Sternberg *et al.* (70) studied temperature effects on lithium reduction of coal and pointed out that reduction at higher temperature (90° ~ 100°C) is much more efficient than at lower temperature (17°C).

The nature of reduction was considered by several groups of investigators (71, 72, 77). As already mentioned, Sawatzky and Montgomery reported a decrease in molecular weight when asphaltenes are reduced and found that ethereal bonds of oxygen and sulfur are cleaved. Lazarov and Angelova (72) used sodium metal in liquid ammonia (at -33°C), since it is known to cleave oxygen and sulfur bonds according to the reaction

The reaction proceeds easily with diaryl ethers, aryl ethers of the benzyl type and aryl-alkyl ethers, but not with the aliphatic ethers. The results indicate, however, that the hydrogen uptake by the 87.6% carbon coal was more than expected by the cleavage of ethereal bonds calculated from the amount of such bonds. Thus, the excess of hydrogen consumed in the reaction was assumed to be used to reduce the aromatic part of coal. This assumption was later justified by other investigators (77) by monitoring the absorbance of bands of the IR spectra due to aromatic rings (810 cm⁻¹ and 745 cm⁻¹) of coals successively reduced by potassium.

The most interesting chemistry of coal reduction has been reported by Sternberg and co-workers (73, 74). These investigators improved methods of reducing coal by introducing naphthalene as an electron-transfer mediator in THF solution. The reaction is catalytic and may be represented by a scheme

The coal anion, containing 12 charges per 100 carbons, can then be alkylated using alkyl halides through the reaction

Using Pocahontas low volatile bituminous coal, they were able to add 8.1 methyl and 8.8 ethyl groups per 100 carbon atoms, respectively. When alkali metals were compared, lithium was least effective with the addition of 7.2 ethyl groups and potassium was most effective with the addition of 8.8 ethyl groups. Sodium had properties similar to those of lithium. The solubility increased from 0% and 3% in benzene and pyridine for untreated coal to 95% in both solvents for the ethylated coal. The same study was later extended to other coals including Colorado subbituminous (72% carbon), Bruceston (83% C), and Pocahontas (90% C), and anthracite (96% C) coals by Sternberg and Delle Donne (74). The results indicate that the Colorado subbituminous coal is most effective in adding alkyl groups (14 alkyl groups added per 100 carbon atoms) while the anthracite is least effective with addition of only 0.6 alkyl groups per 100 carbon atoms. They attributed this to the steric hindrance, since the anthracite was shown to carry as many as 11 electrons per 100 carbon atoms. Similar approaches were used by other investigators in later studies (75-77). The limitation of this method of studying coals, however, was pointed out (78).

In the course of studies described above, the IR spectroscopic method proved to be a powerful technique for

following reactions (72, 77). The increase or decrease in various absorption bands was monitored for successively treated coals.

In summary, coal can be reduced by alkali metals in a variety of solvents; as many as 88 hydrogen atoms per 100 carbon atoms were shown to be added to coal. The reduced coal anions can easily be alkylated using alkyl halides. Alkylated coals have much higher solubilities in organic solvents including benzene and pyridine making many studies on coal in such media possible. Also, many coal derived chemicals may be prepared in organic solvents.

Electrochemical Oxidation and Reduction of Coal

The processes of electrochemical oxidation and reduction of various coals resemble those for chemical oxidation and reduction, reviewed in the previous section. The oxidation has been studied both in basic and acidic media, but not much in nonaqueous media. The reduction of coal has been studied extensively in nonaqueous solvents including tetrahydrofuran (THF), dimethylsulfoxide (DMSO), and dimethyl formamide (DMF). Most of these studies were carried out to elucidate coal structures; some were concerned with the derivatization of coal. Although the first work on electrolytic oxidation appeared in the literature in 1932 (79), the whole area is still fairly new to electrochemists.

Electrochemical oxidation of coal.—Early investigators (79-81) used alkaline media for electrolysis of coal slurries, probably because chemical oxidations were carried out mostly in basic media. The products of oxidation, humic acids, are soluble in a high pH medium. Lynch and Collett (79) performed an extensive study on the electrolytic oxidation of Pittsburg coal in a 3N NaOH solution at copper, nickel, lead, or platinum electrodes. Of these electrodes, the copper electrode was found to perform best. The current density was maintained at 3 mA/cm², and the experiments were carried out at room temperatures. Carbon dioxide, oxygen, humic acids, and traces of carbon monoxide and hydrocarbons were detected as anodic products. Oxygen accounted for about 94% of the gaseous product excluding CO₂. The rate of humic acid formation reached a maximum value at about 70h of electrolysis, whereas the maximum rate of CO₂ formation occurred at about 130h of electrolysis, indicating that the electrolysis of coal produced humic acids first, followed by CO₂ evolution in later stages. The electrolysis reaction appeared to stop at the humic acid stage at copper electrodes but it proceeded to further products at platinum electrodes. When humic acids were subjected to anodic oxidations, they were efficiently oxidized at platinum electrodes but not at copper electrodes. Lynch and Collett (79) therefore suggested that coal may be electrolyzed stepwise to any desired products or intermediate species depending on electrolysis conditions.

Various improvements were made by Eddinger and Demorest (80) on electrolysis conditions for electrolysis of coal in basic media. They used a graphite electrode as well as catalysts such as vanadium pentoxide or cobalt chloride. Belcher (81) published a series of papers detailing anodic oxidations of bituminous coals and some anthracites. Khundkar and Kamal (82) carried out anodic oxidation of peat in an alkaline solution using a current density of 10 ~ 20 mA/cm². They found that a nickel anode at a current density of 20 mA/cm² gave the best yield of humic acids, about 48% yield (dry ash-free basis) for 12h electrolysis. These investigators also used the above-mentioned catalysts without much effect on the reaction rate. Studies on temperature dependencies (20° ~ 80°C) showed that electrolysis at ~60°C gave the highest yield for humic acids. Recently, Senftle *et al.* (83) studied the anodic oxidation of anthracite by employing it as an electrode in an alkaline medium. Results showed that humic acids were generated as products. They proposed after some control experiments that major oxidants for the anthracite oxidation were molecular and radical species

formed by the electrolytic decomposition of water.

Only recently have studies on anodic electrolysis of coal in acidic media appeared in the literature (84-94). Coughlin and Farooque published a series of papers on the anodic oxidation of coal in sulfuric acid solution (84-88). According to them, coal slurries are oxidized at the platinum anode in a sulfuric acid solution, producing carbon dioxide and carbon monoxide as anodic products and hydrogen as a cathodic product. The stoichiometric reactions proposed for the electrolytic process was

or

at the anode and

at the cathode. This stoichiometry offers a possibility of gasifying coal at lower temperatures by electrolysis rather than by other means (high temperature and pressure gasification, since from the above stoichiometry the standard electrode potential for the anodic reaction is calculated to be only 0.228V vs. NHE. They also pointed out that coal slurries could be used as anodic depolarizers for metal electrowinning (85). Various parameters affecting coal electrolysis including coal-particle size, concentration of coal, temperature, and the supporting electrolyte were reported (86). The ratio of H₂ to CO₂ + CO was monitored for as long as about 450h of electrolysis; it was much higher (9 ~ 4) than would be expected from the above stoichiometry, *i.e.*, 2. This indicates that the anodic charge is used not only for the evolution of CO₂ or CO but for other processes, assuming that the current efficiency for the hydrogen evolution is 100%. The electrolysis can be carried out with less than 1V of biased potentials. Of various coals tested, the North Dakota lignite showed the highest current density of about 1.4 mA/cm² at room temperature when 0.475 g/cm² of coal was present in the solution as a slurry (87).

Baldwin *et al.* (90) carried out detailed voltammetric studies on coal oxidation in acidic media and also in nonaqueous solution, and suggested from their results that the major electrolysis current in a coal slurry electrolysis resulted mostly from the oxidation of iron(II), which had been extracted from coal into the strong acidic electrolyte. They made this suggestion by comparing the voltammetric behavior of the extracted solution with that of the iron(II)/iron(III) redox pair. Iron was also shown by the atomic absorption analysis to be a major component in the filtrate. Okada *et al.* (91) reached a similar conclusion, *i.e.*, that Fe(II)/Fe(III), dissolved in the electrolytic solution, is responsible for currents observed at lower anodic overpotential in the electrolysis of coal slurries. There is an apparent disparity, however, between the argument that the anodic current was caused by the oxidation of iron(II) and the observation of Coughlin and Farooque, in which electrolysis currents were maintained for as long as 450h. Either the iron(II) would be leached out continuously or coal itself would undergo the oxidation reaction.

This disparity was resolved by Dhooge *et al.* (92, 93), who performed detailed studies on the mechanism of coal slurry oxidations using various electrochemical techniques. In their studies also, practically no anodic currents were observed with thoroughly washed coal introduced into 1M sulfuric acid solution. Coal particles were washed by stirring in 1:1 H₂SO₄ for more than 50h. When, however, iron(III) was added to the washed coal and the anodic potential was maintained such that iron(II) would be oxidized, the anodic currents were observed, indicating that iron(II) was generated by oxidizing coal. They concluded from their experiments that coal was oxidized by Fe(III) in the solution according to the reaction

followed by an electrode reaction

at the anode and

at the cathode. The catalytic nature of the reaction was also demonstrated by several other experiments, which included controlled potential oxidation of the Fe(II) with the perturbation of washed coal (92) and the direct addition of oxidants to the coal slurry and monitoring the concentration of the reductant produced by electrochemical methods (93). Also, if the stoichiometry outlined by reaction [3] or [11] were correct, the equilibrium potential should be dependent on the pH of the medium (-59 mV/pH unit). Experimental results showed that it was independent of pH, indicating that the anodic reaction does not involve water or ions derived from it, *i.e.*, H^+ or OH^- .

The rate of reaction [4] for various catalysts can be determined by controlled potential experiment methods (92), from the steady-state electrolysis current (92), or by monitoring the concentration of the reductant produced after addition of an oxidant (93). Catalytic rate constants determined with these methods agree well with each other. Some of the rate constant values are listed in Table I; these were determined by monitoring the reductant concentration (93).

A rapid increase in the reaction rate is noted in the table at redox potentials of catalysts of approximately $+0.6$ and $+0.9\text{V}$, respectively. These values seem to indicate that some specific functional groups on the coal are responding to the catalyst oxidants. These functionalities may correspond to hydroquinone- or quinone-like groups (6-9, 15). Note also that Ce(IV) and bromine are the most effective electrocatalysts. The activation energies for the process are in the range of $12 \sim 16$ kcal/mol (86, 91, 92). It is only 7.0 kcal/mol for Ce(IV) for the oxidation of coal (92).

Current efficiencies (CE) for the evolution of CO_2 were reported to be $15\% \sim 30\%$ in early studies (91, 92), but Dhooze and Park reported a 100% CE at longer electrolysis time (93). In general, it appears that the CE is very high at the very beginning of the reaction, probably because of the evolution of CO_2 from carbonates and bicarbonates present in coal. In a very short period (~ 15 min), the CE decreases to $15\% \sim 30\%$ and increases slowly up to 100% after $50 \sim 100\text{h}$ of electrolysis. This is probably because the charge is used up for the formation of surface oxides and humic acids in the first stage of the reaction, and later predominantly, for CO_2 evolution. The formation of surface oxides and humic acids was shown by the difference Fourier transform infrared (FTIR) spectra obtained from coals before and after electrolysis (94).

Dhooze and Park (94) also showed that the oxygen atom in the product, CO_2 , came from water by using 10% H_2^{16}O as a solvent. The ratio of $\text{C}^{18}\text{O}^{16}\text{O}/\text{C}^{16}\text{O}_2$ in the product monitored by the FTIR was $0.23 \sim 0.25$, in agreement with the expected value of 0.249 . This experiment also showed that CO_2 was produced from coal and water by

electrolysis rather than from the decomposition of carbonates or bicarbonates by the action of the solvent acid.

Summarizing this section, the oxidation of coal by electrolytic methods is not fundamentally in its mechanism different from the chemical oxidation. That is, surface oxides and humic acids appear to form first, and eventually smaller molecules and CO_2 are formed as oxidation proceeds. The formation of humic acids is more efficient in an alkaline medium.

One may speculate that iron ions catalyze hydroxylation reactions of methoxy aromatic rings under acidic electrolytic conditions as in oxidation reactions by Fenton's reagent [H_2O_2 and Fe(II)] or H_2O_2 catalyzed by Fe(III) and catechol (95, 96). Consider, for example, the mechanism of Senfile *et al.* (83), in which oxidation products of water such as $\cdot\text{OH}$ were postulated to be responsible for anthracite oxidation to lead to final products, *i.e.*, regenerated humic acids. The postulated species here are similar to those in H_2O_2 , peracetic, or trifluoroacetic acid oxidations. Hydroxylated coal may then undergo further oxidation to quinoids, which could open the ring to finally form dicarboxylic acids. These acids may then lose CO_2 upon further oxidation through the Kolbe electrolysis (97, 98) to produce smaller hydrocarbons. The Kolbe reaction normally requires high overvoltages; however, standard electrode potentials for most acids are quite low as one can verify from simple calculations (99) employing thermodynamic data in the literature (100). When catalyzed by a homogeneous solution species such as iron(III), the Kolbe reaction could proceed at a much lower applied potential. As pointed out already, elucidation of the mechanism of electrochemical oxidation of coal is still in its infancy; more work should be carried out in this area.

Electrochemical reduction of coal.—Electrolytic reductions were first used for the characterization of coal. The reduction process has been studied somewhat more thoroughly than the oxidation, probably because of the fact that only reductions could be carried out with polarographic methods at mercury electrodes by early investigators. Again, the chemistry involved in electrolytic reduction processes is not drastically different from that in chemical reduction. The end product following the initial electron transfer to coal from electrodes is hydrogenated coal.

Brown and Wyss (101) pointed out in their communication that coal extracts in N,N' -dimethylformamide (DMF) were reduced polarographically between -0.15 and -0.9V vs. the Hg pool, with a fairly well-defined wave at approximately -0.5 to -0.6V . They attributed this wave to the reduction of quinones. Given and Schoen (102) performed an extensive study on the polarographic reduction of coal extracts in DMF solution. Polarograms of all the solvent extracts of coals showed distinct waves in the range of -0.5 to -0.7V vs. the Hg pool. Comparison of half-wave potentials with values for known aromatic carbonyl compounds studied under the same conditions (103) showed that carbonyl groups in the solvent extracts of coals must be responsible for the reduction waves observed.

Also, analysis of the $\log(i/i_1 - i)$ vs. E curve gave an n value of approximately 1, indicating that coal accepts one electron from the electrode. Here i , i_1 , and n are the polarographic current, limiting currents, and the number of electrons transferred, respectively. The authors pointed out that the carbonyl groups must be strongly conjugated to aromatic systems, and with some other evidence reached a conclusion that quinone groups should be present in coals. They further estimated from polarographic diffusion currents that the pyridine extracts of coal contained approximately 2 g-atoms of oxygen as quinone per 3000-5000g coal. These investigators also ran an exhaustive electrolysis at -1.5V vs. SCE; the product showed a decrease in the IR peaks corresponding to carbonyl groups (~ 1600 cm^{-1}). In a study published later, Given and Peover (104) showed that several waves were

Table I. Standard electrode potentials and catalytic reaction rate constants of several solution catalysts

System	E° or $E^{o'}$	k_c , at 20°C , s^{-1}
Fe(CN)_6^{3-} in sat. K_2SO_4	0.36	3.6×10^{-6}
Fe(III) in 1M H_2PO_4	0.44	7.3×10^{-7}
Fe(III) in 1M H_2SO_4	0.68	9.6×10^{-6}
Fe(CN)_6^{3-} in 1M H_2SO_4	0.72	2.1×10^{-5}
Fe(III) in 1M HClO_4	0.75	1.9×10^{-5}
Fe(III) in 1M HCl	0.77	1.6×10^{-5}
Br_2 in 1M H_2SO_4	1.06	1.1×10^{-3}
Ce^{4+} in 1M H_2SO_4	1.45	4.1×10^{-4}

observed in a polarogram of coal if the potential is scanned down to about $-2.2V$ vs. Hg pool. Diffusion currents at both -1.0 and $-2.07V$ were increased upon addition of a proton donor, e.g., phenol. This indicates that the intermediate species generated from electrolysis reacts rapidly with protons. Actually, the exhaustive electrolysis of the coal extracts at a controlled potential of -2.1 to $-2.2V$ brought about an increase in hydrogen content corresponding to 15 ~ 38 hydrogen atoms being added per 100 carbon atoms (104-105). Prior reductive acetylation increased the uptake of hydrogen. The electron uptake determined coulometrically was in all cases greater than could be accounted for by the hydrogen introduced, oxygen removed, and carbonyl group reduced. As already pointed out in the previous section, this is probably due to the reduction of aromatic hydrocarbons. Employing reductive acetylation in DMF solution by electrolysis at controlled potentials and ^{14}C -labeled acetic anhydride (106), the carbonyl oxygen was estimated to be 1% ~ 2.5% of total oxygen in coal extracts. About 80%-90% of the oxygen in the extracts could be accounted for as carbonyl plus hydroxyl oxygens. Simple aromatic ketones such as benzophenone accounted for only a small fraction of carbonyl groups in the coal extracts, and there was no evidence that any aliphatic ketones were present (106).

A more extensive study on the electrochemical reduction of coal was reported by Markby *et al.*, using carbon electrodes in ethylene diamine with lithium chloride as supporting electrolyte (107). The current efficiency for this reaction was 46% at the beginning, dropping to about 10% after 15h of electrolysis. These investigators report that as many as 44 hydrogen atoms could be added per 100 carbon atoms for the Pocahontas vitrain. An interesting result was that the solubility of the electrolytically reduced coal in pyridine at room temperature (74%) was higher than that of the chemically reduced coal (63%). Various parameters affecting electrochemical reduction of coal were studied in detail by these investigators (108-110). In these experiments, coal slurries in ethylenediamine, not the coal extracts, were used. When an aluminum cathode was used in a solution saturated with lithium chloride, as many as 53 hydrogen atoms could be added to coal per 100 carbon atoms. Since these investigators used more rigorous reduction conditions, i.e., 0.5A with 110V, many of the polycyclic aromatic hydrocarbons along with quinones must have undergone reduction reactions. Ultimate analysis, catalytic dehydrogenation with palladium, and UV, IR, and NMR spectroscopic methods were used to identify reduced products. The mechanism of reduction is no different from that of chemical reduction using Li as a reductant reported by the same investigators (70). The reaction mechanism may be summarized as follows

At the cathode

In the solution

where R represents an aromatic hydrocarbon-like functional group on coal. This series of reactions is possible because of the high solubility of lithium metal in certain solvents such as ethylenediamine or ammonia. Any compounds, whose reduction potentials are less negative than that of lithium, would be expected to reduce according to this reaction. The proton donor was the solvent in the above case, but phenol was deliberately added by Peover and Given (104) to facilitate protonation steps.

Finally, an interesting remark was made by Sternberg *et al.* (108-111) that sulfur removal from coal might be accomplished by electrolytic reductions. The removal of sulfur from the vitrain took place after the more reactive

aromatic rings were reduced. Specifically, sulfur was removed only after about 25 hydrogen atoms per 100 carbon atoms had been added to the coal. A similarity between the removal of sulfur from coal and from dibenzothio-*phene* by electrolytic reductions has been pointed out (111).

A method of classifying genetic groups of coals using electrochemical oxidation and reduction has been reported by Russian investigators (112, 113). The method is based on the fact that coal is catalytically oxidized or reduced by Ce^{4+} or Cr^{2+} , respectively. The anodic current observed from the oxidation of Ce^{3+} and the cathodic current for the reduction of Cr^{3+} in aqueous solution containing some p-dioxane when the coal powder is present are indicative of the amount of reduced and oxidized functional groups on coal surfaces. The measurements were made at a stationary polarized smooth platinum electrode with KCl as a supporting electrolyte. The integrated areas of the anodic and cathodic currents, S_a and S_c , are used for the definition of the coefficient of the degree of reduction, K_r , according to the equation

$$K_r = \frac{S_c - S_a}{S_a} \quad [20]$$

By this definition, K_r would be 0 when the amounts of the oxidized and reduced groups are the same, while $K_r > 0$ for oxidized coals. The method was tested on some treated anthracites and shown to be sensitive to various states of coal surfaces.

In summary, the electrolytic reduction process has been studied either on organic extracts of coal or on a coal slurry employing catalytic processes in nonaqueous medium. It appears that a quinone type of functional group is reduced at less negative potentials, whereas polycyclic aromatic hydrocarbons are reduced at more negative potentials. Since the solubility of coal in most organic solvents is very low, a reagent whose reduced state can be dissolved must be used. For this purpose, lithium metal was used in the electrolytic reduction. As mentioned already, naphthalene was used as an electron-transfer mediator in chemical reductions employing alkali metals (73-74). Since anion radicals of most organic compounds accept protons rather easily, one should be careful about using organic compounds as catalysts. On the other hand, alkali metals have low solubility in many organic solvents.

As was the case in the chemical oxidation and reduction, coals can be degraded to smaller molecules—humic acids. It would be very interesting, therefore, to combine these two processes. That is, after humic acids are produced through an oxidative process, they may be subjected to the electrolytic reduction. The products are expected to be solids of low melting points or liquids. The electrolytic process has advantages over chemical methods for treating coals, since electrons are used as a reagent. Discovering proper catalysts for both oxidation and reduction would be extremely important in liquefying or derivatizing chemicals from coal.

Also, electrolytic oxidation and reduction may be very profitably used for characterizing coal. By measuring electron exchange rates of various electrocatalysts with coal and with model compounds, one may be able to identify the functional groups on coal surfaces. Oxidations in nonaqueous media and reductions in aqueous media of coal are virtually nonexistent; new structural information may result from these studies.

Photoelectrochemistry of Coal and Carbonaceous Materials

The field of photoelectrochemistry has received much attention since Fujishima and Honda (114) first reported that water could be electrolyzed to oxygen and hydrogen with the aid of light. The energy of the light source must be the same as or greater than the bandgap of the semiconductor electrode. The electron-hole pairs generated in the space-charge region of a semiconductor electrode

upon illumination should be separated effectively; electrons or holes should be captured at the semiconductor electrode surface by an oxidant or a reductant present, depending on the type of the semiconductor used. Various parameters must be considered for efficient conversion of the light energy into the electrical or chemical energy and its storage. Many reviews of this field have appeared (115-117).

Since, as reviewed in previous sections, gasification or derivatization of coal may be achieved by electrochemical techniques, the concept of photoelectrochemistry may also be applied to these reactions. In this section, we will review attempts that have been made employing solar radiation energies to apply these principles to coal conversion. Because coal does not dissolve easily in almost any solvent, no photoelectrochemical cells for coal oxidation have been built yet.

Kawai and Sakata (118, 119) reported in 1979 that carbon monoxide and hydrogen were produced from the reaction of carbon with water in the presence of catalysts (TiO_2 - RuO_2 mixture) when the reaction system was illuminated. Typically 30 mg of TiO_2 , 10 mg of RuO_2 , and 3 mg of active carbon were mixed, placed in a Pyrex glass bulb, and illuminated with a 500W high pressure Hg lamp for 5h. Appreciable quantities of H_2 and CO were formed only when TiO_2 , RuO_2 , C, and H_2O were all present; under such conditions the relative quantum efficiency of the evolution was at least 100 times greater than in a system that contained only TiO_2 and H_2O . When D_2O was used instead of H_2O , D_2 was detected.

More detailed and quantitative studies were carried out by Sato and White (120-122). These investigators used water vapor for the reaction along with carbonaceous materials, e.g., Texas lignites (120), activated charcoal (121, 122), or ethylene (121). Platinized titania was used as a catalyst. Platinized titania upon illumination also catalyzes the oxidation of acetic acid in liquid phase (123). When Texas lignite and water vapor were illuminated with ultraviolet light in the presence of platinized titania (TiO_2), hydrogen and CO_2 were produced as major products with the molar ratio (H_2/CO_2) of 2.5 ~ 2.75. Minor amounts of O_2 and CH_4 were also found. The H_2/CO_2 ratio might be greater than 2.0 (stoichiometric ratio) probably because hydrogen atoms in the lignite were partly converted to H_2 . The authors estimate a quantum yield of about 0.01 with an energy efficiency of 0.0003. Similar results were obtained between carbon (activated charcoal) (121, 122), or ethylene (121) and water vapor in the presence of platinized TiO_2 when illuminated. A study on the wavelength dependency of the reaction (122) showed that the onset of the reaction was observed when the light energy was about the same as or greater than the bandgap of TiO_2 . This indicates that the reaction occurs only if the hole-electron pairs are generated by light illumination as in the photoelectrochemical cell. These investigators thus proposed a mechanism in which the following reactions occur

Here, holes generated upon illumination are captured by water, whereas electrons migrate to platinum and reduce protons. The mechanism thus involves exactly the same concept as in the photoelectrochemical process.

Since in almost all reactions considered in previous and current sections CO_2 was a major anodic product, it

would be beneficial if CO_2 can be reduced to a useful product. The electrolytic reduction of CO_2 at various metal electrodes in both aqueous or nonaqueous media have been reported by many investigators (124-129). Direct electroreductions require applied potentials more negative than about 2V vs. SCE with the production of formic acid as a product in aqueous media. A possibility of reducing CO_2 to CO with the tetraazamacrocyclic complexes of cobalt or nickel present as catalysts has been reported by Fischer and Eisenberg (130). CO_2 was reduced catalytically to CO at potentials less negative than -1.6V vs. SCE in dimethylsulfoxide. The current efficiency, depending on the catalyst used, was in the range of 44 ~ 98%.

Photoelectrochemical (131, 132) or photochemical reductions (133) of CO_2 have also been investigated. Hemminger *et al.* (131) reported that the reaction of water and carbon dioxide in the gas phase led to the product, methane, when the reactants were adsorbed and illuminated on clean single-crystal strontium titanate surfaces of (111) orientation that were in contact with platinum foil. The reaction took place without any externally biased potential when the clean, reduced SrTiO_3 (111) crystal was illuminated with light having energy greater than the bandgap of SrTiO_3 . The reaction may be summarized as

The total amount of methane produced was 5 ~ 10 times the number of surface sites on the SrTiO_3 crystal, indicating a catalytic mechanism. Carbon dioxide in the presence of semiconductor powders suspended in water (132) was reduced photoelectrocatalytically to organic compounds such as formic acid, formaldehyde, methyl alcohol, and methane. Inoue *et al.* (132) used powders of semiconductors such as TiO_2 , ZnO , CdS , GaP , SiC , and WO_3 . When the experiments were carried out in the dark or under illumination with light of lower energy than the bandgap of the semiconductor used, no products were detected. Further, the yields of methyl alcohol increased as the conduction band of semiconductors became more negative than the redox potential of $\text{H}_2\text{CO}_3/\text{CH}_3\text{OH}$. This indicates that the photocatalytic reduction of CO_2 takes place by the action of the photogenerated electrons and holes.

Lehn and Ziesel (133) report that illumination of CO_2 with $\text{Ru}(\text{bipyridine})_3^{2+}$ and cobalt(II) chloride as sensitizers in an acetonitrile-water-triethylamine mixture lead to the production of CO and H_2 as products.

Photoassisted water-gas shift reactions over platinized TiO_2 were studied in detail (134). The activation energy was determined to be 7.5 kcal/mol, and the quantum efficiency was estimated to be approximately 0.5% at 25°C. Similar mechanisms to those described by these authors in the carbon oxidation were proposed (122). The products were CO_2 and H_2 from the reactants, CO and H_2O vapors. Many aspects of the water gas shift reaction have recently been reviewed (135).

As can be seen from the discussion and references cited in this section, work in this area began to appear only after 1979. Both oxidations and reductions were shown to occur through the electron-hole pair generation upon illumination of semiconductor powders present in the system. It has yet to be demonstrated that the same processes occur at illuminated semiconductor electrodes. In addition, the achievement of higher efficiencies for such processes should receive more attention in this area. The advantages of using heterogeneous catalyst systems have been pointed out (120).

Direct Power Generation from Coal Burning Fuel Cells

As a source of energy, coal can be burned directly to release the energy in the form of heat or electrochemically for the direct generation of electricity. Coal may also be utilized after its conversion to other forms, e.g., gas or liquid. Coal gas, for example, can be used as a fuel for fuel cells (136). Molten carbonate and phosphoric acid fuel

cells are being developed for the utilization of coal gas (136). Direct coal burning fuel cells may be more efficient than the ones using coal gas. However, only a few investigations have been carried out on the direct electrochemical oxidation of coal in fuel cells.

McKee and Adams (137) were the first to discuss the direct production of electricity from coal by electrochemical means. They used a cell in which a mixture of WO_3 and CeO_2 was used as an electrolyte with a graphite anode and an iron oxide or platinum cathode, operated at 1150°-1200°C. A current density of 19 mA/cm² at 0.45V or 10 mA at 0.60V was obtained, and the maximum efficiency of energy conversion calculated to be about 2% based on the energy released from the reaction

A much more detailed study on the electrochemical power generation was reported recently by Anbar *et al.* (138). These authors demonstrated the fundamental feasibility of a combined chemical-electrochemical process for generating electrical power from solid carbonaceous fuels. The system converts the free energy of oxidation of coal or coal char directly to electricity by combining electrochemical oxidation of molten lead with carbothermic reduction of the lead oxide. The study was performed in a molten carbonate medium in the temperature range 500°-800°C. The system consisted of electrochemical oxidation of molten lead to produce lead oxide and electricity, and the simultaneous regeneration of the lead metal by reduction of the lead oxide with coal or coal char. The system can be described by the following reactions

The lead oxide is then reduced by coal

Various parameters including the electrochemical kinetics of the lead-air cell, open-circuit potentials, polarization of the lead electrode, the kinetics of lead oxide reduction by carbon, and the electrochemical kinetics of lead oxidation in the presence of carbon have been studied in detail. The system has been shown not to be limited by kinetic factors, either electrochemical or chemical. An operating voltage of up to 0.760V at a current density of 108 mA/cm² was obtained at 700°C; it corresponds to approximately 75% voltage efficiency. The authors list a number of advantages of this integrated chemical-electrochemical energy conversion system for the carbonaceous material.

Although few studies have been carried out in this area, the concept is very interesting and also promising. The direct generation of power eliminates many conversion processes, thus allowing high energy conversion efficiencies. Effects of various components other than carbon such as sulfur, nitrogen, and minerals have not been studied; this process offers many advantages over other types of energy extraction methods, in view of the fact that a large fraction of the cost of the latter methods goes into the clean-up process in all coal conversion processes. Fundamental studies on various aspects in this area are essential for technological development.

Acknowledgment

Grateful acknowledgment is made to the U.S. DOE, Fossil Fuel Program (DE-AC21-81MC16377) for support of this research.

Report of the Electrolytic Industries for the Year 1983¹

Richard D. Varjian*

Dow Chemical Company, Louisiana Applied Science and Technology Laboratory, Plaquemine, Louisiana 70765

Dale E. Hall*

American Cyanamid Company, Chemical Division Laboratories, Stamford, Connecticut 06904

I. Chlorine-Caustic Soda

Production and capacity.—World.—Chlorine production capacity for major world areas is given in Table I (1).

United States.—U.S. chlorine production was about 10.2 million tons in 1983, up about 10% from 1982, according to the Chlorine Institute (2).

U.S. chlorine and caustic soda production capacities are given in Table II (3, 4).

Brine electrolysis accounts for 95% of chlorine production and essentially 100% of the caustic soda production capacity (5).

A few plant expansions were announced.

Vulcan expanded its 500 ton/day (chlorine) plant in Wichita, Kansas, by 210 ton/day (3, 4). The expansion utilizes ion exchange membrane cell technology and is the largest such installation in the United States. Eltech Systems supplied electrolyzer technology, and du Pont provided Nafion membranes (10-14).

Vulcan also started up a 200 metric ton/day ion exchange membrane plant in Birmingham, Alabama (6).

Vulcan added 75 ton/day of chlorine capacity to its 590 ton/day unit in Geismar, Louisiana (3, 4).

LCP Chemicals has announced that its Linden, New Jersey, chlorine-caustic soda facility, which has been temporarily closed (3, 4, 6, 7), will re-open in 1984 as a

chlorine-caustic potash operation (15). Phase I chlorine capacity is 36,000 ton/yr. This comes on the heels of the closure of the joint Occidental Chemical and International Minerals and Chemicals chlorine-caustic potash plant in Niagara Falls, New York. LCP was awarded all potassium product contracts formerly held by the joint venture (16, 17).

Plant closings announced during 1983 are given below.

BASF closed its 920 ton/day (chlorine) plant in Geismar, Louisiana (3, 4, 6, 7).

PPG shut down its 350 ton/day (chlorine) Barberton, Ohio, plant (3, 4, 6, 7).

Shell Oil Company shut down its 300 ton/day chlor-alkali unit at its Deer Park, Texas, manufacturing complex (8, 9).

P. J. Kienholz, Chlor-Alkali Business Manager for PPG, believes that an additional 2890 ton/day of chlorine capacity could be shuttered during the next few years (6).

Four plants have been closed temporarily or are on stand-by status.

Dow's 1000 ton/day (chlorine) unit in Midland, Michigan, was closed temporarily in June, 1982, and remains down (3, 4, 6, 7). Dow wrote off this unit in its fourth-quarter economic statement in 1983 (103, 105).

LCP temporarily closed its 450 ton/day plant at Linden, New Jersey (3, 4, 6, 7).

Olin's 350 ton/day (chlorine) McIntosh, Alabama, plant is on standby (3, 4, 6, 7).

Hooker's 230 ton/day (chlorine) Montague, Michigan, plant is on standby (3, 4, 6, 7).

PPG Industries completed a modernization of its diaphragm cell plant in Lake Charles, Louisiana. The \$100 million plus project involved conversion of outmoded cells to more efficient bipolar electrolyzer technology developed by PPG. The new cells reduce the energy requirement by 25%. PPG has undertaken a similar modernization at its Natrium, West Virginia, complex, scheduled for completion in early 1985 (19-22).

Georgia-Pacific plans to build a \$80-\$100 million cogeneration facility at its Plaquemine, Louisiana, plant.

* Electrochemical Society Active Member.

¹ This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. It represents a summary of the published information on production, plant capacities, consumption, markets and trends, prices, raw materials, new developments, and health and environmental aspects in the electrolytic and related industries.

The material presented herein has been obtained from many sources, as noted in the list of references, and does not necessarily represent the opinions of the authors.

The Industrial Electrolytic Division is grateful for the support received from the Vittorio de Nora-Diamond Shamrock Fund, which assisted with the publication costs of this report.

Others	875	600
Total	40,021	41,511

The unit will produce 140 MW of electricity plus process steam (23).

Plant operating rates increased slightly during the year, according to Chlorine Institute figures. The overall 1982 operating rate was 62% (24), but the rate in December, 1982, was only 57.9% (25). The January, 1983, rate was 63.6% of capacity (25). It climbed above 70% for the first time in May (70.7%), fell back in June, recovered in July, and remained above 70% until November (26-29, 34, 53). The December operating rate was 67.1% (2, 104). The maximum operating rate, 74.7%, was achieved in September (30). Firmer markets accounted for most of the improvement. However, onstream capacity fell about 2.2% between 1982 and 1983 (31).

Actual operating rates were probably 80%-85% of available capacity (26, 32) since some idle capacity may be unusable (33). One observer thought plants might be running at 87% of available capacity (29).

The Chlorine Institute estimates that chlorine capacity will fall to 13.6 million tons per year by 1985, a reduction of 4.2% from 1983 levels. The industry operating rate is expected to average 79% in 1985 (24).

Consulting Resources Corporation states that the average chlor-alkali plant was unprofitable entering 1984. Plants with relatively inexpensive hydropower or cogenerated power might be able to turn a slight profit. New plant economics were decidedly negative at this time. They predict that producers who have neither developed a low-cost position nor a safe market niche will drop out of the business during the next economic downturn (54).

About 20% of industry capacity has been shut down in recent years. Dow Chemical, the world's largest chlorine producer, has kept 25% of its capacity idle and has not announced a restart date for any plants. Some producers wonder whether the industry could produce enough to meet a truly thriving demand (54).

Japan.—Caustic soda output was 2.77 million metric tons in 1982, a 3.3% decrease from 1981 levels (35).

Japanese producers have 1.23 million metric tons of mercury cell capacity (32.4%), 2.23 million metric tons of diaphragm cell capacity (58.5%), and 347,000 metric tons of membrane cell capacity (9.1%) (36). Power accounts for 55% and raw salt 10% of production costs in Japanese plants. Most salt is imported from Mexico, Australia, and China (35).

The Japanese government has given 19 companies a reprieve from the December, 1984, deadline it had imposed for halting mercury cell production. The new deadline is June, 1986. Companies must begin the changeover before the end of 1984. All 19 companies, with a capacity of 1.3 million metric tons of caustic soda, intend to switch to ion-exchange membrane cells. Sixteen companies have already complied with the government's directive, first issued in 1973 (36, 37).

Kureha Chemical will convert its mercury cell plant at Nishiki, Fukushima Prefecture, to Asahi Chemical membrane technology. Annual capacity is 96,000 metric tons per year of caustic soda at the site. Start-up is scheduled in January, 1985 (38).

Tokuyama Soda, Mitsui Toatsu, and nine other producers are switching from diaphragm to ion-exchange membrane plants. Over 33% of existing diaphragm capacity is to be converted. The driving force for the changeover is a reduction in energy costs available with the membrane technology (39).

Nikkei Kako's 36,000 ton/year plant in Kanbara, Japan, built in 1975, will be converted from Diamond-Shamrock's MDC diaphragm cells to Asahi Chemical's bipolar membrane cells. Start-up of the converted plant is scheduled for January, 1984 (40, 41).

Europe.—Akzo Zout Chemie has started up the world's largest membrane process chlor-alkali plant near Rotterdam, The Netherlands. The plant has a capacity of 280,000 metric tons of caustic soda per year and uses Asahi Chemical membrane technology (42, 43).

Mercury cells still account for more than 70% of Euro-

pean capacity, even though diaphragm and membrane cells are more energy efficient (54).

Markets and prices.—Chlorine.—U.S. chlorine consumption by end use and average annual growth for the next ten years are in Table III (6, 44, 45, 54).

Chlorine does not really move in international trade, except for overland shipments. Organic derivatives such as vinyl chloride monomer and polyvinylchloride are exported from the U.S. in large quantities (54).

Chlorine prices rose throughout the year as chlorinated derivative markets recovered from the recession (46, 47). In September, 1983, producers were able to implement their fifth consecutive quarterly price increase for chlorine. These increases totaled almost \$100/ton (46). Producers tried for another increase of \$15/ton beginning January 1, 1984, bringing list prices to \$170.00 FOB plant site (19, 29, 31, 48, 49).

Some producers are forecasting a growth of 7%-9% in chlorine demand through 1984 (46). Chlorine shortages showed up in the fourth quarter. Producers anticipate a double-digit surge in PVC sales in the spring of 1984, which should only aggravate the tight chlorine situation (19, 47).

Producers can expect marginal demand increases in the next decade, according to PPG's P.J. Kienholz. The slow growth is due to a series of adverse environmental, toxicological, and process change impacts as well as a generally slowing world economy (50). Tables III and IV contain Mr. Kienholz's predictions.

Another market analysis foresees a similar pattern. Market growth is expected to track the GNP. Vinyl chloride is expected to be a leading growth market for chlorine averaging a 5%-6% growth rate (3).

Predicasts reports that chlor-alkali markets will grow at only 3.6% per year through 1995 vs. 4.4% per year historically (51).

Substitution of other oxidizing agents in pulp and paper bleaching will hurt chlorine demand in this market (51, 52).

Caustic soda.—U.S. caustic soda consumption by end use and average annual growth rate for the next ten years are in Table IV (6, 44, 45, 54).

Table III. U.S. chlorine consumption and average annual growth rate forecast

	Percent of total market	Annual growth rate
Vinyl chloride monomer	22	4%-5%
Pulp and paper	16	1%
Chlorinated methanes	8	4%
Chlorinated ethanes	9	—
Polyurethane	8	4%
Titanium dioxide	3	2%
Water and waste treatment	6	1%
Other inorganic	9	3%
Other organic	19	2%-3%
Weighted average		2.7%

Table IV. U.S. caustic soda consumption and average annual growth rate forecast

	Percent of total market	Annual growth rate
Pulp and paper	20	2%
Aluminum		
Domestic	4	1%
Export	4	4%
Anhydrous caustic	3	2%
Other inorganic	31	3.2%
Propylene oxide	6	3%
Petroleum production and refining	4	6%
Textiles	3	2%
Other organic	21	4%
Other exports	4	0%
Weighted average		3.0%

Caustic prices fell nearly all year. List prices for 50% solution began the year at \$230/ton on the Gulf Coast, a reduction of \$40/ton from late 1982 levels (55). By October, the list prices were down to \$150/ton in Gulf Coast markets (56, 57). Discounts were available in a buyer's market. Actual prices were firming at about \$75/ton (46). However, one export deal was struck for as low as \$51/ton during the year (4).

Producers were waiting for an upturn in alumina production to spark demand for caustic (58). Though alumina production accounts for less than 10% of demand, it is more cyclical and thus has a substantial effect on demand swings (59). Aluminum makers had large alumina stockpiles early in the year (46). With alumina production moving overseas, caustic soda exports should rise substantially (46).

Pulp and paper markets were not expected to grow much during the year since the paper industry was already operating at high levels (19). U.S. pulp mill consumption should only rise by 6%, to 1.8 million tons (60).

Alkaline oil field flooding is one of the few growth markets for caustic soda (54).

Caustic's long-term outlook is slightly better than chlorine's. The growth rate is expected to range one or two percentage points over chlorine through the eighties. Caustic soda has a broad end-use base and is less sensitive to economic cycles than are many commodity chemicals. The pulp and paper industry will be using more caustic than chlorine. Demand for environmentally related uses, such as waste-water treatment, will grow at a healthy rate. Petroleum and gas exploration production and processing markets should provide moderate growth. Caustic is forecast to be in tight supply more often than not long through this decade (4).

Technological developments.—Ion-exchange membrane plants came of age during 1983 with the start-up of the two major Vulcan installations in the United States (10-14, 61) and the world-scale Akzo Zout plant in The Netherlands (42, 43). Eltech has licensed 11 membrane cell plants worldwide (62). Asahi Chemical's membrane cell technology sales amount to 520,000 metric ton/year of caustic soda capacity. Asahi Glass's sales amount to 42,000 metric ton/year, while Tokuyama Soda's are 13,600 metric ton/year (63). Membrane cell plants announced in 1983 are listed in Table V.

Olin has licensed technology to retrofit diaphragm cells with ion-exchange membranes from Kanegafuchi Chemical of Osaka, Japan. The agreement allows Olin to sub-license the technology in the United States, Canada, and Mexico. The investment cost for retrofitting is said to be lower than that for newly built membrane cells (80, 81). Kanegafuchi says the technology involves narrowing

the anode-cathode gap and expects to receive U.S. Patent protection (82).

Kanegafuchi also has developed technology to retrofit mercury cells with ion-exchange membranes. The cells are specially processed after the mercury is removed. Then the membrane is lined into the cell sections where the mercury used to run. The process cuts switchover costs by 80% (83, 84).

Olin licensed its Remote Computerized Anode Adjuster system to Vulcan. The system monitors, adjusts, and protects anodes in mercury cells in order to maintain optimum electrode spacing. Vulcan is using the system on de Nora cells at its Port Edwards, Wisconsin, plant. Olin also provides adjusters for its own and Uhde cells (85).

Japan's Mitsui Toatsu Chemicals and Chlorine Engineers process membranes into bag-like shapes and slip them over diaphragm cell electrodes in order to retrofit existing plants. Plant conversion costs can be cut by 50%-66% (86, 87).

Dow Chemical has purchased 12 U.S. patents and patent applications and associated technology concerning membranes and membrane cells from Allied. Allied sold its chlor-alkali business in 1979 (88-90).

Asahi Chemical has received U.S. Patent 4,357,218 for making perfluoro ion-exchange membranes with both carboxylic and sulfonic acid groups and the use of the membranes in chlor-alkali cells (91-93).

du Pont and Diamond Shamrock agreed to settle litigation covering membrane technology for chlor-alkali production. du Pont may license customers to use its Nafion membranes for chlor-alkali production under certain Diamond Shamrock patents (94).

Although membrane cell technology has advanced rapidly, PPG's P. J. Kienholz believes that membrane cells are not economical enough to replace large, energy-efficient diaphragm cell plants (95).

Legal, environmental, and toxicological developments.—The Chlorine Institute filed a complaint with the Interstate Commerce Commission (ICC), charging many of the nation's railroads with anticompetitive actions. The complaint says that the railroads have canceled through routes, joint rates, and reciprocal switching arrangements. The Institute has asked the ICC to order the railroads to stop the anticompetitive practices (96).

Hach Company has developed an on-line instrument for monitoring residual chlorine in treated waste-water streams. The on-line monitor eliminates the need for hourly labor-intensive analyses, while assuring adequate disinfection without over-chlorinating the effluent (97).

The EPA is proposing that makers and processors of mono-, di- and trichlorinated benzenes conduct toxicity and environmental effects tests. The proposal is being

Table V. 1983 construction announcements for commercial membrane cell plants

Company/location	Capacity (metric ton/yr)	Completion date	Technology developer	Ref.
General Co. for the Paper Industry, Egypt	3,150	Late 1984	Eltech	(62, 67, 70)
Subentra, Aceh, Indonesia	160,000	1986	ICI	(64)
The Chemical Company of Malaysia, ICI Subsidiary, Padang Jawa, Malaysia	10,000	Late 1984	ICI	(65, 73, 79)
Egyptian Petrochemical Cairo, Egypt	60,000	Early 1986	Asahi Glass	(66, 78)
Bela Chemical, Bela, Pakistan	14,000	1985	Uhde	(69, 71, 72)
Nikkei Kako Kanbara, Honshu, Japan	33,000	January 1984	Asahi Chemical	(68)
Qiqihar Electrochemical Heilong Jing Province Peoples Republic of China	10,000	April 1986	Asahi Chemical	(74, 75)
Kureha Chemical Nishiki, Fukushima, Japan	87,000	January 1985	Asahi Chemical	(77)

made under the Toxic Substances Control Act. EPA has concluded that the tests are necessary because there is insufficient data available on the consequences of exposure to these chemicals (98).

OSHA has ordered asbestos exposure limits lowered from 2 fiber/m³ to 0.5 fiber/m³ (99, 100). European countries have also adopted a similar standard (101). EPA, OSHA, and the Consumer Product Safety Commission have set up a task force on asbestos. The group is to develop a coordinated federal approach to protecting the public from the health hazards of asbestos in the workplace (102).

Other Alkaline and Chlorine Compounds

Caustic potash.—U.S. nameplate capacity for caustic potash is about 260,000 tons annually. Production through June was running at 227,000 ton/yr (106).

Early in the year, the price of liquid caustic potash (45% solution) was increased by \$1.00 to \$13.00 per hundredweight. The price of the dry flake was increased by \$2.50 to \$42.35 per hundredweight (107-111).

Occidental Chemical and International Mineral and Chemicals (IMC) have terminated their 11-year joint venture to make caustic potash, chlorine, and hydrogen in Oxy's facilities at Niagara Falls, New York. Oxy decided to put the plant on standby so that its hydropower load could be shunted to its chlorine-caustic soda plant. The joint venture's sales contracts are being transferred to Linden Chemicals and Plastics (112-114).

In a related move, Linden Chemicals and Plastics will shift its Linden, New Jersey, facility, currently on standby, from a chlorine-caustic soda plant to a chlorine-caustic potash unit. The plant is slated for restart during the second quarter of 1984. Capacity is 62,000 tons of caustic potash (115, 116).

The demise of the Oxy-IMC joint venture leaves Diamond Shamrock, Linden Chemicals and Plastics, Monsanto, and Pennwalt as the only domestic caustic potash producers. Holtrachem says it is the only importer (114).

Soda ash.—U.S. soda ash production reached 8.4 million tons in 1983 vs. 7.8 million tons in 1982 and 8.3 million tons in 1981 (117, 145).

U.S. soda ash production capacity is given in Table VI (118).

Early in the year, plants were only operating at 70-73% of rated capacity (14). Operating rates jumped over 80% during the summer, but overall yearly rates averaged 73% to 74% (131).

The only remaining synthetic soda ash production plant in the United States is Allied's Syracuse, New York, facility. It has a capacity of 635,000 ton/yr (118). Though there is considerable overcapacity in the industry, Allied has strengthened its commitment to the Syracuse plant by expanding its sodium bicarbonate capacity and signing a 10 yr multimillion dollar transport contract with Conrail (119, 120).

Natrona Resources is seeking a partner to develop a 5,000 acre natural sodium bicarbonate deposit in the Piceance Basin of Colorado and Wyoming. The company will develop a solution mining project in Yankee Gulch (121).

Texasgulf Chemicals has acquired all of PQ Corporation's sodium leases in Sweetwater County, Wyoming. The leases cover 9,273 acres adjacent to Texasgulf's existing trona mine and soda ash production facility (122, 123).

Table VI. U.S. soda ash capacity
(millions of tons per year)

Allied Chemical	2.8
FMC	2.5
Stauffer Chemical	1.7
Kerr-McGee	1.3
Texasgulf	1.0
Tenneco	0.9
Total	10.2

Cleveland-Cliffs Iron and Industrial Resources of Chicago are proceeding with their July, 1982, agreement to develop an 8,359 acre deposit of natural sodium bicarbonate. The expected production rate of the facility is one million ton/yr of soda ash (124).

U.S. soda ash production should increase 3.2% per year according to Consulting Resources Corporation (125). A world-wide production forecast for the 1980's is given in Table VII (125).

Several companies are proceeding with development of new routes to soda ash. Akzo Zout Chemie is pursuing a nonelectrolytic route to vinyl chloride monomer and soda ash using a homogeneous catalyst of trimethylamine, copper II chloride, and iodine in adiponitrile solvent (126, 127, 128). Asahi Glass claims to lower the energy to produce synthetic soda ash by 55% reacting ammonia, sodium chloride, and carbon dioxide into ammonium chloride and sodium bicarbonate, which is calcined to obtain soda ash (126, 127). FMC Corporation, among others, is pursuing a solution mining route to soda ash said to cut mining costs by 25%. FMC has invested more than \$30 million in developing the technique and has applied to the Wyoming Department of Environmental Quality for clearance to construct a one million ton/yr facility by the mid-1980's (126). The department issued a permit to FMC to begin mining in December, 1984. However, Tenneco Minerals, operator of a trona mine about 5 miles from the FMC project, objected, stating the FMC's brine might flood its mine. The Department of Environmental Quality is expected to respond to Tenneco's complaint in April, 1984 (146).

The soda ash list price remained at \$84/ton f.o.b. Green River, Wyoming. However, discounts were available. In late October and November, 1983, most producers introduced a temporary voluntary allowance of \$15/ton off the list price (131-135).

The listed prices were \$140/ton in the Northeast and \$198.65/ton in southern California (132).

Major end uses for soda ash are listed in Table VIII (129, 147).

U.S. exports of soda ash were a record 1.64 million tons, up 49% from 1982 levels, according to the Bureau of Mines. Most of the exports went to the Far East, Latin America, and Africa (148).

Container glass markets are hard pressed by plastic resins. Glass recycling is growing, reducing demand for new glass (147). Flat glass and fiber glass, which have rebounded due to increased housing construction and auto production, should offset some lost tonnage. Producers hope exports will eventually rescue them (130). However, foreign markets may be hard to penetrate due to the strength of the U.S. dollar, and due to the fact that West European capacity utilization is currently only 65% of its nominal eight million ton per year capacity (136). The Eu-

Table VII. World soda ash production capacity

Other	11

ropean Common Market instituted a \$20/ton anti-dumping duty against U.S. exporters (137, 138). The Canadian Department of National Revenue, Customs, and Excise also ruled that major U.S. producers dumped soda ash on the Canadian market (139, 140). Japan may prove to be a growing market for U.S. exports. The Japanese Fair Trade Commission has told four Japanese producers to eliminate an agreement to control imports (141).

Soda ash producers hope to develop new markets to relieve the apparent long term supply-demand imbalance. Allied Chemical is trying to reverse acid rain damage to a pond with soda ash. Dry injection of trona or nahcolite into smoke stacks considerably reduces sulfur emissions. The system can only be used on low sulfur (under 1%) coals. A 500 MW utility plant might require 50,000 ton/yr of trona (142-144).

Sodium chlorate.—Annual U.S. capacity for sodium chlorate is given in Table IX (149).

Early in 1983, plants were only operating at 60% of rated capacity (177).

Changes affecting U.S. production capacity announced during 1983 follow.

Kema Nord Bleaching Chemicals purchased one of Occidental Chemical's sodium chlorate plants in Columbus, Mississippi. Kema Nord also obtained Occidental's know-how, patents, and technology for making chlorine dioxide (150, 151).

Pennwalt will close its Calvert City, Kentucky, plant during the first quarter of 1984. The plant has a rated capacity of 50,000 ton/yr, but it reportedly has been operating at a lower rate for over a year. The company cited an increase in Canadian imports over the past few years as the reason for the closing (152).

Huron Chemicals has started an expansion of its plant at Riegelwood, North Carolina. Plant capacity is now 14,800 ton/yr. The expansion project was based on an improved model of the company's 240,000A cells (153).

HO Process Company, a partnership between Olin and Huron Chemicals, is building a 14,000 ton/yr. plant at Clairborne, Alabama. The plant is scheduled for startup in March, 1984. The plant is specially designed to utilize off peak power. Cell technology was developed by Huron (154, 155).

Kerr-McGee expanded its Hamilton, Mississippi, plant capacity from 40,000 to 62,000 ton/yr by installing a second line with dimensionally stable anodes (156).

Nameplate Canadian capacity is reportedly 425,000 ton/yr (157).

PPG Industries Canada completed a 6,400 ton/yr expansion at Beauharnois, Quebec. The Stanchem complex now has a capacity of 80,000 ton/yr (158-162).

Erco Industries' 36,000 ton/yr expansion at Buckingham, Quebec, originally scheduled for completion in the second half of 1983, will now start up in the fourth quarter of 1984. The expansion was delayed by the recession. The cells will use Erco's metal electrode technology. By-product hydrogen will be burned to generate steam (163-166).

BCM Technologies delayed the start-up of its \$15 million, 25,000 ton/yr plant in Amerstburg, Ontario, due to

defective anodes. The anodes were replaced and the plant opened in August, 1983. The plant uses Pechiney-Ugine-Kuhlmann's technology. BCM may double the size of the plant if it can obtain Canadian government financial assistance (167-170).

Kema Nord is planning to double capacity to 65,000 ton/yr at Magog, Quebec. The expected cost is \$21 million (Canadian) (171).

Canadian exports to the United States have been increasing between 8% and 15% per year, and should continue to increase by more than 10% per year in the near future. Through November, the export rate was about 92,000 ton/yr; 7,000 tons above 1982 levels. The reason for the growth in exports is hydropower, which allows Canadian producers to make sodium chlorate less expensively than U.S. producers can. Power prices in Canada have remained relatively stable, while U.S. power costs have been erratic and generally increasing. Canadian sodium chlorate competes with material produced in the northern United States. High shipping costs preclude Canadian product from penetrating markets in the Southeast (152).

List prices for sodium chlorate remained \$420/ton for crystalline material, though discounts were available (172, 173, 177).

Apparent consumption of sodium chlorate in the United States should be about 354,000 tons in 1983, a 4% increase (174). Pulp and paper markets account for 84% of consumption. Other markets include other chlorates 7%, uranium processing 5%, and agriculture 4% (175).

Long-term growth in sodium chlorate demand should be about 3%-4% after 1983, paralleling that of pulp output. Hydrogen peroxide and oxygen are being used increasingly in mechanical and chemical pulping processes hurting sodium chlorate's market share. Some plants should be shut down or modernized after 1985 (176).

Metals

"There is no single cause for America's recent decline as a minerals producer, and there is no single answer to our predicament. The reasons for our growing inability to compete in the world market are many—some specific to an individual deposit, others generic and affecting the entire industry. Usually a combination of forces is at work, but the combination is not the same for any two minerals."

"So let us stop looking for villains on one side, and panaceas on the other. Those of us with a real concern for America's mineral security must understand that, just as the industry's troubles are caused by a combination of forces, so must a combination of policies be assembled to combat those forces" (178).²

Difficult times for nonferrous metals continued in 1983. As a result of high metal stocks in London Metal Exchange warehouses, there was continued downward pressure on prices (179). The anticipated economic recovery was slower and less vigorous than many had hoped, and, to some extent, seemed to pass the nonferrous metals by (180). At the beginning of 1983, there were an estimated 150,000 fewer people working in the U.S. in mining and mining-related jobs than a year earlier, and roughly one-half of the capacity of the U.S. metals mining industry was idle (181).

In Canada, too, the problem was acute. The Canadian mining industry was seen as fighting for survival. The key to survival, according to Charles Baird, chairman and CEO of Inco, Limited, is more efficient production (182). Government assistance, especially in the area of tax policy, was also recommended.

Despite the gloom in the nonferrous industry, however, 1983 produced the beginning of a recovery in the aluminum and zinc markets. The recovery of those two metals was related to improvements in the housing and automotive industries (179).

U.S. Department of Commerce economists predicted that nearly all segments of the nonferrous metal industry

would improve in 1984 (183). However, only a modest increase in demand was predicted for titanium. Military demand for Ti mill products will be flat, and needs for commercial aircraft will be relatively low, according to the Commerce Department economic forecast.

The long-term future of the metals industries can only be viewed with some concern. Major efforts are needed to cope with the accelerating pace of technology (184). At the same time, engineering and plastics are coming of age. In applications, including business machine housings, automobile body components, as well as many others, the use of engineering thermoplastics may jump by 50% by 1987, to 1 billion lb/yr (185).

Aluminum.—Production and capacity.—World.—Table X contains the current world's primary aluminum capacity and the anticipated capacity in 1986 listed by region (186, 187).

United States.—Table XI contains information on the primary aluminum capacity in the United States listed by company (188, 189).

The U.S. aluminum industry was only operating at 58% of capacity in January (188). Capacity utilization rose during the year to 72% as the economic recovery took hold (190). By year-end capacity utilization was about 80% (265).

Primary domestic production of aluminum was 3,696,000 short tons in 1983 compared to 3,609,000 short tons in 1982 (289).

Major manufacturers made the following changes in their operating capacity in 1983.

Alcoa raised its primary aluminum production to 97% of capacity by year end. The firm restarted plants in the following locations: Rockdale, Texas; Badin, North Carolina; Alcoa, Tennessee; and Warrick, Indiana. The factories accounted for 241,240 metric tons per year additional production (191-195). Alcoa may start up two idle potlines with a 44,000 metric ton/yr capacity in Vancouver, Washington, depending on power rates issued by the Bonneville Power Administration. If the lines were reopened, Alcoa's U.S. system would be operating at 100% of rated capacity (194).

Arco Aluminum restarted a 36,000 ton/yr potline in Columbia Falls, Minnesota (196), and 60,000 ton/yr potline in Sebree, Kentucky (197).

Total	5,542

Kaiser shut down two potlines in Chalmette, Louisiana, totaling 55,000 tons/yr capacity but restarted potlines in Spokane, Washington, and a 40,750 ton/yr potline in Ravenswood, West Virginia, shut down since January, 1982 (199, 200, 237).

Reynolds Metals raised its operating rate to 78% of capacity by restarting potlines in the following locations: Jones Mill, Arkansas; Troutdale, Oregon; Longview, Washington; Malvern, Arkansas; and Listerhill, Alabama: totaling 217,000 tons/yr additional operating capacity (201, 202). Some of the restarts were due to lower power rates offered by the Bonneville Power Administration (BPA) in the Northwest (201, 202) and the Tennessee Valley Authority in the Southeast (211), in addition to improving markets. BPA offered the power discount through October, 1983, to firms which restarted idle capacity when it discovered 1,000 MW of surplus power (212). As a result, Alcoa, Kaiser, and Reynolds all restarted idled capacity in the Northwest (213).

Reynolds purchased Consolidated Aluminum's Lake Charles, Louisiana, aluminum production complex, including a 36,000 ton/yr primary aluminum smelter, a 240,000 ton/yr calcine coke plant, and a 135,000 ton/yr carbon anode plant. The anode plant will supply Reynolds' expansion of its Baie Comeau, Quebec, primary smelter scheduled to come on stream in early 1985 (214-216).

Alumax has deferred its plans to build a \$600 million, 220,000 metric ton/yr aluminum plant at Umatilla, Oregon. The main reason is the rapid rise of electricity costs in the Pacific Northwest (217).

Alumax purchased Howmet Aluminum, a subsidiary of Pechiney Ugine Kuhlman. The acquisition increased the size of Alumax by 50%. Alumax is owned 50% by Amax, Incorporated, 45% by Mitsui and Company, and 5% by Nippon Steel (218).

Arco Aluminum has sold its aluminum smelter at Sebree, Kentucky, plus other processing plants in the U.S. and an alumina interest in Ireland to Alcan (249, 250). Arco also wishes to sell 40% of its aluminum plant in Columbia Falls, Montana. Total capacity at the site is 180,000 ton/yr (251).

Alcoa will invest \$120 million over the next two years to modernize its Warrick, Indiana, operations. It is also evaluating an additional \$150 million investment in the aluminum smelting and rolling plant (237).

Reynolds plans to sell its Hurricane Creek alumina plant and related bauxite mining operations in Arkansas. Production ceased on August 1, 1983. The chemical products facility continues to operate using purchased alumina (219, 220).

Toth Aluminum started the first metallic chlorides plant in the U.S. based on kaolin clay raw material rather than bauxite. The plant will produce 100 million lb/yr of silica chloride, titanium chloride, and aluminum chloride by the end of 1984. Plant cost was \$8.5 million (221, 222).

Earth Sciences has applied to the Bureau of Land Management for a lease on a 1,600 acre alunite deposit in southwest Colorado. It estimates the project could support production of 500,000 ton/yr of aluminum (264).

The industry has achieved a 21.9% reduction in the amount of energy used to make aluminum vs. the base year of 1972. The industry had set a 20% reduction for 1985. Energy savings resulted from savings in the reduction process, in holding, casting, melting, and fabrication (223, 224).

Canada.—Canadian primary aluminum capacity is listed in Table XII (188). Canadian producers started the year operating at 85.7% of capacity (188). Capacity utilization was over 98% January, 1984 (233).

Alcan restarted potlines at Arvida-Jonquiere, Quebec, and Kitimat, British Columbia amounting to 41,500 ton/yr of additional production. The company finally started the last two of three potlines delayed since 1981 due to the recession at its Grand Baie, Quebec, site (225-234). The additional production was prompted by ingot orders exceeding Canadian production, especially from Western

Europe and the Far East (231).

Alcan will proceed with plans to build a \$1 billion smelter in Laterriere, Quebec, which will ultimately replace part of the production from the Arvida, Quebec, plant. The company had previously deferred its plans due to the business downturn (235-237).

Alcan may build two aluminum smelters with a combined capacity of 375,000 metric ton/yr and 700,000 kW hydroelectric plant in British Columbia pending government approval. The entire unit could cost as much as \$3 billion (Canadian) (237).

Pechiney Ugine Kuhlman will build a 230,000 metric ton/yr aluminum smelter in Becanour, Quebec. The provincial government will provide a portion of the funding for the project. Hydro-Quebec will provide 400 MW of electricity at reduced prices for 25 yr. Total cost of the project is \$1.2 billion. Capacity could be increased to 345,000 metric tons by adding a third potline. The plant will use Pechiney's 180,000A pots, which consume 13,500 kWh/ton aluminum (238-245). Alumax has an option to participate in the project (243, 246).

Canadian Reynolds will add 125,000 metric ton/yr to its Baie Comeau, Quebec, aluminum plant. The expansion will cost \$500 million. Hydro-Quebec is offering a 50% rebate on electricity until 1990 (246-248).

Alcan completed an \$82 million 1.2 million ton/yr alumina plant in Arvida-Jonquiere, Quebec (252, 253).

Japan.—Aluminum production in 1983 was expected to be about 250,000 metric tons vs. 351,000 metric tons in 1982, reflecting higher power costs. The five Japanese aluminum smelters are running at a combined 2 billion yen/month loss operating at 35% of capacity (254-256). Japanese manufacturers reduced aluminum smelting capacity by 54% between 1979 and 1982 (257).

Japanese import demand will rise to 1.8 million metric tons by 1985 and to over 2 million metric tons by 1990. The Japanese aluminum industry has invested overseas and will be entitled to 700,000 metric tons from these sources in 1985. Another 400,000 metric tons will be supplied to Japan by long-term contract in 1985 (258). The current level of aluminum imports is 1.35 million metric tons (259).

Western Europe.—The leading West European aluminum producers, and their capacities are given in Table XIII (260).

Primary aluminum production in Western Europe for 1982 is listed by country in Table XIV (261).

Australia.—Alcan, which was operating its 90,000 metric ton/yr smelter at Kurri Kurri at 64% of capacity in 1982, reached full capacity at the site by year end (262). It

plans to resume construction of a third potline at the plant, raising capacity to 145,000 metric tons. Startup is anticipated by the end of 1984 (263).

Markets and prices.—Shipments by domestic aluminum producers in 1983 jumped by 16% to 13.9 billion pounds from the depressed level of about 12 billion pounds in 1982 (265). Aluminum supplies tightened as producers rushed to restart idled capacity (266). Consequently, prices rose. Spot prices went from 44 cents/lb in October, 1982 to 76 cents in November, 1983 (266). List prices were raised 6.5% to 81.5 cents/lb in August, 1983, the first list price increase since 1980 (267, 268). Prices may jump another 20% by mid-1984 (269). Some forecasters see a global aluminum shortage developing in 1984 (269), though top industry executives do not foresee a shortage occurring until 1985 (265, 266). 1984 shipments are expected to grow another 7%-9.5% over 1983 (265, 266) with the largest growth areas in transportation (22%), electrical (13.9%), and machinery and equipment (18.9%) (265, 270). In the auto industry, aluminum is being used for intake manifolds and cylinder heads. Pore-free aluminum is being used increasingly for structural components such as wheel and chassis parts and in brake cylinders, brake rotors, and calipers (271).

C. W. Parry, new chairman and chief executive officer of Alcoa, believes that the fundamentals of the aluminum business will never be the same again because 40% of the free-world's capacity is in the hands of government-controlled companies whose policies tend to depress global aluminum prices. He believes that the long-term survival of the U.S. industry will depend on new technology, company-union cooperation, and growth strategies (272, 273).

New products and technology.—TAFE Incorporated has developed an aluminum alloy which has the characteristics of conventional metals—strength, durability, machinability, and electrical conductivity—but can be rapidly dissolved by water. The company foresees a number of uses for the product, such as encapsulation of organic compounds for marine applications, sensors for water alarms for flood control, and for various delayed-release marine or military needs (274-276).

Alcoa has developed three low density aluminum-lithium aircraft alloys formulated to maximize damage tolerance or strength. Weight reductions of 8% are possible with a cocurrent fuel saving (277).

A Japanese firm, Progressive Business Group, has developed a battery using an aluminum anode, a carbon cathode, and an aqueous nitric acid electrolyte. Many efforts have been made to incorporate aluminum into batteries because of its potential ability to supply more electrons per unit weight than most other materials. Because the battery is not rechargeable and spent acid may be hard to dispose of, uses may be limited. The group will commercialize the battery through licensing or partnership agreements with other firms (278, 279).

Arco Metals will develop technology for producing aluminum chloride from kaolin clay under an agreement with Alcoa. Alcoa has already developed a process for producing aluminum via electrolytic reduction of alumi-

num chloride. Kaolin clay is widely available in the U.S. and North America, whereas bauxite, the raw material for the existing Hall process, is not. Commercialization is not expected until the 1990's (280-283).

Alcoa has modernized technology used to make carbon anodes for aluminum cells and is offering it for sale. The new technology uses better insulating materials, eliminates refractory joints, and improves air seals. The anode is more uniformly baked and increases power efficiency of the smelter by approximately 1% (284-286).

The Department of Energy has patented a new aluminum process. Crushed aluminum ore and coke are blended, pressed into pellets, and placed in a reactor. Gaseous sulfur is forced over them converting alumina to aluminum sulfide. Aluminum sulfide is heated in an electric arc furnace, where it decomposes into aluminum monosulfide, which cools and produces molten aluminum metal. The new process consumes 33% less energy than the Bayer-Hall process (287).

Chemfix Technologies has patented a process for disposing of aluminum plant wastes. The wastes, known as red mud tailings, are processed into a substance that can be used for landfill cover (288).

Beryllium.—Domestic beryllium mineral production declined in 1983 (290). Imports for consumption also dropped, from 115 short tons in 1982 to an estimated 100 short tons in 1983.

Apparent beryllium consumption, which plummeted from 303 to 150 short tons between 1981 and 1982, climbed to about 200 short tons in 1983 (290). Consumption was broken down as follows: 40% as metal in nuclear reactors and aerospace applications; 36% as an alloy and oxide in electrical equipment; 17% as an alloy and oxide in electronic components; and 4% in other applications. Beryllium recycling is insignificant.

The price of domestic beryllium metal remained at the \$194 per pound level of 1982 (290). A summary of U.S. production and consumption figures is given in Table XV (290).

Imported beryllium is obtained from China (40%), Brazil (38%), Republic of South Africa (5%), Rwanda (4%), and other sources (13%) (290). World mine production figures are given in Table XVI (290).

In August, the General Services Administration announced that it would buy beryllium from Brush Wellman Company, the free world's only integrated producer (291). The quantity was not disclosed, but was termed "substantial."

Brush Wellman began a \$3.4 million government study on expanding or modernizing the company's metallic beryllium facilities in 1982 (291). Results of the study have not yet been announced. Brush Wellman will also install additional production capacity for beryllium copper round products. Work is expected to be completed by 1985.

A new copper-based alloy was introduced by Penn Precision Products to replace beryllium copper in electronics parts applications (291). The alloy costs about \$8/lb compared with about \$10.50 for beryllium copper. Also, beryllium copper has been listed as a latent carcinogen, while the new alloy is not (292).

In the first change in beryllium copper prices since September, 1982, Brush Wellman announced in December a 5%-8% increase on certain beryllium copper products, although increased discounts on large quantities were also offered (293). Following Brush Wellman's lead, Cabot Corporation posted 5%-6% increases on certain products (294). A quantity discount schedule for annual contract purchases of beryllium strip was also expanded.

Trends (290).—Estimated 1984 beryllium concentrate production will not change markedly from the 1983 level. U.S. consumption of oxide, alloy, and metal will be about 200 tons.

OSHA regulations, issued in 1975 and still under consideration in 1983, may result in higher production costs or loss of some production capacity if accepted.

Identified domestic beryllium resources are estimated at 80,000 tons. This quantity is sufficient to supply U.S. needs for the foreseeable future.

Chromium.—South African chromium ore production was estimated at 2.4 million metric tons in 1983 (a slight increase), reflecting a modest demand increase for chromite. 1983 production in other countries was not yet available (295).

The 1983 production of chromium ferroalloys and metal was running 64% behind the 1982 level (296). Producers had a 22 month supply of chromite stockpiled during the year (297).

The price of vacuum-grade electrolytic chromium metal used primarily by the superalloy industry increased 40¢ to \$4.40 per pound on July 1, 1982 (298).

American dependence on foreign supplies of strategic chromium and cobalt would be sharply reduced with the opening of the California Nickel Corporation mine and processing facility in Crescent City. The proposed \$300 million operation would supply 50% of the nation's defense needs for chromium and 80% of the military needs for cobalt (299).

The world's first plasma recycling plant is being built for Scan Dust AB in Landskrona, Sweden. The plant will recover 35,000 ton/yr of zinc, lead, nickel, chromium, molybdenum, and other metals from 70,000 ton/yr of iron and steel works baghouse dust. Dust availability could be a limiting factor. The plant is scheduled to start operations in early 1985. The technology was developed by SKF Steel (300).

The General Services Administration sent out a request for bids for upgrading chromium ore as part of the government's ferroalloy stockpiling program. Only 125,000 tons of chrome ore will be available for upgrading during the first year of the 10 year program. The total government stockpile of chrome ore is 171,034 tons (301). The stockpile program will focus on higher grade ores first since the higher energy costs to process the lower grade material would have quadrupled the program budget (302).

The British government appointed Brandeis, the Pechiney Ugine Kuhlman trading company based in London, to coordinate its stockpiling program. Various strategic ores are to be purchased, including 40,000 tons of chrome ore, 20,000 tons of high carbon ferrochrome, and 20,000 tons of charge ferrochrome (303, 304).

A new chromate conversion coating based on trivalent instead of hexavalent chromium has been introduced by

Pavco, Incorporated. The new coating will allow users to more easily comply with the stricter January, 1984, regulations (305).

du Pont is forecasting that chromium dioxide will grow at an annual rate of 20% until 1990 and is doubling its current capacity at Newport, Delaware (306).

Concerns over the future supply of chromium have caused vigorous scientific research programs to look for replacements. The most promising materials are fine-grained rapidly solidified alloys, amorphous alloys, eutectic composites, long-range ordered alloys, intermetallic compounds, and structural ceramics (307).

Copper.—The copper industry in 1983 was plagued by low prices, as sagging demand extended the problems of 1982 (308). The general improvement in the economy, particularly in the U.S., had a positive impact on zinc, but produced little optimism among copper producers, concerned with oversupply and long-term problems such as the threatened loss of electrical markets to other technologies. According to Asarco, Incorporated, consumer markets had "responded to the general economic recovery, but the capital goods sector, which accounts for more than 50% of copper consumption, has not (309).

The domestic copper industry was also depressed by high foreign production levels, sparking criticism of international economic policy.

Domestic production.—The domestic copper industry struggled in 1983, as production continued the slide beyond already-low 1982 levels. Production and consumption statistics (310) are given in Table XVII. Imports of refined copper jumped dramatically, as consumption increased while domestic production flagged (310).

Phelps Dodge assumed smelting operations at its Douglas, Arizona, operations after a 5-month shutdown (311), and expected to reach production of 300 short ton/day of anodes. The future of the Douglas smelter, however, is uncertain, because it does not meet the air pollution limits of the U.S. Clean Air Act. To satisfy the federal requirement would require almost total rebuilding, at a cost of more than \$580 million. The plant now operates under an extension permit, which expires in 1987.

Construction of Phelps Dodge's \$35 million solvent extraction electrowinning plant in Tyrone, New Mexico, was proceeding on schedule. The plan leaches low-grade material with water, to produce a copper solution, which is pumped directly to an electrowinning cell. The resulting cathodes are pure enough to sell without further refining (311).

Phelps Dodge planned to spend \$75 million to bring its Morenci smelter within pollution limits. However, the PD smelter at Ajo, which exceeds pollution limits and has no extension permit, will remain closed for the foreseeable future (311). PD's new continuous cast copper rod mill at El Paso, Texas, commenced operating in 1983, and was running at 85% of its rated 500 million lb/yr capacity in April, 1983.

Table XVII. U.S. copper production and consumption (338,363)
(thousand metric tons copper content)

	1982	1983 (prelim.)
Production		
Mine	1,140	1,045
Refinery, Primary	1,227	1,182
Refinery, Secondary	468	431
From scrap, all sources	518	465
Imports for consumption:		
Total	513	655
Ores and Concentrates	118	91
Refined	258	460
Exports		
Total	345	218
Ores and Concentrates	195	50
Refined	31	81
Refined consumption, reported	1,658	1,783
Total consumption, apparent	1,760	2,030
Refined stocks, year end	676	693

At mid-year, Phelps Dodge was struck by union workers when the company requested an 8% reduction in total labor costs (312). However, the strike did not produce a copper market rally, as labor settlements were concluded by Asarco, Ammax, and Magma.

Kennecott closed its McGill, Nevada, custom copper smelter indefinitely, citing a lack of available concentrates (313, 314). The smelter had an annual production capacity of 50,000 short tons of blister copper. Kennecott planned to restart the facility when copper business improved (315). The squeeze in concentrate supply was linked to low domestic mine production, coupled with expanding world smelting capacity, especially in the Philippines and Brazil. Tight concentrate supplies coincided with an oversupply of blister copper, as Zaire reportedly put 50,000 tons of blister on the market (313).

Kennecott was able to cut copper production costs at its Chino, New Mexico, mine and smelter to below \$0.75/lb (316). Further cost reductions are anticipated when the new flash smelter is completed in 1985. Chino's smelting capacity will be increased from 300,000 to 500,000 short ton/yr when the smelter project is finished. The Chino modernization, costing about \$120 million, will be two-thirds paid by Kennecott and one-third by its partner, Mitsubishi Corporation.

Noranda Mines announced the closing of its copper mining and vat leaching operations at Casa Grande, Arizona, in August (317, 318). Ground conditions at the mine, situated on a fault, resulted in high costs and ore losses. However, leaching operations at an adjacent sulfide ore body were continued.

Asarco scheduled the reopening of the Silver Bell copper mine in Arizona for October 1, 1984, to coincide with start-up of Asarco's new oxygen flash furnace at the nearby Hayden, Arizona, smelter (317). Silver Bell production is normally 21,000 short ton/yr of copper as concentrate. At the same time, Asarco also announced layoffs at its Mission mine near Tucson (319), due to depressed market conditions.

Because of low-cost, rich ore bodies in Latin America, it is unlikely that any new U.S. mines will be opened in the near future (320). U.S. porphyry ores average 0.6%-0.7% copper, while Chilean ore has a copper content of about 1.5%, and Peruvian ore is about 1% copper. In addition, U.S. costs per employee are about three times higher than in Chile, while productivity is comparable, according to Leon Kovisars of Met Research, Incorporated (320). Kovisars also claimed that production costs per pound were 25-40¢/lb in Chile, and 45-50¢/lb in Peru. In contrast, North American costs are 60¢ to \$1.30/lb, mostly toward the high end of the range.

In 1983, there was growing criticism from the domestic copper industry that international monetary and banking policy was financing its demise (321). An unidentified mining company official claimed that mines in Peru, Zambia, and Zaire were selling copper at 10¢ per pound below their costs, as roughly 100,000 lb/month of foreign copper are dumped on the world market (319). The World Bank and the International Monetary Fund, largely funded by the U.S., were faulted for making loans to less-developed countries to maintain or expand their state-owned copper production (321). According to L. William Seidman, director and former Vice-President of Phelps Dodge Corporation, over 40% of free-world copper production is owned or under control by governments of less-developed countries. State-owned mines, Seidman said, operate at maximum levels "to maximize foreign exchange revenue, regardless of profitability" with losses, in effect, subsidized by the IMF (322). Seidman's remarks were made in testimony before the Senate Committee on Energy and Natural Resources.

Similar criticisms were made by Charles Barber, former chairman and chief executive of Asarco, during a panel discussion at an economics symposium sponsored by the American Institute of Mining, Metallurgical, and Petroleum Engineers (323). "While U.S. mines were shutting down, the IMF was passing out [large-scale aid] to its six

clients," Barber said, referring to \$568 million in loans to Chile, Zambia, Zaire, Peru, Papua, New Guinea, and the Philippines. Similar concerns over IMF policy have also been expressed in Canada (324).

Representatives from the American Mining Congress and several leading copper producers began an educational campaign to show that copper smelters are not contributing to acid rain (325). The campaign was in response to a White House task-force report which claimed that smelters contribute to acid rain in the eastern U.S. and Canada. The representatives told EPA head William Ruckelshaus that the emissions capture rate had risen from 10% in 1970 to about 60% today, and should rise to 70%-80% by 1988.

Foreign production.—While worldwide copper production fell by 80,000 metric tons between 1982 and 1983, foreign mine production remained approximately constant, as all of the decrease was attributable to the United States. World mine production is summarized in Table XVIII (310).

Despite soft markets, some foreign copper producers made commitments to expansion in 1983. Chile's Codelco began a major expansion and modernization program to raise its smelting and refining capacity from about 533,000 ton/yr to nearly 880,000 ton/yr by the end of the decade (311). The first step was to increase the electrolytic capacity of its El Salvador division, from 78,000 to 90,000 ton/yr during 1983.

Codelco's mining capacity was not planned to increase above the current level of about 1 million ton/yr. This was attributed in part to a 27% drop in ore grade at Chuquicamata, Codelco's largest mine, from 2.2% to 1.6% copper (326). There was also concern over the recent U.S. protectionist sentiments. The U.S. normally consumes about 14% of Codelco's copper.

In Canada, Asarco announced plans to reopen its Buchan, Newfoundland, mine (327). The mine, which yielded 500 ton/yr of copper before closure in 1981, has an ore body with an estimated three-year reserve. After a poor third quarter, largely due to its copper business, Noranda Mines decided to cut its copper output by nearly half (328). Noranda's Montreal refinery was scheduled to produce 110,000 tons in 1983, against 216,590 tons in 1982. In addition, Noranda planned to operate only copper mines with significant by-product yields. Plans for developing Noranda's underground ore body in Murdochville, Quebec, were shelved, and the smelter there, operating mainly on Chilean ores, could be in peril (329).

Falconbridge Copper announced it would sink a \$7.6 million shaft near Schreiber, Ontario, beginning in the spring of 1984 (330). The ore body is estimated to contain 17.8% zinc and 0.94% copper. Cominco began mining low grade ore south of Kamloops, but milled only 23,000 ton/day (331). To raise milling to 45,000 ton/day would require a new \$250 million concentrator, which cannot be justified at a copper price below about 90¢/lb.

Table XVIII. World copper mine production and reserve base (310)
(thousand metric tons of copper content)

	Mine production		Reserve base
	1982	1983 (est.)	
United States	1,140	1,045	90,000
Australia	247	250	16,000

planned economies	462	460	9,000
Total	8,040	7,955	510,000

Brenda Mines of Vancouver mothballed its Peachland, British Columbia, operation (331). Placer Development sharply curtailed production at its Gibraltar mine (331). However, low-cost producer Lornex Mining Corporation, Limited, was operating at full capacity of 86,000-88,000 ton/day (331).

Sherritt Gordon continued to operate its loss-making Ruttan mine in northern Manitoba (332). By March, 1984, the company expected to find a partner to fund the \$30 million expansion necessary for the mine's survival.

Zambian copper shipments through the Dar es Salaam port were increased from 30,000 to 40,000 ton/month after, logistics problems were solved (312). However, backlog problems again surfaced later in the year, as a rail strike halted shipments in the copper belt (328). The Konkola division of Zambia Consolidated achieved a record 1.93 million tons of ore hoisted in the year ending March 31, 1983 (316). In addition, the 48,574 tons of copper output in concentrate was the highest since 1972. However, in late 1983, Zambian president Kenneth Kaunda requested other major copper producing countries to join Zambia in curtailing refined metal output to force a world price rise (333, 334). Copper accounts for over 90% of Zambia's foreign exchange earnings. It appeared that Kaunda's proposal would meet resistance among other members of the Intergovernmental Council of Copper Exporting Countries (CIPEC). In particular, Chile, the largest and most influential copper producer, is committed to expanding copper output through the decade.

CIPEC also expressed concern over draft legislation before the U.S. Congress, which would impose a tax on copper imports (326). The "environmental equalization" tax would reduce the smelting and refining cost advantage of foreign producers over domestic companies, by raising the copper duty from 0.8 to 10¢/lb.

Zaire's copper exports, through its state-owned marketing agency, Sozacom, were expected to rise from last year's 489,535 tons to as high as 500,000 tons (316). The improvement was partly due to increased sales to China and Japan.

Japan purchased more copper from Pasar of the Philippines, as well as Zaire (335). Premiums on Zambian copper through 1983, coupled with low Japanese demand, reduced Zambian exports to Japan. There was speculation that Japanese smelters would cut back production by about 10% in 1984, from current production levels of 85,000 ton/month (336). An eight-member consortium of Japanese companies, led by Nippon Mining Company, withdrew from a copper development project in Zaire, after losing some \$220 million since the project was organized in 1976 (337).

Prices.—Throughout 1983, copper prices were low. To regain market share, three of the big four Canadian producers—Noranda, Kidd Creek, and Inco—moved to COMEX-based pricing formulas, using the COMEX price plus a 3-5¢ premium. The fourth, Hudson Bay, continued with a list price (338). Later in the year, Phelps Dodge moved to price its copper rod at the COMEX price plus about a 7¢ premium (339).

In June, swollen stocks pushed prices to two-month lows (340). Domestic producer prices were 78-79¢/lb, while the COMEX price was 73.8¢/lb. Adding to the problem were worldwide production increases and restarting of North American refineries as producers, notably Inco and Phelps Dodge, attempted to improve cash flow. As a result, prices slid even further, the producer price reaching 77.5-78¢/lb (313).

According to P. E. Shortall, Jr., manager of metals purchasing at Olin Brass, excess inventory would depress prices at least into 1984 (341). Combined warehouse stocks of COMEX and the London Metal Exchange reached 620,000 tons in July, compared with about 350,000 tons in October, 1982 (342). According to the secretary general of CIPEC, Eduardo Llosa, only a further production cutback, from the 750,000 metric tons capacity already shut, mainly in the U.S. and Canada, were neces-

sary for a real boost in prices (343). Llosa said cutbacks should take place at high cost mines, and not among generally low cost CIPEC producers.

Prices slumped even lower in October, as Asarco lowered its quote to 69¢/lb, and a host of domestic producers reacted by dropping prices to 70¢/lb (344). The COMEX price, meanwhile, was 65.95¢. The retreat was blamed on a similar decline in gold and silver prices. Despite this disappointing turn, Anthony Bird Associates predicted an average 94.2¢/lb price in 1984, arising from a 10% consumption increase, coupled with only a 1.9% increase in refined production (345). Metal Trends bulletin likewise forecasted a gradual price firming to a peak in 1985-1986 (346).

At the end of 1983, Robert Horton, Bureau of Mines head, claimed that copper producers now need to get at least \$1.10/lb for copper to turn a profit (347). Horton also said that new amendments to the Clean Air Act would add another 15¢/lb to production cost.

An adequate return for a new copper venture was put at the 15% after-tax range by David James, a Richardson Greenshields mining analyst (348). According to James, this requires a price of about \$1.20/lb.

A report by Dr. Leons Kovisars of MET Research predicted copper prices, rebounding from 1983 lows, may reach more than \$2/lb (in current dollars) after 1990 (349).

Demand.—It was estimated that, at the end of 1983, world inventories of refined copper would rise to about 1.92 million short tons, up from 1.22 million short tons at the beginning of 1982 and 1.65 million short tons at the beginning of 1983 (340). Copper's recovery remained stalled, as mid-year estimates of a consumption increase of 8% in the U.S. and 1%-2% worldwide (340) failed to materialize (350). In fact, consumption in the first half of 1983 was only marginally higher in the U.S. and Great Britain, and dropped in Japan, West Germany, and France (322).

Overly bullish expectations led copper producers, particularly in the U.S., to bring idled capacity into operation too early, according to Anthony Bird Associates (351).

One bright market for copper was in domestic wire, where consumption was running about 10%-20% ahead of 1982, when total wire mill product usage was about 2.35 billion lb (352). Additionally, a long-term copper study indicates that competitive copper producers may benefit from a turnaround in which the Western World demand for refined copper grows from 6.9 million metric tons in 1982 to an estimated 9.9 million metric tons in 1991 (349).

Better times were also predicted by Grieveson, Grant, and Company (353), who saw copper consumption increasing by 5½% in both 1984 and 1985, with demand actually outstripping supply. Particular concern with supply was expressed within the European Economic Community, where increased difficulties were anticipated over the next five years (354).

G. Frank Joklik, president of Kennecott, said that he was "reasonably optimistic" about long-term demand growth for copper (355). Joklik predicted 2% per year growth in refined copper consumption for the rest of the century. Increased demand was seen principally from electrical applications.

A cautionary note was sounded by Henry Bloy of the Mining Association of Manitoba, who pointed out that Chile alone would be capable of meeting the entire world copper demand if it went into full production (348). Similar warnings were made by Sr. Alistair Frame, chief executive of Rio Tinto Zinc (356). Frame told a Metals Society copper conference that "the expected slower rate of industrial growth, the changing requirements of the developed countries, the inroads of substitution, the reduced quantities required for any of copper's surviving applications, and the absence of any really significant new outlet lead us to the inescapable conclusion that the increase in copper consumption in the coming years will at best be only very moderate."

Markets.—Faced with loss of traditional markets to other materials, copper producers need to step up their devel-

opment efforts. That message was given by Alfred Powis, chief executive of Noranda Mines, Limited (357). Powis noted intensified threats from aluminum, magnesium, stainless steels, plastics, and, more recently, from titanium and optic fibers. Calling for more product development and market research, Powis noted that the aluminum and plastics industries spend much more in these areas than does the copper industry. Powis encouraged the Copper Development Association "to strike out and capture new ground."

One challenge to copper comes from fiber optics in the telecommunications industry. Optic cables are easier to install, and can carry 40 times as many simultaneous communications as bulkier copper cables. In addition, optic cables are cheaper than copper (358). In an effort to gain an early lead, Southern New England Telephone Company joined with CSX Corporation, a railroad, to begin laying 5,000 miles of fiber-optic cables along CSX right-of-way in 20 eastern states (358).

In one study (353), fiber-optic cables for high density communications were not seen as cutting into copper's market by more than a few percentage points, despite the great successes of fiber-optic development in recent years. However, fiber optics could displace 300,000 tons of copper by 2000 (359), reducing copper's use in U.S. communication to a modest net growth. Also at stake is a replacement market as nearly 1 billion miles of AT&T copper cable, already installed, wears out (358).

Additional threats in the electrical industry are posed by hybrid graphite fibers with enhanced electrical conduction and inherently high strength (360). Balanced against this, the recent crossover in copper and aluminum prices will aid copper in recapturing market share for not only electrical applications, but also for ship mill sheathing, offshore oil rigs, and other uses (359).

A spot survey of solar industry officials indicated that sales of flat plate collectors and absorbers were up 20%-30% from 1982 (361). According to the Copper Development Association, this emerging market used 16.8 million pounds of copper in 1982. Although small, the industry is growing rapidly. American Solar King Corporation in Waco, Texas, plans to buy about 500,000 lb of copper in 1984, up from 180,000 lb in 1983 (362).

Lithium.—U.S. lithium carbonate production totaled 34 million pounds in 1983 (364).

There are only two United States lithium producers: Lithium Corporation of America and Foote Mineral (365).

The price of metallic lithium in 1000 lb lots has ranged between \$21.70 and \$23.35/lb for more than a year (365). Foote Mineral lowered its price to \$21.70 on October 1, 1983 (366).

The price of technical-grade lithium carbonate increased by seven cents to \$1.48/lb on April 1, 1983 (365-369).

Foote Mineral restarted its Kings Mountain, North Carolina, lithium compound facility during the spring after shutting it in August, 1982. Capacity is over 17,000 ton/yr of salt cake (370).

Pechiney Ugine Kuhlman's subsidiary, Metaux Speciaux, has set up a pilot facility for the electrochemical production of lithium at its Plombieres, France, plant. A decision on a large-scale lithium plant is expected toward the end of 1984 (371).

Two lithium deposits were found in Europe. Minerex AG of Austria announced the discovery of a large lithium deposit near Carinthia, in the Austrian Alps (372). The French Bureau of Geological Research has finished a feasibility study for exploiting the mineral bed of Echasieres in the Allier (373).

The European Economic Commission has reopened an anti-dumping investigation into imports of lithium hydroxide from the United States and the Soviet Union and has started new proceedings against the People's Republic of China. The EEC first imposed a duty on lithium hydroxide from the United States and the USSR in January, 1980. Imports from the three countries have risen from

57.8% to 72.2% of the EEC market. Lithium hydroxide is a lubricant used in oil production (374, 375).

Aluminum alloys containing up to 15% lithium could reduce the weight of commercial airliners making them more fuel efficient. The alloys also have better structural properties than the currently used metals (376, 377).

The key to the future growth of the lithium market rests with the consumer batteries and aerospace (365). Lithium demand could rise to 70,000 ton/yr of contained lithium by 2000 if these new uses are successfully developed. The current oversupply situation could continue for a decade. Reserves are sufficient to raise output thereafter (377).

Chile will add 18% to world capacity with the start-up of a \$61 million, 14 million lb/yr lithium carbonate plant during 1984. The producing company, Sociedad Chilena de Lito is 55% owned by Foote and 45% by the Chilean government (377).

Another new lithium producer is Greenbushes Tin of Australia, which plans to produce 20,000 ton/yr of lithium concentrates (367).

Magnesium.—After years of low sales and restrained prices, magnesium enjoyed a rebound in 1983, and prospects for the next few years are bright. The year was characterized by production and price increases, increased demand, inventory restocking, and healthy existing and new markets.

Production and price.—The recovery of the U.S. economy had a direct effect on magnesium production in the U.S. However, slower recovery elsewhere was reflected in foreign Mg production, which was virtually the same as in 1982. Production figures are shown in Table XIX (378). More detailed domestic production and consumption figures are given in Table XX.

As a result of increased demand during the first half of 1983, Dow began a six-month plan in June to increase magnesium production by 25% at its Freeport, Texas, plant. Previously, the plant had been operating at about 50% of its estimated production capacity of 230 to 250 million lb (379). The move was intended to replenish Dow's inventories, which were purposely drawn down in the preceding two years of low consumption, and to meet the rising Mg demand. In May, Amax, Dow's primary domestic competitor, was operating its Rowley, Utah, plant at about 60% of its 32,000 ton/yr capacity. Later, it was reported that Amax planned to bring on another 10,000 ton/yr capacity in the fourth quarter (380).

During most of 1983, Norsk Hydro operated at about

60% of its production capacity of 50,000 ton/yr (381). This was due, in part, to a modernization program at the Porsgrunn smelter to cut costs and energy consumption, and to increase productivity. The new technology involves production of anhydrous $MgCl_2$ from a magnesium chloride brine mixture, rather than from the more traditional dolomite/seawater mix. Full capacity production was expected to begin at the end of the year.

In October, Alcoa announced that Mg production at its North West Alloys subsidiary had increased, with eight of nine furnaces operating (381). Previously, three furnaces had been shut down for relining (382). Upon completion of a maintenance program, all furnaces will be operated. Despite the increases in power costs announced earlier by the Bonneville Power Authority, optimism in the Mg market led to the decision to increase production. Most of North West's magnesium production is consumed by Alcoa itself in aluminum alloys, for which markets were also firm.

Japan's two magnesium producers, Furukawa Magnesium and Ube Industries, raised production to 2,956 tons in the first half, a 6.8% increase over the same period in 1982 (383).

In May, Dow increased its Mg price for the first time in two years (379). In Europe, both Dow and Norsk Hydro raised prices on July 1, 1983, following the lead of Sofrem (384). Amax did not immediately follow Dow's domestic prices increase, despite sustaining losses on magnesium operations in the first half of the year (382). Further price increases were expected as demand exceeded production levels. Earlier price restraint was attributed not only to low demand, but to conscious plans for new Mg market growth (380).

Demand.—Although demand remained weak relative to the late 1970's, there were signs of a general rise in die casting and automotive markets (379). Some of the increased demand was seen as a chain reaction response to the aluminum upturn (385). The International Magnesium Association estimated that 1983 consumption would exceed production by 44,000 tons, with the shortfall being met from already low stockpiles (381).

Magnesium demand increased by 20% between the second half of 1982 and the first half of 1983 (384). Demand in West Germany in the first half was 13% higher than a year earlier (385). French and Italian producers were operating at full capacity, and were believed to be sold out through the end of the year. Japanese imports rose 4.9% during the first half of the year, to 7,458 tons, with most of the imported material coming from the U.S. (383). At the same time, there was little free market activity, as Russia and China were inactive, and Yugoslavian output was curtailed because of power shortages (385).

Markets.—The optimism among magnesium producers arises from projected increases in new and existing markets. The automotive die casting market, relatively static at 31,000-34,000 ton/yr for the last three years, was projected to rise to 55,000 ton/yr by 1987. Significant pounds per auto increases were seen as possible in the 1985 model year, through easy substitutions of magnesium for aluminum (380). With increasing aluminum prices, the magnesium-to-aluminum price ratio approached a low value of 1:6.

Increased magnesium use has met with success at Honda, and in the clutch housing in Ford Ranger light trucks (380, 386). Chrysler began studying further applications which could result in increased Mg usage of 3-4 lb/yr (383). The current Shelby Charger was fitted with a magnesium gear lever, which was expected to be used in other Chrysler cars next year. Magnesium engine component, interior door handles, and window handles are also under consideration. GM introduced a 6 lb magnesium radiator grille on the 1984 Pontiac, and an air cleaner on the Chevrolet Corvette (387).

However, magnesium substitution requires that car makers either modify their die casting and machining facilities to switch from presently used aluminum, or pur-

Table XIX. World magnesium production (378)

Consumer stocks, year end	35	35

chase finished components from external suppliers (383). George Ditzhazy, divisional purchasing manager of GM's Central Foundry Division, pointed out that Mg applications could be hampered by cost, processing difficulties, and a lack of variety of U.S. sources which can competitively supply magnesium ingot (388). General Motors consumes about 600,000 lb/yr of Mg. According to Ditzhazy, GM forecasts no substantial increase from current consumption levels, aside from increases attributed to forecasted car volume.

Amax began marketing a new high purity magnesium alloy, AZ91HP, which could replace zinc and plastic components now used in computers and peripheral equipment (386, 389). The alloy, while three times as expensive as zinc per pound, is only one-quarter as dense, and is thus less expensive to use. In addition, the alloy offers higher structural strength than plastic and contains fewer corrosion causing impurities than similar alloys. Amax estimated that use in computers could account for 1 million lb of new demand in the U.S. in 1984. The alloy now accounts for about 90% of Amax's total magnesium production (386). Amax is also hoping to replace zinc in telecommunications industry cooling devices.

A decline in U.S. die casting demand from 26 million lb/yr in the 1970's to the current 10 million lb/yr was due largely to the low cost of aluminum (387). As the Mg/Al price ratio shrank from over 3 to about 1.6, an increased Mg usage of 15 million lb for die casting was seen possible in 1984. However, this still represents a small share of the U.S. die casting market, which consumes 600,000 ton/yr of aluminum and 210,000-225,000 ton/yr zinc.

Additional Mg demand is predicted for the desulfurization process used in steel manufacture (380, 381). Magnesium, viewed as both cost effective and environmentally benign, has already made progress in replacing calcium carbide and soda in the U.S. and Europe (381).

Manganese.—Manganese is an efficient and cost effective deoxidizer and desulfidizer of steels. Thus, the steel industry accounts for 95% of the world's manganese consumption (390).

Manganese alloy and metal consumption tended to follow the steel industry lead. All were higher early in the year and slumped slightly later on. Imports of manganese ores were generally increasing all year (391-396).

Electrolytic manganese metal list prices were lowered to 66¢/lb on May 1, 1983 (397). Prices rebounded late in the year to 70¢/lb (398-399).

The United States has an estimated 70 million metric tons of manganese resources. However, commercial sources are contained in low-grade deposits containing 0.6%-14% manganese. Production costs to exploit these deposits are prohibitive. Adequate supplies of high-grade manganese ores (45% and higher) are available from foreign mines. Therefore, the United States imports all of its requirements (400).

Haker has developed a hydrometallurgical technique for recovering silver and manganese from silver sulfide ores. Silver Tech Mines, a joint venture of Haker and Houston Mining and Resources, plans to apply the technique in a pilot plant at a mine near Tombstone, Arizona, designed to process 1-3 ton/day of ore. Conventional silver smelters cannot tolerate much manganese. The inventor claims his proprietary leaching solution overcomes such recovery problems and recovers 90% of the silver and all the manganese (400, 401).

New mineral samples taken from United States-controlled waters in the Pacific Ocean contain 32% manganese, a higher concentration than earlier sampling had indicated (402).

A carpet of manganese nodules containing 40%-41% manganese has been discovered in the Tyrrhenian Sea between Rome and Sicily (403).

United States firms may have access to Mexican manganese that is closer to home than the South African material that now predominates. Three possibilities exist for joint ventures between United States companies and

Mexican manganese producer Cia Mineara Autlan: opening the Noapa deposit near Mexico City; expanding capacity at Autlan's refinery in Tampico; and upgrading carbonate ores found in the Molango deposit to premium-grade manganese (404).

Autlan Manganese's ferromanganese and silicomanganese plant in Mobile, Alabama, did not reopen during 1983 (405).

The Bureau of Mines has developed two chromium-free steels designed to be cost-effective substitutes for standard grades of heat-treatable construction steels. The new alloys use manganese-molybdenum and manganese-nickel-molybdenum and may reduce United States vulnerability to a potential disruption in chromium supplies from South Africa and the Soviet Union, the major exporters to the United States (406).

A maximum of 100,000 tons of manganese ore will be available for processing during the first year of the U.S. government's stockpile upgrading program. The government currently has 153,105 tons of manganese ore on hand (407).

The British stockpiling program includes the purchase of 40,000 tons of manganese ore and a similar amount of high carbon ferromanganese (408).

World demand for electrolytic manganese dioxide totaled 116,900 metric tons in 1982 and should reach 121,000 metric tons in 1983 and 126,100 metric tons in 1984. Table XXI contains 1982 consumption information by region (409).

In Japan, dry cell battery production rose 13% in 1982 vs. 1981, but electrolytic manganese dioxide consumption rose only 3%. The reason is increasing miniaturization of dry cells to make them compatible with ever-smaller electronic devices (409).

Cia. Minera Autlan SA has designed a plant to produce 6,600 ton/yr of electrolytic manganese dioxide. The plant is to be located in Mexico (410).

Nickel.—Free world nickel consumption was 1,070 million lb in 1983, a 7% increase from 1982 (411).

Worldwide 1983 nickel demand exceeded disastrous 1982 levels by healthy margins. Much of the demand included inventory replenishment (412-416). As a consequence, prices rose from year-end 1982 levels of \$1.50/lb (417). Prices were as high as \$2.37/lb (418), but then fell back to the \$2.25 range (417,419). The prices slumped when consumers' inventory building ceased and when the increased availability of scrap from higher stainless steel production impacted the market (420).

Table XXII lists the major suppliers of nickel to the United States in 1982. The 1982 import total was 263,135,000 lb (421).

Hanna Mining Company has signed a new power contract with the Bonneville Power Administration and a new labor agreement with the United Steelworkers Union and will reopen the nation's only integrated nickel mine

and smelter at Riddle, Oregon. The facility had been closed since April, 1982, due to depressed conditions in the worldwide nickel market (422, 423).

Amax suspended operations at its refinery in Braithwaite, Louisiana, during the summer, due to low nickel prices and low demand. The plant had operated at its full capacity of 80 million lb/yr during all of 1982 and the first half of 1983 (424, 425). The plant reopened in September 1983 (426, 427).

Ni-Cal Developments is continuing to progress towards its aim of establishing an open pit nickel mine and processing plant near Crescent City, California. The company will construct a 75 ton/day pilot processing plant there in 1984. An engineering and economic feasibility study says that the plant could produce 19 million lb/yr of nickel and 2.2 million lb/yr of cobalt (428, 429). The plant could supply up to 80% of the nation's need for cobalt and 35% of its needs for nickel (430).

Inco's Sudbury, Ontario, mining and milling operation reopened in April after being closed since May, 1982 (431, 432). Inco's Sudbury nickel refinery and its Thompson, Manitoba, division both closed for a month during the summer (433). Its Port Colborne, Ontario, refinery was shut down for five weeks beginning December 26, 1983 (434).

Falconbridge resumed production at its Sudbury facility early in 1983 after its having been closed since July, 1982 (435). Falconbridge plans to continue production at Sudbury throughout all of 1984 (436).

Sherritt Gordon mines installed a new recovery system at its Fort Saskatchewan, Alberta, refinery raising capacity to 46 million lb/yr from 38.7 million pounds (437).

Inco resumed development of its new open pit mine at Thompson, Manitoba, in June. The development of the mine was halted in June, 1982, to conserve cash. The completion date has been pushed back one year to 1986. The new mine will replace the existing Thompson Pipe mine, which should be depleted in 1985 (438).

Inco may replace its nickel smelter at Sudbury, Ontario, with a new reduction smelting unit to cut sulfur dioxide emission to 50% of the proposed limit. A new plant could cost \$450-500 million. Inco is trying to utilize as much of the existing processing equipment as possible to lower the cost because of its present financial condition (439).

Falconbridge's plans to raise production at Sudbury operations to 90 million lb by 1990 have been shelved. Falconbridge management feels nickel prices must be above \$3.00/lb to justify the investment. Current capacity is 69 million lb/yr (440, 441).

Talent Metal should start a \$6 million 7,000 metric ton/yr plant on Taiwan in early 1984 (442).

Japanese nickel output in 1983 was about the same as 1982—23,000 metric tons. Demand was 38,000 metric tons vs. 38,500 tons in 1982 (443, 444).

Cuba's nickel industry was in the news often in 1983. Cuba produced 40,000 metric tons of nickel oxide in 1982; about 20% was exported to Western Europe. The Punta Gorda nickel project, although delayed, may start up in late 1984. The 107,000 ton/yr Las Camaricocas project will not start up in the next three years due to technical problems and weak market demand (445). Cuban nickel production is expected to double or triple by 1990 (446).

A United States trade ban on materials containing Cuban nickel is still effective (445). The Reagan Administration effectively banned imports of Soviet-made nickel products on the grounds that they contain Cuban nickel ore (447, 448).

The European Economic Commission imposed and then lifted a 7% antidumping duty on Soviet nickel. The Commission lifted the duty when investigations revealed that the USSR prices were undercut by other nickel producers selling in Europe (449-453).

Gipronickel Institute, Leningrad, has introduced a new method for producing nickel directly from concentrates using a new hydrometallurgical process. Nickel concentrate solution is introduced into an electrolyzer cell, from which pure nickel is extracted. Bypassing the smelting

stage saves energy and allows more complete recovery of nonferrous metals. The Soviet nickel and cobalt industry will convert to the process starting in 1987 (454).

After three successive years of decline, western world nickel consumption increased about 6% in 1983. Forecasts for 1984 indicate a further increase of 8%-10% to about 1,120 million/lb (455). Western world nickel consumption is only expected to grow by 1.1%-1.7% annually through 1996. North American nickel production will still not match peak 1979 levels (456). Some market segments are expected to grow much faster. Electroless nickel plating will grow from 10%-20% per year from its current level. The growth in the electronics industry, where electroless nickel is used on computer memory disks, aerospace connectors, and copy machine rollers is the reason for the optimistic outlook (457).

United States nickel production is expected to meet only a small part of the 380,000 ton United States market in the year 2000 unless the relatively low-grade ores in Oregon and California are developed, according to the Bureau of Mines. The report maintains that 1981 nickel reserves of 54.1 million tons and anticipated new discoveries are entirely adequate to meet the high range forecast of United States and world demand (458).

Sodium.—There are three domestic producers of sodium (459). Their estimated production capacities are given in Table XXIII.

Metallic sodium production figures are given in Table XXIV (460).

By comparison, 1981 production was estimated at 109,000 tons, and 1982 production at 103,000 tons (459).

Metallic sodium is primarily used to produce anti-knock additives for motor fuel, a market which is being phased out in the U.S. and is vulnerable elsewhere (461). This caused demand to decline by 4.1% per year between 1970 and 1980. Present sodium markets, at last estimation, are listed in Table XV (461).

Titanium.—As predicted (462), the titanium market did not recover in 1983, although long-term projections are

encouraging (463). In a weak market year, there were explorations of joint ventures between producers, acquisitions, and the formation of the country's first titanium association. Procurement of titanium for the National Defense stockpile by the General Services Administration (GSA) became a major issue in a depressed year.

Production and prices.—Since the late 1970's production capacity for Ti sponge has increased dramatically worldwide (463). In the U.S., expansions and new facilities have increased capacity to more than 72 million lb/yr. In the first quarter, U.S. production remained at about 35% of capacity (464). In Europe, the ICI plant was replaced with the Deeside Titanium Limited plant with an 11 million lb/yr capacity. Japanese production capacity has more than doubled since 1977, and now stands at 73 million lb. Total free-world capacity is thus more than 154 million lb/yr. World sponge production figures are given in Table XXVI (465).

Pechiney's French subsidiary, Cezus, has begun a pilot project to produce Ti sponge to support its manufacture of semi-finished product (465). Viking Metallurgical Corporation brought a new electron beam furnace on stream in mid-year (466). The furnace, with a 7 million lb/yr capacity, increases Viking's melting capacity to 10 million lb/yr.

Showa Titanium Company announced that its Toyama Ti sponge plant would begin test runs by October (467). Capacity was estimated at 2,000 ton/yr of A-grade sponge. Sales were intended to be divided evenly between the U.S., Europe, and the local market. Showa claims that its new technology obtained from joint venture partner Ishizuka Kenkyusho, will produce Ti at 18,000 kWh/ton of Ti. In comparison, power requirements for U.S. production are estimated at 40,000 kWh/ton.

In contrast to the Showa expansion, Japan's major producers, Toho Titanium and Osaka Titanium, reduced operating rates to 40% of capacity (467). Japanese Ti sponge shipments to Europe were depressed (468) as European users turned to much-cheaper Soviet sponge (\$5.90-\$6.00/kg vs. about \$7.90/kg). Spot shortages, however, occurred in the U.S. market, due to depleted inventories. Prices up to \$3.50-\$4.00/lb were reported.

China, with a 20,000 ton/yr capacity, dropped out of the sponge market for over a year (469), and was operating at only about 50% capacity. Threshold price estimates for Chinese re-entry varied from \$3.20 to \$4.50/lb.

A joint project between Howmet and Dow Chemical, to produce Ti sponge electrolytically, was dropped when it turned out to be uneconomical (465). A joint sponge-production venture between Westinghouse Electric Corporation and Mitsubishi Metal Corporation was also dropped (470).

RMI Company and Kobe Steel Limited announced formation of a joint venture in which semi-finished Ti would be shipped from RMI to Kobe, rolled into commercially pure mill products at Kobe, and shipped back to the U.S. (470). The venture will compete with Timet, the dominant U.S. supplier of commercially pure Ti, and ALS Metals, Incorporated. ALS, a joint venture of Allegheny-Ludlum Steel and Japan's Sumitomo group, will produce mill products in the U.S. using semi-finished Ti from Sumitomo. RMI also purchased Micron Metals, Incorporated, a Ti powder producer in Salt Lake City (471), to extend its range of Ti powder products.

Albany Titanium, Incorporated announced plans to begin Ti powder production by late 1984 and sponge production a few months later (472). Revised plans call for a 10 million lb/yr sponge capacity using a process licensed from Occidental Petroleum Company. The process will use ilmenite (\$40-\$50/ton), as its raw material.

The Federal Trade Commission began investigating a proposed acquisition of TiCl₄ and TiO₂ production facilities by SCM Corporation (473). The sale would give 80% of the market to du Pont and SCM. Titanium tetrachloride is used to produce Ti sponge.

Demand.—Despite slow markets, Ti sponge consumers (474), facing dwindling inventories, began negotiating long-term supply agreements running 3-5 yr (470). Recent contracts had been as short as six months. The move to longer contracts was viewed as a ripple effect from attempts by jet engine and airframe builders to obtain long-term contracts from their suppliers.

The Federal Panel on Assessment of Titanium Availability, Current and Future Needs reported that the U.S. supply was "triply secure" (463). This conclusion was based on large domestic resources, current use of cheaper imported ores (thus conserving domestic supplies), and ability to shift Ti supplies from less critical uses in an emergency. Even under the most optimistic assumptions, Ti demand will not reach current production capacity by 1990 (463).

Markets.—The aerospace industry is the largest present market for titanium (475). The depressed state of the aircraft market (470) has had a serious negative effect on titanium demand. Worldwide commercial jet deliveries declined from 460 units in 1980 and 426 in 1981, and again to 290 units in 1982 (463). It was estimated that deliveries would decline severely to less than 200 units in 1983, before rebounding in 1984 and 1985. In commercial aircraft, the main titanium users are the 747, 757 (at 17,000 lb each), 767 (12,400 lb each), DC-10 (20,000 lb each), and Airbus. Discontinuance of L-1011 production, requiring 34,000 lb of purchased Ti per aircraft, means that future aircraft production to meet a given number of seat miles will require less Ti than in the past. However, the increasing use of composite materials in new aircraft may bring a concurrent increase in Ti usage, because Ti is more compatible than aluminum with advanced composites.

Grumman Aerospace Corporation reported advances in superplastic forming and diffusion bonding of titanium aerospace components (476). The production equipment required costs only half as much as an equivalent commercial hydraulic press and can be installed in much less time. Using the new technology, Grumman has built glove vanes for the Navy's F-14 fighter, and has designed a titanium wing section for the next generation of fighter aircraft under Air Force funding.

Testing has begun on titanium propellant and pressurant tanks for the first five Intelsat VI communications satellites (477). The tanks, measuring 4-45 in diam, will be made from standard 6AL4V titanium alloy by the Precision Sheet Metal Division of Fansteel Corporation.

The prospects for new beta and near-beta titanium alloys, which are heat-treatable to high strengths without becoming brittle, are promising (475). Most of the Ti alloys used to date in the aerospace industry have been in the soft annealed state, but the desire for stronger Ti alloys has led to work on beta-type alloys by the Department of Defense, titanium producers, aircraft manufacturers, and forging companies.

Pechiney announced plans to set up titanium sponge plants in France, to expand into high technology uses in Europe and the United States (465). Viking Metallurgical Corporation, a major U.S. producer of titanium forgings, considered moving into the Ti mill products field, which is currently more active than the aerospace industry (466). Despite a moderate decline in industrial markets since the peak year of 1980, their Ti market share has increased (463). A return to positive growth was expected for 1983, with a mature growth rate in succeeding years.

Table XXVI. World Ti sponge production (short tons)

	1982	1983 (est.)
United States	15,600	13,000
Japan	18,600	12,000
United Kingdom	2,600	2,000
China	1,500	1,500
USSR	44,000	44,000
Total	82,300	72,500

GSA stockpiling.—In a generally depressed market year, much attention was focused on government purchases for the National Defense Stockpile. The stockpile goal for Ti sponge is 195,000 short tons, of which only 25,000 short tons were on hand at mid-year (478).

The Federal Emergency Management Agency (FEMA) requested a waiver from the Trade Agreements Act, calling for commodity purchases based on worldwide bidding, to aid domestic producers (479). The request was denied by U.S. Trade Representative, William Brock (480). However, Brock advised that the import duties on foreign sponge, as much as 17.5%, would be considered by the General Services Administration (GSA) in evaluating bids.

In August, GSA announced plans to buy 4,500 short tons of titanium, in either sponge or granule form, in lots of 500 short tons or more (481). Eight bidders, including five with domestically produced material, submitted bids ranging from \$2.92 to \$6.25 per pound (482). Shortly thereafter, low bidder Billiton Metals, offering Ti from the United Kingdom Deeside plant, filed a protest, claiming exemption from import duties because of GATT agreements (483). Oregon Metallurgical also protested, claiming that GSA should invoke the Buy American Act (484).

Contracts were let to one domestic and two foreign suppliers (485). Timet was awarded 1,000 tons at \$3.57/lb, while Philipp Brothers, acting as agent for Japanese producers, received 3,000 tons at \$3.20/lb. Billiton was awarded 500 tons at \$2.92/lb (486). However, RMI Company immediately filed a request for a temporary restraining order to block the sale, and a protest against GSA's actions based on several grounds (487, 488). In December, the injunction was denied (489). RMI's protest also accused Japanese producers of price collusion (490).

Near year end, RMI followed up its earlier protest with a dumping petition against Japanese and British producers, claiming they were selling at less than fair market value (491, 492). The action was supported by Oremet (493). It is interesting to note that, in an unrelated action, four European producers of Ti milled products pushed ahead with anti-dumping proceedings against U.S. and Japanese producers, who have captured 60% of the European market (494, 495).

Titanium Development Association.—The first official titanium association in the U.S. was established in December (496). An earlier meeting, organized by seven leading Ti companies, invited participation from 300 firms to form an organization to focus on "publicity, industry marketing, market and product development, statistics, and education" (497). The 71 active members of the TDA include producers, fabricators, extruders, distributors, and recyclers (498).

Zinc.—Production and prices.—While zinc markets were soft at the beginning of the year, a general upturn in the economy near year's end produced an upsurge in both prices and production plans.

In April, Kidd-Creek, banking on the market upturn, canceled late 1982 plans to close its zinc mine in Timmins, Ontario (499). The company announced that the plant would maintain full production throughout 1983. Cominco's Trail smelter and Kimberley mine in British Columbia were idled by a strike in June (500). On June 12, the strike ended, and resumption of the former production level of 260,000 short ton/yr of zinc was planned (501). As a reaction to continuing losses, Cominco announced that 1983 capital spending would be held to \$120 million, compared with \$230 million in 1982 and \$480 million in 1981. However, modernization of the Trail zinc plant continued.

Minera Mexico began marketing Special High Grade and Prime Western zinc in the U.S. in July (502). Full-scale shipments were expected by year's end. The Mexican electrolytic refinery, partially owned by ASARCO, has a 114,000 metric ton/yr capacity.

Inspiration Mines purchased three zinc mines in Tennessee from Gulf and Western's Natural Resources

Group in July (503). The mines had been shut down earlier by Gulf and Western. Production startup at the mines was targeted for January, 1984, following engineering feasibility studies. Gulf and Western announced that it was writing down its interest in its Natural Resources Group, including a wholly-owned mine in Friedensville, Pennsylvania, and two other Tennessee mines jointly owned with Union Miniere.

U.S. Steel's zinc mine in Jefferson City, Tennessee, reached full production in September, following a 10 month shutdown (504). The reopening of the mine, with a capacity of 36,000 ton/yr of concentrate, was based on a favorable labor contract settlement and improved market conditions. In December, St. Joe Resources Company increased the capacity and operating rate of its Monaca, Pennsylvania, zinc smelter and refinery by 15,000 ton/yr to 100,000 ton/yr (505). The capacity increase was made possible by a \$2.5 million plant modernization program.

Asarco announced a three-point program to enable it to restart the Corpus Christi zinc refinery, idled in October, 1982 (506). Sufficient zinc concentrates had been lined up from Asarco's operations in Tennessee, Mexico, and Canada. In addition, Asarco was attempting to negotiate a power rate of about 35 mill, compared to the current 60 mill rate. The last point involved negotiating a labor contract with a more economical work schedule and productivity rules. Talks were scheduled to begin in December.

At mid-year, U.S. zinc producers were all posting 40¢ prices for benchmark High-Grade zinc (507). Despite considerable uncertainty in the firmness of producer price quotes at that time, zinc prices began an upward movement for the rest of the year. Backed by strong U.S. Mint tender bid quotes and tight Special High Grade supplies, the price of zinc reached 49¢/lb in October, the highest price in two year (508).

Throughout much of the year, the European Economic Community debated a plan to move towards closing of 100,000 ton/yr of zinc capacity (499). The closure plan, submitted by six major companies, called for payments to companies which agreed to shut down plants without replacing closed capacity until 1986 (509). Under the plan, producers were allowed to modernize plants without increasing capacity. However, in November, the plan was informally abandoned as a general upturn in the economy, particularly in the U.S., increased demand and raised zinc prices by one-third over year-earlier levels (506). Because the plan was never formally approved, there is some doubt that it could be reactivated, even if producers wish to reconsider closure (510).

Domestic Zn production statistics (528) are shown in Table XXVII. Although domestic consumption of zinc increased in 1983, production declined slightly, as imports increased. The estimated world mine production and reserve base (511) is shown in Table XXVIII.

Demand.—U.S. zinc consumption showed a dramatic 12% increase in the first quarter of 1983, against a year earlier, to 188,000 tons (512). However, economic recovery was slower elsewhere, as European first-quarter consumption fell 1% to 399,000 tons and Japanese consumption rose only 1.7% to 176,000 tons. Smelter stocks of zinc began to decline markedly before mid-year, dropping from year-earlier levels by 30% in Europe and almost 25% elsewhere (513). Tight supplies of Special High Grade zinc in Japan, as North Korean zinc was diverted to China (514), led to

Table XXVII. Domestic zinc production statistics
(thousand metric tons Zn content)

	1982	1983 (est.)
Mine production	300	280
Primary slab zinc production	254	262
Zn metal exports	17	16
Zn ore and concentrate exports	77	55
Producer and consumer stocks, year end	106	90

Table XXVIII. World mine production and reserve base of zinc (thousand metric ton)

	Mine production		Reserve base
	1982	1983 (est.)	
United States	300	280	53,000
Australia	629	670	39,000
Canada	1,033	1,040	56,000
Mexico	232	245	8,000
Peru	541	575	12,000
Other market economy countries	1,878	1,950	90,000
Centrally planned economies	1,397	1,400	32,000
Total	6,010	6,160	290,000

importation from nontraditional sources, such as Spain, at premium prices (515).

By September, zinc supplies had improved, reducing the chances of "panic" buying by zinc alloyers, although premium prices were common (516). Supplies were tighter on the East and West Coasts than in the Midwest. Merchant zinc was available at producer prices, with little discounting.

Sixteen companies submitted bids for a U.S. Bureau of the Mint tender for up to 23 million lb of zinc (515). While other companies generally bid at or above the prevailing producer price of 43¢ per pound, New Jersey Zinc offered to sell 10 million lb at prices from 38.7¢ to 39.7¢/lb. There was evidence of the firming zinc market in October, as another 10 million lb BuMint tender prompted bids ranging from 46.4 to 51.4¢/lb, and some major producers, particularly in Canada, did not submit bids because of other supply commitments (517). A further 25 million lb Mint tender was made late in the year (518, 519).

Markets.—Optimism in the zinc market was fueled by growing use in coinage, construction, and other markets (520). The new U.S. penny, containing 97.4% zinc, was expected to consume 45,000 tons of zinc in 1983. Galvanizing remains the largest use of zinc, accounting for roughly one-half of total consumption (520, 521). The galvanizing market was predicted to increase 38% by 1985, to 521,000 ton/yr (521).

Two new galvanized products show promise. Galvalume, a coated steel sheet developed by Bethlehem Steel in 1978, has begun to attract interest in the construction industry (521). Galvalume contains 43.5% Zn, 55% Al, and 1.5% Si (522). Galfan, a galvanized coating with 95% zinc and 5% aluminum-mischmetal alloy, was developed by ILZRO to compete with the lower-zinc Galvalume (521, 522). Galfan has been licensed to 19 companies worldwide, including three in Japan (522). However, commercial production of Galfan has been limited, with none yet produced in North America (522). ILZRO has made getting an on-shore producer "a number one priority" (523).

Galvanized parts in automobiles also represent a fast growing market (524, 525). Auto industry usage of galvanized steel sheet and strip may increase from 1982's value of 1.25 million tons to 3 million tons by 1987 (523). members, gutters, and building parts are also being considered for galvanizing, in a drive to increase product lifetime and reduce maintenance cost (523). Other uses include highway guard rails and lights, waste-treatment plants, and utility transmission towers.

Galvanized parts in automobiles also represent a fast growing market (524, 525). Auto industry usage of galvanized steel sheet and strip may increase from 1982's value of 1.25 million tons to 3 million tons by 1987 (523). The average U.S. 1983 model car contained 273 lb of precoated steel in the form of one- or two-sided galvanized, or Zincrometal accounting for 5.34 lb/unit of zinc. Chrysler's new T-van, however, uses 1,012 lb of precoated steel per unit. Future auto industry goals, including no rust perforation for 10 yr and no cosmetic rust for 5 yr, indicate a growing trend towards precoated steel.

Further increasing the automotive market for zinc, Ford Motor Company's Lincoln-Mercury division was ex-

pected to replace plastic grilles on 1985 model Cougar cars with a full zinc diecast grille (526). The move was believed to be the first time in a decade that such a grille has been specified for any U.S. car. In recent years, considerable movement from zinc die castings to plastic had occurred in a drive to reduce automobile weight.

Of the major nonferrous metals, only zinc was expected to gain enough in consumption in 1984 to pull up its market (527). Improved prices and lower stocks were predicted if world consumption grows at the expected 5.4% rate. The total zinc supply was expected to remain in deficit or in balance for 5 yr longer (514). The major source of increased U.S. supplies will come from imports, with import market sharing reaching 70% by 1988. Brass and bronze requirements, accounting for about 14% of zinc usage, will grow at about 2%/yr, while diecasting needs will increase at 2.8%/yr, after sharp declines over the last 10 yr.

The Electric Industry

More electricity was generated in 1983 than in the preceding year, reflecting the general economic upturn which was underway by the second half of the year. At the same time, DOE Secretary Donald Hodel claimed that the U.S. was in a better energy position than in 1981 (529). The fourth National Energy Policy Plan shows that total energy efficiency has increased, U.S. resources are being developed more effectively, oil prices have declined, and U.S. dependence on foreign oil supplies has decreased.

However, the report, "The Future of Electric Power in America," based on a \$2.5 million study begun by the Reagan administration, warns of U.S. power shortages in the 1990's (530). The report cited the need to construct new power plants, to supply demand which is predicted to grow for the remainder of the century. Sources such as solar energy and cogeneration, together with conservation, were viewed as playing only a minor role in the nation's electricity future. Other forecasters were criticized for assuming that high energy prices have permanently reduced demand for electricity, which the study considered to be an increasingly popular energy form.

In contrast, the Industrial Electricity Consumers Resource Council told the Department of Energy it believes expected load growth can be met by planned generating capacity additions (530). Thus, while it is generally agreed that electricity use will increase, a consensus on the magnitude and type of effort required, and thus a comprehensive energy plan, continues to be elusive.

Power generation in the U.S. (531).—After plunging sharply in 1982, electricity generation increased in 1983. However, as Table XXIX shows, U.S. electricity generation was still below 1980 and 1981 values. Despite its unpopularity, nuclear electricity continued to increase, as did electricity from both coal and hydropower. Electricity from natural gas continued a downward trend extending over the last four years.

The fossil fuel mix used in electricity generation has changed markedly in the last decade. As shown in Table XXX, the use of coal has jumped 60% in the last decade, while oil usage has dropped by well over 50%, with most of the decrease occurring since 1979. Natural gas usage has fluctuated considerably, showing a less definite historical trend than either coal or oil.

Despite difficult times, the industry managed to add modestly to its generating capacity, as Table XXXI

Table XXIX. Electricity generated, by type of fuel (531) (billions of kWh)

Year	Nuclear	Coal	Oil	Gas	Total* (Hydro)

1980	569.5	420.2	3681.6
1981	596.8	351.1	3640.2
1982 (rev.)	593.7	249.8	3225.5
1983	625.2	245.5	2910.8

shows. Fifty percent of this increase was from nuclear plants, begun many years ago, which continue to come on stream. The bulk of the remaining increase came from steam generation plants. Capital expenditures for generation, transmission, distribution, and other requirements are shown in Table XXXII. Total expenditures were about the same as in 1982, and a similar level is expected in 1984.

Electric utility industry forecast (532).—In September, 1983, *Electrical World* released its 34th annual forecast for the electric utility industry. As the general economy improved and the recent dislocations in industry trends showed signs of abating, a healthy recovery was forecast. The assumptions used in earlier forecasts were examined, and, in some cases, revised.

A synopsis of some important points from the *Electrical World* forecast follows.

Electricity requirements, 1984-2000.—The U.S. economy is becoming more electrified as its direct dependence on fossil fuels declines. During the past decade, according to DOE Secretary Donald P. Hodel, while "use of all nonelectric forms of energy dropped by 15%, we increased our [use of] electricity by 20%." A forecast of electric utility sales for the remainder of the century is given in Table XXXIII (532).

Industrial electric usage is predicted to rise over the next few years, after the fluctuations of the late 1970's and early 1980's. Projections are shown in Table XXXIV (532). A transition in the industrial sector, from goods to services, is not expected to change the mix of utility energy sources. Electricity's percentage of total utility sales in the industrial sector should remain at 35%-40%.

Forecasts of electricity needs by the aluminum industry have been revised downward from earlier projections. It was concluded that there is little incentive for aluminum producers to develop additional domestic capacity, due to the rate of power cost increases and the availability of lower cost power in other countries.

Industrial self-generation has declined markedly for more than a decade, from 98 billion kWh in 1972 to an estimated 49 billion kWh in 1983. Beginning in the middle of this decade, a modest increase in industrial self-generation is expected, as shown in Table XXXIV.

Projections of consumer electricity use have been revised downward from earlier values, following a drop in 1983, despite an unusually hot summer. A trend towards energy saving appliances will slow demand growth, as consumers look for ways to lower their energy costs without disrupting their lifestyles. A gradual return of the housing market is predicted. As gas deregulation and the attendant price rises occur, the competitiveness of electric space heating will improve. However, other factors, politics, will restrain the number of electrically heated

homes added in the late 1980's and 1990's. Predicted residential electricity usage is given in Table XXXV.

During the remainder of the century, multiple-family dwellings will predominate over single-family dwellings. The electric heat pump will come to dominate the electric-heat housing market.

The predicted penetration of electric vehicles into the transportation market has been drastically revised downward for the remainder of the century. The forecast was cut from about 1 million units on the road in the year 2000 to only about 200,000. This resulted in a 5 million kWh reduction in the amount of electricity required. The lack of a serious effort by major manufacturers to push an electric vehicle, coupled with the lack of improvement in EV performance needed for broad consumer acceptance, were both factors in the downward revision.

In the commercial market, conservation and energy management will reduce electricity usage. However, greater office electrification, through communication and data handling growth, are expected to produce an overall positive growth.

Electricity peak-demand requirements are seen as increasing at an annual compound rate of about 3% for the next decade, and only slightly less thereafter. Growth will taper off to about 2.6% by 2000. This trend toward lower percentage growth arises from four major factors. First, conservation will increase in all market segments. Second, energy-intensive industries, such as aluminum production, will increasingly move abroad. Third, the rate of population growth will continue to decline. Finally, societal changes such as the shift of households from single family to smaller, multifamily residences will result in lower electricity requirements.

The main barrier to strong long-term growth of electric energy is its cost, which will probably rise at a rate slightly faster than general inflation.

Generating capacity.—Recent protests over "imprudent" construction of new capacity have added to the movement, already underway because of financial pressure, to cancel capacity additions.

Planned increases in the number of large coal-fired units, today still in the planning stages, will not alleviate shortages that may develop in several parts of the country later in this decade. Licensing each plant will take about 3 yr, and construction will take an additional 5 yr. In 1982, utilities placed no orders for major units. As a result, there will be very small capacity additions during the period 1987 to 1992, as only units already under construction are brought on line.

Insufficient reserve margins will develop in some regions. These will probably be alleviated by installing substantial quantities of combustion turbines.

The forecast for generating capacity additions is given in Table XXXVI. A forecast of annual capital expenditures by the electric utility industry is given in Table XXXVII.

Conventional fossil fuels.—The electric utility industry is faced with the prospect of massive capital expenditures to replace aging generation facilities. Money could be saved, however, if the operation of existing plants could be extended safely and economically. Toward that end, EPRI announced a 4 yr program to develop and test methods for extending the life of fossil fuel power plants by as much as 50% (533). The work will be funded by EPRI and carried out by project teams that will include turbine and boiler manufacturers, an engineering firm, and a host utility. Higher costs for money and equipment, uncertain demand growth, and difficulty in siting new

units have made extending the normal 35-40 yr plant life economically attractive.

The increased importance of coal as a fuel has led to new technical developments in coal combustion technology. Energy and Minerals Research Company in Exton,

Pennsylvania, has announced an ultrasonic coal grinder which blasts coal with sound waves, leading to stress fatigue and fracture into small, uniform particles (534). The primary motivation for developing the process was the huge amount of energy, some 29 billion kWh/yr, con-

sumed in the coal comminution industry. Saving 10% of the energy cost would represent \$150 million/yr in cost reduction.

A Limestone Injection Multistage Burner (LIMB) system was claimed by the Environmental Protection Agency to be the lowest-cost retrofit alternative for controlling both NO_x and SO_x emissions from coal plants (535). EPA's objectives are to achieve 50%-60% reductions of both SO_x and NO_x, from uncontrolled levels, on retrofit installations. On new systems, EPA is seeking reductions of 70%-80% in NO_x, and 70%-90% in SO_x. For both retrofit and new systems, EPA would like to

achieve those goals for at least \$100/kW less than flue-gas desulfurization. EPA will test several coals of different composition to determine if some are less likely to produce fly ash. The largest plant to use the LIMB technology thus far has been a 100 million BTU/hr unit.

Synthetic fuels.—The U.S. synfuels effort sputtered in 1983. Few synfuel projects now remain active, and are not expected to come close to the original national goal of 2 million bbl/day of synfuels by the early 1990's (536).

The barriers to synfuel development do not seem to involve the fundamental question of whether such develop-

ment must ultimately occur. Nor are technology, availability of capital, or future demand projections the problems. Bernard Lee, President of the Institute of Gas Technology, cites "institutional barriers" (536). Oil price is one such barrier, as the oil exporting countries attempted to peg prices below the break-even point for competing alternatives. However, an IGT study considered imported oil's effects, such as balance of trade effects on inflation on the economy, leading Lee to peg the real cost of imported oil at about \$75/bbl, rather than the market price of \$29.00.

Martin Roberts, Vice-President of Lehman Management, cited communication problems among groups that might contribute to a synfuels industry as another barrier (536). About 80% of western oil shale lies under public lands, and no firm plan has emerged for exploiting it. Also, recent oil price drops have proven that they are more elastic than formerly believed. This, according to Roberts, has reduced the sense of urgency in future energy planning, to the detriment of alternative resources. Environmental and socioeconomic problems have also been troublesome. Satisfying them can raise project costs from 40% to 100%, thus dampening investor interest. In the West, allocating scarce water to synfuel plants is a concern (536).

In many cases, especially in the West, the federal government not only controls mineral rights in leased areas, but has regulatory powers over water rights, and contributes to project subsidies. Roberts points to this as a difficult situation for private competitors to accept. Even under the best conditions, Roberts says, the investment community sees synfuels as essentially a regulated utility with marginal economics (536).

Government and industry have relegated synfuel development to limbo for another decade, or until another energy panic occurs, according to Rex Ellington of the University of Oklahoma (536). Ellington sees recent inflation, high interest rates, and eroded worker productivity as hampering the synfuel effort.

Ellington faults the present administration for encouraging unrestrained oil well drilling as a panacea for the country's oil problems, although the approach has not kept reserves and production from declining. Congress was also criticized for deserting synfuels by shying away from price supports and tax breaks. Finally, industry was

seen as being too single-minded on one line of thought for future development (536).

As a way of restoring synfuel development, Ellington suggests a "beachhead philosophy," involving development of a small technical beachhead, which could be expanded rapidly as required (536).

"World Production of Synthetic Fuels: A Realistic Assessment," a report prepared for *The Economist*, projects a generally bleak outlook, with some bright spots, for worldwide synfuel development (537). The report, based on information gathered from 500 synfuels projects, predicted world synfuel production of about 653,000 bbl/day by 1990. The outlook for coal-based synfuels from liquefaction and gasification was pessimistic. More than 800,000 bbl/day (oil equivalent) of coal gasification projects were canceled in 1982. Abandonment of their Colony oil shale project by Exxon and Tosco last year hurt the investment climate. The report projects a worldwide shale oil production range of 75,000-392,000 bbl/day by 1990, the upper figure based on completion of all projects now under construction. Tar sand and heavy oil recovery looks promising. World production, according to the report, could reach 323,000 bbl/day by 1990.

The third solicitation for synfuels proposals by the U.S. Synthetic Fuels Corporation attracted 46 proposals for loan guarantees, price supports, and other aid (538). Seventeen of the proposals were for new projects; the remainder were resubmissions. Of the projects, 10 were for coal liquefaction plants, nine for coal gasification, 13 for oil shale, and 11 for tar sands.

In May, Senator Pete Domenici (R-NM) introduced a bill to provide significant tax benefits for synfuels projects (539). The bill would extend the qualification deadline for a 10% energy tax credit, which expired on January 1, 1983, to June, 1987.

The value of tax incentives was underscored at a Senate hearing when a Kidder, Peabody, and Company official accused the federal government of being a "fickle partner" (537). Joseph Schell told the Senate Finance Energy Subcommittee that federal tax laws were a better stimulus than Synfuels Corporation loan-and-price guarantees.

A call for increased government assistance came from the National Research Council, which proposed that the United States should initiate a national research and development test fuels program (540). NRC suggested that

the program, which would be administered by the Defense Department, should include a process development-scale refinery. The report committee noted that the past 10 yr of synfuel development have not produced any currently profitable options, and concluded, "there is an urgent need for stronger leadership and commitment by the federal government in recognition of the increasing importance of this issue to future national security."

The Environmental Policy Institute, however, criticized the federal synfuels program, concluding in a report that proposed projects will not make a significant contribution to the nation's energy security (541). Technical reliability and cost-efficiency problems were cited. EPI concluded that energy conservation, fuel switching, and increased domestic oil and gas production have been much more effective. EPI contends that the synfuel industry is not ready for commercialization and cannot exist without huge federal subsidies.

Coal gasification.—The coal gasification outlook, already clouded by earlier project cutbacks, was further dimmed in 1983. The Department of Energy, in an interim report to Congress, said that it sees "no significant U.S. market for coal gasification processes" (542). There is doubt that the BI-GAS coal gasification pilot plant in Homer, Pennsylvania, will be converted to a national gasification test facility, as Congress had suggested earlier.

The Board of Directors of the U.S. Synthetic Fuels Corporation, responding to a request from sponsors of the Great Plains coal gasification project, voted against giving additional financial aid to the project (543). The corporation's analysis found that no financial crisis of the project was likely until 1988.

Despite the pessimistic scenario, a number of efforts forged ahead. The Gas Research Institute plans to spend \$7.6 million on coal gasification research in 1984, to complement \$9.5 million in federal spending and \$4.0 million from industry (537). GRI projects that coal gasification production will reach 0.3 quadrillion BTU by 1990, and 0.6 quadrillion BTU by 2000. Over the next five years, GRI plans to spend \$61.5 million on coal gasification research and development.

The Allis-Chalmers KilnGas coal gasifier, at its Woods River Project in Illinois, was tested for a four day run in June (537). No significant problems were encountered. In further tests, the plant will reach its full 600 ton/day capacity, with the low BTU product gas used in an Illinois power company's 50 MW boiler on site. The \$155 million project is sponsored by 12 utilities, the state of Illinois, EPRI, and Allis-Chalmers. In August, Allis-Chalmers began processing Illinois no. 6 high sulfur coal at Woods River (541).

Lurgi announced that it had developed a new system to allow its commercial coal gasifier to accept coal fines (544). The Lurgi gasifier, the most successful commercial system, has been combined with a circulating fluidized bed reactor and a gas liquor evaporation system to form an integral coal gasification plant. The Lurgi system will accept up to 40% coal fines, and produces substantially less waste liquor than a conventional Lurgi SNG plant.

Exxon has operated a 1 ton/day gasifier demonstration unit at its Baytown facility since 1979. The process accomplishes gasification and methanation in a large fluid bed gasifier. Development has now reached a stage where the final step is to scale up to commercial size (545).

Coal liquefaction.—A marketing and pricing study indicated that, despite recent difficulties, the total market for coal liquids could reach 226,000 bbl/day by the late 1990's (540). The analysis projected that six to ten large plants, with capacities of 25,000-40,000 bbl/day and nine to nineteen smaller plants in the range of 1000 bbl/day capacity will be built by the end of the century. However, it was cautioned that tough air pollution standards could have a serious adverse impact on the coal liquids business.

According to Emil Parente of Fluor Engineers, coal-derived liquids can be produced at a price competitive

with crude oil, but only if a number of criteria are met (545). These include: a liquid methanol product slate; lignite as the coal feedstock; indirect liquefaction technology; coproduction of a natural gas substitute; and a plant location on the Gulf Coast.

DOE's Pittsburgh Energy Technology Center, citing a need for new ideas on liquefaction, issued a solicitation for proposals (544), anticipating receipt of proposals for bench-scale research on new approaches or innovations on existing ideas. Earlier, DOE awarded \$7 million to 27 university and three industrial laboratories to study coal behavior during combustion, liquefaction, and gasification (546). Meanwhile, using lignin, high yields of liquefied coal were obtained at lower-than-normal temperatures, at the University of Connecticut (547). In the presence of lignin and an acid catalyst, yields of 19%-43% were obtained at 300°C. Without lignin, only about 5% conversion was obtained. Liquefaction reactions are usually run at temperatures above 400°C.

The Electric Power Research Institute contracted C-E Lummus to "screen and identify promising two-step liquefaction configurations" (542). The results of the Lumus study will be compared with one-step liquefaction processes.

Despite refusal of its project financing application by the Synthetic Fuels Corporation, A-C Valley Corporation decided to continue its Scrubgrass coal-to-gasoline project in Pennsylvania (542).

Many of the important developments in coal liquefaction during 1983 involved development of coal-water fuel (548). Occidental Research Corporation announced that it would enter a joint venture to produce a coal-water fuel. COM Energy, an Occidental subsidiary in Jacksonville, Florida, with a 15 ton/hr coal-oil facility, will be converted to coal-water production, with an initial capacity of 2000 bbl/day. Occidental and others believe that coal-water mixture can be produced for about \$3.30 per million BTU in commercial quantities.

Sohio also entered the coal-water mixture (CWM) business, purchasing Advanced Fuels Technologies from Gulf and Western (549). Formed in 1980, AFT has produced more than 500 tons of CWM in a 1 ton/hr pilot plant in Bridgeport, Connecticut. Using AFT's technology, Sohio will build a 50 ton/hr demonstration plant.

Several other coal-liquid ventures have been announced recently (548). These include joint efforts by Allis-Chalmers and Fluidcarbon International AB of Sweden, Foster-Wheeler Corporation and A. B. Carbogel of Sweden, and Babcock and Wilcox, Ashland Oil Incorporated, and Slurrytech, Incorporated. Electric Fuels Corporation of St. Petersburg acquired Comco, which has been producing a coal-oil mixture for Florida Power Corporation.

Oil Shale and tar sands.—In November, the Synthetic Fuels Corporation was considering four oil shale projects for future funding (544). Geokinetics, Incorporated was requesting \$50-\$100 million in loan and price guarantees for its \$30 million, 1000 bbl/day Seep Ridge project in Utah. Also under consideration was the 14,100 bbl/day Paraho-Ute project involving Paraho, Sohio, Texas Eastern, Signal Cos., and Raymond International. Union Oil's Phase II 20,000 bbl/day expansion of Parachute Creek, Colorado, was regarded as politically volatile because of Union's prior \$400 million in DOE aid. The final entry was the 16,500 bbl/day plant in White River, Utah, sponsored by Phillips, Sunoco, and Sohio.

Oil production for 1983 by Syn-Crude, the largest oil sands plant in the world, was estimated at 35-40 million barrels (540). Syn-Crude Canada, Ltd. can now produce 109,000 bbl/day, and announced a \$1.2 billion expansion program to increase production by about 20,000 bbl/day.

A new heavy oil and tar sands recovery process was successfully tested over a 2-3 yr period by James Wade Engineering, Limited of Toronto (549). Five Canadian and two or three U.S. oil companies have expressed interest in the process. Bitech of Toronto and Wade hope to con-

struct a 1000 bbl/day test pilot plant next year to process heavy oils and then tar sands.

Nuclear generation.—The nuclear power industry has been beset by numerous problems in recent years. Rapidly escalating plant costs and the long lead time for design, approvals, licensing, and construction have made it difficult to bring new plants on line. The lack of a satisfactory solution to the waste disposal problem and recent events such as the Three Mile Island malfunction have generated adverse publicity and stiffened public resistance.

To regain public acceptance and investor confidence, the industry must sustain an unblemished safety record in the future, according to Nunzio Palladino, chairman of the Nuclear Regulatory Commission (550). According to Palladino, time is the ally of the nuclear industry, provided that there are no episodes such as what happened at Three Mile Island in the future. Acknowledging that the future of the industry ultimately will be decided by the public and its elected representatives, Palladino called for a balanced relationship among the utilities, regulators, legislators, courts, and the general public.

Early in 1983, the Nuclear Regulatory Commission proposed new nuclear plant safety goals (551). The goals will be reviewed for two years before becoming final. However, NRC's Advisory Committee on Reactor Safeguards faulted the proposed guidelines for excluding a statement that social risks ought to be "as low as is reasonably achievable," and for failing to consider long-term health effects on individuals.

NRC also approved a package of legislative changes for consideration by Congress (552). The requested changes include allowing NRC to grant advance approval to standardized reactor designs and possible sites for future plants. The number of issues that could be raised at licensing hearings for new plants would also be limited, and administrative judges presiding over the hearings would be prevented from raising their own questions on potential safety problems.

Hans Bethe of Cornell University, speaking for Scientists and Engineers for Secure Energy, criticized the NRC's adversarial approach and called for a simplification of governmental regulations (553). Procedural and legislative aspects of the nuclear regulatory process, according to Bethe, have expanded to overshadow technical matters.

In April, the Supreme Court provided both good and bad news to the nuclear industry (554). The court unanimously ruled against a citizen's group challenge to NRC's decision not to consider their concerns in deciding whether to restart the undamaged reactor at Three Mile Island. In a second case, however, the court unanimously upheld a California law imposing a moratorium on new nuclear plant construction until the federal government has developed and approved a technology for permanently disposing of nuclear wastes.

After a three-month trial, a suit involving General Public Utilities, operator of the Three Mile Island reactor damaged in 1979, and Babcock and Wilcox, the reactor manufacturer, was settled out of court (555). Under the agreement, GPU will receive \$37 million, while both parties agreed that "neither has established the other as the cause" of the accident. The settlement, in the form of rebates on Babcock and Wilcox services, will be used to clean up the reactor.

Metropolitan Edison, owner of the Three Mile Island Power Plant, was charged by a federal grand jury in Harrisburg, Pennsylvania, with manipulating and falsifying test results on radiation leaks from the plant's cooling system (556). According to the charges, the company lied about leak rate data during the period immediately before the accident in order to avoid plant closure.

As a result of the introduction of new, capital-intensive nuclear plants, residential electric rates are projected to rise sharply in the 1980's and early 1990's (557). The enormous capital cost of nuclear plants now coming into ser-

vice has not, in general, been absorbed into utility rate bases during construction. The capitalization of a large nuclear plant can equal or exceed the previous capitalization of a utility. In the case of the Long Island Lighting Company, protests have already arisen over the possibility of a 50% rate increase attributable to its Shoreham Plant.

Despite the many problems, an increasing fraction of the world's electricity is supplied by nuclear energy. The International Energy Agency, noting that 21 nuclear reactors were hooked into electricity grids during 1982, says that about 10% of the world's electricity is obtained from nuclear reactors (558).

An engineering demonstration of a wet chemistry process produced 10 kg of high purity uranium oxide from scrap nuclear fuel (559). The recycling process, first developed ten years ago by General Electric, was demonstrated by Westinghouse Hanford, in Richland, Washington.

Breeder reactor (560).—After keeping the Clinch River Breeder Reactor project alive for several years, the Senate voted to delete \$1.5 billion in funds, earmarked for the project, from the fiscal 1984 supplemental appropriations bill. The House did not even consider Clinch River funding. Cost overruns have plagued the project. Initial 1971 cost estimates of \$400 million for the reactor have now ballooned to \$4.5 billion. DOE, expressing disappointment, will begin an orderly phase-out of the project, which has cost \$1.7 billion to date.

Fusion.—In tests at the Massachusetts Institute of Technology, the fusion energy break-even point was exceeded for the first time (556). The experiment reached a temperature of about 17×10^6 °C and an energy confinement time of about 50 ms. Self-sustaining fusion reactions will require a temperature of about 2×10^8 °C. The reaction will produce large quantities of high velocity neutrons, posing materials problems that remain to be overcome.

A Center For Fusion Engineering will be established at the University of Texas at Austin (551). Two other organizations engaged in fusion research have already been established at the University. The three units will be able to address experimental, theoretical, and engineering problems of thermonuclear fusion.

Fuel cells (561).—According to Graham Hagey, DOE's fuel cell program manager, the first commercial prototype fuel cells should be available by about 1986. Commercialization is the result of more than 20 yr of work, and several hundred million dollars in expenditures by government and private industry. During the 1983 fiscal year, total U.S. spending on fuel cell development was estimated at about \$100 million.

Under a program sponsored by the Gas Research Institute, DOE, 21 U.S. gas utilities and two Japanese utilities, 49 new 40 kW fuel cell plants are planned. All will use phosphoric acid cells developed by United Technologies Corporation.

Westinghouse is developing two 7.5 MW plants with air-cooled phosphoric acid cells, incorporating work by Energy Research Corporation. Inglehard Industries has tested a 5 MW methanol-air integrated phosphoric acid system. Japan, under the direction of MITI, has a national research and development program for phosphoric acid, molten carbonate, alkaline, and solid oxide fuel cells. The initial goal is to operate a 1 MW phosphoric acid demonstration unit in 1986.

A major near-term task in phosphoric acid technology development is to lower the present cost, approximately \$4000/kW. In comparison, a coal-fired power plant costs \$1450-1700/kW. EPRI hopes to reach an installed cost of \$600-\$700/kW (1981 dollars) by the end of the decade, by increasing operating temperature and pressure, and through commercial volume manufacturing economies. A Con-Edison spokesman indicated that a commercial fuel cell cost of around \$1000/kW could open up a potential utility market of thousands of megawatts.

Three current studies sponsored by EPRI and three utilities are examining coal gasification coupled with fuel cells. The molten carbonate fuel cells are about 45% efficient for electricity production, and produce high grade heat. Commercialization, however, is several years behind acid cells, the largest test so far being a 2 kW cell stack run by United Technologies. A 10 kW demonstration unit was reported to be scheduled for 1983.

Solar energy conversion.—Using a technology developed by Stanford Ovshinsky of Energy Conversion Devices, production of amorphous solar cells has begun in Japan (562). In a continuous roll-to-roll process, amorphous silicon is deposited onto stainless steel sheets. Production is being carried out by Sharp-ECD Solar, Incorporated, which is a joint venture between Japan's Sharp, Incorporated, and Standard Oil (Ohio), which has invested in ECD. Sharp plans to use the amorphous material in solar-powered calculators while ECD will use 1000 ft rolls for field testing of large-scale devices in the U.S.

The world's largest solar electric generating station was begun at a Mojave Desert site belonging to Southern California Edison Company (563). A joint venture of Edison with Luz International Limited, the generating station will use 560 line-focus parabolic trough reflectors to heat fluid circulating through the system. The first 13 MW phase of the planned 43 MW generating plant is expected to begin producing power for Edison customers in late 1984.

At Sandi National Laboratories, the first U.S. solar central receiver to use molten salt in an electricity generator system began operation (563). The molten salt is a 60/40 mixture of sodium nitrate and potassium nitrate. It is used to transfer heat to a water supply, making steam to drive a turboelectric generator. Prototype system testing will continue through the spring of 1984. Full capacity operation will provide 750 kW of electricity, enough for 200-300 typical homes.

A new photoelectrochemical cell uses silicon electrodes, and is capable of storing the generated electricity (564). The cell, developed at the Amoco research center in Naperville, Illinois, has produced a 12% conversion efficiency and a 0.59V output. Operating lifetimes have been increased from minutes to weeks. The lifetime of the cell has been extended by coating the silicon electrodes with a few angstroms of platinum to reduce corrosion. Efficiency increases were obtained by using a doped oxide layer, containing alumina or magnesia, on the silicon surface just below the Pt coating.

Nonaqueous electrolyte photoelectrochemical cells, using gallium arsenide phosphide photanodes, have produced 13.2% efficiency (565). The cells were developed at Stanford University. Providing that water is excluded from the cell, the photoanode is apparently stable. Another Stanford-developed cell uses an n-type silicon photoanode that operates at 10.1% efficiency. The Stanford cells have the highest efficiencies reported to date for nonaqueous cells, which commonly operate at only 1%-2% efficiency.

The Texas Instruments Solar Energy System (TISES) is the only reported commercial photoelectrochemical program. The novel photoelectrodes begin with the production of 0.25-0.4 mm diam silicon microspheres. In a faster, improved production method, TI drops molten silicon onto a rapidly spinning disk, which throws off the small droplets. When illuminated, the cells produce hydrogen at the cathode and bromine at the anode. Conversion efficiencies as high as 13% have been produced. The system also provides low grade thermal heat. Overall (electrical plus thermal) system efficiency is about 7%. TI hopes to increase that efficiency to 8-10% before the system is commercialized, possibly as soon as 1990 (566).

Environmental issues.—Acid rain.—The problem of acid rain, a major environmental issue, became highly politicized in 1983. Friction developed within the U.S., as regional disputes arose over the origin, magnitude, and resolution of the problem. On a larger scale, the problem

developed international overtones, especially between the U.S. and Canada. With the approach of a presidential election year in 1984, the question of acid rain became a campaign issue.

U.S. Senator Gary Hart (D-CO), a candidate for the Democratic presidential nomination, accused the U.S. government of ducking the acid rain issue (567). "There has been much better willingness on the Canadian side to discuss the common problem, to lay out some kind of time frame . . . than we have seen from the American administration," Hart said. According to Hart, it would take a decade to achieve his goal of a 50% emission reduction. Hart quantified the acid rain problem, claiming that it currently costs the U.S. \$5 billion per year.

The National Clean Air Coalition, composed of 12 environmental and labor groups, plus the League of Women Voters, called on the Reagan administration to push a tough acid rain control program (568). The request was made in a letter to the President, after EPA head William Ruckelshaus admitted that a revised acid rain policy was being delayed by sharp differences within the administration (569).

In November, the 27-member New England congressional caucus proposed a program for comprehensive acid rain control legislation (570). The bipartisan bill proposed a 50% reduction in sulfur dioxide emissions, an estimated 12 million tons, by 1993. The proposal would spread the costs of cleanup among electric consumers in the 48 contiguous states. Consumers would pay a surcharge of \$0.75-\$1.50 per month on electricity bills. The move thrust acid rain into the New England states as a major campaign issue.

The issue was especially sharply focused in New Hampshire, where a citizen's task force got the acid rain question onto municipal ballot forms (571). Voters responded overwhelmingly in favor of cutting emissions.

The results of a Louis Harris poll, taken nationwide, showed that 90% of those surveyed felt that acid rain was a serious problem (572). More than 60% favored installing air pollution scrubbers on dirty industries, such as power plants, and 70% would pay \$100 per year in taxes for pollution control. From 63% to 68% of those polled felt that U.S. governments and industries were not doing enough to combat pollution. However, in states which figure to be hard hit by the required cleanup, a different opinion emerged. In Ohio, where pollution limits are often equated with loss of jobs, a survey commissioned by Ohio Edison Company revealed that 65% of Ohioans favored improving the economy at the expense of the environment (573). Only 19% favored the environment at the expense of jobs.

In Canada, the public response to a Gallup poll was decisive (574). Of those polled, 86% favored restrictions to reduce acid rain. Only 6% opposed such restrictions.

The U.S. and Canadian Chambers of Commerce issued a joint statement in December outlining a unified program for dealing with acid rain (575). The first step would involve charting emission reductions that could be expected from full implementation of clean air laws in both countries. If these emission reductions were insufficient, the groups recommended developing a cost-effective control plan with positive economic incentives. The incentives would include accelerated depreciation and write-off of unadaptable, old plants.

Despite intensifying pressure, the Reagan administration remained split over the acid rain issue through the year. All of the cleanup strategies pose problems (576). Putting the cleanup burden on utilities emitting the most pollution would, according to utility industry groups, raise electric bills by as much as 50% (576). Environmental groups, however, claim the actual costs are far lower, i.e., 2.5%-10%. Spreading costs nationwide is unacceptable in the West, where the problem is perceived to be less serious.

At the year end, EPA's Ruckelshaus believed that the administration had only a few weeks to decide on an approach to the acid rain problem (577). Ruckelshaus antic-

ipated the need to testify before Congress when it returned to session in January of 1984. Still, Canadian Ambassador Alan Gotlieb estimated the chances of a U.S. policy announcement before the presidential election at less than 50%, and felt that any new policy would not go as far as Canada wants (578).

In Canada, Milan Nastich, chairman of Ontario Hydro, advocated use of nuclear power, rather than scrubbed coal power, as the better solution to acid rain (579). In 1981, Ontario Hydro pledged to cut acid gas emissions to 300,000 ton/yr within a decade. According to Nastich, Ontario Hydro continues to follow through on its program. A series of mishaps, resulting in Ontario Hydro nuclear plant shutdowns during the summer, put an additional 18,000 tons of sulfur dioxide into the atmosphere (580). An additional 10,000 tons was expected if the Pickering 2 nuclear generator remained shutdown through November for repairs.

In addition to electric generation plants, many of Canada's acid rain sources are related to the mining industry. The Canadian Coalition on Acid Rain proposed that Inco Limited and Canadian taxpayers should spend up to \$525 million to reduce pollution from Inco's Sudbury smelter (581). The coalition called for an 86% reduction in Inco's allowable sulfur dioxide release, from 1997 ton/day to 274 ton/day (582). The statement was backed by the United Steelworkers of America, representing Inco workers, who advocated tax breaks or low cost loans to the financially pressed nickel producer (583).

Behind the political and economic issues, fundamental questions remain on the nature of the problem itself. In the eastern U.S., man-made SO₂ and NO_x emission are 50 to 100 times higher than natural ones (584). The 20 largest coal-fired plants are claimed to account for 20%-25% of all sulfur dioxide emissions in the region (584), yet much of the acid rain problem is not caused locally. Recent studies indicate that the Midwest is the major contributor to acid rain damage in the eastern U.S. and Canada (585). Canadian SO₂ sources, although large, appear to be less significant contributors to the problem in that region, because of prevailing air patterns. When Inco's smelter, Canada's SO₂ source, was shut down, only a slight drop in air pollution occurred (585).

While the acid rain problem is widely acknowledged, some uncertainties persist. Perhaps the best U.S. records on the subject were made in New York State from 1965 to 1975, by the U.S. Geographical Survey (586). No trend in acidification was discerned. Swedish scientists, who have studied the problem longer, likewise have found no trend (586). Richard Funkhouser, former director of the EPA's Office of International Activities, called for more scientific study to clarify the problem before enormous expenditures are made for clean-up (586).

CO₂/climate (587).—Carbon dioxide, a "greenhouse" gas, absorbs little of the shortwave insolation spectrum. It does, however, absorb infrared radiation from the Earth's surface and atmosphere. As a result, increasing atmospheric concentration of CO₂, arising primarily from fossil fuels, could lead to a warmer climate.

A two-year study by the National Research Council concluded that atmospheric CO₂ will most likely double from present levels to 600 ppm late in the next century. The average world temperature increase will be 1.5°-4.5°C, with the lower half of the range more probable. A sea level rise of about 70 cm/century, compared with the current 10-20 cm/century, could occur as a result of ice melting and thermal expansion of the oceans.

However, the study also questioned whether CO₂ should be the central issue, rather than the climate change itself. Over the timespan considered, there may be changes in climate not resulting from human activity. In addition, other greenhouse gases, such as chlorofluorocarbons and nitrous oxide, could have significant effects.

A similar report, more sharply focused, was issued by the EPA. The report addressed the issue of whether specific policies, to limit fossil fuel use, would delay tem-

perature increases over the next 120 yr. Using a "best guess" baseline scenario, atmospheric CO₂ levels of 590 ppm were predicted by 2060. Associated with the CO₂ increase was a temperature rise of 2°C by around 2040, and about 5°C by 2100.

The study applied various policy alternatives to the baseline scenario to determine their effects, finding that only one significantly postponed a 2°C warming. A ban on coal, instituted by 2000, which the study concluded was not feasible, would delay the 2°C temperature rise until 2055. Banning both coal and shale oil would delay it an additional 10 yr.

The EPA study pointed towards three areas of future work, continuing the \$80 million already spent by federal agencies on the CO₂ problem. Research on improving the ability to adapt to a warmer climate should be accelerated. Effects of greenhouse gases other than CO₂ should be determined. Also, uncertainty about the thermal sensitivity of the atmosphere needs to be reduced.

Binary and Ternary Diffusion Experiments in Fe_3O_4 , Mn_3O_4 , and Al_2O_3

Peggy A. Barron

Department of Metallurgical Engineering and Materials Science, Carnegie Institute of Technology, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

(1983 F. M. Becket Memorial Award Report)

In a binary system, when two solids are placed in planar contact at a fixed temperature and pressure, the Gibbs-phase rule states that there are zero degrees of freedom and therefore the boundary must remain planar. In a ternary system, when two solids are placed in planar contact under the same conditions, there is one degree of freedom remaining, and, therefore, different growth morphologies may result (1). Presently of interest is the parameter controlling this additional degree of freedom. One might expect the faster growing phase to select a morphology that would give a large growth area. In this case, the diffusion coefficients of the system may aid in predicting the morphology.

Schmalzried and Köhne (Institut für Physikalische und Elektrochemie, Technische Universität Hannover, Hannover, Germany) are currently investigating this possibility in ternary oxide systems. To observe the effect of the diffusion coefficients on the growth morphologies, it would be necessary to choose systems in which the diffusion rates are very similar, very different, and intermediate, and then compare the reaction interfaces for each type of system. Due to the lack of diffusion data available on oxides, many combinations must be investigated in order to find acceptable systems. Since diffusion coefficients in oxides generally change rapidly with composition, it may be possible to find a single system in which the diffusion coefficients vary with composition in the manner described above.

The purpose of this investigation is to calculate the interdiffusion coefficients in the Fe_3O_4 - Al_2O_3 and Mn_3O_4 - Al_2O_3 binary systems and plot the composition paths in the Fe_3O_4 - Mn_3O_4 - Al_2O_3 ternary system. The ternary diffusion experiments only include coupling the Al_2O_3 corner with Fe_3O_4 - Mn_3O_4 binary. The diffusion paths connecting the Fe_3O_4 - Al_2O_3 and Mn_3O_4 - Al_2O_3 binaries will be plotted later. The ternary diffusion coefficients may then be calculated using the proper assumptions for the ionic nature of the oxides.

Experimental Procedure

Diffusion couples were prepared with Al_2O_3 and mixtures of Fe_3O_4 and Mn_3O_4 . Due to the small solubilities of Fe_3O_4 and Mn_3O_4 in Al_2O_3 , (2, 3) a pure Al_2O_3 single crystal was used for the ternary as well as the binary diffusion couples. A single crystal of Fe_3O_4 was used in the Fe_3O_4 - Al_2O_3 diffusion couple. Sample preparation of the single crystals included cutting to size (avg $2 \times 5 \times 10$ mm) and polishing. The Al_2O_3 single-crystal samples were polished to $40 \mu\text{m}$ on the contact side and also the opposite side to ensure planar contact in the diffusion couple. The Fe_3O_4 single-crystal samples were polished to $3 \mu\text{m}$ on the contact side and $40 \mu\text{m}$ on the opposite side.

A single crystal of Mn_3O_4 could not be easily obtained; therefore, a sample prepared from Mn_3O_4 powder was used for the Al_2O_3 - Mn_3O_4 diffusion couple. The mixtures

for the ternary diffusion couples were also prepared from powders of the oxides.

The oxide powders were sintered separately at 1420°C in air. These powders were mixed in a ball mill in weight ratios (Fe_3O_4 : Mn_3O_4) of 85:15, 60:40, 40:60, and 20:80. The powder was cold-pressed, with the resulting pellets having densities 40% to 60% of the theoretical densities of the mixtures. The cold-pressed pellets were then enveloped in platinum foil, placed in a graphite matrix, and hot-pressed at 1000°C under a 300 kg load. The hot pressed pellets were 1 cm in diameter and 3-5 mm high with densities of 91% to 99% of the theoretical densities. The pellets were sintered at 1400°C in air for 24h. However, the pure Mn_3O_4 pellets were not sintered because a phase transition caused them to crumble. This phase transition occurred during the diffusion experiment, but due to the pressure applied to maintain contact between the oxides, only cracks appeared in the sample. After sintering, the pellets were cut to size and polished to $3 \mu\text{m}$ on the contact side and $40 \mu\text{m}$ on the opposite side.

The samples were washed in acetone and placed in the diffusion couple as shown in Fig. 1. The diffusion couple was then placed in the furnace at 1400°C in air. The ternary mixtures were allowed to react for 24h and the binary reactions were carried out for approximately 22 and 44h. After cooling rapidly in air, the samples were mounted perpendicular to the reaction plane. Often, the platinum foil and alumina slides could not be easily removed and were also mounted. The samples were polished to $1 \mu\text{m}$, and examined in an electron microscope. Finally, concentration profiles were measured using electron microprobe analysis.

Results of Ternary Diffusion Experiments

The results from the electron microprobe analysis were the x-ray counting rates of the various elements present at each point in the sample. The counting rates were converted to mass fraction and then mole fraction of the cat-

Fig. 1. Diffusion couple assembly

ions in the oxides according to the equations in the Appendix. It was assumed that the cations moved on a fixed oxygen lattice, that is, that the oxygen concentration at all points in the sample remained constant. Throughout the samples, there were many instances in which the sum of the cation mole fractions was greater or less than one. Therefore, this assumption, which provided the basis for the cation mole fraction calculation, proved to be inaccurate.

Ideally, when the three cation mole fractions are plotted on the Gibbs triangle, the result is a single path because the sum of the cation mole fractions should be one. However, there are usually small variations, and the points in the path are small triangles with each side representing a cation mole fraction. In these experiments, the variations were so large that these triangles would have rendered the diagram unintelligible. To avoid this, the iron and manganese mole fractions were plotted as a function of the aluminum mole fraction. In all the diagrams, the concentration profiles in the alumina were plotted as a point on the Al_2O_3 corner of the diagram because Fe_3O_4 and Mn_3O_4 have very small solubilities in Al_2O_3 .

The composition paths plotted on the Gibbs triangle are shown in Fig. 2-5. In all these diagrams, the path to the left represents the manganese mole fraction, and the one to the right is the iron mole fraction. As can be seen, the different mixtures produced very different paths. In Fig. 2, the manganese mole fraction appears fairly constant, and the iron mole fraction seems to vary linearly as a function of the aluminum mole fraction. In Fig. 3, the

Fig. 2. Cation mole fraction, $(\text{Fe}_{0.85}\text{Mn}_{0.15})_3\text{O}_4\text{-Al}_2\text{O}_3$

Fig. 3. Cation mole fraction, $(\text{Fe}_{0.6}\text{Mn}_{0.4})_3\text{O}_4\text{-Al}_2\text{O}_3$

Fig. 4. Cation mole fraction, $(\text{Fe}_{0.4}\text{Mn}_{0.6})_3\text{O}_4\text{-Al}_2\text{O}_3$

Fig. 5. Cation mole fraction, $(\text{Fe}_{0.2}\text{Mn}_{0.8})_3\text{O}_4\text{-Al}_2\text{O}_3$

manganese mole fraction is erratic except in the region between $X_{\text{Al}} = 0.2$ and $X_{\text{Al}} = 0.4$, in which it is nearly constant. Again, the iron mole fraction appears to vary linearly with the aluminum mole fraction. In Fig 4, the manganese and iron mole fractions seem to vary linearly over the entire range and from $X_{\text{Al}} = 0.1$ to $X_{\text{Al}} = 0.4$, respectively. The iron mole fraction also appears to remain almost constant from $X_{\text{Al}} = 0.4$ to $X_{\text{Al}} = 0.55$. In Fig. 5, the manganese and iron mole fractions are fairly regular and could be considered to be linear in different aluminum mole fraction ranges.

Figures 6-8 are representative electron micrographs of the ternary diffusion couples in the region of the phase boundary. The dark phase is Al_2O_3 , and the light phase is $(\text{Fe}_x\text{Mn}_{1-x})_3\text{O}_4$. The magnification is $400\times$. In the progression of micrographs, one can see the effect of the compositional variations on the phase boundary. The diffusion couples with higher iron contents developed less planar boundaries and more mixed precipitates in the diffusion region (dark areas in the light phase). In addition, there are very angular regions along these boundaries, possibly indicating a crystallographic relationship.

Results of Binary Diffusion Experiments

The raw data obtained from the electron microprobe analysis was the same as in the ternary experiments. The x-ray counting rates were converted using the same methods as described in the Appendix. Figures 9 and 10 show the aluminum mole fractions for $\text{Fe}_3\text{O}_4\text{-Al}_2\text{O}_3$ and $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$ diffusion couples, respectively, as a function of dis-

Fig. 6. $(\text{Fe}_{0.2}\text{Mn}_{0.8})_3\text{O}_4\text{-Al}_2\text{O}_3$ Fig. 7. $(\text{Fe}_{0.6}\text{Mn}_{0.4})_3\text{O}_4\text{-Al}_2\text{O}_3$ Fig. 8. $(\text{Fe}_{0.85}\text{Mn}_{0.15})_3\text{O}_4\text{-Al}_2\text{O}_3$

tance. The origin of the coordinate system is arbitrary because the chosen method of calculating the interdiffusion coefficients does not require the determination of the location of the Matano interface.

Sauer and Freise (4) derived the equations describing the interdiffusion coefficients in binary systems involving a volume change. A simplified derivation, using molar instead of mass quantities, was given by Wagner (5-7). This approach was used for these calculations.

The general equation is given below

$$\bar{D}(N_2^*) = \frac{(N_2^+ - N_2^-) V_m (N_2^*)}{2t \left. \frac{\partial N_2}{\partial x} \right|_{x^*}} \left[(1 - Y^*) \int_{-\infty}^{x^*} \frac{Y}{V_m} dx + Y^* \int_{x^*}^{\infty} 1 - \frac{Y}{V_m} dx \right]$$

where

N_2^* = mole fraction of 2 at x^*

N_2^+, N_2^- = initial mole fractions on each side of interface

t = diffusion time

$\left. \frac{\partial N_2}{\partial x} \right|_{x^*}$ = derivative of concentration profile at x^*

$Y^* = \frac{N_2 - N_2^-}{N_2^+ - N_2^-}$ for two initially pure components
 $Y^* = N_2$

The molar volumes were assumed to be constant within the phases but different for each phase. Thus, $1/V_m$ could be extracted from the integrals. In Fig. 11, area 1 represents $\int_{-\infty}^{x^*} Y dx$ and area 2 is $\int_{x^*}^{\infty} 1 - Y dx$. The aluminum mole fraction was taken as N_2^* for all the diffusion couples because the concentration profiles obtained appeared to be smoother than those of the iron and manganese mole fractions. Either mole fraction could be used since N_1 and N_2 are not independent (i.e., $N_1 + N_2 = 1$).

Figure 12 is an electron micrograph of a $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$ diffusion couple. It should be noted that three distinct regions are present, unlike the $\text{Fe}_3\text{O}_4\text{-Al}_2\text{O}_3$ binary and $(\text{Fe}_x\text{Mn}_{1-x})_3\text{O}_4$ ternary samples in which only two phases were distinguishable. The dark phase is Al_2O_3 , and the light phase is Mn_3O_4 . The intermediate phase was assumed to be MnAl_2O_4 , and its molar volume was used in the calculation of the interdiffusion coefficients.

In the $\text{Fe}_3\text{O}_4\text{-Al}_2\text{O}_3$ diffusion couples, the concentration profiles were very smooth, and polynomials were fit to the profiles on each side of the interface and used in the calculations. As a result, the plots of the interdiffusion coefficients as a function of composition are also smooth, as seen in Fig. 13 and 14.

The concentration profiles from the $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$ diffusion couples were not as smooth. Many regions were approximated linearly for the calculations. The interdiffusion coefficients are therefore represented discretely as a function of aluminum mole fraction. These plots appear in Fig. 15 and Fig. 16. These interdiffusion coefficients appear somewhat erratic. This may be attributed to the discrete evaluation of the data, or possibly the diffusion time was not adequate, as evidenced in the narrow profiles. The interdiffusion coefficients in the MnAl_2O_4 were fairly constant; the average values were $D = 2.0 \times 10^{-9} \text{ cm}^2/\text{s}$ for $t = 23\text{h}$ and $D = 1.6 \times 10^{-9} \text{ cm}^2/\text{s}$ for $t = 45\text{h}$.

Conclusion

This study has provided a first approximation of the interdiffusion coefficients in the $\text{Fe}_3\text{O}_4\text{-Al}_2\text{O}_3$ and $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$ binary systems. The calculations in the $\text{Fe}_3\text{O}_4\text{-Al}_2\text{O}_3$ system were relatively straightforward because the concentration profiles were smooth. With the $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$ system, not only were more-involved calculations required due to the discrete nature of the data, but also those calculations are probably less accurate. A more complex curve might better describe these concentration profiles, or a spline-type method may be employed.

From the electron micrographs, it can be seen that the $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$ diffusion couples formed a third phase. The phase was assumed to be MnAl_2O_4 and was taken into ac-

Fig. 9. Concentration profiles from $\text{Al}_2\text{O}_3\text{-Fe}_3\text{O}_4$ diffusion couples.

Fig. 10. Concentration profiles from $\text{Al}_2\text{O}_3\text{-Mn}_3\text{O}_4$ diffusion couples.

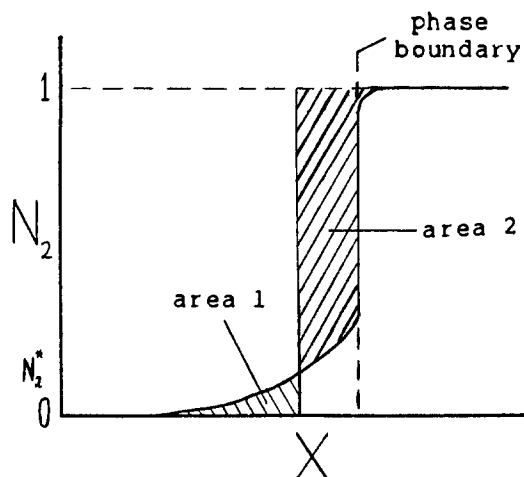

Fig. 11. Schematic concentration profiles

Fig. 12. $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$

count in the calculations. The interdiffusion coefficients within this phase were fairly constant. Other mixed spinel phases may form in the other diffusion couples during longer reaction times, but, these were not observed in these experiments.

With the completion of additional ternary diffusion experiments, the diffusion coefficients in the ternary system may be calculated. At this point, it is not clear whether or not this system will be useful in predicting growth morphologies by comparing diffusion rates. However, the changes observed in the interfaces during the reaction of these few ternary diffusion couples are encouraging.

Acknowledgment

Sincere appreciation is extended to Professor Dr. H. Schmalzried and M. Köhne for their daily supervision, academic guidance, and gracious hospitality during my residence in Hannover, Germany. I am also indebted to The Electrochemical Society for selecting me as the 1983 F. M. Becket Memorial Award recipient and thereby providing me with this tremendous educational opportunity and the funding to study in Hannover. The experience and knowledge that I gained under Professor Dr. H. Schmalzried is invaluable. I am also extremely grateful to Mr. V. H. Braneky, Executive Secretary of The Electrochemical Society, for being very patient and helpful during my association with the Society involving the award.

Manuscript received Feb. 22, 1984.

Fig. 13. Interdiffusion coefficients $\text{Fe}_3\text{O}_4\text{-Al}_2\text{O}_3$. $t = 43\text{h}$

APPENDIX

The mass fraction, Y_i , is proportional to the x-ray counting rate, C_i . The proportionality factor, K_i for each cation i , is determined using a pure oxide sample. If $Y_{i, \text{std}}$ is the mass fraction in the pure oxide and $C_{i, \text{std}}$ is the average counting rate measured from the standard, then

$$K_i = \frac{Y_{i, \text{std}}}{C_{i, \text{std}}}$$

and the measured values were converted by

$$Y_{i, \text{meas}} = C_{i, \text{meas}} \times K_i$$

The mass fraction in terms of the number of moles, n_i , molecular weights of the cations and oxides, M_i and M_o is given by

$$Y_i = \frac{n_i M_i}{M_o}$$

rearranging yields

$$n_i = \frac{M_o Y_i}{M_i}$$

and from the definition of mole fraction, X_i

$$X_i = \frac{n_i}{\sum n} = \frac{Y_i}{\sum \frac{Y}{M}}$$

(a)

(b)

Fig. 14. Interdiffusion coefficients Fe₃O₄-Al₂O₃. t = 21h

where the M_o 's canceled and the sum of the unsubscripted variables is the sum of all the components. The cation mole fractions are then

$$X_{Al} = \frac{\frac{Y_{Al}}{M_{Al}}}{\frac{Y_{Al}}{M_{Al}} + \frac{Y_{Fe}}{M_{Fe}} + \frac{Y_{Mn}}{M_{Mn}} + \frac{Y_O}{M_O}} \times 2.500$$

$$X_{Fe} = \frac{\frac{Y_{Fe}}{M_{Fe}}}{\frac{Y_{Al}}{M_{Al}} + \frac{Y_{Fe}}{M_{Fe}} + \frac{Y_{Mn}}{M_{Mn}} + \frac{Y_O}{M_O}} \times 2.333$$

$$X_{Mn} = \frac{\frac{Y_{Mn}}{M_{Mn}}}{\frac{Y_{Al}}{M_{Al}} + \frac{Y_{Fe}}{M_{Fe}} + \frac{Y_{Mn}}{M_{Mn}} + \frac{Y_O}{M_O}} \times 2.333$$

(a)

(b)

Fig. 15. Interdiffusion coefficients Mn₃O₄-Al₂O₃. t = 45h

The factors 2.500 and 2.333 are added to make the cation mole fractions in the pure oxides unity. Since Y_O was not measured, let $Y_O = 1 - Y_{Al} - Y_{Fe} - Y_{Mn}$ from the definition of mass fraction. The values used in the above equations were

- $Y_{Al, std} = 0.5292$
- $Y_{Fe, std} = 0.7236$
- $Y_{Mn, std} = 0.7203$
- $M_{Al} = 26.98 \text{ g/mol}$
- $M_{Fe} = 55.85 \text{ g/mol}$
- $M_{Mn} = 54.94 \text{ g/mol}$
- $M_O = 16.00 \text{ g/mol}$

Fig. 16. Interdiffusion coefficients $\text{Mn}_3\text{O}_4\text{-Al}_2\text{O}_3$. $t = 23\text{h}$

Moderate Temperature Sodium Cells

V. Discharge Reactions and Rechargeability of NiS and NiS₂ Positive Electrodes in Molten NaAlCl₄

K. M. Abraham* and J. E. Elliot

EIC Laboratories, Incorporated, 111 Downey Street, Norwood, Massachusetts 02062

ABSTRACT

NiS₂ and NiS have been characterized as high energy density rechargeable positive electrodes for moderate-temperature Na batteries of the configuration, Na_{α/β}-Al₂O₃/NaAlCl₄(l), NiS_x. The batteries operate in the temperature range 170°-190°C. Positive electrode reactions during discharge/charge cycles have been characterized. Excellent rechargeability of the batteries has been demonstrated by extended cell cycling. A Na/NiS₂ cell, operating at 190°C, exceeded 600 deep discharge/charge cycles with practically no capacity deterioration. The feasibility of secondary Na/NiS_x batteries with specific energies ≥ 50 Wh/lb and cycle lives exceeding 1000 deep discharge/charge cycles has been demonstrated.

Sodium batteries which operate in the moderate temperature range of 125°-225°C have been pursued in recent times (1-6) as potential alternatives to the liquid Na/molten S system which operates in the range of 350°-400°C (7). The anode in both types of battery comprises liquid Na contained in a Na⁺ conducting solid electrolyte, usually Na-β- or Na-β'-Al₂O₃. A moderate temperature Na battery offers several advantages, including lower corrosion and easier thermal and materials management. A possible limitation is reduced discharge-rate capability due to a lowering of the Na⁺ conductivity in the Al₂O₃ solid electrolyte at the moderate temperature. Nevertheless, with advances in the technology to fabricate very thin Na-β'-Al₂O₃, and with the advent of novel and superior Na⁺ conducting solid electrolytes, a moderate temperature rechargeable Na battery could become a very attractive alternative to its high temperature counterpart.

A major aspect in the development of a high energy density moderate temperature rechargeable Na battery concerns the positive electrode. A useful cathode must exhibit a number of desirable properties including a low equivalent weight, good reversibility for the discharge reaction, long-term thermal stability at the operating temperature, and chemical compatibility with the solid electrolyte. Lately, we have investigated the feasibility of a number of cathode systems for 125°-175°C Na batteries. They include a soluble S cathode consisting of sodium polysulfides dissolved in organic solvents (2) and insoluble cathodes comprising Na intercalating layered transition metal chalcogenides such as TiS₂, VS₂, and VSe₂. The chalcogenide electrodes have been operated in conjunction with both an organic (1) and an inorganic (3) electrolyte. However, organic electrolytes have been found not to have the stability required for long cycle-life Na batteries (1).

In order to circumvent problems encountered with the organic electrolytes, we chose molten NaAlCl₄ as an alternative. This has opened up some new areas of chemistry. The Na intercalating chalcogenides, TiS₂, VS₂, VSe₂, etc., have been found to react with molten NaAlCl₄. In the case of VS₂, however, the reaction products formed during cathode cycling in molten NaAlCl₄ exhibited excellent

rechargeability, providing an extremely useful high energy density rechargeable Na cell (3, 4).

NiS₂ and NiS are non-Na intercalating materials, and we have found their chemistry and electrochemistry in molten NaAlCl₄ to be markedly different from those of Na intercalating TiS₂ and VS₂ in the same medium. Our results are presented in this paper.

There have been studies of other moderate temperature Na batteries utilizing molten NaAlCl₄ as the catholyte. These include a cell utilizing an acidic NaCl-AlCl₃ melt with SCl₃⁺AlCl₄⁻ as the positive electrode (6) and batteries employing a S₂Cl₂-AlCl₃ cathode (5). Our studies of VS₂ and MoS₃, reported elsewhere (1, 3, 4), and of NiS and NiS₂, presented in this paper, represent first examples of the utility of transition metal sulfide cathodes in molten NaCl-AlCl₃ electrolyte medium. It would be apparent from the data presented that these results may be of considerable scientific and technological importance.

Experimental

All air- and moisture-sensitive materials were handled using standard equipment and techniques designed for the manipulation of air-sensitive compounds. All electrochemical experiments were carried out in a glove box (Vacuum Atmospheres Corporation) maintained over an argon atmosphere, which was continuously circulated through a drying column.

Preparation of NaAlCl₄.—The NaAlCl₄ electrolyte was prepared by heating a NaCl (51 mole percent [m/o]) -AlCl₃ (49 m/o) mixture at 190°C to form a liquid. The melt was then purified by constant current electrolysis between two Al disk electrodes for 48-72h. The resulting clear liquid was cooled, and the solid was ground to a fine white powder and stored in a glove box until use.

Nickel sulfides.—NiS₂ and NiS were obtained from Alfa-Ventron, Beverly, Massachusetts. The NiS₂ is believed to have a cubic structure (ASTM File no. 11-29), and the NiS a hexagonal structure (ASTM File no. 2-1280).

Cell construction and tests.—A typical laboratory cell, having a tubular shape, consisted of an outer Pyrex compartment, which contained the cathode mix of the sulfide and NaAlCl₄, and an inner compartment fabricated from a β'-Al₂O₃ tube (Ceramatec Incorporated, Catalog no. CT16A), containing the Na anode. The cathode was fabricated in a graphite felt (Union Carbide, WDF

*Electrochemical Society Active Member.

EST

Felt) matrix by sifting a weighed amount of the sulfide powder into a known area of the felt. The latter, in turn, was wound around the β'' -Al₂O₃ tube. An amount of NaAlCl₄, sufficient to completely wet the carbon felt, was added. A tungsten (W) wire served as the positive electrode lead. The anode compartment contained an excess of Na, and a W wire served as the anode current collector. Before assembly into the cell, the β'' -Al₂O₃ tube containing Na was heated and maintained at 400°C for ~24h, in order to allow good wetting of the β'' -Al₂O₃ with liquid Na.

The cathode mix in a typical Na/NiS₂ laboratory cell consisted of 0.75g (6.1 mmol) of NiS₂, 0.15g of Ni, and 4.75g (24 mmol) of NaAlCl₄. (Early on in the investigation, we discovered that a small amount of Ni, ~20 m/o, initially incorporated in the cell would improve cathode discharge capacity. Therefore, NiS₂ cathodes contained a small amount of Ni powder.) Experiments were also performed with smaller capacity NiS₂ cathodes and with several NiS₂:NaAlCl₄ mole ratios.

Cells were also constructed in an inside-out configuration with the positive electrode contained inside the β'' -Al₂O₃ tube. The outer Na compartment was fabricated from a stainless steel tube. An advantage of the inside-out configuration is that it eliminates most hardware corrosion problems relating to molten NaAlCl₄. A 4 Ah nominal capacity Na/NiS₂ cell was constructed in the inside-out configuration. A schematic representation of this cell is given in Fig. 1. The cathode mix and graphite felt, placed inside the β'' -Al₂O₃ tube, had a height of ~10 cm. A vitreous carbon rod extending the full inside length of the β'' -Al₂O₃ tube served as the cathode lead. The cathode composition of the 4 Ah NiS₂ cell was as follows: 8.1g NiS₂, 1.62g Ni, and 29g NaAlCl₄.

Cells, after assembly, were placed in a thermostated oven, maintained at 170°C. Some of the extended cycling experiments were performed at 190°C. Galvanostatic cycling was carried out with standard cycling equipment. Data collection and retrieval were done with a Bascom-Turner 8000 Recorder equipped with microprocessor accessories.

Analysis of cycled cathodes:—X-ray analyses of cycled cathodes were carried out after washing off the molten salt with carefully distilled CH₃CN. Any adhering NaCl was subsequently removed by washing the cathode in aqueous NH₄OH and then dried in vacuum. X-ray diffraction data were obtained by the Debye-Scherrer method.

Fig. 1. Schematic representation of a Na cell

Results and Discussion

The Na cell being discussed has the configuration

We have operated the cell in the temperature range of 170°-190°C. The MS_r cathode is NiS₂ or NiS. The electrolyte is the basic NaCl-AlCl₃ molten salt, NaAlCl₄, which melts at ~155°C. Acid-base properties of NaCl-AlCl₃ melts have been discussed by others (8). Advantages of the basic melt over the acidic melt for battery applications include lower volatility and fewer corrosion problems. The desirability of molten NaAlCl₄ as a high rate battery electrolyte is evident from the data in Table I, which compares some of its properties with those of Na- β'' -Al₂O₃. In the 170°-190°C range, the specific conductivity of molten NaAlCl₄ is significantly higher than that of Na- β'' -Al₂O₃.

Electrochemical behavior of NiS₂.—Figures 2 and 3 depict galvanostatic discharge/charge cycles of two Na/NiS₂ cells, 10 and 20, at ~170°C. In both cases, the current density is 1 mA/cm² of β'' -Al₂O₃, but the voltage limits in cell 10 are 1.7 and 3.0V and 1.7 and 3.5V in cell 20. The open-circuit voltage (OCV) of the Na/NiS₂ cell is ~3.0V. The first discharge proceeds through three potential plateaus, at 2.40, 2.25, and 2.0V, yielding a mid-discharge potential of 2.3V. The cathode utilization in the first discharge is 2.5 electrons per NiS₂ (e^-/NiS_2).

In cell 20, with a charge limit of 3.5V, a capacity approaching $3e^-/\text{NiS}_2$ is obtained in the second discharge. There is very little change in capacity in this cell after the second discharge.

When the charge limit is 3.0V, the cell capacity decreases by ~10% on going from the first to the second discharge, and by smaller amounts in the next few cycles. In this cycling regime the average rechargeable capacity is $\sim 2e^-/\text{NiS}_2$. The additional capacity obtained when the charge limit is 3.5V appears at the beginning of the second and later discharges at a plateau of 2.7V. The many voltage plateaus which appear in the discharge of NiS₂ most probably correspond to intermediate phases comprising lower nickel sulfides.

Intermediate phases in the discharge of NiS₂ and NiS.—Cathodes from NiS₂ cells after cycling to various depths were isolated and analyzed by x-rays. Some relevant data are given in Table II. The final discharge product is Ni. The data show also that the reduction of NiS₂ to Ni involves the intermediate phases, Ni₃S₄, NiS, and Ni₃S₂. The overall discharge/charge processes in the NiS₂ cathode which conform to the x-ray results are

Additional support for reaction [1] has been obtained by an independent demonstration of the charge part of this reaction in a cell setup with a cathode comprised of Ni and Na₂S, taken in a mole ratio of 1:2. The relevant cycling data are given in Fig. 4. A discharge of Na/NiS₂ cell 20 is included in Fig. 4 for comparison.

In order to verify the intermediacy of the NiS phase in the discharge of NiS₂, we have examined the discharge/charge behavior of Na/NiS cells. The cycles given in Fig. 5 clearly manifest the relationship in the electrochemical

Fig. 2. Galvanostatic cycles of Na/NiS₂ cell no. 20 at 170°C. Current density: $i_d = i_c = 1 \text{ mA/cm}^2$. Voltage limits, 1.7-3.5V.

Fig. 3. Galvanostatic cycles of Na/NiS₂ cell no. 10 at 170°C. Current density: $i_d = i_c = 1 \text{ mA/cm}^2$. Voltage limits, 1.7-3.0V.

behavior of NiS₂ and NiS. The first discharge of NiS shows two voltage plateaus: the first at ~2.3V, encom-

Fig. 5. First four cycles of a Na/NiS cell at 170°C. Current density $i_d = i_c = 1 \text{ mA/cm}^2$. Voltage limits, 1.7-3.0V.

passing $\sim 0.4e^-$ NiS, and the second at $\sim 2.0\text{V}$, yielding $\sim 1.1e^-$ NiS. These plateaus most probably correspond to the reduction of NiS to Ni₃S₂ and that of Ni₃S₂ to Ni. X-ray data obtained at the end of the tenth discharge of the cell in Fig. 5 strongly support this (see Table II). The products at the end of a discharge include Ni, Ni₃S₂, and small amounts of Ni₇S₆. Beginning with the second discharge of NiS, an additional plateau at $\sim 2.7\text{V}$, and a sloping voltage region between 2.7 and 2.4V, appear. The combined capacities in these two regions equal $\sim 20\%$ of the total material utilization. It appears that the charge of the NiS electrode to 3.0V oxidizes it to a composition slightly richer in S than that in NiS.

Cathode reactions in NiS₂ and NiS cells.—X-ray diffraction patterns of discharged NiS₂ or NiS cathodes showed no evidence of Na₂S. This is not surprising, since Na₂S would react with NaAlCl₄, forming NaAlS₂ and NaCl (9), Eq. [2]

Using available thermodynamic data (10, 11), we have calculated the equilibrium potentials at 500 K for the reactions, $\text{NiS}_2 + \text{Na} \rightarrow \text{NiS} + \text{Na}_2\text{S}$ and $\text{NiS} + 2\text{Na} \rightarrow \text{Ni} + \text{Na}_2\text{S}$, and found them to be ~ 1.60 and $\sim 1.30\text{V}$, respectively. These values are significantly ($\sim 0.8\text{V}$) lower than

Fig. 4. Comparison of discharge of $[\text{Ni} + 2\text{Na}_2\text{S}]$ and NiS₂ cells. Temp. 170°C.

Table II. Phases identified in cycled NiS and NiS₂ cathodes

Cathode	Extent of cycling	Cathode composition calculated from net charge passed	Phases identified*
NiS ₂	One discharge to 1.7V	NiS _{0.51}	NiS (minor**), Ni ₃ S ₂ , Ni
NiS ₂	1.5 cycles, terminated prior to onset of 2.0V discharge plateau	NiS _{1.1}	Ni ₃ S ₄ (minor), NiS, Ni ₃ S ₂
NiS ₂	9 cycles, terminating at end of charge to 3.5V	NiS _{1.88}	NiS ₂ , Ni ₃ S ₄ (minor)
NiS	10 cycles, terminating at end of discharge to 1.7V	NiS _{0.025}	Ni ₃ S ₂ (minor), Ni

* By x-ray diffraction, Cu K α radiation.

** Approximate relative ratios based on the observed intensity of the x-ray lines.

the actual potentials observed by measuring the OCV's of NiS₂ and NiS cells during various stages of discharge at 170°C. The calculated equilibrium potential for the Na/S couple at 500 K is ~1.9V, while that observed in the NaAlCl₄ melt is ~2.9V (4, 5). It is clear that an interaction of the molten salt with either the cathode material or a reaction product of it also contributes to the overall free energy change in the cell. The most probable reaction involving the electrolyte is that given in Eq. [2]. Consequently, it is reasonable to assume that the overall electrode process in the cycling of the NiS₂ cathode is that in Eq. [3]

The various intermediate steps may be represented as shown in Eq. [4]-[7]

Reactions [6] and [7] are common to the NiS and NiS₂ electrodes. In extensively cycled cathodes, we have found small amounts of NiCl₂, probably formed from displacement reactions of the sulfide with NaAlCl₄. However, in separate experiments, we have found the reduction of NiCl₂ to Ni to be quite reversible and to occur at ~2.7V.

Most of the intermediate nickel sulfide phases we have identified in this work were found by Preto *et al.* in Li-Al/NiS₂ cells utilizing the LiCl-KCl molten salt electrolyte, at 400°C (11). However, the phase Ni₃S₄, which decomposes at ~300°C, was not detected in the higher temperature system. In the Li-Al/NiS₂ system, the molten salt does not take part in the discharge reaction, and the observed cell equilibrium potentials agree quite well with the calculated values. Electrolyte participation in discharge reactions is a characteristic which distinguishes the electrochemistry of NiS₂ and NiS in molten NaAlCl₄ from that in LiCl-KCl electrolytes.

A fraction of the specific energy lost by inclusion of NaAlCl₄ in the reaction stoichiometry in Na/NiS₂ cells is compensated for by the higher cell voltages achieved in this electrolyte.

Rate and rechargeability of NiS₂ and NiS cells.—Figure 6 gives cathode utilization, represented as electrons/NiS₂, at several current densities for two Na/NiS₂ cells. The NaAlCl₄:NiS₂ mole ratio in cell 30 is 3.5:1 and 2:1 in cell

40. The rate/capacity data were obtained at 190°C. In obtaining the data, each cell was successively discharged at current densities from 2 to 25 mA/cm² with each discharge followed by a charge to 3.5V at 2 mA/cm². Cathode utilizations show practically the same values in both cells at current densities ≥ 20 mA/cm². At lower current densities, the cathode with the smaller amount of NaAlCl₄ exhibits lower capacities. This is probably because of insufficient amounts of NaAlCl₄ in that cell, enabling only a partial utilization of NiS₂. The 25 mA/cm² discharge corresponds to a *c/2* rate. The NiS₂ utilization at the latter current density is nearly 60% of that realized at 2 mA/cm².

Rechargeability of NiS₂ and NiS cells have been evaluated by extended cycling of laboratory cells of 0.5–1 Ah capacities. Figure 7 displays capacity *vs.* cycle number for Na/NiS₂ cell 50. The cathode mix comprised 0.75g (6.1 mmol) of NiS₂, 0.15g of Ni, and 4.75g (24 mmol) of NaAlCl₄. In several initial cycles, the current was varied to arrive at optimum discharge and charge current densities for the extended cycling. Thus, the first four cycles were performed at a constant current of 25 mA (2 mA/cm²). Between cycles 5 and 54, the current was 50 mA (4 mA/cm²). In cycle 55, the current density was 8 mA/cm² for discharge and 4 mA/cm² for recharge. Thereafter, the current was unchanged. The temperature was maintained at 165°C until the 184th cycle, when it was raised to 190°C. All cycles subsequent to 184 were obtained at 190°C. The cell achieved 670, 100% depth-of-discharge cycles before the experiment was ended voluntarily. After the first 540 cycles, the cell was cooled to room temperature and then it remained at open circuit for about 2 months before the cycling was resumed at 190°C to obtain the additional 130 cycles. The cycle test took more than 1 yr. Some typical cycles are given in Fig. 8. The higher temperature of 190°C, at which the cell was maintained during the latter 10 months of cycling, helped increase the cathode utilization. This increase corresponded to an increase in the capacity involved in the 2.1V plateau. The average material utilization in the 650 cycles was ~2.6e⁻/NiS₂.

The excellent compatibility found between β' -Al₂O₃ and molten NaAlCl₄ appears to correlate with the free energies of formation of NaAlCl₄ and NaAlO₂ at 500 K of -233 and -244 kcal/mol, respectively. The observed stability is also in agreement with the estimated bond energies of 55 and 66 kcal for Al-Cl and Al-O_{1,2}, respectively.

Fig. 6. Rate/capacity data for Na/NiS₂ cells 30 and 40. The NaAlCl₄:NiS₂ mole ratio in cell 30 is 3.5:1, and, in cell 40, it is 2:1.

Fig. 7. Cathode utilization vs. cycle number for Na/NiS₂ cell 50. At A, the temperature was raised from 170° to 190°C. At B, the cell was left on open circuit for ~2 months at room temperature, prior to resumption of cycling.

In cell 60, the initial NaAlCl₄ to NiS₂ ratio was 2:1. The cathode mix comprised 1.53g (12.4 mmol) of NiS₂, 0.31g Ni, and 4.75g (24 mmol) of NaAlCl₄. The cell was subjected to more than 200 deep discharge-charge cycles. The average utilization obtained at current densities of 8 mA/cm² for discharge and 4 mA/cm² for charge, between 1.7-3.5V, was ~1.5e⁻/NiS₂. The data are given in Fig. 9. The 1.5e⁻/NiS₂ capacity in cell 60 corresponds to a specific utilization of 37 mAh/cm² of β'-Al₂O₃, which is slightly greater than the 33 mAh/cm² of β'-Al₂O₃ utilization realized in cell 50.

We believe that, with these experiments, we have demonstrated the feasibility of long cycle-life, high specific energy, and excellent system stability for the Na/NiS₂ battery. The results obtained from a 4 Ahr Na/NiS₂ preprototype cell further support these conclusions. That data will be discussed shortly, after presenting the long-term cycling results for a Na/NiS laboratory cell.

Na/NiS cell no. 70 was constructed with a cathode comprising 1.1g (12 mmol) of NiS and 4.7g (24 mmol) of NaAlCl₄. The cell exhibited an OCV of 2.9V at 190°C, the

temperature at which the entire cycling was performed. The cell was cycled between voltage limits of 1.5 and 3.0V, and at the currents of 50 mA (4 mA/cm²) for discharge and 25 mA (2 mA/cm²) for charge. More than 100 cycles have been obtained (see Fig 10 and 11), yielding an average cell capacity of 400 mAh or ~1.3e⁻/NiS. The corresponding specific utilization is 32 mAh/cm² of β'-Al₂O₃, which is of the same order as those realized in NiS₂ cells 50 and 60.

A 4 Ah nominal capacity NiS₂ cell having the specification given in the experimental section was operated at 190°C. The first eight cycles were obtained at a current of 100 mA or 2.5 mA/cm². Beginning with the ninth cycle, the discharge current was changed to 300 mA or 7.5 mA/cm² and the charge current to 3.75 mA/cm². The voltage limits were 1.5 and 3.5V. The cell was cycled more than 75 times (Fig. 12). The highest capacity of the cell was 3.7 Ah, corresponding to a utilization of 2e⁻/NiS₂.

Unlike in the laboratory cell, the capacity showed a tendency to fade gradually with cycling. We believe this was due to a relatively high cell resistance of ~1Ω which

Fig. 8. Typical cycles of Na/NiS₂ cell 50. Current density: cycles 1 and 2, $i_d = i_c = 2 \text{ mA/cm}^2$; cycles 250 and 540, $i_d = 8 \text{ mA/cm}^2$, $i_c = 4 \text{ mA/cm}^2$.

Fig. 9. Cathode utilization vs. cycle number in Na/NiS₂ cell 60. NaAlCl₄:NiS₂ = 2:1. Temp. 190°C. Current density, *i_d* = 8 mA/cm², *i_c* = 4 mA/cm². Voltage limits: 1.7-3.5V.

Fig. 10. Typical cycle of Na/NiS cell 70 at 190°C. Current density: cycles 1 and 3, *i_d* = *i_c* = 2 mA/cm²; cycle 100, *i_d* = 4 mA/cm², *i_c* = 2 mA/cm².

slowly increased with repeated cycling. As a result, only smaller and smaller fractions of the capacity involved in the 2V plateau became accessible in later cycles. The specific energy achieved based on the observed capacity of 3.7 Ah, a mid-discharge potential of 2.3V, and including all weights, except those of β -Al₂O₃ and the can, is ~200 Wh/kg. At least a 25% improvement over this should be possible with further optimization of electrode structures and cell configuration.

Overdischarge and overcharge.—Sodium cells utilizing NaAlCl₄ possess a remarkable overdischarge safety mechanism. When the cell is discharged down to ~1.6V vs. Na⁺/Na, a reversible process involving the reduction of the electrolyte occurs

Fig. 11. Cathode utilization vs. cycle number in Na/NiS cell 70

We have found that these cells can be overdischarged for extended periods of time without any apparent deleterious effect on their subsequent cycle performance. In fact, the capacity corresponding to the overdischarge process can also be harnessed practically, thus increasing the energy densities of cells which contain an excess of the electrolyte.

The effect of overcharge was investigated by repeatedly charging a cell to a potential of 4.0V. This had no detrimental effects on the cell's subsequent cycle performance. The overcharge between 3.5 and 4.0V occurred with a sloping potential profile, and the associated capacity showed some variations from cycle to cycle. When the recharge potential limit was lowered to 3.5V after the overcharge cycles, the cell resumed cycling with capacity and voltage characteristics typical of cells which had never been overcharged.

Fig. 12. Cathode utilization vs. cycle number in a pre-prototype Na/NiS cell. Temp. 190°C.

Table III. Energy densities of nickel sulfide cells

Cathode	Capacity (e ⁻ /metal)	Mid-discharge voltage (V)	Cycling regime (V)	Specific energy* (Wh/kg)
NiS	1.9	2.1	1.7-3.0	337
NiS ₂	1.7	2.4	1.7-3.0	336
NiS ₂	2.5	2.4	1.7-3.5	378
NiS ₂	4.0	2.4	1.7-3.5	424**

* Based on a discharge reaction involving NaAlCl₄, also. About 25%-35% of this should be achievable in a practical battery.

** Maximum, corresponding to reaction [3].

The most likely reaction at the cathode during overcharge to 4.0V is that in Eq. [9] (6, 12)

The Cl₂ would dissolve in the electrolyte, or it would react with the cathode material. Another possible reaction during overcharge is the oxidation of NiS₂ to form S and NiCl₂. In discharges following an overcharge to 4.0V, a fraction of the capacity appeared at a potential of ~3.4V. This, most likely, is associated with the reduction of Cl₂ dissolved in the electrolyte.

An overcharge to 4.5V also proceeds with a sloping potential profile similar to that seen in the region between 3.5 and 4.0V. The OCV of cell after the charge to 4.5V was 3.8V, indicating Cl₂ in solution. Again, no detrimental effect of any sort on cell performance was observed. We can conclude that Na/NiS_x cells utilizing NaAlCl₄ possess excellent built-in overdischarge and overcharge protection features due to reversible chemical processes in addition to those associated with the redox reactions of the sulfides.

Conclusions

The electrochemistry of the sulfides, NiS₂ and NiS, in molten NaAlCl₄ has been found to be different from that of Na intercalating chalcogenides such as TiS₂, VS₂, and VSe₂. The nickel sulfides undergo displacement reactions upon reduction, and these processes, forming Ni as

the final product, pass through the intermediate phases, Ni₃S₄, NiS, and Ni₂S₂. Despite the appearance of these intermediate phases, NiS₂ behaves as a highly reversible positive electrode in the Na battery, permitting high rate discharges. The mid-discharge voltage of the Na/NiS₂ cell is 2.4V. A cell with a mid-discharge voltage of 2.1V is obtained when NiS is used as the initial positive electrode. The specific energies calculated based on experimental data are given in Table III. Practical secondary Na batteries capable of delivering ≥50 Wh/lb and >1000 deep discharge/charge cycles appear feasible.

Molten Carbonate Fuel Cell Cathode Materials Study

Charles E. Baumgartner,* Ronald H. Arendt,* Charles D. Iacovangelo,* and Bradley R. Karas*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Data are presented on the electronic conductivity and molten alkali carbonate stability (Li:K binary of 62:38 mole ratio) of various materials at 923 K under a 30% CO₂/air atmosphere. Of the examined materials, only LaNiO₃ and La_xSr_{1-x}CoO₃ satisfied both criteria sufficiently for acceptable use as molten carbonate fuel cell cathode materials.

Molten carbonate fuel cells (MCFC's) have been under extensive development as high efficiency systems for directly converting gasified coal or natural gas into electricity. Relative to other liquid electrolyte fuel cells, the carbonate system offers the unique advantage of the electrolyte's composition remaining invariant during cell operation. The electrochemical reactions involved during H₂ oxidation at the anode and O₂ and CO₂ reduction at the cathode are shown below

Carbonate ion, consumed at the anode and generated at the cathode, is continuously transported between the

* Electrochemical Society Active Member.

electrodes through an alkali carbonate-filled, porous ceramic electrolyte structure. Conventional fuel cell components consist of a porous stabilized nickel anode, a porous lithium-doped NiO cathode, and a LiAlO₂-reinforced electrolyte structure typically containing a 62 mole percent (m/o) Li₂CO₃:38 m/o K₂CO₃ electrolyte.

A major MCFC problem is dissolution of the lithium-doped NiO (Li_{0.02}Ni_{0.98}O) cathode in the carbonate electrolyte (1-3). Following dissolution, the cathode material is transported diffusively into the electrolyte structure. In an operating cell, an oxygen concentration gradient exists within the electrolyte structure which decreases from the cathode to the anode interface. At some location between the two electrodes the P_{O₂} drops below the region where NiO is stable (4). The equilibrium nickel solubility at this location decreases resulting in the deposition of metallic

nickel from the electrolyte. These metallic nickel "sinks," located within the electrolyte structure, create a nickel concentration gradient which continually transports cathode material away from the cathode/electrolyte structure interface and, hence, facilitates further cathode dissolution. The consequence of such $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$ corrosion is clearly evident in Fig. 1, which displays a Ni x-ray fluorescence map of a 0.18 cm thick electrolyte structure from a MCFC operated at 923 K and atmospheric pressure for 10,080h. Post-test analysis showed that approximately 10% of the cathode had dissolved, transported into the electrolyte structure, and precipitated as metallic nickel during the cell test. These nickel deposits are visible as bright spots in Fig. 1. While such a transport mechanism for NiO was not appreciated previously, a similar cathode corrosion was responsible for the abandonment of Ag and CuO as MCFC cathode materials (5-7).

In response to this acute problem, we have surveyed the molten alkali carbonate stability and high temperature electronic conductivity of selected materials in an attempt to identify a suitable replacement cathode material. The criteria of a successful candidate material were selected to be: (i) 923 K electronic conductivity ≥ 1 ($\Omega \text{ cm}$)⁻¹, (ii) stability in the MCFC cathode environment (923 K, O_2/CO_2 atmosphere, carbonate electrolyte), and (iii) reduced solubility under the cathode environment or, preferably, increased solubility in the anode environment relative to $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$.

The third criterion satisfies the requirement that the cathode-to-anode material transport rate, and associated cathode fluxing, be reduced. Along this line, it is obviously preferable that no species derived from cathode dissolution precipitate within the cell since such "sinks" are directly associated with cathode fluxing. This would mandate that the material's solubility under the anode's environment be at least equal to, and preferably exceed, that under the operating cathode environment. However, since there is little quantitative published data on materials solubility in alkali carbonates (3-7), materials examined in this survey were not selected for their solubility characteristics. Instead, selection was based more on the anticipated material's stability in the oxidizing carbonate environment. Because of this, a few materials were included in our sampling which are thermodynamically stable as metals under the anode's environment (hence possessing a low solubility) when they were known to satisfy the stability requirement.

In addition to the above requirements, an acceptable replacement material must also be catalytically active towards O_2 electroreduction and fabricable into a porous electrode structure. These criteria, however, were not examined in this initial survey.

Experimental

Sample preparation.—Selected candidate materials were synthesized using either a molten salt (MS) mediated synthesis (8) or a more conventional high temperature solid-state synthetic route. The precise details of

Fig. 1. Ni x-ray fluorescence map of a 0.18 cm thick electrolyte structure operated within a MCFC at 923 K and atmospheric pressure for 10,080h. The bright regions correspond to metallic nickel.

each sample's synthesis will not be given; the preparation of one material using each synthetic route will be covered instead. Materials prepared using a MS synthesis are typified by Ti-doped LiFeO_2 . The MS synthesis utilized molten 50 m/o NaCl-KCl as the solvent. This technique has the advantage of yielding a product of close compositional and particle-size uniformity. Ti-doped LiFeO_2 ($\text{LiFe}_{0.96}\text{Ti}_{0.04}\text{O}_2$) was synthesized by combining 1 mol each of KCl and NaCl, 0.48 mol Fe_2O_3 , 0.04 mol TiO_2 , and 1.25 mol LiOH; a 25% excess of LiOH was present to insure the final lithium ratio. These powders were well blended by dry roll milling, placed in a covered 500 ml $\alpha\text{-Al}_2\text{O}_3$ crucible, and heated in air for 16h at 1373 K. Following cooling, the chloride solvent was dissolved in deionized water and the product powder collected by filtration. X-ray diffraction (XRD) and chemical analysis were utilized to confirm product formation. Due to the survey nature of this study, no attempts were made to further identify minor constituents not detectable with XRD.

In addition to the MS synthetic route, materials were also prepared using a high temperature solid-state (SS) reaction. Reactants used in this synthesis were typically organometallics or hydroxides which were dissolved or dispersed in solution. An example of a cathode candidate synthesized by the SS reaction scheme is Ti-doped ZnO ($\text{Zn}_{0.97}\text{Ti}_{0.03}\text{O}$). Here 0.015 mol titanium tetra-butoxide [$\text{Ti}(\text{OBU})_4$] was dissolved in methanol to which was added 0.485 mol of ZnCO_3 powder. The materials were homogenized by ball milling with dense ZrO_2 media. The addition of dilute aqueous NH_4OH converted the $\text{Ti}(\text{OBU})_4$ to a $\text{Ti}(\text{OH})_4$ gel, which uniformly surrounded each ZnCO_3 particle. The mixture was dried under vacuum at 398 K. Conversion to the final composition was accomplished by a 16h air firing at 1373 K.

Material evaluation.—All candidates were evaluated for their stability in the molten 62:38 (mole ratio $\text{Li}_2\text{CO}_3:\text{K}_2\text{CO}_3$) carbonate electrolyte. The powdered material was combined with an approximately 50 \times molar excess of electrolyte in a 7.5 cm high, 1.6 cm diam gold crucible and heated for 50–100h at 923 K under a 30% CO_2 /air atmosphere. Following cooling, the electrolyte was dissolved in either dilute aqueous acetic acid or hot deionized water, the powder collected by filtration, and its identity determined by XRD and chemical analysis. Changes in either the XRD pattern or chemical composition were used as evidence of instability.

The sample's electrical conductivity was obtained using a standard four-probe ac impedance technique on pressed sintered pellets, as described previously (9). The conductivity apparatus is shown in Fig. 2. Pellets, 1.2 cm diam \times ~0.6 cm thick, were prepared by pressing the powders from between 70–120 MPa. Some powders required the addition of a few drops of a binder solution of 1% stearic acid in acetone to facilitate pellet formation. The pellets were air sintered from between 1023 and 1472 K, the actual temperature and time conditions depending on the particular material. Following sintering, the faces of the pellets were polished smooth, sputtered with 0.5–1.0 μm gold, and two gold wires were attached to each face using conductive silver paint (du Pont conductor composition 4922). The samples, held in an $\alpha\text{-Al}_2\text{O}_3$ frame (not shown in Fig. 2) and contained within an $\alpha\text{-Al}_2\text{O}_3$ tube furnace under a 30% CO_2 /air atmosphere, were heated to 773 K overnight to cure the silver paint. The above atmosphere was selected to simulate the in-cell cathode's environment; no atmospheric effects on electronic conductivity were examined. Sample conductivities were measured as a function of signal frequency (50–10,000 Hz) during both heating (773–1123 K) and cooling (1123–923 K) cycles using a PAR 5204 Lock-In Analyzer coupled to a PAR 371 signal source (Princeton Applied Research, Incorporated, Princeton, New Jersey).

Equilibrium solubility measurements were made on selected candidate materials in molten 62:38 electrolyte at temperatures between 923 and 1123 K according to the technique described in detail elsewhere (3, 14). Pellets

Fig. 2. Apparatus used to measure four-probe ac impedance on pressed samples.

prepared similarly to those described above were heated in a 7.5 cm tall \times 1.6 cm diam gold crucible with approximately 20g of electrolyte for between 250 and 500h under a room temperature humidified 30% CO_2 /air atmosphere. Electrolyte aliquots of between 1 and 2g were removed at temperature by inserting an $\alpha\text{-Al}_2\text{O}_3$ pipette into the upper portion of the carbonate melt. This electrolyte was transferred to a clean gold crucible, cooled, and analyzed for dissolved material by atomic absorption analysis. The sampling times were shown previously (14) to yield equilibrium solubility values, being defined here as the analyzed constituent not varying more than $\pm 5\%$ relative to a mean over a 3-day period. The limit of $\pm 5\%$ represents the typical reproducibility attained on identical samples and constitutes the cumulative deviation present in the solubility and analytical techniques. The fact that equilibrium was established here at the time of sampling was verified on several samples. An experimental blank containing electrolyte without any candidate material was processed occasionally with the experimental samples to insure that samples were not contaminated by the furnace environment.

Results and Discussion

Table I lists the candidate materials investigated, the synthetic scheme utilized in their preparation, the materials' electrolyte stability, and the electronic conductivity measured at 923 K and 1 kHz. The state-of-the-art cathode material, $\text{Li}_{0.02}\text{Ni}_{0.98}\text{O}$, is included for comparison. As can be seen from the data, several materials were found to be unstable in the electrolyte; the major source of instability being reactivity with Li_2CO_3 to yield a Li containing product. This is clearly demonstrated in the Fe- or Ti-based systems which always decomposed to yield LiFeO_2 or Li_2TiO_3 . Of those materials found to be stable in the carbonate fuel cell cathode environment, only the La containing perovskites, LaNiO_3 and $\text{La}_x\text{Sr}_{1-x}\text{CoO}_3$, exhibited electronic conductivities which exceeded the required 1 $(\Omega \text{ cm})^{-1}$.

The establishment of 1 $(\Omega \text{ cm})^{-1}$ as an acceptable pressed pellet conductivity minimum was based on the allowable IR drop associated with fuel cell operation. Although the relationship between conductivity and porosity was not determined here, Eq. [3] typifies the correlation found in the literature (10)

$$\sigma = \sigma_0 (1 - P)^x \quad [3]$$

Literature values of x range between 1.5 and 3, with most references (10, 11) determining a value of $x = 1.5\text{--}2.0$. A fuel cell cathode structure possessing a 60% porosity, therefore, is expected to exhibit a conductivity $\sim 3\text{--}5$ times less than that measured using the nominally 80%–90% dense pressed pellets. A typical porous fuel cell cathode thickness is 0.038 cm. If it is assumed that the electrochemical reaction occurs predominantly near the electrode/electrolyte interface, all current must pass through the cathode thickness before reaching the current collector. For a cell current density of 160 mA/cm^2 , a porous cathode conductivity of 0.2 $(\Omega \text{ cm})^{-1}$ [comparable to a pressed pellet conductivity of $\sim 1 (\Omega \text{ cm})^{-1}$] would result in a one-dimensional IR loss of ~ 30 mV. Although the cathodic reaction most likely is not limited to a region close to the electrolyte interface, this approximation illustrates the importance of cathode conductivity on the cell's performance.

Referring to the results in Table I, LiFeO_2 and Li_2TiO_3 were shown to be stable in the MCFC's cathode environment; however, their 923 K electronic conductivities of 3×10^{-3} and $4 \times 10^{-5} (\Omega \text{ cm})^{-1}$, respectively, were considerably below the required cut off. Attempts to improve conductivity by doping with higher valency cations proved counterproductive for LiFeO_2 , the 923 K conductivity decreasing by a factor of ~ 5 upon substitution of 6% Zr or Ti for Fe. The conductivity-temperature curves obtained at 1 kHz for several Zr- and Ti-doped LiFeO_2 samples are shown in Fig. 3. Substitution of 5% Ta for Ti in Li_2TiO_3 did increase the 923 K conductivity by about a factor of 20; however, the conductivity remained orders of

Fig. 3. Influence of Ti and Zr doping on the electrical conductivity of LiFeO_2 under 30% CO_2 /air atmosphere between 773 and 1123 K.

magnitude too low. Similar results were obtained with ZnO and CeO_2 , two other electrolyte-stable materials. As noted previously, only the La containing perovskites appear promising as candidates as a result of these data.

A minor drawback to the use of La-perovskites in MCFC applications is their reactivity towards the state-of-the-art electrolyte structure matrix material, LiAlO_2 . While found to be stable towards the carbonate electrolyte alone, the presence of both LiAlO_2 and the electrolyte leads to the metathetical reaction below

This necessitated the identification of an alternate matrix support material for use with a La-perovskite cathode structure. One promising candidate is SrTiO_3 (8), which has been shown to remain phase pure following exposure to both LaNiO_3 and molten electrolyte in a pot-test of several hundred hours duration.

In addition to an alternate cathode material possessing electrolyte stability and an acceptable electronic conductivity, the material must demonstrate a reduced corrosion rate in the electrolyte under cell operating conditions. This behavior can result from either a decreased solubility under cathode conditions or an increased solubility under anode conditions. Equilibrium solubility measurements were made on several materials as a function of temperature between 923 and 1123 K under a room temperature humidified 30% CO_2 /air atmosphere. These data are given in Fig. 4. Unfortunately, these solubility determinations are severely hindered by the presence of high background impurity levels in the nascent electrolyte. The impurity levels determined on various high purity electrolyte samples are listed in Table II and are also shown, in part, in Fig. 4.

Under experimental conditions where the nascent carbonate's impurity level exceeded the equilibrium solubility, no decrease in solute concentration was found with time up to 500h. The system's failure to approach equilibrium in the direction of decreasing concentration suggests that the solute species either remains supersaturated in solution or precipitates as a fine particulate suspension and was therefore sampled along with the dissolved form.

Despite the problematic impurity levels, however, the linear solubility/temperature relationships for NiO, ZnO,

Fig. 4. Equilibrium solubility temperature dependence for NiO, ZnO, LaNiO_3 , LaCoO_3 , and LiFeO_2 in 62 m/o Li_2CO_3 :38 m/o K_2CO_3 under humidified 30% CO_2 /air atmosphere.

and LiFeO_2 are seen in Fig. 4. In each case, the solubility increased as a function of temperature in contrast to the retrograde NiO solubility-temperature dependence found by Sim *et al.* (12) under similar conditions. The magnitude of these solubilities at 923 K, the operating temperature of a MCFC, were relatively similar, with neither ZnO nor LiFeO_2 offering any particular advantage in equilibrium solubility relative to NiO under the experimental conditions. In contrast, the LaNiO_3 and LaCoO_3 solubilities were found to be temperature invariant, with the magnitude of the solubility not varying significantly from the electrolyte's background impurity levels. Complementary La analysis, performed on the electrolyte from LaNiO_3 samplings using x-ray fluorescence analysis, showed no La to be present, *i.e.*, the La concentration remained below the 5 ppm mole fraction detection limit. Since the LaNiO_3 and LaCoO_3 solubilities could not be measured, they may offer some reduced solubility advantages over NiO as MCFC cathode materials.

The transport rate, rather than the actual cathode environment solubility level, however, is important in determining the cathode dissolution rate. Attempts to determine the equilibrium solubility under simulated

Table II. Impurity levels determined in commercial "high purity" 62:38 (Li_2CO_3 : K_2CO_3) electrolyte

Impurity	Analyzed concentration (ppm mole fraction)
Ni	19-25
Fe	31-35
Co	33-40
Cr	2-7
Cu	0.3-1
Mn	2-7
Zn	2-6
Au	<1
Ti	<5
Al	<5
La	<5
Nb	<3

anode-side conditions (H_2/CO_2 mixture) were precluded by the high background impurity levels. Further studies along this line will require the synthesis of higher purity Li_2CO_3 and K_2CO_3 . It can be assumed, however, that neither $LaNiO_3$ nor $LaCoO_3$ will offer a significant advantage over NiO in anode side stability since both materials decompose to La_2O_3 and MeO ($Me = Ni$ or Co) at low oxygen partial pressures (13), as shown by the equation below

Therefore, dissolved $LaNiO_3$ or $LaCoO_3$ is expected to lead to metallic precipitation in the same fashion as the present cathode, and any advantage associated with this material will necessarily come from a reduced cathode-side solubility.

The results of this study demonstrate several points. First is the difficulty in finding materials which are chemically stable in the molten electrolyte under cathode gas environment. Second, there is the compounding difficulty of finding stable materials which possess a suitably high electronic conductivity. Of the materials examined, only $LaNiO_3$ and $La_{1-x}Sr_xCoO_3$ were found to satisfy these requirements. Third, there is the difficulty in evaluating equilibrium solubilities for materials in molten alkali carbonates. Although the measurements were complicated by high impurity background levels, temperature dependent solubilities were obtained for NiO , ZnO , and $LiFeO_2$ under a humidified 30% CO_2 /air atmosphere. The $LaNiO_3$ and $LaCoO_3$ solubilities were not determined because of the impurity levels in the base electrolyte.

Determination of the Thermoneutral Potential of $Li/SOCl_2$ Cells

N. A. Godshall*¹ and J. R. Driscoll

Altus Corporation, San Jose, California 95112

ABSTRACT

Heat generated during discharge of $Li/SOCl_2$ cells is an important consideration in the design of both active and reserve-activated batteries, and depends critically on the value of the enthalpic portion of the electrochemical reaction, or "thermoneutral potential" (E_H). The thermodynamic basis for the causes of heat generation in $Li/SOCl_2$ cells is described, and the importance of the thermoneutral potential is discussed. Good agreement was obtained between two experimental techniques used to measure E_H : (i) calorimetric studies and (ii) measurements of open-circuit potential as a function of temperature. Electrochemical discharge of $Li/SOCl_2$ cells was found to be exothermic at all discharge rates, with a thermoneutral potential of $3.72 \pm 0.02V$ and a $\partial E/\partial T$ value of -0.21 ± 0.03 mV/C.

The open-circuit voltage (E) of a faradaic electrochemical cell may be related to the thermodynamic free energy (ΔG_r) of the electrochemical reaction taking place within the cell by the relation

$$\Delta G_r = -zF \int_0^x E dx \quad [1]$$

where F represents the Faraday constant (23.06 kcal V^{-1} eq $^{-1}$), z is the charge transport number (eq mol $^{-1}$), and x is the extent of reaction (dimensionless). That is, the standard free energy of reaction (ΔG_r) is simply the area under a discharge curve of a cell discharged at an infinitely low rate. For an electrochemical couple having a

(nearly) flat discharge curve, such as lithium/thionyl chloride, Eq. (1) simplifies to

$$\Delta G_r = -zFE \quad [2]$$

The free energy of the electrochemical reaction is composed of enthalpic (ΔH_r) and entropic (ΔS_r) parts

$$\Delta G_r = \Delta H_r - T\Delta S_r \quad [3]$$

The combined statement of the first and second laws of thermodynamics states that

$$\partial \Delta G = \Delta V \partial P - \Delta S \partial T \quad [4]$$

So that at constant pressure

$$\frac{\partial \Delta G}{\partial T} = -\Delta S \quad [5]$$

* Electrochemical Society Active Member.

¹Present address: Sandia National Laboratories, Albuquerque, New Mexico 87185.

Substitution into Eq. (2) yields

$$\Delta S_r = zF \frac{\partial E}{\partial T} \quad [6]$$

Therefore, the entropy change of an electrochemical reaction at equilibrium may be derived from a knowledge of the way in which the open-circuit potential of the cell varies with temperature.

The enthalpy change of the electrochemical reaction (ΔH_r) follows directly from the above

$$E = \frac{-\Delta H_r}{zF} + \frac{T\Delta S_r}{zF} \quad [7]$$

$$\frac{-\Delta H_r}{zF} = E - \frac{T\partial E}{\partial T} \quad [8]$$

Equation [8] represents the thermoneutral potential, (E_H), and reflects that part of the cell voltage due only to the enthalpy term

$$E_H = \frac{-\Delta H_r}{zF} \quad [9]$$

E_H is that potential at which a cell would need to be operated such that no heat flowed into or out of the cell. It is also the theoretical open-circuit voltage of the cell at absolute zero. Because the enthalpy change of the electrochemical reaction (ΔH_r) is usually quite constant over the temperature range considered, the thermoneutral potential is also nearly independent of temperature.

Heat Analysis

The importance of the thermoneutral potential (E_H) to heat generation, and its derivation, may be found elsewhere (1, 2). The analysis in the previous section was concerned only with "equilibrium" phenomena (*i.e.*, open-circuit conditions). A complete heat analysis also includes nonequilibrium effects, such as those caused by finite discharge currents, corrosion of the lithium anode, etc. The total heat (q_T) generated during an electrochemical discharge is simply the sum of the heat generated by polarization (q_p), entropy affects (q_s), and other sources of heat such as self-discharge (*e.g.*, Li corrosion)

$$q_T = q_p + q_s + q_{\text{other}} \quad [10]$$

where a negative q_T represents a generation of heat by the cell, and a positive q_T represents an absorption of heat by the cell from its local surroundings.

The heat generated by cell polarization is given by the difference between the open-circuit potential (E) and the voltage under load (E_L)

$$q_p = -zF(E - E_L) \quad [11]$$

Likewise, the heat generated or absorbed due to the entropy effects described previously is given by

$$q_s = T\Delta S_r = zFT \frac{\partial E}{\partial T} \quad [12]$$

Considering only these two sources of heat results in

$$q_T = -zF \left(E - E_L - \frac{T\partial E}{\partial T} \right) \quad [13]$$

Substitution of Eq. [8] into Eq. [13] simplifies this result to terms involving only the thermoneutral potential and voltage under load

$$q_T = -zF(E_H - E_L) \quad [14]$$

Differentiation with respect to time renders this relation in terms of heating rate (\dot{q}_T), in watts, and the cell current (I), in amperes

$$\dot{q}_T = -I(E_H - E_L) \quad [15]$$

The behavior of an electrochemical cell, and its relation to heat generation, falls into one of the two cases outlined in Fig. 1-3. Most battery discharge reactions are of the

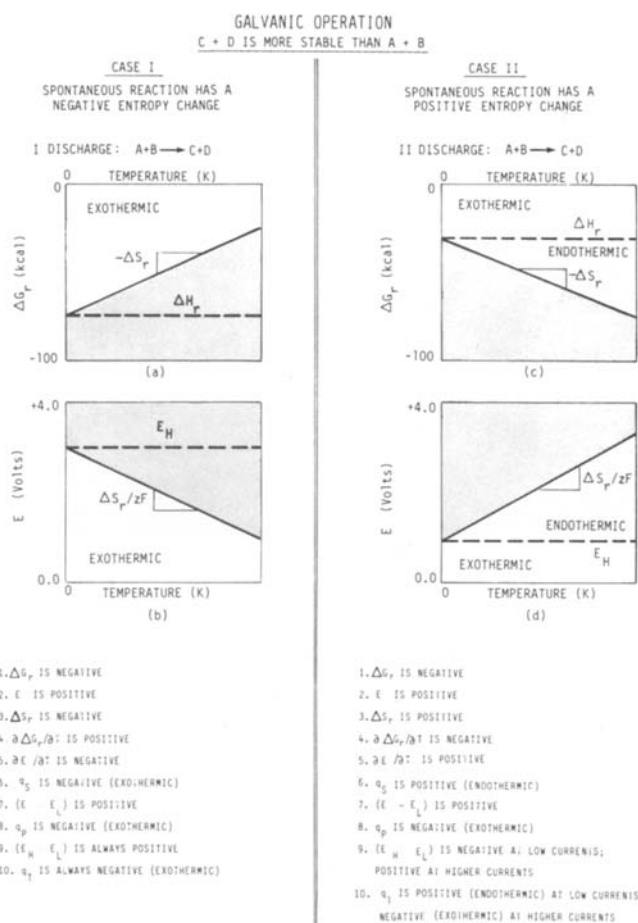

Fig. 1. Discharge of electrochemical cells having (I) negative and (II) positive entropies of reaction.

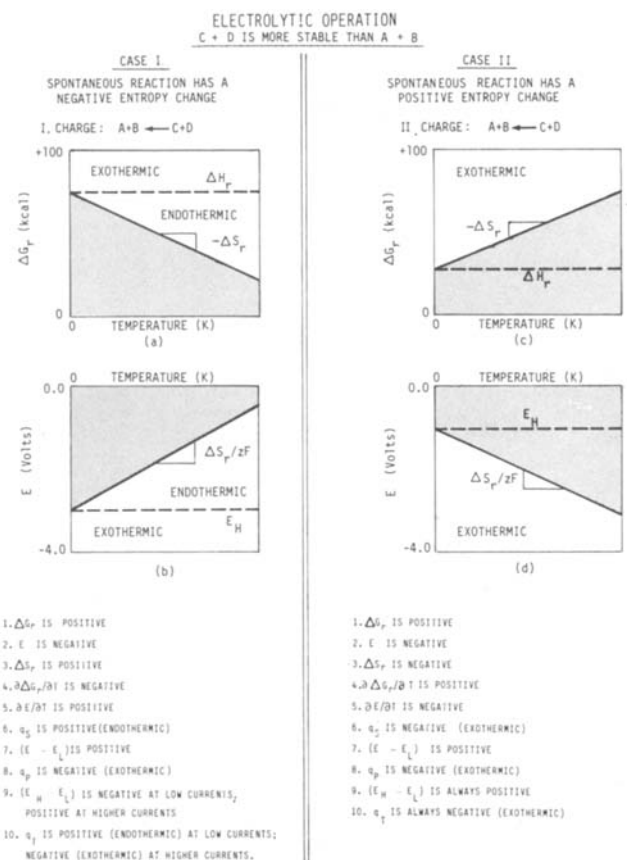

Fig. 2. Charging of electrochemical cells having (I) negative and (II) positive entropies of reaction.

Fig. 3. Heat generation and absorption regions illustrated on idealized Ellingham and E vs. T diagrams for electrochemical reactions with (I) negative and (II) positive entropy changes during discharge (spontaneous reaction).

Case I type. That is, the free energy (ΔG_r) of the galvanic reaction (discharge) is less negative at higher temperatures, due to a negative entropy associated with the reaction (ΔS_r). That is, the products of the spontaneous electrochemical reaction are more ordered than the reactants. The tendency of all systems to increase in disorder (positive entropy) is therefore overridden by the large negative enthalpy of the reaction (ΔH_r). As the temperature increases, the entropy term of Eq. [3] becomes more dominant, and acts to decrease the overall energy (ΔG_r) of the cell, Fig. 1a.

The same behavior is illustrated in the temperature variation of a cell's open-circuit voltage, or equilibrium potential (E), Fig. 1b. The voltage due only to the enthalpic part (E_H) of the electrochemical reaction in Case I (dashed line) is larger than the actual open-circuit cell voltage (solid line) at all temperatures. That is, the negative ΔS_r term is manifested as a negative slope in E vs. T . Galvanic operation (discharge) of the cell is therefore exothermic at all rates. Electrolytic operation (charging of the cell) reverses the sign of most terms and the slope of E vs. T , Fig. 2. The combination of Fig. 1 and 2 is illustrated in Fig. 3 for the discharge direction. Therefore, only at a specific overpotential ($T\Delta S_r/zF$) during electrolytic operation (charge) would a "Case I" cell undergo zero heat flow into or out of the cell, Fig. 3b. This situation would therefore not occur in a primary system such as Li/SOCl₂.

Although occurring less frequently, some electrochemical systems exhibit the interesting properties associated with a positive entropy of reaction, Fig. 1c. That is, in Case II, the products of the spontaneous electrochemical reaction are less ordered than are the reactants. Thus, the cell's open-circuit potential (E) is made up of the typical enthalpic term (E_H) plus a small voltage ($E_s = T\Delta S_r/zF$) due solely to the increasing randomness of the electrochemical reaction, Fig. 1d.

Furthermore, galvanic operation (discharge) near equilibrium would be endothermic (i.e., would absorb heat from the surroundings). Only during a higher rate discharge (overpotential greater than $T\Delta S_r/zF$) would the cell

polarization generate more heat than the entropy of reaction would absorb, resulting in a net exothermic reaction, Fig. 3d. Once again, the point of zero heat flow would occur at a voltage equal to the enthalpic term, or thermoneutral potential (E_H). Charging a reversible "Case II" cell is exothermic at all rates.

The importance of the value of the thermoneutral potential and the sign of the slope of E vs. T are thus evident. Discharge or charge of a cell at a voltage E_L outside the limits of the thermoneutral (E_H) and open-circuit (E) potentials results in an overall exothermic process, or heat generation, Fig. 3. Note that such heat generation is independent of the open-circuit potential of the cell (E), Eq. [15]; it depends rather, on the enthalpic potential (E_H). Furthermore, for a given open-circuit potential (such as 3.65V for Li/SOCl₂ at 25°C), a larger negative E vs. T slope ($\Delta S_r/zF$) for a "Case I" electrochemical reaction results in a substantially higher thermoneutral potential ($E_H = E$ at 0 K); which, consequently, results in a substantially greater heat generation rate.

Conversely, discharge or charge of a cell at a voltage E_L between its thermoneutral (E_H) and open-circuit (E) potentials results in an overall endothermic process or heat absorption by the cell from its surroundings.

Experimental

Two methods were employed to determine the thermoneutral potential of Li/SOCl₂ cells: (i) calorimetric studies performed on discharging cells, and (ii) measurement of open-circuit potential as a function of temperature. Two independent quantities must be measured with each technique in order to calculate the thermoneutral potential (E_H).

Calorimetric measurements yield enthalpy of reaction (ΔH_r) data only; that is, the change in degree of order (entropy) of reactants and products cannot be measured in a calorimeter alone. The additional required information is obtained, then, by discharging the cell at a known current (I) and voltage (E_L) during the calorimetric measurements (\dot{q}_T). The entropy ($\partial E/\partial T$) and enthalpy (E_H) terms are then calculated from Eq. [13] and [15], respectively. In the calorimetry measurements, Li/SOCl₂ cells were equilibrated at temperatures between 0° and 53°C inside a Geosystems calorimeter and discharged at current densities between 1.0 and 20.0 mA/cm².

In the open-circuit potential technique, direct measurement of $\partial E/\partial T$ yields the entropy of reaction from Eq. [6]. The additional knowledge of the open-circuit potential at any temperature permits calculation of the enthalpy of reaction (ΔH_r) and thermoneutral potential (E_H) from Eq. [8]

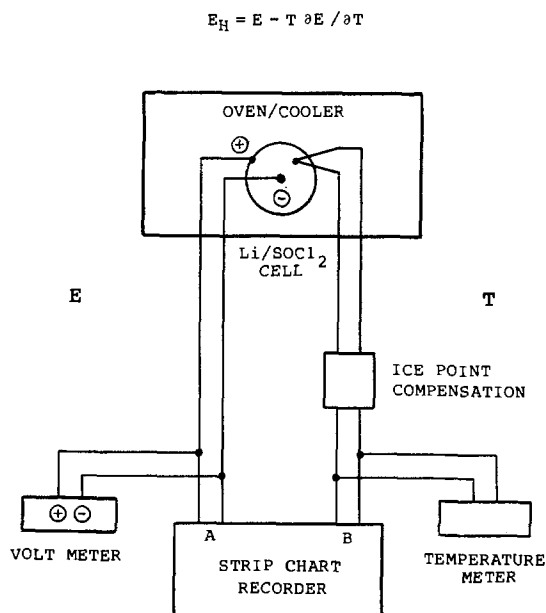

Fig. 4. Schematic of E vs. T experimental apparatus

and [9], respectively. In the $\partial E/\partial T$ measurements, all cells were first discharged at the C/24 rate for 2h (C/24 is that rate which would completely discharge a fresh cell in 24h) followed by equilibration at open-circuit conditions for 20h. This procedure was intended to minimize the effects of voltage delay, which is especially prevalent in undischarged cells. The cells were then placed inside an environmental chamber where the open-circuit potential (E) was measured as a function of incremental changes in temperature. A strip chart recorder was used to determine the steady-state equilibration of E (typically 1-5h) after a new temperature had been selected. The cell temperature was measured using a type "K" thermocouple and an electronic ice point to compensate for changes in ambient temperature. The temperature controller was found to maintain the temperature within $\pm 1^\circ\text{C}$ relative when the measurement temperature was greater than 20°C , and within $\pm 2^\circ\text{C}$ when less than 20°C .

Results

Typical calorimetric results are listed in Table I. The measured heating rates varied between 17 and 376 mW at currents between 58 and 664 mA, respectively. The thermoneutral potentials calculated from these data lie between 3.70 and 3.87V, and appear to be nearly independent of current, Fig. 5. The calorimetric results indicate a thermoneutral potential of $3.783 \pm 0.080\text{V}$, Eq. [15].

The above calorimetric analysis included only the polarization (q_p) and entropy (q_s) terms. Heat generation caused by significant Li corrosion (q_c) would result in erroneously high calculated thermoneutral potentials from Eq. (15). Therefore, lithium electrical efficiencies were measured in thionyl chloride electrolytes to determine their contribution to the total heating power (\dot{q}_T), Fig. 6. Lithium disks (2.5 cm^2 in area; 34 mg in weight) were completely discharged galvanostatically at currents between 2.5 and 120 mA/cm². Their electrical efficiency (ϵ) was calculated simply as the ratio of their integrated currents with respect to time *vs.* their theoretical capacity. Electrical efficiencies in neutral 1.6M LiAlCl₄ thionyl chloride electrolyte were approximately 98% at 21°C and 93% at 45°C below 25 mA/cm². Efficiencies were considerably lower using either higher current densities or acidic electrolyte, as expected (Fig. 6).

The heat generated solely by Li corrosion is given by the enthalpy of reaction between lithium and thionyl chloride (ΔH_r) and the inefficiency ($1 - \epsilon$)

$$q_c = \Delta H_r (1 - \epsilon) = -zFE_H (1 - \epsilon) \quad [16]$$

so that the heating rate due to Li corrosion is given by

$$\dot{q}_c = -I E_H (1 - \epsilon) \quad [17]$$

The total heating rate including polarization, entropy, and lithium corrosion is, therefore, given by

$$\dot{q}_T = -I (2E_H - \epsilon E_H - E_L) \quad [18]$$

Table I. Calorimetric measurements. $E_H = E_L - \dot{q}/I$

Temp. T (°C)	Current I (mA)	Heat \dot{q} (mW)	\dot{q}/I (V)	VUL E_L (V)	Calculated

53	118	-41	-0.348	3.50	3.85	-0.602
53	59	-21	-0.356	3.52	3.87	-0.665

Fig. 5. Thermoneutral potentials obtained from calorimetric measurements.

$$E_H = \frac{E_L - \dot{q}/I}{2 - \epsilon} \quad [19]$$

Therefore, by including a lithium electrical efficiency of 98%, the thermoneutral potential calculated above (3.783V) is reduced to 3.71V.

The results of typical $\partial E/\partial T$ measurements are listed in Table II and illustrated in Fig. 7. These data reflect true E *vs.* T results; that is, the open-circuit potential was not determined from an extrapolation to zero current of various discharge voltages (2). Similar results were obtained regardless of whether the cell temperature was equilibrated from a higher or lower temperature. The open-circuit potential was found to vary with the temperature in a linear fashion over the temperature range -5° to 75°C . A least squares fit of the data resulted in a thermoneutral potential value of 3.723V and a $\partial E/\partial T$ value of negative 0.228 mV/C, indicating that lithium/thionyl chloride discharge is exothermic at all rates (Case I-type reaction).

The thermoneutral potential (E_H) of an electrochemical cell represents the enthalpic portion of the open-circuit potential

$$E_H = -\frac{\Delta H_r}{zF} = \frac{-\Delta G_r - T\Delta S_r}{zF} = E - \frac{T\partial E}{\partial T} \quad [20]$$

Cell operation at the thermoneutral potential results in zero heat absorption or generation by the cell. Cell operation inside a region bounded by the free energy (ΔG_r) and

enthalpy (ΔH_r) terms, or by the open-circuit potential (E) and thermoneutral potential (E_H), always represents endothermic cell operation (heat absorption). Cell operation at voltages lying outside these regions results in exothermic cell operation (heat generation). Cell operation at the thermoneutral potential (E_H) represents a point of zero heat flow, and reflects a smooth transition between endothermic and exothermic cell operation. Conversely, the open-circuit potential (E) represents a discontinuous transition between endothermic and exothermic cell operation.

For an electrochemical reaction which has a negative entropy change (in the discharge direction), the slope of E vs. T will be negative, the open-circuit potential will be less than the thermoneutral potential at all temperatures, and the point of zero heat flow would occur during cell charging. Conversely, for an electrochemical reaction which has a positive entropy change (in the discharge direction), the slope of E vs. T will be positive, the open-circuit potential will be greater than the thermoneutral potential at all temperatures, and the point of zero heat flow would occur during cell discharge.

The thermoneutral potentials of LiSOCl₂ cells, calculated from the two different experimental procedures, exhibited reasonably good agreement. The calorimetric studies, performed on discharging cells and corrected for Li corrosion, yielded a thermoneutral potential of 3.710V

* Thermochemical data of Ref. (3) available for gaseous SOCl₂ only: $\Delta H_f^\circ = -50.75$ kcal/mol, $S^\circ = 73.6$ cal/mol K.

and a E vs. T slope of -0.20 mV/C. The $\partial E/\partial T$ measurements, performed under open-circuit conditions, yielded a thermoneutral potential of 3.723V and an E vs. T slope of -0.23 mV/C. Both values represent exothermic cell discharge, although the thermoneutral potential determined experimentally indicates less heat generation than that predicted by the values calculated thermodynamically ($E_H = 3.73$ - 3.90 V).

A review of the literature (3-7) for measured values of the enthalpic and entropic counterparts of the lithium/thionyl chloride reaction was made for comparison with these results (Table III). The underlined values in each line represent the original data obtained from the reference, from which all other values were calculated according to the above equations.

The first line reflects thermodynamic calculations of this work based on the thermochemical data of Barin *et al.* (3), while the second line reflects similar thermodynamic calculations performed by Miles (4). Calorimetric measurements were also performed on Li/SOCl₂ cells by Frank (7) (Table IV). The cell current (I), heating rate (\dot{q}_T), and voltage under load were taken directly from the original data at midpoint of discharge. Only the cell discharged at 0.1A exhibited results which would suggest endothermic behavior (*i.e.*, positive $\partial E/\partial T$ and E_H less than E). The remaining results of Table IV, though somewhat scattered, all indicate exothermic cell discharge with $3.66 < E_H < 3.84$ V. Similar calorimetric results indicating exothermic behavior were also obtained by Bro (5) and Gibbard (6).

A comparison of all the thermodynamic data is shown in Fig. 8. Only the work of Schlaikjer *et al.* (2) predicts a

positive $\partial E/\partial T$, or Case II (endothermic discharge) type of reaction for Li/SOCl₂. The corresponding E_H value of 3.34V is the only predicted value for the thermoneutral potential which is less than the open-circuit voltage (E) of the cell. In these $\partial E/\partial T$ measurements, the open-circuit voltage was not measured directly; rather, E was extrapolated from cell polarization data at different currents. It is possible that the irreversibilities associated with the lithium/thionyl chloride system might affect a $\partial E/\partial T$ value extrapolated from polarization data.

Conclusions

Electrochemical discharge of Li/SOCl₂ cells is believed to be exothermic at all rates, with a thermoneutral potential greater than the open-circuit potential and a negative E vs. T slope (Case I-type reaction). E_H was found to be 3.72 ± 0.02 V, with a corresponding $\partial E/\partial T$ of -0.021 ± 0.03 mV/C.

The Effect of Different Aluminum Alloy Surface Compositions on Barrier Anodic Film Formation

J. K. G. Panitz and D. J. Sharp

Sandia National Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

We have grown barrier anodic coatings on samples of aluminum alloy with different elemental surface compositions. In one series of experiments, we characterized the surface composition present on 6061 aluminum alloy samples after different chemical treatments including (i) a detergent-water and methyl-ethyl ketone solvent clean, (ii) a 50% nitric acid-water etch, and (iii) a concentrated nitric acid-ammonium bifluoride etch. We anodized samples which were prepared similarly to those analyzed to evaluate the practical effects of the three different surface compositions. The anodization voltage rise time to 950V at constant current was used as a figure of merit. The solvent cleaned and the 50% nitric acid etched samples required, respectively, 113% and 41% more time to reach 950V than the concentrated nitric acid-ammonium bifluoride etched samples. In a second series of experiments, we alternately anodized groups of either 6061 or 1100 (commercially pure) aluminum alloy, observed rise times to 950V, and measured chloride ion concentrations in the electrolyte. Longer rise times and higher chloride ion concentrations were observed for the 1100 samples. It was observed that the chloride ion concentration fell from initially high levels when 6061 samples were anodized. The results of both series of experiments augment the results of other investigators, who report that the surface species initially present on aluminum have a significant effect on anodic film formation.

It is generally observed that the macroscopic characteristics displayed by barrier Al_2O_3 anodic coatings (e.g., growth rate, leakage current, and breakdown strength) are, in part, a manifestation of microscopic flaws which are incorporated in the coatings during anodization. One source of flaws in metal oxide coatings can be related to local topographical or compositional heterogeneities on the surface of the aluminum substrate material (1-3). Another source of flaws in barrier anodized coatings originates from contaminants in the electrolyte which can react with aluminum to form soluble by-products (4). Several groups have evaluated the efficacy of different chemical preparation sequences with regards to subsequent anodization processing (5-8). Shimizu *et al.* (3) have recently reported that flaw sites occur in barrier Al_2O_3 coatings in conjunction with the presence of silicon precipitates on the order of 0.3 nm or larger in the surface region of the Al-1.5% Si alloy which they anodized. Vermilyea (1) reports the formation of flaws in barrier anodized Ta_2O_5 coatings in conjunction with the presence of carbon on the original substrate surface. Badly flawed barrier aluminum oxide coatings are also observed on samples anodized in electrolyte contaminated with as little as 300 ppb chloride ions (4).

One macroscopic manifestation of a flawed barrier coating is slow growth rate (1, 4). Serious flaws in barrier coatings can be associated with locally degraded dielectric properties. The higher leakage currents typical of such coatings result in slower rise times to a desired anodization potential under constant current conditions. We have performed two series of controlled experiments and have observed the anodization voltage rise time to 950V. In interpreting this data, we assume that longer rise times are an indication of the presence of serious flaws which occur during coating growth.

In one series of experiments, we observed the species present on the surface of samples of 6061 aluminum alloy prepared with either: (i) a detergent-water scrub and a water rinse, followed by a methyl-ethyl ketone (MEK) rinse, (ii) a standard cleaning sequence (Fig. 1) terminated at the 50% HNO_3 step, or (iii) a standard cleaning sequence (Fig. 1) through to and including the concentrated HNO_3 - NH_4HF_2 step. Emission spectroscopy was used to determine the bulk composition of the alloy stock which was used. Auger electron spectroscopy (AES) and electron microprobe analysis (EMA) were used to determine what species remained on the surface after these treatments. Samples prepared similarly to those analyzed were anodized in an electrolyte consisting of a solution of ammonium tartrate in ethanol. The anodization voltage rise time to 950V was used as a figure of merit. Signifi-

cant variations in voltage rise time were regularly and reproducibly observed in conjunction with variations in sample surface composition, e.g., the amounts of carbon and silicon present.

In a second series of experiments, groups of samples of either 6061 or 1100 aluminum alloy were prepared using the complete etch sequence described in Fig. 1, and anodized in the ammonium tartrate-ethanol-based electrolyte. The electrolyte was reused for this entire series of experiments. Emission spectroscopy and AES were used to evaluate the bulk and surface compositions of the aluminum alloys. Samples of the electrolyte were taken after representative anodization runs and submitted for chemical analysis. The rise time to 950V was again observed as a figure of merit. Longer rise times and higher chloride ion concentrations were observed when the 1100 samples were anodized. The results of this second series of experiments strongly suggest that one or more of the alloying components in 6061 aluminum play a role in removing chloride ion contamination from the electrolyte.

Experimental

Different surface compositions on 6061 aluminum alloy.—We prepared and barrier anodized $2.5 \times 5.0 \times 0.15$ cm samples of 6061-T6 aluminum alloy sheet stock with an initial, as-received, surface finish of $0.25 \mu\text{m}$ (0.10 in.). The standard preparation sequence which we used (Fig. 1) employs the following etchants: (i) 5% AR-grade NaOH (by weight) in deionized water at 75°C for 2 min, (ii) a 1:1 solution of concentrated (70%) AR-grade HNO_3 (by volume) in deionized water at 27°C for 10 min, and (iii) concentrated (70%) HNO_3 with 63 g/l NH_4HF_2 at 27°C for 10 min. Deionized water with a resistivity of $18 \text{ M}\Omega\text{-cm}$ or higher was used for rinsing the samples and for preparing the chemicals used in these experiments. Absolute ethyl alcohol was used for a final rinse and for preparing the electrolyte.

We analyzed the surface elemental composition and anodized samples which had received either (i) detergent solution-MEK solvent cleaning, (ii) the standard cleaning

Fig. 1. Flow chart showing the alloy preparation sequence

sequence up to and including the 50% HNO₃ etch, or (iii) the complete standard cleaning sequence including the HNO₃-NH₄HF₂ etch (Fig. 1). We also analyzed and anodized samples which had been etched in the HNO₃-NH₄HF₂ bath for 2-15 min in addition to the standard 10 min etch time.

All samples were immersion-rinsed and spray-rinsed with deionized water, then spray-rinsed with ethyl alcohol, and finally blown dry with dry UHP nitrogen before being submitted for AES or EMA analysis, or before being anodized. The center line average (CLA) surface finish¹ of representative aluminum samples was measured with a Talysurf[®] stylus instrument.

The electrolyte consisted of 1 part by volume of a solution of 2.35g AR-grade ammonium tartrate in 470 ml deionized water added to 40 parts ethyl alcohol. These proportions result in an electrolyte with a resistivity varying from 55 to 70 kΩ-cm. Approximately 2 liters of the electrolyte were used in a cylindrical electrolytic trough equipped with a water cooling bath and a Teflon stirrer. Initial electrolyte temperatures of 21°-22°C, which rose to 27°-29°C at 950V, were typically observed during a run. The electrolytic trough contained three electrolytic cells, each with an identical platinized titanium mesh cathode and a sample of aluminum as the anode. Each cell was independently powered by a Fluke Model 330B "calibrator" power supply with an external voltmeter and ammeter (Fluke Model 86600 A digital multimeters). In a typical anodization run, three pieces of aluminum were anodized: two of which had been prepared with variations of the basic etchant sequence and one control which was prepared with the basic etchant sequence. By using a common electrolytic trough with independent power supplies to anodize several samples simultaneously, and by comparing the characteristics observed for the test samples to those observed for the control sample included in every run, we could compensate for experimental uncertainty arising from small variations in the condition of the electrolyte which occurred from one run to the next.

The aluminum samples were anodized to a cell potential of 950V at a constant current density of 1 mA/cm². For certain runs, when the cell voltage reached 950V, it was held constant; during this aging stage, the current drawn by a cell decreased as the oxide continued to grow, and the cell resistance continued to increase. For some representative runs, the coatings were leakage tested by reducing the cell voltage to 900, 800, and finally 700V; 2 min after the initial application of each of the above voltages, the current drawn by each cell was measured. Such wet leakage tests generally provide a good indication of subsequent dry dielectric leakage characteristics of a coating. For every run that we aged and leakage tested, the current drawn by a cell during leakage testing was proportional to the current drawn during aging which in turn was proportional to the rise time to 950V, i.e., the longer the rise time, the larger the leakage current. Because of this relationship, we used the rise time to 950V to establish a figure of merit for evaluating the different aluminum surface compositions. In the discussion which

follows, the percentage difference $\frac{T_r - T_c}{T_c}$ in the rise time of a test sample T_r , compared to the rise time of a control sample, T_c , included in the same run is used to make quantitative comparisons. From anodization runs in which we anodized three identically prepared alloy samples, we can estimate an experimental error of $\pm 2\%$. At least four different anodization runs were performed for each preparation variation studied.

Anodization of 6061 compared to 1100 (commercially pure) aluminum alloy.—In a separate, though similar,

series of experiments, we anodized samples of 6061-T6 aluminum alloy and 1100 (commercially pure) aluminum alloy. The bulk composition of both types of alloy stock were determined using emission spectroscopy. Samples of both types of alloy received the same standard preparation sequence (Fig. 1) and were anodized to 950V in the ammonium tartrate-ethyl alcohol-based electrolyte described above. Either 6061 or 1100 samples were anodized in a run. Representative samples were taken from the stock materials used for mixing the electrolyte and the electrolyte after either 6061 or 1100 alloy samples had been anodized and submitted for ion chromatography studies; chloride ions were one of the species observed in the chemical analysis of the electrolyte samples.

Results and Discussion

Different surface compositions on 6061 aluminum alloy.—Tables I and II and Fig. 2 and 3 exhibit data associated with the first series of anodization experiments. Tables I and II show the bulk composition of the 6061-T6 aluminum alloy stock used in the first series of experiments and the surface composition remaining on the alloy samples after different preparation steps. Figure 2 il-

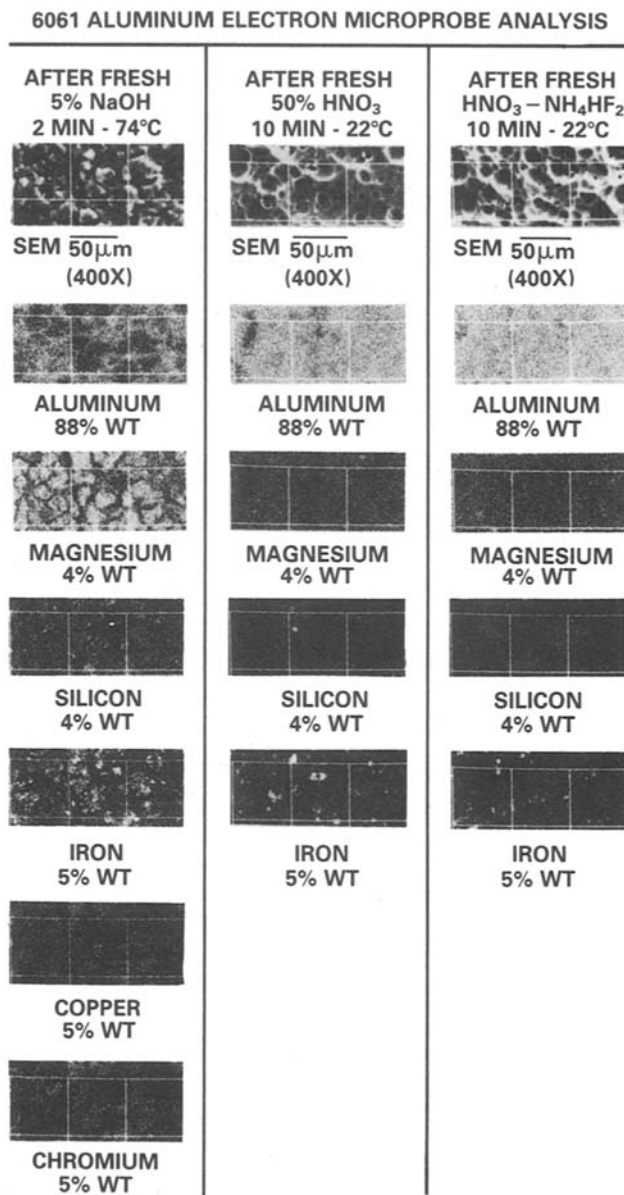

Fig. 2. Components present on the surfaces of 6061-T6 aluminum alloy determined by electron microprobe analysis. Here, the atomic concentrations given below the photomicrographs are the minimal atomic concentrations, which, if present, would result in a totally exposed picture for the gain factors used.

¹ "Center line average" is a surface finish designation which is similar to root mean square (RMS). The CLA is calculated from the integral of the absolute value of the displacement of a surface contour from its base line average value. The RMS is calculated from the square root of the integral of the square of the displacement of a surface contour from its base line average value.

illustrates the results of EMA, micrographs showing the surface topographies of the samples and also the distribution of detectable alloying components present in the near-surface region.

Table III shows the surface finish observed for representative alloy samples which have been etched for 0 (as received), 2, and 4 min in the 5% NaOH etch, and similar samples which have received the complete standard etch sequence. The 5% NaOH etch dominates in determining the surface finish of the aluminum prepared by this etch sequence. The surfaces of samples etched with the 50% HNO₃ and with the HNO₃-NH₄HF₂ baths are only slightly rougher than the samples after the 5% NaOH step. As a general rule, if a group of substrates have similar surface compositions, the samples with rougher surfaces will anodize more slowly. There are two reasons for this: (i) topographic irregularities can initiate defect sites in the growing oxide during anodization, and (ii) the effective surface area of rougher samples is larger than the nominal surface area used to calculate the current which is supplied to each sample during the constant current density period of anodization.

Samples which have been solvent cleaned only are observed to take 113% more time to reach 950V than samples receiving the complete etch sequence. This dif-

ference in rise times must be a result of surface and/or near-surface composition effects since surface topography effects would tend to cause the smoother surfaced, solvent cleaned samples to anodize faster than the rougher surfaced, etched samples. Table I shows that the surfaces of the solvent cleaned samples contain almost twice as much carbon as the samples receiving the complete etch. Significant amounts of carbon are also detected in the near surface region of these samples. This carbon originates from external sources and/or surface segregation effects. (Metallurgical specifications allow no more than 0.05% atomic percent [a/o] carbon in bulk 6061 aluminum alloy, significantly less than was found in the surface region. Carbon could not be examined in the bulk 6061 aluminum alloy stock analyzed by emission spec-

troscopy because carbon electrodes were used.) The fact that the surface region of the solvent cleaned samples consists of more carbon than aluminum may account for the observation that these samples are slow to anodize.

The surfaces of samples etched with 5% NaOH for 2 min at 74°C are covered with a dark powdery, poorly adhering deposit which is commonly called smut. One of the photomicrographs in Fig. 2 shows the surface topography associated with this smut. Electron microprobe analysis of the near (approximately $1\ \mu\text{m}$ deep) surface region of samples etched by 5% NaOH indicate this smut consists primarily of Mg, Si, Fe, Cu, and Cr. Auger electron spectroscopy sputter profiles of these samples indicate the mud-cake-like smut structures consist of a mixture of Al, Mg, Si, and their oxides and are at least $6\ \mu\text{m}$ thick. We did not attempt to anodize any of these samples.

Samples receiving the standard preparation sequence up to and including the 50% HNO_3 etch take 41% more time to anodize than samples receiving the complete etch sequence. The difference in the surface topographies for these two types of samples is small, but the slightly smoother surface of the HNO_3 etched samples would tend to favor faster anodization. The difference in rise times observed must therefore be dominated by surface composition effects. Auger electron spectroscopy indicates the $\text{HNO}_3\text{-NH}_4\text{HF}_2$ etched samples which anodize faster contain significantly less Si ($2 \pm 0.5\%$ a/o vs. $5 \pm 0.5\%$ a/o) and more C ($35 \pm 3.5\%$ a/o vs. $11 \pm 1.1\%$ a/o) than the samples etched with HNO_3 . Table II shows AES sputter profile data for an $\text{HNO}_3\text{-NH}_4\text{HF}_2$ -etched sample that indicates the higher levels of Si which are observed at the surface (2% a/o) diminish rapidly within 50 nm of the surface and approach the bulk concentration (0.68 a/o). These data indicate that the flaws which propagate in association with silicon degrade the dielectric properties of these barrier coatings more than the flaws associated with carbon. The

observation that samples containing less Si anodize faster agrees with the results reported by Shimizu *et al.*, who observe major flaws propagating through anodic Al_2O_3 coatings which originate from Si precipitates with grain sizes greater than approximately 30 nm (8).

Additional insight regarding the magnitudes of the reaction mechanisms involved here is provided by Fig. 3. Figure 3 shows the percentage difference in rise times which are observed as a function of etch time in the $\text{HNO}_3\text{-NH}_4\text{HF}_2$ solution. (Here samples etched for 10 min. The standard etch times were used as controls.) A small but significant minimum in rise time is observed for samples etched for approximately 5 min. The portion of the curve to the left of the minimum shown in Fig. 3 may be dominated by compositional effects. It is probable that some minimal amount of time is necessary for the etchant to chemically remove precipitates which affect or impede the formation of an anodic coating. Since Table I shows no significant differences in the surface composition of similar samples analyzed using AES, the curve on the right of the minimum may be dominated by surface topography effects. It is probable that preferential etching occurs along grain boundaries and for certain grain orientations and results in a rougher surface morphology for longer etch times.

Anodization characteristics of 6061 vs. 1100 aluminum alloy.—In a second sequence of experiments, we prepared and anodized samples of 6061-T6 and 1100 aluminum alloy using the same standard preparation sequence and electrolyte described above. Table IV shows the bulk composition of the aluminum alloy stock used for this series of experiments and the surface composition remaining on the surface of these samples after the complete etch sequence. No significant differences between the two types of samples are apparent over the sensitivity limitations of AES. Extrapolating from the composition data observed for the bulk samples would lead one to expect that less Mg, Si, Mn, Cu, Cr, and Zr and similar amounts of Fe are present in the surface region of the 1100 aluminum alloy samples.

Large variations in the percentage difference in rise time to 950V are observed when the 1100 samples are compared to the 6061 samples. In eight different anodization runs involving four different sets of anodization processing parameters, it was observed that the 1100 samples took 13%, 18%, 52%, and infinitely more time to reach 950V. Figure 4 shows the chloride ion concentration present in the electrolyte after either 1100 or 6061 samples were anodized. Figure 4 also shows the chloride ion concentration present in the stock chemicals used to prepare the electrolyte, and the chloride ion concentrations pres-

Fig. 4. Chloride ion concentration as a function of electrolyte history. Chloride ion concentrations are lower after preconditioning the bath by anodizing "dummy" 6061 samples. Chloride ion concentrations observed after anodizing 6061 alloy are significantly lower than those observed after anodizing 1100 alloy.

ent in samples of new electrolyte taken during the preliminary electrolyte preparation period while the electrolyte was being "dummied." It had previously been empirically observed that it is sometimes necessary to prepare or "dummy" the freshly mixed electrolyte by anodizing samples of 6061 aluminum alloy. It is typically observed that the maximum voltage attainable during the first break-in run is less than the 950V desired. High concentrations of chloride ions are observed in the fresh, unused electrolyte. We have documented that chloride ion contamination can impede or inhibit barrier coating formation on aluminum (4). Chloride ion contamination can be introduced into the electrolyte from (i) the stock ingredients used to prepare the electrolyte, (ii) contact with the anodization apparatus, and (iii) the samples of aluminum alloy themselves. Samples of electrolyte analyzed after successive break-in runs with 6061 show successively lower chloride ion concentrations. Relatively high levels of chloride ion contamination are observed in representative samples of electrolyte taken after 1100 aluminum alloy is anodized in the dummied electrolyte. Lower levels are observed in samples drawn after subsequent anodization runs, however, if 6061 aluminum alloy is anodized. These observations suggest one or more of the alloying components in the 6061 samples which are present in a smaller amount or absent from the 1100 samples react with Cl^- and remove it from solution. Most chloride compounds are known to be somewhat soluble in water and alcohol. However, some oxychloride compounds, such as $\text{CuCl}_2 \cdot 3\text{CuO} \cdot 4\text{H}_2\text{O}$ (Brunswick green) and $\text{Cu}_2(\text{OH})_3\text{Cl}$ (atacamite), exhibit limited solubilities. Additional work is necessary to identify which alloying component(s) causes this effect.

Summary and Conclusions

We have characterized the surface composition of 6061-T6 aluminum alloy samples prepared with different chemicals. We subsequently barrier anodized similar samples in a series of differential experiments. The anodization voltage rise time to 950V during constant cur-

rent density conditions was used to make semiquantitative comparisons of the effect of different surface compositions. From the experimental controls instituted, we can assume that the voltage rise times that were observed are related to the presence of flaws incorporated in the coatings during anodization.

Samples which are solvent cleaned only have a relatively large amount of carbon on the surface and require more than twice as much time to reach an anodization potential of 950V under constant current conditions, as compared to samples receiving the complete etchant sequence, which includes a concentrated nitric acid-ammonium biftuoride bath. Samples receiving a 50% nitric acid etch as the final chemical treatment have approximately twice as much surface silicon (and approximately one third as much surface carbon) and require 41% more time as compared to samples receiving the complete etchant sequence. Samples treated with the complete etch sequence concluded with the concentrated $\text{HNO}_3\text{-NH}_4\text{HF}_2$ treatment for different amounts of time ranging from 0-15 min exhibit reproducible voltage rise times with respect to control samples treated for 10 min. This relationship observed is interpreted as indicating that a certain minimal etch time is necessary to remove precipitates containing Si which impede anodic Al_2O_3 coating formation; beyond a certain optimal time, the rougher surface morphology which results from chemical etching appears to impede Al_2O_3 coating growth.

We also characterized the surface composition of 1100 (commercially pure) aluminum alloy prepared with the complete etch sequence and anodized these samples. Auger electron spectroscopy indicates similar surface compositions present on both the 6061 and the 1100 samples; however, extrapolating from the bulk compositions observed would imply that significantly less Mg, Si, Mn, Cu, and Cr are present on the 1100 surfaces. The voltage rise times and the chloride ion concentrations observed in the electrolyte after anodization for 1100 samples compared to 6061 samples strongly suggest that one or more of the alloying components which are present on the surface of the 6061 samples but not on the 1100 samples can remove Cl^- ions from the electrolyte. Most chloride compounds are very soluble in the electrolyte, i.e., ethyl alcohol and water. However, certain oxychloride compounds are relatively insoluble; the formation of these compounds may deplete the chloride concentration in the contaminated electrolyte coating growth on 6061 aluminum alloy.

In general, the behavior observed augments the work of other investigators, who report the surface composition which is initially present on aluminum significantly affects subsequent anodic coating formation.

Acknowledgments

We would like to express our gratitude for the support of many Sandia National Laboratory personnel who worked with us on this project. In particular, gratitude is due to Raymond Merrill, who dedicated a considerable effort towards developing a technique for chemically analyzing the electrolyte, Paul Hlava, who performed the electron microprobe analysis, Nora E. Campbell, who contributed the emission spectroscopy data, and finally Merrill Chamberlain and William Wallace, who did the AES analyses. This work was supported by the U.S. Department of Energy under Contract DE-AC04-76-DP00789.

Manuscript submitted March 11, 1983; revised manuscript received ca. March 20, 1984.

Sandia National Laboratories assisted in meeting the publication costs of this article.

Kinetics and Mechanism of the Hydrogen Evolution Reaction on Titanium in Acidic Media

Eugene J. Kelly* and H. R. Bronstein*

Oak Ridge National Laboratory, Chemistry Division, Oak Ridge, Tennessee 37831

ABSTRACT

The effects of potential and pH on the rate of the hydrogen evolution reaction on zone-refined titanium have been determined in acidic sulfate and chloride media over the pH range of 0 to 4.0. In all cases, the cathodic Tafel slope is equal to -120 mV, i.e., $(\partial E/\partial \log i_{H,\alpha})_{pH} = -2(2.303 RT/F)$. The reaction order with respect to proton activity, $(-\partial \log |i_{H,\alpha}|/\partial pH)_E$, exhibits a minimum value of 0.49 at $pH = 1.83$, and increases to a limiting value of 1.0 with increasing or decreasing pH. A mechanism in agreement with the aforementioned observations has been proposed. The mechanism consists of two parallel paths for rate-determining proton discharge, one path involving the usual solvated proton and the other involving the adsorbed surface species $(TiOH)_{ads}^+$, followed by the fast recombination reaction. Langmuir adsorption kinetics apply to the adsorbed hydrogen atoms. The proposed mechanism is consistent with what is known concerning the effect of potential upon the rate of absorption of hydrogen by the metal. The mechanism is also consistent with the mechanism of active-state dissolution and passivation of titanium in acidic media, i.e., the hypothetical existence of a 3-d phase oxide (as opposed to adsorbed oxy and hydroxy titanium species on the submonolayer level) on titanium in the active state is rejected.

Although the mechanism of active-state dissolution and passivation of titanium in acidic media has been thoroughly investigated and may be considered to be reasonably well understood, that of the hydrogen evolution reaction (HER) which accompanies corrosion of the metal has remained uncertain (1). In the following discussion, it will be shown that this uncertainty arises not only from the contradictory experimental results and conclusions reported by various investigators, but also from the conflicts which exist between the reported results and those to be expected on theoretical grounds.

Theoretical considerations.—The reactions normally considered in any discussion of the hydrogen evolution reaction are the following

The reactions are commonly referred to as the discharge reaction [1], the electrochemical desorption reaction [2], and the recombination reaction [3]. If one considers just reactions [1] and [2], the system may be described by Eq. [4] and [5]

$$\epsilon_H^{-1} (d\theta/dt) = \bar{k}_1 a_{(H^+)} (1 - \theta) - \bar{k}_{-1} \theta - \bar{k}_2 a_{(H^+)} \theta \quad [4]$$

$$-i_H/F = \bar{k}_1 a_{(H^+)} (1 - \theta) - \bar{k}_{-1} \theta + \bar{k}_2 a_{(H^+)} \theta \quad [5]$$

where i_H is the net current density, and $\bar{k}_{\pm j}$ are electrochemical rate constants for the $\pm j$ th reactions. In this paper, by convention, net and partial anodic (oxidation) current densities are positive, while net and partial cathodic (reduction) current densities are negative. If the Galvani potential difference between the pre-electrode plane (identified with the outer Helmholtz plane) and the bulk of the solution is negligible, as in the present work, then $\bar{k}_{\pm j} = k_{\pm j} \exp(\mp \alpha_{\pm j} FE/RT)$, where E is the electrode potential relative to an arbitrary reference electrode, $k_{\pm j}$ are

* Electrochemical Society Active Member.

chemical rate constants, $\alpha_{\pm j}$ are symmetry factors ($\alpha_{\pm j} = 1 - \alpha_{\mp j}$ and, generally, $\alpha_{\pm j} = 1/2$), and the other symbols have their customary significance. The fractional coverage by adsorbed hydrogen atoms is represented by θ , and ϵ_H is the proportionality constant between the surface concentration of adsorbed hydrogen atoms and θ , i.e., $\theta = \epsilon_H [H_{ads}]$. Initially, the chemical rate constants are assumed to be independent of θ , i.e., Langmuir kinetics prevail. Then, under steady-state conditions ($d\theta/dt = 0$), Eq. [4] may be solved for the steady-state coverage (θ_α) which, when substituted into Eq. [5], gives the steady-state current density ($i_{H,\alpha}$). The following limiting cases are obtained

$$\begin{aligned} \bar{k}_1 a_{(H^+)} &>> (\bar{k}_{-1} + \bar{k}_2 a_{(H^+)}), \\ i_{H,\alpha} &= -2Fk_2 a_{(H^+)} \exp(-\alpha_2 FE/RT), \\ \theta_\alpha &\approx 1, S = -120 \text{ mV}, n = 1 \quad [L-1] \end{aligned}$$

$$\begin{aligned} \bar{k}_{-1} &>> (\bar{k}_1 + \bar{k}_2) a_{(H^+)}, \\ i_{H,\alpha} &= -2Fk_2 K_1 a_{(H^+)}^2 \exp[-(1 + \alpha_2) FE/RT], \\ \theta_\alpha &= K_1 a_{(H^+)} \exp(-FE/RT) \ll 1, S = -40 \text{ mV}, n = 2 \quad [L-2] \end{aligned}$$

$$\begin{aligned} \bar{k}_2 a_{(H^+)} &>> (\bar{k}_1 a_{(H^+)} + \bar{k}_{-1}), \\ i_{H,\alpha} &= -2Fk_1 a_{(H^+)} \exp(-\alpha_1 FE/RT), \\ \theta_\alpha &= (\bar{k}_1/\bar{k}_2) \ll 1, S = -120 \text{ mV}, n = 1 \quad [L-3] \end{aligned}$$

If one considers only reactions [1] and [3], the system is described by Eq. [6] and [7]

$$\epsilon_H^{-1} (d\theta/dt) = \bar{k}_1 a_{(H^+)} (1 - \theta) - \bar{k}_{-1} \theta - 2k_3 \theta^2 \quad [6]$$

$$-i_H/F = \bar{k}_1 a_{(H^+)} (1 - \theta) - \bar{k}_{-1} \theta \quad [7]$$

For this system, under Langmuir conditions, the following steady-state limiting cases are obtained

$$\bar{k}_1 a_{(H^+)} \gg (\bar{k}_{-1} + 2k_3 \theta), i_{H,\alpha} = -2Fk_3, \theta_\alpha \approx 1 \quad [L-4]$$

$$\begin{aligned} \bar{k}_{-1} &\gg (\bar{k}_1 \alpha_{(\text{H}^+)} + 2k_3 \theta), \\ i_{\text{H},\alpha} &= -2\text{F}k_3 K_1^2 a_{(\text{H}^+)}^2 \exp(-2\text{F}E/RT), \\ \theta_{\alpha} &= K_1 \alpha_{(\text{H}^+)} \exp(-\text{F}E/RT) \ll 1, S = -30 \text{ mV}, n = 2 \quad [\text{L-5}] \\ 2k_3 \theta &\gg (\bar{k}_1 \alpha_{(\text{H}^+)} + \bar{k}_{-1}), \\ i_{\text{H},\alpha} &= -\text{F}k_1 \alpha_{(\text{H}^+)} \exp(-\alpha_1 \text{F}E/RT), \\ \theta_{\alpha} &= (k_1/2k_3)^{0.5} \alpha_{(\text{H}^+)}^{0.5} \exp(-\alpha_1 \text{F}E/2RT) \ll 1, \\ S &= -120 \text{ mV}, n = 1 \quad [\text{L-6}] \end{aligned}$$

If the free energy of adsorption of hydrogen atoms is a linear function of θ (Temkin adsorption)

$$\Delta F_{\text{ads}} = \Delta F_{\text{ads}, \theta=0} + m\theta \quad [8]$$

the free energies of activation may also be considered to be linear functions of θ , and, consequently, the chemical rate constants are functions of θ , i.e., $k_1 = k_{1, \theta=0} \exp(-\beta_1 m \theta / RT)$, $k_{-1} = k_{-1, \theta=0} \exp[(1 - \beta_1) m \theta / RT]$, $k_2 = k_{2, \theta=0} \exp(\beta_2 m \theta / RT)$, and $k_3 = k_{3, \theta=0} \exp(2\beta_3 m \theta / RT)$, where β_j are symmetry factors (for reactions [1] and [2], $\beta_j = \alpha_j$) which might be expected to assume values of (1/2), and where m is a constant (2). Temkin kinetics are only applicable in the intermediate coverage range ($0.2 < \theta < 0.8$) where one may assume that the coefficients $(1 - \theta)$ and θ in Eq. [4]-[7] are roughly constant. Then, one may write $k'_1 = k_{1, \theta=0} (1 - \theta)$, $k'_{-1} = k_{-1, \theta=0} \theta$, $k'_2 = k_{2, \theta=0} \theta$, and $k'_3 = k_{3, \theta=0} \theta^2$. Under these conditions, Eq. [4] and [5] yield the following limiting steady-state solutions

$$\begin{aligned} \bar{k}_{-1} &\gg \bar{k}_2 \alpha_{(\text{H}^+)}, \\ i_{\text{H},\alpha} &= -2\text{F}k'_2 (K'_1)^{\beta_2} \alpha_{(\text{H}^+)}^{(1+\beta_2)} \exp[-(\alpha_2 + \beta_2)\text{F}E/RT], \\ \theta_{\alpha} &= -(\text{F}/m)E + (RT/m) \ln K'_1 \alpha_{(\text{H}^+)}, \\ S &= -60 \text{ mV}, n = 1.5 \quad [\text{T-1}] \\ \bar{k}_2 \alpha_{(\text{H}^+)} &\gg \bar{k}_{-1}, i_{\text{H},\alpha} = -2\text{F}k'_2 (k'_1/k'_2)^{\beta_2/(1+\beta_2)} \alpha_{(\text{H}^+)} \\ &\exp[-(\alpha_2 \beta_1 + \alpha_1 \beta_2)\text{F}E/(\beta_1 + \beta_2)RT], \\ \theta_{\alpha} &= -(\alpha_1 - \alpha_2)\text{F}E/(\beta_1 + \beta_2)m \\ &+ [RT/(\beta_1 + \beta_2)m] \ln (k'_1/k'_2), S = -120 \text{ mV}, n = 1 \quad [\text{T-2}] \end{aligned}$$

Finally, under Temkin conditions, Eq. [6] and [7] give the following steady-state limiting cases

$$\begin{aligned} \bar{k}_{-1} &\gg 2k_3, i_{\text{H},\alpha} = -2\text{F}k'_3 (K'_1)^{2\beta_3} \alpha_{(\text{H}^+)}^{2\beta_3} \exp(-2\beta_3 \text{F}E/RT), \\ \theta_{\alpha} &= -(\text{F}/m)E + (RT/m) \ln K'_1 \alpha_{(\text{H}^+)}, S = -60, n = 1 \quad [\text{T-3}] \\ 2k_3 &\gg \bar{k}_{-1}, i_{\text{H},\alpha} = -2\text{F}k'_3 (k'_1/2k'_3)^{2\beta_3/(\beta_1+2\beta_3)} \alpha_{(\text{H}^+)}^{2\beta_3/(\beta_1+2\beta_3)} \\ &\exp[-2\beta_3 \alpha_1 \text{F}E/(\beta_1 + 2\beta_3)RT], \\ \theta_{\alpha} &= -[\alpha_1 \text{F}E/(\beta_1 + 2\beta_3)m] \\ &+ [RT/(\beta_1 + 2\beta_3)m] \ln (k'_1 \alpha_{(\text{H}^+)}/2k'_3), \\ S &= -180 \text{ mV}, n = (2/3) \quad [\text{T-4}] \end{aligned}$$

The diagnostic criteria of primary interest are the magnitudes of the Tafel slope (S) and the reaction order (n) with respect to the proton activity, $(\partial E/\partial \log[i_{\text{H},\alpha}])_{\text{pH}}$ and $(-\partial \log[i_{\text{H},\alpha}]/\partial \text{pH})_E$, respectively. The values of S ($T = 30^\circ\text{C}$) and n shown for each of the limiting cases were obtained by setting all symmetry factors equal to (1/2). In addition to the Temkin cases given above, Thomas discussed two more limiting solutions which one might label [T-3'] and [T-4']. These are given by [T-3] and [T-4] with $\beta_3 = 1$ (nonactivated adsorption of hydrogen atoms), and are characterized by (S, n) values of $(S = -30 \text{ mV}, n = 2)$ and $(S = -150 \text{ mV}, n = 0.8)$, respectively.

It should be emphasized that (S, n) data do not always suffice for the determination of the HER mechanism. As shown above, for example, the frequently observed set of values, $S = -120 \text{ mV}$ and $n = 1$, is generated by four of the limiting cases: [L-1], [L-3], [L-6], and [T-2]. In such a situation, one may, in principle, distinguish among the

four cases on the basis of the magnitude of θ and its variation with potential and/or pH. Such supplemental information enabled the HER mechanism to be uniquely determined for iron ($S = -120 \text{ mV}, n = 1$) in acidic sulfate solutions (3) and, as will be shown below is decisive for the present case involving titanium.

Results of earlier studies.—The experimental results which have been reported for the hydrogen evolution reaction on titanium in deoxygenated acidic media are shown in Table I. The wide diversity of reported (S, n) values, and a comparison of the (S, n) values with those to be expected on theoretical grounds, can only lead one to conclude that previous studies have failed to determine the HER mechanism on titanium.

Few mechanistic proposals have resulted from the data presented in Table I. Armstrong *et al.* stated that their results indicated that the rate-determining step in acidic sulfate media is slow discharge (10). They did not attempt to account for their anomalous Tafel slope. According to Thomas and Nobe (11), the rate-determining step in acidic sulfate media is slow electrochemical desorption. However, in order to account for the unusual reaction order ($n = 0.6$) and the anomalous Tafel slope ($S = -150 \text{ mV}$), they had to invoke both Temkin adsorption for H_{ads} and a dual-barrier model (20) based on the unwarranted premise that active-state titanium is covered with a 3-d oxide film. In analyzing their results for beta III titanium in acidic sulfate media, Dull and Nobe (14) retained Temkin adsorption behavior for H_{ads} , but abandoned the dual-barrier model, and concluded that the rate-determining step is slow recombination. Brynza *et al.* (13) invoked the dual-barrier model, but not Temkin adsorption of H_{ads} , and decided that the rate-determining step in acidic sulfate media is slow discharge followed by electrochemical desorption. Frayret *et al.* (18) noted the problem presented by their (S, n) data in acidic chloride media, $S = -186$ and $n = 0.88$, and merely pointed to the dual-barrier approach of Thomas and Nobe as a possible explanation. Finally, Petit and Dabosi (12) observed an abnormal Tafel slope ($S = -164 \text{ mV}$), but a normal value for the reaction order ($n = 1$) in acidic sulfate solutions. They concluded that Langmuir rather than Temkin kinetics apply, and that the rate-determining step is electrochemical desorption ($\theta \approx 1$). In order to account for their unusual Tafel slope, they rejected the dual-barrier model while accepting the hypothesis that an oxide film exists on active-state titanium in the cathodic potential region. They then assumed that the potential drop across the oxide film is a constant fraction (f) of the metal/solution potential difference. The Tafel slope then becomes equal to $[-2.303 RT/(1 - f)\alpha\text{F}]$ and, with $f = 0.26$ and $\alpha = 0.5$, one

obtains the observed value of S . However, f must be regarded as little more than an arbitrary adjustable parameter (depending on f , one can obtain any value of S between -120 mV and $-\infty$). Indeed, there is no evidence to support the proposed model.

It is apparent that, excepting the proposal of Armstrong *et al.* (10), the mechanisms suggested for the hydrogen evolution reaction on titanium are those of Nobe and co-workers (11, 14), or closely related variations thereof. Consequently, their dual-barrier/Temkin adsorption model will be examined in detail in the "Discussion" section of this paper.

Experimental

The three-compartment cell assembly (test, reference, and counterelectrode compartments) was made of Pyrex glass and Teflon, and was so designed that solutions could be added to or removed from the cell without exposure to the atmosphere. All compartments were jacketed and maintained at a constant temperature of $30.00^\circ \pm 0.02^\circ\text{C}$. Hydrogen was passed through all compartments at all times. The hydrogen source was a Matheson generator which produces ultrapure gas via diffusion of electrolytically generated hydrogen through a palladium membrane. Stirring in the test compartment was achieved with a Teflon-coated magnetic stirrer.

The titanium electrodes employed in this study were made from zone-refined polycrystalline titanium (Materials Research Corporation). The cylindrical electrodes (length = 1.27 cm, diam = 0.635 cm) were polished successively with 320, 400, and 600 silicon carbide, followed by 1.0, 0.3, and $0.05 \mu\text{m}$ Al_2O_3 . The Teflon electrode holders exposed only the cylindrical surface of the electrodes. In order to ensure comparability of results, each electrode had to meet the following criteria in 1N H_2SO_4 : $E_{\text{corr}} = -745 \pm 5$ mV vs. SCE, $E_m = -530 \pm 3$ mV vs. SCE, and $i_m = 5.40 \times 10^{-5} \pm 4\%$ A cm^{-2} (E_m and i_m are defined in the "Results" section). All solutions were prepared from reagent-grade chemicals and triply distilled water. Acidic solutions having the desired pH were prepared by mixing 0.5M H_2SO_4 and 0.5M Na_2SO_4 , or 1M HCl and 1M NaCl. The test solutions were pre-electrolyzed for approximately 24h at -900 mV vs. SCE using a 10 cm^2 titanium cathode.

The titanium electrodes attained a stable active-state corrosion potential (E_{corr}) in all test solutions except that having the highest pH (4.04). Cathodic polarization curves were determined by maintaining each potential just long enough to obtain the minimum value of $|i_H|$ (~ 10 min), then returning to open circuit long enough to reestablish the original value of E_{corr} . Prolonged cathodic polarization was accompanied by a rise in the magnitude of the cathodic current density with time, the effect being more pronounced the more negative the potential and the lower the pH. Since the effect, one which might be attributed to hydriding of the surface layers, resulted in irreproducible and non-Tafel behavior, it was avoided. At the highest pH, titanium spontaneously passivates, and, consequently, a potential of -800 mV vs. SCE served as the reference state in place of E_{corr} .

The electrochemical measurements were made with a PAR potentiostat (Model 173), an Orion pH meter (Model 801-A), and a Hewlett-Packard/Moseley recorder (Model 7100 B, Model 17501 plug-ins).

All electrode potentials (E) were measured against a saturated calomel reference electrode, and all E values are given with reference to SCE.

Results

Typical polarization curves for titanium in acidic sulfate and chloride media are shown in Fig. 1. The cathodic Tafel lines corresponding to the HER have slopes of -120 mV, *i.e.*, $(\partial E/\partial \log |i_H|)_{\text{pH}} = -2(2.303 RT/F)$. Also, one observes that as the potential becomes increasingly positive (noble) relative to the active-state corrosion potential (E_{corr}), the anodic current density rises to a maximum (i_m) at the critical potential (E_m), and then decreases as the

Fig. 1. Anodic and cathodic polarization curves for zone-refined titanium. —●—: 0.5M $[\text{HSO}_4^- + \text{SO}_4^{2-}]$, pH = 2.14. —○—: 1.0M $[\text{Cl}^-]$, pH = 1.00, from Ref. (15).

metal undergoes transformation from the active to the passive state. The partial anodic polarization curve (i_d) corresponding to just the oxidation of the metal to form Ti(III) ions in solution is obtained by adding $|i_H|$ to the observed (net) anodic polarization curve (i). As may be seen in Fig. 1, the current density maximum ($i_{m,d}$) in the i_d curve is greater than the observed value (i_m), and the corresponding value of the critical potential ($E_{m,d}$) is more negative than the observed value (E_m). Previous investigations (7, 15) have established the relationships

$$d \log i_{m,d}/dpH = -2/3 \quad [9]$$

and

$$dE_{m,d}/dpH = -(4/3)(2.303 RT/F) \quad [10]$$

These relationships have an important diagnostic significance in the determination of the mechanism of active-state dissolution and passivation of titanium (1). In addition, as will be shown in connection with Fig. 3, they are useful in the determination of n for the HER.

In Fig. 2, cathodic polarization curves are shown for 0.5M $[\text{HSO}_4^- + \text{SO}_4^{2-}]$ solutions in the pH range 1.03-4.04. For all solutions, the slope (S) of the cathodic Tafel line is equal to $-2(2.303 RT/F)$, *i.e.*, -120 mV. The reaction order (n) with respect to the proton activity, *i.e.*, $(-\partial \log |i_H|/\partial \text{pH})_E$, may be obtained from the data shown in Fig. 2. The values of $|i_H|$ at $E = -875$ mV vs. SCE (Fig. 2) are shown in Fig. 3 as open circles. Additional results obtained for the $[\text{HSO}_4^- + \text{SO}_4^{2-}]$ system in the present study (\square, ∇), as well as those presented in earlier publications (\square, Δ), are also shown in Fig. 3. The solid points in Fig. 3 correspond to the results obtained for the 1M $[\text{Cl}^-]$ system in the present (\bullet) and earlier studies (\blacktriangledown). In Fig. 2, one notes that the potential range in which Tafel behavior is observed, *i.e.*, in which $(\partial \log |i_H|/\partial E)_{\text{pH}}$ is constant, decreases with increasing acidity. In 1N H_2SO_4 , true Tafel behavior was not observed (1), and, consequently, i_H ($E = -875$ mV vs. SCE) for this medium was evaluated by determining i_{corr} and utilizing the relationship, $|i_H|_{(E=-875)} = i_{\text{corr}} \exp[-2.303(-875 - E_{\text{corr}})/120]$. A very sensitive electrochemical technique was used to measure i_{corr} (21). The method involves the use of a passive titanium sensor electrode to monitor changes in the concentration of Ti(III) ions in solution resulting from the dissolution of metal, and can be used to determine i_d at any potential in the active-state potential

Fig. 2. Cathodic polarization curves for titanium in 0.5M $[\text{HSO}_4^- + \text{SO}_4^{2-}]$ at various pH values.

region, including E_{corr} . In the high pH region, where $|i_{\text{H}}|_{E=E_m}$ is significant compared to $i_{\text{m,d}}$, Eq. [9] and [10] provide a fast method for checking the values of $|i_{\text{H}}|_{E=-875}$ determined by direct cathodic polarization. For example, in 1N HCl (pH = -0.07) the values of $i_{\text{m,d}}$ and $E_{\text{m,d}}$ are 1.55×10^{-5} A cm^{-2} and -530 mV vs. SCE, respectively (15). Then, using Eq. [9] and [10], one finds that for pH = 2.01, $i_{\text{m,d}}$ and $E_{\text{m,d}}$ are equal to 6.36×10^{-7} A cm^{-2} and -696.4 mV vs. SCE, respectively. The observed anodic current density at $E_{\text{m,d}}$ was only 1.78×10^{-7} A cm^{-2} . Consequently, $|i_{\text{H}}|$ at $E_{\text{m,d}}$ is equal to 4.58×10^{-7} A cm^{-2} , i.e., $(6.36 \times 10^{-7} / 1.78 \times 10^{-7})$. With $S = -120$ mV, this value of $|i_{\text{H}}|$ at $E = -696.4$ mV vs. SCE corresponds to a value of 1.41×10^{-5} A cm^{-2} at $E = -875$ mV vs. SCE. The value obtained by cathodic polarization, and plotted in Fig. 3, is 1.46×10^{-5} A cm^{-2} . For use with acidic sulfate media, the values of $i_{\text{m,d}}$ and $E_{\text{m,d}}$ in 1N H_2SO_4 (pH = 0.32) are 5.40×10^{-5} A cm^{-2} and -530 mV vs. SCE, respectively (21).

The results presented in Fig. 3 show that the measured reaction order with respect to proton activity, $(-\partial \log |i_{\text{H}}| / \partial \text{pH})_E$, is a minimum (0.49) at pH 1.83, and approaches a limiting value of 1.0 with increasing or decreasing pH. The solid curve which fits the data over the entire pH range was calculated using Eq. [11]

$$|i_{\text{H}}|_E = [A / (1 + B a_{(\text{H}^+)}) + C a_{(\text{H}^+)}] \quad [11]$$

With $E = -875$ mV vs. SCE, the values of the constants in Eq. [11] are $A = 1.72 \times 10^{-5}$ A cm^{-2} , $B = 4.89 \times 10^{-3}$, and $C = 4.24 \times 10^{-4}$ A cm^{-2} . In practice, $a_{(\text{H}^+)}$ in Eq. [11] is obtained from the measured pH and the relationship, $\text{pH} = -\log a_{(\text{H}^+)}$. It is especially important to note that there is no significant difference in the kinetics of the hydrogen evolution reaction in the chloride and sulfate media. In either medium, the Tafel slope is -120 mV and, as shown in Fig. 3, Eq. [11] is equally applicable to either system. Consequently, the peculiar nature of the order plot cannot be attributed to media effects such as, for example, the pH-dependent ($\text{HSO}_4^- / \text{SO}_4^{2-}$) ratio. Instead, one must look to the surface for an explanation of the results.

Discussion

Proposed mechanism for the HER.—The results shown in Fig. 2 and 3 immediately suggest a HER mechanism involving two parallel reaction paths of the ($S = -120$ mV, $n = 1$) type, i.e., of the [L-1], [L-3], [L-6], or [T-2] type. For

the sake of brevity, it is appropriate to anticipate the ultimate conclusion and derive the overall rate expression on the basis of just the [L-6] type mechanism (slow discharge—fast recombination). Justification for selecting [L-6] from the four possible ($S = -120$ mV, $n = 1$) limiting cases will be provided below. Of the two parallel reaction paths, one is that leading to [L-6], namely, reactions [1] and [3]. For titanium, it is proposed that one must also consider reactions [I] and [II]

and

where S_{ads} represents an adsorbed entity, the nature of which will be discussed below. The HER is then described by the following equations

$$\epsilon_{\text{H}}^{-1} (d\theta/dt) = \bar{k}_1 a_{(\text{H}^+)} (1 - \theta - \lambda) - \bar{k}_{-1} \theta - 2k_3 \theta^2 + \bar{k}_{\text{II}} \psi (1 - \theta - \lambda) - \bar{k}_{-\text{II}} \theta \phi \quad [12]$$

$$\epsilon_{\text{SH}}^{-1} (d\psi/dt) = -\epsilon_{\text{S}}^{-1} (d\phi/dt) = k_1 a_{(\text{H}^+)} \phi - k_{-1} \psi - \bar{k}_{\text{II}} \psi (1 - \theta - \lambda) + \bar{k}_{-\text{II}} \theta \phi \quad [13]$$

$$-i_{\text{H}}/F = \bar{k}_1 a_{(\text{H}^+)} (1 - \theta - \lambda) - \bar{k}_{-1} \theta + \bar{k}_{\text{II}} \psi (1 - \theta - \lambda) - \bar{k}_{-\text{II}} \theta \phi \quad [14]$$

where ψ and ϕ represent the fractional coverages by $(\text{SH}^+)_{\text{ads}}$ and S_{ads} , respectively, and ϵ_{SH} and ϵ_{S} are the proportionality constants between ψ and ϕ and surface concentrations of $(\text{SH}^+)_{\text{ads}}$ and S_{ads} . In addition, $\lambda = (\psi + \phi)$, and the other symbols retain their previous definitions. In the steady state, $(d\theta/dt) = 0$, the current density is equal to $-2Fk_3\theta^2$. Subject to the condition, $2k_3\theta_{\infty} \gg (\bar{k}_1 a_{(\text{H}^+)} + \bar{k}_{-1} + \bar{k}_{\text{II}}\psi + \bar{k}_{-\text{II}}\phi)$, the steady-state current density is given by Eq. [15]

Fig. 3. (21). \triangle : from Ref. (7). \square : from Ref. (15) or Fig. 1. \bullet : present study. \blacktriangledown : from Ref. (15) or Fig. 1.

$$|i_{H, \infty}| = F\bar{k}_1\alpha_{(H^+)}(1 - \lambda) + F\bar{k}_{II}\psi(1 - \lambda) \quad [15]$$

If reaction [I] is in virtual equilibrium, ψ is given by Eq. [16]

$$\psi = k_1\alpha_{(H^+)}\lambda/(k_1\alpha_{(H^+)} + k_{-1}) \quad [16]$$

Substitution of this expression for ψ into Eq. [15] gives the result

$$|i_{H, \infty}| = F\bar{k}_1\alpha_{(H^+)}(1 - \lambda) + F\bar{k}_{II}\lambda(1 - \lambda)/(1 + K_{-1}\alpha_{(H^+)})^{-1} \quad [17]$$

where $K_{-1} = k_{-1}/k_1$. Since $\bar{k}_1 = k_1 \exp(-\alpha_1 FE/RT)$ and $\bar{k}_{II} = k_{II} \exp(-\alpha_{II} FE/RT)$, it is apparent that, with $\alpha_1 = \alpha_{II} = 1/2$, and with λ constant, the Tafel slope given by Eq. [17] is equal to $-2(2.303 RT/F)$, i.e., -120 mV. Moreover, at constant potential and constant λ , Eq. [17] is identical with Eq. [11]. Thus, Eq. [17] is in complete agreement with the experimental results. For either of the parallel reaction paths, the mechanism is rate-determining slow discharge followed by fast recombination. When $\lambda = 0$, Eq. [17] reduces to the limiting current density equation presented for the limiting case [L-6]. An equation of the same form as Eq. [17] may be derived on the basis of reactions (I) and (II) with and [L-1]- or [L-3]-type mechanism and, consequently, S and n values again are insufficient to differentiate among these possibilities, and reference must be made to the effect of potential on θ (see below).

Nature of titanium surface species.—The generally accepted mechanism for the active-state dissolution of iron in acidic media involves the adsorbed surface intermediate $(FeOH)_{ads}$, with $\theta_{(FeOH)} \ll 1$. Since the surface of the metal is essentially an aquated one, it is not surprising that the HER on iron in acidic sulfate solutions ($S = -120$ mV and $n = 1$ throughout the entire pH range 0.32-3.50) is adequately described by reactions [1]-[3], with recourse to reactions [I] and [II] being unnecessary. The nature of the surface of titanium in the active and active-passive transition potential regions has already been discussed in great detail in connection with the so-called "monolayer" mechanism of active-state dissolution and passivation of the metal in acidic media (1). In contrast to iron, the surface of active-state titanium is not primarily an aquated surface, but one occupied predominantly by adsorbed oxy and hydroxy titanium species at the submonolayer level. These species, analogous to $(FeOH)_{ads}$, are of the form $(TiOH)_{ads}^{z-1}$ (with $z = 1, 2$, and 3) and $[Ti(OH)_2]_{ads}^{+2}$. The "monolayer" mechanism provides a quantitative description of the active-state dissolution and passivation processes. In particular, the experimentally confirmed relationships expressed by Eq. [9] and [10] derive directly from the mechanism. At $E_{m,d}$, coverages of the univalent and trivalent titanium species are negligible. If θ_2 and θ_4 represent the coverages by the divalent and quadrivalent species, then at $E_{m,d}$, $(\theta_2/\theta_4) = 2$ and $(\theta_2 + \theta_4) \approx 1$. With decreasing potential, at constant pH, θ_2 increases at the expense of θ_4 . Consequently, in the cathodic potential region, one may identify $(SH^+)_{ads}$ with $(TiOH)^+_{ads}$ and write reactions [I] and [II] in the form

where, it should be emphasized, $(TiO)_{ads}$ does not represent a 3-d phase oxide. Also, the total coverage (λ) by the divalent species remains virtually constant in the cathodic Tafel region.

Hydrogen absorption by titanium.—The question remains as to the justification for selecting a mechanism equivalent to [L-6], slow discharge-fast recombination, from among the four possible types of ($S = -120$ mV, $n = 1$) mechanisms. Justification for this selection derives primarily from information concerning the effect of potential on the coverage by H_{ads} . In addition to participating in reactions [1]-[3] and [II], electrolytically generated hydrogen atoms can penetrate into the metal, as represented by Eq. [III]

where H_{abs} ($x = 0$) refers to absorbed hydrogen atoms just inside the electrode. According to Brauer *et al.* (22), absorbed hydrogen atoms do not permeate significantly into the bulk of the metal, but, instead, concentrate in the near surface region in the form of a hydride layer having a concentration of 63 atom percent hydrogen ($TiH_{1.65}$). Further absorption simply results in an increase in the thickness of the $TiH_{1.65}$ layer by diffusion of hydrogen atoms through the hydride to the hydride/metal interface. This viewpoint is essentially the same as that proposed earlier by Brauer and Nann (23), Phillips *et al.* (24), and Tomashov and co-workers (25). All of the aforementioned investigators have observed that, at constant pH, the rate of absorption of hydrogen atoms increases with increasing magnitude of the applied cathodic current density. Phillips *et al.* (24), for example, found that the rate of absorption of hydrogen by initially hydrogen-free titanium increased with increasing $|i_H|$ in the region from 10^{-5} to 3×10^{-3} A cm $^{-2}$ in 0.05M H_2SO_4 ($T = 25^\circ C$). Others have noted a limiting cathodic current density above which further increases in $|i_H|$ have no effect on the absorption rate (22, 25). Regardless of the ultimate fate of hydrogen atoms once inside the metal, the rate of absorption of hydrogen atoms, r (mole cm $^{-2}$ s $^{-1}$), may be written, in accordance with reaction [III], in the form

$$r = k_{II}\theta(1 - \chi) - k_{-III}C_H^0(1 - \theta) \quad [18]$$

where C_H^0 is the concentration of H_{abs} ($x = 0$), χ is the fractional occupancy of absorption sites, and C_H^+ is proportional to χ . According to Eq. [18], an increase in θ results in an increase in r , i.e., $(\partial r/\partial \theta) > 0$. Consequently, the observed increase in r with increasing $|i_H|$ at constant pH reflects an increase in θ with increasing $|i_H|$. Actually, the investigators referred to above were mainly interested in the diffusion-controlled stage of the absorption process, i.e., the stage in which the absorption at constant cathodic current density followed a parabolic rate law. It was assumed that during this stage reaction [III] is in virtual equilibrium. According to Eq. [18], with $r \approx 0$, an increase in θ results in an increase in C_H^0 (in fact, if θ and χ are small, C_H^0 is directly proportional to θ). With C_H^0 serving as a boundary condition for diffusion of hydrogen atoms into the interior, the diffusion flux increases with increasing C_H^0 , i.e., with increasing θ . Consequently, the observed increase in the absorption rate with increasing $|i_H|$ at constant pH was attributed to an increase in θ , with θ attaining its maximum possible value at the limiting cathodic current density referred to above. At constant pH, an increase in $|i_H|$ corresponds to a decrease in potential, and, therefore, on the basis of the absorption studies, one may conclude that θ increases with decreasing potential at constant pH. Above, equations have been presented for θ_∞ for each of the limiting cases. For [L-1], $\theta_\infty \approx 1$ and, consequently, θ_∞ cannot increase with decreasing potential. For [L-3], $\theta_\infty \ll 1$, but θ_∞ is independent of potential. For [T-2], a Temkin case for which θ is restricted to a range of approximately 0.2 to 0.8, the expression for θ_∞ shows that if $\alpha_1 = \alpha_2$, as expected, then θ_∞ is independent of potential. For [L-6], in contrast to the other cases, θ_∞ increases with decreasing potential at constant pH, i.e., $(\partial \log \theta_\infty / \partial E)_{pH} = -(\alpha_1/2)(F/2.303 RT)$. Consequently, the results of the absorption studies are consistent only with the slow discharge-fast recombination mechanism, [L-6], or the modified [L-6] mechanism in which reactions [I] and [II] are added to reactions [1]-[3].

Phillips *et al.* (26) reported that the rate of absorption of hydrogen atoms at constant cathodic current density decreases with increasing pH. They attributed this decrease to a decrease in θ with increasing pH, and stated that this conclusion was in agreement with the HER mechanism proposed by Thomas and Nobe (11). In fact, the Temkin absorption-dual-barrier mechanism proposed by the latter authors requires that, at constant i_H , θ_∞ increase with an increase in pH, i.e.

$$(\partial \theta_\infty / \partial pH)_{i_H} = 2.303 RT (1 - \alpha_2)/(\alpha_2 + \beta_2)m \quad [19]$$

Equation [19] also applies to the simple [T-1] mechanism,

upon which the mechanism of Thomas and Nobe is based. However, according to the [L-6] mechanism, a constant $|i_{H,c}|$ corresponds to a constant θ_{α} , i.e., $|i_{H,c}| = 2Fk_3\theta_{\alpha}^2$, and, therefore, the absorption rate at constant i_H should be independent of pH. Tomashov and co-workers (25) found little effect of pH on the absorption rate in the pH region of interest in this study. In fact, in changing from pH = 0.3-1.3, Phillips *et al.*, also found a rather small effect, with a larger effect showing up at higher pH values. It seems possible that the effect noted might be attributed to the fact that the time required to activate titanium (remove the air-formed oxide film) increases markedly with increasing pH. The decrease in the absorption rate with increasing pH would then be attributed to the increased duration of the oxide film which serves as a barrier to hydrogen absorption.

3-d oxide film models.—In order to rationalize their abnormal (S, n) data, Thomas and Nobe (11) proposed that a 3-d oxide film exists on titanium in the active state, even under cathodic polarization in strongly acidic media, and that the hydrogen evolution reaction occurs at the oxide-dissolution interface. It was further assumed that the HER is described by just reactions [1] and [2], and that a Temkin adsorption isotherm applies to the adsorption of hydrogen atoms at the oxide surface. Consequently, in accordance with the definitions provided above, the rates of reactions [1] and [2] are given by Eq. [20]-[22]

$$r_1 = k'_1\alpha_{(H^+)} [\exp(-\beta_1 m\theta/RT)] [\exp(-\alpha_1 F\psi/RT)] \quad [20]$$

$$r_{-1} = k'_{-1} [\exp(1 - \beta_1)m\theta/RT] [\exp(1 - \alpha_1)F\psi/RT] \quad [21]$$

$$r_2 = k'_2\alpha_{(H^+)} [\exp(\beta_2 m\theta/RT)] [\exp(-\alpha_2 F\psi/RT)] \quad [22]$$

where ψ , the potential difference across the solution double layer at the oxide-solution interface, appears in place of E . If reaction [1] is assumed to be in quasiequilibrium, with reaction [2] rate-determining, then one may equate r_1 and r_{-1} to obtain a relation between θ_{α} and ψ

$$\theta_{\alpha} = -(F\psi/m) + (RT/m) \ln K'_1\alpha_{(H^+)} \quad [23]$$

Since the steady-state current density ($i_{H,c}$) corresponding to the HER is equal to $-2Fr_2$, one may substitute θ_{α} from Eq. [23] into Eq. [22] and obtain the result

$$i_{H,c} = -k_H\alpha_{(H^+)}^{(1+\beta_2)} \exp[-(\alpha_2 + \beta_2)F\psi/RT] \quad [24]$$

where k_H is equal to $2Fk'_2(K'_1)^{\beta_2}$. Except for ψ in place of E , Eq. [23] and [24] are identical to those given for the limiting Temkin case, [T-1]. (It should be noted in passing that Eq. [19] derives directly from Eq. [23] and [24].) The electrons participating in the HER must traverse the oxide film, and the electron current density through the oxide was presumed to be correctly described by Eq. [25]

$$i_t = k_t \exp(-\alpha_t F\psi_t/RT) \quad [25]$$

where α_t is the transfer coefficient for the activation-controlled electron transfer across the film, and ψ_t is the potential drop across the oxide. Under steady-state conditions, i_t must equal $|i_{H,c}|$, and, therefore, with the total potential difference (ψ_T) equal to $(\psi + \psi_t)$, Eq. [24] and [25] may be combined to yield the final result

$$\log |i_{H,c}| = C - [(1 + \beta_2)\alpha_t/(\alpha_2 + \beta_2 + \alpha_t)]pH - [\alpha_t(\alpha_2 + \beta_2)/(\alpha_2 + \beta_2 + \alpha_t)](F/2.303 RT)\psi_T \quad [26]$$

where C is a constant. According to Eq. [26], since $(d\psi_T/dE) = 1$, the Tafel slope (S) and reaction order (n) with respect to proton activity are given by the expressions

$$S = (\partial E/\partial \log |i_{H,c}|)_{pH} = -(2.303RT/F) [(\alpha_2 + \beta_2 + \alpha_t)/(\alpha_2 + \beta_2)\alpha_t] \quad [27]$$

and

$$n = (-\partial \log |i_{H,c}|/\partial pH)_E = [(1 + \beta_2)\alpha_t/(\alpha_2 + \beta_2 + \alpha_t)] \quad [28]$$

If the measured values, $S = -150$ mV and $n = 0.60$, are substituted into Eq. [27] and [28], then, assuming $\alpha_2 = \beta_2$, the calculated values of α_t and $\alpha_2 (= \beta_2)$ are 2/3 and 1/2, respectively. Similarly, the data of Brynza and Danilova (13) lead

to a value of 0.93 for α_t , while that of Frayret *et al.* (18) corresponds to values of 1.15 and 0.22 for α_t and $\alpha_2 (= \beta_2)$, respectively. Consequently, it is apparent that there are problems with the 3-d oxide model.

The only justification presented by Thomas and Nobe (11) for assuming that a stable 3-d oxide exists on titanium in the active state was that "... a mixed oxide film of TiO_2 and Ti_2O_3 is present on the surface of passive titanium. The thermodynamic data of these oxides indicate their possible presence even on active titanium in the Tafel region of the HER." The same authors subsequently invoked the concept of a 3-d oxide film on titanium in the active state in order to account for the results of their study of the active-state dissolution of titanium in acidic media (27). Unfortunately, one now finds such statements as "the presence of an oxide layer on the metal during both active dissolution and hydrogen evolution is indicated by... [the fact that]... both hydrogen evolution [Ref. (11) of this paper] and active dissolution [Ref. (27) of this paper] have been interpreted in terms of a dual-barrier model..." (28). With regard to whether an oxide layer exists on titanium in the active-state, thermodynamic considerations are basically useless since they also fail to preclude the possibility that the metal is preferentially oxidized to form Ti(III) ions in solution, with no oxide film present on the surface. Basically, it is a matter of kinetics, i.e., thermodynamics is useful as an indicator of what cannot occur, but not of what does occur when several options are thermodynamically possible. A recent study (i) found no definitive evidence to support the contention that a stable 3-d oxide layer exists on titanium in the active and transition states, (ii) demonstrated that the active-state dissolution and passivation of titanium in acidic media is not correctly described by mechanisms based on the presence of an oxide film, including that of Thomas and Nobe (27), and (iii) showed that active-state dissolution and passivation of the metal in acidic media is quantitatively described (including, for example, Eq. [9] and [10]) by the monolayer mechanism in which the surface is occupied by adsorbed oxy and hydroxy titanium reaction intermediates at the submonolayer level, and not a 3-d oxide film (1). Aside from the fact that a 3-d oxide layer on the surface of active-state titanium is likely nonexistent, it should be noted that, even if there were such an oxide layer, it is doubtful that Eq. [25] represents an accurate description of the electron current in the oxide (justification for Eq. [25] has not been provided, nor have the nature and properties of the oxide to which it supposedly applies ever been specified). This criticism applies whether the oxide be considered an insulator or a semiconductor (29). In the former case, one would expect a higher order dependency of the current density upon the potential drop across the oxide. In the latter case, the kinetics of the reduction reaction would be formulated quite differently, and limiting Tafel behavior would be expected (i) in the potential region in which ψ is constant and changes in ψ_t accompanying changes in ψ_T serve only to alter the surface concentration of electrons (tenfold change per 60 mV change in ψ_t), and (ii) at high cathodic current densities where $(d\psi/d\psi_T) \rightarrow 1$ as the semiconductor behaves increasingly like a metal (30). For a simple reduction reaction such as proton reduction, the Tafel slopes for cases (i) and (ii) would be -60 and -120 mV, respectively. One would not expect a Tafel region with $|S| > 120$ mV. Studies of redox reactions occurring on semiconducting oxide films formed on titanium typically yield abnormal anodic Tafel slopes, but normal cathodic Tafel slopes of -120 mV (30-32).

Although it is not incumbent upon the present authors to explain the diverse results of others, a plausible explanation for some of the reported values of n is afforded by the results of the present study. In Fig. 4, the points shown as triangles (\blacktriangle) were calculated by means of Eq. [11], and correspond to the solid curve in Fig. 3. The points shown as circles (\bullet) in Fig. 4 were abstracted from the paper of Thomas and Nobe (11). It is apparent that over the limited range of pH (0.25-2.25) encompassed by the data of Thomas and Nobe, one might reasonably but erroneously conclude that $(-\partial \log |i_{H,c}|/\partial pH)_E$ is constant, and that $n = 0.62$. The same

Fig. 4. Current density of the hydrogen evolution reaction on titanium as a function of pH in acidic sulfate media. ▲: Eq. [11] or solid curve in Fig. 2. ●: data of Thomas and Nobe (11). $E = -875$ mV vs. SCE.

explanation applies to the data of Brynza and Danilova (13), who reported a value of n equal to 0.63 over the pH range 0.1-2.32. In addition, Fig. 3 shows that in strongly acidic media one should expect n to equal 1.0, as reported by Petit and Dabosi (12) and by Armstrong *et al.* (10).

Summary

The rate of the hydrogen evolution reaction on zone-refined titanium in H_2 -saturated acidic sulfate and acidic chloride media ($T = 30.0^\circ\text{C}$) over the pH range 0-4.0 has been shown to be accurately described by the equation

$$|i_{H,ac}| = F(1 - \lambda) [k_1 a_{H^+} + k_2 \lambda / (1 + K_{-1} a^{-1}_{OH^+})] \exp(-FE/2RT)$$

i.e., by Eq. [17]. The rate equation may be derived on the basis of a mechanism invoking two parallel paths for proton reduction, one involving the usual solvated proton and the other involving the adsorbed titanium species, $(TiOH)_{ads}^+$. A consideration of the reported effect of potential on the rate of adsorption of hydrogen by the metal served to differentiate among the few HER mechanisms consistent with the rate equation, and led to the conclusion that the proton discharge reactions are rate determining, followed by the fast recombination reaction. The notion that a 3-d oxide layer (as opposed to adsorbed oxy and hydroxy titanium species on the submonolayer level) exists on titanium in the active state is rejected, as are HER mechanisms based upon its presumed existence.

In Situ Laser Raman Spectroscopic Study of Anodic Corrosion Films on Nickel and Cobalt

C. A. Melendres* and S. Xu¹

Argonne National Laboratory, Argonne, Illinois 60439

ABSTRACT

In situ laser Raman spectra of anodic corrosion films formed on Ni and Co in 0.05M NaOH have been obtained for the first time and the composition of the surface films deduced. The Raman spectrum of the film found on Ni at about 0.6V vs. Hg/HgO corresponds closely to that of hydrated Ni₂O₃. The anodically formed film on Co at about 0.45V appeared to consist of a mixture of CoO and Co₃O₄.

Laser Raman spectroscopy has been found to be a very valuable technique for the *in situ* identification of anodic corrosion films on metals such as Pb (1), Ag (2), and Cu (3), etc. This communication reports some results on a study of the composition of anodic corrosion films on Ni and Co using this technique in conjunction with electrochemical methods.

Experimental

Electrodes of Ni and Co were prepared from 0.010 in. thick foils of Marz grade material (99.999% purity) purchased from Materials Research Corporation, Orangeburg, New York. Counterelectrodes of the same metal were employed. The reference electrode was Hg/HgO in the same solution as the electrolyte. The 0.05M NaOH electrolyte solution was prepared from reagent-grade NaOH using four-times-distilled water. The corrosion specimens were anodized at constant potential in ambient air using a three-compartment spectroelectrochemical cell described previously (4). The applied potential was controlled with a Princeton Applied Research (PAR) Model 173 potentiostat while a PAR Model 179 Universal Programmer was used for potential scanning. The Raman measurements were carried out using a SPEX Model 1403 double monochromator fitted with a photomultiplier tube detector. Sample excitation was by an Ar⁺ laser (Coherent Model CR-6). Laser Raman spectra of standard samples, either obtained commercially or prepared by us, were taken to verify the assignment of the Raman bands to the appropriate compound. Additional confirmation of the composition of the corrosion films formed was attempted using x-ray diffraction (XRD) analysis.

Results and Discussion

Anodic corrosion films on Ni.—The electrochemistry of Ni has been studied fairly extensively in view of its practical application in alkaline batteries (5-8). The results, however, have not led to a general consensus on the composition of the anodic phases formed as a function of potential at different pH's. For Ni in basic solutions, it is widely held that the anodic corrosion proceeds in stages, resulting in the formation of Ni⁺, Ni²⁺, and higher valent oxides and hydroxides. Thus, Guzman *et al.* (8), for example, proposed the following electron transfer reactions for Ni in KOH solution

Further oxidation to NiO₂ is indicated by the Pourbaix (9) diagram (Fig. 1). The same diagram, however, does not show the existence of either NiO or β-NiOOH, which electrochemists have proposed; it indicates rather that

the stable phases are Ni₃O₄ and Ni₂O₃. However, it must be noted that Pourbaix diagrams show only which phases have been considered thermodynamically possible and not those which are preferred.

Figure 2 shows a typical cyclic voltammogram of Ni in 0.05M NaOH solution. Starting at an open-circuit potential of about 0.05V vs. Hg/HgO, potentiodynamic scans were made to the hydrogen evolution region at about -1.2V and to potentials as positive as 1.1V. After potential excursions to about -1.2V, we at times find an anodic wave at about -0.5V on the return sweep. This wave is, however, not always reproducible. Only the features shown in Fig. 2 appeared consistently during single-scan and cyclic voltammetric sweeps. We now consider the assignment of the observed waves on the basis of previous work by others (5-8). There seems to be general agreement that the wave at about -0.5V is due to the oxidation of Ni to form Ni(OH)₂ or what Davies and Barker (6) formulate as NiO · H₂O (*i.e.*, a hydrated nickel oxide). This assignment is consistent with the phases indicated in the Pourbaix diagram for our solution pH of about 11.9 (Fig. 1). There is a consensus in assigning the wave at about +0.5V to the further oxidation of Ni(OH)₂ to NiOOH or Ni₂O₃ · H₂O. However, there seems little agreement among various workers as to the degree of hydration or actual formulation of the NiOOH. MacArthur (7), for example, starting with the α modification of Ni(OH)₂, claimed that the oxidation product in KOH solution was 3NiOOH · 7/2 H₂O · 3/4 KOH. Bode *et al.* (10) have given the formula for the oxidized γ structure as [NiO(OH)]₃O₃(OH)K₂. Bourgault and Conway (11), probably starting with β-Ni(OH)₂, derived the formula 2NiOOH · 0.14KOH. Zedner (12), Forster (13), and Kornfeil (14) gave the formulations 2NiOOH · H₂O, 2NiOOH · 0.2H₂O, and 2NiOOH ·

Fig. 2. Cyclic voltammogram of Ni in 0.05M NaOH solution. Scan rate: 10 mV/s.

$0.067\text{KOH} \cdot 1.16\text{H}_2\text{O}$, respectively. It is quite apparent that the electrochemistry of the nickel electrode is rather complex. Onset of oxygen evolution on the oxide coated surface occurs at about point b (Fig. 2), and massive O_2 evolution ensues beyond 0.8V. It is interesting to note other salient features of the voltammogram in Fig. 2, such as the shoulders on both anodic and cathodic portions of the wave at 0.5, the small wave at about 0 V, and one at about 0.8V.

Figure 3 shows typical laser Raman spectra of a Ni electrode in 0.05M NaOH as a function of potential. Spectra taken *in situ* at the open-circuit potential of about 0.05V exhibit a small background in the region of about 300-900 cm^{-1} that may be due to fluorescence from the glass window. On potentiostating the electrode past the wave (II) at 0.6V, two bands appear at about 477 and 555 cm^{-1} , respectively. These bands are relatively strong (signal:

Fig. 3. Laser Raman spectra of Ni electrode at various potentials in 0.05M NaOH; Ar⁺ laser, $\lambda = 4880 \text{ \AA}$ line, $P = 80\text{-}150 \text{ mW}$. (a): At open circuit (OCV), $E = 0.05 \text{ V}$ vs. Hg/HgO. (b): $E = 0.6 \text{ V}$. (c): $E = 1.1 \text{ V}$. (d): *Ex situ* after anodization at $E = 0.7 \text{ V}$.

noise $\sim 3:1$), even with only 10 mC/cm^2 of charge passed (which would correspond roughly to about 20 layers of anodic film, assuming no film dissolution occurs). The bands disappear on scanning back to -0.1 V but persist if the potential is swept to more anodic values, e.g., 1.1V and held there for 2 or 3h, during which time oxygen is being evolved from the electrode surface. As might be expected, the electrode when potentiostated in the hydrogen evolution region (e.g., -1.2 V) did not show any apparent surface film. Figure 3d shows that the same bands are observed *ex situ* after removing the electrode from the cell at 0.7V. Repeated attempts to find other Raman bands in the potential range of -1.2 to $+0.4 \text{ V}$, where we had hoped to detect $\text{Ni}(\text{OH})_2$, have not been successful. Likewise, no other bands were found in the potential region of about $+0.7$ to 1.1 V , where higher oxides of Ni are expected to be formed. It is likely that whatever film is formed in these regions is neither thick enough nor a strong enough Raman scatterer to enable us to obtain a spectrum.

It is interesting to consider the probable origin of the observed bands at 558 and 477 cm^{-1} . As a first step, x-ray diffraction analysis was carried out on material scraped from electrodes following anodization at 0.6V. This, however, was not successful presumably due to the thinness of the film; the film may also have been amorphous, and, hence, would not have shown a diffraction pattern. As a further step towards film identification, Raman spectra were taken of standard samples of $\text{Ni}(\text{OH})_2$, Ni_2O_3 , NiO , and NiO_2 . The first was synthesized following the procedure prescribed by Hüttig and Peter (15), and the product obtained confirmed by x-ray analysis to be $\text{Ni}(\text{OH})_2$. The Ni_2O_3 , NiO , and NiO_2 were purchased from Alfa-Ventron (Danvers, Massachusetts). The first was reported to contain six waters of crystallization. Detailed elemental analysis indicated the composition to be $\text{Ni}_{1.2}\text{O}_{3.4} \cdot 2\text{H}_2\text{O}$ instead. X-ray analysis confirmed the composition of the NiO , but the NiO_2 was nearly amorphous with lattice parameters that somewhat resembled those given for $\beta\text{-NiOOH}$ or $\text{Ni}_3\text{O}_2(\text{OH})_4$. Spectra of the standard samples are shown in Fig. 4. We were unable to obtain the spectrum of NiO_2 which was a rather dark black sample. It is

Fig. 4. Laser Raman spectra of standard samples of Ni compounds (20%/80% in KBr pellet); Ar⁺ laser, $\lambda = 4880 \text{ \AA}$ line, $P \approx 80\text{-}120 \text{ mW}$. (a): NiO . (b): $\text{Ni}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$. (c): Charged Ni electrode for Ni/Fe battery. (d): $\text{Ni}(\text{OH})_2$.

evident from the results that the spectrum which corresponds most closely to what we observe for the anodized electrodes is that of $\text{Ni}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$. As we have indicated in the beginning of this section, the anticipated product of anodic oxidation of Ni at about 0.5V is hydrated $\beta\text{-NiOOH}$ (8, 10). This compound is also generally accepted to be the active material in fully charged Ni electrodes in Ni/Cd or Ni/Fe alkaline batteries. Unable to purchase NiOOH commercially or to prepare it ourselves chemically, we examined the Raman spectrum of a charged Ni electrode obtained from the General Electric Company. The spectrum is shown in Fig. 4c. A broad band centered at about 530 cm^{-1} is observed. An electrode in the discharged state with composition corresponding to $\text{Ni}(\text{OH})_2$ was also charged electrochemically and then examined *ex situ*. A similar spectrum was obtained but a weak OH band at 3580 cm^{-1} was present, presumably owing to unconverted $\text{Ni}(\text{OH})_2$. If we assign the broad band at 530 cm^{-1} to NiOOH, we are led to the conclusion that the anodic film formed on Ni at 0.5V corresponds more closely to hydrated Ni_2O_3 than to $\beta\text{-NiOOH}$. Davies and Barker (6) have proposed the structural equivalence of NiOOH and $\text{Ni}_2\text{O}_3 \cdot \text{H}_2\text{O}$. Such equivalence, however, has not been experimentally established. Our results show a subtle difference between the two. The sharper bands for $\text{Ni}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$ suggest a more crystalline structure compared to NiOOH. We searched for a difference in OH vibration for the two samples but were unable to find any OH or water vibrational frequency.²

The finding on the presence of Ni_2O_3 is in good agreement with that predicted by the Pourbaix diagram. However, we find no NiO or $\text{Ni}(\text{OH})_2$ as likewise predicted. This may be due to insufficient quantity of these compounds in the film. Davies, for example, calculates the thickness of the $\text{Ni}(\text{OH})_2$ film on Ni passivated in alkaline solutions to correspond to only one or two monolayers. The sensitivity of the Raman technique in the case of Ni is apparently not sufficient to detect this quantity of material. Finally, our study could not confirm the further oxidation of Ni^{+3} to Ni^{+4} to form NiO_2 because of our inherent inability to detect NiO_2 . Based on our experience, this is a problem commonly associated with Raman spectral determination of dark or black materials. Strong sample absorption of the incident light results in insufficient detectable scattered Raman light.

Surface corrosion films on Co.—A number of investigations have dealt with the electrochemical behavior of Co in basic and near-neutral solutions (16-19). Characterization of the nature and composition of the films formed was done notably by Sato (19, 21) and by Leidheiser (18, 20) using ellipsometry and Mössbauer spectroscopy, respectively.

Figure 5 shows an abbreviated Pourbaix diagram (9) for the Co/ H_2O system. The broken vertical line at pH 11.8 indicates the operating region corresponding to the 0.05M NaOH solution in which our electrodes were anodized. Depending on the applied potential, one sees that the phases that can be formed during the anodic corrosion of Co are $\text{Co}(\text{OH})_2$, Co_3O_4 , $\text{Co}(\text{OH})_3$, and CoO_2 .

Figure 6 shows a cyclic voltammogram of Co in 0.05M NaOH. The main features of the voltammogram appear to be the wave at about -0.5V and the set of reversible oxidation-reduction waves in the region of 0-0.4V prior to the onset of oxygen evolution at about 0.5V. The former has been assigned by Sato (19, 20) as due to the formation of a passive CoO film on the electrode. The range of potential from 0 to about 0.5V corresponds to what Sato has termed the primary and secondary passivation regions where $\text{Co}(\text{OH})_2$ and Co_3O_4 are formed, respectively. If waves II and III are associated with the formation of these compounds, waves VI and VII would correspond to their reduction. According to Sato, Co_2O_3 is formed beyond 0.5V, but there is no visible indication of an anodic wave in our voltammogram that could be attributed to

²The presence of water in the Ni_2O_3 sample has now been shown by infrared spectroscopy.

Fig. 5. Pourbaix diagram of the Co- H_2O system at 25°C

Fig. 6. Cyclic voltammogram of Co in 0.05M NaOH solution. Scan rate: 10 mV/s.

this. It may very well be masked by the large anodic current due to the other corrosion processes and the oxygen evolution reaction in this region.

Figure 7 shows the results of our Raman spectral measurements on Co electrodes. At the open-circuit potential of -0.16V, only background either from the glass window or the solution between the window and the electrode could be observed. On anodizing the electrode at 0.45V, four bands at 475, 515, 587, and 690 cm^{-1} , respectively, are observed. There is also an apparent increase in the background in the region of 400-900 cm^{-1} . The Raman bands disappear following a cyclic sweep and cathodic reduction at -0.35V (Fig. 7c). Spectral measurements in the interval between -1.1 to 1.2V did not yield additional Raman bands. *Ex situ* examination of the electrode surface following anodization at 0.45V yielded the result shown in Fig. 7d. It is obvious that there is an overlap of multiple vibrational bands in the relatively narrow frequency region of about 400-800 cm^{-1} . No bands were found in the OH^- stretching region, e.g., 3400-3700 cm^{-1} , for the film studied *ex situ*.

To facilitate interpretation of the observed spectra, an attempt was made to examine the films formed using x-ray diffraction. The films were, however, apparently so thin that a sufficient amount of material could not be scraped off the surface to get an XRD pattern. The material may have also been amorphous so that no pattern was obtained. We, therefore, concentrated on obtaining the spectra of standard samples of the possible and anticipated corrosion products of Co. Figure 8 shows results for the compounds $\text{Co}(\text{OH})_2$, CoO, and Co_3O_4 . The $\text{Co}(\text{OH})_2$ was prepared following the procedure of Hüttig

Fig. 7. Laser Raman spectra of Co electrode at various potentials in 0.05M NaOH; Ar⁺ laser, $\lambda = 4880 \text{ \AA}$ line, $P = 80\text{-}140 \text{ mW}$. (a): At open circuit (OCV), $E = -0.16 \text{ V}$ vs. Hg/HgO. (b): $E = 0.45 \text{ V}$. (c): $E = -0.35 \text{ V}$. (d): Ex situ after anodization at $E = 0.45 \text{ V}$.

and Kassler (22, 23); the composition of the product was confirmed by XRD analysis to be $\beta\text{-Co(OH)}_2$. The CoO

and Co_3O_4 were from Cerac (Milwaukee, Wisconsin). All the standard samples were pressed with KBr to make a pellet and rotated during the spectral measurement.

Comparing the *in situ* spectrum at 0.45V (Fig. 7b) with that obtained *ex situ* (Fig. 7d), one finds that there are more bands observed in the latter than in the former case. Two factors contribute to this: (i) the higher intensity obtainable when taking spectra outside the electrochemical cell, and/or (ii) masking of the spectra by the background fluorescence from the glass or solution is eliminated in the out-of-cell sample, resulting in better resolution and intensity. It is, however, unlikely that there would be more bands *ex situ* than *in situ*, so that it would be safe to assume that the bands observed *ex situ* are really also present *in situ*. The difference in peak frequencies between the corresponding bands may be more due to frequency shift associated with superposition of the spectrum on the high background. Comparing the *in situ* bands with the standards shows a one-to-one correspondence between the 515 and 516 cm^{-1} bands of the surface film and the CoO standard, respectively. Likewise, the 475 and 587 cm^{-1} bands of the electrode sample have counterparts in the Co_3O_4 spectrum. Further indication of the presence of Co_3O_4 in the film is the similarity in the gross features of the *ex situ* film spectrum with the Co_3O_4 standard. The absence of OH^- bands in the *ex situ* spectrum suggests that Co(OH)_2 is either not present in the film or is at a level below the detection sensitivity limits. One can then conclude that the anodic corrosion film formed at a cobalt electrode anodized at +0.45V consists of a mixture of CoO and Co_3O_4 . This is the first spectroscopic confirmation of Sato's finding of the existence of a bilayer CoO/ Co_3O_4 oxide film on Co in this potential region.

Acknowledgments

This research work was done under the auspices of the Division of Materials Sciences, Office of Basic Energy Sciences, U.S. Department of Energy. Thanks are due to B. Tani for the x-ray diffraction analysis of the samples and to Dr. D. Poa for supplying the Ni electrodes from alkaline Ni batteries.

ABSTRACT

The formation of cadmium sulfide thin films by cathodic deposition of Cd²⁺ ions from a solution containing sulfur on different substrates (platinum, molybdenum, aluminum) is described along with the influence of the substrate on the formation and morphology. By evaporating a Cu₂S layer on the CdS films deposited on aluminum, a heterojunction which exhibits photovoltaic effect is formed.

Cadmium sulfide is one of the semiconductor materials widely used in solar cells. Together with copper sulfide, it forms the well-known CdS/Cu₂S solar cell (1, 2).

It is generally admitted that electrodeposition is an efficient method of film formation, allowing a more economical production and better control of properties and stoichiometry of the resulting layers than thermal evaporation, pyrolytic spraying, or sputtering.

Recent studies have shown that the anodization of cadmium in sulfur solutions can be used for preparing photoactive cadmium sulfide films (3-5). However, the films obtained in this way do not have a homogeneous composition because the surface is much more affected by the electrochemical reaction than the deep layers. A lack of macroscopic uniformity of these films is also observed.

In this work, we have followed the approach reported by Power *et al.* (6). The CdS film is cathodically deposited from a solution containing cadmium and thiosulfate ions. The thiosulfate ions disproportionate, depending on the pH, according to

Thus, the overall electrode reaction is

Although this process has been studied on platinum electrodes, we have extended the study to other electrode ma-

terials, which seem more appropriate for use in solar cell applications.

Experimental

The voltammograms presented were obtained with a potentiostatic system consisting of scan generator, X-Y recorder, and potentiostat, using a standard three-electrode electrochemical cell in which the reference electrode was a saturated calomel electrode (SCE) and the counterelectrode a cylindrical platinum grid. The electrode impedance was measured with a PAR Model 128A lock-in amplifier.

The plating solution was $2 \times 10^{-3}M$ CdSO₄, 0.1M Na₂S₂O₃. The pH was adjusted with H₂SO₄. All products were from Merck p.a. grade.

Solutions were prepared using twice-distilled water that had subsequently been passed through a Millipore Mili-Q system. The electrode surfaces were grazed with carborundum paper and then with alumina powders containing particles as small as 0.05 μm. After polishing, the electrodes were cleaned with doubly distilled water followed by acetone p.a. grade. All the measurements were performed at 25° ± 0.1°C.

In order to form the CdS/Cu₂S heterojunctions, a 1500Å Cu₂S film was evaporated at 10⁻⁵ torr on a CdS film previously grown.

The composition and morphology of the CdS thin films were analyzed by scanning electron microscopy (SEM) and x-ray dispersive analysis, with a Philips-EDAX scanning microprobe system.

Results and Discussions

The cyclic voltammetric curves obtained with a Pt electrode at neutral pH are shown in Fig. 1. From the results, it became evident that at potentials more negative than -550 mV a reduction process occurs due to deposition of cadmium metal. The anodic peak ($E_{ap} = -250$ mV) corresponds to the redissolution of the Cd. A reversible character became apparent by the constant value of the E_{ap} with sweep rate. The cathodic and anodic charges are different, and the excess cathodic charge may be due to hydrogen evolution rather than to the formation of a CdS film, which was not observed after subjecting the electrode to a potential of -850 mV for a few hours.

Figure 2 shows a voltammetric curve for an acid solution pH 2.3. In this condition, the $S_2O_3^{2-}$ is decomposed to colloidal sulfur, which is reduced to sulfide ions that together with the Cd^{2+} present in the interface form a CdS film on the electrode. The cathodic peak appears at more negative potentials ($E_{ap} = -750$ mV) and the cathodic currents are strongly increased, while the anodic peak has almost disappeared. These characteristics can be interpreted on the basis of the formation of a CdS film which is not redissolved until very anodic potentials are reached. The small anodic peak due to redissolution of cadmium appears at -250 mV vs. SCE.

The feasibility of forming CdS films on Pt by this method led us to investigate other metallic electrodes more suitable for the preparation of photovoltaic cells. We have initially investigated the cathodic deposition of CdS on molybdenum electrodes. Figure 3 shows the corresponding voltammogram. A rather higher cathodic current is observed, due partially to hydrogen evolution, and partially to the formation of a CdS film. The surface roughness of the metallic substrate prevented an exact determination of film thicknesses. However, it was never

Fig. 3. Linear potential scans of a solution containing $2 \times 10^{-3}M$ $CdSO_4$ and $0.1M$ $Na_2S_2O_3$, pH = 2.3 at a Mo electrode. Scan rate: 200 $mV s^{-1}$. Reference electrode: SCE.

greater than about 1000\AA , which is clearly insufficient for applications in solar cells. If the CdS is so thin, the number of defects in the active region will probably increase and the collection efficiency will deteriorate (7).

These results led us to test aluminum as working electrode because of its good electrical characteristics. Figure 4 shows the voltammogram corresponding to the formation of CdS on this electrode at acid pH. The behavior of this system is qualitatively similar to the previous case, the cathodic current appearing at more negative potentials ($-1V$ vs. SCE). When this potential was applied for a

Fig. 5. Frequency dependence of the real component of the interfacial admittance Y'_{el} / \sqrt{w} vs. \sqrt{w} for indicated values of potential, at a Mo electrode.

Fig. 6. Frequency dependence of the real component of the interfacial admittance $Y'_{el} \cdot \sqrt{w}$ vs. \sqrt{w} for indicated values of potential, at an Al electrode.

sufficiently long time, the electrode covered itself with a yellow, uniform, translucent, rather thick film. For shorter electrolysis times, thin, nonadherent CdS films were formed. Therefore long electrolysis times were used (1-2h). With the aim of producing thicker films, the cell solution was periodically changed, thus avoiding reduction of the sulfur concentration due to the precipitation of colloidal sulfur.

Molybdenum electrodes behaved somewhat differently. In order to investigate the difference in behavior of molybdenum and aluminum electrodes, we have performed ac impedance measurements, analyzing the real and imaginary components of the faradic admittance.

For the Mo electrode, Fig. 5 shows the variation of the real part of electroodic admittance (Y'_{el}) with frequency, w , at several potentials. The observed diminution of $Y'_{el} \cdot \sqrt{w}$ corresponds to anomalous values of the phase angle of the faradic impedance higher than 45° . This could be indicative of a faradic process with adsorption of an electroactive species (8). This effect can be the reason for the low thickness obtained and the impossibility of growing CdS films on Mo electrodes, now interpreted in terms of blocking of the electrode surface by adsorbed species.

Fig. 7. Scanning electron micrograph of an electrode of molybdenum after 15 min deposition (640X).

The behavior of the parameter $Y'_{el} \cdot \sqrt{w}$ with frequency for an Al electrode is markedly different for all the studied potentials (Fig. 6). An increase with frequency is observed, followed by stabilization at a certain level, and in some cases by a slight diminution. This is not in agreement with Randles behavior in the whole frequency range, but can be explained by a chemical reaction coupling to charge transfer, which led to the described behavior of $Y'_{el} \cdot \sqrt{w}$.

Figure 7 shows the SEM micrograph of the film formed on molybdenum. Two zones can be seen. The first one consists of white stains whose composition is 98% sulfur and 2% cadmium. The second one is a large zone with less cadmium. These compositions are not very accurate due to the superposition of the sulfur K line at 2.3 keV, and the molybdenum L line at 2.29 keV, but, nevertheless, the data are significant. In every sample, the sulfur content is much greater than the cadmium content, indicating the preferential formation of a yellow layer of adsorbed sulfur instead of CdS. Figure 8 is a micrograph of a CdS film grown on the Al electrode. Three zones can be distinguished. The first one consists of white grains containing 91% sulfur and 9% cadmium. The second zone is made up of clusters the mean composition of which is 68% Cd and 32% sulfur, corresponding practically to stoichiometric CdS. The last zone is the uncovered substrate. A longer electrolysis time results in films with a lower cadmium content (58% Cd and 42% S) and the different morphology seen in Fig. 9. Thermal treatment *in vacuo* (200°C, 1h) leads to a higher degree of homogeneity demonstrated in Fig. 10.

Fig. 8. Scanning electron micrograph of an electrode of aluminum after 2h deposition (2500X).

Fig. 9. Scanning electron micrograph of an electrode of aluminum after 2.5h deposition (2500X).

Fig. 10. Scanning electron micrograph of an electrode of aluminum after 2.5h deposition followed by thermal treatment (1500X).

A 1500Å Cu_2S film was deposited on CdS by vacuum evaporation. The heterojunction formed on a Mo substrate did not exhibit a photovoltaic effect due to the very small thickness and poor stoichiometry of the CdS film. However, the heterojunction formed on Al substrate exhibited a low photovoltaic effect, which was more evident in the heat-treated samples. Under 80 mW/cm^2 illumination, with a 300W General Electric ELH lamp, the open-circuit voltage was 10-15 mV, and the short-circuit current only a few microamperes.

Conclusions

The results reported above indicate that the metal used as a substrate has an important effect in the formation of

CdS films with suitable thickness and stoichiometry. Best results were obtained on aluminum. The different behavior of the metals studied has been attributed to different electrode mechanisms: surface blocking by adsorbed sulfur in the case of molybdenum, and chemical reaction coupled to charge transfer for aluminum.

Optimum conditions for the formation of a CdS layer on aluminum substrates were: pH = 2.3, potential -1V vs. SCE, and electrolysis time > 2h.

Thermal treatments improve the characteristics of the films and their photovoltaic properties.

These results are promising with regard to the feasibility of the electrochemical formation of CdS, for solar cell applications, where thicker and more adherent films are needed. Work is now in progress to achieve these objectives by trying electrodeposition at higher temperatures and different thermal treatments of the samples.

Detection of Gas Bubbles and Organic Molecules Included in Electrodeposited Films by Transmission Electron Microscopy

S. Nakahara*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A transmission electron microscope method was developed for distinguishing the defocused images of organic inclusions from those of gas bubbles included in electrodeposited films. The method, in principle, utilizes a difference in the defocus contrast between the images of organic inclusions and gas bubbles. This contrast difference can be attributed to a difference in the mean inner potential between two types of inclusions. Experimental results of the defocus contrast from inclusions in copper electrodeposits were compared with theoretical image-intensity calculations. The results were found to be in good agreement with the theoretical predictions.

A recent transmission electron microscope (TEM) study (1) has established that electrodeposited films often contain small ($\approx 10\text{\AA}$) gaseous and/or organic inclusions. Gaseous inclusions, which are most likely to be hydrogen bubbles, result from the incorporation of hydrogen into a deposit at a cathode during electrocrystallization. The inclusion of hydrogen in a form of gas bubbles was previously found to cause the so-called "hydrogen embrittlement" in electroless copper films (2). Organic inclusions, however, originate primarily from addition agents deliberately added to an electrolyte.

In TEM, such small inclusions can be detected by a method known as the through-focus imaging (3). In this method, the images of inclusions may be seen with the defocus contrast, if the inclusions are sufficiently large

($\geq 10\text{\AA}$). The defocus contrast arises from phase contrast as a result of the interference at a chosen distance of defocus between electrons passing through an inclusion and those through its surrounding metal matrices. In TEM, therefore, such inclusions are regarded as "phase objects" (1).

Most recently, a simple method was developed (4) for distinguishing gas bubbles from organic inclusions ("polymer") in cobalt-hardened gold electrodeposits from their defocused images. An idea is to reveal statistical characteristics in the size distribution for two kinds of inclusions. It was found experimentally that gas bubbles exhibit a size-distribution curve much different from that of organic inclusions. Here, the size distribution of singly incorporated organic molecules in the gold deposits was quite uniform, whereas that of gas bubbles was random.

* Electrochemical Society Active Member.

Accordingly, the existence of organic inclusions in the deposit was manifested by the appearance of a relatively sharp peak in their size-distribution curve. This was the case for "polymer" inclusions in hard gold electrodeposits (4). The incorporation of gas bubbles, however, resulted in a broader curve, indicating a random size distribution. In this method, therefore, the presence of organic inclusions and gas bubbles and their relative amount can be estimated from their size-distribution curve. It is, however, obvious that this method cannot be applied to electrodeposits containing both organic molecules and gas bubbles, which happen to be comparable in size.

In this communication, we report another method for distinguishing organic inclusions from gas bubbles. The method is based upon the use of a significant difference present in the defocus contrast between organic inclusions and gas bubbles. The contrast difference was found to originate from the difference in the mean inner potential (MIP) between two types of inclusions, and to vary sensitively with the amount and sign of defocus. An optimum amount of defocus for distinguishing one type of inclusions from the other was determined from both experimental and theoretical results.

A Method of Intensity Calculation for Defocus Contrast

A simple method for computing the defocus contrast of "phase objects" having circular symmetry was previously described by Rühle (5). In this calculation, the effects of an incident beam divergence, lens aberration, and inelastic scattering were neglected. Furthermore, the presence of a finite objective aperture was not taken into account, which is equivalent to the aperture-free case. In order to describe the theoretical formulations based upon the above assumptions, we illustrate an electron-optic system in relation to the mathematical coordinate system. In an electron-optic system, there are four important planes, as shown in Fig. 1. These planes are object, objective lens, backfocal, and image planes. We consider a circular-phase object, the electron exit surface of which is located precisely at the object plane. Cartesian coordinates x , y , and z are defined in the object plane, where the origin is taken at the center of the phase object. When the object plane ($z = 0$) is focused by an objective lens, the focused image of the object is seen at the image plane. If a plane ($z \neq 0$) different from the object plane is focused, the defocused image of the phase object appears at the image plane. For example, the overfocused image can be seen if a plane below the object is focused (see Fig. 1). The distance between the object and the imaged planes is defined as an amount of defocus (Δf). The positive and negative signs of Δf imply the overfocused and underfocused conditions, respectively.

The theoretical formulation is based upon an information theory for image transfer, in which successive Fourier transforms are used to derive the wave function at the image plane. We assume that the wave function at the object plane (or more precisely at the electron exit surface of an object) is expressed as $\Psi(\vec{r})$, where \vec{r} is the position vector in the object plane x - y (see Fig. 1). The wave function, $\tilde{\Psi}(\vec{\xi})$, at the back-focal plane is then described as the Fourier transform of the function, $\Psi(\vec{r})$, where $\vec{\xi}$ is the Fourier wave vector at the back-focal plane which is defined by the cartesian coordinate ξ_1 and ξ_2 . The wave function, $\Psi_o(\vec{r})$, at the image plane is the inverse Fourier transform of the function, $\tilde{\Psi}(\vec{\xi})$, multiplied by an appropriate phase factor which accounts for a phase shift due to defocusing. The final intensity distribution, $I(\vec{r})$ at the image plane is expressed as the product, $\Psi_o(\vec{r}) \cdot \Psi_o^*(\vec{r})$, where the wave function, $\Psi_o^*(\vec{r})$, implies a complex conjugate of the function, $\Psi_o(\vec{r})$.

The function, $\Psi_o(r)$, was previously obtained (5, 6) to be

$$\Psi_o(\gamma, \Delta f) = C [1 - 2i\epsilon \exp(i\epsilon\gamma^2) \int_0^1 \{e^{i\gamma'^2} - 1\} \exp(i\epsilon\gamma'^2) J_0(-2\epsilon\gamma'\gamma)\gamma'd\gamma'] \quad [1]$$

where $C = \exp(2\pi i\Delta fK)$, K being the wave vector of an in-

Fig. 1. Schematic illustration showing an electron-optic system for a transmission electron microscope.

cident electron beam, Δf the amount of defocus, $\gamma = |r|/r_0$, $\gamma' = r'/r_0$, $\epsilon = (\pi K/\Delta f) r_0^2$, r_0 the radius of the phase object, and J_0 the Bessel function of the 0th order. A function, $f(\gamma')$, represents a phase shift at the electron exit surface of a phase object. For spherical-phase objects

$$f(\gamma') = \Phi_0 \sqrt{1 - \gamma'^2} \quad (|\gamma'| \leq 1) \quad [2]$$

where Φ_0 is the phase shift at $\gamma' = 0$. The phase, Φ_0 , can be expressed in terms of MIP, V_0 , as

$$\Phi_0 = \pi t V_0 / \lambda E \quad [3]$$

where t is the thickness of an object along an electron-beam direction at $\gamma' = 0$, λ the wavelength of an electron beam, and E the accelerating voltage. The intensity distribution, $I(\gamma, \Delta f)$, at the image plane is obtained from the relation

$$I(\gamma, \Delta f) = \Psi_o(\gamma, \Delta f) \cdot \Psi_o^*(\gamma, \Delta f) \quad [4]$$

Experimental

Copper films were electrodeposited on annealed OFHC copper sheets in a sulfate electrolyte (200 g/l $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 50 g/l H_2SO_4) containing 5 mM/l O-phenanthroline as an organic additive. Plating was carried out at room temperature and at the current density of 5 mA/cm². The films plated in this condition were previously found (7) to contain O-phenanthroline molecules incorporated into the film without any decomposition. Furthermore, a selection of this particular organic as an additive was expected to be appropriate for studying by the defocus contrast, as O-phenanthroline molecules have previously been shown to be detectable in nickel electrodeposits by the defocus contrast using TEM (3).

Copper films used for TEM observations were jet polished in a mixture of 50 ml nitric acid and 100 ml methanol at room temperature. If a slow rate of polishing was required, the solution was chilled to the temperature of Dry Ice.

TEM micrographs were taken with a JEM 200 electron microscope operated at 200 kV. For through-focus sequences, an amount of defocus (Δf) was previously calibrated against the excitation current of an objective lens.

All the through-focus sequences for imaging inclusions were taken under the kinematical condition. This imaging condition allowed one to avoid the so-called amplitude contrast arising from multiple-diffraction events in a

crystal and thus provided pure phase contrast for inclusion images.

Results and Discussion

Observation of inclusions.—Through-focus sequences revealed numerous inclusion images in a copper deposit. Figures 2a and 2b show TEM micrographs of inclusions in the single grain, taken in the overfocused ($\Delta f = +3.9 \mu\text{m}$) and underfocused ($\Delta f = -3.9 \mu\text{m}$) conditions, respectively. Inclusions are seen as black dots surrounded by white rings in the overfocused condition (Fig. 2a) and as white dots surrounded by black rings in the underfocused condition (Fig. 2b). The density of these inclusions was $\sim 1 \times 10^{17}/\text{cm}^3$. As indicated by a dotted line in Fig. 2, all inclusions are seen to be distributed along a specific crystallographic direction. In order to insure that the inclusions were indeed distributed internally within the grain,¹ we took a stereo-pair, while keeping the identical defocus condition (8). Overfocus and underfocus stereo-pairs are shown in Fig. 3 and 4, respectively. A stereographic trace analysis made for several differently oriented grains indicated that the direction of the inclusion alignment lies along the $\langle 001 \rangle$. An origin of the directional alignment along the $\langle 001 \rangle$ will be discussed later. As shown previously by Wipper *et al.* (7), the inclusions are most likely to be O-phenanthroline molecules.² More information concerning these image features is, however, needed to determine whether or not all the inclusions are of organic origin.

As described in the earlier section, one of the indirect methods for determining the possible presence of organic inclusions or gas bubbles is to take the size-distribution curve of inclusions from their defocused images. Following this method, we made the size measurements from 200 inclusions visible in Fig. 2a. The number of inclusions *vs.* the image size³ is plotted in Fig. 5. A relatively well-defined peak is located at the size of $\sim 27 \text{ \AA}$. It is also seen from the curve that the majority of inclusions lies in the size range of $27 \pm 10 \text{ \AA}$. These inclusions are uniform in size, indicating the presence of O-phenanthroline molecules. This does not, however, insure that there are no gas bubbles in the deposit. Only a tentative conclusion here is that within 200 inclusions the deposit did not contain enough gas bubbles. A question then arises as to how one can recognize a small number of gas bubbles which are hidden inside a large number of organic inclusions, in

¹Unambiguous distinction cannot be made between inclusions at the surfaces and those inside a grain, unless the stereo-pair is taken.

²Inclusions in metal matrices, which are seen as white dots surrounded by black rings in the underfocused condition, consist of lower atomic elements than the metal. In an electrodeposited metal, only the possible inclusions of low atomic elements are organic molecules and/or gas bubbles.

³In defining the size of images taken in the overfocused condition, we took the outer diameter of black dot as a measure of the size. It has previously been shown (1) that the actual size of an inclusion is close to the outer diameter of black dot taken in the overfocused condition.

Fig. 2. Micrograph of a copper film taken in the (a) overfocused ($\Delta f = +3.9 \mu\text{m}$) and (b) underfocused ($\Delta f = -3.9 \mu\text{m}$) conditions.

Fig. 3. A stereo-pair taken at $\Delta f = +3.9 \mu\text{m}$, showing a spatial alignment of inclusions.

Fig. 4. A stereo-pair of the area corresponding to Fig. 3, taken at $\Delta f = -3.9 \mu\text{m}$.

particular if the size of gas bubbles is similar to that of organic inclusions. A method of taking the size distribution does not appear to be a reliable solution to this problem here.

So far, we have limited ourselves to an analysis of image size from a micrograph taken at one defocus. There is, in fact, one more important variable that has not yet been considered here. An additional variable is an intensity distribution of the image as a function of defocus distance. If there is a sufficient difference in MIP between two inclusions, it may be possible to observe a difference in the defocus contrast. Based on this consideration, we made a further systematic study on the image contrast of the inclusions by changing the amount and sign of defocus. Figures 6a and 6b are TEM micrographs of the inclusions, taken in focus and at the defocus distance of $+1.3 \mu\text{m}$ (overfocus), respectively. The images taken in the in-focus condition are practically invisible. At $\Delta f =$

Fig. 5. A size distribution of inclusions in a copper deposit. The size represents a measured image size from micrographs obtained at $\Delta f = \pm 3.9 \mu\text{m}$.

Fig. 6. Images of inclusions in a copper deposit. (a) $\Delta f \approx 0$ and (b) $\Delta f = +1.3 \mu\text{m}$.

Fig. 7. Images of inclusions in a copper deposit. The area is the same as that shown in Fig. 6. (a) $\Delta f = +2.6 \mu\text{m}$, and (b) $\Delta f = -2.6 \mu\text{m}$.

+1.3 μm , it is noted that several inclusions (for example, those indicated by three arrows) exhibited slightly darker dots than the rest of inclusions. As most of inclusions in Fig. 6 are comparable in size, the difference in contrast should originate from that in MIP. Considering the fact that gas bubbles containing hydrogen should have a lower MIP than organic inclusions, it is suspected that these darker dots may originate from gas bubbles. The same area shown in Fig. 6 is further taken with $\Delta f = \pm 2.6 \mu\text{m}$ (see Fig. 7). Here, the corresponding inclusion images indicated by arrows can be recognized much more clearly than those in Fig. 6. In addition, the contrast difference between gas bubbles and organic inclusions is seen to be much more obvious here, but this difference tends to become smaller again with a further increase in defocus distance. For example, the images taken at $\Delta f = \pm 3.9 \mu\text{m}$ (see Fig. 2a and 2b) demonstrate this trend in a loss of contrast difference at a larger defocus distance.

These results strongly suggest that there is an optimum amount of defocus distance for obtaining the maximum difference in contrast between two types of inclusions. The optimum amount of defocus appears to lie between 1.3 and 2.6 μm . A quantitative analysis on the contrast difference is, however, needed to confirm this conclusion.

It should be mentioned here that the overlapped images of inclusions could also give rise to an enhanced contrast due to a linear superposition of phase shift along the electron-beam direction. For selecting probable gas bubbles (as indicated by three arrows in Fig. 6 and 7), care was taken to avoid overlapped inclusion images. A possible image overlap was further checked by taking a stereopair, which also supported the validity of our assumption that the inclusions are more or less spherical in shape.

Theoretical intensity calculation.—Based upon the above experimental observations, we made a theoretical analysis on the image contrast of inclusions. Equation [4] was used to compute an intensity profile as a function of radial distance, r . For this computation, the following parameters were used. From the size distribution curve shown in Fig. 5, we chose the average size of inclusions to be 27 Å diam. The shape of inclusions was assumed to be spherical. The MIP of copper was chosen to be 23.5V from the data obtained by Buhl (9). We assumed that gas bubbles contain hydrogen. Since hydrogen could readily diffuse out of the film at room temperature (2), gas bubbles could be effectively a spherical hole at the time of TEM observations. The MIP of hydrogen gas bubbles was therefore taken to be 0 V. Data for the MIP of O-phenanthroline are not available in literature. However, noting that its chemical formula is $\text{C}_{12}\text{H}_9\text{N}_2$, it is reasonable to assume that its MIP may not differ too much from that of other organic substances containing similar atomic elements. From published data (10), MIP's for stearic acid, $\text{C}_{30}\text{H}_{62}$, and $\text{C}_{31}\text{H}_{64}$ were 6.3, 6, and 7.2V, respectively. We chose 6V for the MIP of O-phenanthroline molecule. Equation [1] was numerically evaluated using a high-speed computer.

Figures 8a, 8b, and 8c are the intensity profiles of the hydrogen gas bubble (dotted line) and the organic molecule (solid line) computed for $\Delta f = +1.3$, +2.6, and +3.9 μm , respectively. Here, the vertical axis is normalized to the background intensity, I_0 , whereas the horizontal axis is normalized to the radius, r_0 , of an inclusion. As is evident in Fig. 8, a difference in primary intensity minimum at $r/r_0 = 0$ between two inclusions varies markedly with an amount of defocus. It is noted here that there is in fact 7% ~ 13% contrast difference at the peak ($r/r_0 = 0$) between the two inclusions. This contrast difference seems to be larger for a smaller amount of defocus. In Fig. 9, we plotted the intensity difference at $r/r_0 = 0$ between the gaseous and the organic inclusions as a function of defocus distance. From this curve, an optimum amount of defocus for distinguishing the images of organic inclusions from those of gas bubbles appears to lie between 1 and 3 μm , which is in good agreement with the experiment.

Fig. 8. Theoretical image intensity profile computed for spherical gaseous and organic inclusions in copper. Normalized intensity I/I_0 is plotted against normalized radial distance r/r_0 , where I_0 is the background intensity and r_0 is the radius of inclusion. The distance ($r/r_0 = 1$), therefore, represents the actual size of an inclusion. (a): $\Delta f = +1.3 \mu\text{m}$. (b): $\Delta f = +2.6 \mu\text{m}$. (c): $\Delta f = +3.6 \mu\text{m}$.

Fig. 9. Calculated intensity difference in primary intensity minimum at $r/r_0 = 0$ between gaseous (I_p^G) and organic (I_p^M) inclusions vs. the defocus distance (Δf).

Comparison of theoretical predictions with experimental results.—Our theoretical estimate shows a remarkable agreement with the experiment. This is rather surprising, considering the fact that identification of the nature of inclusions is still speculative here. Regardless of this experimental uncertainty, it is clear from the theoretical predictions that there is indeed a significant contrast difference expected between two types of inclusions. The contrast difference of course varies with the size of inclusions and the MIP of metal matrices. This contrast difference method may not be applicable to all situations, but at the present time there seem no other microscopic methods that provide further details on the nature of inclusions. Nevertheless, organic and gaseous inclusions generally play an important role in determining the physical prop-

erties of electrodeposited films. The present method should be useful in the TEM investigations of such films.

Origin of the Molecule Alignment along the $\langle 001 \rangle$ Direction

It was established from a stereographic trace analysis that lines of O-phenanthroline molecules lie along the $\langle 001 \rangle$ direction of copper lattice. This spatial alignment can be rationalized by the mode of impurity adsorption and subsequent incorporation during copper electrocrystallization. The adsorption of these molecules on the growth surface is expected to cause the inhibition of step movement, and this step slow-down eventually develops the formation of multi-atomic steps. Newly developed planes bounding these steps are expected to be of low index type. Once these steps are developed, they may even become convenient sites for additional incoming molecules to be trapped. Consequently, such incorporated molecules will be seen to lie along a specific crystallographic direction. One example is shown in Fig. 10, together with its probable incorporation model (see Fig. 11). It is seen that in the $[130]$ -oriented grain, the low index planes of (100) and (010) appear to develop after the adsorption, resulting in the molecular alignment along the $[001]$. We found the similar interpretation is applicable to the $[001]$ - and $[110]$ -oriented grains.

ABSTRACT

An investigation of the flow of the two superposed liquids (the electrolyte and the molten aluminum) and of the interface shape has been carried out with the intention of revealing the main mechanisms and to clarify the hydrodynamic behavior of Hall-Héroult cells. The wide channels present around the anodes and between the two anodes rows in modern cells appear responsible, in the final analysis, for the electrolyte motion. The horizontal component of the current density in the aluminum layer largely determines the interface shape. It can also drive an organized motion when it is not a pure gradient. Two main ideas are at the source of this theory: (i) the shallow depth of the fluid layers (compared with their horizontal dimensions) justifies an approximation of zero inertia, and (ii) a linear approximation is proposed for the horizontal shear stresses. This almost explicit theory results in predictions that are not completely realistic, but it is shown how certain features of actual cell behavior can be revealed.

There is considerable interest in better understanding the general behavior of Hall-Héroult cells, because these large devices, in which aluminum oxide is reduced electrolytically to produce molten metal, are known as the major energy consumer in the production of aluminum from its ores. For a full description of these cells, the reader is referred to Lympny *et al.* (1). For the sake of brevity, it will only be mentioned that the electric current coming from the anodes (see Fig. 1) has to pass first through a horizontal liquid layer, the electrolyte (often known as "cryolite") before entering into the molten aluminum layer (where it is partially redirected in the horizontal direction), and thence through the carbon lining and into the collector bars.

Electromagnetics, hydrodynamics, heat and mass transfer, as well as electrochemistry, enter immediately into any complete description of the cell. Indeed, magnetohydrodynamic effects are responsible for the motion and the turbulence of the two liquids, and play a significant role in determining the current efficiency. In recent work (2), the development of a mathematical model, based on general equations of electromagnetics and hydrodynamics, has been attempted in order to compute the main behavior of these cells. The objective was to build a convenient tool for conception of new cells with better efficiency (3).

It has, however, been recently realized that the two-dimensional Navier-Stokes equations and the usual turbulence modeling ($k-\epsilon$) could not describe the true mechanisms involved in the motion of the two thin liquid layers. Using the $k-\epsilon$ model for turbulence in a supposed two-dimensional flow leads to neglect of the vertical transport of momentum, and this is unrealistic in this configuration, where it is, in fact, dominant over the horizontal one. Besides, a purely two-dimensional schema could not take into account the presence of channels between the anode blocks and around the cell periphery. These have, however, a strong influence on the flow of the electrolyte because they connect this flow with the atmospheric pressure, almost without head losses.

It is the purpose of this paper to propose a new basis of approximations to the hydrodynamics of the two superposed liquids, and to develop a better understanding of the influence of each parameter on the fluid flows and the interface shape. To do this, the concept of an ideal cell, in which the electromagnetic forces are pure gradients, is introduced. As a consequence, the cryolite is the only moving fluid. The pressure differences between the two liquids in different motion vary from one place to another, and this is responsible for the shape of the interface. It is also shown that second-order effects can easily

be superimposed on this state of reference predicted for the ideal cell, and an example is treated.

Each liquid layer may be characterized by its vertical thickness (under the anodes), H , its length, $2a$ and its width $2b$. It appears convenient to introduce also a typical horizontal length scale, L , which can be either a or b or some combination of them, in order to characterize the thinness of the layer by the ratio H/L . The thickness H is of the order of 0.04m in the cryolite and 0.16m in the aluminum. In typical modern cells, L may be of the order of 4m, so that H/L is of the order of 10^{-2} in the cryolite and $4 \cdot 10^{-2}$ in the aluminum. The smallness of H/L is of prime importance in the justification of the approximations proposed in the "Basic Equations" section below. Other important orders of magnitude are the typical electric current ($\approx 2 \cdot 10^6$ A) and the current density j_0 ($\approx 6 \cdot 10^3$ A m^{-2}).

The coordinates are defined in Fig. 2, with x in the long horizontal axis and y in the small one. The z axis is along the upward vertical, with its origin at the mean level of the interface between cryolite and aluminum. To illustrate the results, all the numerical computations have been done with a cell whose aspect ratio was $a/b = 2$. Unit vectors are denoted $\bar{e}_x, \bar{e}_y, \bar{e}_z$.

Basic Equations and Approximations

The relevant magnetic Reynolds number.—The question of a possible influence of the velocities in the two superposed liquids on the magnetic field has often arisen. Clearly, the relevant magnetic Reynolds number characterizing this effect must be the ratio between the diffusion time of the magnetic field through the whole cell and the

Fig. 1. Sectioned view of a Hall-Héroult cell as seen looking in the long horizontal direction.

*Electrochemical Society Active Member.

Fig. 2. Coordinates and main notations in a typical horizontal plane.

transit time of the fluid elements LV^{-1} . In the idealized configuration of a thin layer of conducting material located between two insulating media, any disturbance would diffuse instantaneously through these media, so that its diffusion time would be $\mu\sigma H^2$ (where μ and σ denote the permeability and the electrical conductivity of the conducting layer, respectively). The situation with which we are concerned is more complex because the media above and below the aluminum layer are conducting: they are thick (let H^* denote their total thickness) and they are conducting (let σ^* denote their conductivity). Forgetting the extremely short diffusion through the electrolyte layer, the total diffusion time through the cell may be estimated as $\mu(\sigma H^2 + \sigma^* H^{*2})$. Therefore, the relevant magnetic Reynolds number is

$$R_m = \mu\sigma VL \cdot \frac{H^2}{L^2} \left(1 + \frac{\sigma^* H^{*2}}{\sigma H^2} \right) \quad [1]$$

It appears that, although $\mu\sigma VL$ may be of the order of a few units, H^2/L^2 is extremely small ($\approx 3 \cdot 10^{-4}$). This means that the vertical diffusion time through the aluminum layer is extremely small compared with the transit time. Besides, the ratio σ^*/σ is sufficiently small ($\approx 2 \cdot 10^{-3}$) to also render negligible the diffusion time through the electrodes. Then it may be concluded that the classical approximation of a zero magnetic Reynolds number is valid.

The "shallow water" approximation.—Because of the shallowness of the two liquid layers and because of the very active mixing due to turbulence and to gas bubbles generated at the anode, the interest is essentially in describing the mean horizontal motion. If \bar{u}_H denotes the horizontal velocity field, the definition of this mean motion is

$$\langle \bar{u}_H \rangle = 1/H \int_{-H}^0 \bar{u}_H dz \quad [2]$$

The equations for such a two-dimensional flow are

$$\bar{\nabla}_H \cdot \langle \bar{u}_H \rangle = 0 \quad [3]$$

$$\rho \langle (\bar{u}_H \cdot \bar{\nabla}_H) \bar{u}_H \rangle = -\bar{\nabla}_H \langle p \rangle + \langle (\bar{j} \times \bar{B})_H \rangle + \frac{\partial}{\partial x_i} \left(\eta_e \frac{\partial}{\partial x_i} \langle \bar{u}_H \rangle \right) - \frac{\bar{\tau}}{H} \quad [4]$$

The subscript H stands for the horizontal vectors or operators, so that $\bar{\nabla}_H = (\partial/\partial x, \partial/\partial y, 0)$, $i = (1, 2)$, and p denotes the pressure, ρ the density, η_e the effective viscosity, and $\bar{\tau}$ the sum of the shear stresses at the top and bottom of the fluid layer.

To appreciate the consequences of the small values of H/L , let us write Eq. [4] in a nondimensional form. Since the driving mechanism is the difference between the Lorentz forces and the pressure gradient, it is convenient to introduce the nondimensional pressure

$$P = \frac{p}{\mu j_o^2 L^2} \text{ and the velocity scale } V = \left(\frac{\mu j_o^2 LH}{p} \right)^{1/2}$$

Then, with

$$X_i = \frac{x_i}{L}, \bar{U} = \frac{\bar{u}_H}{V}, T = \frac{\bar{\tau}}{\rho V^2}, \bar{F} = \frac{\langle \bar{j} \times \bar{B} \rangle}{\mu j_o^2 L}$$

the nondimensional equation is

$$\frac{H}{L} (\bar{U} \cdot \bar{\nabla}_H) \bar{U} = -\bar{\nabla}_H P + \bar{F} - \bar{T} + \frac{H}{L} \frac{\nu}{VL} \frac{\partial}{\partial X_i} \left(\frac{\eta_e}{\eta} \frac{\partial \bar{u}}{\partial X_i} \right) \quad [5]$$

With the typical values of H/L previously mentioned, for modern cells, with current of the order of $2 \cdot 10^5$ A, V is of the order of 0.1 ms^{-1} , and the Reynolds number VL/ν is of the order of $4 \cdot 10^6$. Therefore, even if η_e is much higher than the molecular viscosity η because of the intense mixing present in each liquid, it is clear that the two-dimensional friction (or the horizontal transport of momentum) cannot compete with the Lorentz forces. Inertia also appears unable to balance the driving forces. Consequently, the dominant equilibrium is between the difference $\bar{F} - \bar{\nabla}_H P$ (which is not exactly zero, as will be seen later) and the friction on the horizontal boundaries \bar{T} . Then the equations for the two-dimensional flow of each liquid reduce to

$$\bar{\nabla}_H \cdot \bar{U} = 0 \quad [6]$$

$$\bar{T} = \bar{F} - \bar{\nabla}_H P \quad [7]$$

Of course, this approximation still needs an assumption for the relation between the drag \bar{T} and the velocity \bar{U} . Two ideas suggest that a linear expression, *i.e.*

$$\bar{T} = \kappa \bar{U} \quad [8]$$

could be quite plausible, and certainly better than a quadratic expression (as in turbulent duct flows). One idea is the previously established fact that inertia is negligible in these shallow layers of liquids. The other derives from the fact that the typical scale of random eddies responsible for the vertical transport of momentum is H , which is much smaller than the typical horizontal length scale of the mean motion L . The situation appears then more similar to the kinetic theory of gases (with a mean free path much smaller than the macroscopic scales) than usual

turbulent flows (with an integral scale of the same order as the length scales of the mean flow). We will therefore retain this very simple expression [8]. It will be seen that it has also the advantage of allowing a clear illustration and understanding of the mechanism of stirring in each liquid.

The influence of the cryolite channels.—Since the cryolite is a poor conductor, compared to the carbon electrodes, the fraction of the electric current crossing the channels between the anode blocks may be neglected. Then the flow in these channels behaves like an open-channel flow, having the capability of exchanging mass and momentum with the neighboring two-dimensional flow underneath the anodes. In spite of this mass exchange, the mean flow in a straight channel is such that the pressure variation in the cross-section follows the law of hydrostatics. However, pressure differences develop underneath the anodes, in order to partially balance the Lorentz forces according to Eq. [7]. Because of the continuity of pressure between the cryolite layers and the channels, pressure gradients may also exist in the channels, where they would necessarily drive some flow and be balanced by friction and momentum transport.

Let S denote the area of the cross section, \mathcal{P} the wet perimeter, and q the flow rate which is a function of the abscissa ξ along the channel. If u_n and u_s stand for the outward normal and tangential velocity components of the two-dimensional cryolite flow along the anode edge, and if τ_w denotes the wall shear stress, the mass and momentum conservation equations can be written

$$\frac{dq}{d\xi} = u_n H \quad [9]$$

$$\frac{d}{d\xi} \left(\rho \frac{q^2}{S} \right) - \rho u_n u_s H = -S \frac{dP}{d\xi} - \mathcal{P} \tau_w \quad [10]$$

Because of the variations of the liquid depth, themselves related to the topology of the free surface and of the interface, and because of possible variations in the shape of the solidified ledge of cryolite (for the peripheral channel), the parameters S and \mathcal{P} may slowly vary from one place to another. However, in this theory they are supposed to be constant for the sake of simplicity. The wall friction τ_w is assumed to follow the usual quadratic law

$$\tau_w = \lambda \rho \frac{q^2}{S^2} \quad [11]$$

where the friction coefficient λ has still to be estimated.

Introducing the nondimensional quantities

$$Q = \frac{q}{VLH} \quad t = \frac{\xi}{L} \quad U_n = \frac{u_n}{V} \quad \text{etc.} \quad [12]$$

Eq. [10] and [11] reduce to

$$\frac{H^3 L}{S^2} \frac{dQ^2}{dt} - \frac{H^2}{S} U_n U_t = - \frac{dP}{dt} - \frac{\mathcal{P} L^2 H^3}{S^3} \lambda Q^2 \quad [13]$$

This equation exhibits three dimensionless numbers, essentially depending on the geometry, which characterize the three possibilities of balancing any longitudinal pressure gradient: momentum transport along the channel, or toward the horizontal layer of cryolite under the anodes, and friction.

There are two kinds of channels: the wide ones present around the cell periphery (or between the two rows of anodes in modern cells with automatic feeding of alumina), and the narrow ones between the anode blocks, 3 or 4 cm apart. In the wide channels typical values $S = 0.5 \text{ m}^2$ and $\mathcal{P} = 0.6 \text{ m}$ seem to be realistic and provide the following orders of magnitude

$$\frac{H^3 L}{S^2} \approx 10^{-3}, \quad \frac{H^2}{S} \approx 3 \cdot 10^{-3}, \quad \frac{\mathcal{P} L^2 H^3}{S^3} \lambda \approx 5 \cdot 10^{-3} \lambda$$

The consequence of these very small values is that any

pressure difference along the large channels could not be balanced. In other words, the channels are so large that their free surface must be horizontal. Therefore, the presence of these large channels is dictating the striking boundary condition that P must be constant at the edge of the anode rows.

In the narrow channels, with \mathcal{P} of the same order but S smaller ($\approx 0.1 \text{ m}^2$), the nondimensional numbers have the following orders of magnitude

$$\frac{H^3 L}{S^2} \approx 2.5 \times 10^{-2}, \quad \frac{H^2}{S} \approx 1.6 \times 10^{-2}, \quad \frac{\mathcal{P} L^2 H^3}{S^3} \lambda \approx 0.6 \lambda$$

It still appears that the momentum transport could not balance any pressure gradient. But the situation is not as simple with regard to friction because λ is very difficult to estimate. If these channels behaved like ordinary turbulent duct flows, λ would be in the range 10^{-2} – 10^{-1} . But the intense bubbling activity (carbon dioxide evolved from the anodes), particularly important in these channels because of their narrowness, would increase λ by a few orders of magnitude. Therefore, one has to accept the idea that some pressure differences (and variations in the height of the free surface) can take place. They could be modeled by the equation

$$\frac{dP}{dt} + \frac{\mathcal{P} L^2 H^3}{S^3} \lambda Q^2 = 0 \quad [14]$$

with a convenient guess for the λ coefficient. Since it is one of the aims of this paper to simplify rather than to inspect all the details, it will be considered that the friction term is dominant over the pressure gradient, as it would be if the gap between the anode blocks were smaller ($\leq 1 \text{ cm}$). Then, Eq. [14] reduces to $Q = 0$, and these channels may be ignored in this asymptotic limit.

It has still to be noticed that the cryolite channels have another consequence in allowing U_n to be nonzero at the boundary of the layer underneath the anodes. The flow rate in these channels Q follows from relations [8] and [12]. This is to be contrasted with the aluminum layer, at the border of which no such channels exist; U_n has to be zero at the aluminum boundary, but no restriction applies on the pressure.

The interface equation.—In each liquid, the vertical variation of pressure is of the form

$$p = -\rho_i g z + f_i(x, y) \quad [15]$$

where z is the upward vertical, g gravity, and where the values 1 and 2 will be used for the subscript i , respectively, in the cryolite and the aluminum. The functions $f_1(x, y)$ and $f_2(x, y)$ can only be determined by solving first Eq. [6] and [7] in each liquid with the relevant boundary conditions. Then the continuity of pressure at the interface $z = z_0$ gives the equation of this surface

$$(\rho_2 - \rho_1) g z_0 = f_2(x, y) - f_1(x, y) \quad [16]$$

A First Model for an Ideal Cell

Assumptions for currents and magnetic fields.—In each cell, the current density has a specific distribution depending on parameters like the geometry of each anode block, the particular design of the risers, the position of the collector bars, etc. The magnetic field also is dependent on many parameters (the effect of which is not easily taken into account explicitly), such as the position of the cell in a pot line or the shielding effect of the steel shell surrounding the cell. Therefore any distribution of the Lorentz forces $\vec{j} \times \vec{B}$ which could be considered as sufficiently exact for a given cell would certainly be imprecise for many others. Since a main goal of this study is to reach a general understanding of the hydrodynamics of cells, it has been chosen to use some "ideal" distributions of \vec{j} and \vec{B} , rather than to compute them. (Notice that even computed distributions would not be "exact.") Of course, such distributions have to be in agreement with some

first-order requirements, such as the respective positions and voltages of the anodes, the two liquids, the carbon cell lining, and the collector bars. They should also contain a small number of parameters which are to be adjusted by comparison with measurements or computed distributions such as those of Lypany and Evans (3). The first approximation developed in this section is based on the following assumptions: (i) the j_x component in the long horizontal direction is taken to be zero since the collector bars usually drive the horizontal current in the y direction, (ii) because of the very small electrical conductivity and depth of the cryolite layer, the current density is supposed purely vertical and uniform in this liquid ($j_z = -j_0$), (iii) in the aluminum the distribution of the current density is taken as

$$j_y = j_1 \frac{y}{H}, \quad j_z = -j_0 + j_2 \frac{z}{H} \quad [17]$$

where H is the depth of the aluminum layer; the level variations of the interface are neglected for electromagnetic calculations, and (iv) the magnetic field of all the external conductors is neglected by comparison with that of the internal current, which is itself assumed purely horizontal ($B_z \ll B_x, B_y$) and without variations with z in the gap of interest. Then the vector potential is purely vertical

$$B_x = \frac{\partial A}{\partial y}, \quad B_y = -\frac{\partial A}{\partial x} \quad [18]$$

and follows Ampere's law

$$\nabla_H^2 A = -\mu j_z \quad [19]$$

Clearly, these assumptions are open to discussion and improvements. For instance, the "Second-Order Improvement" section below shows an example of such an improvement obtained by adding a supplementary term and supplementary parameter in relations [17] in order to include a new effect. Indeed these relations [17] may be considered as the simplest combination of two conservative fields allowing the study of the influence of the horizontal current density via the parameter j_1 . Assumption (iv) may be understood as a tool to isolate the internal characteristics of the cell from external characteristics such as the arrangement of risers and collectors. Of course, an explicit approximation of the magnetic field induced in the two liquids by the external conductors could be added in Eq. [18] and [19]. But it follows from computed results (3) that this external magnetic field is definitely a second-order effect (a few gauss compared to 50G due to internal current).

Equation [19], together with $\nabla_H^2 A = 0$ outside the rectangle $2a \times 2b$, and the conditions of continuity of A and its two first derivatives on the boundary, has a solution of the form

$$A = (j_0 + j_1 \frac{z}{H}) \mu G(x, y) \quad [20]$$

where $G(x, y)$ is completely determined by equation

$$\nabla_H^2 G = \begin{cases} 1 & \text{inside the rectangle} \\ 0 & \text{outside the rectangle} \end{cases} \quad [21]$$

and by the continuity conditions. This solution, analogous to the distribution of the electric potential created by a charge density which is uniform in a rectangle and zero outside, is explicitly known (Durand, see Appendix A).

It follows from these assumptions that the Lorentz force has a simple expression in terms of A

$$\vec{j} \times \vec{B} = j_z \vec{\nabla}_H A = -\frac{1}{\mu} \nabla_H^2 A \cdot \vec{\nabla}_H A \quad [22]$$

Since we only need its mean value in each fluid layer, let us write

$$\vec{j} \times \vec{B} = -\mu j_0^2 C \vec{\nabla}_H G$$

where C is a nondimensional parameter representing the influence of the horizontal current j_y . It follows from our assumptions that $C = 1$ in the cryolite layer, whereas in the aluminum it has the value

$$C = 1 - \frac{j_1}{j_0} + \frac{1}{3} \frac{j_1^2}{j_0^2} \quad [24]$$

Motion and pressure in the cryolite layer.—The nondimensional form of Eq. [23] to use with Eq. [6], [7], and [8] in the electrolyte is $\vec{F} = -\vec{\nabla}_H G$. Therefore, the motion equations in this layer are

$$\vec{\nabla}_H \cdot \vec{U}_1 = 0 \quad [25]$$

$$\kappa_1 \vec{U}_1 = -\vec{\nabla}_H (P_1 + G) \quad [26]$$

Taking the divergence of [26] yields the equation for the pressure distribution

$$\nabla_H^2 P_1 = -1 \quad [27]$$

The solution satisfying the boundary condition that $P_1 = 0$ at the boundary of a rectangle is explicitly known; it is analogous to the temperature distribution in a rectangle with uniform heat production and boundaries at a constant temperature (Carslaw and Jaeger, see Appendix A).

This solution is illustrated in Fig. 3, and may be compared with the solution of Eq. [21] for G . It is clear that the boundary condition, imposing a stricter condition on P_1 than on G , makes all the difference between these two functions and prevents the two gradients from canceling each other. To emphasize this difference, which is the key to the mean flow in the cryolite, one could say that because of the presence of the wide channels, the isobars resemble rectangles, whereas the lines $G = \text{constant}$ look rather like circles.

The influence of a wide central channel appears very important when Fig. 3a is compared with Fig. 3b, where a center channel has been introduced. The center channel has essentially two main effects: (i) there are two symmetrical pressure domes, one under each anode row, when there is a wide central channel, rather than one bigger dome centered in the middle of the cell when no wide central channel is present (Fig. 3a), and (ii) in forcing $P_1 = 0$ at the center and along the x axis as well as at the boundary, the presence of a wide central channel reduces the pressure differences and the pressure forces, for the same given value of the Laplacian (by a factor 3.7 in the computed case).

It is straightforward to deduce the velocity field from Eq. [26] when P_1 and G are known. Figure 4 shows the streamlines of this potential flow deduced from equations

$$\kappa_1 U = \frac{\partial \Psi}{\partial y} = -\frac{\partial}{\partial x} (P_1 + G) \quad [28]$$

$$\kappa_1 V = \frac{\partial \Psi}{\partial x} = -\frac{\partial}{\partial y} (P_1 + G)$$

The influence of a wide central channel again appears dramatic since the nature of the main flow is completely different between Fig. 4a and 4b. It is, however, easy to interpret these flow patterns: when there is no central channel, the same pressure difference does exist along the small and the large axes, but the inward electromagnetic forces are dominant along the large axis, whereas the outward pressure gradient is dominant along the small axis. When a wide central channel is present, the general reduction of pressure differences makes the electromagnetic forces predominant everywhere and provides a velocity field almost parallel to the force field.

It is also of interest to notice that the value of the stream function Ψ is 3.5 times greater with, than without, a central channel in the computed case, and that the place where Ψ is maximum is not at all the same in the two cases. Also, the direction of the mean flow in the periph-

Fig. 3. Potential lines ($G = \text{const.}$) of the $\langle \vec{j} \times \vec{B} \rangle$ force field, and pressure lines ($P = \text{const.}$) a (top): For a cell without central channel. b (bottom): For a cell with central channel.

erent channel is changed when a wide central channel is present.

These predictions could be checked with direct observations on real cells since the wide channels are more accessible than the shadow of the anode (6). The flow rate in these channels is easily deduced from the values of Ψ at the boundary

$$q = \left(\frac{\mu j_0^2 H^3 L^3}{\rho} \right)^{1/2} \frac{\Psi}{\kappa_1} \quad [29]$$

and seems to be the first quantity to be checked with measurements.

It is remarkable that in this inertia-free approximation it is not necessary to give a numerical value to the friction

Fig. 4. Streamlines of the cryolite flow underneath the anode. a (top): For a cell without central channel. b (bottom): For a cell with central channel.

coefficient κ_1 to find out the flow pattern. This is, however, necessary to get some numerical value of the flow rates in the channel from Eq. [29]. Inversely, this relation could be used as an empirical way to determine κ_1 .

Pressure in the aluminum and interface shape.—In the aluminum layer, the motion equations are very similar to Eq. [25] and [26], with the only difference being that the velocity potential is now $P_2 + CG$. The important feature is the absence of channels or anything equivalent. The force distribution Eq. [23] is assumed to be valid everywhere, and the depth of the aluminum layer is assumed to be uniform. Then the only boundary condition demands that the normal component of the velocity be zero on the edge of the rectangle. The only irrotational plane motion satisfying this condition is $\vec{U}_2 = 0$. As a consequence, the pressure distribution in the aluminum is

$$p = -\rho_2 g z - \mu j_0^2 L^2 C G + \text{const.} \quad [30]$$

The analogous equation in the cryolite layer is

$$p = -\rho_1 g z + \mu j_0^2 L^2 P_1 \quad [31]$$

and it is straightforward to deduce from Eq. [30] and [31] the interface equation

$$(\rho_2 - \rho_1) g z_0 = -\mu j_0^2 L^2 (P_1 + C G) + \text{const.} \quad [32]$$

Our choice that the z origin be at the mean level of the interface determines the constant, and final equation of the interface is

$$\frac{(\rho_2 - \rho_1) g}{\mu j_0^2 L^2} z = \overline{P_1 + C G} - (P_1 + C G) \quad [33]$$

where the upper bar is used to designate the average value in the rectangle.

Figures 5, 6, and 7 show the results for our cell of reference (aspect ratio: 2), with and without a wide central channel, and for two values of the parameter C . The unrealistic case $C = 1$ has interest only as a reference to illustrate the influence of the horizontal current in the aluminum when C is smaller than one. It appears that the predicted shape looks like a dome, with deviations which are worthy of discussion.

To interpret these results, remember first that the overpressure which is developed under the anodes in the cryolite layer is the strongest when there is no central channel. Furthermore, the pressure differences which arise in the aluminum layer are exactly those necessary to balance the electromagnetic forces. In particular, the smaller $|j_y|$ ($C = 1$), the larger $|j_x|$, and the higher these pressure differences. The general dome shape is due to the fact that the central overpressure is generally smaller in the cryolite than in the aluminum; therefore, the only possibility of generating such a departure on a vertical line is to vary the height of the denser liquid. This is particularly clear along the boundaries of the rectangle where the interface is always like a dome, because $p = \text{const.}$ in the cryolite, whereas in the aluminum it has to be a maximum at the middle of each side and smallest at the corners in order to balance the inward electromagnetic forces. Therefore, one understands that in the four computed cases the dome is the most significant when $C = 1$ and when a large central channel is present. It is, on the contrary, the weaker when $C = 0.5$ and without any central channel.

From among the noticeable deviations from this dome shape, notice the central saddle or trough in the middle of a cell without a central channel. It comes from the fact that the central overpressure is higher in the cryolite than in the aluminum. It is remarkable that the depth of this trough increases when C decreases, thus illustrating the influence of increasing the horizontal current in the aluminum. Varying the coefficient C would also show that the lower point of the interface (still for a cell without central channel), which is at the corner when $C = 1$, moves along the small side to its middle and then along

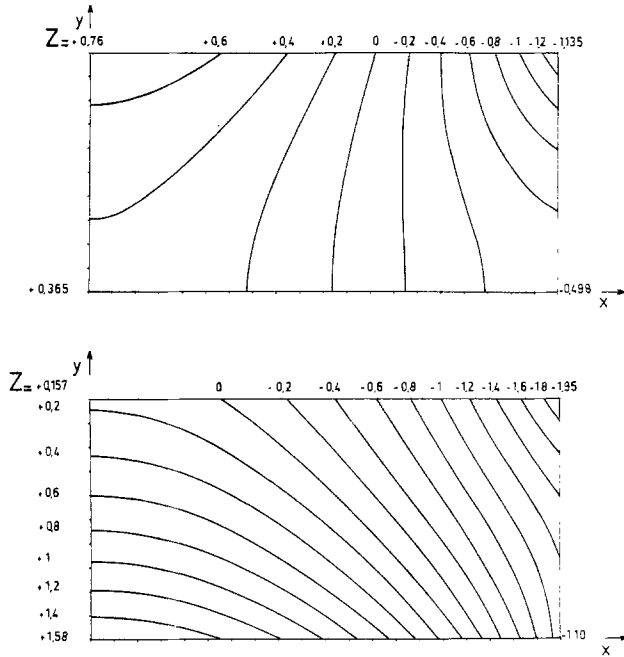

Fig. 5. Interface contour lines when $C = 1$ ($j_1 = 0$, i.e., no horizontal current in the aluminum). a (top): For a cell without central channel. b (bottom): For a cell with central channel.

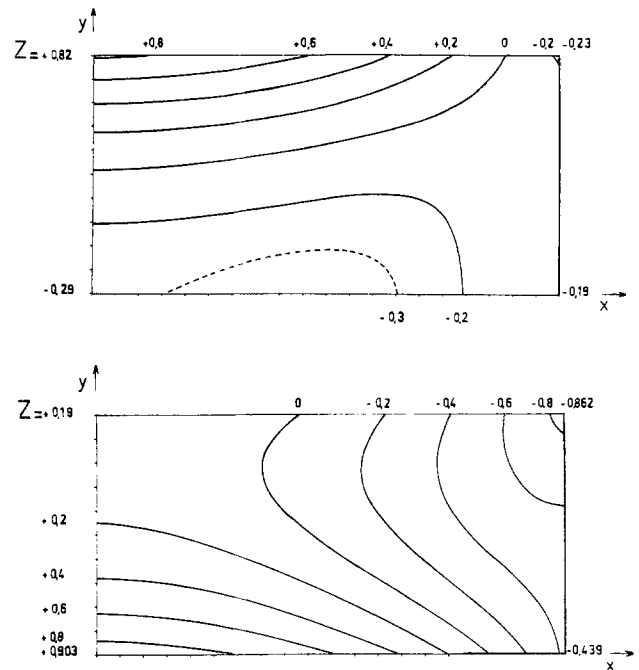

Fig. 6. Interface contour lines when $C = 0.5$ ($j_1/j_0 = 0.634$). a (top): For a cell without central channel. b (bottom): For a cell with central channel.

the large axis to the cell center as C decreases monotonically to its limit of 0.25 imposed by Eq. [24].

Example of a Second-Order Improvement

Correction of the electromagnetic data.—When expressions [17] are compared with plausible values such as those computed by Lympany and Evans (3), their linear variation with the coordinates does not seem to be correct for more than three-quarters of the cell width. It appears that in the outermost quarter some reduction should be introduced in relations [17]. This comes from the fact that the aluminum pool is wider than the anode. Indeed, the geometry of the external boundary of the aluminum layer is in itself a difficult question. The key point is the shape and the position of the ledge of solidified electrolyte all around the cell. It is, or course, strongly dependent on the thermal behavior of the cell, and it exhibits important variations from one cell to another, as well as in a given cell during its life.

In this section, consequences of this boundary phenomenon are studied as a disturbance of the reference state

described in the previous section. Because of the linearity of the motion Eq. [6], [7], and [8], this disturbance need not be supposed to be very small. However, the thickness of the region through which such a disturbance is concentrated is assumed to be small enough, so that ideas and techniques of the boundary layer theory apply.

The disturbance of the current density is supposed to take place in a plane (n,z) , where n is the outward normal to the rectangle edge (Fig. 2), and to have the following distribution

$$j_n = -j_2 \frac{\delta}{H} e^{n/\delta}, j_z = j_2 \frac{z}{H} e^{n/\delta} \quad [34]$$

Clearly, two new parameters (j_2 and δ) are thus introduced to characterize this disturbance. No restriction applies on j_2 , but the thickness δ of the disturbed layer is supposed to be much smaller than the width of the rectangle, so that the derivative $\partial/\partial t$ may be neglected in comparison with $\partial/\partial n$, except in the vicinity of the corners, where this theory fails.

Fig. 7. Interface shape in the four computed cases. a (top left): $C = 1$, without central channel. b (top right): $C = 1$, with central channel. c (bottom left): $C = 0.5$, without central channel. d (bottom right): $C = 0.5$, with central channel.

The vector potential of the magnetic field may then be written

$$A = (j_0 + j_1 \frac{z}{H}) \mu G(x, y) - \mu j_2 \delta^2 \frac{z}{H} e^{n/\delta} \quad [35]$$

where the last term (the correction to [20]) is the solution of the simplified form of Eq. [19].

It follows that the mean value of the electromagnetic forces in the aluminum layer is now

$$\langle \bar{j} \times \bar{B} \rangle = -\mu j_0^2 \left[C \bar{\nabla}_H G - D \{ e^{n/\delta} \bar{\nabla}_H G + \delta^2 \bar{\nabla}_H (e^{n/\delta}) \} + E \frac{\delta^2}{2} \bar{\nabla}_H (e^{2n/\delta}) \right] \quad [36]$$

where nondimensional coefficients D and E , characterizing the importance of j_2 , have the definitions

$$D = \frac{j_2}{j_0} \left(-1/2 + 1/3 \frac{j_1}{j_0} \right), \quad E = 1/3 \frac{j_2^2}{j_0} \quad [37]$$

The two terms proportional to δ^2 in Eq. [36] can be neglected in comparison with $D e^{n/\delta} \bar{\nabla}_H G$, which appears as the essential correction. Notice also that they are pure gradients and could not drive any aluminum motion. It is then interesting to notice the distribution of the curl of the forces

$$\bar{\nabla}_H \times \langle \bar{j} \times \bar{B} \rangle = \frac{\mu j_0^2 D}{\delta} e^{n/\delta} \frac{\partial G}{\partial t} \cdot \bar{e}_z \quad [38]$$

Since $\delta G/\delta t$ is zero at the middle of each side and increases or decreases towards the corners as an odd function of the abscissa, it is clear that the flow driven along each side by this force has the directions and symmetries shown on Fig. 2.

The motion in the aluminum.—Let us introduce the decomposition

$$\bar{U} = \bar{U}_c + \bar{u}^*, \quad \bar{P} = \bar{P}_c + \bar{p}^* \quad [39]$$

where \bar{U}_c and \bar{P}_c stand for the dimensionless values of \bar{u} and \bar{p} in the central core of the aluminum rectangle, and vary on the typical length scale L . The corrections \bar{u}^* and \bar{p}^* are concentrated in the boundary region along the edge and vary along the normal on the short length scale δL . Clearly, \bar{U}_c and \bar{P}_c are no longer the values determined in the reference state, since the flow driven in the boundary region by the electromagnetic forces has to recirculate in the central core. Dimensionless Eq. [6] - [8] then become

$$\bar{\nabla}_H \cdot \bar{U}_c = 0 \quad [40]$$

$$\kappa_2 \bar{\nabla}_c = -\bar{\nabla}_H (P_c + CG) \quad [41]$$

$$\bar{\nabla}_H \cdot \bar{u}^* = 0 \quad [42]$$

$$\kappa_2 \bar{\nabla}_c^* = -\bar{\nabla}_H \bar{p}^* + D e^{n/\delta} \bar{\nabla}_H G \quad [43]$$

In the boundary region, the normal component u_n^* is negligible compared to the tangential component u_t^* . Therefore, with the matching condition $p(n \rightarrow -\infty) = 0$, the normal projection of Eq. [43] gives the disturbance of the pressure

$$p^* = D \int_{-\infty}^n e^{n/\delta} \frac{\partial G}{\partial n} dn = D \delta \left(\frac{\partial G}{\partial n} \right)_{n=0} e^{n/\delta} \quad [44]$$

Then after substitution of $\partial p^*/\partial t$, the tangential projection gives the u_t^* velocity component

$$\kappa_2 u_t^* = \frac{D}{\delta} \int_{-\infty}^n e^{n/\delta} \frac{\partial G}{\partial t} dn = D \left(\frac{\partial G}{\partial t} \right)_{n=0} e^{n/\delta} \quad [45]$$

Finally, the continuity equation and the matching condition $u_n^*(n \rightarrow -\infty) = 0$ give the u_n^* velocity component

$$\kappa_2 u_n^* = -D \delta \left(\frac{\partial^2 G}{\partial t^2} \right)_{n=0} e^{n/\delta} \quad [46]$$

It follows from the two last expressions that the non-dimensional flow rate driven by the electromagnetic forces in the boundary regions is $\frac{D \delta}{\kappa_2} \left(\frac{\partial G}{\partial t} \right)_{n=0}$

The core has essentially to feed these boundary regions. This demands

$$U_{cn} (n=0) = D \delta \left(\frac{\partial^2 G}{\partial t^2} \right)_{n=0} \quad [47]$$

in order that the total normal velocity component be zero at the boundary. Therefore, the molten aluminum cannot stay at rest in the core as in the reference state. The potential flow satisfying [40] and [41] may be determined in terms of a stream function Ψ_c . Taking account of the symmetries, in the cell quarter $x > 0$ and $y > 0$, this stream function, whose definition is

$$\kappa_2 U_{cx} = \frac{\partial \Psi_c}{\partial Y}, \quad \kappa_2 U_{cy} = -\frac{\partial \Psi_c}{\partial X} \quad [48]$$

is completely determined by the Laplace equation $\nabla_H^2 \Psi_c = 0$ together with the boundary conditions

$$\left\{ \begin{array}{ll} \Psi_c = 0 & \text{on the axes} \\ \Psi_c = -D \delta \left(\frac{\partial G}{\partial X} \right)_{y=b} & \text{on side AC} \\ \Psi_c = D \delta \left(\frac{\partial G}{\partial Y} \right)_{x=a} & \text{on side B} \end{array} \right. \quad [49]$$

Some typical streamlines shown in Fig. 8 illustrate the main character of this flow. For the core flow, the corners are source points from which comes the flow rate necessary to feed the boundary regions. And, in return, they are the sink points to which goes all the flow of the boundary regions. Of course, this singularity of the corners is nothing but a consequence of the asymptotic character of this theory which is only rigorous in the limit of $\delta \rightarrow 0$.

It is also straightforward to calculate the pressure distribution. The velocity potential $\phi_c = P_c + CG$ which has also to satisfy the Laplace equation following [40] is completely determined by the Neumann boundary condition [47]. Some typical potential lines are also shown in Fig. 8. The pressure correction is proportional to $D \delta G$ and is therefore much smaller than the pressure differences found in the state of reference (proportional to CG). Therefore, it cannot introduce any important change into the interface topology. It is, however, interesting to notice that this second-order effect tends to compensate for the differences of level found at the state of reference, since the higher pressure correction takes place in the corners and tends to raise these lowest points of the interface.

Remarks and Discussion

The hydrodynamics of Hall-Héroult cells have been the subject of many investigations since the pioneering work by Givry (7). The fact that the governing mechanisms were still unclear, and that the numerical predictions [2] and [8] did not predict the same flow pattern, have given to this problem the reputation of being extremely difficult. In this context, this paper introduces a new point of view and some simplifications which provide an important clarification. From two main approximations (the way to model the channel's influence on the cryolite flow, and the shallow water approximation) arises an almost elementary solution for an ideal cell. This solution may be seen as a first-order solution and remains open to improvements. It shows that phenomena like the interface shape and the cryolite motion are controlled at the

Fig. 8. Typical streamlines of the core flow feeding the side boundary layers in the aluminum pool.

first order of approximation by the geometry of the channels between the anode blocks and around the cell, and by the distribution of the horizontal current in the aluminum layer.

This elementary theory still has, however, some weaknesses suggesting future work.

1. The analysis supposes that the channels are either very wide or very narrow, and that their width is not taken as a parameter. To remedy this first weakness, numerical solutions of the motion Eq. [6]-[8], together with relation [14] as a boundary condition at the edge of each anode block, should be used in the cryolite (see Appendix B).

2. Another resides in the fact that the idealized force distributions [23] or [36] do not coincide with those of a real cell. The remedy is obviously in the numerical computation of electric currents, magnetic fields, and force fields, as done by Evans *et al.* (2). It would permit the real distributions of $\langle \vec{j} \times \vec{B} \rangle_H$ to be introduced in the motion equations before computing the velocity fields.

3. It must also be pointed out that this first investigation is only concerned with a steady state, which is assumed to coincide with an average of the actual unsteady states. The unsteadiness and the turbulence are only taken into account through the friction coefficients κ_1 and κ_2 . To make significant progress in the understanding of the cell's behavior, it would be now important to study the mechanisms of instability of the interface. In this context, it is felt that the present concept of an ideal cell with an elementary steady state of reference offers the necessary basis into which small disturbances could be introduced and studied.

4. Assumption [8] that \bar{T} is proportional to the local velocity can only be justified in an ideal cell with mean velocities much smaller in the aluminum than in the cryolite. For cells with rotational Lorentz forces, relation [8] could be generalized under the form

$$\left\{ \begin{array}{l} \bar{T}_1 = \kappa_1 \bar{U}_1 + \gamma \bar{U}_2 \\ \bar{T}_2 = \kappa_2 \bar{U}_2 + \gamma \bar{U}_1 \end{array} \right\} \quad [50]$$

Such expressions that retain the linearity of the problem would not really make the numerical computation more difficult. The interest in their use would be to introduce some coupling between the two fluid flows. This coupling should not be ignored since each liquid tends to drive the neighboring one in the direction of its own motion.

5. In itself, this theory cannot give any idea of the numerical values of coefficients κ_1 , κ_2 , and γ . It is the hope of the authors that some comparison of measurements such as those made by Johnson (6) with numerical predictions deduced from equations of Appendix B could provide a good estimation for these parameters.

APPENDIX A

Explicit Solutions of Equations [21] and [31]

With notations defined in Fig. 9 and $c = (a^2 + b^2)^{1/2}$, the solution of Eq. [21], such that the functions $G(x, y)$ and its two first derivatives be continuous on the edge of the rectangle, may be written

$$\begin{aligned} 2\pi G = & h_1 h_2 \log \left(\frac{r_1}{c} \right) + h_2 h_3 \log \left(\frac{r_2}{c} \right) + \\ & h_3 h_4 \log \left(\frac{r_3}{c} \right) + h_4 h_1 \log \left(\frac{r_4}{c} \right), \\ & + 1/2 [h_1^2 (\beta_1 - \beta_4) + h_2^2 (\beta_2 - \beta_1) \\ & + h_3^2 (\beta_3 - \beta_2) + h_4^2 (\beta_4 - \beta_3)] \\ & + \frac{\pi}{4} [h_1^2 + h_2^2 + h_3^2 + h_4^2] \quad [A-1] \end{aligned}$$

The last term is a particular solution of the Poisson equation $\nabla^2 G = 1$. The other terms are solutions of Laplace equation $\nabla^2 G = 0$. At the origin of coordinates, the value of G is

$$G(0) = \frac{1}{2\pi} \left[\pi b^2 + 2(a^2 - b^2) \arctan \left(\frac{b}{a} \right) \right] \quad [A-2]$$

It can be subtracted from [A-1] to get a zero value at the origin.

The solution of Eq. [27] such that P_1 is zero at the edge of the rectangle is

Fig. 9. Definition of notations used in Eq. [A-1]

$$P_1 = \frac{a^2 - x^2}{2} - \frac{16a^2}{\pi^3} \sum_{n=0}^{\infty} \frac{(-1)^n \cos [(2n+1) \pi x/2a] \cosh [(2n+1) \pi y/2a]}{(2n+1)^3 \cosh [(2n+1) \pi b/2a]} \quad [\text{A-3}]$$

APPENDIX B

Procedure for Computation of Velocity Fields and Interface Shape in Real Cells

When the distributions of the force fields \bar{F}_1 and \bar{F}_2 have been computed, the equations to solve to determine the velocity and pressure distributions in the two liquids are [6] and [7] with expressions [8] or [50] for the drag \bar{T}_i .

In the cryolite, the boundary condition to use on the edge of each anode block is

$$\left\{ \begin{array}{ll} P_1 = 0 & \text{in wide channels} \\ \frac{dP_1}{dt} + \Lambda Q^2 = 0 & \text{in narrow channels} \end{array} \right\} \quad [\text{B-1}]$$

where $Q = \int U_n(n=0) dt$ stands for the dimensionless flow rate in the channels, and where

$$\Lambda = \frac{\rho L^2 H^3}{S^3} \lambda$$

denotes the dimensionless friction coefficient. Taking the divergence of Eq. [7] gives a Poisson equation, the solution of which $P_1(x,y)$ is completely determined by Eq. [B-1]. Then Eq. [7] gives

$$\kappa_1 \bar{U}_1 + \gamma \bar{U}_2 = \bar{F}_1 - \bar{\nabla}_H P_1 \quad [\text{B-2}]$$

In the aluminum, the boundary condition to use on the edge of the metal pool is $U_n = 0$. Taking the curl of

the motion equation and eliminating $\bar{\nabla}_H \times \bar{U}_1$ with Eq. [B-2] gives

$$\left(\kappa_2 + \frac{\gamma^2}{\kappa_1} \right) \bar{\nabla}_H \times \bar{U}_2 = \text{curl } \bar{F}_2 - \frac{\gamma}{\kappa_1} \text{curl } \bar{F}_1 \quad [\text{B-3}]$$

The technique to solve Eq. [B-3] for a conservative velocity field ($\bar{\nabla}_H \cdot \bar{U}_2 = 0$) is quite straightforward. A stream-function is usually introduced, and appears to be determined by a Poisson equation together with the boundary condition that $U_n = 0$ at the edge of the aluminum pool. The velocity field \bar{U}_2 is thus determined. Then Eq. [B-2] gives the velocity field \bar{U}_1 , and the pressure distribution $P_2(x,y)$ follows from the motion equation.

Finally, the interface shape is given by

$$\frac{(\rho_2 - \rho_1) g z_0}{\mu_j^2 L_2} = P_2(x,y) - P_1(x,y) - (\bar{P}_2 - \bar{P}_1) \quad [\text{B-4}]$$

Mass Transfer in Alternating Current Electrolysis

Anthony M. Pesco* and H. Y. Cheh**

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

ABSTRACT

A diffusion model was used to obtain an analytical solution for the mass transport to a rotating disk electrode under superimposed sinusoidal and triangular alternating current conditions for the case where the polarity of the applied current does not change. The analytical solution was compared to a numerical solution which resulted from a convective-diffusion model. Using the analytical solution, an expression for the instantaneous diffusion limiting current density was derived and verified experimentally using a ferri-ferrocyanide reaction system. Further, a quantitative comparison was made between the maximum rate of electrolysis under superimposed sinusoidal, triangular, and rectangular alternating current conditions with equal cycle times.

Electrolysis by a periodic variation of the applied current modifies the mass transport by producing a pulsating diffusion layer (1) in which the time-dependent concentration variation is important. This phenomenon is responsible for the fact that higher instantaneous rates of mass transport, without the initiation of a second reaction, are possible when compared to dc electrolysis.

Electrolysis by periodically varying currents has been used extensively in electrodeposition because of the changes produced in the morphology of the electrodeposits. The advantages most frequently cited by investigators are that smoother and more uniform deposits can be obtained with a better adherence to the substrate. Chin (2) presented a theory for the mass transport to a rotating disk electrode and the current-potential relationship during pulse electrolysis with rectangular current pulses, periodic pulse reversals, and double rectangular pulses with relaxations. The results indicated that the current pulses can change the current-potential relationship and thus af-

fect the properties of the electrodeposits. Electrolysis with a periodically varying current has also been used in anodic-dissolution, anodizing, and corrosion processes. A review of the fundamentals involved in alternating current electrochemical processes was given by Venkatesh and Chin (3).

An important quantity in the study of mass transport during electrolysis by alternating currents is the diffusion limiting current density, which is defined as the instantaneous current density that causes the lowest surface concentration of reacting species to reach zero. The limiting current density is a measure of the maximum rate of electrolysis for a particular system.

Using a simple diffusion model to study the mass transport of reacting species to a rotating disk electrode, Cheh (4, 5) derived an expression for the instantaneous diffusion limiting current density during electrolysis by rectangular current pulses, with and without periodically reversing the polarity of the applied current; Viswanathan and Cheh (6) derived an expression for the instantaneous diffusion limiting current density during electrolysis by

* Electrochemical Society Student Member.

** Electrochemical Society Active Member.

ramp and saw-tooth currents. Chin (2) used a simple diffusion model to obtain a solution for the fluctuating concentration of reacting species at the surface of a rotating disk electrode during electrolysis by rectangular current pulses, periodic pulse reversals, and double rectangular pulses with relaxations. Tokuda and Matsuda (7, 8) and Venkatesh (9) also used a diffusion model to study the fluctuating surface concentration of reacting species during electrolysis under ac conditions.

In this paper, a further study of the mass transport to a rotating disk electrode under superimposed sinusoidal ac conditions is presented. This study is limited to cases where the pulsating diffusion layer thickness remains much smaller than the steady-state diffusion layer thickness. In this case, a simple diffusion model is used to obtain an analytical solution for the surface concentration of reacting species. The analytical solution is compared to a numerical solution which results from a convective-diffusion model.

In an effort to demonstrate the effects of waveform characteristics on the mass transport, expressions for the instantaneous diffusion limiting current density are derived for electrolysis under superimposed sinusoidal as well as triangular and rectangular alternating current conditions, as a function of the fundamental properties of the system.

Theoretical

Assume that a rotating disk electrode is situated in an electrolyte of large extent and is rotating at a constant velocity. The radius of the disk and the distance from the disk to the counterelectrode are both large when compared to the thickness of the Nernst diffusion layer. The number of coulombs passed during an experiment is small, so that the concentration of the reacting species at the edge of the diffusion layer remains constant. An excess of supporting electrolyte is present, so electrical migration effects are negligible.

It has been shown by Viswanathan and Cheh (10) that the simple diffusion model used by Cheh (4) adequately predicts the concentration of reacting species at the electrode surface under pulse current electrolysis.

Using the diffusion model, the concentration of reacting species is governed by Fick's law of diffusion, which is expressed by the equation

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial z^2} \quad [1]$$

with the boundary conditions

$$c = c_0 \text{ at } t = 0 \text{ and all } z \quad [2]$$

$$c = c_0 \text{ at } t > 0 \text{ and } z = 0 \quad [3]$$

$$D \frac{\partial c}{\partial z} = \frac{i}{nF} \text{ at } t > 0 \text{ and } z = \delta \quad [4]$$

where c is the concentration of the reacting species, c_0 is its concentration in the bulk of the solution, D is its diffusion coefficient, δ is the thickness of the Nernst diffusion layer, i is the applied current density, n is the number of electrons transferred during the reaction, F is Faraday's constant, t is time, and z is the axial coordinate extending from the edge of the boundary layer towards the disk surface.

The thickness of the Nernst diffusion layer was given by Levich (11) as

$$\delta = 1.612 \left(\frac{D}{\nu} \right)^{1/3} \left(\frac{\nu}{\Omega} \right)^{1/2} \quad [5]$$

where ν is the kinematic viscosity of the electrolyte, and Ω is the disk rotation speed.

DC electrolysis.—The solution of Eq. [1] subject to boundary conditions Eq. [2]-[4] was obtained by Rosebrugh and Miller (12). The surface concentration of the reacting species is given by the equation

$$c_s^* = 1 - \frac{i_{dc}}{(i_{dc})_l} \left[1 - \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{1}{(2j-1)^2} \exp(-[2j-1]^2 \alpha t) \right] \quad [6]$$

where

$$c_s^* = c/c_0 \quad [7]$$

$$(i_{dc})_l = \frac{nFDc_0}{\delta} \quad [8]$$

$$\alpha = \frac{\pi^2 D}{4\delta^2} \quad [9]$$

$(i_{dc})_l$ is the limiting current density under dc conditions, and i_{dc} is the applied current density. When the transient term has vanished

$$c_s^* = 1 - \frac{i_{dc}}{(i_{dc})_l} \quad [10]$$

Sinusoidal ac electrolysis.—The solution of Eq. [1] subject to boundary conditions, Eq. [2]-[4] for alternating current electrolysis, when the applied current is of the form

$$i = I \sin(\omega t) \quad [11]$$

where I is the amplitude of the applied density and ω is the frequency, was solved by Warburg (13) for an infinitely large diffusion layer thickness, and by Rosebrugh and Miller (12) for a finite diffusion layer thickness.

The surface concentration of the reacting species can be expressed as

$$c_s^* = 1 - \frac{I}{2\delta(i_{dc})_l} \left(\frac{D}{\omega} \right)^{1/2} A \sin(\omega t + \gamma - \pi/4) + \frac{2I}{nF\delta} \sum_{j=1}^{\infty} \frac{\omega \exp(-[2j-1]^2 \alpha t)}{(2j-1)^4 \alpha^2 + \omega^2} \quad [12]$$

where

$$A = \frac{[\sinh^2(2\mu\delta) + \sin^2(2\mu\delta)]^{1/2}}{\sinh^2(\mu\delta) + \cos^2(\mu\delta)} \quad [13]$$

$$\mu = \left(\frac{\omega}{2D} \right)^{1/2} \quad [14]$$

$$\gamma = \tan^{-1} \left(\frac{\sin(2\mu\delta)}{\sinh(2\mu\delta)} \right) \quad [15]$$

When the transient term in Eq. [12] has vanished, the system reaches a periodic state, and the surface concentration of reacting species is given by the equation

$$c_s^* = 1 - \frac{I}{2\delta(i_{dc})_l} \left(\frac{D}{\omega} \right)^{1/2} A \sin(\omega t + \gamma - \pi/4) \quad [16]$$

Superimposed sinusoidal ac electrolysis.—If both the dc and sinusoidal alternating currents act simultaneously on the system, the applied current is of the form

$$i = \bar{i}_{dc} + I \sin(\omega t) \quad [17]$$

where \bar{i}_{dc} is the dc offset in alternating current electrolysis. The concentration change produced at the electrode surface is the sum of the concentration change that would be produced by the direct current, \bar{i}_{dc} , and the alternating current, $I \sin(\omega t)$.

The surface concentration, after the transient terms have vanished, is given by the equation

$$c_s^* = 1 - \frac{\bar{i}_{dc}}{(i_{dc})_l} - \frac{I}{2\delta(i_{dc})_l} \left(\frac{D}{\omega} \right)^{1/2} A \sin(\omega t + \gamma - \pi/4) \quad [18]$$

Mathematically, this analysis is valid regardless of whether the surface concentration is positive or negative, although, physically, its validity is limited to cases when the surface concentration is greater than or equal to zero.

Using Eq. [5], one readily obtains

$$\frac{1}{\delta} \left(\frac{D}{\omega} \right)^{1/2} = K\sigma \quad [19]$$

where

$$K = \frac{(Sc)^{-1/6}}{1.612} \quad [20]$$

and

$$\sigma = \left(\frac{\Omega}{\omega} \right)^{1/2} \quad [21]$$

Equation [18] can be transformed into

$$c_s^* = 1 - \frac{\overline{i_{dc}}}{(i_{dc})_l} - \frac{IAK\sigma}{2(i_{dc})_l} \sin(\omega t + \gamma - \pi/4) \quad [22]$$

Rosebrugh and Miller (12) demonstrated for sinusoidal ac electrolysis that with increasing values of $\mu\delta$, A approaches 2 and γ approaches 0. These limits can be substituted into Eq. [22] with an error of no more than one-half percent if $\mu\delta > 3$ where

$$\mu\delta = \frac{1}{2^{1/2}K\sigma} \quad [23]$$

For a system with a Schmidt number of 1000, the substitutions may be made when σ is less than 1.20.

When the appropriate substitutions are made, Eq. [22] is simplified to

$$c_s^* = 1 - \frac{\overline{i_{dc}}}{(i_{dc})_l} - \frac{IK\sigma}{(i_{dc})_l} \sin(\omega t - \pi/4) \quad [24]$$

The surface concentration was also obtained by performing a numerical integration of the convective-diffusion equation (see Appendix B). The results were compared with those obtained by using Eq. [24], for a particular set of experimental conditions. Very good agreement between the two results was obtained, as is shown in Fig. 1.

Electrolysis by superimposed ac may be performed in two ways. One way is such that the polarity of the applied current changes during a cycle. Another way is such that the current polarity remains the same throughout the cycle. In this investigation, only the latter will be considered.

Let us consider Eq. [22]. c_s^* reaches its lowest value for a particular current offset and amplitude when $\sin(\omega t - \pi/4) = 1$. In this case

$$c_s^* = 1 - \frac{\overline{i_{dc}}}{(i_{dc})_l} - \frac{IK\sigma}{(i_{dc})_l} \quad [25]$$

By setting Eq. [25] to zero and rearranging terms, an expression for the offset current required to reach the limiting current density is obtained. For a particular current amplitude, the equation is expressed as

Fig. 1. Surface concentration at the periodic state in superimposed sinusoidal ac electrolysis ($Sc = 1000$, $\omega = 60$ Hz, $\Omega = 1640$ rpm).

$$(\overline{i_{dc}})_{l,s} = (i_{dc})_l - IK\sigma \quad [26]$$

where $(\overline{i_{dc}})_{l,s}$ is defined as the dc offset at the limiting current density in superimposed sinusoidal ac electrolysis. The corresponding limiting current density is the sum of the offset and the amplitude, and can be expressed by the equation.

$$(i_s)_l = (\overline{i_{dc}})_{l,s} + I \quad [27]$$

Rearranging Eq. [26] gives

$$\frac{(\overline{i_{dc}})_{l,s}}{(i_{dc})_l} = 1 - \frac{I}{(i_{dc})_l} K\sigma \quad [28]$$

$(\overline{i_{dc}})_{l,s}/(i_{dc})_l$ can also be defined as the ratio of the average rate of electrolysis under superimposed sinusoidal ac, at a particular value of I , σ , and K , to that under dc electrolysis. Even though higher instantaneous mass transfer rates can be achieved with superimposed sinusoidal ac, Eq. [28] implies that the average rate of electrolysis under superimposed sinusoidal ac is less than that which can be obtained under dc electrolysis. This is because $IK\sigma/(i_{dc})_l$ is always greater than zero.

Looking at the limiting cases for Eq. [28], we can clearly see that as I or σ approaches zero, the average overall rate of electrolysis by superimposed sinusoidal ac approaches that for dc electrolysis. The upper limit for I is bounded by the restriction placed on the applied current. Therefore, the maximum value for I occurs when $I = (\overline{i_{dc}})$. In this case, the applied current waveform is such that the lowest value of the current just reaches zero. Under this condition

$$\frac{(i_{dc})_l}{(\overline{i_{dc}})_{l,s,\max}} = 1 + K\sigma \quad [29]$$

and

$$\frac{(i_s)_{l,\max}}{(i_{dc})_l} = \frac{2}{1 + K\sigma} \quad [30]$$

where $(i_s)_{l,\max}$ is the maximum value for the limiting current density, and $(\overline{i_{dc}})_{l,s,\max}$ is the maximum value for the dc offset at the limiting current density.

Rectangular ac electrolysis.—The limiting current density for electrolysis with rectangular pulses separated by intervals of zero current is given by (4)

$$\frac{(i_p)_l}{(i_{dc})_l} = \frac{1}{1 - \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{1}{(2j-1)^2} \frac{[\exp([2j-1]^2 a\theta_2) - 1]}{[\exp([2j-1]^2 a\theta) - 1]}} \quad [31]$$

where θ_2 is the off time of the applied current and θ is the cycle time (on time plus off time).

In order to compare the mass transport under pulse current conditions to that under superimposed sinusoidal ac conditions, the pulse characteristics will be restricted to cases where the off time equals the on time, or $\theta_2 = \theta/2$. By performing algebraic manipulations (as shown in Appendix A), Eq. [31] can be transposed into

$$\frac{(i_p)_l}{(i_{dc})_l} = \frac{2}{1 + 1.52K\sigma} \quad [32]$$

and

$$\frac{(i_{dc})_l}{(\overline{i_{dc}})_{l,p}} = 1 + 1.52K\sigma \quad [33]$$

where $(\overline{i_{dc}})_{l,p}$ is the dc offset at the limiting current density in pulsed current electrolysis.

Triangular ac electrolysis.—Rosebrugh and Miller (12) demonstrated that the concentration changes at the electrode surface produced by time varying currents can be expressed by the equation

$$c_s^* = 1 + \frac{2}{nF\delta C_0} \sum_{j=1}^{\infty} \exp(-m^2 at) \int_0^t \exp(m^2 au) i(\mu) du \quad [34]$$

where $m = 2j - 1$, and $i(\mu)$ is the expression for the time

varying current density. Consider a triangular shaped current wave which does not change polarity and is restricted so that the lowest value of the current just reaches zero. The expression for the current is written

$$i(t) = (\bar{i}_{dc}) \left[1 + \frac{8}{\pi^2} \sum_{l=1}^{\infty} \frac{(-1)^{l/2(p-1)}}{p^2} \sin(p\omega t) \right] \quad [35]$$

where $p = 2l - 1$, and (\bar{i}_{dc}) is the dc offset for the triangular current wave. By inserting Eq. [35] into Eq. [34] and performing the integration, an expression for the surface concentration is obtained in terms of an infinite series (see Appendix A). When the transient terms become negligible, the surface concentration is expressed by the equation

$$c_s^* = 1 - \frac{(\bar{i}_{dc})}{(i_{dc})_l} [1 + T] \quad [36]$$

where

$$T = \frac{64}{\pi^4} \sum_{j=1}^{\infty} \sum_{l=1}^{\infty} \frac{(-1)^{l/2(p-1)}}{p^2} \frac{m^2 \sin(p\omega t) - \frac{p\omega}{a} \cos(p\omega t)}{m^4 + \frac{p^2\omega^2}{a^2}} \quad [37]$$

The lowest concentration during a cycle occurs when T reaches its maximum value, T_{max} . The limiting current density and dc offset at the limiting current density can be written as

$$\frac{(i_l)}{(i_{dc})_l} = \frac{2}{1 + T_{max}} \quad [38]$$

and

$$\frac{(i_{dc})_l}{(i_{dc})_{l,t}} = 1 + T_{max} \quad [39]$$

where

$$T_{max} = 0.81K\sigma \quad [40]$$

(see Appendix A for details), (i_l) is the limiting current density, and $(i_{dc})_{l,t}$ is the dc offset at the limiting current density in electrolysis with a triangular current.

Summary.—A graphical representation of $(i_l)/(i_{dc})_l$ as a function of σ , for the three types of waveforms that were investigated, is shown in Fig. 2. The general solution for the limiting current density and dc offset at the limiting current density can be written as

$$\frac{(i_x)_l}{(i_{dc})_l} = \frac{2}{1 + AK\sigma} \quad [41]$$

$$\frac{(i_{dc})_l}{(i_{dc})_{l,x}} = 1 + AK\sigma \quad [42]$$

$x = (s, \max), p, t$

where A is a constant which appears to be dependent only on the current waveform.

Waveform	A
Rectangular	1.52
Sinusoidal	1.00
Triangular	0.81

Considering the pulsating diffusion layer in the same fashion as Viswanathan and Cheh (10), an expression for the maximum value for the thickness of the pulsating diffusion layer can be expressed as

$$\frac{(\delta_p)_{max}}{\delta} = \left[\frac{(i_l)}{(i_{dc})_l} \right]^{-1} = \frac{1}{2} + \frac{A}{2} K\sigma \quad [43]$$

By substituting the expressions for K and σ , Eq. [43] can be transposed into

$$\frac{(\delta_p)_{max}}{\delta} = \frac{1}{2} + \frac{A}{3.224} Sc^{-1/6} \left[\frac{Re_n}{\omega R^2} \right]^{1/2} \quad [44]$$

Fig. 2. Limiting current density for ac electrolysis by the three waveforms, as a function of σ .

where Re_n is the Reynolds number based on the disk rotational speed ($\Omega R^2/\nu$) and R is the disk radius.

Experimental Procedure

The reduction of ferricyanide ions in a ferri-ferrocyanide solution was chosen to study the mass transport to a rotating disk electrode under superimposed sinusoidal alternating current conditions.

The experiments were carried out in an experimental system consisting of a Pine Instrument Pt disk electrode with an area of 0.461 cm^2 , a Pt counterelectrode, and a Fisher Scientific saturated calomel electrode with a Luggin capillary. The electrolyte consisted of $0.01M \text{ K}_4\text{Fe}(\text{CN})_6$ and $0.01M \text{ K}_3\text{Fe}(\text{CN})_6$ in $1M \text{ KCl}$. Purified N_2 was bubbled for 0.5h prior to the experiments and passed over the solution during the experiments. All experiments were carried out at $22^\circ \pm 1^\circ\text{C}$. The kinematic viscosity of the electrolyte was measured with an Ostwald viscometer and found to be $0.00953 \text{ cm}^2/\text{s}$.

The dc limiting current densities for both the anodic and cathodic reactions were plotted as a function of $\Omega^{1/2}$, and the diffusion coefficients were calculated by using the Levich equation (11)

$$(i_{dc})_l = -0.6203 nFD^{2/3}\nu^{-1/6}\Omega^{1/2}C_0 \quad [45]$$

The diffusion coefficients for $[\text{Fe}(\text{CN})_6]^{-3}$ and $[\text{Fe}(\text{CN})_6]^{-4}$ were found to be 7.3×10^{-6} and $6.0 \times 10^{-6} \text{ cm}^2/\text{s}$, respectively. These values are in good agreement with those obtained by John and Vielstich (16).

For alternating current electrolysis, the current was supplied by feeding the sinusoidal wave output of a General Radio Three Phase Oscillator (1305-A) to an ECO Potentiostat (551). Both the offset and the amplitude of the potential difference between the rotating disk and reference electrodes were measured using a Keithley TRMS Multimeter (179-20A) and observed on a Tektronix Single Beam Storage Oscilloscope (5103N). Experiments were carried out at rotation speeds of 409, 920, and 1640 rpm, frequencies of 25, 60, and 120 Hz, and current amplitudes ranging from 0.9 to 6.0 mA/cm^2 .

The ac limiting current density was measured by using two methods. The first method consisted of observing the sudden increase in the amplitude of the potential difference and simultaneous distortion of the wave from its original sinusoidal shape on the oscilloscope, during a gradual increase of the current offset, for a particular applied current amplitude. In the second method, the root-mean-square of the overpotential, η_{rms} , was recorded and plotted as a function of the current offset normalized with respect to the dc limiting current density, as is shown in Fig. 3 for a particular rotation speed and various frequencies of the applied current. The current at which η_{rms} increases abruptly is the ac limiting current density, and

Fig. 3. Experimental results for the root-mean-square value of the overpotential as a function of current offset ($\Omega = 1640$ rpm).

the current at which η_{rms} reaches a maximum is identified to be the dc limiting current density.

The limiting current density for triangular and rectangular ac electrolysis was also measured in the same system by using the method that involves direct measure of the limiting current density from the oscilloscope. The current was supplied by feeding the triangular and rectangular wave outputs of a Tacussel (GSTP-3C) function generator to an ECO Potentiostat (551). Experiments were carried out at rotation speeds of 409, 920, and 1640 rpm and at frequencies of 25, 50, and 100 Hz.

Results and Discussion

Figure 4 is a graphical representation of the experimental results at a particular rotation speed of 1640 rpm, using both of the methods described for obtaining the limiting current density. The figure shows the current offset that was needed to reach the limiting current density at particular values of current amplitude in superimposed sinusoidal ac electrolysis.

According to Eq. [28], a linear relationship between the current amplitude and the current offset should exist at

Fig. 4. Experimental results for the relationship between the current amplitude and current offset at the limiting current density ($\Omega = 1640$ rpm).

the limiting current density, and the slope equal to $-K\sigma$. A comparison between the experimental and calculated values for $-K\sigma$ is shown in Table I. The average error between the calculated values and the experimental values is approximately 7% for the graphical method and 4% for the method that involves a direct measure of the limiting current density from the oscilloscope.

The maximum limiting current density can be extrapolated from the experimental data by using the experimental values for $K\sigma$ in Eq. [30]. The results are plotted in Fig. 5 along with the calculated values.

Also plotted in Fig. 5 are the experimental results for the limiting current density during triangular and rectangular ac electrolysis along with the calculated values, as a function of σ . The average error between calculated and experimental values is approximately 2% for both of the waveforms.

Figure 5 indicates satisfactory agreement between the experimental and calculated results for all three cases studied in this investigation.

Conclusions

A solution based on a simple diffusion model was obtained for the concentration of a reacting species on the surface of a rotating disk electrode during electrolysis by sinusoidal and triangular alternating currents, which do not change polarity during a cycle. Using the solutions, as well as the solution for the surface concentration during electrolysis by rectangular currents separated by equal intervals of zero current, a simplified expression for the instantaneous diffusion limiting current density was derived based on four fundamental properties of the system: (i) Sc (Schmidt number) (ii) Re_n (Reynolds number based on Ω), (iii) a dimensionless group, $\omega R^2/\nu$, and (iv) A , a constant which is based on the waveform characteristics.

The expression for the instantaneous diffusion limiting current density during superimposed sinusoidal, triangular, and rectangular ac electrolysis was verified experimentally by using a ferri-ferrocyanide reaction system.

APPENDIX A

Limiting Current Density for Rectangular AC Electrolysis

Consider Eq. [31]. Upon substitution of $\theta_2 = \theta/2$, the equation can be expressed as

$$\frac{(i_p)_l}{(i_{dc})_l} = \frac{1}{1 - \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{\left[\exp\left(m^2 \alpha \frac{\theta}{2}\right) - 1 \right]}{m^2 [\exp(m^2 \alpha \theta) - 1]}} \quad [\text{A-1}]$$

where

$$m = 2j - 1 \quad [\text{A-2}]$$

and

$$\alpha \theta = \frac{\pi^2 D \theta}{4 \delta^2} \quad [\text{A-3}]$$

By using Eq. [5] and substituting $\theta = 2\pi/\omega$ into Eq. [A1-3]

$$\alpha \theta = \frac{\pi^3 K^2 \sigma^2}{2} \quad [\text{A-4}]$$

If a variable q is defined such that

$$q = (\alpha \theta)^{1/2} = \left(\frac{\pi^3}{2}\right)^{1/2} K \sigma \quad [\text{A-5}]$$

$$\frac{(i_p)_l}{(i_{dc})_l} = \frac{1}{1 - \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{\left[\exp\left(m^2 \frac{q^2}{2}\right) - 1 \right]}{m^2 [\exp(m^2 q^2) - 1]}}$$

and

$$\frac{(i_{dc})_l}{(i_{dc})_{l,p}} = 2 - \frac{16}{\pi^2} \sum_{j=1}^{\infty} \frac{\left[\exp\left(m^2 \frac{q^2}{2}\right) - 1 \right]}{m^2 [\exp(m^2 q^2) - 1]} \quad [\text{A-7}]$$

Differentiating Eq. [A-7] with respect to q yields

$$\frac{d \left[\frac{(i_{dc})_l}{(i_{dc})_{l,p}} \right]}{dq} = \frac{-16}{\pi^2} \sum_{j=1}^{\infty} q \left[\frac{\exp\left(m^2 \frac{q^2}{2}\right)}{[\exp(m^2 q^2) - 1]} - \frac{2 \exp(m^2 q^2) \left[\exp\left(\frac{m^2 q^2}{2}\right) - 1 \right]}{[\exp(m^2 q^2) - 1]^2} \right] \quad [\text{A-8}]$$

which was found numerically to be independent of σ .

$$\frac{d \left[\frac{(i_{dc})_l}{(i_{dc})_{l,p}} \right]}{dq} = \frac{d \left[\frac{(i_{dc})_l}{(i_{dc})_{l,p}} \right]}{\left(\frac{\pi^3}{2}\right)^{1/2} K d\sigma} = 0.3861 \quad [\text{A-9}]$$

$$\frac{d \left[\frac{(i_{dc})_l}{(i_{dc})_{l,p}} \right]}{d\sigma} = 1.52K \quad [\text{A-10}]$$

The ratio $(i_{dc})_l / (i_{dc})_{l,p}$ in Eq. [A-7] was found to approach unity as q approaches zero. Therefore, Eq. [A-6] and [A-7] can be expressed as

$$\frac{(i_p)_l}{(i_{dc})_l} = \frac{2}{1 + 1.52K\sigma} \quad [\text{A-11}]$$

and

$$\frac{(i_{dc})_l}{(i_{dc})_{l,p}} = 1 + 1.52K\sigma \quad [\text{A-12}]$$

Limiting Current Density for Triangular AC Electrolysis

The expression for the concentration changes produced at the electrode surface is given as

$$c_s^* = 1 + \frac{2}{nF\delta c_0} \sum_{j=1}^{\infty} \exp(-m^2 at) \int_0^t \exp(m^2 au) i(\mu) d\mu \quad [\text{A-13}]$$

where $i(\mu)$ is the time varying applied current density.

A triangular current waveform which does not change polarity during a cycle and is restricted so that the lowest value of the current just reaches zero, can be expressed by

$$i(t) = (\bar{i}_{dc}) \left[1 + \frac{8}{\pi^2} \sum_{l=1}^{\infty} \frac{(-1)^{1/2(p-1)}}{p^2} \sin(p\omega t) \right] \quad [\text{A-14}]$$

where $p = 2l - 1$ and (\bar{i}_{dc}) is defined as the offset current density. By combining Eq. [A-13] and [A-14], one readily obtains

$$c_s^* = 1 + \frac{2}{nF\delta c_0} \sum_{j=1}^{\infty} \exp(-m^2 at) \int_0^t \exp(m^2 au) (\bar{i}_{dc}) du + \frac{16(\bar{i}_{dc})}{\pi^2 nF\delta c_0} \sum_{j=1}^{\infty} \exp(-m^2 at) \int_0^t \exp(m^2 au) \sum_{l=1}^{\infty} \frac{(-1)^{1/2(p-1)}}{p^2} \sin(p\omega u) du \quad [\text{A-15}]$$

Upon further manipulation, Eq. [A-15] becomes

$$c_s^* = 1 - \frac{(\bar{i}_{dc})}{(i_{dc})_l} \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{1}{m^2} [1 - \exp(-m^2 at)] + \frac{16(\bar{i}_{dc})}{\pi^2 nF\delta c_0} \sum_{j=1}^{\infty} \sum_{l=1}^{\infty} \frac{(-1)^{1/2(p-1)}}{p^2} \exp(-m^2 at) \int_0^t \exp(m^2 au) \sin(p\omega u) du \quad [\text{A-16}]$$

which, after the appropriate integration, becomes

$$c_s^* = 1 - \frac{\overline{(i_{dc})}}{(i_{dc})_1} \frac{8}{\pi^2} \sum_{j=1}^{\infty} \frac{1}{m^2} [-\exp(-m^2 at)] - \frac{64}{\pi^4} \frac{\overline{(i_{dc})}}{(i_{dc})_1} \sum_{j=1}^{\infty} \sum_{l=1}^{\infty} \frac{(-1)^{1/2(p-1)}}{p^2} \left[\frac{m^2 \sin(p\omega t) - \frac{p\omega}{a} \cos(p\omega t)}{m^4 + \frac{p^2\omega^2}{a^2}} + \frac{\frac{p\omega}{a} \exp(-m^2 at)}{m^4 + \frac{p^2\omega^2}{a^2}} \right] \quad [A-17]$$

When the transient terms have become negligible

$$c_s^* = 1 - \frac{\overline{(i_{dc})}}{(i_{dc})_1} [1 + T] \quad [A-18]$$

where

$$T = \frac{64}{\pi^4} \sum_{j=1}^{\infty} \sum_{l=1}^{\infty} \frac{(-1)^{1/2(p-1)}}{p^2} \left[\frac{m^2 \sin(p\omega t) - \frac{p\omega}{a} \cos(p\omega t)}{m^4 + \frac{p^2\omega^2}{a^2}} \right] \quad [A-19]$$

A graph of T during a cycle, for two values of σ , is shown in Fig. A-1 along with the applied current waveform.

The lowest surface concentration during a cycle occurs when T reaches its maximum value, T_{max} . The limiting current density and dc offset at the limiting current density can be expressed by the equation

$$\frac{(i_l)_1}{(i_{dc})_1} = \frac{2}{1 + T_{max}} \quad [A-20]$$

and

$$\frac{(i_{dc})_{l,t}}{(i_{dc})_{l,t}} = 1 + T_{max} \quad [A-21]$$

T_{max} was evaluated for various values of σ , and a linear relationship between them was found to exist.

Equations [20] and [21] can be rewritten as

$$\frac{(i_l)_1}{(i_{dc})_1} = \frac{2}{1 + 0.81K\sigma} \quad [A-22]$$

and

$$\frac{(i_{dc})_{l,t}}{(i_{dc})_{l,t}} = 1 + 0.81K\sigma \quad [A-23]$$

Fig. A-1. The behavior of T during a cycle for two values of σ .

APPENDIX B

Numerical Integration of the Convective-Diffusive Equation

If one considers the convective flux contribution to the mass transport, the equation which governs the concentration of the reacting species is of the form

$$\frac{\partial c}{\partial t} + v_z \frac{dc}{dz} = D \frac{\partial^2 c}{\partial z^2} \quad [B-1]$$

where v_z is the axial component of the velocity. Equation [B-1] can be rearranged into the dimensionless form

$$\frac{\partial c^*}{\partial \tau} = \frac{\partial^2 c^*}{\partial \xi^2} + K \xi^2 \frac{\partial c^*}{\partial \xi} \quad [B-2]$$

where

$$c^* = \frac{c}{c_0} \quad [B-3]$$

$$\tau = \frac{Dt}{\delta^2} \quad [B-4]$$

$$\xi = \frac{z}{\delta} \quad [B-5]$$

and

$$K = -\frac{v_z \delta^3}{z^2 D} = 2.136 \quad [B-6]$$

A time-independent spatial mesh can be formed which consists of a series of N equally spaced points which lie in the region from $\xi = 0$ to $\xi = 1$, such that for each ξ there exists a corresponding $c_i^*(\tau)$ where $i = 1, 2, 3, \dots, N$. At each ξ , there is also a corresponding $dc_i^*/d\tau$, such that

$$\begin{aligned} \frac{dc_1^*}{d\tau} &= f_1(\tau, c_1^*, c_2^*) & c^*(\tau) &= c_s^*(\tau) \\ \frac{dc_i^*}{d\tau} &= f_i(\tau, c_{i-1}^*, c_i^*, c_{i+1}^*) & c_i^*(\tau) & \\ \frac{dc_N^*}{d\tau} &= f_N(\tau, c_{N-1}^*, c_N^*) & c_N^*(\tau) &= 1 \end{aligned} \quad [B-7]$$

where f_i is the central finite difference approximation of the right-hand side of Eq. [B-2], in which

$$\frac{dc_i^*}{d\xi} = \frac{c_{i+1}^* - c_{i-1}^*}{2\Delta\xi} \quad [B-8]$$

$$\frac{d^2c_i^*}{d\xi^2} = \frac{c_{i-1}^* - 2c_i^* + c_{i+1}^*}{(\Delta\xi)^2} \quad [B-9]$$

By performing a spacial discretization, one partial differential equation [B-2], continuous in both space and time, was transformed into N ordinary differential equations of the initial value type [B-7], continuous in time only. The method used to solve this system of ordinary differential equations was developed by Hindmarsh (14), based on the backward differentiation formulas of Gear (15).

LIST OF SYMBOLS

- A defined by Eq. [13]
- a defined by Eq. [A-3]
- c concentration
- c_0 bulk concentration
- c_s^* surface concentration
- c_s^* dimensionless surface concentration
- D diffusion coefficient

- f_i defined by Eq. [B-7]
- i current density
- $\frac{i_{dc}}{i_{dc}}$ dc current density
- $\frac{i_{dc}}{i_{dc}}$ dc offset in electrolysis by periodic varying currents
- $(i_{dc})_1, (i_s)_1$ diffusion limiting current densities for dc, superimposed sinusoidal, rectangular, and triangular alternating current waveforms, respectively
- $(i_p)_1, (i_l)_1$

$(\bar{i}_{dc})_{l,ss}$, $(\bar{i}_{dc})_{l,p}$	dc offset at the diffusion limiting current density for superimposed sinusoidal, rectangular, and triangular alternating current waveforms, respectively
$(\bar{i}_{dc})_{l,t}$	
$(i_s)_{l,max}$, $(\bar{i}_{dc})_{l,max}$	the maximum value for the diffusion limiting current density and dc offset at the diffusion limiting current density that can be obtained in superimposed sinusoidal ac electrolysis for the case where the polarity of the applied current does not change
I	current amplitude in sinusoidal ac electrolysis
K	defined by Eq. [20]
N	number of spacial discretization points
n	number of electrons transferred in the electrochemical reaction
q	defined by Eq. [A-5]
R	disk radius
Re_n	Reynolds number based on disk speed ($\Omega R^2/\nu$)
Sc	Schmidt number (ν/D)
T	defined by Eq. [37]
T_{max}	the maximum instantaneous value of T , as defined by Eq. [37]
u	dummy variable of integration
v_z	axial component of fluid velocity
z	axial coordinate extending from the edge of the Nernst boundary layer ($z = 0$) towards the disk surface ($z = \delta$)
Greek letters	
γ	defined by Eq. [15]
δ	Nernst diffusion layer thickness
$\delta_{p,max}$	maximum value for the pulsating diffusion layer thickness
η_{rms}	root-mean-square overpotential in ac electrolysis
θ, θ_2	cycle time and off time in rectangular ac electrolysis

ξ	dimensionless axial coordinate defined by Eq. [B-5]
μ	defined by Eq. [14]
ν	electrolyte kinematic viscosity
σ	defined by Eq. [21]
τ	dimensionless time defined by Eq. [B-4]
ω	frequency of the applied current
Ω	rotation speed

Maximum Power Spectroscopy for Photovoltaic Devices

Barry Miller* and Joseph M. Rosamilia

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Maximum power spectroscopy for the study of photovoltaics is described. The technique is based on analyzing the modulated maximum power output of the photojunction cell for a controlled input spectrum in a dual beam (bias plus modulated monochromatic probe) arrangement. The differential power conversion efficiency is thus measured. The input spectrum is programmed by a computer and servo loop to be either neutral (wavelength independent) or solar in shape, from a stored reference table. The operation of the system, applicable to laboratory spectrum simulation, and the function of the bias beam are demonstrated. Spectra of a p-n Si diode with added series resistance simulate the differences between maximum power efficiency and the conventional short-circuit quantum efficiency. There are advantages to the power measurement in sensitivity to competitive kinetic processes governing cell conversion efficiency and to wavelength dependent effects on junction potential gradients.

The spectral response of solid-state photovoltaic and photoelectrochemical devices is usually taken as the set of monochromatic quantum efficiencies under short-circuit photocurrent (I_{sc}) collection. A less common alternative is based on the open-circuit voltage (V_{oc}) output. Both conditions correspond to measurement under zero power output since one of the current (I) or voltage (V) parameters is zero. Light-to-electrical conversion is, however, the raison d'être of the device. We have developed and describe herein the methodology of maximum power spectroscopy to capitalize on the evident advantages of measuring the power parameter.

We measure the modulated maximum power output response, ΔP_o , of the photovoltaic system of a chopped monochromatic power input, ΔP_i , which is superimposed on a steady beam of power, P_s . It must be noted that the spectral response of solar cells is a measurement with a long history of development and refinement whose status has been recently reviewed (1). Numerous references exist therein to spectroscopic response defined by differential short-

circuit current efficiency for chopped monochromatic beams superimposed on white or controlled-spectrum dc beams which bias the cell to some operating point. Previous experience in our laboratories with this technique (2) is illustrative of its possibilities in tracing the location and effects of surface and near-surface recombinative processes traceable to structural defects.

Nevertheless, there are a number of factors determining power conversion efficiency in solid-state cells and photoelectrochemical cells based on semiconductor-electrolyte junctions which do not influence spectral response under short-circuit conditions except when they are dominant. For the liquid junction cells, electrode kinetics, counterelectrode behavior, and internal resistance could be cited. Recombination processes will also likely have more dramatic effects on the maximum power output than the short-circuit current.

We have thus approached the power measurement in a dual beam mode yielding the differential efficiency $\Delta P_o/\Delta P_i$. The P_s source (either mono- or polychromatic) gives flexibility to the choice of operating level and allows probing of nonlinearity and saturation effects, as it does in

* Electrochemical Society Active Member.

traditional short-circuit current techniques. The important distinction is in the quantity controlled (ΔP_i) and measured (ΔP_o) differentially. By computer selection of reference voltages, we provide any chosen function of ΔP_i vs. wavelength, λ , from a constant value for all λ to a normalized duplication of the intensities of a solar spectrum in our region of interest here, 400-1000 nm. Appropriate analysis of this data can relate the solar responses of different systems in the laboratory, within the range restrictions.

To clarify the difference in response between this maximum power sensitive methodology and the conventional short-circuit approach, we use the experimental model of a junction device with variable added series resistance. The latter simulates, for these purposes, the effect on I-V curves of losses from the important photobarrier rate processes mentioned above (recombination of photogenerated hole-electron pairs and electron transfer kinetics). In this regard, we also show the relation of the total power output, P_o , as a function of the P_s level, to the corresponding $\Delta P_o/\Delta P_i$ derivative ratio for the same model experiments. This illustrates the enhanced sensitivity of the maximum power spectroscopy modulation technique to the junction loss factors and any consequent nonlinear and saturation effects of the P_s level. Applications to Schottky barrier metallizations and various liquid junction cells will follow separately.

Experimental

The central element of the new system is a servo scheme (3), which drives a photovoltaic device to its point of maximum power output, P_o . That instrumentation was primarily applied to fixed or relatively slowly changing light intensity measurements. The response was, however, also shown to follow accurately a modulated (~ 10 Hz) light input, and this capability is required for the present spectral application. Also essential is a means for generating the $\Delta P_i - \lambda$ relation, most simply for spectroscopy a constant ΔP_i . This programming is done with computer software and a light control servo loop. Such output intensity control has been initiated previously by means such as mechanical cams (4), function generators (5, 6), and step-by-step calibration and burn in of an EPROM (uv erasable programmable read only memory) (7).

The combination of functions is schematically shown in Fig. 1A and 1B. In path 1 on Fig. 1a the Apple IIe computer, through an 8-bit D-A converter (Interactive Structures, Incorporated, AO-03), outputs a stored set of voltages. These represent power outputs which are equated to the radiometer detector signal through the servo loop controlling the

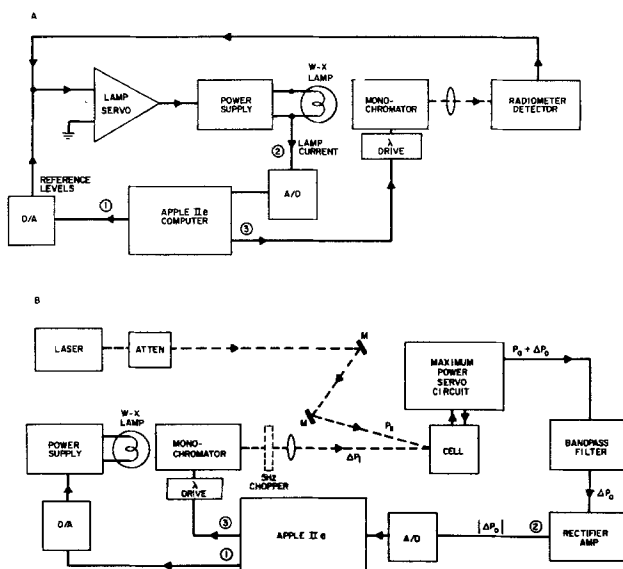

Fig. 1. A: Scheme for servo control and acquisition of lamp currents generated by a given set of computer reference voltages (powers). B: Schematic of maximum modulated power spectrometer. Computer program controls monochromator power output (path 1), data is acquired from cell (path 2), and wavelength is stepped (path 3).

lamp current. Thus, the monochromatic intensity incident on the detector follows the desired wavelength-power program. The necessary lamp current at each wavelength, in the form of a programming voltage that produces it, is read back to the computer via path 2 and a 12-bit A-D converter (Interactive Structures, Incorporated AI13). These values are then stored on disk.

If a constant power output from the monochromator is sought, the reference levels are identical at all wavelengths. Then the necessary lamp currents reflect the overall system light throughput at that wavelength. In that case, the wavelength of least efficiency determines the maximum constant ΔP_i attainable within the lamp operating limits. The light source for the monochromator (Oriol 7240) was a 100W tungsten-halogen bulb driven from a Hewlett-Packard 6024A 200W supply in a current-programmed by voltage mode.

The primary radiometer on which we rely as a neutral detector is a thermopile (Oriol 7102). For convenience in the lamp current control servo, we use a radiometric silicon detector (Metrologic 60-530) which is much faster and more stable, though nominally $\pm 10\%$ in spectral flatness (400-1000 nm). The Si detector is calibrated against the thermopile, and these factors are entered into the computer reference set in spectral programming. (The calibration is accomplished from the spectral data shown in Fig. 2, which are power spectra obtained for constant lamp current in this system.)

To obtain solar-shaped $\Delta P_i - \lambda$ spectra, the reference levels are a series of numbers in relative proportion to tabulated (8) values ($\text{mW cm}^{-2} \text{nm}^{-1}$) for the terrestrial solar power under different air mass conditions. The interval has been taken as 10 nm, and the tables have been interpolated to this increment where necessary. The monochromator drive (Oriol 7286) is indexed in 10 nm steps to computer command (path 3 in Fig. 1A or 1B) after steps 1 and 2 are completed. The spectral bandwidth has been kept about 10 nm throughout these experiments and is the limit to sharp resolution of any input spectral features.

If the optical elements in the system, particularly lamp characteristics, are stable, the stored lamp currents can repeatedly generate the desired $\Delta P_i - \lambda$ spectrum. The practical limits are determined by the 8-bit accuracy of the D-A converter (± 1 bit = ± 20 mV in the 5V equivalent to 10A lamp current).

Figure 1B shows the "playback" of lamp currents and the maximum power (ΔP_o) measuring mode. Path 1, then, is the lamp programming sequence operating in conjunction with the monochromator stepping (path 3). The P_s source was normally a Hughes 3235 H-PC He-Ne laser of about 12 mW output. Adjustment of P_s intensity was accomplished with a Karl Lambrecht KLOA series Optical Attenuator. The cell and maximum power circuitry blocks refer to the previously described system (3). In brief, it employs a small

Fig. 2. P_i vs. λ at constant lamp current monitored by a radiometric silicon detector (—) and thermopile (---).

ac signal (5 mV) superimposed on the cell voltage and a lock-in amplifier to detect the synchronized component produced in the analog product of cell I and V. The lock-in output is part of a servo loop, and its dc level drives the cell voltage to the minimum $d(VI)/dV$ point. This makes the VI product a maximum. The superimposed ac signal is at 800 Hz and the light is square wave chopped (ΔP_i) at 5 Hz in the dual beam mode ($\Delta P_i + P_s$). Proper filter time constant and gain adjustment in the PAR 128 lock-in feedback loop allows the square wave output ΔP_o to be strictly followed.

The ΔP_o signal is passed through a bandpass filter (Wavetek-Rockland 452) set at two (low pass) and one-half (high pass) the chopping frequency, then full-wave rectified, filtered, and amplified by π to restore the peak-to-peak value if the signal was sinusoidal. These aspects are described in detail for another modulation context (9, 10). This data are acquired in path 2 by the A/D converter and the computer.

Figure 3 summarizes the input/output experiments to be described in this paper and the accompanying symbols. One or two sources may be superimposed on a sample or detector. If two, the P_s source may be combined with either the monochromator output P_i or its 5 Hz chopped version ΔP_i , P_s or P_i may be used separately. Thus dc (unvarying) incident beams are P_s , P_i , or $P_s + P_i$. The respective dc outputs are P_o and I_{sc} for maximum power or short-circuit current configurations of the cell electronics, respectively. With the dc + ac input, or $P_s + \Delta P_i$, which is the maximum power spectroscopy mode, we measure the ac output ΔP_o . For comparison to the conventional spectral response technique, we can measure the ac component ΔI_{sc} in that cell connection mode and the same bandpass filter-rectifying arrangement.

All timing sequences were adjusted to allow the light detectors, servo loops, and rectifier filtering to stabilize appropriately before data acquisition and 10 nm stepping. Experimental elapsed time was typically of the order of 1 s/nm in the wavelength stepping mode. An order sorting filter was manually inserted at 800 nm by programming an audible warning and sufficient delay in the software at that point. Since this was done in the lamp programming stage as well, there is no discontinuity in the spectral output because of the filter insertion.

It is to be noted that an alternative approach is use of a neutral beam splitter for illuminating a known response detector and a sample cell simultaneously, thus effectively combining the Fig. 1A and 1B functions. Our experience was that the problems of neutral beam splitting (7), and the managing of the monochromatic and bias beams in this more complex physical arrangement far outweighed any apparent advantages of such a "simplification."

Results and Discussion

The cell output measuring and light source input programming aspects are considered first separately, then in combination. For the photovoltaic output we test the measurements of P_o and ΔP_o for $P_i = \Delta P_i$ and fixed P_s . For input spectra generation, we compare their measured values to the desired flat or solar $\Delta P_i - \lambda$ relations.

The gain to a known square wave in the modulated output measuring system was calibrated. Then in the scheme of Fig. 3, this value of 1.27 was reproduced within $\pm 1\%$ with

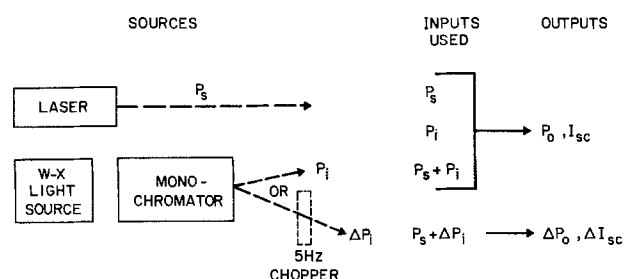

Fig. 3. Block diagram and symbology of the experimental sources and combinations of input light with the corresponding outputs.

Table I. Calculated and actual outputs

Input	Outputs	
$P_i + P_s$	$P_{o2} = 0.283$ mW	$I_{sc2} = 770$ μ A
P_s	$P_{o1} = 0.243$	$I_{sc1} = 662$
$\Delta P_i + P_s$	$\Delta P_o = 0.051$	$\Delta I_{sc} = 138$
Calc.	$\frac{\Delta P_o}{P_{o2} - P_{o1}} = 1.28$	$\frac{\Delta I_{sc}}{I_{sc2} - I_{sc1}} = 1.28$

a 5 Hz ΔP_i signal incident on a p-n Si diode. The outputs P_{o2} and P_{o1} were measured for inputs of $P_i + P_s$ and P_s , respectively. Next, ΔP_o was measured for the input $\Delta P_i + P_s$. Correspondingly, I_{sc2} , I_{sc1} , and ΔI_{sc} were also obtained. Table I shows the output measurements and calculations.

The excellent agreement of the $\Delta P_o/(P_{o2} - P_{o1})$ and $\Delta I_{sc}/(I_{sc2} - I_{sc1})$ ratios to the theoretical gain confirms the quantitative capability of the system to measure ΔP_o for a photovoltaic detector. The short-circuit data are obtained in a conventional zero voltage, current follower configuration. The number 1.27 is the ratio of outputs to square and sine wave inputs when such signals of the same amplitude are fed into the bandpass filter-rectifier- π gain circuit.

After the calibration of the radiometric Si detector against the thermopile (Fig. 2) and the subsequent generation of the lamp current set for flat power output, the spectrum was played back onto the reference thermopile and also onto a pyroelectric radiometer, an independent neutral detector. These outputs are shown in Fig. 4 (curves I and II). The flatness indicates the spectral neutrality achieved for ΔP_i vs. λ inputs. Curve III is the ΔP_i vs. λ solar spectrum generated as described above and measured by the thermopile. The solar air mass 1.0 reference levels [Table I in Ref. (8)] normalized to this scale are also shown on Fig. 4 as points. The fit between the tabulation and the playback values is illustrative of the software flexibility and calibration accuracy. The 1-bit (± 0.020 V) accuracy in lamp programming is $\pm 2-3\%$, typically, of ΔP_i . The variation in curves I and II at the 10 nm intervals is virtually all due to this 8-bit conversion limit, and further smoothing can be achieved by a better D-A.

A radiometric p-n Si diode (Oriol 7190, $\pm 8\%$ in A/W, 450-950 nm) was used to test the combined system, including modulated maximum power detection. Figure 5, curve I, shows P_o for P_i fixed, $P_s = 0$. ΔP_o , curve II, was obtained for the $\Delta P_i = P_i$, $\Delta P_i + P_s$ mode. These plots coincide experimentally when scaled as shown, confirming the circuit operation and the fact that the P_o/P_i ratio is constant through this level of P_i , which was controlled by the bias

Fig. 4. P_i vs. λ programs. Curve I (—) and curve II (---) are constant power programs incident on a thermopile and pyroelectric radiometer, respectively. Curve III is the solar AM1 program onto thermopile with same total power, $\sum_{\lambda} P_{i\lambda}$, as others. Points are tabulated (relative) values for AM1.

Fig. 5. Power spectra of radiometric Si diode. Curve I (---): P_0 spectrum with fixed P_1 and $P_s = 0$. Curve II: ΔP_0 spectrum with $P_s + \Delta P_1$ fixed. Curve III: ΔP_0 spectrum with P_s fixed and ΔP_1 follows AM1 program.

level, P_s . The ΔP_0 output corresponding to the $\Delta P_1 - \lambda$ solar spectrum of curve III, Fig. 4 follows in curve III.

A more rigorous test of the accuracy of modulated operation is shown as a function of λ in Fig. 6. There we compare the responses to a steady input level of P_1 , found by manually determining the maximum VI product, P_0 , and the values of ΔP_0 when the composite signal $\Delta P_1 + P_s$ is applied. In this case, $\Delta P_1 = P_1 = 0.5 \text{ mW/cm}^2$ and $P_s = 12 \text{ mW/cm}^2$. For the $\Delta P_1 + P_s$ mode, the ΔP_0 values were obtained automatically. The two spectra normalized are identical, as is required for the same inputs (P_1 and ΔP_1) and linear power response.

The effect of added series resistance on I-V curves for a blue enhanced p-n Si diode with active area = 0.05 cm^2 is shown for a fixed incident laser power in Fig. 7. Maximum power output is lowered without altering V_{oc} or I_{sc} until the load effect is very high. P_0 vs. P_1 plots from such sets with fixed laser input powers are shown in Fig. 8 with the corresponding values of I_{sc} . These latter do not vary except at the combination of high resistance (1 K) and high power ($P_1 > 1 \text{ mW}$).

The equivalent modulated spectrum from a $\Delta P_1 + P_s$ experiment is now repeated for P_s of 12 mW/cm^2 (0.6 mW on the Fig. 8 P_1 abscissa), with both ΔP_0 and ΔI_{sc} measured. The ΔP_0 spectra of Fig. 9 are sensitive at all wavelengths to the slopes of the $P_0 - P_1$ data at this fixed P_1 and varying resistance. Thus, as expected, the ΔI_{sc} spectra are virtually im-

Fig. 6. ΔP_0 and P_0 [•] vs. λ for a p-n Si diode of 0.05 cm^2 active area. P_0 is manually measured maximum VI for fixed $P_1 = 0.5 \text{ mW/cm}^2$. ΔP_0 is measured with $\Delta P_1 = P_1, 12 \text{ mW/cm}^2$.

Fig. 8. I_{sc} (---) and P_0 (—) vs. P_1 as a function of added series resistance. [Δ], [■], and [•] represent 0Ω , 500Ω , and $1 \text{ k} \Omega$ series resistance, respectively.

immune to the added resistance, as they would be to any factor that affects the I-V curves only in the maximum power region.

From the individual wavelength data stored in the computer, the power output measurements may be summed for each 10 nm step over the spectrum to obtain a total power output $\sum_{\lambda} \Delta P_0$ at fixed $P_s + \text{fixed } \Delta P_1$. P_0 as a function of varying resistance at fixed input was calculated from Fig. 8 data. These are both displayed as a function of series resistance in Fig. 10. P_0 drops more slowly than the summed differential quantity $\sum_{\lambda} \Delta P_0$, as would be expected from Fig. 8; in the limit of saturation (horizontal, infinite resistance characteristic in a normal diode curve), $\Delta P_0 \rightarrow 0$, whereas P_0 remains a definite nonzero value.

Fig. 9. Effect of added series resistance as marked on modulated spectra, ΔI_{sc} (---) and ΔP_o (—) vs. λ .

Fig. 11. Modulated power spectra, ΔP_o vs. λ , of a Si diode. Curve I (—): Modulated input, ΔP_i , flat. Curve II (---): ΔP_i follows AM1 solar spectrum with $\sum P_i$, flat at curve I equaling $\sum P_i$, solar of II. Curve III (---): Input with constant lamp current, $\Delta P_i - \lambda$ as in Fig. 2. P_s is fixed in all cases.

The response to solar shaped and flat power input spectra of the Si diode employed in Fig. 7-10 is given in Fig. 11 (curves I and II). The prior constraint here was $\sum_{\lambda} \Delta P_{i,flat} = \sum_{\lambda} \Delta P_{i,solar}$, applied by computing the right-hand member and then dividing by the number of intervals to calibrate $\Delta P_{i,flat}$.

This approach permits the relative efficiency of devices to be simply compared in the modulated mode for the same total power, $\sum_{\lambda} \Delta P_i$, incident in different spectral form. Curve III on Fig. 11 shows the spectral response (without total power constancy restriction) at constant lamp current, where ΔP_i vs. λ is shown in Fig. 2.

A corollary to this is the comparison of the response of different bandgap devices to the same source. Different bandgaps are simulated by running the Si diode with a set of shortwave transmitting interference filters (Melles Griot) intercepting ΔP_i . The $\sum_{\lambda} \Delta P_o$ will take on the appearance of the outputs of a series of progressively different bandgap semiconductors. This effect of "bandgap" on solar and flat spectra is shown in Fig. 12 for two cutoff wavelength (half-maximum transmission) values of the filters, under the equal total input restraint. The values of $\sum_{\lambda} \Delta P_i$ were corrected for filter transmission; this approximation has little effect on the point being demonstrated.

These data were treated under two measures of relative and absolute power conversion efficiencies. We define $Q_1 = \frac{\sum_{\lambda} \Delta P_{o,solar}}{\sum_{\lambda} \Delta P_{o,flat}}$ and $Q_2 = \frac{\sum_{\lambda} \Delta P_{o,solar}}{\sum_{\lambda} \Delta P_i}$. Plots of filter cutoff at half height (simulated bandgap) vs. Q_1 and Q_2 for Fig. 12-style spectra are given in Fig. 13.

The Q_1 plot, because of the cutoff values and the solar 550 nm irradiance peak, makes the solar spectral output relatively higher than that from a flat input spectrum. This effect is consistent with the Q_1 ratios paralleling the $\frac{\sum_{\lambda}^{cutoff} \Delta P_{i,solar}}{\sum_{\lambda}^{cutoff} \Delta P_{i,flat}}$ ratios, which are also shown on Fig. 13. Q_2 , a more conventional definition, shows the reduced efficiency of bandgaps greater than the 1.4 eV level, which best matches the solar spectrum (11).

Fig. 12. Modulated power spectrum for a Si diode with two different short-wave transmitting filters, labeled by their wavelengths at 50% of maximum transmission, ΔP_i is flat as $f(\lambda)$ for the solid line and AM1 solar for the dash line.

Conclusions

Computer-controlled instrumentation for monitoring the maximum power delivered by a photovoltaic junction device under selectable input spectrum programming leads to the technique of maximum power spectroscopy. The input spectrum is applied in modulated form superimposed on an adjustable bias. The benefit of varying bias intensity as well as wavelength dependent parameters, in the manner

often applied to conventional spectral response (1), is also available to this methodology.

For photovoltaics, the relative sensitivity of maximum power output to loss factors is usually greater than that of short-circuit current, and our present method extends this to spectroscopic studies. A solar-derived or other selected input spectrum in the dual-input-beam mode permits inter-comparisons of wavelength response over any selected region for semiconductor cells. The differential scheme means the spectra also have enhanced sensitivity to intensity (bias) effects and the losses ascribable to high rate operation or concentration of light.

Energetics of Reaction of Al^{3+} with O^{2-} in an Alkali Halide Environment

Comparisons of *ab initio* Molecular Orbital Calculations with Molten Salt Data

L. A. Curtiss and M. Blander*

Argonne National Laboratory, Chemical Technology Division, Argonne, Illinois 60439

ABSTRACT

Ab initio molecular orbital calculations of the structures and energies of $LiAlF_4$, Li_2AlF_5O , $LiAlCl_4$ and Li_2AlF_5O are presented. These molecules were chosen so as to approximate Al^{3+} and O^{2-} in a molten salt environment. Calculated energies for vapor-phase reactions involving oxide addition to $LiAlX_4$ ($X = F, Cl$) are consistent with experimental data from molten halide melts. Comparison is also made between the quantum mechanical calculations and results from simple coulomb models.

The formation of complex species involving Al^{3+} and O^{2-} in molten salts is of fundamental scientific significance as well as of technological importance in current and advanced aluminum smelting processes and in batteries. Complex species of Al^{3+} with O^{2-} or S^{2-} have been extensively studied experimentally in fluoride and chloride solvents (1-10). Little experimental work (4, 6) and no quantum mechanical studies of the energetics of bonding have been published. In this paper, we report quantum mechanical calculations of the structures and energetics of gaseous molecules involved in reactions between Al^{3+} and O^{2-} ions. Insofar as is possible, the molecules were chosen so as to contain species which are expected or possible in molten halide melts. With a

* Electrochemical Society Active Member.

judicious choice of molecules, one might hope that the differences in solvation energies of reactants and products of the reaction can be minimized so that the energy changes for the reactions between gaseous molecules can represent the corresponding reaction in the liquid reasonably well. In addition to deducing reaction energies, we also calculate the structures of species, some of which exist in molten salt solutions.

We also compare our quantum mechanical calculations of the energetics of reactions between gaseous species with coulomb models. Our ultimate aim is to refine a simple coulomb model (4, 6) for predicting the energetics of complex species between Al^{3+} and O^{2-} in molten salts in order to make it accurate enough for reasonable predictions of the energetics of complexing.

Quantum Mechanical Calculations

In order to emulate the energetics of formation of solvated AlO^+ species in alkali chloride and fluoride melts, we chose the vapor molecules $\text{Li}_2\text{AlF}_3\text{O}$ and $\text{Li}_2\text{AlCl}_3\text{O}$ in which the AlO^+ species is coordinated by halide and alkali atoms. Because quantum mechanical calculations of the energies of ions, especially those with valences of two or more, are relatively inaccurate, we chose to perform calculations only for neutral species. In addition, electron correlation is an important factor which must be taken into account in calculations of energies of these molecules. However, if one calculates the energetics for reactions in which there are the same number of bonds in the reactants and products, there should be considerable cancellation of correlation energies and the error introduced into the calculated energy change, for the reaction is likely to be small (11, 12). Consequently, we considered the gas-phase reactions

and

Ab initio molecular orbital LCAO-SCF calculations (13) at the extended 3-21G (14) basis set level were carried out on the $\text{Li}_2\text{AlF}_3\text{O}$ and $\text{Li}_2\text{AlCl}_3\text{O}$ complexes. The structures of these complexes were optimized with respect to their total energy using the geometrical parameters illustrated in Fig. 1. The structures were optimized under a C_{3v} constraint which requires one of the Li atoms to be face-bridged with the Al (*i.e.*, three halide atoms in the bridge) and the Al-O-Li bridge to be linear. It is possible that structures having edge-bridges are more stable since similar calculations (15) on the related LiAlF_4 complex found the edge-bridged structure to be more stable by 9 kcal mol^{-1} . However, by using the face-bridged structures of LiAlF_4 and LiAlCl_4 on the left side of reactions [1] and [2], any error introduced by not using the lowest energy structure should nearly cancel. We have not investigated the other bridge structures for these oxide complexes because our interest here is in the strength of the Al-O bond compared to the Al-X ($X = \text{F}, \text{Cl}$) bond.

In order to determine energies for reactions [1] and [2], the energies of a number of other related molecules and complexes are needed. Table I contains the energies and optimized geometries of LiF , LiCl , Li_2O , AlF_3 , AlCl_3 , LiAlF_4 (face-bridged structure), and LiAlCl_4 (face-bridged structure) at the 3-21G level. The experimental geometries of LiF , LiCl , Li_2O , AlF_3 , and AlCl_3 are also given. The extended 3-21G basis set gives good agreement with experiment except for the bond lengths in LiCl and AlCl_3 , which are too long by 0.09 and 0.18 Å, respectively. A larger basis set with d-functions and, possibly, inclusion of correlation energy are necessary for better agreement with experiment for these bond lengths. These errors should be taken into account when considering the calculated oxide geometries.

The 3-21G optimized geometries of $\text{Li}_2\text{AlX}_3\text{O}$ ($X = \text{F}, \text{Cl}$) are given in Table I. The 3-21G geometries indicate that the LiX_3Al groups in the oxides have geometries which are very similar to the LiX_3Al groups in the LiX_3AlX complexes. Hence, the replacement of a halide by the OLi group does not significantly perturb the other end of the

complex. In addition, the 3-21G geometries indicate that the Al-O bond is quite strong, as it has a bondlength of 1.65 Å in both complexes. The Li-O bond is apparently weakened somewhat in the complex as it lengthens by about 0.07 Å over its value in Li_2O .

The 3-21G energies for reactions [1] and [2] are -31.2 and -72.3 kcal mol^{-1} , respectively. They indicate that replacement of F or Cl by OLi is exothermic and that the reaction energy for the chloride reaction is more exothermic than that for the fluoride.

The calculational method used in this study does not include polarization functions or correlation energy. Higher level calculations on reactions involving small molecules including these factors have found that they are important in the determination of bond energies (16). However, at the present time such computations are not feasible for large molecules such as those we are considering. Hence, we have selected for this investigation only reactions in which the same number of formal type of bonds is retained on both sides of the reaction (isodesmic reaction). In an extensive study (11) of isodesmic bond separation reactions involving molecules containing first row atoms (C to F), it has been found that errors inherent in the theoretical treatment will cancel to a large extent. The mean absolute deviation between theory and experiment in that study of 21 reactions was 3.1 kcal mol^{-1} at the extended basis set level. We have carried out a limited investigation (17) of isodesmic bond separation reactions involving molecules containing Li, O, and second row atoms and have found a similar cancellation of errors to exist. Hence, the available evidence indicates that the 3-21G energies for reactions [1] and [2] should be reasonably accurate, since the reactions are isodesmic bond separation reactions. We now proceed to compare the calculated gas phase reaction energies with reaction energies in solution.

Comparisons of Calculated Energies with Measurements in Solution

The calculated energies of the two gas-phase reactions are now compared with energies deduced for the formation of Al-O bonds in molten salts. It is of particular interest to see if the large calculated difference between fluorides and chlorides is reflected in the molten salt data. Recent measurements of the solubility of Al_2O_3 in LiCl-KCl-AlCl_3 solutions at 723 K (18) are consistent with the reaction

having an equilibrium constant (in mole fraction units) of 8.0×10^{12} . (The dipolar AlO^+ ion is, of course, solvated by Cl^- and Li^+ ions.) From this value it can be shown (18) that

the equilibrium corresponding to formation of the solvated AlO^+ species in dilute solutions of Al^{3+} and O^{2-} in the LiCl-KCl eutectic

has a formation constant of 2.94×10^{22} . From a statistical mechanical expression for such formation constants (19)

$$K = Z[\exp(-\Delta A_1/RT) - 1] \quad [5]$$

where Z is the coordination number, one can deduce the value of the specific bond free energy, ΔA_1 , for reaction [4] (18). For a coordination number of 4, ΔA_1 is -71.74 kcal mol $^{-1}$, (for $Z = 6$, it is -71.16 kcal mol $^{-1}$), a value which is remarkably close to the quantum mechanically calculated value of -72.3 kcal mol $^{-1}$ for formation of the Al-O bond in the gas-phase reaction.

Comparison of the calculated gas-phase reaction energy with the bond energy in the melt includes a number of assumptions: (i) the solvation of AlO^+ is emulated by the vapor molecules, (ii) the differences in vibrational energy are small; the zero point vibrational energy contribution to the reaction energy is not expected to be more than about 3 kcal mol $^{-1}$ (20), and (iii) the quantity ΔA_1 is a bond free energy and could contain contributions from nonconfigurational entropy. However, measurements in molten salts indicate that such nonconfigurational contributions are small for spherical ions (19). When one considers these assumptions and the uncertainties in the reaction energies themselves, a larger difference might have been expected between the calculated gas-phase value and the molten salt value. The relatively small difference may be due to fortuitous cancellation of factors. However, the results suggest the encouraging speculation that one might predict these bond free energies reasonably well from quantum mechanical calculations of vapor molecules, if isodesmic reactions are studied.

Unfortunately, experimental data for the fluorides are not complete enough to test this speculation. However, one can calculate a lower limit for the specific bond free energy of forming an Al-O bond in the NaF, AlF_3 , Al_2O_3 ternary system. One can perform this calculation using compositional data for the ternary eutectic at 881 K between Na_3AlF_6 , NaF, and $\beta\text{-Al}_2\text{O}_3$ at the composition (in mole percent) NaF-85.8, AlF_3 -13.1, and Al_2O_3 -1.1 (1). The largest uncertainty in the calculation stems from the lack of knowledge of the solution species. If one assumes that all of the oxide ions are present as AlO^+ species, then the apparent concentration of this species will be larger than it really is. As a consequence, this species will appear to be more stable, and the specific bond free energy deduced will be a lower limit, i.e., it will be more negative than a value calculated from the exact concentration of the AlO^+ species. From available information, AlO^+ is not likely to be the major species (2) and is hence less stable than is calculated here. If we assume that essentially all the oxygen is present as this species and that the reaction

is the only significant mode of solubilization of Al_2O_3 , then the concentrations of the three solution components (in mole percent) are NaF-84.4, AlF_3 -12.4, and AlOF -3.2, and the logarithm (base 10) of the equilibrium quotient for reaction [6] is -3.57 . From this quantity combined with data from the JANAF tables (21) and the activity of AlF_3 in the melt (22), we deduce a lower limit for the standard free energy of formation of the AlOF component in solution, $\Delta G_{\text{AlOF}}^\circ/2.3025RT = -38.234$. Using this quantity as well as data for $\text{Na}_2\text{O}_{(l)}$, $\text{AlF}_{3(s)}$, (21), and for the activity coefficients for AlF_3 (22), and if we also make the reasonable assumption that $\text{Na}_2\text{O}_{(l)}$ forms an essentially ideal solution with NaF, one can deduce that the upper limit to the equilibrium constant for the reaction

is 1.236×10^9 . This is also an upper limit for the formation constant of AlO^+ . From this, we calculate a lower limit to

the specific bond free energy using Eq. [5]. For $Z = 4$, $\Delta A_1 = -44.8$ kcal mol $^{-1}$ (for $Z = 6$, $\Delta A_1 = -43.9$ kcal mol $^{-1}$). This energy is expected to be somewhat more negative in a sodium salt melt than in a lithium containing melt (4, 6). The quantum mechanically calculated energy of -31.2 kcal mol $^{-1}$ is consistent with this lower limit. (A specific bond free energy of -31.2 kcal mol $^{-1}$ is consistent with a concentration of AlO^+ species, which is a factor of 380 lower than we used in the calculation.) In any case, it can be seen that as is calculated quantum mechanically, the Al-O bond in chlorides is relatively much more stable than that in fluorides. As an added indication of the strength of Al-O bonds in the fluoride vapor species, the Al-O bond length is much shorter than that of Al-F. The Al-O bond length is 1.65Å in the $\text{Li}_2\text{AlF}_5\text{O}$ species; whereas, the Al-F bond length is 1.74Å in the same species and 1.71Å in LiAlF_4 . This occurs despite the fact that the Pauling radius of O^{2-} is 0.04Å larger than that of isoelectronic F^- .

Discussion

The concept of coulomb complexing has been proposed as a means of predicting what types of complexes might form between polyvalent cations and anions. In this concept, polyvalent cations should associate with polyvalent anions in alkali halide solvents to form coulomb complexes (4, 6). Without considering charge compensation due to rearrangements of solvent ions when the coulomb complex is formed and without considering quantum mechanical effects, one can make predictions of the energetics of such associations based on simple coulomb models. Such predictions cannot be expected to be accurate, although they do lead to the correct prediction that coulomb complexing leads to stronger Al-O bonds in chlorides than in fluorides and that the Al-O bond is stronger than the Al-S bond. In order to try to make this model more quantitative, one should compare quantum mechanical results such as ours with a variety of coulomb models in order to see what properties coulomb models would need in order to be useful. We performed calculations on a very simple coulomb model in which pairs of ions interact with a coulomb potential and a soft repulsion of the form r^{-9} ($u_{ij} = Z_i Z_j e^2 / r_{ij} + A/r_{ij}^9$, where r_{ij} is the distance between the i th and j th ion, and u_{ij} is a pair potential between them). We chose the distances deduced from our quantum mechanical results and calculated a coulomb energy change for reaction [1] of -86.4 kcal mol $^{-1}$. Obviously, the coulomb model is too simple and needs modification. There are many ways to accomplish this. For example, softening the $\text{Al}^{3+} - \text{O}^{2-}$ repulsion by use of a $r^{-3.5}$ repulsion rather than a r^{-9} repulsion would make up the difference. However, because other possible modifications to the pair potential could also accomplish this, careful examination is needed in order to test the utility of the potentials which might make the concept of coulomb complexing a useful predictive tool.

Conclusions

Quantum mechanical calculations of the energies of formation of Al-O bonds in carefully chosen vapor molecules are strikingly similar to bond free energies in a chloride melt and consistent with data in a fluoride melt. Quantum mechanical calculations of well-chosen vapor molecules may be valuable for studying the energetics of bond formation in molten salts. Comparison of the quantum mechanical calculations with a very simple coulomb model supports our expectation that such models (although able to predict the relative effects of different solvents or of different ligands complexing Al^{3+}) cannot provide reasonably accurate predictions of the energetics without further development. More sophisticated coulomb pair potentials are needed to improve the utility of such models.

ABSTRACT

Investigation of the electrochemical intercalation of lithium into several high oxidation-state transition metal compounds (V_2O_5 , V_2O_3 , V_2O_4 , and TiS_2) has been undertaken in low temperature chloroaluminate melts: $AlCl_3$ -butyl pyridinium chloride-LiCl at 60°C and $AlCl_3$ -LiCl at 175°C. The reversibility of the different steps of intercalation and deintercalation has been examined. Cycling tests have shown a good stability and capacity of V_2O_5 and TiS_2 in these molten salt media.

Transition-metal sulfides like TiS_2 , NbS_2 , TaS_2 , etc., and oxides of high oxidation state (V_2O_5 , MoO_3 , CrO_3 , V_6O_{13}) which insert alkali ions during their reduction appear to be among the most promising cathode materials in rechargeable lithium batteries (1-3). Insertion of Li^+ ion in these materials has been widely investigated in recent years. The general intercalation-deintercalation reaction in a cathodic material can be presented as follows (4)

where $[H]$ is the host structure which inserts M^+ at a variable mole ratio (concentration) x , up to a maximum value x_{max} . The reversibility of this reaction seems to be linked to the existence of only a single solid phase. This reversibility has been demonstrated in many organic solvents such as propylene carbonate (6-8), 1,2-dimethoxyethane-propylene carbonate (80%-20% PC by volume) (5), methylacetate (8), N-N-dimethylformamide (9, 10), 1,2-dimethoxyethane (9, 10), and 2-methyltetrahydrofuran (9, 10).

The compatibility between lithium metal and the organic solvent appears to be the main impediment to the

development of Li/transition metal oxide or sulfide reversible batteries. A good solution would be to use a nonorganic electrolyte. Molten salts appear to be good candidates as electrolytes for these batteries (11-14).

$LiCl$ - KCl melts have been used with $LiAl$ and $LiSi$ alloys (15-17) at operating conditions where the number of charge-discharge cycles exceeds 500 (18). $NaAlCl_4$ at 165°C also seems to be compatible with these anodic materials (19).

Molten chloroaluminates present a large liquid temperature range, and mixtures of the $AlCl_3$ - RCl type, where R is an organic cation like butylpyridinium, are liquid at ambient temperature. These media, which combine the advantages of molten salts with those of relatively low temperature, have been widely studied during recent years, particularly by Osteryoung *et al.* (21, 22).

A major problem in the utilization of these electrolytes is the compatibility of the organic cation R^+ and a strongly reducing agent like Li or $LiAl$ alloy. A solution to this problem is the use of another ternary eutectic like $AlCl_3$ - $NaCl$ - $LiCl$ or $AlCl_3$ - $NaCl$ - KCl , but these mixtures are not liquid below 80°C (23, 24).

Whatever the anodic system, the most important condition for battery electrolyte utilization is that the cathodic materials must be insoluble in the electrolyte to avoid

*Electrochemical Society Active Member.

self-discharge. This condition limits the choice of convenient molten salt electrolytes in which the solubility of certain oxides has to be taken into account. There is very little in the literature concerning this point.

In this paper, we present the first results of an electrochemical study of lithium intercalation into several materials using low-temperature chloroaluminates as electrolytes.

Experimental

Solvents.—The melts used were the following: a ternary mixture N-n-butylpyridinium chloride (31.2 mole percent [m/o]), aluminum chloride (55.5 m/o), LiCl (13.3 m/o) at 60°C, and the mixture LiCl-AlCl₃ (49.25 m/o AlCl₃, *i.e.*, LiCl saturated LiAlCl₄) at 175°C.

N-n-butylpyridinium chloride (BpCl) was prepared according to the Osteryoung *et al.* procedure (25-27). AlCl₃ (Fluka AG) was purified by vacuum sublimation in the presence of pure aluminum wire. LiCl PROLABO (France) was dried according to the following procedure: (i) the LiCl was maintained overnight at 180°C, and then for 2h at 250°C under vacuum, (ii) Pure HCl (COOP LABO) was bubbled for 3h at 250°C, (iii) argon was bubbled for 2h at 250°C, (iv) LiCl was kept under vacuum for 3h at 250°C. All products dried and purified as above were kept in an argon-filled glove box (with less than 6 ppm of water inside).

The preparation of the ternary mixture BpCl-AlCl₃-LiCl was carried out as follows: the corresponding quantity of BpCl was slowly added to the stoichiometric quantity of AlCl₃. Once the mixture was molten, LiCl was added to obtain the expected concentration.

The preparation of LiCl (saturated)-LiAlCl₄ was done by weighing appropriate quantities of LiCl and AlCl₃, and introducing the mixture in a bulb in presence of pure aluminum wire. The bulb was sealed under vacuum and held at 240°C for 8h. After the melting of the mixture, the bulb was taken out of the furnace and the melt separated from the aluminum wire. The molten salt was allowed to crystallize slowly in the bulb and afterwards kept in an anhydrous argon-filled glove box. All weighings were carried out in the argon-filled glove box.

Products.—Oxides were Alfa-Ventron products. They were used without further purification and stored in a dry atmosphere.

The graphite for the working electrodes was supplied by Koch-Light (purity: 99.99%).

After some preliminary work with commercially supplied TiS₂ (Ventron), it was found that the material was not sufficiently pure, and, therefore, this compound was prepared and purified as follows.

TiS₂ was prepared by direct synthesis from the elements [Koch-Light titanium sponge (99.9%) and sulfur powder 99.99%]. 1% excess sulfur was used. The tube was placed in the oven in order to create a slight temperature gradient. The temperature was progressively increased from 200° to 550°C. On cooling, the excess sulfur gives a small amount of TiS₃ at the lower temperature end. The disulfide obtained by this method under a small sulfur pressure has the TiS_{1.988} stoichiometry determined by calcination.

The working electrode consisted of a platinum grid of 1 cm diam with a finely powdered mixture of the cathodic active materials and graphite (50% by weight). 10-16 mg of this mixture were pressed under 5 ton/cm² for 5 min over platinum grid. These electrodes were dried and sintered under vacuum at 220°C for 3h, then kept in an inert atmosphere of argon.

Important fluctuations in the results are observed when the content of the active material was higher than 50%, probably due to a bad contact between the graphite and electrode active material. Similar results were obtained by Tranchant and Messina (5, 6).

Aluminum wires were used as the reference and the auxiliary electrodes.

Experimental technique.—Experiments were performed using 25 ml of electrolyte and a three-electrode galvanostatic device permitting the control of the current during the determination of discharge-charge curves (potentiostat Tacussel PRT 10-0.05 L).

The electrode potential values were measured with a Tacussel Minisis 6000 millivoltmeter connected to a Tacussel EPL 1 potentiometric register.

All the experiments were carried out under argon in a dry glove box.

Voltage range.—It was determined by cyclic voltammetry that the available voltage range of the AlCl₃-BpCl-LiCl mixture, at 60°C, at a graphite disk microelectrode, lies between -0.03 and 2.0V with respect to the aluminum reference electrode (in the same medium). The potential range in LiAlCl₄ at 175°C is nearly the same (0.0-1.9V).

The galvanostatic curves without active material (*i.e.*, with only graphite in the electrode), recorded under identical operating conditions as those employed for discharge-charge voltage curves at constant current, have shown that no reduction or oxidation occurs in these voltage windows, either in BpCl-AlCl₃-LiCl at 60°C or in LiCl-saturated LiAlCl₄ at 175°C.

Results and Discussion

V₂O₅ in BpCl (31.2)-LiCl (13.3)-AlCl₃ (55.5 m/o).—The reduction of V₂O₅ with insertion of Li⁺ ion (that is, the electrochemical intercalation of lithium ion into V₂O₅) in BpCl-AlCl₃ + LiCl has been studied by voltammetry and by galvanostatic discharge-charge experiments.

The discharge curves of electrodes made of 50% graphite-50% V₂O₅, at various current densities and at 60°C, are reported in Fig. 1. Curve 4 shows that the reduction process implies the Li⁺ insertion: an electrode polarization appears at the beginning of the discharge when no Li⁺ ions are present in solution.

At low current densities (0.1 mA cm⁻²), the reduction proceeds in three steps. The first one begins at a potential value of about 1.2V (*vs.* Al) and needs about 1 F/mol of V₂O₅. At the end of this process, the oxidation state of vanadium is about 4.5. The second reduction process, which occurs at 0.3V, shows a large voltage plateau. It needs also 1 F/mol of V₂O₅. The last step appears at approximately 0.05V with another voltage plateau. At the end of this process, the mean oxidation state of vanadium is around 3.75.

The same three reduction steps were observed at a higher current density (0.5 mA cm⁻²). These results are in good agreement with previously reported results dealing with the electrochemical reduction of this oxide in organic solvent at ambient temperature.

The reversibility of the different processes has been studied by successive discharge-charge cycles at 0.5 mA cm⁻² for different discharge voltage cutoffs.

Figure 2a shows the results when the discharge was performed on the largest potential range (between 1.90

Fig. 1. V₂O₅ galvanostatic discharge at different current densities in BpCl (31.2)-LiCl(13.3)-AlCl₃(55.5 m/o) at 60°C (curves 1, 2, and 3) and in BpCl (45.5)-AlCl₃(55.5 m/o) (curve 4).

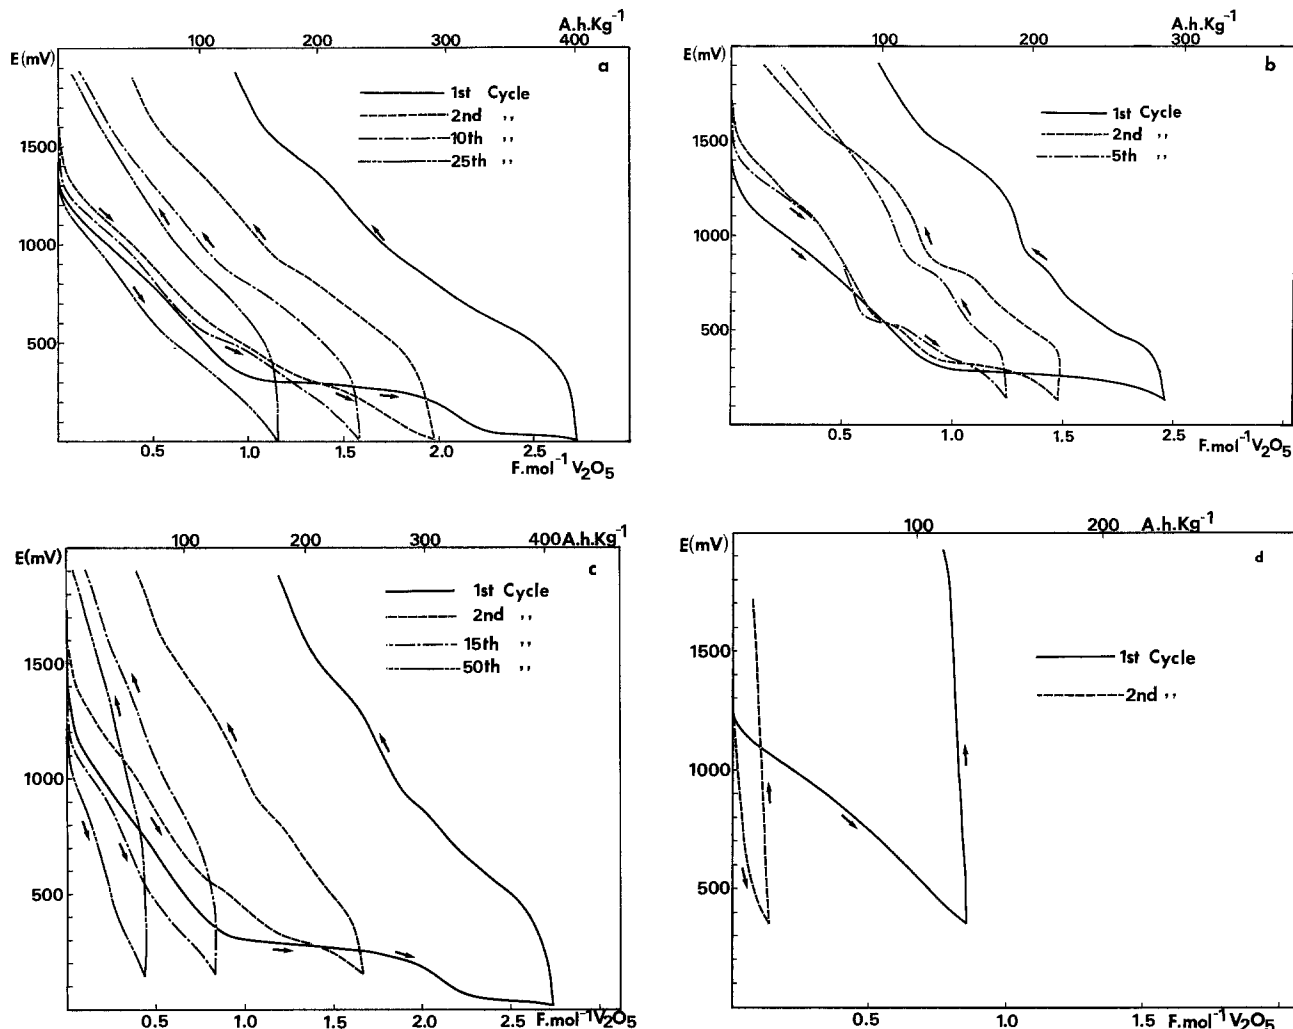

Fig. 2. Discharge-charge cycle of V_2O_5 in $BpCl(31.2)-LiCl(13.3)-AlCl_3(55.5 \text{ m/o})$ at $60^\circ C$, 0.5 mA cm^{-2} . Voltage cutoff: (a) 0.00 V , (b) 0.15 V , (c) 0.15 V , after a first discharge at 0.00 V voltage cutoff, and (d) 0.35 V .

and 0.00 V vs. Al). Cycling transforms the material, and the first cycle appears very different from the following ones. The large voltage plateau observed during the first discharge at 0.30 and 0.05 V have almost disappeared in the second cycle and completely in the following ones. Another modification was observed after the first cycle. The first part of the curve, between 1.90 and 0.3 V was divided into two steps at around 1.3 and 0.5 V .

The yield of the second cycle is 70% - 80% of the first discharge capacity. The decrease of yield becomes smaller after the second cycle and 95% - 99% of the preceding discharge capacity was obtained.

The nature of the phenomena was not greatly changed when the discharge voltage cutoff was raised to 0.15 V (Fig. 2b). However, the different reduction steps were better developed in the cycles following the first one up to 0.15 V . The yield of the second cycle is 70% - 75% of the first discharge capacity, and the following ones are 90% - 98% of the immediately preceding discharge capacity.

The successive discharge-charge cycles in the voltage window 1.90 - 0.15 V vs. Al are shown in Fig. 2c (after carrying out the first cycle at the discharge voltage cutoff of 0.00 V). Around 80% of the faradaic capacity of the first discharge is recovered at the second one. The yield is between 90% and 96% of the preceding discharge for the 15 following cycles, and very close to 100% thereafter.

These results suggest that the reduction step at 0.05 V does not significantly affect the cycling process. On the contrary, important changes appear when the discharge voltage cutoff was fixed at 0.35 V , which is before the first large voltage plateau. Then, the total amount of Li^+

ion inserted during the first reduction could not be recovered by the subsequent recharge process (Fig. 2d).

The normal capacity of 1 F/mol was recovered only when the first cycle was complete, from 1.90 to 0.00 or 0.15 V . The yield is then 95% for the third cycle, and 97% - 100% of the capacity of the immediately preceding discharge for the following cycles (Fig. 3).

V_2O_4 and V_2O_3 in $BpCl-LiCl-AlCl_3$.—Vanadium (IV) and (III) oxides have also been investigated in $BpCl(31.2)-LiCl(13.3)-AlCl_3(55.5 \text{ m/o})$.

The electrochemical reductions of V_2O_3 and V_2O_4 at 0.5 mA cm^{-2} take place, respectively, at 0.80 and 0.95 V at higher potentials than the V_2O_5 reduction step. Conse-

Fig. 3. Galvanostatic discharge capacity (percentage of the initial recovered capacity) of V_2O_5 as a function of the cycle number in $BpCl(31.2)-LiCl(13.3)-AlCl_3(55.5 \text{ m/o})$. $J = 0.5 \text{ mA cm}^{-2}$. $T = 60^\circ C$.

Fig. 4. V_2O_4 discharge-charge cycle at 0.5 mA cm^{-2} in $\text{BpCl}(31.2)\text{-LiCl}(13.3)\text{-AlCl}_3$ (55.5 m/o). $T = 60^\circ\text{C}$.

quently, the formation of V_2O_4 or V_2O_3 during the electrochemical reduction of V_2O_5 must be excluded.

Successive galvanostatic discharge-charge curves for V_2O_4 (Fig. 4) show that the cycling behavior of this material is reversible. The second discharge yield is 84% of the first cycle, and the following cycles recover 96%-100% of the capacity of their immediately preceding cycle. So, 77% of the faradaic capacity of the second discharge is recovered at the 17th cycle. However, this capacity is rather low, so that this material appears to be of little interest as reversible cathodic material.

In contrast, V_2O_3 behaves irreversibly, and a very small part of the initial faradaic capacity is recovered during the second cycle.

V_2O_5 in LiCl (saturated) LiAlCl_4 .—Attempts to electrochemically reduce V_2O_5 in LiCl (saturated) LiAlCl_4 at 175°C have failed because of the strong oxidizing power of V_2O_5 at this temperature. We have observed a chemical oxidation of LiAlCl_4 with chlorine evolution.

TiS_2 in $\text{BpCl}(31.2)\text{-LiCl}(13.3)\text{-AlCl}_3$ (55.5 m/o).—Electrochemical reduction of TiS_2 with Li^+ insertion was investigated in the $\text{BpCl-AlCl}_3\text{-LiCl}$ melt by voltammetry and galvanostatic reduction. Characteristic discharge curves at various current densities are represented in Fig. 5. For current densities between 0.1 and 2.5 mA cm^{-2} , the experimental curves show a horizontal plateau at 0.40 V (*vs.* Al reference electrode). The capacity is near to 1 F/mol at low current density.

As expected, the discharge curve obtained in BpCl-AlCl_3 (55.5 m/o) at 60°C , without Li^+ ions (curve 4), shows an important polarization similar to that of V_2O_5 . This confirms that the electrochemical process involves Li^+ intercalation.

Charge-discharge cycles have been performed for a current density of 0.5 mA cm^{-2} in the voltage window $1.60\text{-}0.00 \text{ V}$. Results are reported in Fig. 6. The general shape is the same for all curves. The faradaic capacity at the first discharge is about 0.86 F/mol of TiS_2 . 92%-96% yield is obtained in the second cycle, and the following discharges give between 96% and 100% yield with respect to the immediately preceding discharge. Figure 8 shows that the recovered capacity after 50 cycles is about 40% of the initial capacity. The reversibility of the process is rather good, and the aspect of the curves shows that TiS_2 behaves towards Li^+ ions in this medium in a way comparable to other (organic) media.
