Methods to Improve Electrochemical Reversibility at Carbon Electrodes

Department of Chemistry, Indiana University, Bloomington, Indiana 47405

ABSTRACT

Carbon electrodes are frequently used for electroanalytical studies of oxidizable compounds. However, for many compounds, heterogeneous charge-transfer rates are very slow at carbon electrodes, leading to ill-defined voltammograms. Ascorbic acid (vitamin C) is perhaps one of the best examples of such phenomena, with a peak potential that is approximately 350 mV more positive at most carbon surfaces than at mercury electrodes. Ferricyanide also exhibits voltammetry at carbon electrodes that is less reversible than at noble metal electrodes. Various electrode surface treatments have been employed to accelerate the rates of ascorbate and ferricyanide electrolysis. Pretreatment of carbon fiber electrodes with a high current density results in a significant shift of the voltammetric waves for both compounds to potentials where they are more easily electrolyzed. Similar results are obtained with glassy carbon surfaces that have been heated at 500°C under reduced pressure. An alternate method to increase reversibility is the judicious use of polishing procedures. Thus, it appears that the surface properties of carbon electrodes can have profound effects on the observed voltammetry.

Carbon electrodes are widely used in electroanalytical applications because of the very low residual current over the large potential range accessible in aqueous solution. Several different types of carbon have been employed, including wax impregnated graphite rods (1), carbon powder bound with an inert, viscous liquid [carbon paste, Ref. (2)], glassy carbon (3), pyrolytic graphite (4), and carbon fibers (5). These electrodes have been used in applications as diverse as measuring diffusion coefficients, understanding oxidation mechanisms of organic compounds, and trace analysis (6).

At all of these types of carbon electrodes, very few molecules show diffusion-controlled electrochemical behavior in aqueous solutions, even at the relatively slow scan rates usually employed in voltammetry with conventional X-Y recorders (less than 500 mV s⁻¹). Therefore, the various factors that control charge-transfer processes at carbon electrodes must be considered. In addition to the inherent electron-transfer rates of the molecules being considered, it is also necessary to recognize that the surface of carbon has a rich chemistry of its own (7) that may well affect the observed electrochemistry (8). Charge-transfer rates at the basal plane of cleaved, highly oriented graphite are impaired for several redox couples (8-10). Since microscopic sites of basal orientation may occur on isotropic carbons, the effect of these sites could be convoluted with the observed electrochemistry. At carbon paste electrodes, a decrease in the apparent electrochemical reversibility is observed with an increase in concentration of the pasting liquid. This decrease in reversibility has been attributed to a decrease in sites for electron transfer at the electrode surface (11, 12). An equally important parameter appears to be the degree of oxidation of the carbon surface (13).

In this paper, the relative rates of electron transfer at carbon and metallic electrodes are compared for two different redox systems. The systems studied are ferricyanide, a one-electron, outer-sphere reduction, that has been well characterized previously, and ascorbate, a two-electron oxidation that also involves a proton transfer. It will be shown qualitatively that the rates of these processes are much slower at many forms of carbon than at metallic electrodes, but that these rates can be accelerated by a variety of surface treatments. Faster rates of electron transfer result in well-defined voltammetric behavior. This leads to greater resolution of voltammetric waves, an advantageous feature for chemical analysis.

Experimental

Reagents.—All chemicals were reagent grade and used as received from commercial sources. Ascorbic acid was

*Electrochemical Society Student Member.

Key words: carbon electrodes, carbon fibers, oriented graphite, glassy carbon.

studied in a buffer containing citrate and phosphate (9.2 mM, 181.6 mM, pH 7.4). The reduction of ferricyanide was studied in 0.5M K₂SO₄ or KCl solutions that were adjusted to neutral pH. All solutions were prepared with water distilled in glass from alkaline permanganate and were purged thoroughly with nitrogen before use.

Electrodes and instrumentation.—Carbon paste was prepared by thoroughly mixing carbon powder (UCP-1-M, Ultra Carbon, Bay City, Michigan) with Nujol (20% by weight). The electrode was formed by press fitting a copper rod through a Teflon tube, and packing the well at the end with the carbon paste. Vapor-deposited, pyrolytic graphite-coated disks (1 mm thick) also were obtained from Ultra-Carbon. The disks were fabricated into electrodes with the use of heat-shrinkable Teflon so that only the face of the disk was exposed to the solution. The surfaces were not polished. Electrical connection was made with mercury on the interior of the electrode assembly.

Electrodes fabricated from low-modulus carbon fibers (AS4-6K, Hercules) were constructed by inserting a single carbon fiber in a glass capillary, tapering the glass around the fiber with a commercial pipet-puller (David Kopf Instruments), and sealing the fiber to the glass by carefully placing a drop of epoxy at the end of the glass so that it entered the tube by capillary action. This was done so that the carbon fiber that extends beyond the glass was not coated. Electrodes prepared in this manner have the geometry of a cylinder of micrometer dimensions. Because of their geometry and very small size, voltammograms exhibit a significant contribution from cylindrical diffusion effects.

Experiments which employed carbon-fiber, carbon-paste, and pyrolytic graphite electrodes were conducted in an electrochemical cell fabricated from a 25 ml beaker. All experiments employed a commercial potentiostat (Model 174A, Princeton Applied Research Corporation).

Pressure annealed pyrolytic graphite (PAPG), a highly oriented graphite, was a gift from Union Carbide. This material is sufficiently well oriented that a new basal plane can be exposed by removing the existing one with adhesive tape. Glassy carbon (GC-20, Tokai, Japan) was polished successively with 5.0, 3.0, and 0.05 μm alumina until a mirror finish was obtained. Sheets of the PAPG and the glassy carbon were cut into 2.5 × 0.8 cm rectangles. The rectangles were used as the floor of a cell fabricated from plexiglass and the area (0.0381 cm²) of the electrode exposed to the solution was defined by a polyethylene gasket between the plexiglass and carbon. The upper part of the cell contained the auxiliary and reference electrodes.

Results

Reduction of Fe(CN)₆³⁻ at different forms of carbon.—The negatively charged ion, Fe(CN)₆³⁻, is reduced

in an outer-sphere mechanism. Several investigators have studied its heterogeneous electrochemistry (14-21), and the reaction rate has been found to depend on the electrolyte composition. The reaction rate is greatest in solutions containing potassium ions (17), and the effect of anions on the rate is rather small (18). The results presented here for the reduction of $\text{Fe}(\text{CN})_6^{3-}$ have been obtained in 0.5M K_2SO_4 in order to optimize the solution conditions. Under these conditions, the peak separation for the cathodic and anodic scans (ΔE_p , a measure of the rate of the heterogeneous reaction) at platinum is approximately 70 mV for the cyclic voltammograms of $\text{Fe}(\text{CN})_6^{3-}$. However, increased peak separations are observed at glassy carbon (170 mV), the edge plane of PAPG (190 mV), and carbon paste (380 mV) (Fig. 1). These results were obtained at neutral pH, where differences between platinum and carbon electrodes are more pronounced than in acidic solutions. The greatest peak separation is obtained at the basal plane of PAPG (710 mV). Thus, at all of the unmodified carbon surfaces, the reduction of $\text{Fe}(\text{CN})_6^{3-}$ is significantly slower than at platinum with the slowest rate obtained at the basal plane of PAPG.

Oxidation of ascorbate at carbon electrodes.—The oxidation mechanisms of ascorbic acid and its optical isomer, d-araboascorbic acid, have been studied extensively at gold and mercury electrodes (22-25). At pH 7.4 the oxidation involves the loss of two electrons and one proton. Although the oxidation is chemically irreversible (the oxidized form is rapidly hydrated), the oxidation process is not kinetically hindered at mercury electrodes (Fig. 2). In contrast, the oxidation of ascorbate at glassy carbon is electrochemically less reversible, as characterized by a very drawn-out oxidation wave whose peak is found approximately 350 mV more positive than that observed on mercury. At carbon paste, low-modulus carbon fibers, and the edge orientation of PAPG, the voltammetric peak for the oxidation of ascorbate lies at similar potentials as that of glassy carbon. At pyrolytic graphite the oxidation of ascorbate is even more electrochemically irreversible.

Effects of electrochemical treatments.—Electrochemical treatments can be used to improve the electrochemical reversibility at carbon electrodes (9, 26, 27). For example, electrolysis of the basal plane of PAPG causes an increase

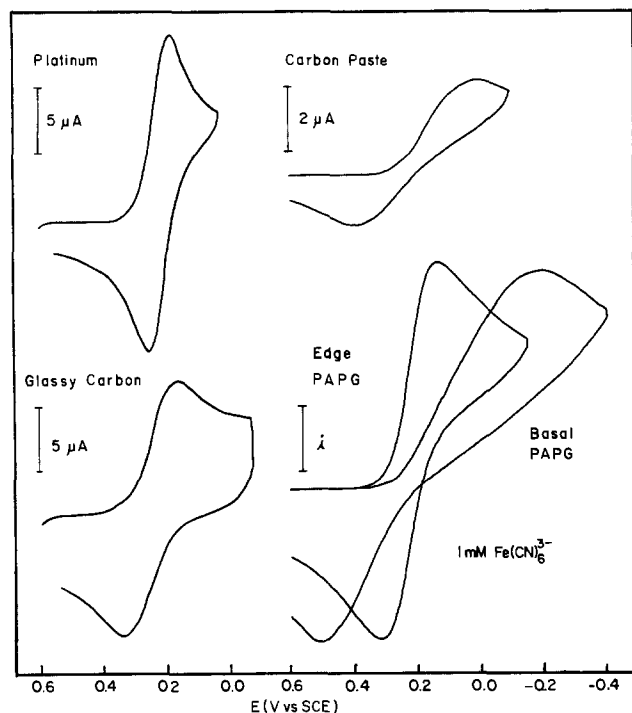

Fig. 1. Cyclic voltammograms of ferricyanide at platinum, carbon paste (20% Nujol), glassy carbon (Tokai GC-20), and pressure-annealed pyrolytic graphite (PAPG, Union Carbide). Conditions: scan rate 0.100 V s^{-1} , $1 \text{ mM Fe}(\text{CN})_6^{3-}$, and $0.5 \text{ M K}_2\text{SO}_4$ neutral solution.

in the degree of electrochemical reversibility for the reduction of $\text{Fe}(\text{CN})_6^{3-}$ (Fig. 3) and the oxidation of ascorbic acid (Fig. 4). The electrolysis treatment used in this case is relatively mild ($E_{\text{app}} = +1.4 \text{ V vs. SCE}$ in citrate buffer, pH 5.2, 8 mA cm^{-2} current density, 20 min). Background scans of the treated electrodes have not shown peaks near 0.2V, usually attributed to quinone functional groups on the surface. This method has been used to fabricate an electrode surface that is useful as an amperometric liquid chromatography detector (10). Identical electrochemical reversibility is obtained with pyrolytic graphite disks after they have been exposed to a RF plasma (28), a treatment that has been shown to shift ascorbate oxidation to that observed on the edge orientation. However, with the basal plane of PAPG or with pyrolytic graphite, these

Fig. 3. Cyclic voltammograms of ferricyanide at the basal plane of PAPG (curve a) fresh surface (curve b) after 15 min electrolysis at $+1.5 \text{ V}$. Conditions: scan rate 0.100 V s^{-1} , $2 \text{ mM Fe}(\text{CN})_6^{3-}$, $0.5 \text{ M K}_2\text{SO}_4$, pH 3.0.

Fig. 4. Cyclic voltammetry of ascorbic acid (AA) at pressure-annealed pyrolytic graphite (PAPG) (curve a) at the basal plane before electrolysis (curve b) at the basal plane after 20 min electrolysis at +1.4V, and (curve c) at edge-oriented PAPG. Conditions: scan rate 0.100 V s^{-1} , 1.0 mM AA , $\text{pH } 7.4$.

mild surface treatments are only able to give electrochemical reversibility that is comparable to that observed at carbon paste or the edge orientation of PAPG. Both the plasma and electrochemical treatments on these types of carbon give an increased amount of surface roughness (10, 13, 29), and thus an increased amount of edge orientation exposed to the solution.

The small surface area of carbon fibers permits much greater current densities to be applied to these electrodes. Exposure to high current densities (2 A/cm^2) leads to an increase in surface functionalities (30), and a decrease in the interior order of the fibers (31). However, this type of treatment has been shown to increase the electrochemical reversibility of several compounds, including the catecholamines (32). The voltammetric wave for the oxidation of ascorbate is shifted to the potential where it occurs on mercury electrodes (Fig. 5). This treatment also causes an increase in the electrochemical reversibility for the reduction of $\text{Fe}(\text{CN})_6^{3-}$ (Fig. 5). The change in shape of the voltammogram from sigmoidal to peaked is either a reflection of the greatly altered microscopic area of the electrode or an increase in the amount of adsorption.

Effect of polishing procedures.—Carbon materials, such as low-modulus carbon fibers, the basal plane of PAPG, and pyrolytic graphite, can be used without preparation of the surface. Thus, electrochemistry at these surfaces reflects the properties of the carbon that were determined during its manufacture. In contrast, the response obtained at glassy carbon surfaces is highly dependent on the manner in which the surface is prepared (3). Most investigators polish the surface to a mirror-like surface using a fine grade of alumina. A highly polished surface is found to have low residual current, resulting in a more usable electrode for analytical applications. However, surface analysis has shown that the polishing material may be embedded in the surface (33), and this may affect the electrochemical results.

Previously, it has been shown that certain polishing procedures can provide more reversible electrochemical

Fig. 5. Cyclic voltammetry of ascorbic acid (above) and ferricyanide (below) at low-modulus carbon fiber (curves a) untreated carbon fiber (curves b) electrolyzed carbon fiber ($0 - +3.0\text{V}$, 70 Hz , 20s , $+1.5\text{V } 20\text{s}$). Conditions: scan rate 0.100 V s^{-1} , 0.2 mM AA , $1 \text{ mM Fe}(\text{CN})_6^{3-}$, $\text{pH } 7.4$.

behavior. For example, glassy carbon electrodes prepared by polishing the electrode with α -alumina (1 μm particle size) exhibit a shift in the oxidation wave for ascorbate in pH 7.0 buffer to the potential observed on mercury (34). X-ray photoelectron spectroscopic and electron microscopic examination of the surface show that this treatment embeds the alumina on the surface. This alumina-coated surface is highly efficient at adsorbing organic species which leads to the observed increase reversibility of oxidation. The rate of reduction of $\text{Fe}(\text{CN})_6^{3-}$ at glassy carbon electrodes can be increased by polishing with alumina using high rotation speeds [1500 rpm, Ref. (35)].

The effects of polishing procedures can be minimized if the electrode surface is carefully cleaned before use. The use of ultrasonic cleaning (34) or soxhlet extraction of the electrode surface have been found to be effective. For glassy carbon that has been hand polished with 0.05 μm alumina, no change is observed in the reduction of $\text{Fe}(\text{CN})_6^{3-}$ on freshly polished surfaces or surfaces that have been polished and extracted in toluene ($\Delta E_p = 160$ mV at 100 mV/s scan rate, 0.5M K_2SO_4 , pH 7.4). Electrochemistry at surfaces prepared in this manner is very similar to that obtained at the edge orientation. Soxhlet extraction of glassy carbon electrodes in a more active solvent does affect the reversibility: the use of methanol results in a large increase in the reversibility of $\text{Fe}(\text{CN})_6^{3-}$. Thus, for voltammetric studies with glassy carbon, the electrode has been refluxed in toluene subsequent to surface polishing with 0.05 μm alumina, and this has been used as the control surface with which comparisons of reversibility can be made with carbon surfaces treated by alternate means.

Recent investigations in our laboratory have shown that increased rates can be obtained at glassy carbon surfaces that have been polished with diamond paste and subsequently soxhlet extracted with toluene. The reversibility of both $\text{Fe}(\text{CN})_6^{3-}$ and ascorbate is improved over that obtained at the control electrode (Fig. 6). A large shift is seen for the oxidation of ascorbate, but the effect on $\text{Fe}(\text{CN})_6^{3-}$ is less pronounced. Adsorption is not evidenced for the compounds tested. The surface gives reproducible behavior for repeated scans.

Heat-treated carbon surfaces.—Heat-treatment of glassy carbon surfaces (36) or carbon fibers significantly improves the observed electrochemical reversibility. The carbon to be treated is heated to 500°C under 1 torr of vacuum for two or more hours. As with the electrodes pol-

ished with diamond paste, a drastic improvement in reversibility is observed. This is illustrated for the oxidation of ascorbate at a carbon fiber electrode in Fig. 7.

The heat-treatment produces identical results at glassy carbon. The heat-treatment only involves a surface change since abrading the carbon surface eliminates the effects of heat-treatment. The effects of the heat-treatment are long lasting both in solution and when exposed to the laboratory atmosphere. Surface analysis of heat-treated glassy carbon using x-ray photoelectron spectroscopy shows only a small change in the C_{1s} region of the spectrum (Fig. 8). These changes presumably reflect a change in oxygen binding to the surface; however, they are too small for quantitative information. Examination of the surface with electron microscopy reveals no change in the surface morphology.

Discussion

The data in this paper clearly show that the degree of electrochemical reversibility for the compounds tested at carbon electrodes is highly dependent on the surface state of the carbon. Differences are very profound between the edge and basal plane of PAPG. Mild electrochemical treatment of the basal plane results in a surface that yields electrochemistry comparable to the edge orientation. Slow rates are also found at the pyrolytic disks; however, the rates can be accelerated by electrochemical or RF etching procedures. Since all of these treatments roughen the surface, with a corresponding increase in edge orientation, the data suggest that charge transfer is severely impaired at the basal plane, and that the presence of sites of edge orientation is necessary for electron transfer to occur. The slow rate of electron transfer at the basal plane may have several different origins. One that has been proposed is that the basal surface is hydrophobic, and thus wetting of the electrode by aqueous solutions is impaired (37). The edge orientation is formed by cleaving carbon-carbon bonds. If this is done in air or aqueous solutions, oxygen containing functional groups can be formed on the surface, resulting in a more polar surface than the basal plane (8).

Isotropic carbons such as carbon paste, low-modulus carbon fibers, and glassy carbon all show electrochemistry that is similar in degree of reversibility to that obtained at the edge orientation. With carbon paste, the interpretation of the results is complicated, since the degree of reversibility is affected by the pasting composition (12).

Fig. 6. Cyclic voltammetry of ascorbic acid (left) and ferricyanide (right) at glassy carbon. Curves a: control. Curves b: after polishing with 1 μm diamond paste and extracting in toluene 2h. Conditions: scan rate 0.100 V s^{-1} , 0.2 mM AA, 1 mM $\text{Fe}(\text{CN})_6^{3-}$, pH 7.4.

Fig. 7. Oxidation of ascorbic acid at carbon fiber. Curve a: untreated carbon fiber. Curve b: after 4.5h heat-treatment at 540°C under reduced pressure, cooled in air. Conditions: scan rate 0.100 V s⁻¹, 0.20 mM AA, pH 7.4.

However, even with a dry paste, the rate for Fe(CN)₆³⁻ reduction is much slower than that observed at platinum electrodes (13, 35). Mild electrochemical treatments, which accelerate the observed rates on the basal plane of PAPG and on pyrolytic graphite, do not affect the rates at glassy carbon. Rather, it appears that the mild electrochemical treatments simply alter the morphology of the basal plane so that electrochemical results are obtained which are similar to the isotropic carbons. Electrochemical rates are found to be slower on the cylindrical axis of high modulus carbon fibers when compared to low-modulus carbon fibers (data not shown). This may arise because high modulus fibers have a greater degree of basal character on the cylindrical axis than the low modulus fibers.

Thus, to increase electrochemical reversibility at carbon, it appears that an important step is to increase the

availability of edge orientation. However, this approach reaches a limit, defined by the nature of edge orientation. The rates observed at edge-oriented carbon are slower than at metal electrodes for both of the compounds tested, which have very different electrolysis mechanisms. As shown, other changes which favorably affect the electrochemistry can also be accomplished, at least for the compounds examined here. Heat-treatment, high current density, and certain polishing techniques all significantly increase the rates that are observed at carbon electrodes. Rates at some treated surfaces approach those observed on metal electrodes. Polishing and the application of a high current density both evolve heat. Thus, these results may have a common origin. It is established that these surface treatments alter the chemical nature of the functional groups on the surface (31, 38). This may be the cause of the increased reversibility. For example, the removal of carboxyl groups would be expected to enhance the rate of the negatively charged compounds examined in this study. Surface spectroscopy (Fig. 8) does not indicate a loss of oxygen functionalities. However, spectral resolution of surface oxides in this experiment is poor. Alteration of surface sites would certainly produce changes in the double layer structure. These variations which can affect surface hydrophobicity or the double layer potential could play a dominant role in the variation of observed rate constants at carbon surfaces. Future studies of the nature of the physical and chemical nature of the surface of these carbon materials will be required to understand the origin of these results.

ABSTRACT

The maximum quantity of bulk Hg(0) which can exist on the surface of a gold electrode in acidic media corresponds to a coverage of $\theta_{\text{Hg}(0)} = 1$. Deposited Hg(0) in excess of this quantity diffuses into the Au substrate to form a bulk Au-Hg alloy; however, no alloy is formed until $\theta_{\text{Hg}(0)} = 1$. The potential for the stripping peak of the Au-Hg alloy is positive of the peak potential for the stripping of bulk Hg(0) by ca. 0.4V. The diffusion rate for Hg in the Au-Hg alloy is sufficiently slow so that the alloyed Hg is never totally stripped under the usual condition of cyclic voltammetry. Evidence is also given for the formation of Hg(I) adions during the underpotential deposition process for which $n_{\text{app}} = 1.6 \text{ eq mol}^{-1}$.

The underpotential deposition and stripping (UPD and UPS) of the equivalent of up to a monolayer of Hg adatoms/ions at Au electrodes in acidic media has been studied by Sherwood and Bruckenstein (1) and Lindstrom (2). The apparent number of electrons, n_{app} , involved in the formation of the adlayer was determined from ring-disk experiments to be 1.8 eq mol^{-1} (1). Several anodic peaks are observed for the UPS of the complete adlayer of Hg, which is consistent with the conclusion that more than one surface state exists for the deposited Hg, even in the first single adlayer. For a very small quantity of UPD Hg, e. g., $\theta_{\text{Hg}} < 0.1$, a single, sharp, anodic stripping peak is obtained at a potential difference (ΔE) of approximately 0.5V with respect to the stripping peak for bulk Hg(0). The value of n_{app} for $\theta_{\text{Hg}} < 0.1$ was determined in our laboratory by flow-injection coulometry to be 1.6 eq mol^{-1} (3), which is in reasonable agreement with the

value reported for the full ad layer by Sherwood and Bruckenstein (1). The energy of stabilization for the initial UPD of Hg on Au, i. e., $\Delta G_{\text{stab}} = -n_{\text{app}} F(\Delta E)$, is estimated to be $18.4 \text{ kcal mol}^{-1}$ for $n_{\text{app}} = 1.6$. The value of $n_{\text{app}} = 1.6$ corresponds approximately to a closest-packed model for the product of UPD in which Hg(I) is coadsorbed with Hg(0) in the ratio 1:2 (3). Accordingly, each Hg(I) is bound in a cluster with six Hg(0) adatoms and each Hg(0) is bound to three Hg(I) adions and three other Hg(0) adatoms. The UPD of Hg clusters having mixed oxidation states for $\theta_{\text{Hg}} < 0.1$ has not been proved; however, evidence for the existence of Hg(I) adions as proposed in this model is presented here. The UPD and UPS of Hg in the adlayer at low surface coverage has been the basis of quantitative determinations of Hg(II) at the ppb level and below (4-6).

The area under the combined anodic peaks for the UPS of Hg at a freshly polished Au rotating-disk electrode (Au RDE), on which bulk Hg(0) is deposited under conditions of cyclic voltammetry, is observed to increase with scan number. Furthermore, the ratio of the integrated anodic and cathodic charges (Q_a/Q_c) becomes constant only after many successive triangular potential scans; however, the ratio is always less than 1.0. We report here the results of a study of this phenomenon by cyclic voltammetry at an Au RDE and an Au, coulometric, flow-through electrode.

Experimental

Instrumentation.—The Au ring-disk electrode (Model DT6; R_1 , R_2 , and $R_3 = 0.382$, 0.399 , and 0.422 cm respectively; $\beta^{2/3} = 0.352$; $N = 0.177$) and a Model MSR rotator were from Pine Instrument Company, Grove City, Pennsylvania. The electrode was polished according to customary metallographic procedures using $1.0 \mu\text{m}$ alumina on Buehler microcloth. The electrolysis cell was of a conventional design with a miniature calomel reference electrode (no. 476017), Corning Scientific Instruments, and a Pt-wire counterelectrode. All potentials are given with respect to this reference electrode (V vs. SCE). Nitrogen was dispersed through the solutions in the cell to remove dissolved O_2 prior to voltammetric studies, and an inert atmosphere was maintained over the solution during experimentation. The potentiostats (Models RDE-2 and RDE-3) were from Pine Instrument Company, and the X-Y recorder (Model 7035B) was from Hewlett Packard Instruments. The Au flow-through electrode for flow-injection coulometry has been described previously (3). All work with this electrode was performed under O_2 -free conditions within a dry box which was flushed with N_2 for 24h prior to experimentation.

Chemicals.—All chemicals were Analytical Reagents from Mallinckrodt, Incorporated, or Fisher Scientific Company. The supporting electrolyte was 2.0M HNO_3 , 1.0M H_2SO_4 , or 0.1M HClO_4 . Standard solutions of Hg(II) were prepared by slow dissolution of the triply distilled metal in warm nitric acid, followed by stepwise dilutions with supporting electrolyte. All water was triply distilled with demineralization after the first distillation; the second distillation was from an alkaline solution of KMnO_4 .

Results and Discussion

Cyclic voltammetry at the Au RDE.—Results were virtually identical for the three acidic solutions investigated, and only representative data are shown. Current-potential (I-E) curves obtained at the Au disk of the RRDE and shown in Fig. 1 are characteristic of the changes in voltammetric response observed for a freshly polished Au electrode with consecutive triangular scans of applied potential in $1.0 \times 10^{-4}\text{M}$ Hg(II) . Bulk Hg(0) is stripped from the electrode on the positive sweep at 0.4V (peak A) by the reaction $\text{Hg(0)} \rightarrow \text{Hg(I)} + e$, i.e., $n = 1$ (1, 2). The anodic current observed in the range $0.45\text{--}1.00\text{V}$ for the UPS corresponds to stripping of Hg stabilized by interaction with the Au substrate to produce Hg(II) , i.e., $n = 2$ (1, 2). The cumulative area of the stripping peaks in the range $0.45\text{--}1.00\text{V}$ increases for successive triangular scans, finally becoming constant after 10-20 scans. Whereas several anodic peaks can be observed for UPS of the complete adlayer, i.e., $\theta_{\text{Hg}} \cong 1$ (1-3), these peaks cannot be discerned in comparison to the very large single peak (B) when bulk Hg(0) has been deposited.

The majority of the current for peak B is tentatively concluded to correspond to the stripping of Hg from a bulk Au-Hg alloy, which is formed within the electrode following deposition of a large quantity of bulk Hg(0) at $E < 0.4\text{V}$. When the I-E curves obtained for the Au RDE had become reproducible (ca. 20 triangular scans) the electrode was electrochemically stripped of deposited mercury by application of the triangular waveform of applied potential for approximately 15 min in a solution of supporting electrolyte without added Hg(II) . The electrode was then returned to the solution used for producing Fig. 1 and successive I-E curves were recorded. The curve for the first scan contained peak B with an area nearly equivalent to the reproducible value obtained after 20 scans in the previous experiment which produced Fig. 1. If the electrode was polished after stripping in the supporting electrolyte, the area of peak B in the succeeding I-E curves obtained for the Hg(II) solution was again slow to be reestablished, as shown in Fig. 1. We conclude that a significant fraction of the Hg(0) deposited at $E < 0.4\text{V}$ under these conditions diffuses into the Au electrode, per-

Fig. 1. I-E curves for Hg(II) at a Au RDE in 0.1M HClO_4 . Conditions: $C^b_{\text{Hg(II)}} = 1.0 \times 10^{-4}\text{M}$ Hg(II) , $W = 3600 \text{ rev min}^{-1}$, $\phi = 2.0 \text{ V min}^{-1}$. Scan number given in figure.

haps along grain boundaries, to form a bulk Au-Hg alloy. The Hg in the alloy very near the surface of the electrode is quickly oxidized by the UPS process; however, the Hg which has diffused to a significant depth within the Au is not completely stripped during the time in which the potential is in the region of UPS during the positive potential scan. Such behavior can be interpreted on the basis of differences in the solid-state diffusion rates of Hg for the deposition and stripping processes. Diffusion is the direct result of an activity gradient, and the gradient resulting from the deposition of bulk Hg(0) having an activity of 1.0 will be significantly higher than that corresponding to the stripping process, where, even for a large concentration of the Au-Hg alloy, the activity of Hg in the alloy is much less than 1.0. For $E > 1.0\text{V}$, the oxide formed on the Au surface might serve also as a barrier against diffusion of Hg from the bulk alloy to the electrode surface. When the oxide has been cathodically removed from the Au surface on the negative potential scan to ca. 0.7V , the electrode potential is more negative than required for complete anodic stripping of the Au-Hg alloy. Hence, a significant quantity of Hg can be trapped within the Au electrode under the voltammetric conditions typically used in these studies. X-ray analysis of Au electrodes previously plated with bulk Hg(0) and then stripped at 1.6V confirmed the retention of Hg in Au electrodes. Those results will be reported in the future.

Based on the results of Fig. 1 and the general knowledge that Au is extensively amalgamated when placed in contact with liquid Hg(0) , it was anticipated that the area of peak B could be varied substantially by altering the quantity of bulk Hg(0) deposited at $E < 0.4\text{V}$ without significant change in area of peak A for stripping of bulk Hg(0) . This was confirmed, and typical data are shown in Fig. 2. The triangular sweep of the electrode potential was interrupted on the negative scan at 0.00V for time periods increased by 5s intervals from 0-20s on successive triangular scans. The area of peak A, for anodic stripping of bulk Hg(0) , did not change; only peak B increased, for stripping the Au-Hg alloy. For other experiments in solutions of higher concentration of Hg(II) than used for Fig. 2, the area of peak B was several times larger than shown in Fig. 2 without an increase in peak A. The area of peak A in Fig. 2 was determined with a planimeter, based on the triangular approximation shown in Fig. 2, to correspond to $235 \mu\text{C}$ for the stripping of bulk Hg(0) , i.e., $n = 1$ (1, 2). Using $20 \mu\text{F cm}^{-2}$ (7, 8) as the double layer capacity for polycrystalline Au, the roughness factor was estimated from the charging current at 0.0V vs. SCE to be ca. 2.5 for the Au electrode polished with $1.0 \mu\text{m}$ alumina.

Fig. 2. I-E curves for Hg(II) at a Au RDE in 0.1M HClO₄. Conditions: $C_{\text{Hg(II)}}^b = 5.0 \times 10^{-5} \text{M}$, $W = 3600 \text{ rev min}^{-1}$, $\phi = 2.0 \text{ V min}^{-1}$. Time delay at 0.0V: curve a = 0s, curve b = 5s, curve c = 10s, curve d = 15s, and curve e = 20s.

Furthermore, based on a packing density of 1.5×10^{15} at. cm^{-2} for pure Au, the limiting area of peak A is calculated to correspond to the equivalent of 0.85 atomic layer of bulk Hg(0). Since the triangular approximation of peak A will underestimate the true area, we conclude the limiting coverage corresponds to $\theta_{\text{Hg(0)}} = 1$.

A slight increase in surface roughness of the Au electrode is a result of the deposition and stripping process. The area of the cathodic peak for reduction of the surface oxide on the negative scan (ca. 0.9V) is observed to increase slightly, and the anodic current for formation of the surface oxide is observed also to increase with each successive scan, as shown in Fig. 2. The increased cathodic charge for oxide reduction is not, however, as large as the increased anodic charge for $E > 1.0\text{V}$. We conclude that Hg which has diffused into the interior of the Au during deposition of bulk Hg(0) continues to be stripped for $E > 1.0\text{V}$ at a rate controlled by the solid-state diffusion of Hg. As peak B is increased, corresponding to the formation of larger quantities of alloy, a greater amount of Hg remains within the Au after the alloy near the surface is stripped and the anodic current for $E > 1.0\text{V}$ is increased. The gold oxide, therefore, is not a totally effective barrier against diffusion of Hg from the interior of the electrode to the electrode-solution interface.

The Au electrode was polished after obtaining the data in Fig. 2 and returned to a solution of $2.0 \times 10^{-4} \text{M}$ Hg(II). The I-E curves for 40 consecutive triangular scans of electrode potential were recorded on a stripchart recorder. The areas corresponding to deposition and stripping of bulk Hg(0) and the Hg-Au alloy were determined by a planimeter; representative values of the ratio Q_a/Q_c are plotted in Fig. 3 as a function of scan number. The increase in the ratio after scan 15 is barely perceptible in Fig. 3. The average for scans 15-40 is $Q_a/Q_c = 0.81$ with a standard deviation of 0.03. The triangular potential scans were continued, and the I-E curves recorded for scans 71 and 72, for which the charge ratio had the values 0.83 and 0.85, respectively. One factor contributing to the observation of values of the charge ratio less than unity is that bulk Hg(0) is deposited with $n = 2$, whereas it is stripped (peak A) with $n = 1$ (1, 2). The charge ratio for scan 72 was adjusted for this fact by integrating twice the triangular approximation of peak A (as indicated in Fig. 2) in the computation of Q_a . The adjusted value for Q_a/Q_c is 0.91. Indeed, the Hg deposited even for scan 72 apparently is not totally stripped during the subsequent positive potential sweep, and the quantity of the Au-Hg alloy continues to increase slowly even after so large a number of consecutive triangular potential sweeps.

The formation of the Au-Hg alloy requires the prior deposition of bulk Hg(0) in the equivalent of $\theta_{\text{Hg(0)}} = 1$, even when the Hg-Au alloy has been formed on previous scans for $E < 0.4\text{V}$, but only partially stripped during the positive scan for $E > 0.4\text{V}$

This was demonstrated when the negative potential scan for the Au RDE in $1.0 \times 10^{-4} \text{M}$ Hg(II) was interrupted for 1.0 min at 0.45V. The subsequent positive sweep from 0.45V resulted in an I-E curve with the virtual absence of peak B, even though 0.45V is substantially negative of the peak potential (0.8V) for stripping of the Au-Hg alloy. No bulk Hg(0) is deposited at 0.45V, and, consequently, no alloy was formed. Clearly, the formation of the Au-Hg alloy can only occur if an activity gradient for Hg(0) exists which can bring about diffusional mass transport into the Au substrate. As described above, this diffusional transport ceases when the quantity of bulk Hg(0) has decreased to the equivalent of $\theta_{\text{Hg(0)}} = 1$.

Cyclic voltammetry at the Au RDE.—A cathodic peak (peaks C in Fig. 1 and 2) is obtained on the limiting current plateau for deposition of Hg(0) during the negative

Fig. 3. Q_a/Q_c vs. scan number for Hg(II) at Au RDE in 0.1M HClO₄. Conditions: $C_{\text{Hg(II)}}^b = 5.0 \times 10^{-5} \text{M}$, $W = 3600 \text{ rev min}^{-1}$, $\phi = 2.0 \text{ V min}^{-1}$.

Fig. 4. I-E curves for a Au coulometric electrode. Conditions: $C_{\text{Hg(II)}}^b = 1.28 \times 10^{-4} \text{M}$, $V_s = 193 \mu\text{l}$, Carrier stream: $1.0 \text{M H}_2\text{SO}_4$, $v_f = 0.5 \text{ ml min}^{-1}$. Curve: o = blank, b = following deposition of Hg at 0.5V.

potential scan for $E \sim 0.3 \text{V}$. This peak current is in excess of the mass-transport-limited value for Hg(II) and is concluded tentatively to correspond to the reduction of Hg(I) adions produced on the Au surface for $E > 0.40 \text{V}$. Shielding and collection experiments with the Au ring-disk electrode confirmed the absence of any soluble species produced or consumed at the disk electrode corresponding to peak C (2). The area of peak C for scan 1 in Fig. 1 was determined to be $40 \mu\text{C cm}^{-2}$, which corresponds to an estimated surface coverage of 0.17 for Hg(I). This value is compared to that of 0.33 for the cluster model of the adlayer produced by UPD containing Hg(I) and Hg(0) in the ratio of 1:2 (3).

Flow-injection coulometry and voltammetry.—Determination of n_{app} by flow-injection coulometry, as reported by Lindstrom and Johnson (3), was repeated with the apparatus housed completely within a dry box purged for 24h with N_2 to eliminate interference by cathodic detection of dissolved O_2 . Injections consisted of $193 \mu\text{l}$ aliquots of $2.066 \times 10^{-5} \text{M Hg(II)}$. The deposited Hg was voltammetrically stripped from the electrode after the

Table I. Evaluation of n_{app} for deposition of Hg(II) by flow-injection coulometry

E (V)	Injection no.	$10^4 Q$ (C)	n_{app}
0.45	1	4.606	1.59
	2	4.652	1.61
	3	4.615	1.60
	4	4.791	1.66
	5	4.606	1.59
	6	4.615	1.60
	average	4.648	1.61
0.00	1	5.631	1.95
	2	5.705	1.97
	3	5.668	1.96
	4	5.779	2.00
	5	5.834	2.02
	6	5.723	1.98
	average	5.723	1.98

Conditions: $C_{\text{Hg(II)}}^b = 2.066 \times 10^{-5} \text{M}$, $V_s = 193 \mu\text{l}$.
Carrier stream: 0.1M HCO_3^- , $v_f = 0.5 \text{ ml min}^{-1}$.

peak for each injection had been produced. Hence, deposition of bulk Hg(0) was negligible, and formation of the Au-Hg alloy was avoided. Results for n_{app} are reported in Table I for the cathodic reactions at $E = 0.45$ and 0.00V . The averages of six determinations are $n_{\text{app}} = 1.61 \pm 0.01 \text{ eq mol}^{-1}$ at 0.45V and $1.98 \pm 0.02 \text{ eq mol}^{-1}$ at 0.00V . These results are in agreement with the cluster model for UPD of Hg at $E > 0.45 \text{V}$ as proposed by Lindstrom and Johnson (2), as well as the evidence presented above (Fig. 1 and 2) that the Hg(I) adions are reduced to Hg(0) at $E < 0.3 \text{V}$.

In a separate study, a $193 \mu\text{l}$ aliquot of $1.28 \times 10^{-4} \text{M Hg(II)}$ was injected for an electrode potential of 0.50V . Following passage of the sample aliquot through the electrode, I-E curves were recorded for triangular potential scans between the limits of 0.45 and 0.00V with the continuing flow of supporting electrolyte through the electrode. Reproducible cathodic and anodic peaks were obtained in the region 0.2 - 0.3V (Fig. 4), which did not diminish in size during the repeated triangular potential scans. Hence, both oxidation states of Hg in the half-reaction involved are strongly adsorbed to the Au surface. The reaction is concluded to correspond to $\text{Hg(I)}_{\text{ads}} + e = \text{Hg(0)}_{\text{ads}}$. On the last positive scan, the potential was allowed to increase to 1.2V ; the I-E curves recorded are included in Fig. 4. The large anodic peaks obtained are from oxidative stripping of the Hg(0) adatoms and Hg(I) adions as Hg(II).

It can be observed in Fig. 1 and 2 that no anodic peak is obtained at ca. 0.3V for the positive potential scan at the Au RDE. This is easily explained, since, for the conditions of Fig. 1 and 2, the Au electrode is covered with bulk Hg(0) when the positive potential scan reaches 0.3V and adsorbed Hg(I) cannot form because of the absence of any exposed Au metal, which is necessary for the stabilization of Hg(I) adions.

Current-potential curves were recorded following injections of $193 \mu\text{l}$ aliquots of $1.28 \times 10^{-4} \text{M Hg(II)}$ as a function of variation in the deposition potential in the range 0.9 - 0.3V ; the corresponding curves are shown in Fig. 5, together with a residual I-E curve. The cathodic peak at 0.2V attributed above to the reduction of Hg(I) adions is observed only for $E_{\text{dep}} = 0.4$ and 0.5V . We conclude that the presence of Hg(I) adions and the validity of the cluster model pertain only to regions of the electrode surface for which the UPD process results in the nearly complete development of the adlayer of Hg.

The question remains unanswered as to the nature of the product of the UPD process for $0.9 > E_{\text{dep}} > 0.5 \text{V}$, for which $n_{\text{app}} = 1.6$, but the adlayer is not completely filled.

ABSTRACT

Transient photocurrents induced by short laser pulses at WSe₂ and MoSe₂ photoanodes were studied as a function of electrode morphology, solution redox species, incident laser power and power density, concentration of redox species, and added load resistance. Dual exponential current decay transients were observed in most cases, and a speculative qualitative model is proposed to explain the shape of the transients. The pitfalls associated with such measurements are discussed, and suggestions are made for improved measurement techniques.

Most of the recent research in photoelectrochemistry has been focused on increasing the efficiency and stability of cells for the production of chemicals or electricity. Much of the more fundamental research has been directed at understanding the energetics of the semiconductor/electrolyte interface (1-4). There has been relatively little investigation of the dynamics of charge transport and equilibration across the semiconductor/electrolyte interface. One method of studying such dynamics would be to examine the currents, voltages, and luminescence produced by ultrashort laser pulses impinging on the interface. Perone and Richardson *et al.* have investigated photopotential transients at TiO₂ (5) and CdS (6) electrodes in the submicrosecond time domain with a "coulostatic flash" technique. A similar technique was employed by Kamat and Fox (7) to study native and chemically modified TiO₂ electrodes in acetonitrile solutions. Frippiat *et al.* (8) studied the dye sensitization of SnO₂ with rhodamine B using a similar method.

The "coulostatic flash" technique involves studying the open-circuit potential change of a semiconductor electrode in response to a short (~10 ns) laser pulse of photons with energies above the bandgap. Recently, Gottsfeld and Feldberg (9) have done a theoretical analysis of the photopotential transients obtained in such experiments. They considered both surface and bulk recombination and back diffusion of carriers to derive mathematical expressions to describe the decay of photopotential as a function of time and pertinent semiconductor parameters. The decay of photopotential may provide some information on carrier lifetimes, surface and bulk recombination mechanisms, the role of traps, and sensitization by adsorbed dyes. However, it provides no information about net electron transfer to the solution. The fact that the experiment is performed at open circuit necessitates that any electron transfer to the solution must be compensated by an equal and opposite charge transfer to the semiconductor in order to maintain charge neutrality in the electrode. This is in contrast to conventional couloustatics where the charge is injected into the double

layers of the working and counterelectrodes before the potential decay of the working electrode is followed at open circuit.

There have also been several studies of photocurrent transients induced by short laser pulse illumination of a semiconductor/electrolyte interface which is at a potential near short circuit. Harzion *et al.* (10) have studied the fast photocurrent transients in CdSe cells with a sulfide/poly-sulfide redox electrolyte. They have also recently extended their measurements to the time resolved luminescence at the interface induced by the fast light pulses (11). Kawai *et al.* (12) investigated photocurrent transients at the MoSe₂ electrode immersed in iodide electrolytes. They studied the dependence of the photocurrent transients on light intensity, bias voltage, and electrolyte concentration, and observed transients with two current peaks, which were explained as charge carrier generation in the solid followed by electron transfer across the interface. The extreme stability of the Group VI semiconducting diselenide electrode materials in halide electrolytes and the high efficiencies obtained for the conversion of sunlight to electricity or stored chemical energy, make them of interest in various energy conversion schemes (13-16). A more detailed investigation of photocurrent transients produced by short laser light pulses impinging upon these materials seemed worthwhile, and the results of our study are reported herein.

Experimental

The MoSe₂ and WSe₂ crystals were grown and mounted as described previously (13). The doping level of these crystals is between 10¹⁶ and 10¹⁷ cm⁻³. In the cases when the van der Waals surfaces were exposed to the solution, the crystals were carefully cleaved with transparent tape before mounting in Torr-Seal epoxy. Figure 1 shows a diagram of the experimental apparatus with an insert giving the detail of the electrochemical cell. The leads connected to the cell were kept as short as possible to minimize stray capacitance and inductance. A platinum electrode with an area very large in comparison to the semiconductor was used to prevent any counterelectrode process from controlling the current flow in the cell. The cell was enclosed within a metal Faraday cage to reduce

noise and remove RF interference generated by the flash lamp.

The semiconductor and counterelectrode leads were connected directly to the 50 Ω signal input and ground return of a Hewlett Packard Model 1830A dual channel vertical amplifier situated within a HP 183D oscilloscope mainframe. For the load resistance studies with $R_L > 50\Omega$, a Tektronix Model 7704 oscilloscope was used with a 7A18 dual trace amplifier plug-in (input impedance 1 M Ω). The light source was a flashlamp-pumped dye laser operating at 607 nm (rhodamine 6G). Short light pulses were generated with a Pockels cell and had a full width at half maximum of 5 ns (see Fig. 2C). A HP 4220 PIN photo-

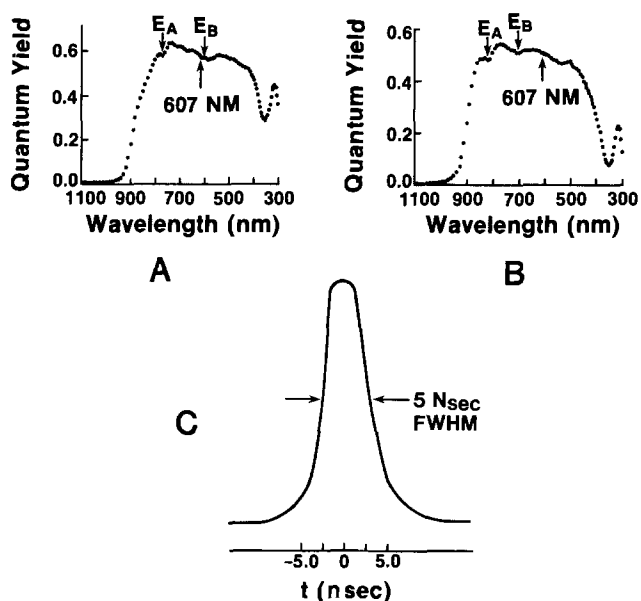

Fig. 2. (A) WSe₂ photocurrent spectrum showing laser excitation wavelength. (B) MoSe₂ photocurrent spectrum showing laser excitation wavelength. (C) Laser excitation pulse.

diode was used to measure the pulse energies, which were varied by insertion of neutral density filters into the light path. The power density impinging on the sample was varied by using a lens to focus or defocus the laser spot onto the semiconductor at a fixed power. The size of the laser spot on the sample was measured by exposing Polaroid film at the position where the crystal was mounted. The photocurrent transients were recorded directly from the oscilloscope onto Polaroid film. The area of the spot varied from 0.108 to 0.0038 cm², and in combination with neutral density filters resulted in power densities from 8 to 21,000 W/cm². The electrolytes were prepared from reagent grade chemicals which were used without further purification. Measurement of dark cell resistances and capacitances were made using a Hewlett Packard vector impedance meter model 4815A or by Mott-Schottky techniques using a lock-in amplifier.

Results

The photocurrent spectra for WSe₂ and MoSe₂ are shown in Fig. 2A and 2B. Structural features in the spectra, which are indicated with arrows, reveal the position of excitonic transitions in the material, a phenomenon which was described previously (18). The wavelength of the excitation pulse, with respect to the photoresponse of the crystals, is also indicated. The 607 nm wavelength is well above the bandgap of both materials, and so the absorption coefficient is about 10⁵ cm⁻¹ at this wavelength. The high absorption coefficient dictates that the light is absorbed within 200 nm of the semiconductor/electrolyte interface. The current-voltage curves in the dark and under illumination for various crystals whose transient behavior was investigated are shown in Fig. 3. The strong correlation between the surface perfection of the crystal and the dark currents, photocurrents, and photovoltage obtained in a regenerative photovoltaic cell is evident in the figure. This relation between surface morphology and junction properties of the cell has been discussed extensively in the literature (19-21). The edge-mounted crystal (Fig. 3C) and the crystal with many exposed non-van der Waals surfaces show much lower fill factors and photocurrents than the carefully cleaved van der Waals surfaces of the crystals in Fig. 3A and 3B. The iodide/triiodide electrolyte has been demonstrated to give the best photoresponse with this class of semiconductors due to the adsorption of the triiodide ion on the surface of the electrode (22) and the favorable redox potential. The iron(II)/iron(III) redox system was also studied although the steady-state current-voltage behavior is less ideal with this redox system, resulting in a lower light to electrical energy conversion efficiency.

Figure 4 shows the transient photocurrent response produced with laser pulses of the same energy for a WSe₂ electrode with a smooth van der Waals surface in both iodide and iron redox electrolytes. The transients are characterized by a rapid rise followed by a decay of the current which lasts until about 1 μ s. The peak photocurrent in the iodide solution is considerably higher than in the iron electrolyte.

Figure 5 shows the photocurrent transients for samples with a lower degree of surface perfection than the WSe₂ sample in Fig. 4. The sample in Fig. 5A is the same MoSe₂ sample as that whose current-voltage behavior was shown in Fig. 3D. Although the pulse energy is more than twice that of the WSe₂ sample in Fig. 4, the peak photocurrent is much less, and the peak quickly decays to a weaker component, which itself decays with a timescale on the order of 100 ns. A more extreme example of the surface structure controlling the transient is shown in Fig. 5B. The WSe₂ sample in this case was mounted edge-on such that no van der Waals surfaces were in contact with the solution. The transient photocurrent is more than ten times less than the corresponding peak current on the well cleaved surface, even though the laser power was more than 50 times higher. The current transient in this case virtually follows the laser pulse in that the

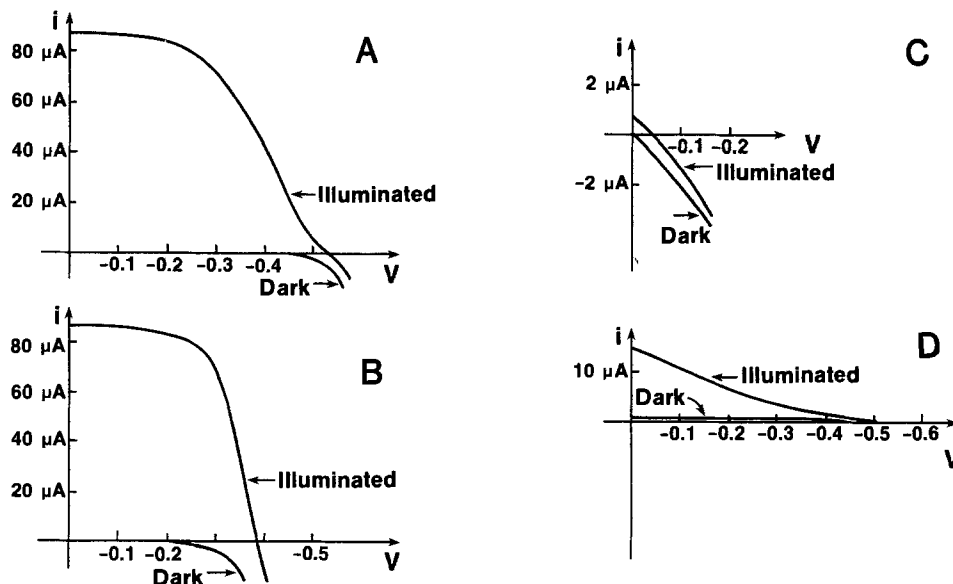

Fig. 3. Current-voltage curves for various semiconductor samples under CW illumination of 632.8 nm (1.87 mW/cm^2). All samples in $5.0 \text{ M KI}/10^{-2} \text{ M I}_2$. (A) WSe_2 50-4. (B) MoSe_2 33-2. (C) WSe_2 50-1 (edge-mount). (D) MoSe_2 2 (concave surface).

FWHM is less than 10 ns. Figure 5C shows a frequently observed behavior for short-time scales with samples that have primarily van der Waals surfaces exposed to the solution. This behavior is characterized by an increase in the photocurrent occurring about 30 ns after the initial risetime and preceded by a small decay or plateau region. Transients of this nature were also observed on MoSe_2 by Kawai *et al.* (12).

Figure 6 shows the risetime to the peak photoresponse for WSe_2 electrodes in both iodide and iron electrolytes. The risetime is dependent on both the laser power and the laser power density in a complex fashion. At low laser power densities, the risetimes are shorter than at the higher power densities. The risetimes tend to be constant at about 50 ns for the intermediate power densities while for the higher power densities, an initial increase followed

by a decrease in the risetime is observed for the iodide solutions. The risetimes always decrease with increasing laser power for the iron solutions.

Figure 7 shows the natural logarithm of the normalized peak photocurrent for a typical transient obtained with a WSe_2 sample in both iodide and iron(II)/iron(III) electrolytes. For all transients, this analysis reveals two linear

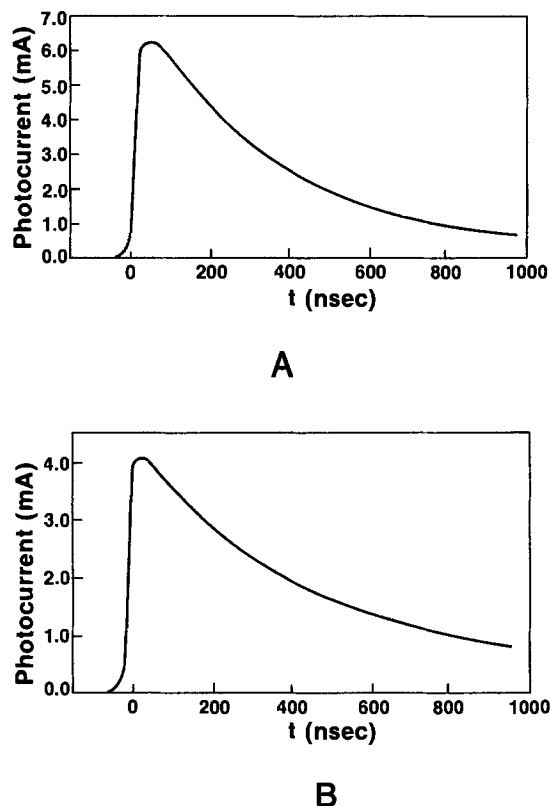

Fig. 4. Photocurrent transients for sample with high fill factor and high efficiency (WSe_2 50-4). Incident pulse energy 80.3 nJ (750 nJ cm^{-2}). (A) $5.0 \text{ M KI}/10^{-2} \text{ M I}_2$. (B) $0.5 \text{ M Fe}^{2+}/0.05 \text{ M Fe}^{3+}$.

segments with a transition occurring at about 400-600 ns. At low laser power densities in iodide solutions, the transition comes at slightly less than 400 ns. Less than ideal crystal surfaces yielded very fast decays possibly limited by the RC time constant of the cell. These fast transients could not be analyzed using a dual exponential fit.

The decay times for WSe_2 sample 50-4, which followed the dual exponential discussed above, were analyzed by fitting the transients to a function of the form

$$I = A[\exp(-t/\tau_1)] + B[\exp(-t/\tau_2)] \quad [1]$$

τ_1 is this expression, which corresponds to the first decay, was found to be approximately constant at about 120

$\pm 25\text{ ns}$ independent of pulse energy, energy density, or redox couple. However, at low power and power densities in the iodide electrolyte, a significant decrease in τ_1 was noted as a value between 40 and 80 ns. A systematic trend in the τ_2 values was observed, as is shown in Fig. 8. This second decay time increased with increasing laser power and laser power density, and significantly longer decay times were measured in the iron electrolytes.

Figure 9 shows the dependence of the peak photocurrent on the incident pulse energy at four different power densities for the iodide and iron electrolytes, respectively. In both cases, the photocurrent saturates at pulse energies above 100 nJ, although the peak current is higher in the iodide solution. It is also apparent from the figures that, for a given pulse energy, the peak is higher for the transients with the lower energy or power density. It should be reemphasized that the power densities are many times the power density of solar photons ($\sim 100\text{ mW/cm}^2$).

The quantum yields for charge transfer can be obtained from the integration of the photocurrent time transients, to obtain the charge which has passed through the interface, and dividing it by the number of incident photons. Figure 10 shows that the quantum yields rapidly diminish with increasingly pulse energy. The largest quantum yields, which are observed at the lowest power densities, are still well below the quantum yields which are measured at even lower intensities with either chopped or CW radiation [see Fig. 2 and Ref. (18)].

The quantum yield for electron transfer was also measured as a function of the concentration of triiodide in the electrolyte. Triiodide concentration was varied because it can be either oxidized to iodine, or reduced to iodide, enabling the counterelectrode reaction to proceed. Figure 11 shows the results of this experiment. The quantum yield is increased by a factor of almost two by changing the I^- concentration from 3×10^{-5} to 10^{-2}M . The solution was maintained at a constant ionic strength of 3.16 by adding KCl to the solution. The ionic strength was maintained at this high level to assure that the solution resistance was kept relatively low and constant and that no ion migration effects were controlling the response of the system. It is unknown exactly what the residual quantum yield is due to at low iodide concentration, but chloride oxidation has been shown to occur on these electrodes (16).

The time resolved photocurrents were also studied as a function of added load resistance. This type of study was also done by Harzion *et al.* (10). The load resistance was connected directly between the semiconductor and counterelectrode. The overall load resistance was calculated from the parallel combination of the added load resistance and the $50\ \Omega$ input impedance of the oscilloscope. For this study, the transient was fit to the best single ex-

ponential decay (τ). Figure 12B shows the decay time constant (τ) plotted against the overall load resistance for the cell in the low resistance region. A linear behavior is observed much like that reported by the Israeli group for CdSe (10).

Figure 12A shows the influence on the decay time (τ) of adding substantial resistance to the cell and using a high impedance scope input. In this case, the decay times can be as long as a millisecond for a load resistance of $1\text{ M}\Omega$. The high resistance measurements approach the open-circuit experiments of the type reported by Perone *et al.* (5, 6) and Kamat and Fox (7). Figure 13 shows the effect that increasing the load resistance has on the quantum yield for electron flow. At low resistances, the quantum yield remains constant but begins to diminish at resistances above about $5\text{ k}\Omega$. This curve is exactly analogous to the load curve of a photovoltaic cell in that it progresses from a high quantum yield at short circuit (at zero load) to virtually no photocurrent at very high loads (near the open-circuit potential).

Discussion

It will be helpful to establish some boundary conditions which may be controlling the transient currents in these

Fig. 11. Quantum yield as a function of the log of the triiodide concentration for the WSe_2 50-4 electrode with a constant pulse energy of 80 nJ and an ionic strength held constant at 3.16 with KCl.

Fig. 12. (B) τ (transient decay time constant) as a function of load resistance R_L , MoSe_2 33-2 in $5.0\text{M KI}/10^{-2}\text{M I}_2$, incident pulse energy 227 nJ, and $\sim 1\Omega < R_L < 50\Omega$.

systems. The diffusion of electroactive species to the electrode surface can be shown to be unimportant to the shape of the current transient in several ways. First, the time decay of the photocurrent does not follow a $t^{-1/2}$ decay which would be expected for the case of semi-infinite linear diffusion of the electroactive species to the in-

Fig. 13. Quantum yield of charge transfer as a function of $\text{log} R_L$, MoSe_2 33-2 in $5.0\text{M KI}/10^{-2}\text{M I}_2$, and incident pulse energy 227 nJ.

terface. The decay also does not follow a $t^{-2/3}$ dependence as was observed over limited time scales for TiO_2 and CdS under open-circuit conditions (5, 6). Other workers have reported complex shapes of photopotential decays under open-circuit conditions (11).

Secondly, although the quantum yield is influenced by the concentration of redox species in the electrolyte, the biexponential nature of the transients is not. Furthermore, the quantum yield is not a linear function of concentration of redox species. Thirdly, a calculation of the diffusion length of iodide or iron(II) during the duration of the laser pulse (5 ns) reveals that only in the case of the 0.5M iron(II) solution at the smallest spot size (highest power density) does the number of photons in the pulse approach the number of redox atoms within the diffusion length of the electrode on this timescale. Triiodide can also be adsorbed on the surface, and, thus, there will be no need for these molecules to diffuse to the surface. The result is that despite the high power laser pulses the shortness of the light pulse renders the total charge injected into the semiconductor insufficient to induce concentration polarization.

A second question is whether the RC time constant of the cell is limiting the current flow in the system as a result of the inherent resistance in the semiconductor and electrolyte and the capacitance associated with the semiconductor space charge layer, Helmholtz layer, and associated electronic components. Our data support the point of view that processes other than the cell resistance and capacitance also influence the temporal current flow in the system. The cell RC constant can be measured independently by measuring both the total resistance of the cell [5.5Ω for WSe_2 (sample 50-4) and 6.1Ω for MoSe_2 (sample 33-2)] and the total cell capacitance (7 nF for WSe_2 and 11 nF for MoSe_2), and results in calculated cell time constants of from 35 to 75 ns. The time scale in which we are making measurements are, with the exception of the fastest risetimes, much longer than this. Furthermore, semiconductor samples with many surface imperfections show decays which are much shorter than samples with more perfect surfaces, even though the resistivity of the samples are nearly identical and the capacitance associated with the imperfect surfaces is much larger. In summary, we believe that, although the RC components of the cell and measurement electronics have some influence on the decay transient, information about other effects, including charge transfer and recombination, is also contained in the transient.

Lateral minority carrier transport can be shown to be unimportant, even for small spot sizes, from the measured diffusion length of minority carriers in these crystals (23). The maximum minority carrier diffusion length (L_p) measured in these materials is around $3\mu\text{m}$, negligible compared to the 350μ radius of the smallest spot. An anisotropy factor of 10 to 20, due to the fact that L_p was measured perpendicular to the layers, would only increase the effective radius of the charge transfer area 8-17%. However, the saturation of recombination centers, by the large hole flux, could increase the effective diffusion length. Since such effects are unknown in these samples, they were neglected. Majority carriers, which have much higher mobilities (23), were assumed to be quickly separated by the space charge and removed into the bulk of the crystal.

The risetime to the peak photocurrent shown in Fig. 6 for WSe_2 in iodide and iron electrolytes can be as fast as 5 ns. No explanation is offered for the dependence of the risetime on laser pulse energy or energy density. Intuitively, one might expect that a smaller illuminated area would produce a transient current with a faster rise due to the lower capacitance associated with the smaller portion of the photoanode through which current flows. The data, on the other hand, show a trend opposite to this expectation. Because of the unusual behavior of the risetimes (MoSe_2 in iodide/triiodide electrolytes behaves similarly to WSe_2 in this electrolyte), most of the discus-

sion in this paper will be concerned with the decay transients.

The double hump in the photocurrent decay shown in Fig. 5C was also observed by previous workers (12). These workers attributed the two peaks to electron hole separation followed by charge transfer. We think this is unlikely because electron hole separation occurs on a picosecond time scale, much faster than any of the measurements reported here. A simple calculation of the transit time for electrons across a distance equal to the width of the depletion layer, without field assistance but based only on the measured mobility of electrons in these crystals, yields a value of about 30 ps. Feldberg and Gottesfeld (9) also arrive at the conclusion that electron hole separation cannot be directly observed on the time scale of our experiments.

A possible explanation of the effect is that undissociated excitons can be dissociated by the return of the space charge field, which was temporarily eliminated by the large concentration of electron hole pairs created by the intense laser pulse. Recent experiments on WS_2 crystals where the excitation energy was tuned from below the first excitonic transition to above the exciton energy showed no difference in the shape of the transients with energy (24). The result of this experiment makes excitonic effects unlikely as an explanation for the double hump. Back diffusion of majority carriers, due to the flattening of the bands at the surface, may also be an explanation for the double hump. These effects have been considered for photovoltage transients (9) but should be less significant when a conduction path is available for the separation of the charges.

A recent theoretical model based on the interaction of the capacitive and resistive elements in the cell predicts that, under some conditions, a reversal of the current can be seen after the light pulse (25). Preliminary experiments at an InP electrode have actually revealed such an effect (24). The suggestion is that the dip between the two humps may be caused by a small temporary reinjection of holes back into the semiconductor. The back injection of holes could be the result of a surface state which fills when the Fermi level is driven past the state by the large influx of photogenerated carriers. When the Fermi level relaxes back to the original energy position, some of the photo-oxidized triiodide at the surface will be reduced by the electrons in the surface states, causing a temporary dip in the transient response.

A large photon flux is likely to cause the movement of the bandedges of the semiconductor. Even much smaller levels of illumination have been shown to cause the movement of the semiconductor bands with respect to the solution levels (26). The movement of the bands would be expected to have a dramatic effect on the electron or hole transfer rate from the semiconductor to the solution. We propose that the dual exponential observed for the decay of the photocurrent is the result of band movement. The initial fast decay can be attributed to the relaxation of the bandedges back to their original energy position while the slower decay is due to the kinetic limitations of hole transfer to the solution from long-lived traps near the valence band. Long-lived traps were postulated (by previous workers) to explain the long photovoltage decay transients lasting 20 ms (5-7). Another explanation given in Ref. (9 and 11) for long photovoltage transients is the back-diffusion following charge separation of majority carriers to the surface to recombine with the minority carriers or oxidized solution species.

The low quantum yields observed, relative to the steady-state quantum yields, indicate that the dominant process in all cases is recombination. High recombination rates are not surprising due to the large concentrations of electrons and holes produced by the intense laser pulse. Recombination rates are dominant for samples with only edge sites exposed to the solution

(Fig. 3C and 5B), and result in only small transient currents and quantum yields. Band movement is not important in this case due to the large concentration of surface states which effectively pin the Fermi level. Similar results are also seen for another sample whose van der Waals surface has a large concentration of edge sites (Fig. 3D and 5A).

The difference in the behavior of the two redox electrolytes employed in this study can be understood from the differences in the electron transfer rate constants between the two couples and also to the different band bending in the semiconductor. The faster electron transfer rate for the iodide couple, along with the fact that there is adsorption at high triiodide concentrations (22), results in a higher peak current for this system and a faster decay for the second component. The longer-lived τ_2 component of the transients in iron solutions compensates for the higher peak currents in the iodide case, which results in similar quantum yields for the two systems. However, at very high power densities, the quantum yields in iodide are significantly higher, suggesting that the adsorbed charge may help sustain more charge transfer under these conditions. τ_2 is also a function of the triiodide concentration in the electrolyte, whereas τ_1 is virtually independent of the donor concentration. τ_2 increases from about 700 ns at triiodide concentrations of $3 \times 10^{-4}M$ to over 1000 ns at concentrations of 0.1M. The sigmoidal shape of quantum yield as a function of concentration parallels the "isotherm" for the adsorption of triiodide on a WSe_2 electrode, recently measured by chronocoulometry (22). The adsorption maximum was reached at a concentration of 0.1M as determined by this electrochemical technique which directly measures the surface excess of an electroactive species. The quantum yield also reaches a maximum near this concentration.

The differences in the band bending in the semiconductor in either of the redox electrolytes is expected to be within several hundred millivolts. The 236 mV difference in the standard redox potentials (E°) for the two systems (0.771 for Fe(II)/Fe(III) and 0.535 for I^-/I_3^-) is more than compensated by the shift in flatband potential caused by the adsorption of I_3^- (22). Flatband shifts of up to 500 mV were observed on $MoSe_2$ electrodes resulting from the addition of I_3^- to I^- solutions. Regenerative cells with $MoSe_2$ photoanodes show open-circuit photovoltages which at high light intensities are several hundred millivolts higher for the iodide electrolytes than the iron electrolytes (27). At low intensities, the photovoltage for the iron system was greater by 150 mV (27). Power conversion efficiencies and fill factors, both of which are strongly influenced by the kinetics of interfacial charge transfer, are much smaller in the cells with the iron redox systems due mainly to the slower charge transfer rate constant for this system. The band bending in the semiconductor may influence the measured peak photocurrents and quantum yields, but we believe the interfacial charge transfer is also very important.

In summary, the entire decay transient is described as follows and depicted schematically in Fig. 14. The initial light pulse creates a large number of carriers which drives up the Fermi level and flattens the bands (Fig. 14B). In this process, the Fermi level passes a surface state near the conduction band, resulting in a small flow of electrons into this state and producing a dip in the anodic photocurrent at between 20 and 40 ns. The charge accumulated on the surface state causes the bands to move (Fig. 14C). After about 60 ns (depending on the laser power and power density), recombination and charge transport have removed enough carriers to permit the bands to move back towards the equilibrium position, removing the electrons from the surface level and accounting for the temporary increase in anodic current. The discharging of the surface state continues for the duration of the first transient, allowing the

Fig. 14. Band diagram showing the position of the semiconductor bands in response to the light pulse. A full description appears in the text.

bands to return to their initial position (Fig. 14A). The holes in the long-lived (up to 1000 ns) traps then transfer to the electrolyte. The latter charge transfer is sensitive to such variables as electron transfer rate and solution donor concentration. The surface state is in communication with the solution rather than the bulk of the semiconductor, which is why its position remains fixed while the band edges move. These surface states are also responsible for the dark current at these junctions (28).

Conclusion

It is obvious from this report that the temporal behavior of the photocurrent and photovoltage at a semiconductor/electrolyte interface is very complex. The complexity arises from the interaction of semiconductor parameters (carrier lifetimes, dielectric constants, bulk and surface states, band structure, carrier mobilities, doping level, etc.), electrolyte parameters (concentration, standard potential and standard rate constant of any redox species, solution resistance, adsorption and diffusion of redox species and counterions, etc.), and external electronic parameters (noise, stray capacitance and inductance, impedance matches, etc.). In order to gain a more complete understanding of the light pulse-induced photocurrents, it will be necessary to further isolate these various parameters to examine their importance. We have begun experiments with more well characterized III-V materials in order to get a handle on the influence of the semiconductor properties. The electrolyte properties are rather easily controlled by proper selection and variation of the redox and electrolyte ions. The external electronic parameters are difficult but not impossible to sort out, as long as the time scale is not too short and the effect of the RC components can be deconvoluted. Time resolved luminescence may be able to provide complementary information about radiative recombination without interference from the equivalent electrical circuit elements of the cell itself (11).

Another refinement that can be made is to reduce the intensity of the incident laser pulses. One could hope to reduce the amount of band movement and recombination, prevalent at high laser powers, and probe the electron transfer events more directly. The difficulty is that

the small signal-to-noise ratio at the very low laser intensities necessitates the use of signal averaging techniques.

Electrocatalytic Oxidation of As(III)

I. Voltammetric Studies at Pt Electrodes in 0.5M HClO₄

Tim D. Cabelka¹, Deborah S. Austin, and Dennis C. Johnson

Department of Chemistry and Ames Laboratory—U.S. Department of Energy,² Iowa State University, Ames, Iowa 50011

ABSTRACT

Hydrodynamic voltammetry and hydrodynamically modulated voltammetry at a disk electrode, and shielding experiments at a ring-disk electrode, were applied in a study of the electrochemical response of As(III). The adsorption of As(III) occurs at Pt electrodes with partial charge transfer. The adsorption isotherm was determined and a maximum coverage is established for $C_{As(III)}^b > 6 \times 10^{-5} M$. The oxidation of As(III) is electrocatalyzed dramatically by formation of PtOH on the electrode, but is slow for a surface covered by a well developed layer of PtO. The rate-determining step (rds) for As(III) oxidation at the PtO-covered electrode does not involve charge transfer in the region $E = 0.9 - 1.2V$ vs. SCE. The log of the rate constant for the rds measured at 1.1V decreases linearly with the increasing charge equivalent to the surface oxide. The oxidation of As(III) at an oxide-covered electrode is catalyzed by evolution of O₂(g). The electrocatalysis is concluded to be the result of ·OH generated at the electrode surface.

The majority of publications on the electrochemical reactions of As(III) pertain to cathodic studies at Hg electrodes; key reviews and recent studies are cited (1-5). Significant studies of the cathodic reaction of As(III) at solid electrodes have been described (6-10), and applications for trace analysis have utilized the anodic peak for voltammetric stripping of the electrodeposited As(0). The earliest anodic studies of As(III) at solid electrodes were motivated by the application for the industrial preparation of arsenates (11-15), and alkaline media were used almost exclusively. MacNevin and Martin (16) found that the current efficiency could be as high as 100% at Pt electrodes in concentrated acid solutions, but the efficiency was significantly lower for pH > 3. No evidence was found for oxidation of As(III) by dissolved O₂(g) in acidic solutions, nor was there evidence for anodic production of the intermediate oxidation state As(IV). A large decrease was observed in the anodic current at $E \approx 1.0V$ vs. SCE under constant conditions of mass transport when the Pt electrode had been prepolarized at $E \gg 1.0V$ to generate the surface oxide. The anodic signal was restored following cathodic polarization to reduce the surface oxide. The oxide was found to be removed slowly by exposure of the electrode to the As(III) solution under open-circuit conditions.

Catherino (17) analyzed Tafel plots of *i*-*E* data for As(III) at a Pt electrode in the potential region where concentration polarization can be ignored. The results were consistent with a mechanism involving two consecutive one-electron transfer steps. The results were interpreted on the basis of As(IV) as the intermediate product in agreement with previous conclusions from kinetic studies of the homogeneous oxidation of As(III) (18-19). The possible involvement of surface oxide was not considered.

Zakharov and Songina (20) reported briefly on the oxidation of As(III) at a Pt anode. They observed that As(III) is oxidized simultaneously with the formation of the oxide layer on the electrode surface and concluded that the oxide participates in the mechanism as a donor of oxygen atoms as indicated by the reaction

Accordingly, the faradaic current results from the regeneration of the surface oxygen by the reaction

A similar mechanism involving adsorbed ·OH was proposed more recently by Zakharov *et al.* (21) for oxidation of As(III) at Au electrodes. We have chosen the anodic ox-

idation of As(III) as one of several model systems for the study of electrocatalysis by surface oxides at solid metal electrodes in anodic reactions where oxygen is transferred from the aqueous solvent to the reaction product. In a recent paper (22), the oxidation of I⁻ to IO₃⁻ at a Pt anode was concluded to be catalyzed by formation of the surface oxide and by the evolution of O₂(g). In the present series, we describe our voltammetric studies of As(III).

Because of the apparent catalytic involvement of the surface oxide on Pt electrodes with many anodic oxidation reactions, including that of As(III), a brief review concerning pertinent aspects of the present status of thinking regarding formation of the oxide in acidic media is appropriate. An excellent summary of the older literature is given by Gilman (23). More recently, Angerstein-Kozłowska, Conway and co-workers (24-26) demonstrated that the anodic wave for oxide formation can be deconvoluted into three peaks corresponding to the stepwise formation of the lower surface oxides with empirical surface stoichiometries of Pt₄OH (ca. 0.89V vs. NHE), Pt₂OH (ca. 0.95V vs. NHE), and PtOH (ca. 1.05V vs. NHE). In potentiodynamic experiments at a scan rate of 100 mV/s, the equivalent of a monolayer of PtOH (*i.e.*, $\theta = 1$) is generated on the positive scan to $E = 1.1V$ vs. NHE (0.85V vs. SCE). With the continued positive scan, PtOH is converted fully to PtO (*i.e.*, $\theta = 2$) at $E = 1.4V$ vs. NHE (1.15V vs. SCE). Reversal of the positive scan at potential values for which $\theta \ll 1$ produces a cathodic peak for reduction of PtOH, which is in support of the conclusion that the reaction $Pt + H_2O = PtOH + H^+ + e$ is reversible for $\theta \ll 1$. When the PtOH ($\theta \ll 1$) is allowed to age, or for increased values of the positive scan limit for which $\theta \rightarrow 1$, the cathodic peak for reduction of the surface oxide is shifted to more negative values. This is concluded to result from induced surface rearrangement of PtOH, the so-called "place exchange," to yield a thermodynamically more stable product designated "HOPT". Shibata found that the diffraction pattern obtained by LEED for an electrode polarized at $E > 1.15V$ vs. NHE, followed by reduction of the oxide, was identical to the pattern for Pt black. It is at a potential of 1.15V where place exchange is concluded to become significant.

Vetter (28) and Vetter and Schultze (29) investigated the growth mechanism of the surface oxide on Pt electrodes. The accumulated anodic charge (Q_{ox}) corresponding to formation of the oxide at $1.0 < E < 2.0V$ increases linearly with $\log t$ for $t = 2 \text{ ms} - 1000s$. At a fixed value of t , Q_{ox} increases as a linear function of E . They concluded that only a phase oxide exists at the electrode surface which increases in thickness with increasing time and potential. The growth mechanism was concluded to include the field-assisted place exchange of Pt²⁺ and O²⁻ ions to produce the phase oxide lattice. Such a mechanism had been proposed by Visscher and Devanathan (30) and Ord and Ho (31). For low surface coverage, the rate-determining

Key words: platinum oxide, modulated voltammetry, anode, ring-disk electrode.

step (rds) is that between the Pt^{2+} at the electrode surface and O^{2-} in the inner Helmholtz plane. At high coverages, the place-exchange mechanism is still operative, but the rds cannot unambiguously be assigned as occurring at the metal-metal oxide interface or the metal oxide-inner Helmholtz interface.

The anodic signal for As(III) at an oxide-covered Pt electrode can decrease significantly below the theoretical transport-limited value, and yet the current is essentially independent of potential over a significant range (32). Hence, the rds does not involve charge transfer, nor is inhibition the result of iR-loss across a poorly conducting oxide layer. Faradaic reactions at rotating disk electrodes (RDE) under mixed control by mass transport and kinetics produce electrode currents (33) which are smaller than the transport-limited value, as described by

$$i = \frac{nFA DC^b}{\delta + K} \quad [3]$$

where n , F , A , D , and C^b have their usual electrochemical significance. The thickness (δ) of the diffusion layer at the electrode-solution interface is

$$\delta = 1.62 D^{1/3} \omega^{-1/2} \nu^{1/6} \quad [4]$$

where ω is the angular velocity (rad/s) of electrode rotation and ν is the kinetic viscosity (cm^2/s) of the solution. The parameter K in Eq. [3] is of a form dependent on the nature of the kinetic mechanisms involved. For mixed control involving a slow chemical step at the electrode surface, $K = D/k$ where k is a potential-independent rate constant. For slow electron-transfer kinetics, k is potential dependent. The numerical value of K is easily calculated from the intercept of a plot of i^{-1} vs. $\omega^{-1/2}$. The slope of such a plot is identical to that for the transport-limited case (i.e., $K = 0$) for which the intercept is zero.

Experimental

Instrumentation.—Disk and ring-disk electrodes were from Pine Instrument Company, Grove City, Pennsylvania. These included: a Model DD20 Pt RDE (area = 0.455 cm^2), a Model DT06 Pt-Pt RRDE (disk area = 0.459 cm^2 , $\beta^{2/3} = 0.368$, and $N = 0.178$), and a Model AFMD18 (area = 0.166 cm^2). The electrodes were polished according to the usual metallographic procedures with $1 \mu\text{m}$ alumina on microcloth for the final step. The Model ASR-2 and Model MSR rotators were from Pine Instrument Company. The MSR rotator is designed for hydrodynamically modulated voltammetry and can accelerate from 1000 to 4000 rev/min in 22 ms. The potentiostat was a Model RDE3, Pine Instrument Company, or a Model 173, EG&G Princeton Applied Research, Princeton, New Jersey, equipped with a Model 176 current-to-voltage converter. Voltage waveforms generated by a Model 175 Universal Programmer, EG&G Princeton Applied Research, were used occasionally. The Model RDE3 bipotentiostat was used for all ring-disk studies. The reference electrode was a miniature saturated calomel electrode (SCE), Corning Scientific Instruments, Corning, New York. Current-potential (i-E) curves were recorded on an Omnigraphic Series 100 X-Y recorder, Houston Instruments, Austin, Texas. Instrumentation for square wave hydrodynamically modulated voltammetry has been described elsewhere (22).

Chemicals.—All chemicals were reagent grade from Baker Chemical Company. Solutions of As(III) were prepared by dissolving As_2O_3 in a minimal volume of a concentrated solution of NaOH with subsequent dilution by H_2O . All H_2O was triply distilled; demineralization followed the first distillation, the second distillation was from alkaline permanganate solution (ca. 0.1M KMnO_4 , 0.1M KOH), and the final distillation was from $1\text{M H}_2\text{SO}_4$. Dissolved O_2 was removed by dispersed N_2 .

Procedures.—The technique of square wave modulated hydrodynamic voltammetry (22, 34) is based on the measurement of the component of total electrode current

which is coupled to the frequency of a square wave variation of the rotational velocity during application of a slow, staircase potential waveform. The modulated signal is free of contributions from surface controlled processes, e.g., double layer charging, oxide formation, and solvent breakdown. The experimental conditions were similar to those used previously (22): $t_d = 150 \text{ ms}$, $N = 10$, $\Delta E = 5 \text{ mV}$, and $\phi = 0.15 \text{ V/min}$.

Results and Discussion

Voltammetric study of As(III) as a function of concentration.—Current-potential (i_d - E_d) curves obtained at the Pt RDE are shown in Fig. 1. A residual curve is included for comparison. In the absence of As(III), the surface oxide is formed during positive scan of potential for $E_d > 0.55 \text{ V}$; this oxide is reduced on the subsequent negative scan to produce peak D at $E_p = 0.48 \text{ V}$. Faradaic formation and subsequent dissolution of adsorbed atomic hydrogen occurs for $0.1 > E_d > -0.2 \text{ V}$, and evolution of $\text{H}_2(\text{g})$ occurs for $E_d < -0.2 \text{ V}$. The adsorption of As(III) results in suppression by ca. 150 mV of the anodic formation of surface oxide; and the large peak-shaped wave (C) with $E_p = 0.85 \text{ V}$ corresponds to the simultaneous processes of (i) oxide formation, (ii) oxidation of adsorbed As(III), and (iii) oxidation of As(III) transported to the electrode surface by the convective-diffusional process. The total anodic current decreases steadily during the continuing positive scan of $E_d > 0.85 \text{ V}$, until the onset of $\text{O}_2(\text{g})$ evolution at $E_d > 1.25 \text{ V}$. The predominant cause of the decay for this high rate of potential scan ($\phi = 6.0 \text{ V/min}$) is the loss of the contribution from oxidation of the adsorbed As(III). A current plateau (i.e., potential-independent current) is observed for As(III) oxidation during the negative scan in the region $1.2 > E_d > 0.7 \text{ V}$. Oxidation of As(III) ceases with reduction of the surface oxide to produce peak D. Because oxidation of As(III) can occur during the negative scan at the oxide-covered surface at least to $E_d = 0.6 \text{ V}$, whereas oxidation of As(III) at the oxide-free surface does not commence on the positive scan until $E_d > 0.7 \text{ V}$, it is concluded that oxidation of As(III) is catalyzed by the surface oxide, in agreement with the conclusion of Zakharov and Songina (20). Because of the similarity of the height for peak D in the presence and absence of As(III), it is concluded to a first approximation that the extent of oxide formation for $E_d > \text{ca. } 1.0 \text{ V}$ is unaffected by the presence of As(III). The nature of the faradaic process generating peak E will be discussed later.

Fig. 1. Current-potential curves for Pt RDE as a function of $C^b_{\text{As(III)}}$. Electrode: DD20 Pt RDE. Conditions: $\omega = 104.7 \text{ rad/s}$, $\phi = 6.0 \text{ V/min}$, 0.50M HClO_4 . (---) residual, (—) $4.01 \times 10^{-5}\text{M As(III)}$, (---) $1.97 \times 10^{-4}\text{M As(III)}$, (— · —) $3.83 \times 10^{-4}\text{M As(III)}$.

Variation of scan limits.—Wave F on the negative scan for $E_d < 0.0V$ in Fig. 1, and peaks A and B on the subsequent positive scan, correspond to cathodic deposition and oxidation of As(0), respectively. Peaks A and B are not obtained when the cathodic (*i.e.*, negative) scan limit (E_c) is $\geq 0.0V$. When the quantity of deposited As(0) is increased beyond that for Fig. 1, accomplished by use of higher concentrations of As(III) or by cessation of the potential scan at $E_c < -0.2V$, the area of peak A continues to grow in proportion to the amount of deposited As(0); however, the area of peak B reaches a limiting value. Peak A is concluded to correspond to the anodic stripping of bulk As(0), which is not stabilized by interaction with the Pt substrate, and peak B is concluded to correspond to oxidation of As(0) adatoms. The potential for onset of $H_2(g)$ evolution (*ca.* $-0.25V$) does not change with As(0) deposition.

Current-potential curves were recorded as a function of the anodic (*i.e.*, positive) scan limit (E_a) for $E_c = 0.7-1.4V$. For $E_a = 0.8V$, only a slight quantity of oxide is formed, and the cathodic peak for oxide reduction is barely perceptible on the negative scan. Clearly, the quantity of oxide increases substantially for $E_a > 0.8V$ and E_p for peak D is shifted to more negative values, as is observed for the absence of As(III) (23-26). Although accurate integration of peak D is not possible as a function of the variation in E_a , due to interference by peak E, the height of peak D is approximately the same in the presence and absence of As(III) for all values $E_a \geq 1.0V$. This is consistent with the conclusion made above that the presence of As(III) has minimal effect on the quantity of oxide produced on the time scale of the cyclic voltammetry, provided the adsorbed As(III) has been totally oxidized to soluble As(V) during the positive scan.

Variation of rotational velocity (ω).—The effect of variation of ω on the i_d-E_d curve for As(III) is shown in Fig. 2. As ω is increased, the anodic current for any value $E_d > 0.8V$ also is increased because of the increased flux of As(III) from the bulk solution to the electrode surface. The observation of a plateau current on the negative scan in the region $1.2 > E_d > 0.8V$ could be easily mistaken as diagnostic evidence that the corresponding electrode reaction is mass-transport limited. Accordingly, a plot of i_d vs. $\omega^{1/2}$ would be expected to be linear (see Eq. [3] and [4] for $K = 0$) with a slope of $0.62nFAD^{2/3}\nu^{-1/6}C^b$, as predicted by Levich (33, 35). For the oxidation of As(III) with $\phi =$

Fig. 2. Current-potential curves for As(III) as a function of ω . Electrode: DD20 Pt RDE. Conditions: $\phi = 6.0 V/min$, $1.97 \times 10^{-4}M$ As(III) in $0.50M$ $HClO_4$, ω (rad/s): (—) 0.00, (—) 10.47, (---) 104.7, (----) 418.9.

$6.0 V/min$, such a plot deviates severely from linearity and the expected slope, and is indicative of mixed control.

There is a dramatic difference between the features of the i_d-E_d curves for $\omega = 0$ rad/s and those for $\omega > 0$ rad/s. Peak E is made very prominent, and peaks A and B appear distinctly for the absence of rotational velocity. For $\omega = 0$ rad/s, the As(V) produced anodically for $E_d > 0.8V$ remains in the diffusion layer during the time in which E_d is scanned to E_c . It is concluded that As(V) is deposited as As(0) at underpotential in the region of peak E and subsequent oxidation of the deposition product yields peaks A' and B. The lesser peak E observed for $\omega > 0$ rad/s is concluded to result from As(V) adsorbed on the oxide-covered surface.

Voltammetric study of As(V).—While the electrochemistry of As(V) is not of primary interest here, it is informative to consider the voltammetric response of As(V) as it relates to our understanding of the As(III)-As(V) half-reaction. Arsenic(V) is generally considered to be electroinactive without the benefit of extensive coordination by ligands other than water. Several i_d-E_d curves are shown in Fig. 3 for As(V) as a function of E_c ; a residual curve is included for comparison. Peak E, concluded to result in part from the underpotential deposition of As(V), is clearly visible, as are peak A', B, and C. Since the potential of peak A' (0.25V) for As(V) in Fig. 3 is slightly different than the potential of peak A (0.20V) in Fig. 1 observed when an extensive quantity of bulk As(0) is deposited from a solution of As(III), the stability of the As(0) adatoms producing peak A' is concluded to be slightly greater than that of bulk As(0). We conclude that peaks A' and B represent oxidation of As(0) adatoms to As(III) adions on the polycrystalline surface. The As(III) adions produced by anodic processes yielding peaks A' and B are oxidized to soluble As(V) by the process producing peak C. The combined area of peaks A', B, and C, measured by a planimeter with respect to the residual curve, was found to be within *ca.* 10% of the area for peak E. This is in excellent agreement with the proposed mechanism for production of these peaks, in view of the probable error in the assumption that the residual curve shown accurately represents the background signal in the presence of As(V). Although a clear distinction is made here between peak A' for As(V) (see Fig. 3) and peak A for As(III) (see Fig. 1), oxidation of As(0) adatoms at 0.25V certainly contributes to the larger peak A obtained for stripping of bulk As(0).

Ring-disk studies.—The rotating ring-disk electrode (RRDE) is recognized as a valuable tool for the investigation of electrode reactions (35, 36). Since As(V) does not exhibit continuous electroactivity at a constant electrode potential, meaningful collection experiments cannot be performed for solutions of As(III) with detection of As(V) at the ring electrode. The use of a Pt ring electrode for

Fig. 3. Current-potential curves for As(V) as a function of E_c . Electrode: DD20 Pt RDE. Conditions: $\omega = 100.0$ rad/s, $\phi = 6.0 V/min$, $1.41 \times 10^{-4}M$ As(V) in $0.50M$ $HClO_4$, E_c (vs. SCE): (---) 0.10, (----) -0.10, (—) -0.28, (—) -0.25 (Pt residual).

shielding experiments was not satisfactory because of the continual decay of activity of the Pt electrode for anodic detection of As(III) caused by buildup of surface oxide at the detection potential. The oxidation of As(III) at a Au electrode occurs at a transport-limited rate (18), and the Pt ring of the RRDE was electroplated with Au. The i_d - E_d and i_r - E_d curves for $E_r = 1.0V$ are shown in Fig. 4 for a solution of 0.098 mM As(III). The ring current at $E_d = 0.0V$ is slightly less than the predicted value of 22.2 μA , for this value of $C^b_{As(III)}$; however, i_r increases slightly beyond the predicted value as E_d is scanned positive. This phenomenon is concluded to result from the potential-dependent adsorption and desorption of As(III) at the disk electrode for $E_d < 0.6V$. If the scan of E_d was halted at any value in the region $0.0 < E_d < 0.6V$, the value of I_r quickly drifted to the theoretical limiting value. At $E_d = 0.65V$ on the positive scan, the oxidation commences for As(III) from the bulk solution, and i_r decreases accordingly (*i.e.*, the ring electrode is shielded). The value of i_r measured at $E_d = 0.85V$ on the positive scan is 11.1 μA for $\phi = 6.0$ V/min, in excellent agreement with the predicted value of 11.4 μA for a transport-limited reaction at the disk electrode. For $E_a > 1.3V$, at the scan rate used here, the value of i_r measured in the region $0.8 < E_d < 1.2V$ during the negative scan is slightly greater than that predicted for the mass-transport-controlled oxidation of As(III) at the disk electrode. This observation is in agreement with the conclusion based on the plot of i_d vs. $\omega^{1/2}$ that oxidation of As(III) at an oxide-covered surface is under mixed control, *i.e.*, the value of i_d is less than the transport-limited value. Shielding of the As(III) flux to the ring electrode during the negative scan of E_d continues to ca. 0.7V, in agreement with the previous observation (see Fig. 1) that oxidation of As(III) at a Pt electrode is made more reversible by the presence of the surface oxide.

Shielding of the ring electrode decreases as the oxide at the disk electrode is cathodically reduced ($E_p \approx 0.4V$), but then increases again for E_d in the region of peak E (see Fig. 1). We conclude that As(III) is adsorbed at the disk electrode in the region of peak E with partial charge transfer. Loucka (38) concluded that As(III) is adsorbed from 0.5M H_2SO_4 with electrodeposition as As(0) for $E < 0.7V$ vs. NHE. We are hesitant to agree with Loucka's conclusion because of the absence of distinct anodic peaks in the region $0.1 < E_d < 0.6V$ during the subsequent positive scan for oxidation of the As(0) adatoms. The adsorption of As(III) at the disk electrode is complete for $E_d \approx 0.05V$, and i_r increases to the unshielded value.

Fig. 4. Current-potential curves for As(III) at RRDE. Electrode: DT06 Pt-Pt RRDE. Conditions: $\omega = 100.0$ rad/s, $\phi = 6.0$ V/min, $9.8 \times 10^{-5}M$ As(III) in 0.50M $HClO_4$, $E_r = 1.00V$ vs. SCE. E_a for disk electrode (vs. SCE): (---) 1.40V, (—) 1.50V, (- · -) 1.60V.

The ring-disk experiment was repeated with variation of E_a and E_c , and the i_d - E_d and i_r - E_d curves are shown in Fig. 5 for 0.524 mM As(III). Of greatest interest is the case of $E_c = -0.2V$, in which bulk As(0) is deposited at the disk electrode. Anodic peaks A and B for the i_d - E_d curve, previously concluded to correspond to oxidation of bulk As(0) (peak A) and As(0) adatoms (peaks A' and B'), result in production of some soluble As(III), which is subsequently detected at the ring electrode. (Note: the oxidation of As(0) at the disk electrode involves 3 eq/mol, whereas the detection of As(III) at the ring electrode involves 2 eq/mol.) The value of the peak current at $E_d = 0.2V$ on the i_r - E_d curve is $70 \pm 10\%$ of the value expected if all As(III) produced for peak A in the i_d - E_d curve is soluble, whereas the peak current at $E_d = 0.5V$ on the i_r - E_d curve is $90 \pm 10\%$ of the theoretical for peak B in the i_d - E_d curve. Hence, a significant stripping fraction of the As(III) produced by the anodic stripping of bulk As(0) remains adsorbed at the electrode surface. The possibility that oxidation of As(0) to As(V) could occur at the disk electrode for $E_d < 0.7V$ is not likely, given the value of 0.132V vs. SCE for the standard reduction potential of the As(V)-As(0) couple, which is 0.125V positive of the standard reduction potential for the As(III)-As(0) couple.

It is important to observe that the area of peak C in the i_d - E_d curve, resulting from oxidation of adsorbed As(III) adions to As(V), is not increased substantially if bulk As(0) is deposited for $E_c < 0.0V$ (compare the i_d - E_d curves for $E_c = 0.0$ and $-0.2V$). Apparently, the surface coverage by As(III) is fixed by the adsorption isotherm and the bulk concentration for As(III) whether or not As(0) has been deposited previously on the electrode. The adsorption isotherm for As(III) was determined from transient ring-disk experiments as a function of $C^b_{As(III)}$ in the manner reported previously for I^- at Pt (37). In essence, the quantity of As(III) adsorbed was calculated from the integrated area of the shielding wave in the i_r -time curves recorded following a step of E_d from 1.2 to 0.2V and to 0.0V. The isotherms, shown in Fig. 6, are virtually the same for both experiments. The limiting surface coverage by adsorbed As(III) is produced for $C^b_{As(III)} > 6 \times 10^{-5}M$ and corresponds to 2.3×10^{-9} mol/cm² or 1.38×10^{15} at./cm². The approximate surface density of Pt atoms for a perfectly smooth polycrystalline electrode is 1.35×10^{15} at./cm². There was no effort to determine the surface roughness of

Fig. 5. Current-potential curves for As(III) at RRDE. Electrode: DT06 Pt-Pt RRDE. Conditions: $\omega = 100.0$ rad/s, $\phi = 6.0$ V/min, $5.24 \times 10^{-4}M$ As(III) in 0.50M $HClO_4$, $E_r = 1.00V$ vs. SCE. Scan limits for disk electrode (vs. SCE): (---) $E_a = +1.10V$, $E_c = -0.20V$; (····) $E_a = +1.10V$, $E_c = 0.00V$; (—) $E_a = +1.40V$, $E_c = 0.00V$.

the electrode; however, if a roughness factor of 2 is reasonable, a 1:2 correspondence exists for As(III): Pt.

Variation of potential-scan rate (ϕ).—The effects of increasing ϕ on the i_a - E_d curve for As(III) were observed. As expected for the surface-controlled reactions contributing to peaks C and D, these peaks increase with increasing ϕ in the range $\phi = 1-6$ V/min. Of greater interest, however, are the large, cathodic, surface-controlled currents observed during the negative scan in the region $0.4 > E_d > 0.0V$ and the anodic current during the positive scan for $0.0 < E_d < 0.7V$ (see Fig. 2 for $\omega > 0$ rad/s). Peak E has been assigned on the basis of ring-disk studies (Fig. 4 and 5) to the adsorption of As(III) with partial charge transfer. Given the absence of a sharp anodic peak on the subsequent positive scan, we conclude tentatively that As(0) adatoms, as a discreet oxidation state, are not involved. The double layer capacitance for a Pt electrode in

a pure acidic electrolyte is ca. $40 \mu fd/cm^2$. Estimates of the apparent capacitance from the observed currents as a function of ϕ yielded values of $1050 \mu fd/cm^2$ at 1.0 V/min and $856 \mu fd/cm^2$ at 10.0 V/min. The anomalously large capacitance calculated for an adsorption process accompanied by partial charge transfer to produce adions having an intermediate oxidation state is described as "pseudocapacitance" (39-42). The arsenic adions, in whatever oxidation state integral or fractional, are probably reduced to As(0) for $E_d < 0.0V$ (see Fig. 1), and the subsequent voltammetric oxidation of As(0) yields distinct anodic peaks (A and B in Fig. 1). The underpotential deposition of As(V) as As(0) adatoms in the region of peak E eliminates the appearance of the pseudocapacitance for the region $0.0 \leq E_d \leq 0.15V$ (Fig. 2).

We rationalize the adsorption of As(III) with partial charge transfer on the basis of π bonding. It is known for some compounds containing arsenic that if the atom to which arsenic has donated electrons also has an orbital of the same symmetry as the empty d orbitals of arsenic, back-donation can occur resulting in overall multiple-bond character (43). While it may be meaningless to discuss Pt d orbitals on the surface of a polycrystalline metal which is not perfectly smooth, there is solid evidence of Pt contributing to $d\pi$ - $d\pi$ bonding in CO adsorption (44). Such back-donation implies a specific preferred orientation of the adsorbed species on the electrode surface. The conclusion of specific binding of arsenic adions to Pt atoms is not contradicted by any voltammetric observations.

Square wave hydrodynamically modulated voltammetry (QHMV).—The total anodic current observed for As(III) at $E_d > 0.8V$ on the positive scan is the result of two surface-controlled processes plus the oxidation of As(III) from the bulk solution under mixed transport-kinetic control. The application of QHMV has been described for distinguishing the transport-controlled component of electrode currents (22, 34) in the presence of surface-controlled reactions. The modulated technique ignores the surface-controlled currents from double layer charging, faradaic reaction of adsorbed species, formation and dissolution of surface oxides, and the evolution of $O_2(g)$ and $H_2(g)$ by breakdown of the solvent.

In Fig. 7 are shown Δi_a - E_d curves obtained by QHMV for 2.0 mM As(III). The residual response is not shown because Δi_a remained at zero for virtually the entire range of E_d shown. The value of Δi_a measured on the positive scan is at a maximum for $0.8 < E_d < 0.9V$, which is concluded to correspond to an appreciable surface coverage by

Fig. 7. Current-potential curves by square-wave hydrodynamically modulated voltammetry for As(III) at RDE. Electrode: AFMD18 Pt RDE. Conditions: $\Delta\omega^{1/2} = 20.47-10.23$ (rad/s) $^{1/2} = 10.23$ (rad/s) $^{1/2}$; $\phi = 0.15$ V/min; 2.0 mM As(III) in $0.50M$ $HClO_4$. E_d (vs. SCE): (a) 0.90V, (b) 1.00V, (c) 1.10V, (d) 1.20V, (e) 1.30V, (f) 1.40V, (g) 1.50V, (h) 1.60V, (i) 1.70V.

PtOH ($\theta \ll 1$). The Δi signal gradually decreases as the positive scan of E_d continues. When the scan is reversed for $E_a > 1.2V$, Δi_d drops significantly below the maximum value to a value which is, to a good approximation, independent of E_d for $0.9 < E_d < 1.2V$. Hence, the rate-determining step does not involve charge transfer and is concluded to involve a slow chemical transfer of oxygen to As(III) from the oxide-covered surface. The value of Δi_d measured at $E_d = 1.00V$ on the negative scan decreases significantly as E_a , for the preceding positive scan, is increased beyond 1.2V. It should be noted that the slow scan rate used allows a greater amount of surface oxide to be formed for $E_d > 1.2V$ as compared with the high scan rate used for Fig. 1. This undoubtedly corresponds to oxide coverage beyond the equivalent of a monolayer of PtO (i.e., $\theta > 2$). Even for an extensive layer of surface oxide (e.g., $E_d = 1.6V$), oxidation of As(III) in the region $E_d \gg 1.2V$ occurs at a rate nearly equal to the maximum value observed for the highly active PtOH surface. We note with enthusiasm that evolution of $O_2(g)$ ceases at ca. 1.2V on the negative scan (see residual curve of Fig. 1) which is the potential at which Δi has decreased to its minimum value during the negative scan. In a separate experiment, the negative scan from $E_a = 1.50V$, was reversed at $E_c = 1.0V$; Δi_d increased again to the value shown in Fig. 7 for $E = 1.50V$. We conclude that the oxidation of As(III) at the oxide-covered surface is catalyzed by the evolution of $O_2(g)$. Since the homogeneous oxidation of As(III) by $O_2(g)$ occurs at a negligible rate in acidic media (16), we conclude the catalytic mechanism occurs by way of adsorbed $\cdot OH$ generated as the first step in the mechanism for evolution of $O_2(g)$ (45, 46).

The role of the formation of surface oxide, starting at $E_d = ca. 0.8V$ on the positive scan, in the electrocatalysis of the oxidation of As(III) is amplified further by a wave analysis performed for the rising part of the Δi_d - E_d curve in the vicinity of $E_{1/2}$. The value of $E_{2/3} - E_{1/3}$ is ca. 20 mV in comparison to the value 17.8 mV expected for a reversible process ($n = 2$) without electrocatalytic involvement of the electrode surface. This apparent "reversibility," in spite of the fact that the value of $E_{1/2} = 0.78V$ is ca. 0.46V positive of the value of E° for the As(V)-As(III) half-reaction in this medium (0.32V), is further diagnostic evidence of electrocatalysis in which the value of $E_{1/2}$ is determined by the potential dependence of the catalytic surface state rather than the standard reduction potential of the electroactive species in the solution. The value of $E_{1/2}$ for the electrocatalyzed-oxidation of As(III) observed on the negative scan for $E_a = 0.90$ is 0.65V, which is ca. 0.13V negative of the value observed for the positive scan. The loss of electrocatalytic activity on the negative scan is the result of the reduction of the surface oxide to produce peak D (see Fig. 1).

Effect of variation of E_a .—The catalytic benefit of the formation of the surface oxide for oxidation of As(III) at Pt electrodes is clearly indicated, although the maximum transport-coupled signal is less than the theoretical. Yet, the formation of oxide beyond the equivalent of $\theta = 1$ ($E_a > 1.0V$) results in a decrease of the anodic current for As(III) well below the transport-limited value, and for $\theta > 2$ ($E_a > 1.3V$) the current is severely inhibited (see Fig. 7). The involvement of the surface oxide in the reaction mechanism was characterized further by the determination of the rate constant (k) for the mixed control from current measurements made at $E_d = 1.0V$ following anodic polarization of the electrode to values of $E_a > 1.1V$. Accordingly E_d was cycled at $\phi = 6.0$ V/min between $E_c = 0.0V$ and the designated value of E_a . After several cyclic scans to insure the reproducibility of the i - E response, the scan of E_d was halted at 1.0V on the negative scan and i_d was obtained as a function of ω within a time period of ca. 50s. The rate of oxide growth at 1.0V is minimal under these conditions when $E_a > 1.1V$, and the quantity of oxide was presumed constant during the time in which the i_d - ω data was recorded. The corresponding value of k for each value of E_a was calculated from the intercept of plots

of i^{-1} vs. $\omega^{-1/2}$. The resulting plot of $\ln k$ vs. E_a is linear, as shown in Fig. 8 (curve on right).

The area (Q_{ox}) under the reduction peak for the surface oxide (peak C in the residual curve of Fig. 1) was measured as a function of E_a in the absence of As(III). The values of Q_{ox} were determined to be a linear function of E_a as represented by

$$Q_{ox} = (546 \mu C/V) (E_a - 0.79) \quad [5]$$

The quantity ($E_a - 0.79$) in Eq. [5] represents the effective overpotential observed for oxide formation (η_{ox}). The linear correspondence of Q_{ox} and E_a has already been noted (23, 28, 29). Continuing with our conclusion made earlier that Q_{ox} for $E \geq 1.0V$ is the same for the presence or absence of As(III), the values of $\ln k$ were replotted as a function of Q_{ox} , and the result is shown in Fig. 8 (curve on left). The equations of the linear plots in Fig. 8 are as follows: for $\log k$ vs. E_a

$$\log k = 1.77 - 2.46 E_a$$

and for $\log k$ vs. Q_{ox}

$$\log k = -0.174 - (4.48 \times 10^{-3}) Q_{ox}$$

In the equations above, k has dimensions in centimeters per second and Q_{ox} is in microcoulombs. Alternately

$$k = M \cdot \exp \{ -E_a/E_0 \} \quad [6]$$

and

$$k = N \cdot \exp \{ -Q_{ox}/Q_0 \} \quad [7]$$

where $M = 58.9$, $E_0 = 0.177V$ vs. SCE, $N = 0.670$, and $Q_0 = 97.0 \mu C$.

Conclusions

We conclude that oxygen from adsorbed $\cdot OH$ (i.e., PtOH) generated as the first step in the formation of surface oxide at a Pt electrode, and in the evolution of $O_2(g)$, is rapidly transferred to As(OH)₃ in the electrocatalyzed production of OAs(OH)₃. The rate of the surface reaction between adsorbed $\cdot OH$ and As(OH)₃ can be sufficiently rapid (i.e., $\theta \rightarrow 1$) so that the faradaic current for As(III) is nearly equal to the transport-limited value for low ω .

Results reported here for Pt electrodes bearing extended layers of PtO (i.e., $\theta > 2$) do not rule out the possibility of oxygen abstraction by As(OH)₃ directly from the PtO as well; however, the abstraction reaction is very slow, is independent of potential for a constant oxide coverage, and decreases with increases in the quantity of oxide (Q_{ox}). The $O_2(g)$ evolution reaction on oxide-covered Pt electrodes has been reported also to occur at a rate which decreases with increases in the oxide coverage (45, 46).

Mechanisms are proposed below for the electrocatalyzed oxidation of As(III) at an oxide-free Pt electrode initiated by discharge of adsorbed $\cdot OH$ (Scheme I) and the possibility of the much slower oxygen abstraction from an oxide-covered surface (Scheme II). The variant of Scheme I involving $\cdot OH$ adsorbed at an oxide-covered surface is self-evident.

Scheme I (oxide-free surface)

Scheme II (oxide-covered surface)

Fig. 8. Plot of $\log k$ vs. E_a and Q_{ox} .

The product of the reaction in Eq. [10] can be viewed simply as the activated state in a mechanism analogous to a bimolecular substitution reaction. Accordingly, the approach of the lone electron pair of As(III) toward the antibonding orbital of the surface oxygen results in a shift of electron density, as illustrated below. Ultimately, the surface oxygen is released from the Pt, and formation of $\text{OAs}(\text{OH})_3$ is complete.

Adsorbed As(III) at an oxide-free Pt surface reacts rapidly with $\cdot\text{OH}$ discharged at adjacent surface sites; however, there is no evidence yet that adsorption of As(III) at sites adjacent to the oxygen bearing site is a prerequisite to reactivity. If adsorption of As(III) at oxide-free Pt sites is indeed a prerequisite to oxidation, a seemingly convenient explanation of the loss activity for a surface covered by an extended layer of PtO (*i.e.*, $\theta > 2$) could be based on the consequential decrease in the surface density of Pt adsorption sites. Such an electrode surface would not be uniformly accessible, and the observed limiting current would be much less than the theoretical transport-limited current (*i.e.*, the "Levich current") for a uniformly accessible electrode. The response of nonuniform electrodes has been considered by Nagy *et al.* (47), and by Landsberg and Thiel (48). This explanation of the mixed control observed for oxidation of As(III) will be tested in Part II of this work. Also in Part II, the results of kinetic studies of the electrocatalyzed oxidation of As(III) at Pt electrodes will be presented.

ABSTRACT

Mixtures of SbCl₃ and N-(1-butyl)pyridinium chloride (BPCl) containing 75-87 m/o (mole percent) SbCl₃ and SbCl₃-AlCl₃-BPCl mixtures containing 60 m/o SbCl₃ and 16-23 m/o AlCl₃ were found to be liquid at 25°C. Dilute solutions of anthracene were stable in ternary mixtures containing 18 m/o AlCl₃, but in mixtures containing 22-24 m/o AlCl₃, anthracene reacted under the influence of the solvent, which behaved as both oxidant and H-transfer catalyst. The oxidized product was protonated anthracene, which was stable in this melt. The source of protons was provided by hydrogen liberating Scholl condensations combined with the reduction of Sb(III). A part of the hydrogen from Scholl reactions reacted with anthracene to form 9,10-dihydroanthracene. By contrast, a liquid mixture without SbCl₃, AlCl₃-BPCl (2:1 mole ratio) proved to be a much less active H-transfer catalyst than the SbCl₃-rich liquids even though it is a stronger Lewis acid, and it did not induce protonation beyond a trace attributable to protic impurities. The role of impurities in these mixtures was investigated with results that are relevant to earlier investigations of liquid AlCl₃-BPCl mixtures. An improved procedure for purifying BPCl is described.

Studies of polycyclic aromatic hydrocarbons and hydroaromatics in anhydrous SbCl₃-based melts have shown these melts to be extremely active solvent-catalysts for a variety of hydrogen redistribution reactions at surprisingly low temperatures, 80°-130°C (1-5). Under certain conditions, these melts can also act as oxidizing reagents toward arenes, and some of the resulting reactions are of unusual types (4, 5). The melts investigated previously have either been pure SbCl₃ or SbCl₃ with 1-10 m/o (mole percent) of added chloride ion donor, such as KCl, or chloride ion acceptor, such as AlCl₃. The added chloride ion donor reduces the oxidizing power of the melt while the added acceptor increases it.

The development by Osteryoung *et al.* (6) of low-melting chloroaluminate systems by replacing the usual alkali-metal cations with N-(1-butyl)pyridinium cations (BP⁺) led us to investigate the possibility of preparing

SbCl₃-rich mixtures that are molten at ambient temperatures by adding moderate amounts of BPCl or BPAICl₄ to SbCl₃. We felt these mixtures might retain the useful properties of the higher melting salts and, at the same time, have the convenience of being liquid under ambient conditions. We found that SbCl₃-BPCl mixtures containing 75-87 m/o SbCl₃ and SbCl₃-BPAICl₄ mixtures containing 75 m/o SbCl₃ are liquid at 25°C. In the latter mixtures, BPAICl₄ is formed *in situ* by adding BPCl and AlCl₃ in equal amounts to SbCl₃. The SbCl₃-BPAICl₄ mixture was of particular interest to us because of the possibility of varying the melt acidity and oxidizing power over substantial ranges by adding relatively small amounts of the base BPCl, or generating acidic SbCl₂⁺ ions by adding AlCl₃, which reacts with SbCl₃ to form SbCl₂⁺ and AlCl₄⁻ (see below). Although we made no attempt to establish the solubility limits of those additions, we showed that systems formed by mixing 60 m/o SbCl₃, 17-24 m/o BPCl, and the balance, AlCl₃, are liquid at 25°C.

Having established the occurrence of these low-melting SbCl₃-rich melts, we wished to determine to what extent SbCl₃ diluted by 25 m/o BPAICl₄ at ambient temperature retains the catalytic properties that SbCl₃ displays at ele-

Key words: catalysis, organic, spectra.

ated temperatures. For this purpose, we chose anthracene as the hydrogen-transfer substrate because of the extensive research (1, 3-5) on its reactivity in SbCl_3 -rich high-melting mixtures. The results of this investigation are given here.

It is important to recognize that the solvent-catalyst properties of SbCl_3 - BPAICl_4 with added AlCl_3 are fundamentally different from those of ambient temperature chloroaluminate melts. In the SbCl_3 -rich melts, SbCl_2^+ is the Lewis acid and has an additional redox functionality, whereas, in the chloroaluminate melts, the Lewis acidity resides in Al_2Cl_7^- , which has no redox functionality. In this paper, we demonstrate the consequences of these differences.

A final and by no means trivial item considered here is our discovery that BPCl purified by the procedures conventional in studies of ambient temperature chloroaluminate melts is contaminated by water and ethyl acetate to a degree that has serious consequences for investigations of the chemistry of dilute solutions of organics both in SbCl_3 -rich and in chloroaluminate melts.

Experimental Section

Materials.—Antimony(III) chloride (Alfa, 99% minimum) was purified by the following procedure. It was first melted under argon and mixed with Sb metal in order to reduce any Sb(V) and with Sb_2O_3 to remove volatile chloride impurities. This was followed by two sublimations under dynamic vacuum and then zone refining a minimum of thirty passes. The resultant colorless crystals melted to give a clear colorless liquid.

Aluminum chloride (Fluka, puriss.), to which 1 w/o (weight percent) purified NaCl was added, was refluxed over high purity aluminum (Alfa, M6N) for 3 days in sealed quartz ampuls, and then distilled away from the NaAlCl_4 phase. This procedure was repeated twice and the resulting AlCl_3 crystals were then vacuum sublimed through a fine porosity Pyrex frit. The purified AlCl_3 crystals were colorless and melted to form a colorless liquid. The NaCl used in this procedure was prepared from reagent grade material, purified by vacuum drying in the solid state followed by melting and bubbling first HCl and then argon (both high purity grades) through the melt.

BPCl was prepared from pyridine (Fisher, certified ACS) and 1-butylchloride (Matheson, Coleman, and Bell, >98%). The starting materials were further purified by distillation from P_2O_5 under argon. The synthetic procedure given by Robinson and Osteryoung (8) was followed. As an added precaution, each step was carried out under argon because BPCl is exceedingly hygroscopic. The product was recrystallized five times under argon from acetonitrile (Fisher, certified ACS), which had been distilled under argon from P_2O_5 . In the original procedure (8), ethyl acetate was used in recrystallizing the final product but we omitted this material because we were unable to remove it completely from crystalline BPCl even after prolonged heating under vacuum at 110°C . The BPCl was dried under vacuum in the presence of P_2O_5 in a drying pistol at 110°C and the drying pistol was transferred to the glove box while still under vacuum. During preparation and all subsequent handling, BPCl was shielded from exposure to light. The water content of the final product was determined by Karl Fischer analysis (Galbraith Laboratories) to be $\leq 0.2\%$. The elemental analysis (Galbraith Laboratories) showed 62.75% C, 8.06% H, 8.34% N, 20.59% Cl, and 0.14% O (calculated values: C 62.97; H 8.22; N 8.16; Cl 20.65). The BPCl was further analyzed for organic impurities by dissolving a 1g sample in a small amount of water and then extracting with three 30 ml aliquots of methylene chloride. After drying with CaSO_4 and reducing the volume to 5 ml, the methylene chloride was analyzed using a Hewlett Packard Model 5880 gas chromatograph equipped with a flame ionization detector and an OV-101, 12m capillary column. No measurable levels of organic impurities were found in BPCl that had been purified without the use of ethyl ace-

tate. The melting point of the final product was $132.3^\circ\text{--}133.1^\circ\text{C}$ (corr.).

Anthracene (Eastman, scintillation grade) was recrystallized from acetic acid and then toluene before sublimation. Analysis by HPLC and GC showed less than 0.1% impurities.

9H-anthracenium heptachlorodialuminate ($\text{C}_{14}\text{H}_{11}\text{Al}_7\text{Cl}_7$) **1** was prepared in Schlenk-ware according to the procedure of Koptuyug (9). Thereafter, it was stored and handled in a glove box. The 200 MHz $^1\text{H-NMR}$ spectrum of a solution of this compound in molten SbCl_3 -10 m/o AlCl_3 was that of the 9H-anthracenium **2** (the cation of compound **1**, shown in Fig. 1) ion without extraneous peaks.

2-Ethylanthracene (Aldrich, 98%) was recrystallized twice from ethanol. No impurities were detected by GC or HPLC analysis.

Preparation of solvents and solutions.—All handling of salts (including weighing on an analytical balance) was carried out in an argon atmosphere glove box in which both water vapor and oxygen were monitored instrumentally and kept below 1 ppm by continuous circulation of the atmosphere through a purification train. In preparing SbCl_3 - AlCl_3 - BPCl melts, SbCl_3 and BPCl were mixed to form a binary liquid to which AlCl_3 was slowly added. This procedure allowed dissipation of the heat generated by the AlCl_3 - BPCl reaction so that the rise in temperature was only slight. In the preparation of AlCl_3 - BPCl melts, a substantial temperature rise could not be avoided.

The formal compositions of melts are specified here in terms of mole percentages of the three constituents in the order SbCl_3 - AlCl_3 - BPCl . Melts for which the mole ratio AlCl_3 : BPCl exceeded unity are referred to as acidic, while those for which this ratio was less than unity are termed basic.

For the preparation of solutions, anthracene and 2-ethylanthracene were weighed on a microbalance outside of the glove box while compound **1** was weighed on an analytical balance in the glove box. The quantity of solvent (SbCl_3 - AlCl_3 - BPCl) was determined by analytical weighing in the glove box. Solvent volume was calculated from density values (7). Values for other compositions were determined by linear extrapolation.

Fig. 1. Spectra of anthracene and the 9H-anthracenium ion in SbCl_3 - AlCl_3 - BPCl melts with compositions of 60:18:22 and 60:22:18, respectively.

Decomposition reactions.—The decomposition of anthracene in acidic ternary melts was initiated by mixing a solution of anthracene in a basic 60:19:21 melt with an appropriate amount of an acidic melt. For anthracene solutions at the 150 mM concentration level, the extent of reaction was measured by quench and separation at the end of a given reaction period. The same quench and separation procedures were followed as those used previously to study the decomposition of anthracene in SbCl_3 -rich melts at elevated temperatures (1). These solutions contained 160–200 mg of solute. Product analysis included antimony metal as well as organics.

Studies of solutions at the 30 mM level included *in situ* optical spectroscopy (see below) in addition to quench and separation. Product analysis did not include antimony metal because of the small amounts of material involved. After a solution had been prepared, it was divided into two portions. One portion was weighed and left in the glove box for quench and separation at the end of the reaction period. This portion contained 10 mg or more of solute. The other portion (~1 ml) was loaded into an optical cell (see below) which was then sealed, removed from the glove box, and placed in the spectrophotometer. In several runs, a second 1 ml spectroscopy sample was withdrawn from the quench-and-separation portion after 23h. The spectrum of this second sample was the same as the 23h spectrum of the sample that had been removed at the beginning of the run.

Optical spectroscopy.—Optical absorption spectra were measured either with a Cary 14 or a Cary 219 spectrophotometer. The optical cell, shown in Fig. 2, consisted of a 1 cm pathlength quartz glass cuvette attached by means of a graded seal to a 100 cm long Pyrex glass neck with a 15 Ace threaded glass joint at the top. A quartz glass insert, to which an eyelet was attached, could be lowered into the cell by means of a glass rod with a hook on the end. A Teflon bushing and O-ring provided an airtight seal. The quartz insert could be rotated so that two different optical pathlengths of about 60 and 110 μm were obtainable. The sample compartments of both spectrophotometers were modified to accommodate these cells. Pathlengths of cells with inserts in place were calibrated using the 373 nm band of K_2CrO_4 solutions in aqueous 0.05N KOH [$\epsilon = 4842 \text{ M}^{-1} \text{ cm}^{-2}$ (10)]. Measurements were made with at least four independently prepared concentrations of dichromate for each calibration, and the results were reproducible to within 0.5%.

ESR spectroscopy.—The spectrometer, sample tubes, and experimental procedures have been described previously (11). All material transfers were performed in a dry box. The loaded sample tubes were sealed under argon a vacuum line. Concentration of anthracene in the melts was ~5 mM. ESR spectra were obtained at ambient temperatures (22°–23°C).

Results and Discussion

Reactions among solvent components.—The SbCl_3 - AlCl_3 -BPCl mixtures considered here have formal compositions with the following mole fractions: 0.60 SbCl_3 , (0.20 + a) AlCl_3 , and (0.20 - a) BPCl, where $-0.04 \leq a \leq 0.03$. Since these components vary enormously in chloride donor/acceptor strength, extensive chloride-exchange chemistry occurs on mixing. Aluminum trichloride is a strong chloride ion acceptor while SbCl_3 is a much weaker chloride ion acceptor, and BPCl is a chloride ion donor. Therefore, the dominant chloride exchange reaction is

Since the AlCl_3 :BPCl is close to unity for all melts, the liquid may be regarded as consisting of the binary mixture SbCl_3 -25 m/o BP(AlCl_3) with relatively small additions of AlCl_3 or BPCl. Pure molten SbCl_3 is very slightly ionized as shown in Eq. [2] (12)

It is plausible to suppose that the same equilibrium occurs in our low-melting mixtures and is displaced strongly to the left. Likewise, it has been shown that in liquid BPCl- AlCl_3 mixtures at ambient temperatures, the AlCl_4^- ion is in equilibrium with Al_2Cl_7^- and Cl^- ions (13). In our mixtures, a similar equilibrium must occur as shown in Eq. [3]

where Cl^- is solvated by SbCl_3 molecules. Since Al_2Cl_7^- is a much stronger chloride ion acceptor than SbCl_3 , the equilibrium in Eq. [3] is strongly displaced to the left. The Al_2Cl_7^- anion should also be a stronger chloride ion acceptor than $\text{SbCl}_2^+(\text{solvated})$ so that the equilibrium in Eq. [4]

should be displaced to the right. This also appears to be the case in SbCl_3 - AlCl_3 mixtures at elevated temperatures (12). Thus, when AlCl_3 is added to liquid SbCl_3 -BP(AlCl_3), the dominant acidic species should be $\text{SbCl}_2^+(\text{solvated})$ rather than Al_2Cl_7^- . On the other hand, BPCl is expected to dissolve in SbCl_3 -BPCl to form BP^+ cations and $\text{Cl}^-(\text{solvated})$ anions with the concomitant suppression of the formation of $\text{SbCl}_2^+(\text{solvated})$, according to Eq. [2].

In summary, for all of the SbCl_3 - AlCl_3 -BPCl compositions considered here, the primary constituents are SbCl_3 molecules and the spectator ions BP^+ and AlCl_4^- . Secondary constituents are $\text{SbCl}_2^+(\text{solvated})$ and $\text{Cl}^-(\text{solvated})$. When the formal mole ratio AlCl_3 :BPCl exceeds unity to a significant degree, the concentration of $\text{SbCl}_2^+(\text{solvated})$ is correspondingly increased, while that of $\text{Cl}^-(\text{solvated})$ is greatly suppressed. This situation is reversed when the AlCl_3 :BPCl ratio is significantly less than unity. The Al_2Cl_7^- anion is at most no more than a minor constituent in the melts considered here.

Optical spectra.—During the decomposition of anthracene, the principal species observed by optical spectroscopy are unreacted anthracene and the anthracenium ion. Therefore, for purposes of both identification and quantification, the spectra of these species were measured in SbCl_3 - AlCl_3 -BPCl melts under nonreactive conditions.

Figure 2 shows the spectrum of a 31.1 mM solution of anthracene in a basic 60:18:22 melt, and that of a 9.75 mM solution of 9H-anthracenium heptachlorodialuminate 1 in an acidic 60:22:18 melt. The positions and molar absorptivities of the three maxima in the anthracene spectrum are as follows: 347 nm, $4130 \text{ M}^{-1} \text{ cm}^{-1}$; 366 nm, $4660 \text{ M}^{-1} \text{ cm}^{-1}$; and 384 nm, $3830 \text{ M}^{-1} \text{ cm}^{-1}$. We attribute these bands to vibronic components of the $^1\text{L}_a \leftarrow ^1\text{A}$ electronic transition (14). By comparison, we found that the corresponding bands for anthracene in methanol have as coordinates the following: 339 nm, $5447 \text{ M}^{-1} \text{ cm}^{-1}$, 356 nm, $8130 \text{ M}^{-1} \text{ cm}^{-1}$; 375 nm, $7967 \text{ M}^{-1} \text{ cm}^{-1}$. Other bands in this group that we shall make use of later have maxima at 309 and 323 nm. The vibrational spacing for all five bands is close to $0.14 \mu\text{m}^{-1}$. The bands of anthracene in the molten salt are much broader than those of anthracene in methanol so that the band areas and oscillator strengths are more nearly comparable than are the molar absorptivities.

The spectrum of the solution of compound 1 in Fig. 2 consists of an intense band with maximum at 424 nm and molar absorptivity of $34,500 \text{ M}^{-1} \text{ cm}^{-1}$. This is plausibly attributed to the 9H-anthracenium cation 2, the structure of which is shown in the figure. The spectrum of this ion in anhydrous HF at 25°C (15) has a similar band at 408 nm ($37,400 \text{ M}^{-1} \text{ cm}^{-1}$), while in concentrated H_2SO_4 at 25°C (16) the band maximum is at 424 nm (ca. $30,000 \text{ M}^{-1} \text{ cm}^{-1}$).

Spectral data and the results of analysis by hydrolysis and separation show that both the solution of anthracene in the basic melt and that of compound 1 in the acidic melt are stable. Their spectra remained unchanged after 24h. Following hydrolysis of the anthracene solution, the starting material was recovered and no decomposition products were found. Hydrolysis of the solution of com-

compound 1 resulted principally in the deprotonation of compound 1 and led to recovery of anthracene equivalent to 85% of the starting material. A similar recovery factor was found when solutions of anthracene in SbCl_3 -10 m/o AlCl_3 were hydrolyzed by the procedure used here.

Anthracene decomposition reaction.—We found that the reactions by which anthracene decomposes in acidic SbCl_3 - AlCl_3 - BPCl mixtures at 28° - 40°C are closely related to those that occur in SbCl_3 -rich melts at 80° - 175°C . These elevated temperature reactions are of two types. First, in SbCl_3 -10 m/o AlCl_3 , anthracene reacts rapidly and completely with the solvent in a redox process that is schematically illustrated in Eq. [5] (4)

The oxidized product is the 9H-anthracenium ion 2, produced in 55-65% yields. The source of protons for this product is a combination of Scholl-type condensation-dehydrogenation reactions and the reduction of Sb(III) . The dominant condensed product is anthra[2,1-a]aceanthrylene 3, produced in yields of ~ 20 w/o of the starting anthracene. The remaining organic material (~ 15 - 25 w/o) consists of a variety of condensed compounds. The accompanying reduction reaction converts Sb(III) into a lower oxidation state, which, when hydrolyzed, disproportionates into Sb metal and Sb(III) (17). Stoichiometry requires that the mole ratio compound 2: Sb(metal) be 3:1.

The second type of reaction occurs when anthracene is dissolved in SbCl_3 without AlCl_3 . This reaction is a relatively slow catalytic hydrogen-transfer with the melt serving as solvent/catalyst (1). Part of the anthracene is hydrogenated to form mostly 9,10-dihydroanthracene 4, and the source of hydrogen is Scholl-type condensation-dehydrogenation reactions

A wide variety of condensed products is formed, including compound 3, but no single product predominates.

In the present study, we find that both of the above types of reactions occur simultaneously for anthracene in acidic SbCl_3 - AlCl_3 - BPCl mixtures at 28° - 40°C . Evidence regarding the formation of compound 2 comes from the optical spectroscopic measurements. As noted earlier, this cation is destroyed by hydrolysis so that its presence in the melt cannot be established by quench and separation. The spectra in Fig. 3 are typical of those obtained when ~ 30 mM anthracene reacts in the acidic melt during a 23h run at 28° - 30°C . These spectra are referenced to air and can be converted to absorbance by subtracting the curve labeled solvent. The solvent melt was quite transparent except at the shortest wavelengths so that, over most of the wavelength range in Fig. 3, the apparent absorption of the solvent consists of light losses due to reflections at cell windows.

After 20 min reaction time, the concentration of anthracene fell to $\sim 95\%$ of its starting value of 34.4 mM. A shoulder at ~ 420 nm is attributed to compound 2 at a concen-

tration estimated to be 1-2 mM. Bands at 510 and 530 nm are due to unidentified reaction products. With increasing time, absorption due to anthracene slowly decreased, while that due to compound 2 slowly increased along with bands due to other reaction products at longer wavelengths. At the end of 1380 min (23h), some anthracene remained but the concentration could not be evaluated accurately because of interference from the band of compound 2. The concentration of compound 2 reached ~ 7.5 mM, which is 22% of the initial anthracene concentration.

Identified substances obtained from quench and separation were the following: anthracene (partly unreacted starting material and partly from the hydrolysis of compound 2), compound 3, compound 4, four isomers of bianthracene grouped together here as compound 5 (2, 9'-isomer produced in highest yield), a dihydroanthraaceanthrylene 6, (not identified as to isomer), and antimony metal (recovered only for runs at the 150 mM concentration level)

In addition, small quantities of unidentified products (usually ~ 5 w/o of the initial anthracene) were obtained, and when the HPLC column was washed with CH_2Cl_2 , some highly condensed material came off.

Quench and separation was performed for eight runs, each terminated after 23h. Five of these runs were made with 60:22:18 melts at 28° - 30°C and used initial anthracene concentrations of 31, 34, 34, 141, and 157 mM. One run was made with a 60:22:18 melt at 40°C and an initial concentration of 31 mM, while 2 runs were made with slightly more acidic 60:23:17 melts at 28° - 30°C and initial concentrations of 28 and 139 mM. The only substantial differences in the relative amounts of substances recovered from these runs was between those with initial concentrations of 28-34 mM and those with initial concentrations of 139-157 mM. Table I summarizes the five runs made with 60:22:18 melts at 28° - 30°C . In this table, the amounts of substances are given as w/o of the initial weight of anthracene. Results for the three runs with initial concentrations of 31, 34, and 34 mM are averaged under the column headed ~ 30 mM, and those with initial concentrations of 141 and 157 mM are averaged under ~ 150 mM. Typical of deviations about the average values were those for anthracene, namely: 57-67% and 27-30%, respectively. The amounts of anthracenium ion for runs with initial concentrations of

Fig. 2. Optical cell. (A) Pyrex glass rod with hook, (B) threaded Teflon bushing, (C) threaded Pyrex glass joint, (D) FETFE O-ring, (E) quartz glass insert, and (F) quartz glass optical cell.

~30 mM were obtained from optical spectra, and those for the other runs were calculated from the amounts of Sb metal recovered from quench and separation (moles of anthracenium = $3 \times$ moles of Sb).

The anthracene recovered from quench and separation consisted of unreacted starting material plus that regenerated from hydrolysis of the anthracenium ion. We estimate a recovery factor of 85% for hydrolysis, hence the amounts of unreacted anthracene were on the order of 43-47% and 15-18% for initial concentrations of ~30 mM and ~150 mM, respectively. Identified products typically accounted for ~80% of the starting material for the former and ~70% for the latter concentration. In both cases, an additional amount of material (~5%) consisted of small amounts of various unidentified products observed during chromatography. The highly condensed material accounted for an appreciable part of the remainder in runs with initial concentrations of ~150 mM, but very little of this material was found for runs with initial concentrations of ~30 mM.

These results show that a part of the hydrogen lost in forming condensed products was consumed in forming hydroarenes, while the rest was consumed in protonating anthracene. The same reactions occurred in melts with initial anthracene concentrations of 31-157 mM. At the higher concentrations, the conversion of anthracene was greater, and relatively less protonated product 2 formed than at the lower initial concentration. Thus, the decom-

Fig. 3. Spectra measured during the decomposition of anthracene in an $\text{SbCl}_3\text{-AlCl}_3\text{-BPCI}$ (60:22:18) melt at 30°C together with the spectrum of the solvent. All spectra referenced against air.

position of anthracene in acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCI}$ melts proceeded by a combination of the same types of reactions found at elevated temperatures in $\text{SbCl}_3\text{-10 m/o AlCl}_3$ and in SbCl_3 alone. It is as though the low-melting mixtures were intermediate in oxidizing power to SbCl_3 with and without 10 m/o AlCl_3 . Further evidence that this is, in fact, the case is provided by the ESR studies described below and the EMF studies in the following paper (7). The reactions in the low-melting mixtures at $28^\circ\text{-}40^\circ\text{C}$ were very much slower than those at higher temperatures in SbCl_3 and $\text{SbCl}_3\text{-10% AlCl}_3$.

ESR spectra.—The fact that Sb(III) in acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCI}$ melts acts as a mild oxidizing agent toward anthracene was established by the recovery of Sb metal. It is interesting, therefore, that we were also able to identify the presence of the anthracene radical cation in these solutions by means of ESR spectroscopy. Dilute solutions (~5 mM) of anthracene in two acidic melts, 60:22:18 and 60:21:19, were examined by ESR at ambient temperatures ($22^\circ\text{-}23^\circ\text{C}$). In both cases, the ESR spectrum of the anthracene radical cation was observed, and the measured pro-

ton hyperfine coupling constants ($a_1 = 3.05$, $a_2 = 1.37$, and $a_3 = 6.47\text{G}$) were similar to those measured in $\text{SbCl}_3\text{-}8\text{ m/o AlCl}_3$ at elevated temperatures (11). However, these spectra were much less intense than the corresponding anthracene radical cation spectrum observed in $\text{SbCl}_3\text{-}8\text{ m/o AlCl}_3$, suggesting that the $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ melts are weaker oxidants. EMF studies presented in the following paper support this conclusion (7). Thus, the acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ melts can act as oxidants toward anthracene, producing radical cations that may be key reactive intermediates in the protonation-condensation reaction as previously proposed for arenes in $\text{SbCl}_3\text{-}10\text{ m/o AlCl}_3$ (4).

Anthracene in $\text{AlCl}_3\text{-BPCl}$ (2:1).—The important role that SbCl_3 played in the anthracene decomposition reactions in acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ melts is emphasized by comparison with the behavior of this solute in a solvent containing only AlCl_3 and BPCl . For this comparison, we chose the formal composition $\text{AlCl}_3\text{-BPCl}$ (2:1), which is, in fact, the liquid compound $\text{N-(1-butyl)pyridinium heptachlorodialuminate BPA}_2\text{Cl}_7$ (13). This is a very strong Lewis acid, and if Lewis acidity in combination with such protonic impurities as our melts may contain is sufficient to catalyze the decomposition of anthracene, then the 2:1 melt should be a very active catalyst.

Studies using optical spectroscopy and quench and separation were carried out on a 35 mM solution of anthracene in the 2:1 melt and followed the same general procedures used with acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ melts in so far as possible. The calculation of concentrations was based on the value 1.33 g cm^{-3} for the density of the melt (19). The reaction temperature was 30°C , the time to quench was 24h, and optical spectra were measured at intervals from 0.5 to 29h after mixing and included a spectrum taken at the time of quench.

After quench and separation, the only substances found in more than trace amounts were anthracene (78 w/o), compound 4 (2 w/o), and compound 5 (6 w/o). No more than a trace of highly condensed material was found when the HPLC column was washed with CH_2Cl_2 .

Spectra measured after 0.5 and 24h are shown in Fig. 4. These are referenced to air and can be converted to solute absorbance by subtracting the curve labeled solvent. In between 0.5 and 24h, the spectra changed slowly and progressively, never exceeding the extremes shown in the figure. The spectrum measured at 29h was almost indistinguishable from that measured at 24h.

The $\text{AlCl}_3\text{-BPCl}$ solvent melt transmitted further into the ultraviolet than did $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ mixtures so that, for the anthracene solution, five vibronic bands of the ${}^1L_a \leftarrow {}^1A$ electronic transition were exposed at 312 (sh), 328, 344, 362, and 381 nm, with a $0.14\text{ }\mu\text{m}^{-1}$ vibra-

tional spacing. These are slightly red-shifted with respect to the corresponding bands of anthracene in methanol (see above), and the 344, 362, and 381 nm bands are very close to the corresponding bands for anthracene in $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$. Assuming the concentration of anthracene after 0.5h to be 35 mM or slightly less, the molar absorptivity of the 362 nm band is calculated to be about $6 \times 10^3\text{ M}^{-1}\text{ cm}^{-1}$. This value is intermediate to those for anthracene in methanol and in $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$, respectively, which is in keeping with the fact that the band widths for anthracene in the 2:1 melt are likewise intermediate.

The only absorption in the 0.5h spectrum not attributable to anthracene was a band at $\sim 420\text{ nm}$ that we attribute to compound 2. Assuming that the molar absorptivity of compound 2 has a value similar to that for compound 2 in $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$, we estimate that its concentration in $\text{AlCl}_3\text{-BPCl}$ was $\sim 1\text{ mM}$. This small amount of compound 2 probably came from impurity proton sources. With increasing time, the concentration of compound 2 diminished although a small amount persisted after 24h.

The only product absorption (other than compound 2) found after 24h was a very broad band centered near 640 nm. This does not correspond to either of the major products found on quench and separation; the bands of compound 4 should lie well out of range in the UV, and those of compound 5 should lie in the same general region as the anthracene bands. The most reasonable source of the 640 nm absorption is a trace of a highly condensed arene in a protonated or oxidized form. Such cations usually have intense absorptions in the visible range, and the parent arenes are usually more easily protonated and oxidized than anthracene, compound 4, or compound 5.

The long wavelength absorption bands of bianthracenes in methanol were found to be very similar to those of anthracene in the same solvent. Among other small differences, they were somewhat red-shifted. Assuming that a similar state of affairs holds in the 2:1 melt, the absorption in the 300-400 nm region of the spectrum after 24h was what one would expect for a mixture of anthracene and compound 5 in the ratio found on quench and separation with an anthracene concentration reduced to roughly 80% of its initial value.

Thus, we find that the 2:1 melt, unlike the acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ melt, did not promote the oxidative protonation of anthracene to an appreciable extent. It did catalyze the Scholl condensation-dehydrogenation reaction (to form compound 5) accompanied by a partial hydrogenation of the substrate (to form compound 4), but even for these reactions the 2:1 melt was not nearly as active a catalyst as the less acidic melts containing SbCl_3 .

Fig. 4. Spectra measured during the decomposition of anthracene in an $\text{AlCl}_3\text{-BPCl}$ (2:1) melt at 30°C together with the spectrum of the solvent. All spectra referenced against air.

Effects of impurities.—Because of the low concentration of anthracene used in the spectrometric studies, we found it necessary to pay close attention to the effects of impurities. Thus, it was not until water and ethylacetate were identified and eliminated as impurities in BPCI that we obtained consistently reproducible results. Since BPCI is a widely used constituent in low-melting salt mixtures and since studies of the spectroscopy and electrochemistry of solutes in these melts is commonly done at low concentrations, we describe what we learned about impurity effects.

We found that when BPCI was dried by a less rigorous procedure than that described above and then used to prepare acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCI}$ melts, solute anthracene was protonated at a much faster rate, and the concentration of compound 2 reached a much higher level than it did in the reactions described above. When BPCI was dried under vacuum over P_2O_5 at 110°C for progressively longer times, the amounts of compound 2 diminished. The concentration level for promptly formed compound 2 achieved after prolonged drying was about 1-2 mM, and this we attribute to impurities (not necessarily water).

In the literature procedure (8) for the preparation of BPCI, ethyl acetate is used as a cosolvent along with acetonitrile in the recrystallization of the product. In our initial experiments, which followed this procedure, an unknown product was observed in 16% yield from the reaction in an acidic room temperature melt containing 11 mM anthracene. This product was identified by GC-MS as three isomeric ethylantracenes. The ethyl group could not have come from the fragmentation of anthracene since no other fragments of the parent arene were found. It is well known (18) that esters will alkylate arenes in organic solvents with a Lewis acid present as catalyst. Analysis of the BPCI showed that the small ethyl acetate content of the sample could account for all of the ethylantracene found in the reaction of anthracene in the acidic $\text{SbCl}_3\text{-AlCl}_3\text{-BPCI}$ mixture. Vacuum drying of the BPCI crystals resulted in a decrease in the ethyl acetate content and thus in the yield of ethylantracene. However, traces of ethyl acetate remained even after a week of drying. To determine whether the presence of ethyl acetate and thus ethylantracene would significantly effect our results, the reaction of 2-ethylantracene was followed spectroscopically in the acidic room temperature melts under the same conditions utilized for the reaction of anthracene. Protonated ethylantracene was formed and found to absorb at 424 nm (the same wavelength observed for the anthracenium ion). In addition, ethylantracene reacted more rapidly than anthracene, probably because ethylantracene is more easily oxidized and protonated than anthracene. Since the presence of ethylantracene would obviously interfere with the investigation of the anthracene reaction, all subsequent purifications of BPCI excluded the use of ethyl acetate.

In a study published after the present paper was submitted, Sahami and Osteryoung (20) reported an electrochemical procedure for determining water in liquid $\text{AlCl}_3\text{-BPCI}$ mixtures containing excess BPCI. They found 7.5-20 mM residual water initially present in their melts. In agreement with our findings, they concluded that this water originated as an impurity in the highly hygroscopic BPCI from which the melts were made. They also showed that water in liquid $\text{AlCl}_3\text{-BPCI}$ mixtures of all compositions reacts with chloroaluminate ions to form HCl, which has appreciable solubility in these melts. This result supports our observation that water in $\text{AlCl}_3\text{-BPCI}$ containing excess AlCl_3 acts as a strong proton source capable of protonating anthracene.

In a pioneering investigation of aromatic hydrocarbons in liquid $\text{AlCl}_3\text{-BPCI}$ mixtures, Robinson and Osteryoung

(8) reported that when these hydrocarbons were added to acidic melts, colored solutions were formed that could be reversibly decolorized by making the melt basic, and the UV-visible spectra of these colored solutions were similar to those of arene σ complexes. In the case of anthracene, they reported a band maximum at 417 nm, very close to the position of the intense visible band of the 9H-anthracenium ion in liquid BPAl_2Cl_7 , as reported here. At the time that Robinson and Osteryoung reported their findings, $\text{AlCl}_3\text{-BPCI}$ melts were generally believed to be anhydrous; therefore, these authors proposed that the σ complexes they observed were of the $\text{AlCl}_3\text{-arene}$ type formed in an equilibrium such as $\text{arene} + \text{Al}_2\text{Cl}_7^- = \text{AlCl}_3\text{-arene} + \text{AlCl}_4^-$. In view of our results and those of Sahami and Osteryoung (20), it is most likely that the σ complexes were of the $\text{H}^+\text{-arene}$ type, i.e., arenium ions, since HCl in the presence of acidic chloroaluminates has long been known to be an exceedingly strong protonating agent, and chloroaluminates cannot displace H^+ from the resulting complexes (note compound 1, above).

ABSTRACT

Physical and electrochemical properties are reported for $\text{SbCl}_3\text{-AlCl}_3\text{-N-}$ (1-butyl)pyridinium chloride (BPCI) mixtures that are liquid at ambient temperatures, and studies of the electrogeneration and open-circuit decay of some arene radical cations, both in this medium and in $\text{SbCl}_3\text{-KCl}$ at elevated temperatures, are described. Specific conductivities, densities, and viscosities of the compositions [m/o (mole percent)] 60:19:21 (basic) and 60:21:19 (acidic) $\text{SbCl}_3\text{-AlCl}_3\text{-BPCI}$ were measured over the temperature range 24°-100°C. For a potentiometric titration between the compositions 60:18:22 and 60:22:18 with SbCl_3 fixed at 60 m/o, the potential of the Sb(III)/Sb(0) couple increased by 0.43V at 27°C. Electrochemical studies showed that perylene (Per), 9,10-dimethylantracene (DMA), and 9,10-diphenylantracene (DPA) can be reversibly oxidized to their radical cations in a 60:19:21 melt, whereas the oxidation of anthracene (Ant) is irreversible. Spectroelectrochemical studies showed that Per radical cations were stable in this melt, those of DPA decayed very slowly, those of DMA decayed somewhat faster, and those of Ant were too transient to be observed optically. Similar degrees of stability were found for these radical cations in SbCl_3 containing 1M KCl at elevated temperatures, and transient spectra of Ant radical cations were observed in this solvent.

Molten SbCl_3 has proven to be a remarkable reaction medium for arenes (1-7). In some cases, these hydrocarbons undergo solvent-catalyzed hydrogen transfer chemistry, while in others the solvent acts as an oxidizing agent, and the primary reaction products include solvent-stabilized carbocations, either arenium ions or arene radical cations. To a great extent, reaction rates and even the type of reaction can be markedly altered by adding relatively small amounts of a chloride ion donor (e.g., KCl) which makes the melt less active, or a strong chloride ion acceptor (e.g., AlCl_3) which increases the oxidizing power of Sb(III) as well as the Lewis acidity of the melt.

When used as a reaction medium, SbCl_3 has the disadvantage of an elevated melting point, 73°C. Therefore, it was interesting to learn that when SbCl_3 is diluted with 25 m/o (mole percent) N-(1-butyl)pyridinium tetrachloroaluminate ($\text{BP[AlCl}_4\text{]}$), the mixture is liquid at 25°C, and anthracene, dissolved in this liquid, displays some of the same chemistry as in SbCl_3 at elevated temperatures (8). As a next step toward utilizing $\text{SbCl}_3\text{-BP[AlCl}_4\text{]}$ mixtures to study the oxidative chemistry of arenes, we explored the possibilities and problems of applying electrochemical and spectroelectrochemical tools to this medium, with results that are reported here.

The importance of electrochemical and spectroscopic methods for the study of arene chemistry in SbCl_3 -rich liquids deserves special emphasis. Since very reactive carbocations occur as solvent-stabilized primary products in many of these reactions, conventional quench and separation procedures often do not give adequate information and, in fact, can be misleading. Spectroscopic methods (NMR, ESR, and optical) applied *in situ* are required to identify the carbocations and to calibrate quench and separation procedures for purposes of quantification. Furthermore, since these carbocations, whether they be radical cations or arenium ions, are products of reactions in which the solvent acts as an oxidant, it is essential to establish the relative oxidizing power of the solvent as a function of added chloride ion donors and acceptors, and the relative oxidizability of the solutes.

Finally, there is the question of whether radical cations that are relatively stable in inorganic SbCl_3 -rich melts will have a similar degree of stability in $\text{SbCl}_3\text{-BP[AlCl}_4\text{]}$,

where they have a greater opportunity of being scavenged by adventitious nucleophiles or, possibly, by BP^+ ion via hydrogen abstraction. To answer this question, we compared the persistence of a series of different arene radical cations in $\text{SbCl}_3\text{-BP[AlCl}_4\text{]}$ with their persistence in molten $\text{SbCl}_3\text{-KCl}$.

As a practical matter, the solvent is prepared by mixing SbCl_3 , AlCl_3 , and BPCI. For this reason, the solvent compositions are, throughout this paper, expressed in mole percentages of these formal constituents in the above order. It should, however, be kept in mind that the chemically active species are chloroantimony species and not chloroaluminate ions. (See Ref. (8) for a discussion of the reactions among melt components.)

Materials.—Purification of the melt constituents has been described (8). 9,10-Dimethylantracene (Aldrich, >99%) and anthracene (Reilly Tar and Chemical Corporation, Scintillation Grade) were used without further purification. Perylene (Aldrich, 99%, Gold Label) and 9,10-diphenylantracene (Aldrich, 99%) were recrystallized from toluene. Antimony metal (Bradley Mining Company, 99.99%) was vacuum cast into 3 mm diam single crystals that were drilled and threaded to serve as electrodes.

Cells and electrodes.—The spectroelectrochemical (SE) cell, electrodes, and fittings have been described (9), except that tungsten (Alfa, 99.98%) was substituted for platinum wire as a working electrode material, and the reference electrode was fitted with a Pyrex screw joint, FETFE O-ring, and Teflon bushing (Ace Glass) for easy assembly. The electrolyte in the reference electrode was a binary $\text{SbCl}_3\text{-BPCI}$ melt saturated with solid SbCl_3 . This reference electrode is designated $\text{SbCl}_3\text{-BPCI(l)}$, $\text{SbCl}_3\text{(solid)/Sb}$. The indicator electrode for the EMF measurements was an Sb metal rod which was machined to expose a fresh surface and cleaned with methanol. The acid-base titration was performed by pipetting a known volume of acidic melt into a known volume of basic melt. For measurements using $\text{SbCl}_3\text{-KCl}$ melts, the spectroelectrochemical cell and reference electrode, as well as the purification procedure for KCl, were the same as described previously (9). The conductivity cells, instrumentation, and experimental procedures were the same as described previously (10).

Density and viscosity measurements.—Density measurements were made with a picnometer which consisted of a Pyrex bulb (~8 ml in volume) to which two Pyrex precision-bore graduated tubes (Aceglass, 2 mm id, grad-

Key words: EMF, voltammetry, organic.

uated in mm) were fused vertically, parallel to each other. The tubes were joined via a bridging tube at the top to allow for pressure equalization in each arm. An extension of tubing above the bridge allowed for addition of melt and seal-off. After addition of melt, the apparatus was sealed off under ~ 0.8 atm of argon. The densitometer was submerged vertically in a water bath controlled to $\pm 0.03^\circ\text{C}$ by a Lauda Model K2-R circulator. The graduations on the arms of the picnometer were calibrated using accurately weighed amounts of Hg. Temperature was measured with a Pt resistance thermometer using a Minco RTB 8078 bridge, whose calibration is traceable to NBS standards. For this experimental configuration, the error in density values is estimated to be less than 0.2% over the temperature range $25^\circ\text{--}100^\circ\text{C}$.

Viscosity measurements were made in a glove box using a Sargent-Welch Model S-83400D falling ball viscosimeter. Calibration of the viscosimeter (cell constant = $4.07 \pm 0.01 \times 10^{-4} \text{ cm}^2 \text{ s}^{-2}$) was accomplished as described in the literature (11). The tube fitted snugly into a bored-out 1 in. diam aluminum rod wound with coaxial heating element. Temperature was controlled by a Leeds and Northrup controller to $\pm 0.5^\circ\text{C}$ and was measured with a copper/constantan thermocouple calibrated against a Pt resistance thermometer. Three or more determinations were made at each temperature.

Instrumentation.—The electrochemical instrumentation consisted of a Princeton Applied Research Model 174A Polarographic Analyzer, a Model 173 Potentiostat/Galvanostat equipped with a Model 179 Digital Coulometer, and a Model 175 Waveform Generator. Data were recorded with either a Hewlett-Packard Model 7045A X-Y recorder or a Nicolet Model 2090-III digital storage oscilloscope.

Absorption spectra for the spectroelectrochemical (SE) experiments were measured in the visible region with the following equipment. Radiation from a 10W tungsten/quartz/halogen lamp was filtered with neutral density filters to control intensity and a long pass filter to eliminate second-order light. An image of the filament was focused on a square aperture to crop the edges, and a 4×4 mm image of the aperture was focused on the optical cell, which had a 1 mm path length and contained an optically transparent electrode (OTE). Light transmitted through the cell was focused on the entrance slit (0.025 mm) of a flat field 0.32m spectrograph (Instruments SA, Incorporated Model HR-320) equipped with a $152.5 \text{ grooves mm}^{-1}$ grating. Dispersed light was focused on the face of a solid state multichannel detector, which constituted the front end of an optical multichannel analyzer (Princeton Applied Research OMA-2 system). Two types of detectors were used. One was a Vidicon (Princeton Applied Research Model 1216 detector controller. This detector provided 500 optical channels over a spectral window ~ 260 nm wide to give a resolution of ~ 0.5 nm. The window could be positioned anywhere in the range 420–800 nm. The other type of detector was a Reticon (Princeton Applied Research Model 1412) with a linear silicon photodiode array thermoelectrically cooled to -20°C and operated by Princeton Applied Research Model 1412 detector controller. This detector provided 1022 optical channels over a spectral window ~ 505 nm wide to give a resolution of about ~ 0.5 nm. This window could be positioned in the range 420–1000 nm. The system processor was Princeton Applied Research Model 1215 with extended memory. Operation of the detectors was monitored with a Tektronix 604A oscilloscope, and hard copy was obtained with a Hewlett-Packard 9872B plotter and a Data Access Systems Model 360 line printer. Wavelength calibration and resolution verification were performed with Hg, Ne, Ar, and Xe atomic lamps. For the spectra reported here, the time used to measure a spectrum, including signal integration to improve S/N, was negligibly small compared with the time interval between spectra. The spectra were corrected for dark current and lamp intensity drift. Two

optical references were used in SE measurements. One reference was the spectrum of the solution prior to electrolysis while the other contained only corrections for light losses at the OTE and due to reflections at the cell windows. Cary Models 14 and 219 spectrophotometers were used for nonspectroelectrochemical optical measurements.

Experimental procedures.—All material transfers were performed in an argon-filled glove box where O_2 and H_2O were continuously monitored and kept below 1 ppm by circulation of the atmosphere through a purification train. Weighings were performed on an analytical balance in the glove box. Positive feedback circuitry was employed during voltammetric measurements to compensate for solution resistance. In order to remove gas bubbles trapped in the OTE, the SE cell was partially evacuated for a short period prior to the experiment and refilled with argon.

All temperatures (unless otherwise noted) were measured with copper/constantan thermocouples, which were calibrated against the platinum resistance thermometer described above.

Results and Discussion

Physical properties.—The electrical conductivities of the $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ 60:19:21 (basic) and 60:21:19 (acidic) melts were measured over the temperature range $24^\circ\text{--}100^\circ\text{C}$ with results that are shown in Fig. 1. The specific conductivities of the two ternary mixtures are almost equal at ambient temperatures, but at higher temperatures the basic melt becomes more conducting. The conductivities are comparable to those reported for binary $\text{AlCl}_3\text{-MCl}$ (2:1) ambient temperature liquids (12), but are about one order of magnitude less than the conductivities reported for acidic alkali metal chloroaluminate melts at slightly higher temperatures (13). For comparison with $\text{SbCl}_3\text{-AlCl}_3$ melts, we have included in Fig. 1 the conductivity of the binary melt whose composition most closely resembles the $\text{SbCl}_3\text{-AlCl}_3$ ratio in the ternary melts (10).

The densities of a 60:19:21 melt and a 60:21:19 melt were measured over the temperature range $25^\circ\text{--}100^\circ\text{C}$. The data were fitted to the equation $\rho = mT + b$, where ρ is the density (g cm^{-3}) and T is the temperature ($^\circ\text{C}$). For the 60:19:21 melt, $m = -1.3595 \times 10^{-3}$, $b = 2.0637$, and the correlation coefficient is $r = 0.99991$. For the 60:21:19 melt,

Fig. 1. Specific conductivities of (a) $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ (60:21:19); (b) $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ (60:19:21); and (c) $\text{SbCl}_3\text{-AlCl}_3$ (3:1) [Ref. (10)].

Fig. 2. Arrhenius plots of the viscosities (μ) of (a) 60:21:19 melt; and (b) 60:19:21 melt.

$m = -1.4236 \times 10^{-3}$, $b = 2.0813$, and $r = 0.99983$. The density of a 60:16:24 melt was determined by pycnometric weighing in the glove box at 28°C to be $1.998 \pm 0.002 \text{ g cm}^{-3}$.

The viscosities of these two melts were also measured over the temperature range 25°–100°C, and Arrhenius plots are shown in Fig. 2. These viscosities are comparable to those measured for chloroaluminate mixtures molten at ambient temperatures (12).

Sb(III)/Sb(0) couple.—For reasons given in the Introduction, the reduction of Sb(III) plays a key role in the chemistry of arenes in SbCl₃-rich melts. Therefore, a knowledge of the composition dependence of the Sb(III)/Sb(0) couple is very useful in elucidating the composition dependence of arene reactions. However, before trying to measure the potential of this couple, we felt it prudent to check for the electrochemical reversibility of the Sb(III)/Sb(0) couple in an acidic 60:21:19 melt by means of current-overvoltage (i - η) curves. The anodic branch of $\log i$ vs. η plots displayed Tafel behavior, and the apparent exchange current density was $13 \mu\text{A cm}^{-2}$. The cathodic branch did not display Tafel behavior, and previous measurements have shown that the reduction of Sb(III) to Sb(0) is a complex process (14, 15). The magnitude of the apparent exchange current density indicates that the redox couple behaves reversibly for potentiometry performed with high impedance circuitry (as is the case in the present investigation). Thus, the following EMF data are thermodynamic values and the Sb(III)/Sb(0) couple is suitable for use as a reference electrode.

The change in the potential of an antimony electrode resulting from changes in melt composition was measured using the following concentration cell

where $x:y$ varied from 22:18 to 18:22. The lack of information regarding the transference numbers of charge carriers prevented a calculation of the junction potential.

Fig. 3. EMF of Sb(III)/Sb(0) couple at 27°C for SbCl₃-AlCl₃-BPCl = 60:18:22 to 60:22:18 m/o. Sb metal working electrode.

The EMF data are shown in Fig. 3 and demonstrate that the potential of the Sb(III)/Sb(0) couple may be tuned over a range of 0.43V for the compositions indicated. For comparison, at 99°C the variation in potential across the composition range 98:2 m/o SbCl₃-KCl to 98:2 m/o SbCl₃-AlCl₃ is 0.48V (14).

The marked concentration dependence of the EMF is understood qualitatively. It arises from a combination of the dependence of SbCl₃ reduction on Cl⁻ activity and the large changes in this quantity that occur when excess BPCl is titrated with AlCl₃. However, attempts to model this behavior in terms of simple reactions such as $\text{AlCl}_3 + \text{SbCl}_3 \rightarrow \text{SbCl}_2^+ + \text{AlCl}_4^-$ combined with $\text{SbCl}_3 \rightleftharpoons \text{SbCl}_2^+ + \text{Cl}^-$ were not fruitful, and this is not surprising. SbCl₃ is an associated molecular liquid with a moderate dielectric constant in which ion pairing and complex ion solvation processes are known to occur (10, 16-19). Nevertheless, these EMF values have the same utility when applied to problems in arene chemistry as would values calculated for a suitably elaborate model of Cl⁻ activity.

Voltammetry and chronocoulometry.—In this section we describe the application of several electrochemical methods to studies of the oxidation of 9,10-dimethylanthracene (DMA) in 60:19:21 melts. Also, as a preliminary to the spectroelectrochemical studies in the next section, we report $E_{1/2}$ values for the oxidation of perylene (Per) and 9,10-diphenylanthracene (DPA), and the potential at which the irreversible oxidation of anthracene (Ant) begins.

The available electrochemical window in the SbCl₃-AlCl₃-BPCl mixtures (Fig. 4) is somewhat larger than that reported for SbCl₃-CsCl and SbCl₃-AlCl₃ (>90 m/o SbCl₃) melts at 100°C (9). The potential span for both the 60:21:19 and 60:19:21 compositions is about 1.8V, compared to 1.4V for the binary melts. The negative potential limit in the ternary melts is the reduction of Sb(III) to Sb metal. As can be seen in Fig. 4 in comparison to Fig. 3, overpotentials for the reduction process at an inert electrode exist for both ternary melts. The anodic limit for the liquids is the oxidation of Sb(III) to Sb(V).

DMA, Per, and DPA are sparingly soluble in a 60:19:21 melt and the dissolution rate is slow. Solutions were prepared by adding the arene to the melt and heating to 80°–100°C with stirring in a closed container for a period of about 1h.

Voltammetry of DMA solutions in basic melts yielded data summarized in Table I. Scan rates up to 20 V s^{-1} revealed no significant shift in the anodic peak potential, and the half-wave potentials determined by differential pulse polarography (21) (avg = 0.47V) corresponded well to the values obtained from the voltammetric results.

Fig. 4. Background cyclic voltammograms of (a) $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ (60:19:21); (b) $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ (60:21:19). Glassy carbon electrode, area = 0.071 cm^2 . Sweep rate = 100 mV/s , temp = 20°C .

The integrated Cottrell equation (22) predicts that for diffusion-controlled electrode reactions, a linear relationship holds between the charge (Q) and the square root of time ($t^{1/2}$). Figure 5 is a plot of Q vs. $t^{1/2}$ for times up to 20s; it is clearly linear. The intercept of the plot yields a value of the apparent double layer capacitance of approximately $5 \mu\text{F cm}^{-2}$, while the slope (uncorrected for impurities) gives an upper limit on the diffusion coefficient of neutral DMA of $2.5 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$. Finally, the technique of double potential step chronocoulometry (22) demonstrated that the charge consumed around a square potential cycle obeys theoretical predictions ($Q_{2s}/Q_{10s} = 0.414$) (23) for 10 and 20s pulse widths. Thus, there is no significant reaction of the DMA radical cation on a voltammetric time scale.

Cyclic voltammograms of Per and DPA in 60:19:21 melts at 20°C corresponded to those expected for simple reversible behavior for scan rates up to 0.5 V s^{-1} , demonstrating that the radical cations of both are unreactive on a voltammetric time scale. An $E_{1/2}$ of 0.43V was obtained for Per while the $E_{1/2}$ of DPA was 0.54V . The oxidation of Ant was quite irreversible. For a voltammogram measured at a sweep rate of 0.2 V s^{-1} on a 8.7 mM solution of Ant at 19°C , the onset of oxidation occurred at about 0.6V .

These results for the 60:19:21 melt are similar to those reported by Bauer *et al.* (14, 24) and by Texier (25) in voltammetric studies of arene oxidation at 99°C in molten SbCl_3 with 0.1M KCl. Relative to a SbCl_3 saturated with KCl/Sb electrode, $E_{1/2}$ values of 0.24 , 0.31 , 0.39 , and 0.51V for Per, DMA, DPA, and Ant, respectively, are reported with mention that the anthracene radical cation is unstable.

Table I. Electrochemical parameters for a 1.2 mM solution of DMA in a 60:19:21 melt at 27°C . Glassy carbon working electrode area = 0.071 cm^2

ν (mV/s)	E_{p_a} (V) ¹	E_{p_c} (V) ¹	ΔE_p (mV) ²	$E_{p/2a}$ (V)	$E_{1/2a}$ (V) ³	n ⁴

Fig. 5. Charge-time^{1/2} plot for a 1.4 mM solution of DMA in $\text{SbCl}_3\text{-AlCl}_3\text{-BPCl}$ (60:19:21). Potential step: $+0.35$ to $+0.65\text{V}$. Glassy carbon electrode area = 0.071 cm^2 , temp = 27°C .

It is noteworthy that SbCl_3 containing 0.1M ($\sim 1 \text{ m/o}$) KCl at 99°C is a significantly stronger oxidizing medium with respect to Per, DPA, and DMA than is the 60:19:21 melt at ambient temperatures. In particular, the difference between $E_{1/2}$ and $E(\text{Sb(III)/Sb})$ for Per, DMA, and DPA in $\text{SbCl}_3\text{-KCl}$ at 99° (14 , 24 , 25) is $0.16 \pm 0.03\text{V}$ less than the same difference for these arenes in the 60:19:21 melt at ambient temperatures.

Spectroelectrochemical studies.—Measurements of absorption spectra at an OTE during electrolysis and subsequent open-circuit decay provide further information about the relative stabilities of Per, DMA, DPA, and Ant radical cations in 60:19:21 melts and allow us to compare these stabilities with those in molten SbCl_3 containing 1M KCl at elevated temperatures. In a previous SE study (9), the Per radical cation was shown to be exceedingly stable following its electrochemical generation at 100°C in SbCl_3 containing 1M KCl. No optical spectroscopic measurements have been reported for the Ant, DPA, and DMA radical cations in SbCl_3 at elevated temperatures. The results of such measurements are described here.

The absorption spectrum of a dilute solution of Per in a 60:19:21 melt was measured over the range $350\text{-}1000 \text{ nm}$ at 20°C . It consisted of a complex vibronic band with a profile similar to that for Per in 95% ethanol (26). In the 60:19:21 melt, this band is somewhat red-shifted with respect to that in 95% ethanol (longest wavelength peak: 451 nm , melt: $\sim 434 \text{ nm}$, ethanol). There is also a very weak band at 548 nm in the melt spectrum due to a trace of the Per radical cation (*vide infra*), probably formed by an oxidizing impurity.

SE measurements were made on a 0.34 mM solution of Per in the 60:19:21 melt at 26°C with a Vidicon detector covering the range $430\text{-}690 \text{ nm}$. Spectra were measured at 1 min intervals during electrolysis at $+0.65\text{V}$ and during a subsequent period with the circuit open. As electrolysis proceeded, the 451 nm band of Per diminished while the 548 nm band of Per^+ grew in. The presence of a well-defined isosbestic point where the Per and Per^+ spectra cross and the absence of bands due to anything, except these two species, are strong evidence that Per^+ was the only electrolysis product and that it did not react further. After 35 min of electrolysis, 26% of the Per had been oxidized. At this point, the circuit was opened and the spectrum of the Per/ Per^+ mixture did not change during another 30 min of observation. Measurements of the spectrum of electrogenerated Per^+ in a 60:19:21 melt out to 1000 nm with a Cary 14 spectrophotometer showed it to be closely similar to the spectrum of Per^+ in $\text{SbCl}_3\text{-KCl}$ and $\text{SbCl}_3\text{-AlCl}_3$ melts (9).

Electrogenerated DMA^+ , in contrast with Per^+ , reacted at a moderate rate, both in a 60:19:21 melt at ambient temperatures and in $\text{SbCl}_3\text{-KCl}$ at elevated temperatures. SE measurements were made with a Reticon de-

Fig. 6. Spectra measured every 60s during 20 min electrolysis at 0.65V of 1.2 mM DMA in a 60:19:21 melt. Pre-electrolysis spectrum used as reference. Pt-screen OTE and 1.0 mm path-length.

tector on a ~ 1 mM solution of DMA in a 60:19:21 melt, with results show in Fig. 6 and 7. To within experimental uncertainty, these spectra have the same profiles reported for transient DMA⁺ in benzonitrile at a much lower optical resolution than that reported here (27). Bands assigned to DMA⁺ are at 550, 600, ~ 656 (sh), and 678 (max) nm. Weak broad shoulders at about 620, 760 and 850 nm are attributed to subsequent reaction products because they develop at a much slower rate during electrolysis and are more persistent under open-circuit conditions than those assigned to DMA.

Similar SE measurements were made on 1.0-2.7 mM solutions of DMA in SbCl₃ containing 1M KCl at 75° and 100°C and gave similar results. The profile of the DMA⁺ spectrum (540-800 nm) in these melts did not differ in any important respect from that shown in Fig. 6 and 7. At 75°C, the DMA⁺ band positions were 549, 596, ~ 660 (sh), and 677 (max) nm. Weak broad shoulders at about

624 and 760 nm were observed and attributed to subsequent reaction products for the reasons cited above. Also, after prolonged electrolysis a broad band grew in with a peak at ~ 600 nm, and during open-circuit decay, this band continued to grow while the DMA⁺ bands diminished. Decay rates at the elevated temperatures were about an order of magnitude faster than at ambient temperature. This difference in rates may not be entirely due to the temperature difference since the DMA⁺ concentrations during open-circuit decay were higher in the elevated temperature runs than in the ambient temperature runs.

From the value of $E_{1/2}$ for DMA and the formal potential of the Sb(III)/Sb(0) couple in the 60:21:19 melt at 25°C, it is estimated that DMA should be partially oxidized with the simultaneous reduction of Sb(III) in this medium. The optical spectrum of DMA in the acidic melt revealed weak absorption bands due to DMA⁺, but

Fig. 7. Spectra measured every 180s during 57 min open-circuit decay following electrolysis in Fig. 6. Reference same as in Fig. 6.

the lack of accurate values for the molar absorptivities of the optical transitions prevented a quantitative determination of the concentration.

The absorption spectrum of a 4.1 mM solution of DPA in a 60:19:21 melt was measured at 31°C over the range 340-1000 nm with a Cary 14 spectrophotometer. The only absorption was due to the near-UV electronic band of the neutral molecule for which the longest wavelength vibronic maxima were found at 385 and 405 nm, slightly red-shifted from their positions in acetonitrile (28).

SE measurements were made on a 4.1 mM solution of DPA electrolyzed at +0.73V in a 60:19:21 melt. Spectra, taken with a Vidicon detector covering the range 530-790 nm, were measured at 1 min intervals during 30 min of electrolysis and a subsequent 40 min of open-circuit decay. The spectral profile of the resulting DPA⁺ cation was about the same as in acetonitrile (28) with bands at 559 (shoulder), 598, 658, and 734 nm. When the spectra obtained in the molten salt were normalized and compared, no absorption attributable to anything other than DPA⁺ was found. During open-circuit decay the time required for the DPA⁺ concentration to decrease by 10% was 22 min.

Similar SE measurements were made on a 0.49 mM solution of DPA in SbCl₃ containing 1M KCl at 100°C. Spectra taken with a Vidicon detector over 490-750 nm were measured at 0.5 min intervals during 17.5 min of electrolysis at 0.55V and during a subsequent 15 min of open-circuit decay. The DPA⁺ bands at 562 (shoulder), 599, 660, and 736 nm were not significantly displaced from their positions in the 60:19:21 melt. The decrease in absorbance during open-circuit decay was approximately logarithmic with a half-life of 20 min so that the time required for the DPA⁺ concentration to decrease by 10% was about 3 min.

SE studies of the electrolysis of Ant in a 60:19:21 melt at 26° and in SbCl₃ containing 1M KCl at 75°C showed that Ant⁺ is very reactive in both cases. During the initial stages of electrolysis in SbCl₃-KCl, a very weak spectrum, closely similar to that of Ant⁺ in other media (29), occurred but was soon obscured by a similar but red-shifted spectrum. The latter is reasonably attributable to the radical cation of a bianthracene or a substituted anthracene, both of which are possible products of Ant⁺ decay reactions. During electrolysis in the 60:19:21 melt, the Ant⁺ spectrum was not observed. Presumably Ant⁺ reacted so rapidly that its concentration remained extremely low.

These SE experiments provide comparative data on the stabilities of arene radical cations in the 60:19:21 melt and in molten SbCl₃-KCl. The examples chosen cover a very wide range of stabilities. Per⁺ is stable in both types of melts while Ant⁺ is very reactive in both. DPA⁺ and DMA⁺ show intermediate stabilities with DPA⁺ being the more persistent in both kinds of melts, even though the $E_{1/2}$ of DPA is more positive than the $E_{1/2}$ of DMA. The observed rates of decay of the latter two cations were slower in the 60:19:21 melt. This effect need not be due entirely to the lower temperature since the concentrations of the cations and their neutral precursors are also likely to be important rate determining factors.

The Effect of Cyanide on the Oxidation of Formaldehyde on Au, Cu, and Pd Electrodes

Jean Horkans*

IBM, Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The effect of the CN^- ion on the formaldehyde electro-oxidation reaction has been examined in basic EDTA solutions at 75°C on Au, Pd, and Cu electrodes. The results are compared with the cyclic voltammetry of these three metals in HCHO-free EDTA solutions. The cyanide ion poisons HCHO electro-oxidation on Au and Pd; on Cu, however, substantially higher HCHO-oxidation currents can be sustained in the presence of cyanide. The poisoning on Au and Pd is related to the suppression of dissolution of the metal by the formation of a sparingly soluble metal cyanide on the surface. Metal dissolution is apparently also suppressed on Cu electrodes, but the greatest promoting effect of CN^- occurs in a potential range in which CN^- adsorbs on the unoxidized Cu surface.

The electro-oxidation of formaldehyde is a reaction of considerable technological importance. Formaldehyde can serve as a fuel in fuel cells. It is also used as the reducing agent in electroless deposition of metals, particularly Cu. There is thus ample incentive to gain a better understanding of its electrochemistry. Nonetheless, formaldehyde oxidation has been studied much less extensively than the oxidation of methanol or formic acid, and little work has been done under the high pH conditions of electroless deposition.

Formaldehyde is known to interact strongly with polar solvents (1). It is present in dilute aqueous solution primarily as methylene glycol, $\text{H}_2\text{C}(\text{OH})_2$, which will be ionized to the methylene glycolate ion at high pH. In dilute solutions, polymer formation is insignificant. For the sake of convenience, formaldehyde will be designated as HCHO throughout this paper.

The cyclic voltammetry for the oxidation of HCHO has a similar shape on a variety of electrodes and in solutions of various compositions (2-10). Buck and Griffith (2) studied this reaction on Pt electrodes in acidic and basic electrolytes. They found a Tafel behavior only in a narrow potential range where oxidation current just begins to flow in the anodic sweep. The HCHO-oxidation current does not attain its diffusion-limited value, but rather reaches a peak at a potential determined by oxide formation on the Pt surface. Formaldehyde oxidation continues on the oxidized surface, but at a slower rate than on clean Pt. When the platinum oxide is reduced in the cathodic sweep, the HCHO-oxidation current increases suddenly. There is considerable structure in the curves, and the details in the shape depend on pH. A two-electron reaction to formate was found to occur above pH 11.5. In the pH range 7-10, a three-to-four-electron reaction occurs.

The involvement of the surface oxide of Pt in the HCHO-oxidation reaction is also discussed by Kuliev *et al.* (3).

In basic solutions, HCHO is oxidized to the formate ion. van den Meerakker (4) examined a number of electrode materials and showed that the reaction could proceed by either of the following two stoichiometries

or

On Pt and Pd, the reaction proceeds according to [2]. It largely does so on Au as well, depending on the electrode potential. On Cu electrodes, HCHO is oxidized according to [1].

Conway (5) has discussed the mechanism of the oxidation of organic substances on noble metal electrodes, but does not specifically treat formaldehyde. He points out

*Electrochemical Society Active Member.

Key words: metal oxidation, electroless deposition, cyclic voltammetry, catalysis.

that there is a clear relationship between the currents for the oxidation of the organic species and those for surface oxidation and reduction, but that this is complicated by inhibition and catalytic effects. Dissociative adsorption is generally the first step of the reaction. The adsorbed species can then react with adsorbed oxygen or hydroxide, which may be in a form not yet incorporated into the stable surface oxide film. Strongly bound intermediates can form, however, and serve to poison the reaction.

Gold shows a behavior qualitatively similar to that of Pt (6, 7). The catalysis of HCHO oxidation by the UPD of foreign metal adatoms on noble metal electrodes has been examined by Adzic *et al.* (6, 7) and by Motoo and Shibata (10).

In industrial electrochemical processes using formaldehyde, the electrolyte may include other components that can influence the HCHO-oxidation reaction. Electroless plating baths contain a particularly large number of chemical species. One of the more common of these is the cyanide ion, which is often used to stabilize the Cu(I) that is produced as an intermediate in electroless Cu deposition (11), or which can be released as a by-product during the electroless deposition of metals from their cyanide complexes.

Molenaar (12) has considered the effect of the cyanide ion on the electroless plating of Au-Cu alloys. Gold cannot be plated from its cyanide complex using HCHO as the reducing agent, but Au-Cu alloys can be plated over a wide composition range. It has been proposed (12) that the CN^- poisons the HCHO-oxidation reaction on Au electrodes but not on Cu.

The present work examines the effect of cyanide ion concentration on the HCHO-oxidation reaction on Au, Pd, and Cu electrodes. The measurements were made in EDTA solutions at elevated temperatures under conditions approaching those used in real electroless-deposition processes. The results are related to oxide formation processes on these metals in HCHO-free solutions.

Experimental

The electrodes were thin metal foils. The Pd and Au were cleaned in concentrated HNO_3 before use. Copper foils were cleaned by a brief etch in 10% HNO_3 ; they were discarded after one use.

The solutions were prepared from reagent-grade chemicals and deionized H_2O that had then been distilled under O_2 and passed over a hot Pt filament. The pH of the solutions was adjusted with NaOH. No measures were taken to purify the formaldehyde, but bottles of formaldehyde were discarded when they showed significant polymer formation at the bottom. To minimize the extent of any possible homogeneous reactions of HCHO, it was not added to the solution until just prior to the measurement. As received, the HCHO contains CH_3OH as a stabilizer. It was verified that CH_3OH oxidation does not interfere with the results by running experiments in HCHO-free

solutions containing an equivalent amount of CH_3OH ; no significant methanol-oxidation currents were observed.

Solutions were thoroughly deaerated with N_2 before the measurements were made. During the measurement, the solution was blanketed with N_2 .

Formaldehyde reacts with the cyanide ion to form formaldehyde cyanohydrin according to the following reaction (1)

The formaldehyde cyanohydrin can then react further; hydrolysis can occur with ammonia evolution and a variety of other products can form. Thus, in the presence of HCHO , CN^- is consumed. This fact makes it very difficult to control the $[\text{CN}^-]$ during the measurement. Studies that assume a $[\text{CN}^-]$ from the amount added to the solution can be grossly in error. In the present work, an aliquot of the solution was removed immediately after the electrochemical measurement and cooled to room temperature. The $[\text{CN}^-]$ was then determined using a specific ion electrode. The range of concentrations studied was limited by the consumption of CN^- . At nominal free NaCN concentrations on the order of 150 ppm, the resulting $[\text{NaCN}]$ as determined with the CN^- electrode at the time of the measurement was <20 ppm.

The working electrode was mounted horizontally (facing down) in a Teflon holder. The counterelectrode was a Pt screen parallel to the working electrode at the bottom of the cell. The reference electrode was a $\text{Hg}/\text{Hg}_2\text{SO}_4$, sat. K_2SO_4 electrode in a separate compartment at room temperature. Potentials are quoted *vs.* the mercury sulfate electrode (MSE) at room temperature, which has a potential of 0.68V *vs.* NHE. A Luggin capillary probed the potential near the surface of the working electrode. The jacketed cell was made of Pyrex; circulating water maintained the solution in the cell at 75°C .

Results

All data were obtained at both room temperature and 75°C . To avoid an excessive number of figures, only the 75°C data will be given here; the room temperature data show the same trends and lead to the same general conclusions. The trends are emphasized at the higher temperature, however, since HCHO oxidation and metal dissolution are faster. In addition, the technologies employing HCHO oxidation often proceed at elevated temperatures, and it is informative to study the reaction near the temperature at which it is used.

Since the HCHO -oxidation reaction has such a strong relationship to oxide formation on the electrode surface, the cyclic voltammetry characteristic of HCHO oxidation will be compared to that in HCHO -free solution at a similar value of the $[\text{CN}^-]$. Such a comparison assumes that the surface-oxidation processes are the same in the presence and the absence of the adsorbed organic species. Kalcheva *et al.* (13) believe this to be true. Conway (5) also discusses this subject.

In the presence of CN^- , which reacts with HCHO , there may be electroactive species other than the methylene glycolate ion. The CN^- is present in trace amounts, however, and the concentration of methylene glycolate ion in solution should be much greater than that of either formaldehyde, cyanohydrin or any of the products of cyanohydrin reactions.

Au.—Figure 1b shows the cyclic voltammetry of a Au foil electrode in a solution of 0.12M EDTA, pH 11.7, at 75°C . During the initial stages of the oxidation of the Au surface, significant dissolution can occur. Thus, the charge under the oxidation peak in the anodic scan is substantially greater than that necessary to form an oxide film of monolayer dimensions. At sufficiently positive potentials, the surface becomes passivated by a protective oxide film. The situation is analogous to that described by Frankenthal and Siconolfi (14) for concentrated Cl^- solutions. In the cathodic sweep, the electrode remains passive until the oxide film begins to be reduced. Reduction of the oxide depassivates the Au, and dissolution

Fig. 1. Cyclic voltammetry of a Au foil electrode in 0.12M EDTA, pH 11.7, 75°C , (a) with 0.03M HCHO , and (b) with no HCHO . The sweep speed was 20 mV/s .

again occurs; this sequence of events results in an oxidation peak in the cathodic sweep.

The result of adding 0.03M HCHO to the EDTA solution is shown in Fig. 1a. Formaldehyde oxidation begins at $\sim -0.7\text{V}$ in the anodic sweep, and the current rises gradually as the potential is made more positive. A maximum current is reached at $\sim 0\text{V}$ in the anodic sweep, the same general potential region in which the electrode passivates in HCHO -free solution. In the cathodic sweep, the current remains low until $\sim 0.0\text{V}$, where a large spike of oxidation current occurs. Thereafter, the curve more or less retraces the anodic sweep. The spike in the cathodic sweep occurs at the potential at which the gold oxide film begins to be reduced and bare Au sites are once again exposed on the surface.

Low concentrations of CN^- influence the behavior of Au electrodes in HCHO containing and HCHO -free solutions. Representative curves for the highest NaCN concentration studied are given in Fig. 2. (A NaCN concentration of 1 ppm is $2 \times 10^{-5}\text{M}$.) Addition of CN^- to HCHO -free solutions suppresses the dissolution of the Au electrode, as evidenced by a reduction in the peak heights in both the anodic and cathodic sweeps (Fig. 2b). In HCHO solutions (Fig. 2a), addition of CN^- shifts the HCHO -oxidation currents in the anodic sweep to more positive potentials and the spike in the cathodic sweep to more negative potentials. The curves show features not observed in the absence of CN^- , but these are not clearly related to features in the curves in HCHO -free solutions (in Fig. 2b).

The effect of CN^- concentration is summarized in Fig. 3. The maximum currents in both the anodic sweep (solid circles) and the cathodic sweep (open circles) are plotted as a function of $[\text{NaCN}]$. Information about potential shifts is, of course, lost in such a representation.

In HCHO -free solution (Fig. 3b), the peak height in both sweep directions is substantially reduced by CN^- ion. Although the gold cyanide complex is highly soluble, the

Fig. 2. Cyclic voltammetry of a Au foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO and 6.6 ppm NaCN, (b) with no HCHO and 12.2 ppm NaCN, and (c) with no HCHO and 4.3 ppm NaCN. The sweep speed was 20 mV/s.

cyanide ion is present at low concentration and is in insufficient supply to form significant amounts of soluble $\text{Au}(\text{CN})_2^-$ ions. Instead, when the electrode is oxidized, compounds such as AuCN , which are less soluble than the gold-EDTA complex, probably form on the surface. The suppression of the dissolution current is pronounced at $[\text{NaCN}] = 1.9$ ppm and increases with $[\text{CN}^-]$ in the concentration range studied. Dissolution of gold as the EDTA complex still occurs, as evidenced by the magnitude of the currents flowing and by the continued presence of an anodic peak in the cathodic sweep.

The currents due to HCHO oxidation (Fig. 3a), are increased slightly at the lowest CN^- levels, but thereafter decrease monotonically with CN^- . Thus it appears that the adsorption of CN^- to form sparingly soluble gold compounds decreases the catalytic activity of Au for HCHO oxidation in EDTA solution, possibly through a reduction in the number of surface sites on which adsorption of formaldehyde can occur.

Pd.—The cyclic voltammetry of a Pd electrode in CN^- -free EDTA solution at 75°C is shown in Fig. 4b. The sorption of hydrogen just begins at the negative limit of the sweep; significant hydrogen sorption does not occur in the same potential range as HCHO oxidation on Pd. Both oxide formation and Pd dissolution occur in this potential range, as evidenced by the anodic peak that appears once oxide reduction begins in the cathodic sweep. The magnitude of the currents is generally smaller than for Au in the same solution.

Upon addition of HCHO to the solution, the behavior shown in Fig. 4a is obtained. Current begins to flow at $\sim -0.8\text{V}$ in the anodic sweep, increasing to a peak value at $\sim -0.3\text{V}$. The potential of the maximum current is slightly positive to the first peak in the cyclic voltammetry in HCHO-free solution. The simultaneous occurrence of palladium oxidation and dissolution make it impossible to

Fig. 3. The dependence of the peak current on CN^- concentration for a Au foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO, and (b) with no HCHO. The closed circles are the anodic sweep, the open circles the cathodic sweep.

relate the HCHO-oxidation peak to the state of oxidation of the electrode, but it appears that the HCHO current begins to drop when the Pd electrode becomes covered with an oxide or hydroxide film, perhaps a monolayer in thickness. Formaldehyde oxidation proceeds at a lower but significant rate during the cathodic sweep; the structural details in this region are not clearly related to any structure in the curve of Fig. 4b. As soon as the reduction of the Pd oxide begins in the cathodic sweep and free Pd sites are once again available on the surface, a sharp HCHO-oxidation spike appears.

In the presence of ~ 6 ppm NaCN, the behavior of Fig. 5 is obtained. In HCHO-free solution, the Pd dissolution reaction is suppressed, Fig. 5b. The onset of palladium oxidation in the anodic sweep is shifted to more positive potentials. Oxidation currents (due to Pd dissolution) are no longer observed in the cathodic sweep. In HCHO solution, 5.5 ppm of NaCN has depressed the peak in the anodic sweep and shifted it to a slightly more positive potential. The peak in the cathodic sweep, which has almost disappeared, has shifted to a more negative potential. The cathodic sweep in the presence of CN^- shows none of the structure that appears in CN^- -free solution.

The CN^- -dependence of the peak currents is shown in Fig. 6. In HCHO-free solution, Fig. 6b, the peak current in the anodic sweep is not very dependent on $[\text{NaCN}]$. The total oxidation charge is lower in the presence of CN^- , however, because of the shift in the onset of oxidation to more positive potentials. The shift occurs even at the lowest CN^- concentrations and has little concentration dependence. A more dramatic effect of CN^- is seen in the cathodic sweep. At $[\text{NaCN}] = 1.3$ ppm, a reduction peak is followed by a small oxidation peak. At higher concentrations, oxidation currents are no longer observed in the cathodic sweep.

The dependence of HCHO oxidation of $[\text{CN}^-]$ is complicated, as shown in Fig. 6a. Low levels of CN^- somewhat

Fig. 4. Cyclic voltammetry of a Pd foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO, and (b) with no HCHO. The sweep speed was 20 mV/s.

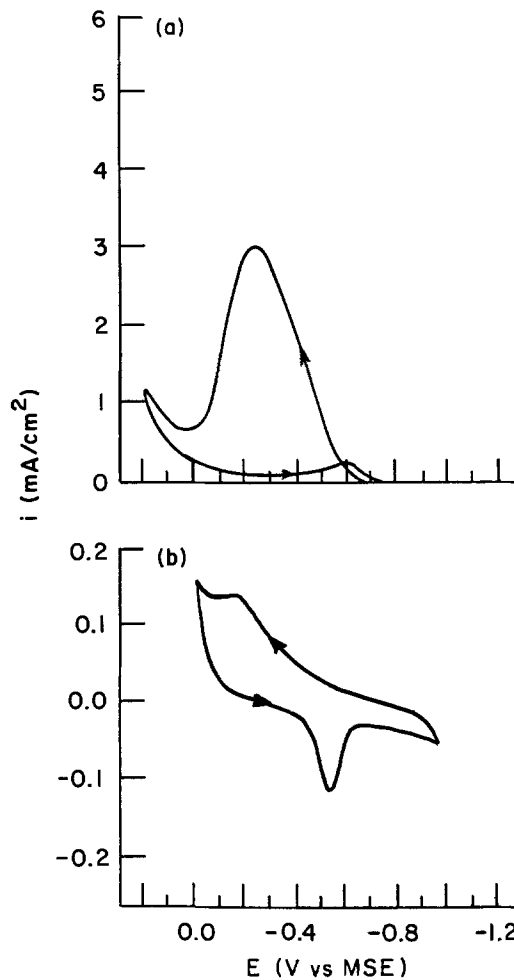

Fig. 5. Cyclic voltammetry of a Pd foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO and 6.0 ppm NaCN, and (b) with no HCHO and 5.5 ppm NaCN. The sweep speed was 20 mV/s.

reduce the peak currents in both the anodic and cathodic sweeps. Further addition of CN^- causes a maximum in the peak height. Sufficiently high $[\text{NaCN}]$ suppresses HCHO oxidation on Pd.

Cu.—Copper is a less noble metal than either Pd or Au, and EDTA strongly complexes Cu(II) ions. In addition, the stoichiometry of the HCHO-oxidation reaction is different on Cu than on Pd and Au (4). Thus, HCHO oxidation is studied in a different potential region on Cu than on the other metals of this investigation.

Figure 7b shows the cyclic voltammetry of Cu in the pH 11.7 EDTA solution at 75°C. In this potential range, only one redox couple, presumably Cu/Cu₂O, is observed. (Pourbaix diagrams (15), calculated at room temperature and in the absence of complexing anions, are not very helpful in assigning oxidation states in this system. The cyclic voltammetry of Cu in 0.4M Na₂SO₄ solution at pH 11.7 and 75°C has also been studied, however. In that solution, there are two pairs of peaks, due to Cu/Cu₂O and Cu₂O/Cu(OH)₂. In Na₂SO₄ the Cu/Cu₂O peaks appear in the same potential region as the pair of peaks in the EDTA solution. This observation gives some confidence to the assignment of the peaks in Fig. 7b to the Cu/Cu₂O couple).

The charge under the anodic peak (Fig. 7b) is several times that under the cathodic peak. This discrepancy may be the result of some copper ions leaving the surface as dissolved species. Unlike Au and Pd, however, Cu does not show an oxidation peak in the cathodic sweep.

On Au and Pd electrodes, the currents measured in HCHO solution are much larger than those due to the reactions of the metal in HCHO-free solution. Figure 7a shows that this is not the case on Cu electrodes. In the

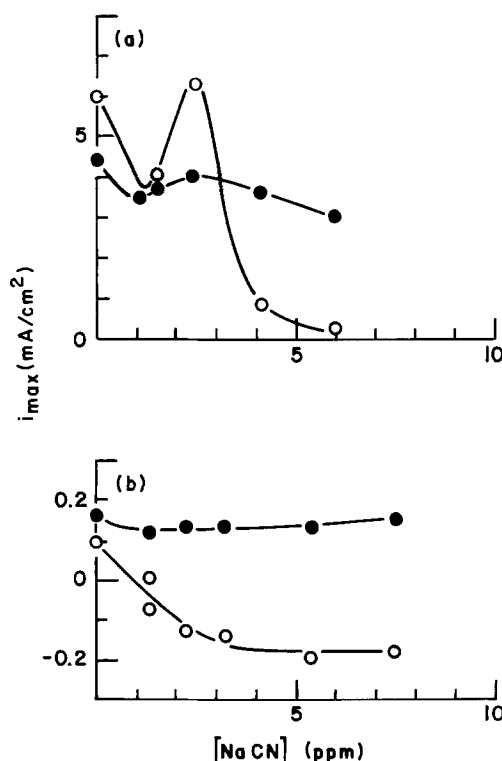

Fig. 6. The dependence of the peak current on CN^- concentration for a Pd foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO, and (b) with no HCHO. The closed circles are the anodic sweep, the open circles the cathodic sweep.

Fig. 7. Cyclic voltammetry of a Cu foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO, and (b) with no HCHO. The sweep speed was 20 mV/s.

anodic sweep, there is a narrow potential range (between $\sim -1.0\text{V}$ and $\sim -0.8\text{V}$) in which a very slightly higher current flows in the presence of HCHO; otherwise, the observed currents are actually higher in HCHO-free solution. Formaldehyde oxidation does occur on this electrode, however, as evidenced by the anodic peak that appears in the cathodic sweep as soon as the Cu_2O reduction begins.

The lower current in the presence of HCHO can be explained by a complex interaction of the processes of copper oxidation, copper dissolution, and HCHO oxidation. The adsorption of HCHO on the Cu electrode can suppress the Cu dissolution reaction. In other words

$$i_{\text{Cu diss.}} + i_{\text{HCHO ox.}} + i_{\text{Cu ox.}}$$

in the presence of adsorbed HCHO is lower than

$$i'_{\text{Cu diss.}} + i'_{\text{Cu ox.}}$$

in the HCHO-free solution because adsorbed HCHO suppresses Cu dissolution, and

$$i_{\text{Cu diss.}} < i'_{\text{Cu diss.}}$$

Nonetheless, the HCHO oxidation currents must be of the order of or less than the currents due to the other processes occurring on the surface.

Figure 8 shows the effect of CN^- on Cu oxidation and the electro-oxidation of HCHO. The cyclic voltammetry of Cu in CN^- containing EDTA solution (Fig. 8b) exhibits increased currents in the potential range negative to the $\text{Cu}/\text{Cu}_2\text{O}$ couple. Formaldehyde oxidation in the presence of CN^- proceeds at a higher rate than in its absence. (Compare Fig. 7a and 8a). An especially large enhancement in the current is observed in the same potential

range as the increased currents in Fig. 8b (*i.e.*, negative to the Cu_2O peak).

The effect of CN^- concentration is shown in Fig. 9. Cyanide has a smaller effect on the cyclic voltammetry of Cu in EDTA solution (Fig. 9b) than on that of Au or Pd. Sodium cyanide concentrations of up to 2.7 ppm result in virtually no change in the curve. At higher $[\text{NaCN}]$, the Cu_2O reduction peak is somewhat reduced in magnitude and has a shoulder on the negative side. This shoulder at potentials negative to the $\text{Cu}/\text{Cu}_2\text{O}$ couple is probably due to adsorption of the cyanide ion.

Formaldehyde electro-oxidation is highly dependent on the CN^- concentration (Fig. 9a). Addition of 1.2 ppm

Fig. 8. Cyclic voltammetry of a Cu foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO and 8.7 ppm NaCN, and (b) with no HCHO and 9.4 ppm NaCN. The sweep speed was 20 mV/s.

Fig. 9. The dependence of the peak current on CN^- concentration for a Cu foil electrode in 0.12M EDTA, pH 11.7, 75°C, (a) with 0.03M HCHO. The open circles represent the peak in the cathodic sweep. The closed circles represent the two peaks in the anodic sweep: the solid line the peak at $\sim -0.75\text{V}$ and the dashed line the peak at $\sim -0.9\text{V}$. (b) The same solution with no HCHO. The closed circles are the anodic sweep, the open circles the cathodic sweep.

NaCN increases the currents over the entire potential range. Further increase in the current occurs at $[\text{NaCN}] = 2.5$ ppm, and a second major peak in the anodic sweep appears at more negative potentials ($\sim -0.9\text{V}$). As $[\text{NaCN}]$ increases further, the peak at -0.75V in the anodic sweep goes through a maximum, and the -0.9V peak in the anodic sweep continues to increase in height. The oxidation peak in the cathodic sweep increases with $[\text{CN}^-]$ and shifts to more positive potentials in the range of concentrations studied. The substantial increase in the magnitude of the HCHO-oxidation currents caused by the addition of CN^- contrasts to the behavior on Au and Pd, for which the HCHO oxidation reaction becomes poisoned at fairly low cyanide concentrations.

Discussion

The HCHO-oxidation reaction requires rather specific surface conditions for the electrode material on which it proceeds. Information about the state of the surface can be gained by comparing the cyclic voltammetry in HCHO-free solution with that in HCHO containing solutions. Such a comparison leads to the conclusion that HCHO oxidation requires the availability of bare metallic sites on the surface; complete oxide coverage effectively impedes the reaction.

The effect of CN^- on HCHO oxidation on Au and Pd electrodes can be interpreted in light of this model. Cyanide was found to suppress the dissolution of these two metals in EDTA solution. At low cyanide levels, slightly soluble metal cyanide may form on the electrode surface. The surface population of bare metal sites would then be reduced, suppressing the rate of HCHO oxidation.

The situation is apparently somewhat more complex on Pd than on Au electrodes, as reflected in the fact that the HCHO-oxidation peaks go through a maximum as a function of the cyanide concentration. The maximum may result from the separate effects of the CN^- ion on the adsorption of hydrogen and the adsorption of the formaldehyde fragment on the Pd electrode. In the absence of further experimental evidence, however, such a model remains speculative.

The electrochemistry of Cu in EDTA solutions is quite different from that of Au or Pd. Whereas Au and Pd in CN^- -free solution sustain HCHO-oxidation currents that are significantly larger than the currents due to surface processes (oxidation and dissolution), Cu does not. The effect of CN^- on HCHO oxidation on Cu depends on the electrode potential. In the potential region of Cu_2O formation, the effect is much the same as on Pd: the size of the peak goes through a maximum as a function of $[\text{CN}^-]$. At more negative potentials, where CN^- adsorption is indicated from the cyclic voltammetry in HCHO-free solution, the HCHO oxidation current increases with $[\text{CN}^-]$ in the concentration range studied. Unlike Au and Pd, which show poisoning of HCHO electro-oxidation by CN^- , Cu can sustain substantially higher HCHO-oxidation currents in the presence of CN^- .

The uniqueness of the effect of CN^- on HCHO oxidation on Cu is related to the fact that the reaction proceeds by a different stoichiometry and in a different potential range than on Au or Pd. On Cu, formaldehyde oxidation occurs in a potential range in which cyanide adsorption is the dominant process, and thus cyanide can strongly influence this reaction.

Transport Numbers in Molten Acidic Aluminum Chloride-1-Methyl-3-Ethylimidazolium Chloride

Their Relationship to EMF Measurements in Chloroaluminate Melts

ABSTRACT

External and internal transport numbers were determined for the aluminum chloride-1-methyl-3-ethylimidazolium chloride room-temperature ionic liquid in the range of aluminum chloride mole fractions, $0.50 < x_{\text{AlCl}_3} < 0.67$. The 1-methyl-3-ethylimidazolium cation external transport number was found to be 0.71, while the internal transport number was found to be 1.00. The latter result may be of a general nature for all chloroaluminate melts and provides justification for using simplified formulas to represent the relationships between the EMF of concentration cells and the chemical potentials of chloroaluminate melts.

Molten mixtures of aluminum chloride and 1-methyl-3-ethylimidazolium chloride (MEIC) have been found to be useful solvents for electrochemistry and spectroscopy (1). Attractive features of this molten salt system are its low melting temperature, which is 20°C or less over the range of AlCl_3 mole fractions extending from 0.35 to 0.66 (2), and its wide range of Lewis acidity (1). AlCl_3 -MEIC mixtures are very similar in all respects to another much-studied low temperature chloroaluminate melt, the aluminum chloride-1-(n-butyl)pyridinium chloride (BPC) system. However, MEIC is easier to synthesize and purify than BPC, and AlCl_3 -MEIC melts exhibit significantly lower melting temperatures.

Both the AlCl_3 -MEIC and AlCl_3 -BPC systems have been studied using ^{27}Al NMR spectroscopy (3, 4). In addition, the latter has been investigated using Raman spectroscopy (5). From these studies it was established that AlCl_4^- and Al_2Cl_7^- are the principal anionic constituents of acidic (AlCl_3 -rich) melts in the range of AlCl_3 mole fractions, $0.50 < x_{\text{AlCl}_3} < 0.67$, while AlCl_4^- and Cl^- are the anionic constituents of basic melts. Potentiometric studies indicate that the acid-base properties of these melts can be represented by an equilibrium with Al_2Cl_7^- , AlCl_4^- , and Cl^- (1, 6-8)

Molecular AlCl_3 or Al_2Cl_6 appear to be absent from acidic AlCl_3 -MEIC and AlCl_3 -BPC in the range $0.50 < x_{\text{AlCl}_3} < 0.67$, unlike acidic AlCl_3 -alkali chloride melts, since aluminum chloride vapor pressures above the organic salt-based systems are negligible at elevated temperatures.

Concentration cells with aluminum electrodes have been used extensively to obtain potentiometric data in chloroaluminate melts (1, 6-11). However, the use of these cells to obtain thermodynamic data presupposes a knowledge of the transport numbers of the ionic components of the melt. It has been generally assumed in these studies that the external transport number of the melt cation is unity. This assumption has been questioned, especially for chloroaluminate melts with organic cations where the ionic radius of the cation may be comparable to or even larger than that of the prevalent anions, e.g., AlCl_4^- and Al_2Cl_7^- (12). However, no comprehensive study of transport numbers in chloroaluminate melts has appeared in the literature.

Basic Principles

In order to gain insight into ionic transport in chloroaluminate melts with organic cations, the transference experiment depicted in Fig. 1 was conducted. In this experi-

* Electrochemical Society Active Member.

ment current was passed between aluminum electrodes in a three-compartment cell. Before the start of the experiment, the three compartments, separated from one another by porous disks, were filled with AlCl_3 -MEIC melt of the same composition. Then, a known charge, Q , was passed through the cell and the concentration and weight changes in the catholyte and anolyte were determined.

The experimental arrangement is similar to a Hittorf cell, but the experiments permit the calculation of external transport numbers (relative to the porous membranes) as well as internal transport numbers (relative to a chosen reference, e.g., chloride ion). The first type of transport numbers give information about cooperative movements relative to the membranes. However, only the internal transport numbers are needed for the calculation of the EMF of concentration cells, although the more detailed external transport numbers also can be used. The pertinent equations for calculation of transport numbers and specific relationships between the various types of transport numbers are delineated below.

Transport numbers relative to an external reference.—If it is assumed formalistically that the melt is composed of 1-methyl-3-ethylimidazolium cation, R^+ , aluminum ion, Al^{3+} , and chloride ion, Cl^- , then the number of moles of these ions, n_{R} , n_{Al} , and n_{Cl} , respectively, in a sample of melt with weight, w , are given by

$$n_{\text{Al}} = \frac{x_{\text{Al}}w}{x_{\text{Al}}M_{\text{AlCl}_3} + (1 - x_{\text{Al}})M_{\text{RCI}}} \quad [2]$$

$$n_{\text{R}} = \frac{(1 - x_{\text{Al}})w}{x_{\text{Al}}M_{\text{AlCl}_3} + (1 - x_{\text{Al}})M_{\text{RCI}}} \quad [3]$$

$$n_{\text{Cl}} = n_{\text{R}} + 3n_{\text{Al}} = \frac{(2x_{\text{Al}} + 1)w}{x_{\text{Al}}M_{\text{AlCl}_3} + (1 - x_{\text{Al}})M_{\text{RCI}}} \quad [4]$$

where M is the molecular weight of the designated component, and x_{Al} the mole fraction of AlCl_3 . The external transport number for R^+ , t_{R} , can be calculated directly

Fig. 1. Schematic diagram of the transference experiment and definition of the formal external transport numbers.

from the expression shown below and an analogous equation written for the anode compartment

$$t_R \cdot \frac{Q}{F} = \frac{(1 - x_{Al}^c)w^c}{x_{Al}^c M_{AlCl_3} + (1 - x_{Al}^c)M_{RCl}} \quad [5]$$

$$- \frac{(1 - x_{Al}^o)w^o}{x_{Al}^o M_{AlCl_3} + (1 - x_{Al}^o)M_{RCl}}$$

The charge passed, Q , is given in coulombs, and F is Faraday's constant. The superscript o denotes the condition before the experiment, and the superscript c indicates the condition in the cathode compartment after passing current.

The moles of Al^{3+} transported into the catholyte, corrected for the loss or gain of Al^{3+} due to the electrode reactions, is given by Eq. [6]

$$(t_{Al} - 1) \cdot \frac{Q}{3F} = \frac{x_{Al}^c w^c}{x_{Al}^c M_{AlCl_3} + (1 - x_{Al}^c)M_{RCl}} \quad [6]$$

$$- \frac{x_{Al}^o w^o}{x_{Al}^o M_{AlCl_3} + (1 - x_{Al}^o)M_{RCl}}$$

An analogous expression can be written for the anode compartment. The external transport number for chloride ion can then be calculated from t_R and t_{Al}

$$t_{Cl} = 1 - t_R - t_{Al} \quad [7]$$

Transport numbers with chloride ion as the reference.—The amount of Cl^- is presumed constant in a compartment when internal transport numbers are calculated with Cl^- as the reference. By using Eq. [4] and considering the cathode compartment, the following condition must be fulfilled in which the number of moles of Cl^- ion in the compartment before and after electrolysis are equal

$$\frac{(2x_{Al}^o + 1)w^o}{x_{Al}^o M_{AlCl_3} + (1 - x_{Al}^o)M_{RCl}} = \frac{(2x_{Al}^c + 1)w^c}{x_{Al}^c M_{AlCl_3} + (1 - x_{Al}^c)M_{RCl}} \quad [8]$$

A similar expression can be written for the anode compartment.

Insertion of Eq. [8] into Eq. [5] so as to eliminate w_o and replacing t_R with t'_R , the internal transport number of R^+ , gives

$$t'_R = \frac{3Fw^c(x_{Al}^o - x_{Al}^c)}{Q[x_{Al}^c M_{AlCl_3} + (1 - x_{Al}^c)M_{RCl}](2x_{Al}^o + 1)} \quad [9a]$$

A similar expression can be written for the anode compartment

$$t'_R = \frac{3Fw^o(x_{Al}^a - x_{Al}^o)}{Q[x_{Al}^o M_{AlCl_3} + (1 - x_{Al}^o)M_{RCl}](2x_{Al}^a + 1)} \quad [9b]$$

The superscript a refers to the condition in the anode compartment following electrolysis. It should be noted that it is not necessary for w^c and w^a to correspond to the total amount of sample in each electrode compartment as used here. As in a Hittorf experiment, these weights must simply encompass the quantity of melt in which concentration changes occur. The definition that $t_{Cl} = 0$ gives the following relationship between internal transport numbers

$$t'_R + t'_{Al} = 1 \quad [10]$$

Relationships between external transport numbers.—In an acidic $AlCl_3$ - RCl ionic liquid, $0.50 < x_{AlCl_3} < 0.67$, the constituent ions have been shown to be R^+ , $AlCl_4^-$, and $Al_2Cl_7^-$ (5). As shown by Øye and King (12), the external transport numbers t_{Al} and t_{Cl} may be substituted by t_{AlCl_4} and $t_{Al_2Cl_7}$, i.e., the external transport numbers for the actual ionic constituents of the melt

$$t_{Al} = -3t_{AlCl_4} - 6t_{Al_2Cl_7} \quad [11]$$

$$t_{Cl} = 4t_{AlCl_4} + 7t_{Al_2Cl_7} \quad [12]$$

and therefore

$$t_R + t_{AlCl_4} + t_{Al_2Cl_7} = 1 \quad [13]$$

Combination of Eq. [11] and [12] and rearrangement gives the anion external transport numbers in terms of t_{Al} and t_{Cl}

$$t_{AlCl_4} = \frac{7t_{Al} + 6t_{Cl}}{3} \quad [14]$$

$$t_{Al_2Cl_7} = \frac{-4t_{Al} - 3t_{Cl}}{3} \quad [15]$$

Relationships between external and internal transport numbers.—The external and internal (relative to chloride ion) transport numbers are related to one another by stoichiometry, since movement of Cl^- is equivalent to movement of R^+ and Al^{3+} in the other direction, i.e., chloride transport is divided between the anions proportional to their equivalent fractions. Hence

$$t'_{Al} = t_{Al} + \frac{3n_{Al}}{3n_{Al} + n_R} t_{Cl} \quad [16]$$

or

$$t'_{Al} = t_{Al} + \frac{3x_{Al}^o}{2x_{Al}^o + 1} (1 - t_{Al} - t_R) \quad [17]$$

similarly

$$t'_R = t_R + \frac{n_R}{3n_{Al} + n_R} t_{Cl} \quad [18]$$

or

$$t'_R = t_R + \frac{1 - x_{Al}^o}{2x_{Al}^o + 1} (1 - t_{Al} - t_R) \quad [19]$$

The mole fraction of the original melt is used since no change in concentration near the membrane is assumed. The consistencies of these equations can be demonstrated by combining Eq. [19] with Eq. [5] and [6]. The result is Eq. [9a].

Cooperative movement of aluminum and chloride ions.—In the present experiments t_{Al} is found to be negative, indicating that aluminum is transported toward the anode and away from the cathode (*vide infra*). Cooperative movement of Cl^- and Al^{3+} can be defined as

$$C = \frac{t_{Cl}}{-1/3t_{Al}} = \frac{3(t_{Al} + t_R - 1)}{t_{Al}} \quad [20]$$

where C refers to the ratio of the number of moles of Cl^- and Al^{3+} transported to the anode or away from the cathode.

Experimental

Apparatus.—The preparation of melt and all subsequent transference experiments were conducted in a dry, oxygen-free nitrogen atmosphere inside a Kewaunee Scientific Engineering Corporation dry box system equipped with a Model 202500 30-cfm inert gas purifier. The quality of the atmosphere inside the dry box was tested by measuring the lifetime of a lighted 25W light bulb with a hole pierced in its glass envelope. The dry box atmosphere was found acceptable when the bulb remained lighted for 12h or more. Electrolysis experiments were conducted using a Hewlett Packard Model 6216A direct current power supply. The charge passed was determined via an AMEL Model 731 digital integrator.

Chemicals.—Anhydrous $AlCl_3$ (Fluka, A.G.) was sublimed under vacuum directly inside the dry box a minimum of three times. The organic salt, 1-methyl-3-ethylimidazolium chloride, was synthesized and purified according to the procedure of Wilkes *et al.* (1). The oxide content of the melt was determined using the procedure described by Stojek *et al.* (13). Melts that were 5 ppm or greater in oxide were discarded.

Fig. 2. Transference cell

Cell.—Transport data were obtained using a Hittorf-type cell (Fig. 2). The compartments in this cell were isolated by means of 10 mm diam fine porosity fritted disks. The porous areas of these disks were reduced by about 75% by heating them moderately with a glassblowing torch. The hydrostatic resistances of these disks were checked with melt, and it was determined that corrections for hydraulic flow were unnecessary under the experimental conditions employed. It should be noted in this regard that acidic AlCl_3 -MEIC melts are fairly viscous at room temperature compared to water and to ionic liquids used at elevated temperatures (2) and that only slight differences in the liquid levels in compartments A, B, and C (Fig. 2) arose during an experiment. The porous disks, prepared as above, were highly resistant to diffusional mixing also. A cell with melts of different composition, but with equal liquid levels in A, B, and C, was stored for several days without detectable changes in the composition of the melt in each compartment. The aluminum electrodes used in compartments A and C were fashioned from 80 cm of 1.0 mm diam wire (Alfa Products, m5N purity). Approximately 77 cm of the wire was immersed. The electrodes were pretreated by immersion in an aqueous etching solution that was 5% HF and 15% HNO_3 by volume and dried in an oven before use.

Analysis of melt.—The AlCl_3 -MEIC melt was analyzed using an absorption spectroscopic procedure. Figure 3 shows an absorption spectrum for the 1-methyl-3-ethylimidazolium cation dissolved in distilled water. The absorption maximum, λ_{max} , for the cation is observed at 211.5 nm with a molar absorptivity of $4.21 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$. This species obeyed the Lambert-Beer law in very dilute solutions. Melt samples were analyzed by measuring the cation absorbance at λ_{max} for solutions of melt appropriately diluted with distilled water. (Caution: the addition of water to acidic melts results in a violent exothermic reaction!) UV analyses of these samples were conducted in 1.0 cm path length quartz cells using a Perkin-Elmer Hitachi 200 UV-vis spectrophotometer. This instrument is equipped with a digital display and could be read to 0.001 absorbance units. However, the stated photometric accuracy of the instrument was 0.002 absorbance units. The results obtained for triplicate analyses of known melt samples are listed in Table I. These results reflect both the accuracy and precision of this analytical procedure.

Procedure.—Melt was added to compartments A and C until equal levels were attained in both compartments. The cell was disassembled, and the weight of the melt in A and C was determined. The cell was reassembled, and compartment B was filled with melt until its liquid level

matched that in A and C. A current of 3.0 mA (0.12 mA cm^{-2}) was passed between the aluminum electrodes. After the desired period of electrolysis, the cell was again disassembled, excess melt was cleaned from the inside and outside of the male joints D and E, and compartments A and C were reweighed. The weight of melt in each compartment was corrected for the change in weight of the aluminum electrodes in the compartment. Triplicate samples of the original melt and melt in compartments A, B, and C after electrolysis were analyzed. No difference between the composition of melt in the original sample and that in compartment B after electrolysis was ever detected. All experiments were conducted at $28^\circ \pm 2^\circ\text{C}$, and compartments A, B, and C were open to the dry box atmosphere during electrolysis.

Fig. 3. Absorption spectrum for $2.4 \times 10^{-4} \text{ M}$ 1-methyl-3-ethylimidazolium chloride in distilled water.

* Average deviation from the mean.

Results and Discussion

Electrolysis experiments conducted in acidic melt indicated that aluminum could be efficiently stripped from the anode and deposited as shiny, moderately adherent dendrites at the cathode. No discoloration of the acidic melt was noted, and no new organic species were detected in the melt by NMR spectroscopy after electrolysis. The aluminum anode weight loss was about 3-5 weight percent (w/o) larger than predicted theoretically from the charge passed. Similar effects were noted by Robinson and Osteryoung (14) in acidic AlCl_3 -BPC and were attributed to corrosion of the electrode by impurities in the melt. Fortunately, corrosion of the anode has minimal effect on the transport numbers reported herein, since the analytical procedure used for determining melt composition is not based on analysis of the aluminum content of the melt. Therefore, the effects of this corrosion were neglected. Cathode efficiencies could not be calculated accurately because it was not possible to remove this electrode from the cell and clean it without disturbing the aluminum dendrites. The cathode efficiency was assumed to be 100%. Transference experiments were also attempted in basic melt. However, the melt in the cathode compartment became discolored, suggesting that the electrode reaction occurring at aluminum did not correspond to the expected deposition of aluminum metal. The transference experiments reported herein were restricted to acidic melts.

Experimental transference data are listed in Table II. The lower case letter following each run number indicates whether the data were taken from the anode compartment, a, or cathode compartment, c, of the cell. Identical run numbers denote experiments in which the data were taken from both the anode and cathode compartments during a single run. Runs 2a through 6c were made during the initial phase of this study and were single compartment runs. The precision with which the initial and final values of x_{Al} could be determined are based on the relative average deviation from the mean for triplicate samples.

* Mole fraction of AlCl_3 in the anode or cathode compartment after electrolysis.

Calculated transport numbers as well as calculated values of the cooperative movement ratio, C , are recorded in Table III. Both t_{Al} and C vary with melt composition. However, significant variation of t_{r} and t'_{r} is more equivocal. Least squares analysis of the data for t_{r} and t'_{r} in Table III vs. x_{Al} yielded slopes of -0.30 ± 0.13 and 0.11 ± 0.22 , respectively, at the 95% confidence level. Thus, t_{r} appears to be statistically independent of melt composition with an average value of 1.01 ± 0.04 at the 95% confidence level. Values of t_{r} may decrease slightly as x_{Al} increases, but this result is questionable. The mean value of t_{r} is 0.71 ± 0.02 at the 95% confidence level. The standard deviations for t_{r} and t'_{r} are about 7%. This uncertainty is to be expected since the major source of error contributing to the precision with which these transport numbers may be calculated is the precision with which the melt could be analyzed. An uncertainty of ± 0.002 in x_{Al} translates to an uncertainty of ± 0.04 in the calculated value of the transport number. The mean value of t'_{r} calculated from anode data was 1.01 ± 0.06 at the 95% confidence level, while the mean value of t'_{r} estimated from cathode measurements was found to be 1.01 ± 0.07 . Thus, the experimental results appear to be independent of the electrode from which they were derived.

The negative values for t_{Al} (Table III) indicate that aluminum is transported toward the anode and away from the cathode during electrolysis. This implies that aluminum migrates in anionic complexes and that transport of aluminum by a naked aluminum ion, Al^{3+} , or cationic complex is unlikely. The result that t'_{r} is approximately 1.00 (strictly 1.01) can be used to provide straightforward structural interpretation in terms of ionic movements. For in this case, Eq. [17] reduces to

$$t_{\text{Al}} = \frac{-3x_{\text{Al}}}{2x_{\text{Al}} + 1} t_{\text{Cl}} \quad [21]$$

and the cooperative movement ratio is

$$C = \frac{2x_{\text{Al}} + 1}{x_{\text{Al}}} \quad [22]$$

Thus, if $x_{\text{Al}} = 0.50$, the melt stoichiometry corresponds to RAICl_4 and C is 4. Likewise, if $x_{\text{Al}} = 0.67$, the melt stoichiometry can be written as RAL_2Cl_7 , and C would have a value of 3.5. Thus, anionic transport corresponds to melt stoichiometry.

Numerical models for transport numbers.—The results obtained for the various transport numbers can be translated into the numerical models shown below by using Eq. [7], [17], and [19] as well as Eq. [13] to [15], if t_{r} and t'_{r} are presumed to be constant.

Internal transport numbers for R^+ , Al^{3+} , and Cl^-

$$t'_R = 1.00, t'_{Al} = 0, t'_{Cl} = 0 \quad [I]$$

External transport numbers for R^+ , Al^{3+} , and Cl^-

$$t_R = 0.71, t_{Al} = 0.29 \frac{-3x_{Al}^0}{1 - x_{Al}^0}, t_{Cl} = 0.29 \frac{1 + 2x_{Al}^0}{1 - x_{Al}^0} \quad [II]$$

External transport numbers with respect to the actual component ions for $0.50 \leq x_{Al}^0 \leq 0.67$

$$t_R = 0.71, t_{AlCl_4} = 0.29 \frac{2 - 3x_{Al}^0}{1 - x_{Al}^0}, t_{Al_2Cl_7} = 0.29 \frac{2x_{Al}^0 - 1}{1 - x_{Al}^0} \quad [IIIa]$$

If it is assumed that the reaction shown in Eq. [1] has a small equilibrium constant and that significant formation of Al_2Cl_6 does not occur in acidic melt in the range of x_{Al}^0 examined, then the anion fractions of $AlCl_4^-$ and $Al_2Cl_7^-$ are

$$x_{AlCl_4} = \frac{2 - 3x_{Al}^0}{1 - x_{Al}^0} \quad [23]$$

and

$$x_{Al_2Cl_7} = \frac{2x_{Al}^0 - 1}{1 - x_{Al}^0} \quad [24]$$

Hence

$$t_R = 0.71, t_{AlCl_4} = 0.29x_{AlCl_4}, t_{Al_2Cl_7} = 0.29x_{Al_2Cl_7} \quad [IIIb]$$

Applications to $AlCl_3$ - RCl concentration cells.—Oye and King (12) derived the following equation for the EMF of $AlCl_3$ - RCl concentration cells with aluminum electrodes and chlorine electrodes, respectively

$$Al: \quad -FdE = \frac{(1 - t_{Al})(1 - x_{Al}) + 3t_R x_{Al}}{3(1 - x_{Al})} d\mu_{AlCl_3} \quad [25]$$

$$Cl_2: \quad -FdE = \frac{-t_{Al}(1 - x_{Al}) + 3t_R x_{Al}}{3(1 - x_{Al})} d\mu_{AlCl_3} \quad [26]$$

Since the EMF calculated from these equations must be independent of the reference frame used for the transport numbers, these equations must be the same when using internal transport numbers. This can be seen by inserting Eq. [17] and [19] into Eq. [25] and [26]. The expressions obtained are

$$Al: \quad -FdE = \frac{(1 - t'_{Al})(1 - x_{Al}) + 3t'_R x_{Al}}{3(1 - x_{Al})} d\mu_{AlCl_3} \quad [27]$$

$$Cl_2: \quad -FdE = \frac{-t'_{Al}(1 - x_{Al}) + 3t'_R x_{Al}}{3(1 - x_{Al})} d\mu_{AlCl_3} \quad [28]$$

These equations can be reduced further by using the relationship $t'_R = 1 - t'_{Al}$

$$Al: \quad -FdE = \frac{t'_R(1 + 2x_{Al})}{3(1 - x_{Al})} d\mu_{AlCl_3} \quad [29]$$

$$Cl_2: \quad -FdE = \frac{t'_R(2x_{Al} + 1) + x_{Al} - 1}{3(1 - x_{Al})} d\mu_{AlCl_3} \quad [30]$$

The result that t'_R is approximately 1.00 and is independent of composition is of great significance from a thermodynamic viewpoint. Inserting this result into Eq. [29] and [30] gives the EMF of a concentration cell with aluminum electrodes, which is simply

$$Al: \quad -FdE = \frac{1 + 2x_{Al}}{3(1 - x_{Al})} d\mu_{AlCl_3} \quad [31]$$

while that for a concentration cell with chlorine electrodes is

$$Cl_2: \quad -FdE = \frac{x_{Al}}{1 - x_{Al}} d\mu_{AlCl_3} \quad [32]$$

As shown previously (12), Eq. [31] may also be given the alternate formulation

$$Al: \quad -FdE = \frac{1}{3} d\mu_{MAICl_4} - \frac{4}{3} d\mu_{MCl} \quad [33]$$

while Eq. [32] can be written as

$$Cl_2: \quad -FdE = 1/2d\mu_{Cl_2} - d\mu_{MCl} \quad [34]$$

Although the present study was limited to the acidic compositions of the aluminum chloride-1-methyl-3-ethylimidazolium chloride melt, some of the results obtained appear to be applicable to chloroaluminate melts in general. This is because the internal movement of Al^{3+} and Cl^- , which are bound in the complexes $AlCl_4^-$ and $Al_2Cl_7^-$, is probably insensitive to the nature of the cation. While t_R may be different for each system, the finding that t'_R is 1.00 may be a general result for chloroaluminate melts with alkali metal cations as well as organic cations. Actually, one would expect t'_R to be close to unity in the $AlCl_3$ - $NaCl$ system, since t_R for this melt is expected to be larger than found in the present system. Therefore, contributions due to anion transport would be smaller. The general use of Eq. [31]-[34] is therefore justified in the range $0.50 < x_{Al} < 0.67$. The applicability of these equations for $x_{Al} < 0.50$ is presently under investigation.

External transport numbers were obtained for the anions in the present work. The $AlCl_4^-$ and $Al_2Cl_7^-$ mobilities (t/x_i) were found to be equal, cf., [IIIb]. However, this does not necessarily indicate that the $AlCl_4^-$ and $Al_2Cl_7^-$ ions physically move in the melt with the same mobility. For example, a bridge exchange mechanism in which $AlCl_3$ is transferred between $AlCl_4^-$ and $Al_2Cl_7^-$ units may also account for the results that were observed.

Electron Transfer Kinetics of Redox Centers Anchored to Metal Surfaces: Weak vs. Strong Overlap Reaction Pathways

S. W. Barr, K. L. Guyer, T. T.-T. Li, H. Y. Liu, and M. J. Weaver*

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

ABSTRACT

Unimolecular rate constants k_{et} are presented for the one-electron electroreduction of various $\text{Co}^{\text{III}}(\text{NH}_3)_5\text{X}$ complexes bound to mercury, platinum, and gold surfaces via either small inorganic or extended organic ligands X. These "surface intramolecular" rate parameters are compared with estimates of k_{et} for outer-sphere pathways obtained from homogeneous rate data in order to ascertain the consequences of reactant-surface binding upon the electron transfer energetics. Only small or moderate decreases in the elementary reorganization barrier ΔG^*_{et} occur upon surface attachment, suggesting the occurrence of weak overlap pathways. Aside from the dependence of k_{et} upon the bridging ligand X at a given electrode potential due to differences in thermodynamic driving force, the observed variations in k_{et} appear to be due in part to variations in the electronic transmission coefficient κ_{el} . Measurements of electrochemical frequency factors for reactants containing a series of thiophenecarboxylate bridges indicate that the substantial decreases in k_{et} observed upon interruption of ligand conjugation arise predominantly from decreases in κ_{el} .

Although electrode processes commonly occur via reaction pathways involving specifically adsorbed intermediates, our understanding of the manner and extent to which the reaction-electrode interactions influence the electron transfer energetics, *i. e.*, determine the degree of electrocatalysis, is still at a rudimentary level. A difficulty that has hampered the elucidation of such "surface environmental" effects is that the reactions often occur via complex and/or uncertain mechanisms. One approach is to select for detailed study electrode reactions where the reactant, or reaction intermediate, is sufficiently strongly adsorbed to enable unimolecular rate constants (s^{-1}) for the heterogeneous electron transfer step to be evaluated in addition to the usual rate constants ($\text{cm}^2 \text{s}^{-1}$) for the overall reaction (1-3). We have been interested in examining such systems that also are mechanistically simple, enabling detailed molecular-level interpretation of the rate data to be undertaken.

An especially tractable class of "model reactions" are one-electron transition metal redox couples

where the solution species Ox and Red are substitutionally inert and bind strongly to the surface via a suitable coordinated ligand (1-3). Such electrode reaction pathways can be labeled "inner sphere" by analogy with homogeneous electron transfer processes between a pair of metal ions bound via a common ligand. Providing that the electron transfer step is rate determining, the overall ("apparent") rate constant, k_{app}^{is} ($\text{cm}^2 \text{s}^{-1}$), for reaction [1] can be expressed simply as (2-6)

$$k_{app}^{is} = K_p^{is} k_{et}^{is} \quad [2]$$

where k_p^{is} is the stability constant for forming the adsorbed ("precursor") state from the bulk reactant, and k_{et}^{is} (s^{-1}) is the rate constant for the elementary electron transfer step involving the surface-attached intermediate. This "pre-equilibrium" treatment provides a convenient separation between electrocatalytic influences upon k_{app}^{is} arising from variations in the cross-sectional reactant concentration at the electrode surface contained in K_p^{is} , and those due to variations in the electron transfer energetics themselves, embodied in k_{et}^{is} .

Fundamental information on the surface environmental factors influencing k_{app}^{is} can therefore be obtained by separately examining the sensitivity of k_{et}^{is} as well as K_p^{is} to variations in the electrode composition and the structure of the bridging ligand (3-5). We have demonstrated that a number of cobalt(III) and chromium(III) complexes are sufficiently strongly adsorbed at several metal surfaces, especially mercury, silver, platinum, gold, and copper, to enable values of k_{et} to be obtained for the one-electron re-

duction of the surface-bound redox center (2, 3). These complexes contain a simple inorganic (Cl^- , Br^- , NCS^- , N_3^-) or an organic ligand (*e. g.*, pyrazine, 4, 4'-bipyridine, thiophenecarboxylates) featuring a halide, nitrogen, or sulfur lone pair as a surface "lead-in" group. These processes are closely analogous to the intramolecular reduction of Co(III) by homogeneous reducing centers such as Ru(II) and Fe(II) that have been extensively investigated in the last few years (7). Therefore, they can be perceived as "surface intramolecular" reactions.

In this paper, we shall examine some of our recent results, chiefly for reductions of pentaamminecobalt(III), in order to illustrate the virtues of such strategies for unraveling the structural factors influencing the kinetics of electrocatalytic reactions. More complete descriptions of these results along with the experimental details are available elsewhere (2, 3).

Rate Formulations

Rate constants for surface-bound as well as other "intramolecular" free energy for the elementary electron transfer step ΔG^*_{et} by (6, 8)

$$k_{et} = \kappa_{el} \Gamma_n \nu_n \exp(\Delta G^*_{et}/RT) \quad [3]$$

The nuclear frequency factor ν_n (s^{-1}) describes the effective frequency with which the configuration of the various nuclear coordinates appropriate for electron transfer is approached from the precursor state. The electronic transmission coefficient κ_{el} denotes the probability that electron transfer will occur once the transition state is reached. The nuclear tunneling factor Γ_n is a quantum mechanical correction which accounts for the contribution to the measured rate from molecules which react without entirely surmounting the classical free energy barrier (6, 8). Although ν_n is a composite term arising from a weighted mean of manifold frequencies associated with reactant vibration and solvent reorientation modes, it will be close to $1 \times 10^{13} \text{ s}^{-1}$ for reactions, such as those considered here, where inner-shell reorganization provides an important component of ΔG^*_{et} (6). The nuclear tunneling factor Γ_n is usually close to unity (*ca.* 1-4) at room temperature. However, κ_{el} may well be orders of magnitude below unity if the electronic coupling between the donor and acceptor orbitals is weak (*vide infra*).

The reorganization energy ΔG^*_{et} at a given electrode potential E can be separated into "intrinsic" and "thermodynamic" contributions (4)

$$\Delta G^*_{et} = \Delta G^*_{int} + \alpha_{et} [RT(\ln K_p - \ln K_s) + \mathbf{F}(E - E^\circ)] \quad (4)$$

Here, α_{et} is the transfer coefficient for the elementary step (≈ 0.5), K_s is the equilibrium constant for forming the successor state (*i. e.*, the ground state immediately follow-

* Electrochemical Society Active Member.

ing electron transfer) from the bulk product, and E° is the standard potential for the redox couple. The "intrinsic barrier" ΔG_{int}^* is the value of ΔG_{et}^* that remains when the free energies of the precursor and successor states are equal (4). It is of particular interest since it is the free energy barrier usually calculated from contemporary electron transfer theories. The first and second sets of terms in parentheses in Eq. [4] constitute "surface" and "bulk" components, respectively, of the thermodynamic driving force for the elementary electron transfer step.

Consequences of Surface Attachment Upon Electron Transfer Energetics

A central question in the examination of electrocatalytic reactions is to what extent the elementary barrier to electron transfer is modified by binding the reactant to the electrode surface. In view of Eq. [3], the rate constant k_{et} for passage over this barrier may well be increased by surface attachment as a result of an increase in κ_{el} as well as from a decrease in ΔG_{et}^* . Such variations in κ_{el} are characteristic of "weak overlap" reactions where the metal redox center is almost entirely insulated from the electron donor (or acceptor) site provided by the electrode surface. On the other hand, variations in ΔG_{et}^* , more specifically in ΔG_{int}^* , are characteristic of "strong overlap" reactions. Here, $\kappa_{\text{el}} \approx 1$ and the interaction with the electron donor (or acceptor) site is sufficient to significantly distort the reactant and product potential energy surfaces in the intersection region so that the net free energy barrier is "rounded off" (9), thereby decreasing ΔG_{int}^* and increasing k_{et} .

At first sight, the question of the influence of surface attachment upon k_{et} may seem hypothetical since values of k_{et} cannot usually be measured directly for unattached reactants. Nevertheless, the pre-equilibrium rate formalism embodied in Eq. [2] and [3] also applies to outer-sphere pathways (6); i. e., those where the reactant in the transition state is separated from the electrode surface by at least one layer of solvent molecules (10). For such processes, the precursor stability constant K_p^{os} can be estimated from (6)

$$K_p^{\text{os}} = \delta r \exp(-w_p/RT) \quad [5]$$

where w_p is the average work involved in transporting the reactant from the bulk solution to the reaction site (precursor state), and δr is the effective thickness of the reaction zone. The latter equals the effective distances from the plane of closest approach over which electron tunneling can occur with sufficient probability to contribute significantly to the observed rate. Although the typical values of δr are uncertain, it is probably within a factor of two of ca. 1×10^{-8} cm for structurally simple reactants (6). The average work term w_p can simply be estimated from $w_p = ZF\phi_r$, where Z is the reactant charge number and ϕ_r is the average potential at the reaction site. An essentially equivalent formalism to this "encounter pre-equilibrium" model has been employed recently for outer-sphere redox reactions in homogeneous solution (8). Besides their practical value, such treatments are fundamentally more correct than the gas phase collisional model which commonly has been employed for describing outer-sphere reactions (6).

Admittedly, electrode reactions usually follow rate dominating inner-, rather than outer-, sphere pathways for reactants featuring surface attachment sites. Consequently, apparent rate constants and hence, values of k_{et} for outer-sphere pathways, $k_{\text{et}}^{\text{os}}$, will be unobtainable, at least within the same surface environment for which values of k_{et} for inner-sphere pathways, $k_{\text{et}}^{\text{is}}$, are determined. Nevertheless, the desired estimates of $k_{\text{et}}^{\text{os}}$ can be obtained by several routes as follows:

Method I.—Suitable chemical modification of the electrode surface, such as the monolayer adsorption of iodide or an underpotential deposited (upd) metal, can eliminate the competing inner-sphere route, enabling $k_{\text{et}}^{\text{os}}$ to be obtained from the measured value of $k_{\text{app}}^{\text{os}}$, provided that

K_p^{os} can be estimated from double layer structural data (3a, 11).

Method II.—At least relative values of $k_{\text{et}}^{\text{os}}$ at a given electrode potential E for a series of structurally related reactants may be obtained directly from the corresponding second-order rate constants, k_{h} , for their homogeneous reduction (or oxidation) with a suitable reagent (e. g., $\text{Ru}(\text{NH}_3)_6^{2+}$) that constrains the reaction to occur by an outer-sphere pathway (3a). Thus, providing K_p^{os} is approximately the same for each reactant

$$(k_{\text{et},1}^{\text{os}}/k_{\text{et},2}^{\text{os}})_E = (k_{\text{h},1}/k_{\text{h},2})_R \quad [6]$$

where the subscripts 1 and 2 refer to a pair of reactants, and R refers to a fixed homogeneous coreactant. This relationship follows from the "weak overlap" model of Marcus and others (12), and has been shown to apply to a number of reactions involving transition metal complexes (11, 13, 14). Additionally, if one or more of the electrochemical rate constants is known to refer to an outer-sphere pathway, Eq. [6] can be utilized to obtain estimates of $k_{\text{et}}^{\text{os}}$ for the remaining members of the series.

Method III.—For reactants where the surface attachment site is relatively remote from the redox center, such as for extended organic bridges, $k_{\text{et}}^{\text{os}}$ may be identified approximately with that obtained for a related reactant containing a similar ligand that lacks the surface binding group (3c).

Methods II and III will be utilized here. Various illustrative kinetic data for the one-electron reduction of 15 $\text{Co}^{\text{III}}(\text{NH}_3)_5\text{X}$ complexes (RoX) are gathered in Tables IA and IB. With the exception of OH_2 , NH_3 , F^- , and acetate (OAc^-), all the ligands X feature a lone pair on a nitrogen, sulfur, or halide atom, which induces sufficiently strong binding at suitable metal surfaces to enable the extent of reactant adsorption, and, hence, $k_{\text{et}}^{\text{is}}$ to be measured. The values of $k_{\text{et}}^{\text{is}}$ given in Table I were obtained either from the corresponding apparent rate constants $k_{\text{app}}^{\text{is}}$ combined with K_p^{is} (Eq. [2]) or directly from the transient currents for reduction of the initially adsorbed species. Details are given elsewhere (2, 3). The precursor stability constant K_p^{is} was determined from $K_p^{\text{is}} = \Gamma_p/C_b$ (cm), where Γ_p is the surface concentration (mol cm^{-2}) in the precursor state at a given electrode potential, and C_b (mol cm^{-3}) is the corresponding bulk reactant concentration. Mercury-, platinum-, and gold-aqueous interfaces were selected for detailed study of these reactions. The polarizable potential range at platinum and gold extends to sufficiently positive values to enable kinetic data to be obtained even for the most reactive complexes. The mercury-aqueous interface provides an especially suitable surface with which to obtain outer-, as well as inner-, sphere rate data in view of its reproducibility and well-defined structure. The values of Γ_p were obtained primarily using rapid linear sweep voltammetry and, at mercury, by additionally using chronocoulometry (2, 3). The rate constants in Table I all refer to a common electrode potential, 0 mV vs. SCE. This choice, although somewhat arbitrary, was made to minimize the extent of data extrapolation that was involved. The relative values of k_{et} are approximately independent of the potential chosen.

Outer-sphere values of k_{et} , $k_{\text{et}}^{\text{os,Hg}}$, are listed in parentheses in Table I for the four $\text{Co}^{\text{III}}(\text{NH}_3)_5\text{X}$ reductions, $\text{X} = \text{OH}_2$, NH_3 , F^- , and OAc^- , expected to refer to outer-sphere electrochemical pathways at mercury electrodes. These were obtained from the apparent rate constants at mercury in NaClO_4 and/or KPF_6 electrolytes by using Eq. [3] with $\delta r = 1 \times 10^{-8}$ cm, w_p being estimated from the diffuse layer potentials, ϕ_r , as described in Ref. (15) and (16).

Values of $k_{\text{et}}^{\text{os}}$ are also given for most other reactions in Table I. These values, labeled $k_{\text{et}}^{\text{os,Ru}}$, $k_{\text{et}}^{\text{os,Cr}}$, and $k_{\text{et}}^{\text{os,Fe}}$, refer to the homogeneous reduction of a given $\text{Co}^{\text{III}}(\text{NH}_3)_5\text{X}$ complex by $\text{Ru}(\text{NH}_3)_6^{2+}$, $\text{Cr}(\text{bpy})_3^{2+}$ ($\text{bpy} = 2, 2'$ -bipyridine), and $\text{Fe}(\text{CN})_6^{4-}$, respectively. They were obtained from the corresponding second-order rate constants for reduction of each complex relative to that for $\text{Co}(\text{NH}_3)_5\text{OH}_2^{3+}$ reduction (Method II). The values of $k_{\text{et}}^{\text{os}}$ were derived by

combining these relative values of $k_{\text{et}}^{\text{os}}$ with the estimate of $k_{\text{et}}^{\text{os, Hg}}$ for $\text{Co}(\text{NH}_3)_5\text{OH}_2^{3+}$ reduction, ca. $2 \times 10^3 \text{ s}^{-1}$, obtained at the mercury-aqueous interface at 0 mV vs. SCE. The validity of this procedure is supported by the approximate agreement (within ca. two fold) between the corresponding values of $k_{\text{et}}^{\text{os, Hg}}$, $k_{\text{et}}^{\text{os, Ru}}$, and $k_{\text{et}}^{\text{os, Cr}}$, although somewhat larger differences in these quantities are seen for $\text{Co}(\text{NH}_3)_5\text{OAc}^{2+}$ reduction (Table I).

Close examination of values of $k_{\text{et}}^{\text{is}}$ and $k_{\text{et}}^{\text{os}}$ reveals several interesting trends. Broadly speaking, the variations in k_{et} for the surface-attached reactants obtained by altering the bridging group X follow those for the corresponding values of k_{et} for outer-sphere homogeneous environments. This indicates that the reorganization barrier to electron transfer is not greatly altered by surface attachment via these bridging ligands. In other words, the substantially larger rate constants for the overall reaction at mercury, $k_{\text{app}}^{\text{Hg}}$, seen for reactions following ligand-bridged pathways (Table I) can be attributed in large part to the increases in K_p , i.e., the greater cross-sectional reactant concentrations at the electrode surface, brought about by reactant-surface bond formation.

Nevertheless, significant differences in k_{et} are seen for a number of reactants in the various reaction environments. Thus, for $\text{X}^- = \text{NCS}^-$, Br^- , and Cl^- , k_{et} differs by up to 100-fold between the corresponding values obtained for inner-sphere electrochemical, and outer-sphere homogeneous reaction environments. The values of $k_{\text{et}}^{\text{os}}$ are not expected to depend significantly upon the reaction environment. However, the homogeneous reductants $\text{Ru}(\text{NH}_3)_6^{2+}$ and $\text{Cr}(\text{bpy})_3^{2+}$ yield larger values of $k_{\text{et}}^{\text{os}}$, yet the reductant $\text{Fe}(\text{CN})_6^{4-}$ yields smaller values than those of $k_{\text{et}}^{\text{is}}$ obtained for the corresponding inner-sphere electrochemical pathway. Moreover, the ratios of $k_{\text{et}}^{\text{is}}$ for $\text{Co}(\text{NH}_3)_5\text{Cl}^{2+}$ relative

to those for $\text{Co}(\text{NH}_3)_5\text{NCS}^{2+}$ reduction at gold and platinum are 200 and 2×10^3 , respectively. Although comparable ratios of $k_{\text{et}}^{\text{os}}$ are seen for $\text{Ru}(\text{NH}_3)_6^{2+}$ and $\text{Cr}(\text{bpy})_3^{2+}$ (4×10^2 and 75, respectively), the corresponding $k_{\text{et}}^{\text{os}}$ ratio is only ca. 6 for reduction by $\text{Fe}(\text{CN})_6^{4-}$. These results suggest that the reactant orientation can have an important influence upon k_{et} . Thus, the anionic ligand NCS^- or Cl^- is anticipated to be oriented towards the cationic reductants $\text{Ru}(\text{NH}_3)_6^{2+}$ and $\text{Cr}(\text{bpy})_3^{2+}$, but away from the anionic reductant $\text{Fe}(\text{CN})_6^{4-}$. However, "strong overlap" pathways are very unlikely for outer-sphere reactions. Therefore, the much larger values of $k_{\text{et}}^{\text{is}}$ for $\text{Co}(\text{NH}_3)_5\text{Cl}^{2+}$ relative to $\text{Co}(\text{NH}_3)_5\text{NCS}^{2+}$ reduction at gold and platinum may well be associated with the necessary orientation of anionic ligands towards the electrode, rather than any diminution of the reorganization barrier caused by binding the reactant to the metal surface (3a). The origin of such orientation effects may lie in the increased orbital overlap, and hence, larger values of κ_{et} , brought about by interposing chloride (or bromide) ligands between the donor and acceptor orbitals located at the metal surface and $\text{Co}(\text{III})$, respectively.

In order to more fully understand the effects of varying the bridging ligand X upon the intramolecular reactivity, it is necessary to estimate the variations in the thermodynamic driving force term $[RT(\ln K_p - \ln K_s) + F(E - E^\circ)]$ in Eq. [4]. Although, to a first approximation, the "surface" component $RT(\ln K_p - \ln K_s)$ can be neglected since we expect that $K_p \approx K_s$, at a given electrode potential, the "bulk" driving force $F(E - E^\circ)$ may vary greatly, due to the dependence of the standard potential E° on the ligand structure. Although values of E° are largely unknown for the present $\text{Co}(\text{III})/\text{Co}(\text{II})$ couples, information on the likely variations in E° with X can be obtained as follows.

The variation in k_{et} relative to that for $\text{Co}(\text{NH}_3)_5\text{OH}_2^{3+}$ reduction, $k_{et}^{\text{OH}_2}$, caused by variations in the driving force term $F(E - E^\circ)$ can be expressed as

$$k_{et}^{\text{th}} = k_{et}^{\text{OH}_2}(K_{\text{II}}/K_{\text{III}})^{1/2} \quad [7]$$

where K_{III} is the equilibrium constant for $\text{Co}^{\text{III}}(\text{NH}_3)_5\text{OH}_2 + \text{X} \rightleftharpoons \text{Co}^{\text{III}}(\text{NH}_3)_5\text{X}$, and K_{II} is the equilibrium constant for formation of the corresponding Co(II) complex. Although values of K_{II} are unknown, they are expected to be, in most cases, smaller and markedly less dependent on X^- than are the values of K_{III} , in view of the difference in electronic configuration between Co(III) and Co(II) (t_{2g}^6 and $t_{2g}^5 e_g^2$, respectively). Therefore, an approximate (and probably limiting) estimate of the expected driving force effects upon k_{et} can be obtained by inserting the appropriate literature values of K_{III} into Eq. [7], along with the experimental value of $k_{et}^{\text{OH}_2}$, taking K_{II} as a constant.

The resulting "thermodynamic" estimates of k_{et} , k_{et}^{th} , are also listed in Table IA. (The sources of K_{III} are given in the footnote to Table I. The value of K_{II} was taken as $0.1 M^{-1}$; although somewhat arbitrary, this choice is intuitively reasonable given that Co(II) is expected to have some affinity for anionic ligands relative to H_2O , the value $K_{\text{II}} \approx 0.02 M^{-1}$ corresponding to an absence of such affinity). Comparison of the values of k_{et}^{os} and k_{et}^{is} with the corresponding estimates k_{et}^{th} shows that the observed variations of k_{et}^{is} as well as k_{et}^{os} with the nature of X are in large part accounted for by this "thermodynamic" component, although the values of k_{et} for $\text{Co}(\text{NH}_3)_5\text{Cl}^{2+}$ and $\text{Co}(\text{NH}_3)_5\text{Br}^{2+}$ reduction in electrochemical ligand-bridged and cationic outer-sphere environments are somewhat larger than expected on this basis. We therefore conclude that binding Co(III) to the electrode surface via simple halide or pseudohalide ligands produces only relatively minor changes in the elementary electron transfer barrier, although some "inner-sphere catalysis" does occur for chloride and bromide ligands at platinum and gold. The latter, nonetheless, may be due to increases in κ_{el} caused by more favorable electronic coupling rather than to diminutions in ΔG^*_{in} caused by the occurrence of "strong overlap" reaction pathways.

Turning now to the organic ligand-bridged reactions, comparison of k_{et} values for the seven thiophene-attached reactants in Table IB provide further evidence of the occurrence of electronic coupling effects. The k_{et}^{is} values at mercury for the reactants featuring uninterrupted conjugation between Co(III) and the sulfur surface binding site are relatively constant ($25\text{-}30 s^{-1}$) and close to k_{et}^{os} for $\text{Co}(\text{NH}_3)_5\text{OAc}^{2+}$ reduction. However, k_{et}^{is} for reactants containing one or more saturated carbons between the carboxylate group and the thiophene ring are 10- to 20-fold smaller (Table I). In contrast, k_{et}^{os} for $\text{Ru}(\text{NH}_3)_6^{2+}$ reduction of these complexes show only a relatively small dependence on the thiophenecarboxylate structure, the nonconjugated ligands yielding somewhat larger k_{et}^{os} values than the conjugated systems. This indicates that the smaller k_{et}^{is} values for the former systems at mercury are characteristic of the ligand-bridged mechanism itself, rather than to variations in the properties of the isolated Co(III) redox center, such as the E° values. The most likely explanation is that the electronic coupling between the Co(III) acceptor and surface donor orbitals is sufficiently weak for the conjugated ligands to yield smaller values of κ_{el} , and, hence, smaller k_{et}^{is} values (Eq. [3]), than for the conjugated ligands. This is supported by the activation parameter data discussed below. The absence of further decreases in k_{et}^{is} as the number of saturated carbons is increased from one to three may well be due to the involvement of an alternative reaction pathway where the electron tunnels "directly" between the surface and the Co(III) rather than via the bridging ligand. Interestingly, these ligand conjugation effects are absent for the reduction of the surface-bound thiophene complexes at gold, the relative values of k_{et}^{is} following instead the $k_{et}^{\text{os, Ru}}$ values (Table I). One explanation is that the mode of adsorption of the bridging ligand at gold differs from

that at mercury; the thiophene ring possibly lying flat or the carboxyl oxygen binding to the metal in the former case. This may enable reasonable electronic coupling to be maintained even in the absence of bridging ligand conjugation.

Activation Parameters for Surface-Bound Reactants

In addition to the evaluation of k_{et}^{is} at a single temperature, valuable information on the factors influencing the electron transfer energetics for surface-bound reactants may be obtained from measurements of electrochemical activation parameters. We have recently discussed their significance for surface-bound reactants (17). Since neither the standard potentials nor their temperature dependences are known with any accuracy for the present systems, so-called "ideal" activation enthalpies ΔH^*_i were determined from Arrhenius plots of $\ln k_{et}^{\text{is}}$ against $(1/T)$ at a constant cell potential using a nonisothermal cell arrangement. These measurements enable the frequency factor for the elementary electron transfer step, A_{et} ($= \nu_n \kappa_{el} \Gamma_n$, Eq. [3]), to be determined from

$$\ln A_{et} = \ln k_{et}^{\text{is}} + \Delta H^*/RT - \Delta S^*/R \quad [8]$$

where ΔS^*_i is the "ideal" activation entropy. Although ΔS^*_i is not negligible, it can be estimated from $\Delta S^*_i = 0.5 \Delta S^*_{et}$, where ΔS^*_{et} is the entropic driving force ("reaction entropy") for the electron transfer step. For the present Co(III)/(II) couples, on the basis of the available reaction entropy data (18), ΔS^*_{et} is expected to lie in the range 20-30 cal/K · mol.

Values of ΔH^*_i and A_{et} for reduction of selected surface-bound reactants at mercury electrodes are summarized in Table II. Since the estimated values of ΔS^*_{et} have uncertainties in the range ca. 5-10 cal/K · mol, the resulting frequency factors A_{et} may be up to 3- to 10-fold in error. Nevertheless, the relative values of A_{et} , particularly for structurally similar reactants, are more reliable. The two Cr(III) reactants both yield values of A_{et} that are close to the value, $1 \times 10^{13} s^{-1}$, expected for adiabatic pathways ($\kappa_{el} \approx 1$) for which $A_{et} \approx \nu_n$. The A_{et} values for the two Co(III) reactants, $\text{Co}(\text{en})_2(\text{NCS})_2^+$ (I) and $\text{Co}(\text{NH}_3)_5(2\text{-thiophene acrylate})^{2+}$ (IV) (both $1 \times 10^{12} s^{-1}$), suggest that these reactions are also close to being adiabatic ($\kappa_{el} \approx 0.1$). However, the remaining thiophene complexes (V, VI, VII), which have interrupted conjugation, exhibit markedly (10^2 - to 10^3 -fold) smaller values of A_{et} as well as k_{et} . This supports the above suggestion that the smaller reactivity of these latter complexes arises from the weaker electronic coupling (i.e., smaller values of κ_{el}) brought about by the interposition of saturated carbon atoms between the donor and acceptor sites (3, 17).

Conclusions

The foregoing analyses indicate that attachment of Co(III) to mercury, platinum, and gold surfaces via either simple inorganic or organic bridging groups yields only small or moderate changes in the elementary reorganization barrier ΔG^*_{et} . Thus, the corresponding values of k_{et}^{is} and of k_{et}^{os} obtained either in other reaction environments or estimated from the reactivities of structurally similar reactants are typically within ca. 5- to 30-fold of each other. In addition to the influence of the bridging ligand upon k_{et} arising from variations in the thermodynamic driving force, the dependence of k_{et}^{is} on the nature of the bridging ligand appears to arise in part from alterations in κ_{el} as a result of changes in the degree of electronic coupling between the surface donor and Co(III) acceptor orbitals. These reactions can therefore be considered to involve weak rather than strong overlap electron transfer. The possible exceptions are halide bridges at platinum and gold, where the surface bonds are expected to be relatively covalent, thereby weakening the Co(III)-halide bonds and decreasing the component of ΔG^*_{in} and, hence, ΔG^*_{et} , associated with the inner-shell (metal-ligand) reorganization energy. However, the relatively large values of k_{et}^{is} observed for these reactions can be attributed in part

to increases in k_{et} arising from the enhanced electronic coupling provided by the interposition of the monatomic ligand between the donor and acceptor orbitals.

The experimental frequency factors for the surface intramolecular reactions at mercury, $A_{et} \approx 10^{10}$ - 10^{13} s⁻¹, suggest that κ_{et} lies in the region ca. 10^{-3} -1.0 (*i.e.*, nonadiabatic pathways occur), although κ_{et} probably approaches unity (*i.e.*, adiabaticity is achieved) only with small inorganic bridging ligands. These conclusions are similar to those from recent experimental and theoretical work for related homogeneous electron transfer processes. Thus, values of κ_{et} substantially below unity are predicted for some homogeneous outer-sphere reactions even at small internuclear separations (5-6Å) (19). Nonadiabatic pathways for homogeneous intramolecular Co(III) - Ru(II) reactions bridged by bipyridine ligands featuring interrupted conjugation are also evidenced by the values of A_{et} obtained for these processes (7), especially after correction for the entropic driving force (20).

It is interesting to compare this situation with the catalyses induced by the ligand-bridged reduction of Co^{III}(NH₃)₆X complexes by homogeneous reagents such as Cr²⁺, Eu²⁺, V²⁺, and Fe²⁺. The analysis of the reaction energetics is considerably more tenuous than for the electrochemical reactions since little information is available on the precursor complex stabilities K_p^{is} . Moreover, the comparison of rate constants for corresponding outer- and inner-sphere pathways is less straightforward for homogeneous reactions since cognizance must be taken of the contribution to the reorganization energy from the coreactant. This component will probably be different for the outer- and inner-sphere routes since the coreactant's coordination sphere will necessarily be altered in forming the precursor complex.

Nevertheless, some useful deductions can be made from the available rate data. The most remarkable ligand-bridged rate accelerations occur for reductions by Cr²⁺; for example, Co(NH₃)₅Cl²⁺ is reduced by Cr²⁺ nearly 10¹⁰-fold more rapidly than is Co(NH₃)₆³⁺ (21). The corresponding rate ratios for reduction by V²⁺ and Eu²⁺ are about 10⁴, similar to that for Ru(NH₃)₆²⁺ (Table I) (21). The Co(NH₃)₅Cl²⁺-Cr²⁺ reaction clearly follows an inner-sphere pathway, whereas the latter two processes may follow outer-sphere mechanisms. Although the binding constant of Cr²⁺ to Co(NH₃)₅Cl²⁺ is unknown, it would need to be ca. 10⁶-fold higher than for the other reagents to account for the additional rate acceleration, which is highly implausible. Therefore, this, and also other ligand-bridged Co^{III}(NH₃)₅X - Cr²⁺ reactions seem certain to occur via "strong overlap" pathways; *i.e.*, where the elementary electron transfer barrier ΔG^*_{et} is lowered substantially by electronic interactions between the redox centers (4).

There have been several recent discussions of the factors influencing such inner-sphere catalyses (22, 23). It suffices to note here that such rate enhancements appear to be dependent upon the symmetry of the donor and acceptor orbitals, the most dramatic rate accelera-

tions occurring for systems where both orbitals have e_g symmetry (22). For such systems, it has recently been suggested that the precursor formation and electron transfer steps are merged such that the bridge forms a "three-center" bond with the two metal cations (23). The absence of such dramatic catalyses for the electrochemical reduction reactions is probably related to the relatively weak electronic coupling expected between the surface and Co(III) e_g acceptor orbitals, although the donor orbitals at gold, and especially platinum, surfaces are expected to have some d orbital character. Nevertheless, strong overlap electron transfer may well occur for electrochemical processes involving adsorbed redox centers, such as oxygen, which bind directly to metal surfaces rather than via a bridging group.

The evaluation of electrochemical rate constants and activation parameters for surface-bound reactants, especially for a series of structurally related systems, clearly provides detailed information on the electron transfer energetics that are unavailable from measurements of electrochemical reactivities for bulk phase reactants. We anticipate that a wealth of hitherto unavailable information on the factors influencing the degree of adiabaticity of heterogeneous electron transfer reactions can be extracted from systematic studies of the dependence of A_{et} as well as k_{et} on the structure of the metal redox center, the metal surface, and the mediating group.

Technical Notes

Preliminary Results of *In Situ* Al₂S₃ Preparation in MgCl₂-NaCl-KCl Eutectic Melt

Chen C. Hsu*

Argonne National Laboratory, Chemical Technology Division, Argonne, Illinois 60439

Because of the rising cost of electrical energy, a number of industrial processes have been proposed (1) for saving energy in the production of aluminum. Three of these processes were evaluated for their energy saving potential; all three involve reduction of a compound containing aluminum: Al₂O₃, AlCl₃, or Al₂S₃. Theoretically, the energy required for direct Al₂S₃ electrolysis is less than that required for the reduction of the other two compounds (2); for AlCl₃ by 24% and Al₂O₃ by 34%. The energy needed for conventional high temperature preparation of Al₂S₃, however, is very high (3). Unless other methods requiring less energy can be used for Al₂S₃ preparation, there is little advantage to the use of the Al₂S₃ process in terms of the overall energy requirements. One obvious way to decrease the energy requirement is to reduce the reaction temperature for the Al₂S₃ preparation by using molten-salt media.

Molten salts have been used extensively as reaction media for both inorganic and organic chemical preparation (4-6). There are several advantages for the use of molten-salt solutions: (i) the intimate contact in either a homogeneous solution phase, or in heterogeneous systems where reactants are dispersed in the solution, enhances the reaction rate. (ii) Local overheating due to exothermic reaction or freezing due to endothermic reaction is minimized. The molten salt acts as a heat transfer medium, which results in a better process control. (iii) Ease of removal of the gas reaction products increases the reaction efficiency. (iv) Reaction thermodynamics are improved due to the inherent physicochemical properties of the

melt in regard to the acid-base, redox, and complexing ability. One of the disadvantages, however, is the difficulty of separating the products from the media. One

possible solution in the case of Al_2S_3 reduction in a melt would be to prepare Al_2S_3 in the same melt used for electrolysis. Consequently, *in situ* Al_2S_3 preparation in a chloride melt was undertaken.

Experimental

Al_2S_3 preparation.—Chemicals used for this investigation are high purity $\text{MgCl}_2\text{:NaCl:KCl}$ eutectic salt [50:30:20 m/o (mole percent)] (Anderson Physics Laboratories), Al_2O_3 (Aluminum Company of America), and COS (Matheson Gas Company). All materials were used as received except for Al_2O_3 , which was further dehydrated in an oven at approximately 150°C for at least a week before use. All salts were stored inside a glove box under recirculating helium gas purified with charcoal embedded in a Dewar flask containing liquid nitrogen.

Alumina crucibles (Coors Company) with dimensions of 5.48 cm od, 5.16 cm id, and 9.05 cm high were baked overnight in a 250°C oven before being transferred to the glove box and filled with the reactants. After 55-65g of the chloride eutectic salt and 3-5g of Al_2O_3 were loaded into the crucible, the crucible was placed inside a larger covered graphite crucible filled with argon and transferred to a quartz-lined stainless steel furnace tube (see Fig. 1 and 2). The top of the furnace tube was closed immediately and the system was evacuated to a vacuum of approximately $5\ \mu\text{m}$, then backfilled with helium gas until a slightly positive pressure was produced in the furnace tube. As soon as the desired temperature was reached, the motor-driven stirrer was turned on and COS was passed through the melt. A platinum-10% rhodium + platinum thermocouple with a Trenderator (Omega Engi-

neering, Incorporated) was used to monitor the temperature, while a flow transducer with a digital display was used to show the mass flow rate of COS. The reaction conditions were as follows: a temperature of approximately 850°C , a COS flow rate of $68\text{--}135\text{ cm}^3/\text{min}$, and a reaction duration of $1.33\text{--}3.22\text{ h}$. At the end of each experiment, COS flow was stopped, and the furnace power and inlet and outlet tube valves were turned off. The graphite crucible was covered with aluminum foil and transferred back into the glove box for electrochemical analysis.

Electrochemical analysis of Al_2S_3 .—The apparatus for the electrochemical analysis, shown schematically in Fig. 3, consists of two 7 mm diam, high density, cylindrical graphite rods used as working and counterelectrodes, a Pt quasi-reference electrode, and a thermocouple for monitoring the temperature of the system. A Princeton Applied Research Model 175 Universal Programmer and Model 173 Potentiostat/Galvanostat along with a HP 7044A X-Y recorder were used to generate cyclic voltammograms (CV) in which the peak current was correlated with Al_2S_3 concentration. The peak currents of various Al_2S_3 concentrations were converted to peak current densities. The electrode areas in the melt varied from 2.31 to 4.05 cm^2 .

For qualitative and quantitative analysis of the synthesized Al_2S_3 with cyclic voltammetry technique, a correlation of peak current densities with various known Al_2S_3 concentrations in the chloride eutectic melt was carried out using the apparatus shown in Fig. 3.

Results and Discussion

The aluminum cation reduction peak in the cyclic voltammograms occurs at approximately -490 mV , while the sulfur anion oxidation occurs at around $+540\text{ mV}$ with a total peak-peak potential of 1.03 V vs. Pt quasi-reference at 750°C with the scan rate of 20 mV/s . Typical

Fig. 5. Correlation of Al^{3+} reduction peak current density with Al_2S_3 concentration at 750°C .

Fig. 6. Estimate for Al_2S_3 concentration of sample 7 from cyclic voltammograms.

cyclic voltammograms at 750°C using various scan rates are shown in Fig. 4. Only two peaks are obtained; one for aluminum cation reduction and the other for sulfur anion oxidation. The electrochemical reactions at the cathode and anode can be represented as follows (7)

The overall reaction can be shown as

The peak current of Al^{3+} was converted to peak current density for various Al_2S_3 concentrations at four different scan rates at 750°C , the temperature used for Al_2S_3 electrolysis. A plot of Al^{3+} reduction peak current density vs. Al_2S_3 concentration is shown in Fig. 5. This figure clearly shows the linear relationships between peak current density and Al_2S_3 concentration that exist at scan rates from 20 to 200 mV/s at 750°C . This correlation is the basis on which the analyses of the synthesized Al_2S_3 were performed.

Al_2S_3 formed in the molten salt reactor was analyzed in the glove box using the cyclic voltammetry method described above. Despite the concentration variations in synthesized Al_2S_3 , a reduction peak and an oxidation peak in a typical cyclic voltammogram of the sample occur at -490 and $+540\text{ mV}$, respectively. This information clearly indicates that conversion of Al_2O_3 to Al_2S_3 in the melt does occur. The peak current density of Al_2S_3 from the CV was used to estimate the Al_2S_3 concentration in the melt. A typical plot for this kind of estimate is shown in Fig. 6, where the heavy dots denote the synthesized Al_2S_3 at various scan rates. The Al_2S_3 concentration is taken to be the average value as shown in Fig. 6. Analyt-

^a Eutectic chloride salt mixture having the composition, MgCl₂:NaCl:KCl = 50:30:20 m/o.

ical results and reaction conditions are shown in Table I. A plot of Al₂S₃ concentration vs. COS flow rate shows that the yield of Al₂S₃ is not strongly dependent upon flow rate, Fig. 7. The best result so far obtained in terms of Al₂S₃ concentration is about 0.4 w/o (weight percent), as shown in Table I. Similar amounts of Al₂S₃ were formed for samples 2, 3, and 6, all of which had essentially the same COS flow rate but different reaction times. The smallest amount of Al₂O₃ conversion to Al₂S₃ is 0.07 w/o of

Fig. 7. Relation of the converted Al₂S₃ concentration with COS flow rate. The number by the dot is the sample number.

sample 4. The fact that the conversion is not dependent on reaction time suggests that equilibrium may be attained under the conditions used for samples 2, 3, and 6. If this is true, high temperatures will be needed for higher degrees of conversion. The Al₂O₃ concentration in the melt should not affect the results from electrochemical analyses since Al₂O₃ solubility in the melt is extremely low (8) (e.g., 0.0059 w/o at 901°C). It is interesting to note that the reaction of Al₂O₃ and COS in a gaseous environment requires a temperature of 1300°C (3, 9).

Further work is needed, particularly at a temperature higher than 850°C for kinetic and mechanistic studies to improve Al₂S₃ yield in this synthesis process. Obviously, at the present low Al₂S₃ concentration, it is not practical to use the aforementioned synthesis method for aluminum electrowinning purpose. Nevertheless, it has been demonstrated that *in situ* synthesis of Al₂S₃ can occur in the chloride eutectic melts, and that cyclic voltammetry is indeed a valid method for species identification and concentration determination.

Oxygen Evolution Study on Porous Molybdenum Naphthalocyanine Electrodes

H. Dieng, O. Contamin, and M. Savy*

Laboratoire d'Electrochimie Interfaciale du CNRS, 92195 Meudon Principal Cedex, France

In order to minimize the cathodic and anodic overvoltages taking place during water electrolysis in alkaline solution several authors have tried using as electrode catalysts oxides of the metals of the 3d series codeposited with molybdenum compounds (1-5). Among all the samples investigated, NiMoO₄ gave the best performances in endurance tests.

It has been employed for both oxygen and hydrogen evolution (4). By increasing the working temperature from 80° to 115°C one can observe a concomitant decrease of about 200 mV in the voltage between the anode and the cathode.

Cobalt oxide doped with lithium has also been reported recently (6) as offering relatively good performances for oxygen evolution at 70°C in KOH solutions. In the vicinity of ambient temperatures, molybdenum naphthalocyanine NPcMo loadings on carbon black (7) allow oxygen evolution at relatively small overvoltages (100 mV) but at current densities of only several hundred microamperes per square centimeter.

The aim of the present note is to determine whether in comparison with Mo oxides NPcMo can be employed with a certain degree of stability in electrolyzers at current densities of several hundred milliamperes per square centimeter and at working temperatures reaching 115°C or more and remain stable.

Experimental

The electrodes consisted of the carbon black powders ex CO or ex CH₄ (8) previously tested for their stability under anodic polarizations during more than 3000h. The carbon black powder was put into a sealed tube with an initial mixture of dicyanonaphthalene and ammonium paramolybdate. The thermal treatment conditions and the characterization of the final products by x-ray and XPS spectroscopy have been reported elsewhere (9). This impregnation was supported on a nickel-sintered electrode provided by Compagnie Générale d'Electricité. It presented a BET surface of 0.1 m²/g, 0.3 mm thickness, 70% porosity with 10μ diameter pores. The level of impregnation of NPcMo/C was 2.5 and 20% by weight. It must be noticed that in the present work the amount of Teflon deposited from the Soreflon suspension was relatively high, 56 mg for 50 mg of carbon black powder. This amount of Teflon turned out to be necessary to secure electrode cohesion. With large amounts the ohmic drop became too high. The charge of carbon black to the nickel support was about 50 mg/cm², and this corresponds to the maximum of activity.

From x-ray analysis (9) Mo oxides appear to be always associated with the naphthalocyanine. In order to distinguish between the oxide and the naphthalocyanine, several samples have been prepared varying the ratio dicyanonaphthalene/ammonium paramolybdate. Loadings of 2.5 and 20% have been chosen to reveal any possible kinetic factors in the synthesis able to modify the ratio Mo oxide/NPcMo. In order to appreciate the variations of activity or stability due to the amount of residual oxides, an extended washing with concentrated KOH has been carried out on several samples. In all cases the samples were prepared under deaerated conditions. They were washed with benzene, ethanol, 10% hydrochloric acid solutions, then distilled water and ethanol. In each case two samples were prepared to test the reproducibility of their performances.

*Electrochemical Society Active Member.

The nickel support covered with carbon black powder was mounted in an electrode carrier in Teflon inside a Teflon cell (Fig. 1). The anode compartment is separated from the cathode compartment by a porous Teflon membrane. The Hg/HgO reference electrode was placed inside the compartment of the working electrode. 8M KOH solutions were used. For voltammetric studies standard equipment was employed consisting of a signal generator Fabelle ST.1, a potentiostat Wenking 66TAI, and an X-Y recorder Ifelec M100. For transient studies the equipment was similar to that presented in Ref. (10). A galvanostatic pulse was sent to the cell, and the corresponding potential was measured through an oscilloscope and stored by a transient recorder (Biomation). The potential is related to the applied constant current i_0 by the equation

$$U(t) = Ri_0 + \frac{i_0 t}{C} \quad [1]$$

The slope yields the value for C and the intercept the value of R (see Table II). Corresponding frequencies f vary from $5 \cdot 10^{-7} > f > 5 \cdot 10^{-6}$.

Using current reversal it is possible to determine R and C separately, the circuit becoming equivalent to a resistance and a capacitance in series.

The impedance measurements have been performed after several cycles of polarizations but before the endurance tests for which a separator was used in the cell.

Results and Discussion

In Tables Ia and Ib, corresponding to temperatures of 25° and 80°C, respectively, are given the data obtained on the most active samples for a 2 day polarization at 560 mV Hg/HgO. The current densities are given in milliamperes per square centimeter (geometric).

In all cases the addition of catalytic material to the grid is accompanied by a corresponding increase in the current densities visible, even with the uncatalyzed carbon black samples. A modification in the order of activity at 25° and 80°C can be observed between samples containing molybdenum oxides and sample A (2.5% loading on carbon black carefully washed with concentrated KOH). At

F C + DCN 20% loadings	inactive			

25°C the most active sample consisted of a 20% loading without any washing with KOH. With sample A only a weak increase in the activity was observed. The stability of NiMoO₄ can also be underscored.

In contrast at 80°C sample A presented the best activity and stability. It can be compared with the NiMoO₄ and ammonium molybdate sample E which have been investigated in Ref. (1-5).

The results of impedance measurements are given in Table II.

Table Ib. Activities of the samples compared to the Ni support
 $T = 80^{\circ}\text{C}$

NiMoO ₄	4.75	2.6	1.2	653.0	1130.0
A	4.60	2.29	0.9	229.0	322.0
B	4.76	2.87		246.5	307.0
C	4.87	2.57		365.0	442.0
D	5.12	1.69		158.0	350.0
E	5.20	2.55		771.0	930.0
F	5.3	2.7		237.0	307.0

This table displays a relatively small variation of the resistivities between the different samples in the range of the temperatures investigated from 25° up to 115°C. For the samples which contain Mo naphthalocyanine (presence of DCN in the synthesis) there was only a small difference between the capacitances from 307 to 350 μF at 80°C. They remained lower than that of the support covered with carbon black but of the same order. For molybdenum oxide and NiMoO₄ an increase by about a factor of three was observed. Therefore the higher activity observed with the naphthalocyanine samples cannot be correlated with a difference in specific areas which increase as the capacitance increases. In contrast the increase in capacitances *vs.* temperature observed on all the samples may correspond to an increase of the surface in contact with the electrolyte due to improved wetting (capacitances becoming higher with the penetration of the electrolyte into the pores).

Cyclic voltammetry.—Typical results at 80°C are given in Fig. 2, with correction being made for the ohmic drop given in Table II. All samples containing NPcMo gave reproducible results, with oxygen evolution occurring be-

Fig. 2. i - E curves at 80°C KOH 8 mol initial. 1, Ni support; 2, carbon black; 3, NiMoO₄; 4, ammonium molybdate; 5, NPcMo sample A. Reference Hg/HgO scanning velocity 0.2 mV/s.

Fig. 3. *i-E* curves at 110°C KOH 8 mol initial. a, NPcMo sample A; b, NiMoO₄; c, Ni support. Same conditions as for Fig. 2.

tween 440 and 450 mV (Hg/HgO) at 300 mA/cm², the scanning velocity being fixed at 0.2 mV/s. At a current density of 300 mA/cm² the potential gain for NPcMo was about 80 and 40 mV compared with NiMoO₄ and MoO₃, respectively. Humps before O₂ evolution can be attributed to Ni²⁺/Ni³⁺ couple which is present in the carbon black structure ex CO (7) and also found with the nickel support. On the same figure data for hydrogen evolution are represented. The carbon black support yielded the same activity as NPcMo. It must be pointed out however from Table Ib that the carbon black samples without any loading were not as stable as NPcMo.

Data concerning the support NiMoO₄ and NPcMo at 110°C are represented in Fig. 3, with the scanning velocity being fixed at 0.2 mV/s. With correction being made for the ohmic drop, at a constant current density, the overvoltage for O₂ evolution on NPcMo sample A is about 100 mV lower than on NiMoO₄, which is roughly equivalent to the support. The variation of the O₂/4 OH⁻ reversible potential *vs.* temperature can be obtained from Eq. [58] and Fig. 6 of Ref. (11) (also see Appendix). It may be stressed that on the NPcMo sample, several hundred milliamperes per square centimeter are obtained at an overvoltage less than 125 mV from the theoretical potential of the O₂/4 OH⁻ couple. For H₂ evolution the support and NPcMo were equivalent and more active than NiMoO₄.

Results for a cell with a cathode and anode of the same material with a constant potential of 1.5V between the electrodes are represented in Fig. 4 as a function of time. The Teflon cell with a separator as given in Fig. 1 has been used. The absence of separator introduced a lack of stability in the electrode performances. Curve a refers to NPcMo sample A, curve b to NiMoO₄, and curve c to the support. It must be noted that good stability was obtained only with the NPcMo sample A and NiMoO₄. However in these conditions the current density with NPcMo sample A remained twice that observed with NiMoO₄.

Therefore the comparison between the Mo naphthalocyanine samples shows that there is greater stability in

the performance for both H₂ and O₂ evolution for the lowest ratios NPcMo/C. Thus, sample A had the best stability.

At 110°C the fact that the ohmic drop for both H₂ and O₂ evolution was of the same order for the support and

Fig. 4. Tests of stability at 110°C. $E = 1.500V$ (time in hours). (a) NPcMo sample A electrode, (b) NiMoO₄, (c) Ni support.

NPcMo sample A suggests that the residual resistivity can be attributed to the ohmic drop occurring in the pores of the support. Taking into account the stability of these materials for practical utilization in electrolyzers, one can choose the highest possible temperature (112°C or more). The performances obtained with this preparation can be compared with those described (1-6). In addition an important advantage of the stability at 110°C is that the porous separator can be operated under favorable conditions, since it has a high resistivity at temperatures below 110°C.

Acknowledgments

The authors wish to thank Professors Guerchais and Sala Pala for the synthesis of the samples, Dr. Roger Parsons for a critical reading of the manuscript, and the Direction d'Etudes et Recherches Techniques for its financial support.

APPENDIX

The ΔG° vs. temperature is given for water by the Lewis and Randall (12) expression

$$\Delta G^\circ \text{ cal/mol} = -57,410 + 0.94T \log T + 0.00165T^2 - 3.7 \cdot 10^{-7}T^3 + 3.92T \quad [\text{A-1}]$$

which is related to the standard potential of the cell by the thermodynamic relation

$$E_o^T = - \frac{\Delta G^\circ}{2F} \quad [\text{A-2}]$$

because 2 electrons are needed for the formation of one water molecule.

At $T = 383$ K one obtains

$$E_o^T = 1.16V$$

Taking into account the partial pressure of oxygen

$$E_{eq} = E_o^T + \frac{RT}{4F} \ln \frac{P_{O_2} P_{H_2}^2}{P_{H_2O}^2} \quad [\text{A-3}]$$

Substituting the pressures by their values one obtains

$$E_{eq} = 1.26V$$

$$E_{o, eq} = 324 \text{ mV Hg/HgO in KOH } 8M$$

Desorption Rates at Electrode/Electrolyte Interfaces

Yehuda Zeiri, Antonio Redondo, and William A. Goddard III

Arthur Amos Noyes Laboratory of Chemical Physics, California Institute of Technology, Pasadena, California 91125

ABSTRACT

A recently proposed theoretical approach using classical stochastic diffusion theory (CSDT) to predict desorption rates from solid surfaces is generalized to treat desorption of a particle from a solid surface into a liquid phase. Such systems are characterized by large friction constants resulting in a strong dependence of the desorption rate on the microscopic parameters of the liquid (e.g., solvent self-diffusion constant). The dependence of desorption on the different microscopic parameters of the system is examined. Based on these results, we propose electrochemical measurements which can be combined with the CSDT method to obtain microscopic information on the particle-surface interaction potentials at the solid/liquid interface.

The understanding of the microscopic details of processes occurring at metal and semiconductor electrodes have great importance in the design and improvement of electrochemical cells, fuel cells, etc., as well as in the fundamental study of solid/liquid interfaces. The basic and most important step in any system that contains a solid/liquid interface is the charge transfer process. Although a large amount of work has been devoted to the study of charge transfer at electrodes, relatively little is known about the detailed microscopic dynamics of these processes. The rate of charge transfer at an electrode can be regarded, in general, as a combination of the rates of three basic steps; (i) adsorption to the electrode surface, (ii) charge or atom transfer between the adsorbate and the electrode, and (iii) desorption of the newly formed adsorbate from the surface to the solvent. We can write these three steps in the following schematic form

where the subscripts sol and ad stand for solvated and adsorbed, respectively, and it was assumed that particle X was transformed into Y after the charge transfer takes place. In general, it is impossible to measure experimentally the individual rates of these three processes. Theoretical determination of the charge transfer rate, $X_{\text{ad}} + \text{electrode} \rightarrow Y_{\text{ad}} + \text{electrode}$, is possible provided that the adsorbate-electrode interaction potentials and the corresponding coupling terms are known. However, since the adsorption and desorption steps are complicated many-body processes that take place on a very long time scale compared to a molecular vibrational period, a theoretical estimate of the corresponding rates is very difficult.

Recently we have described a new method to evaluate rates of desorption for atoms and molecules adsorbed on solid surfaces, which is based on classical stochastic diffusion theory (CSDT) (1). Using the CSDT formalism (in the following we shall refer to Ref. (1b) as paper I), we have derived simple analytic expressions for atoms and molecules desorbing from solid surfaces (to vacuum), where the desorption rates were given in terms of the microscopic parameters of the system (e.g., D_e , the binding energy, Ω_0 , the stretching frequency of the adsorbate-surface interaction, k_r , the force constant for frustrated rotation, and T , the temperature). Similar expressions for the rate of desorption of both atoms (2) and molecules (3) from solid surfaces have also been obtained using transi-

tion state theory (TST). These rate expressions have the form

$$R = \frac{\Omega_0}{2\pi} f(T) \exp \left[- \frac{D_e}{kT} \right] \quad [2]$$

where $f(T) = 1$ for atomic adsorbate and $f(T) \propto k_r/kT$ for molecules. An interesting feature of Eq. [2] is that the desorption rate does not depend on the characteristics of the solid surface (e.g., Debye frequency) except through the adsorbate-surface interaction potential. This behavior is a result of the thermal averaging, incorporated in both the CSDT and TST methods, which suppresses the individual dynamical events occurring during the desorption process.

In this paper, we derive an expression for the rate of desorption of an atom (or ion) from an electrode surface into a condensed phase, namely, the solution. In so doing, we shall follow a derivation similar to the one employed in gas phase desorption (1). An expression for the desorption rate is derived below followed by the presentation and discussion of the results obtained for some model calculations. Finally, in the last part of the paper we outline some conclusions related to the calculated rates.

CSDT for Desorption from Electrode Surfaces

We shall start by considering a system composed of a desorbing particle (atom or ion), with mass M , interacting with a solid surface (electrode) and a number of solvent particles, with mass M_1 , as illustrated schematically in Fig. 1. For the description of the surface, we shall follow the ideas introduced by Adelman and Doll (4, 5) and divide the electrode atoms into two groups: (i) a small number of atoms which are strongly interacting with the adsorbed particle, this group will be called the primary zone, and (ii) the rest of the solid which is assumed to act as a heat bath. Without loss of generality we shall assume that the primary zone contains only one atom whose mass will be denoted by M_s . A further simplification is introduced by limiting both the desorbing particle and the primary zone atom to a one-dimensional motion normal to the solid surface. Thus, the motion of the adparticle will be described by a Newtonian equation of motion

$$M\ddot{R} = - \frac{\partial V(R, \zeta, \mathbf{Z})}{\partial R} \quad [3]$$

where ζ represents the displacement of the surface pri-

1555

mary zone atom from its lattice point. The vector \mathbf{Z} includes the displacement from equilibrium along the line connecting the centers of the adparticle and the solvent particles surrounding it. The total interaction potential, $V(R, \zeta, \mathbf{Z})$, felt by the adparticle is assumed to be given by a sum of pairwise interactions

$$V(R, \zeta, \mathbf{Z}) = V(R - \zeta) + \sum_{i=1}^{N(R)} V_i(R - \mathbf{Z}_i) \quad [4]$$

where $N(R)$ is the number of solvent particles surrounding the adsorbate at any given R . In the following, we shall use harmonic potentials to represent the interaction between the desorbing particle and the solvent

$$V_i(R - \mathbf{Z}_i) = 1/2 k_i [r - \mathbf{Z}_i]^2 \quad [5]$$

The interaction between the surface and the desorbing particle will be represented by a properly dissociating potential (e.g., Morse or Lennard-Jones) which is fitted with parabolic splines (see paper I)

$$V(R - \zeta) = \sum_i V_i(x) \quad [6]$$

where $x = R - \zeta$ and

$$V_i(x) = \begin{cases} 0 & x < x_i \\ A_i + B_i x + 1/2 C_i x^2 & x_i \leq x \leq x_{i+1} \\ 0 & x_{i+1} < x \end{cases} \quad [7]$$

x_i and x_{i+1} being the boundaries of the i th interval. The fit of Eq. [7] is performed in such a way that at any boundary point, x_i , the functions V_{i-1} and V_i and their first derivatives are continuous.

The motion of the surface primary zone atom as well as the motion of the solvent molecules will be described using the equivalent harmonic chain representation (EHCR) introduced by Adelman (6). We shall use this representation to construct model heat baths and employ the Markovian approximation in reducing the resulting generalized Langevin equations of motion to the corresponding Langevin equations (Appendix A). The introduction of the Markovian approximation is justified (see paper I) due to the large difference in the desorption time scale compared to a molecular vibrational period. Using the effective equation of motion derived in Appendix A to describe the motion of the primary zone surface atom, we have

$$M_s \ddot{\zeta} = -M_s \Omega_s^2 \zeta - M_s \beta_s \dot{\zeta} - \frac{\partial V(R, \zeta, \mathbf{Z})}{\partial \zeta} + f_s(t) \quad [8]$$

and similarly, the motion of the i th solvent particle is described by

$$M_i \ddot{\mathbf{Z}}_i = -M_i \Omega_i^2 \mathbf{Z}_i - M_i \beta_i \dot{\mathbf{Z}}_i - \frac{\partial V(R, \zeta, \mathbf{Z})}{\partial \mathbf{Z}_i} + f_i(t) \quad [9]$$

The effective frequencies and friction constants of Eq. [8] and [9] are given in terms of the EHCR parameters as discussed in Appendix A.

Next we substitute the potentials of Eq. [2]-[7] into Eq. [8] and [9] and solve them formally (using Laplace transforms). These solutions are then substituted into Eq. [3] to give

$$M \ddot{R} = \sum_{i=1}^{N(R)} \left[-k_i R + \frac{k_i^2}{M_i} \int_0^t \Theta_i(t-t') R(t') dt' + k_i f_i(t) \right] + \sum_{i=1}^n \left[-(B_i + C_i R) + C_0 \frac{C_i}{M_s} \int_0^t \Theta_s(t-t') R(t') dt' + C_i f_s(t) \right] \chi_i \quad [10]$$

where C_0 represents the force constant associated with the desorbing particle-surface interaction and χ_i is the characteristic function of the i th interval ($\chi_i = 1$ if R is in the i th interval and $\chi_i = 0$ otherwise). The memory kernels Θ_i and Θ_s in Eq. [10] are given by

Fig. 1. Schematic description of the adsorbate at a solid/liquid interface.

$$\Theta_i(t) = \frac{1}{S_i} \left\{ \exp \left[-\frac{1}{2} (\beta_i - S_i) t \right] - \exp \left[-\frac{1}{2} (\beta_i + S_i) t \right] \right\} \quad [11]$$

where $S_i = [\beta_i^2 - 4\bar{\Omega}_i^2]^{1/2}$ and $\bar{\Omega}_i^2 = \Omega_i^2 + k_i/M_i$. Similarly

$$\Theta_s(t) = \frac{1}{S_s} \left\{ \exp \left[-\frac{1}{2} (\beta_s - S_s) t \right] - \exp \left[-\frac{1}{2} (\beta_s + S_s) t \right] \right\} \quad [12]$$

where $S_s = [\beta_s^2 - 4\bar{\Omega}_s^2]^{1/2}$ and $\bar{\Omega}_s^2 = \Omega_s^2 + C_0/M_s$.

Assuming that the adsorbate-solvent interaction has the same form for all the $N(R)$ solvent particles, we can eliminate the first summation in Eq. [10] and instead multiply each term by $N(R)$. Furthermore, we may also eliminate the second summation and replace C_i and B_i by $C(R)$ and $B(R)$. Integrating by parts the two convolution integrals in Eq. [10] and rearranging terms, we can rewrite the effective equation of motion for the desorbing particle as

$$M \ddot{R} = -\{[N(R)k_i - \Gamma_i(0)] + [C(R) - \Gamma_s(0)]\}R - B(R) - \int_0^t [\Gamma_i(t-t') + \Gamma_s(t-t')] \dot{R}(t') dt' - [\Gamma_i(t) + \Gamma_s(t)] R(0) + F(t) \quad [13]$$

where

$$\Gamma_i(t) = N(R) \frac{k_i^2}{M_i} \int_t^\infty \Theta_i(t') dt' \quad [14]$$

$$\Gamma_s(t) = \frac{C_0 C(R)}{M_s} \int_t^\infty \Theta_s(t') dt' \quad [15]$$

The term in braces in Eq. [13] represents the total potential felt by the desorbing particle. It includes the corrections due to the thermal motion of both the surface atoms and the solvent particles surrounding the desorbing particle; thus, this is the potential that one would obtain experimentally. In the following, we shall denote this total potential by $V_{\text{tot}}(R, \zeta, \mathbf{Z})$. Due to the large difference in time scales one may introduce the Markovian limit to Eq. [13] and obtain the corresponding Langevin equation

$$M \ddot{R} = -\frac{\partial V_{\text{tot}}(R, \zeta, \mathbf{Z})}{\partial R} - (\tilde{\beta}_i(R) + \tilde{\beta}_s(R)) \dot{R} + \tilde{F}(t) \quad [16]$$

where

$$\tilde{\beta}_i(R) = \frac{N(R)k_i^2\beta_i}{M_i\bar{\Omega}_i^4} \quad [17]$$

$$\tilde{\beta}_s(R) = \frac{C_0 C(R)\beta_s}{M_s\bar{\Omega}_s^4} \quad [18]$$

Equation [16] represents an effective equation of motion for the desorbing particle whose motion is coupled to a heat bath constituted by the electrode surface

and the solvent particles. Since $V_{tot}(R, \zeta, \mathbf{Z})$ is an anharmonic function, we may fit it by a parabolic spline fit of the form introduced in Eq. [4]-[7]

$$V_{tot}(R, \zeta, \mathbf{Z}) = \sum_i V_i(R) \quad [19]$$

$$V_i(R) = \begin{cases} 0 & R < R_i \\ A_i + \bar{B}_i R + \frac{1}{2} \bar{C}_i R^2 & R_i \leq R \leq R_{i+1} \\ 0 & R_{i+1} < R \end{cases} \quad [20]$$

To express $\bar{\beta}_1$ and $\bar{\beta}_s$ in terms of the microscopic parameters of the system, one should evaluate the effective frequencies and friction constants of Eq. [8] and [9]. One can use as an estimate of these quantities the expressions obtained in Appendix A (Eq. [A.7] and [A.9]) and rewrite β_1 and β_s in the form

$$\bar{\beta}_1 = \frac{N(R)kT\kappa_1^2}{D_1 M_1^2 \left(\Omega_{01}^2 + \frac{\kappa_1}{M_1} \right)^2} \quad [21]$$

where D_1 is the self-diffusion coefficient of the liquid, and

$$\bar{\beta}_s = \frac{0.52547 \omega_D C_0 C(R)}{M_s \left(0.33295 \omega_D^2 + \frac{C_0}{M_s} \right)^2} \quad [22]$$

Thus, the final effective equation of motion for the desorbing particle is given by

$$M\ddot{R} = -\bar{B}(R) - \bar{C}(R)R - \beta_{tot}(R)\dot{R} + \tilde{F}(t) \quad [23]$$

where $\bar{B}(R)$ and $\bar{C}(R)$ are the first and second derivatives of the total potential, V_{tot} , evaluated at the point R , and $\beta_{tot}(R) = \bar{\beta}_1(R) + \bar{\beta}_s(R)$.

As discussed above, Eq. [23] describes the motion of the desorbing particle in terms of a Brownian oscillator where the interaction with the heat bath is given in terms of the microscopic quantities of the system. The amplitude of the random force, $\tilde{F}(t)$, is defined by its relation to β_{tot} through the second fluctuation-dissipation theorem. To derive an expression for the rate of desorption, one should first evaluate the probability distribution function for the desorbing particle and use this to obtain the flux at any given point in space. In evaluating the expression for the flux, we shall closely follow the derivation in paper I. The steady-state probability distribution is the solution to the (time independent) generalized Liouville equation (1, 7) and is given by

$$W(R, U) = A_0 F(R, U) \exp \left[-\frac{MU^2}{2kT} - \frac{V_{tot}(R)}{kT} \right] = A_0 F(R, U) W_{MB}(R, U) \quad [24]$$

where A_0 is a normalization constant, U is the velocity of the desorbing particle, W_{MB} is the Maxwell-Boltzman distribution function, and

$$F(R, U) = \left[\frac{\alpha - \tilde{\beta}_{tot}}{2\pi q} \right]^{\frac{1}{2}} \int_0^\xi \exp \left[-\frac{(\alpha - \tilde{\beta}_{tot})\xi'^2}{2q} \right] d\xi' \quad [25]$$

where $\xi = U - \alpha R - b$, $q = kT\tilde{\beta}_{tot}$, $\tilde{\beta}_{tot} = \beta_{tot}/M$ and

$$\alpha = \frac{1}{2}[\tilde{\beta}_{tot} + (\tilde{\beta}_{tot}^2 - 4d_1)^{\frac{1}{2}}] \quad [26]$$

$$b = -\frac{2d_0}{\alpha - \tilde{\beta}_{tot}} \quad [27]$$

where $d_1 = \bar{C}(R)/M$ and $d_0 = \bar{B}(R)/M$. The functional form of $F(R, U)$ is such that $F(R, U) = 1$ for $R = 0$ while $F(R, U) \rightarrow 0$ as $R \rightarrow \infty$.

In order to obtain an expression for the rate of desorption, we will calculate the flux of desorbing particles at a given distance from the surface, R_0 . The calculated flux must take into account only those particles at R_0 which have sufficient kinetic energy (and the proper velocity direction) to escape. Thus, the expression for the flux at a given value of R_0 is

$$j(R_0, U_0) = \int_{U_0}^\infty W(R_0, U) U dU \quad [28]$$

where U_0 is the smallest (positive) velocity for which a particle at R_0 will desorb, i.e.

$$D_e = V_{tot}(R_0) + \frac{1}{2}MU_0^2 \quad [29]$$

and where D_e is the well depth of V_{tot} . Substitution of Eq. [24] and [25] into [28] gives

$$j(R_0, U_0) = A_0 \left(\frac{\alpha - \tilde{\beta}_{tot}}{2\pi q} \right)^{\frac{1}{2}} \exp \left[-\frac{V_{tot}(R_0)}{kT} \right] \times \int_{U_0}^\infty \exp \left[-\frac{MU^2}{2kT} \right] \int_0^\xi \exp \left[-\frac{(\alpha - \tilde{\beta}_{tot})\xi'^2}{2q} \right] d\xi' U dU \quad [30]$$

Integrating by parts and rearranging we obtain

$$j(R_0, U_0) = A_0 \frac{kT}{M} \exp \left\{ -\frac{[MU_0^2 + 2V_{tot}(R_0)]}{2kT} \right\} Y(T) \quad [31]$$

where

$$Y(T) = \Phi(\alpha_1) + \exp(-\eta) \left[\frac{\pi\beta_{tot}kT}{2Ma} \right]^{\frac{1}{2}} [1 - \Phi(\alpha_2)] \quad [32]$$

with $\alpha_1 = \left(\frac{M(\alpha - \beta_{tot})}{2kT\beta_{tot}} \right)^{\frac{1}{2}} [U_0 - (\alpha R_0 + b)] \quad [33]$

$$\alpha_2 = \left(\frac{Ma}{2kT\beta_{tot}} \right)^{\frac{1}{2}} [-\vartheta(\alpha R_0 + b) + U_0] \quad [34]$$

$$\vartheta = 1 - \beta_{tot}/\alpha \quad [35]$$

and

$$\eta = \vartheta\beta_{tot}(\alpha R_0 + b)^2/2q \quad [36]$$

The symbol $\Phi(\alpha)$ represents the error function (8). Substituting Eq. [29] into Eq. [31]-[32] leads to the final expressions for the flux

$$j(R_0, U_0) = A_0 \frac{kT}{M} Y(T) \exp \left[-\frac{D_e}{kT} \right] \quad [37]$$

The rate for a desorption process is given (1, 7) by the ratio of the flux (Eq. [31]-[32]) at R_0 to the number of particles, N_0 , at the surface. The distribution function of the particles in the neighborhood of the equilibrium distance, $R = 0$, is given by W_{MB} , Eq. [24], leading to

$$N_0 = A_0 \int_{-\infty}^\infty \int_{-\infty}^\infty \exp \left[-\frac{MU^2}{2kT} - \frac{V_{tot}(R)}{kT} \right] dR dU = A_0 \left[\frac{2\pi kT}{M} \right]^{\frac{1}{2}} \int_{-\infty}^\infty \exp \left[-\frac{V_{tot}(R)}{kT} \right] dR \quad [38]$$

where the limits in the integral over R have been taken from $-\infty$ to ∞ because the integrand becomes negligibly small for values of R far away from $R = 0$.

For experimentally interesting temperature ranges (where $kT \ll D_e$), one can approximate the interaction potential, $V_{tot}(R)$, by a harmonic potential to obtain

$$N_0 = A_0 \left(\frac{2\pi kT}{M\Omega_0} \right) \quad [39]$$

where Ω_0 is the stretch frequency associated with the bottom of the potential well, V_{tot} .

Combining Eq. [37] and [38] leads to a desorption rate of the form

$$R = \frac{j}{N_0} = \left[\frac{kT}{2\pi M} \right]^{\frac{1}{2}} Y(T) \left\{ \int_{-\infty}^\infty \exp \left[-\frac{V_{tot}(R)}{kT} \right] dR \right\}^{-1} \exp \left[-\frac{D_e}{kT} \right] \quad [40]$$

and using Eq. [39] for N_0 leads to

$$R = \frac{\Omega_0}{2\pi} Y(T) \exp \left[-\frac{D_e}{kT} \right] \quad [41]$$

as the final expression for the desorption rate of atoms from solid surfaces.

In concluding this section, it should be emphasized that the major assumptions in deriving the expressions for the desorption rate are the introduction of the Markovian limit in Eq. [30] and [A.4]. As discussed above, the justification for the use of this approximation is based on the large difference between the time scale for the process of interest (desorption) compared to the molecular time scale (the vibrational period). Namely, we have assumed that the long time behavior of the different motions is well described by the Langevin equation of motion. It should be noted that a similar derivation can be made for this case in which Eq. [30] and [A.4] are used without the introduction of the Markovian approximation. Such derivation is much more complicated, due to the algebraic complexity of the equations. At present, we are in the process of performing these calculations to check the validity of the use of the Markovian limit.

Results and Discussion

In this section, we shall discuss the dependence of the desorption rate on the different microscopic parameters of the system. One of the major difficulties in most microscopic theories of solid/liquid interfaces arises from the lack of reliable interaction potentials for such systems. In the present study, we have chosen a model potential of the Morse type. One of our main objectives will be the study of the relationship of desorption rates to the potential parameters (D_e and Ω_0). Moreover, in the calculations described below, we have introduced a further approximation, namely, we assumed that $\Omega_{0(1)}^2 \ll k_f/M_1$. Since $\Omega_{0(1)}$ corresponds to the low frequency limit (it is zero for the case of free diffusion), this assumption is valid for most systems (especially in the case where the adsorbate-solvent interaction is strong, e.g., for ions in polar solvents). Using this approximation, we can rewrite the friction due to the solvent (Eq. [21]) in the form

$$\tilde{\beta}_1 = \frac{N(R)kT}{D_1} \quad [42]$$

A comparison between the magnitudes of $\tilde{\beta}_1$ in Eq. [42] and $\tilde{\beta}_s$ of Eq. [22] for typical values of the different parameters show that $\tilde{\beta}_s$ is smaller than $\tilde{\beta}_1$ by about two to four orders of magnitude (for example, for $M_s = 50$, $\Omega_0 = 600 \text{ cm}^{-1}$, $D_1 = 1.0 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, $T = 300 \text{ K}$, $\omega_0 = 278 \text{ cm}^{-1}$, and $R = 6.0 \text{ bohr}$, we obtain $\tilde{\beta}_1 = 38.6 \text{ a.u.}$ and $\tilde{\beta}_s = 0.36 \text{ a.u.}$). As a result, one may neglect $\tilde{\beta}_s$ and write

$$\beta_{\text{tot}}(R) = \tilde{\beta}_1(R) \quad [43]$$

In obtaining Eq. [43], we have taken into account the fact that $C(R)$ at $R = R_0$ is smaller than C_0 by about two orders of magnitude.

In Fig. 2, we present the calculated desorption rate as a function of temperature for two different values of Ω_0 (all other parameters are kept constant). In both cases, the solid line represents the actual rate while the dashed line represents the rate that one would obtain by setting $Y(T) = 1$. It is clear from these results that $Y(T)$ is very sensitive to changes in the stretch frequency while its dependence on the variation in T is weak. Moreover, it is clear from the functional form of Y (Eq. [32]) that this quantity will tend to reduce the desorption rate into a liquid with respect to that into vacuum. Figure 3 shows the variation of $\log(Y)$ as a function of the mass of the adparticle for different frequencies and bond strength of the total potential. This figure shows that $Y(T)$ exhibits a strong dependence on M , Ω_0 , and D_s , while it is weakly dependent on both D_1 (in the physically meaningful range of the diffusion constant, $5 \times 10^{-6} - 5 \times 10^{-5}$) and T .

Under typical electrochemical experimental conditions, it is difficult to change the temperature in the controlled manner (temperature programmed desorption) so useful at the gas/solid interface, but systematic changes in the applied voltage are very easy to perform. To relate our theory to these conditions, we have calculated the varia-

Fig. 2. Rates of desorption vs. temperature for two different stretch frequencies (a, top) $\Omega_0 = 600 \text{ cm}^{-1}$ and (b, bottom) $\Omega_0 = 900 \text{ cm}^{-1}$. The solid line corresponds to the calculated rate while the dashed line represents the rate that would be obtained by setting $Y(T) = 1$.

tion of the desorption rate as a function of the applied voltage. In the absence of an external field, the potential felt by the desorbing particle, V_{tot} , was assumed to have a Morse form. The potential profile due to the applied field through the diffuse layer was chosen to vary according the Gouy-Chapman (9) model

$$V_{\text{elec}}(X) = 2kT \{ \log(1 + A(V_0) \exp[-\alpha X]) - \log(1 - A(V_0) \exp[-\alpha X]) \} \quad [44]$$

where $1/\alpha = 30.4 \text{ \AA}$, X is the distance from the electrode and

$$A(V_0) = \tanh\left(\frac{V_0}{4kT}\right) \quad [45]$$

V_0 being the potential difference between the electrode and the bulk of the solution. We then assumed that the net potential felt by the adparticle (considered to be an ion in this case) is given by

$$V_{\text{net}} = V_{\text{tot}} + V_{\text{elec}} \quad [46]$$

Figure 4 shows the dependence of the desorption rate on the applied voltage. It is evident from these results that there is a large change in the rate (about three orders of magnitude) at low applied fields, and one obtains a saturation at voltages that are larger than 0.3V. This saturation is a result of the fast exponential decay of $V_{\text{elec}}(X)$ at high voltages. The increase in the rate is a consequence of our choice of the sign of the potential difference between the two electrodes. A decrease in the rate would be obtained if we would choose a reversed sign for this potential difference.

Conclusions

We have described in this paper a microscopic model which leads to analytic expressions for the desorption

Fig. 3. Variation of $Y(T)$ with the adsorbate mass for different dissociation energies. (a, top) $D_e = 0.5$ eV; (b, middle) $D_e = 1.0$ eV; and (c, bottom) $D_e = 2.0$ eV.

rate of an adsorbate from an electrode into the solvent. These expressions are easy to implement, provided that the microscopic parameters of the system are known. We have also proposed a procedure to calculate the dependence of the desorption rate on an applied electric field. Unfortunately, the microscopic details of processes that occur at electrode/electrolyte interfaces are very difficult to obtain experimentally, and hence, it is necessary to link these microscopic quantities to experimentally measurable data. A possible example corresponds to the measurement of the equilibrium rate constant (ratio between adsorption and desorption rates), which can then be used to obtain estimates of the adparticle-electrode binding energy. For example, one could obtain the equilibrium rate constant from measurements of the variation of the flatband potential, $V_H(C_{tot})$, of semiconductor electrodes as a function of ion concentration, C_{tot} (10). Consider a parallel plate capacitor model of the interface. The surface charge density, $\sigma(C_{tot})$, can be obtained by using the Schottky model of a metal-semiconductor junction (11),

$$\sigma(C_{tot}) = [2e\epsilon N_D V_H(C_{tot})]^{1/2} \quad [47]$$

where e is the fundamental charge, ϵ is the dielectric constant, and N_D is the impurity concentration in the semiconductor. If one assumes that the change in flatband

Fig. 4. Rate of desorption vs. applied voltage

potential as a function of the concentration of ions in the solution is mainly due to adsorption of ions on the electrode surface, then the adsorbate concentration in the Helmholtz layer, C_{ad} (number of particles per unit volume), is given by

$$C_{ad} = \frac{[\sigma^2(0) + 2e\epsilon N_D \Delta V_H]^{1/2} - \sigma(0)}{ed} \quad [48]$$

where d is the width of the Helmholtz layer, and $\sigma(0)$ corresponds to the surface charge density when $C_{tot} = 0$. In Eq. [48], we assumed that the adsorption of ion on the electrode surface does not change the initial surface charge density, that is

$$\sigma(C_{tot}) \approx edC_{ad} + \sigma(0) \quad [49]$$

This assumption should be particularly applicable at low coverages of the electrode surface. Equation [48] relates the measured change in flatband potential, ΔV_H , to C_{ad} . Assuming equilibrium conditions for a given C_{tot} , we have

$$C_{ad}k_d = (C_{tot} - C_{ad})k_{ad} \quad [50]$$

where k_d and k_{ad} are the rates for desorption and adsorption, respectively. Equations [48] and [50] provide a means to determine the equilibrium constant of the system, k_{ad}/k_d , from measurements of C_{tot} and ΔV_H , as a function of applied voltage.

Once the equilibrium constant is known, one could use the results of CSDT (Eq. [41]) to determine the adparticle-electrode binding energy, D_e , as follows. From a knowledge of the vibrational frequencies for the adsorbate-electrode system (e.g., from IR reflection experiments) and an independent determination of the adsorption rate, k_{ad} , (e.g., by using Langmuir adsorption-desorption kinetics), one would determine the binding energy from Eq. [50] and [41].

APPENDIX A

In this appendix we shall outline the procedure by which the parameters of the Langevin equations of motion (Eq. [8] and [9]) can be evaluated. We start by describing the motion of the primary zone surface atom and the motion of a solvent particle using the equivalent harmonic chain representation introduced by Adelman (6). For simplicity, we shall use a two atom model heat bath chain

$$\begin{aligned} \ddot{Q}_0(t) &= -\omega_{e1}^2 Q_0(t) + \omega_{e1}^2 Q_1(t) \\ \ddot{Q}_1(t) &= -\Omega_1^2 Q_1(t) + \omega_{e1}^2 Q_0(t) - \beta_2 \dot{Q}_1(t) + f_2(t) \end{aligned} \quad [A-1]$$

where Q_0 is the actual position of the particle, and Q_1 is the position of a fictitious particle. The coefficients ω_{e0}^2 and ω_{c1}^2 represent the Einstein and coupling frequencies while Ω_1^2 and β_2 are the low frequency and friction constant, respectively. Reference (6) provides a description of the derivation and the relations between these parameters. We now solve formally (using Laplace transforms) the equation of motion for Q_1 and substitute the result in the equation for Q_0

$$\ddot{Q}_0(t) = -\omega_{e0}^2 Q_0(t) + \omega_{c1}^4 \int_0^t \Theta(t-t') Q_0(t') dt' + \tilde{f}(t) \quad [A-2]$$

where

$$\Theta(t) = \frac{1}{S} \{ \exp(-\frac{1}{2}(\beta_2 - S)t) - \exp[-\frac{1}{2}(\beta_2 + S)t] \} \quad [A-3]$$

and $S = [\beta_2^2 - 4\Omega_1^2]^{\frac{1}{2}}$. Integration by parts of the memory integral of Eq. [A-2] yields

$$\ddot{Q}_0(t) = -\omega_{e0}^2 Q_0(t) + \omega_{c1}^4 \beta(0) Q_0(t) - \omega_{c1}^4 \int_0^t \beta(t-t') \dot{Q}_0(t') dt' - \omega_{c1}^4 Q_0(0) \beta(t) + \tilde{f}(t) \quad [A-4]$$

where $\beta(t)$ is related to Θ by

$$\beta(t) = \int_t^\infty \Theta(t') dt' \quad [A-5]$$

We introduce now the Markovian limit to reduce Eq. [A-4] into a Langevin equation of the form

$$\ddot{Q}_0(t) = -\Omega_{\text{eff}}^2 Q_0(t) - \beta_0 \dot{Q}_0(t) + F(t) \quad [A-6]$$

where the frequency and friction constants are given by

$$\Omega_{\text{eff}}^2 = \omega_{e0}^2 - \frac{\omega_{c1}^4}{\Omega_1^2} \quad [A-7]$$

and

$$\beta_0 = \frac{\omega_{c1}^4 \beta_2}{\Omega_1^4} \quad [A-8]$$

Thus, Eq. [A-6] represents an effective equation of motion which governs the motion of both the primary zone surface atom and the solvent particle. The coefficients in these equations of motion are given in term of the equivalent harmonic chain representation parameters which for a Debye solid take the values (6): $\omega_{e0}^2 = 0.6 \omega_D^2$, $\omega_{c1}^2 = 0.262 \omega_D^2$, $\Omega_1 = 0.507 \omega_D$, and $\beta_2 = 0.161 \pi \omega_D$. Using these values for the EHCR parameters, we obtain that

$$\Omega_{\text{eff}}^2(\text{solid}) = 0.33295 \omega_D^2 \quad [A-9]$$

and

$$\beta_0(\text{solid}) = 0.52547 \omega_D \quad [A-10]$$

It is much more difficult to estimate the EHCR parameters for a liquid particle since a knowledge of the velocity autocorrelation function is required. However, we may use the relation (6)

$$\Omega_1^2 = \frac{\omega_{c1}^4}{\omega_{e0}^2 - \Omega_0^2} \quad [A-11]$$

and

$$\beta_2 = \beta_1 \frac{\Omega_1^2}{\omega_{e0}^2 - \Omega_0^2} \quad [A-12]$$

where we used the Einstein relation $\beta_1 = kT/M_1 D_1$ (k = Boltzmann factor, M_1 = solvent particle mass, and D_1 = self-diffusion constant of the solvent). One can use these relations to rewrite Ω_{eff}^2 and β_0 in the form

$$\Omega_{\text{eff}}^2 = \Omega_0^2 \quad [A-13]$$

and

$$\beta_0 = \beta_1 = \frac{kT}{M_1 D_1} \quad [A-14]$$

The low frequency constant, Ω_0^2 , is usually equal to zero for a freely diffusing particle (6), however, in our case, this frequency is nonzero since the solvent particles of interest are interacting strongly with both the electrode surface and the desorbing particle and hence, are not freely diffusing.

Low Temperature Oxidation of Metals and Semiconductors

Francis P. Fehlner*

Corning Glass Works, Research and Development Division, Corning, New York 14831

ABSTRACT

The growth of oxide films on metals and semiconductors at low temperatures has been interpreted using the Cabrera-Mott theory which assumes a uniform oxide structure. Kinetic data taken from the literature were introduced into the Ghez integration of the Cabrera-Mott equation. Results were found to correlate with a division of oxides into network formers, intermediates, and modifiers. The network formers and intermediates were best fit by inverse logarithmic kinetics (Cabrera-Mott), while the modifiers appeared to follow direct logarithmic kinetics. Values of activation energy for ion movement, the number of potentially mobile ions, and the self-induced voltage across the oxide have been derived for the network forming and intermediate oxides. These values are compared with those obtained from other experiments.

The field of low temperature oxidation has been experimentally handicapped by a lack of extensive data on simple systems. Several reasons account for this paucity of data: the difficulty of measurements, poor reproducibility of metal samples, little control of impurities (especially water vapor), and incomplete characterization of the product oxide. Fortunately, this situation is changing as semiconductor techniques and surface analytical methods are applied to the problem. As a result, data over an extensive temperature and pressure range are becoming available.

Analysis and interpretation of such kinetic data is the next difficulty. Historically, linearity of a plot on graph paper has been taken to be indicative of a particular mechanism. However, it has become apparent that for low temperature oxidation, both direct logarithmic (x vs. $\log t$, where x is oxide thickness and t is time) and inverse logarithmic kinetics ($1/x$ vs. $\log t$) can often fit the same set of data.

One resolution of this dilemma is to examine the principles upon which each derived rate equation is based and calculate values for physical quantities which are measurable in other experiments. Many descriptive models of low temperature oxidation have been put forward, but the Cabrera-Mott theory (1) stands out as having proven validity. For this reason, it is emphasized here as the basis for interpreting kinetic data from low temperature oxidation.

The Cabrera-Mott approach (1) assumes a quasiequilibrium of electrons tunneling across the thin oxide. Some electrons are trapped on oxygen sites at the oxide-gas interface, setting up a spontaneous voltage which is taken to be constant. The resulting field aids cation incorporation at the metal-oxide interface. This process is assumed to be rate limiting. Fehlner and Mott (2) have applied these ideas to anion incorporation at the oxide-gas interface and conclude that the same equation may be applied to both anion and cation movement.

In experiments, oxide thickness x is measured as a function of time, t , while pressure P , temperature T , number of potentially mobile ions N , activation energy for ion movement W , voltage across the oxide V , ion-jump distance $2a$, frequency of vibration ν , and oxide volume per ion Ω are assumed to remain fixed. An oxide film with uniform properties is also assumed to exist.

Following the approach of Ghez (3), the Cabrera-Mott equation is expressed as

$$dx/dt = N\Omega\nu \exp \left[- \left(W - \frac{qaV}{x} \right) / kT \right] \quad [1]$$

where the field across the oxide is $E = V/x$. Equation [1] can (2) be integrated for $x \ll x_1$, to give

$$x_1/x = -\ln [(t + \tau)/x^2] - \ln(x_1, u) \quad [2]$$

where

*Electrochemical Society Active Member.

Key words: oxidation at low temperatures, vitreous oxide, kinetics.

$$u = N\Omega\nu \exp(-W/kT) \text{ (}\AA \text{ sec}^{-1}\text{)} \quad [3]$$

$$x_1 = |ZeaV/(kT)| \text{ (}\AA\text{)} \quad [4]$$

and τ is an adjustable parameter, related to initial oxide thickness x_0 . Compared to t , τ is often taken to be negligible. The absolute value is used for x_1 in Eq. [4] because dx/dt should be positive (4).

Experimental Procedure

Mainly data for dry oxidation have been included in this work and then only if the data were available over a sufficiently large span of temperature. In addition, the oxide formed had to be noncrystalline to x-ray diffraction, or microcrystalline at the worst.

A discussion of the degrees of perfection in a vitreous oxide has been presented by Revesz and Fehlner (5). Any long-range order in a vitreous oxide may be considered to be a defect, just as disorder in a single crystal is considered to be a defect. The implications of the noncrystalline state for low temperature oxidation are pointed out by Fehlner and Mott (2). The division of oxides into network formers and network modifiers is a key point.

In some cases, data analysis based on Eq. [1] was available in the literature. In other cases, data points were taken from the original curves in the literature by using a digitizing technique. Values of x and t at a particular temperature were converted into values of $1/x$ and $\log(t/x^2)$ (x in angstroms and t in seconds) using a computer program. These points were then plotted, and values of the slope m and intercept b determined based on a least squares analysis. Values of correlation coefficient R were also determined. A value of 1 indicated perfect correlation.

Continuing with the computer program, values of u and x_1 were calculated from m and b and plotted vs. $1/T$ according to Eq. [3] and [4]. The slope based on Eq. [3] was used to determine activation energy W , while the intercept gave a value of N . The vibrational frequency ν was taken to be 10^{12} s^{-1} , while Ω was derived from the density of the relevant oxide.

The value of $|V|$ was determined from Eq. [4] using the slope of x_1 vs. $1/T$. The value of $2a$ was assumed to be approximately equal to the ionic spacing in the crystalline oxide as obtained from x-ray diffraction data. This assumption is considered valid since short-range order is maintained in bulk vitreous oxides. It is expected to hold true for similar oxides formed as films during low temperature oxidation.

Results

Low temperature oxidation of semiconductors and metals analyzed in the present study are reported below. Low temperature is defined by the relative magnitude of thermal to electrostatic energy available to drive the reaction. Temperatures for transition from low to high temperature oxidation have been estimated from the Cabrera-Mott equation by Fehlner (6). For instance, for Al, it is $\sim 300^\circ\text{C}$, and for Si, $\sim 500^\circ\text{C}$ at 1 atm.

Fig. 1. Log u vs. $1/T$ for germanium

Values of W , N , and $|V|$ are reported and compared with values from the literature. The activation energy W is compared with values determined at high temperatures, although it is not altogether clear that either the parabolic or linear rate constants are directly relevant. The Cabrera-Mott equation assumes interface control through incorporation of the mobile ion, while the parabolic equation is based on control by diffusion in the bulk oxide. The linear rate constant depends on interface control, but at the reaction interface rather than the incorporation one. The comparison is therefore valid only if both the low and high temperature processes depend on the same key event such as breaking a metal-oxide or metal-metal bond.

The best comparison of W may be made with values reported for anodization (7). The similarity between anodization and low temperature oxidation lies in the fact that

Table I. Correlation coefficient R for germanium oxidation (8)

$T(^{\circ}\text{C})$	x vs. $\log t$	$1/x$ vs. $\log (t/x^2)$
25	0.985	-0.967
50	0.995	-0.988
100	0.991	-0.992
125	0.982	-0.990
150	0.981	-0.988
200	0.983	-0.993
250	0.991	-0.998
300	0.996	-0.997
350	0.996	-0.992
400	0.989	-0.997

both are field-driven processes. As a result, direct comparison between the two is possible. However, such results are scarce due to temperature restrictions and the limited ability of some metals to anodize.

Germanium.—Data for the low temperature oxidation of germanium were taken from the work of Ligenza (8). He measured the rate of dry oxidation for germanium powder at 75 torr between 25° and 400°C. The data were analyzed using the Ghez formulation of the Cabrera-Mott equation, $1/x$ vs. $\log (t/x^2)$, as well as with a plot of x vs. $\log t$. Table I gives the correlation coefficients for the two approaches, and it is evident that no choice can be made on this basis between the two kinetic expressions.

For the reason stated above, the data were further analyzed using the Cabrera-Mott expression. Hence, values of $\log u$ were plotted vs. $1/T$, as shown in Fig. 1. The correlation coefficient was 0.970. A value of $W = 1.1$ eV was calculated from the slope and a value of $N = 2 \times 10^6$ cm⁻² from the intercept taking $\Omega = 41\text{\AA}^3$ (hexagonal GeO₂). This value of W is difficult to compare with activation energies obtained at high temperatures because the volatility of the suboxide leads to linear kinetics (9). As a result, the activation energy obtained at high temperatures is not representative of ionic movement during diffusion as represented by parabolic kinetics.

It is interesting to note that the present analysis gives rise to a temperature independent activation energy for ion movement, as contrasted with Ligenza's analysis, where W was a function of T .

The plot of x_1 vs. $1/T$, shown in Fig. 2, produced a correlation coefficient of 0.736. Taking $Z = 2$ for anion conduction as discussed below and $2a = 3\text{\AA}$, $|V|$ was determined to be 0.2V. This magnitude is close to the surface potential value of -0.3V obtained by field emission for monolayer coverage of oxygen on germanium (10).

Fig. 2. x_1 vs. $1/T$ for germanium

Silicon.—The 1972 paper of Fehlner (6) summarized literature data for low temperature oxidation of single-crystal silicon at 25°, 400°, and 600°C, but these data were insufficient to define the kinetics. Kamigaki and Itoh (11) found that silicon oxidation between 950° and 1100°C followed Cabrera-Mott kinetics, provided that the oxygen partial pressure in an O₂/N₂ mixture held at 1 atm was less than 10⁻¹ atm. This agreed with curve fitting performed for the present work. As a result, the data at 10⁻² and 10⁻³ atm were analyzed along with the 1 atm data at 400° (6) and 600°C (12).

The results of Kamigaki and Itoh throw into question the ~500°C upper temperature limit for Cabrera-Mott kinetics. However, the explanation for the discrepancy may lie in the nature of the diffusing species. Field-driven oxidation at lower temperatures relies on ion movement (13), while oxygen molecules are the mobile species at higher temperatures (14-16). At 1 atm pressure of oxygen, the temperature of transition from ionic to molecular movement is estimated to be 500°C.

Oxygen solubility in SiO₂ varies directly with pressure. Thus, a pressure reduction to 10⁻² atm would decrease the O₂ concentration in SiO₂ by a factor of 100, and it might be expected that the temperature of transition from ionic to molecular movement would rise. As a result, the change in kinetics would occur at a higher temperature.

The correlation coefficients for the direct log and inverse log plots are compared in Table II. The Cabrera-Mott fit is slightly better in this case. The Ghez analysis of log *u* vs. 1/*T* in Fig. 3 yielded *R* = 0.959. The value of *W* was calculated to be 1.5 eV, which may be compared with the values of 1.8 and 1.4 eV found by Lie *et al.* (16) for parabolic oxidation from 800°-900°C and 900°-1000°C, respectively. They also found a value of 1.9 eV for linear oxidation over the same temperature range. The rate-limiting step in the parabolic oxidation is taken to be diffusion of a reactant through the oxide, while that for the linear oxidation is taken to be reaction at the silicon-oxide interface. The value for logarithmic kinetics falls between the two and may be compared with the Si-Si bond energy of 1.8 eV (17) and the O-O bond energy of 1.44 eV (18).

The value of *N* was calculated assuming Ω = 45 Å³ (vitreous silica). It was found to be 1 × 10⁶ cm⁻². Voltage was determined from the slope of *x_i* vs. 1/*T* in Fig. 4, where the correlation coefficient was 0.858. The value of |*V*| was 2.6V, taking *Z* = 2 and 2*a* = 3Å.

Lead.—A detailed study of lead oxidation has been carried out as part of the tunneling device investigation at IBM (19-21). Ellipsometry was used to follow the growth rate of PbO on a single-crystal lead film at temperatures between -90° and 150°C. Comparative oxide thicknesses determined by ellipsometry, x-ray absorption, and electron tunneling all agreed within an order of magnitude. A small dependence of PbO growth rate on oxygen pressure at 25°C was also determined for the range 4 × 10⁻² to 7.6 × 10² torr.

Eldridge and Dong (19, 20) had calculated values of *u* and *x_i*, but they applied them to an oxidation model based on piezoelectric effects. In the present approach, these values of *u* and *x_i* were analyzed using Eq. [2]-[4].

The plot of log *u* vs. 1/*T* (Fig. 5) gave a value of *W* = 0.44 eV. This may be compared with a value of 0.56 eV reported by Archbold and Grace (22) for parabolic oxida-

Fig. 3. Log *u* vs. 1/*T* for silicon

tion of molten lead (453°-643°C). However, Weber and Baldwin (23) report higher values, ~1.3 eV for molten lead (460°-700°C) and ~2.0 eV for solid lead (254°-321°C). It should be noted that the structural morphology of the oxide changes with temperature and can thus affect the kinetics of oxidation.

The value of *N* was found to be 7 × 10² cm⁻² based on Ω = 38.9 Å³ (tetragonal PbO). The plot for *x_i* vs. 1/*T* (Fig. 6) contained data points which were all bunched together. Since Eq. [4] implies an intercept of (0, 0), an estimate of the voltage was obtained by drawing a straight line through the origin and the center of the experimental points. A value of |*V*| = 1.5V was estimated for anion conductivity using 2*a* = 4Å and *Z* = 2. This may be compared with the surface potential value of +0.6V reported for oxygen adsorption on a lead film at 23°C and 6 × 10⁻³ torr (24).

Aluminum.—Dry oxidation of aluminum foil at 1 torr has been treated by Dignam *et al.* (25, 26) for the temperature range 250°–505°C. A time-temperature-dependent relationship was found for the transition from an “amor-

Fig. 6. x_1 vs. $1/T$ for lead

phous” oxide to γ -alumina crystallites. The sigmoidal kinetics characteristic of this process have been discussed in terms of oxide crystal nucleation and growth by Pryor (27), Bartlett (28), and others. The initial growth kinetics prior to crystal formation could be fitted by Dignam *et al.* only with an equation derived from the Cabrera-Mott theory using computer-aided procedures. Values for the constants were obtained as follows:

$$2\Omega\nu an = 2.5 \times 10^6 \text{ \AA sec}^{-1}$$

$$W = 1.60 \text{ eV}$$

$$2qaV = 8.2 e \text{ \AA V}$$

The value of W may be compared with 1.3 eV determined from anodization (7a). In the above, n is the volume concentration of the mobile species and Ω is the oxide volume per ion. For $\Omega = 45.6 \text{ \AA}^3$, $\nu = 10^{12} \text{ s}^{-1}$, and $2a = 5.6 \text{ \AA}$; $n = 9.8 \times 10^{15} \text{ cm}^{-3}$ ($N = 2an = 5.6 \times 10^8 \text{ cm}^{-2}$). Assuming $q = 3$ for Al^{3+} ion movement, $|V|$ equals 0.49V. If $q = 2$ for anion movement, then $|V| = 0.73\text{V}$. These values agree in general with the magnitude of values obtained through surface potential measurements. Both positive and negative surface potential values have been reported, depending upon whether polycrystalline rods (29) [+0.15V] or films (30) [−0.3 to −0.7V] were examined.

The pressure dependence of aluminum oxidation at low temperatures was reported to be dependent on the square root of oxygen pressure (31).

Grimblot and Eldridge (32) report on a study of aluminum film oxidation for conditions of 27°–427°C and 25–600 torr oxygen. They interpret their results in terms of the Cabrera-Mott equation. However, different values of the derived constants were found: W was 0.8–1.0 eV, $|V|$ was $\sim 3\text{V}$, and N can be calculated from their results to be $2 \times 10^3 \text{ cm}^{-2}$. The lack of agreement between their values and those of Dignam *et al.* (25, 26) reflect the fact that Grimblot and Eldridge (their Fig. 4) found larger values of oxide thickness at lower temperatures. The latter authors also report that the initial oxide formed is heavily doped with aluminum and is therefore not characteristic of Al_2O_3 .

Chromium.—Oxidation of chromium in dry oxygen at 300°–600°C has been reported by Young and Cohen (33) for a pressure of 4.0×10^{-3} torr. A transition from Cabrera-Mott to parabolic kinetics at $\sim 450^\circ\text{C}$ was found to be a function of both time and temperature. The transition could be correlated with a change in oxide structure from a flat, fine-grained, almost vitreous Cr_2O_3 to a strongly preferred fiber texture containing ridges and nodules. Since the activation energy for oxide growth in both regions was less than that self-diffusion of Cr in Cr_2O_3 (34), the rate-controlling process appeared to be transport via preferred pathways. Numerical integration of the Cabrera-Mott expression (35) led to two equations, one based on interstitial cations and the other on cation vacancies. The former depended on N , the number of surface metal atoms in sites suitable for movement into the oxide, while the latter depended on the number of adsorbed anions on the oxide. The major difference between the two kinetic expressions lies in a pre-exponential factor in $1/x$. The cation mechanism follows Eq. [1], while the vacancy mechanism adds the term $1/x$ to the right side of Eq. [1].

If cation interstitials were assumed, then $N = 5 \times 10^{13} \text{ cm}^{-2}$ and $W = (W_i + u) = 1.8 \text{ eV}$, based on $\Omega = 48.1 \text{ \AA}^3$. The activation energy for ion movement W was the sum of W_i , the heat of solution of an interstitial cation and u , the energy barrier to movement within the oxide.

Values of $|V| = 2.8\text{V}$ for cation interstitials and $|V| = 2.4\text{V}$ for vacancies were derived from the data. These may be compared with the values of −2.1 to −2.4V obtained from surface potential measurements (36, 37) at 25°C.

The vacancy mechanism gave an activation energy of $Q \approx 1.9 \text{ eV}$ for small x , where Q is the activation barrier to ion movement at the oxide-gas interface. The above values of activation energy may be compared with the high temperature values for Cr_2O_3 as obtained by Gulbransen

and Andrew (38) at 76 torr. For the first 5000Å of oxide growth, $W = 1.63$ eV, based on parabolic kinetics.

Iron.—Graham *et al.* (39) measured the rate of oxidation of iron from 24° to 200°C using a manometric technique. Starting pressure was 1.3×10^{-2} torr. Relative rates of oxidation were polycrystalline $> (110) > (112)$ at 24°C. The difference between (110) and (112) essentially disappeared at 200°C. Results were interpreted in terms of magnetite growth by a direct logarithmic rate law, although after 60 min, an inverse logarithmic rate law fit equally well. No particular mechanism was chosen as a result.

Data for the polycrystalline iron, for which there was the most data, were plotted according to inverse and direct logarithmic laws. In both cases, correlation coefficients were greater than 0.940, except for the direct log plot at 200°C. This had a value of 0.887. Hence, the indirect log plot appeared to be slightly better.

Values of the constants were found using $Z = 2$, $2a = 8.3\text{Å}$, and $\Omega = 25\text{Å}^3$ (cubic Fe_3O_4) in Eq. [2]-[4]. The activation energy was calculated to be 0.8 eV. This compares with a value of 1.39 eV found for the parabolic oxidation at 200°-400°C (39). The polycrystalline nature of the iron film and the polycrystalline oxide growing epitaxially on it may explain the difference in results. However, the amount of data is limited, making the results imprecise.

Values of N equal to 5×10^8 and $|V|$ equal to 0.1V were also found, the latter from the plot of x_1 vs. $1/T$. Unfortunately, the correlation coefficient for this plot was only 0.07, so that the value of voltage is unreliable. However, values of N and W were derived from the $\log u$ vs. $1/T$ plot, which had a correlation coefficient of 0.83.

Nickel.—Graham and Cohen (40) determined the oxidation rate of polycrystalline nickel sheet in dry oxygen. Pressures were 5×10^{-3} - 6×10^{-1} torr. Temperatures varied from 23° to 450°C. The results were interpreted in terms of an initial fast oxidation followed by a logarithmic rate for oxide thicknesses between 8 and 30Å. A parabolic rate law fit the data for thicker oxides. The oxides were polycrystalline, and diffusion occurred via easy diffusion paths for parabolic growth.

Two different sets of points were analyzed. The 23°-340°C data fit both direct and inverse logarithmic kinetics with equally high (>0.970) correlation coefficients. Further analysis of the inverse log data using $Z = 2$, $2a = 4.2\text{Å}$, and $\Omega = 16.6\text{Å}^3$ (cubic NiO) gave the following results: $W = 1.6$ eV, $N = 2 \times 10^{13}$ cm $^{-2}$, and $|V| = 2.6$ V. The correlation coefficient of x_1 was 0.957, and that of u was 0.998.

The data between 23° and 400°C were also analyzed. The 450°C curve was omitted, since it obviously did not fit the inverse log kinetics. Correlation coefficients were slightly higher for the inverse log (>0.970) than for the direct log (>0.910) kinetics. Analysis of inverse log results gave $W = 1.6$ eV, $N = 3 \times 10^{13}$ cm $^{-2}$, and $|V| = 2.3$ V. Correlation coefficients were 0.933 for x_1 and 0.998 for u . The value of W may be compared with that of 1.8 eV found by Graham and Cohen (40) when they analyzed the higher temperature results according to parabolic kinetics. Surface potential measurements (41) on a nickel film showed a change of -0.95 V when oxygen was adsorbed at 25°C and 10^{-2} torr.

Tantalum.—Vermilyea's (42) data for the anodization of tantalum between 150° and 300°C were utilized by Ghez (3) as his prime example illustrating the Cabrera-Mott law. Values of $W = 1.6$ eV and $N = 3 \times 10^{12}$ cm $^{-2}$ were derived from the data taking $\Omega = 84 \text{Å}^3$ (rhombohedral Ta_2O_5). The value of W may be compared with that obtained at higher temperatures, 1.1 eV, as found for the oxidation range 250°-450°C at 0.1 atm where parabolic oxidation yields an adherent oxide (43). Values of W equal to 0.71 eV (7b) and 2.185 eV (7c) were found through fitting of empirical rate equations for anodization.

Ghez calculated a value of $|V| = 1.79$ V using $z = 5$ and $a = 1.5\text{Å}$. However, assuming anion conductivity, z may be taken to be 2. With $2a = 4.38\text{Å}$, the value of $|V|$ becomes 1.5V.

Copper.—The data of Rhodin (44) were analyzed at four temperatures between -195° and 50°C as reported for the (100), (110), and (111) faces of a copper crystal. Isotherms had been recorded by Rhodin over the course of 1 month and included data for two typical runs made under each set of experimental conditions. No pressure dependence was noted in the range 10^{-2} - 10^2 torr O_2 . The relative oxidation rates were (100) $>$ (110) $>$ (111).

Plots of $(1/x)$ vs. $\log(t/x^2)$ had correlation coefficients ranging from 0.35 to 0.99. Much of the scatter was due to combining the dual runs. Unfortunately, no sensible values of W , N , or $|V|$ could be determined from this data.

Similar data of Young *et al.* (45) were also plotted. Isotherms for the oxidation of (100), (111), (110), and (311) faces of a copper single crystal had been reported for five temperatures between 70° and 178°C. The relative rates were (100) $>$ (111) $>$ (110) $>$ (311). Care had been taken to prepare a clean, strain-free copper surface, since contaminants greatly affected the (110) rate relative to the (111) rate.

Plots of both x vs. $\log t$ and $(1/x)$ vs. $\log(t/x^2)$ showed excellent correlation coefficients. On this basis, there would be little reason to choose one set of kinetics over the other.

Values of W and N calculated from the plots of $\log u$ vs. $1/T$ (correlation coefficients for the crystal faces varied between 0.77 and 0.96) are listed in Table III. All are reasonable for copper oxidation except the high value $N = 2 \times 10^{18}$ cm $^{-2}$ for (111) copper. This is greater than a monolayer. It is noteworthy that Young *et al.* fitted the data from 70° to 178°C to an inverse logarithmic plot for only the (311) and (110) faces. Their qualitative fit was not confirmed by more quantitative studies. The lack of agreement was ascribed to imperfections in the oxide.

Values of $|V|$ in Table III were too large and the correlation coefficients for x_1 vs. $1/T$ too small (0.29-0.46). Hence, $|V|$ is not considered to be correct for copper oxidation.

The data sets of Rhodin and Young *et al.* covered two different temperature ranges so that, despite the scatter in Rhodin's data, it seemed logical to try combining both sets of data. Figure 7 contains the combined result for $\log u$ vs. $1/T$, while Fig. 8 contains x_1 vs. $1/T$. In Fig. 7, the data for all crystal faces group together as a function of temperature except those obtained at -195°C .

The plot in Fig. 7 was used to obtain values of $W = 1.9$ eV and $N = 1 \times 10^{21}$ cm $^{-2}$, taking $\Omega = 39.6 \text{Å}^3$ (cubic Cu_2O). The value of W can be compared with those obtained for parabolic oxidation in air (46): 0.87 eV for 300°-550°C and 1.63 eV for 500°-900°C. Moisture tends to decrease the rate of copper oxidation (47), so the comparison is only approximate.

It is apparent that the value of N found by combining the data sets is too large, since the number of sites is $\sim 10^6$ times that of a monolayer.

A value for $|V|$ could not be obtained from Fig. 8 because the scatter in the points made it difficult, if not impossible, to define a straight line that would cut the Y-axis even when the points at -195°C were omitted. The implication is that the combined data for copper do not fit the Cabrera-Mott rate law.

Copper was investigated further by analyzing the data of Campbell and Thomas (47). They measured the rate of both wet and dry oxidation between 100° and 256°C. Oxygen pressure was 150 torr with 15 torr added moisture in the wet runs. They found that kinetics appeared to follow a cubic rate law.

Table III. Results for copper (45)

Crystal face	N (cm $^{-2}$)	W (eV)	V (V)
(311)	4×10^9	0.93	-11.28
(110)	4×10^8	0.87	-19.55
(111)	2×10^{18}	1.53	-11.98
(100)	4×10^{15}	1.28	-49.54

Fig. 7. Log u vs. $1/T$ for copper

The data for dry oxidation were plotted according to both the direct and inverse logarithmic rate laws. While correlation coefficients were >0.920 in both cases, they were higher for the direct log plots. Even so, values of N and W were calculated. Values of voltage calculated from the inverse log data were too high. This was also true of wet oxidation between 100° and 169°C .

The overall conclusion from the three sets of data on copper oxidation is that direct rather than inverse logarithmic kinetics fit the low temperature data better.

Fig. 8. x_1 vs. $1/T$ for copper

Sodium.—The dry oxidation rate of sodium was measured between -79° and 48°C by Cathcart *et al.* (48). A manometric method was used at ~ 200 torr pressure. Carefully purified sodium films on glass formed the substrate. Oxide film structure was not determined, but logarithmic-type kinetics were followed.

Analysis according to the direct and inverse logarithmic kinetics gave good correlation coefficients for the direct log plot (>0.957 , except for -20°C , which was 0.885) but poor ones for the inverse log plot (>0.572 , except for 35°C , which was 0.821). Attempts to calculate values of W , N , and $|V|$ gave impossible results, as shown in Table IV. Values of $Z = 1$, $2a = 5\text{\AA}$, and $\Omega = 22.7\text{\AA}^3$ were used.

It was concluded that direct log kinetics are a better fit to the sodium data than inverse log kinetics.

Beryllium.—Fowler (49) under the guidance of Blakely, has measured the rate of oxidation of a Be (0001) crystal face. An ultrahigh vacuum apparatus was used in the temperature range 27° – 497°C at oxygen pressures of 3×10^{-8} to 2×10^{-6} torr. Adsorption of oxygen on the clean Be surface was followed by oxide island nucleation and growth. The islands coalesced into an oxide film which grew according to direct logarithmic kinetics. At high temperatures, BeO (0001) epitaxy on Be (0001) was found. As temperatures decreased, epitaxy became progressively poorer, being unobservable at 27°C .

Reconstruction of the BeO (0001) surface was observed at a critical thickness of 6–7 monolayers of oxide. This was attributed to intrinsic polarization of the wurtzite structure of BeO. Electron enhancement of oxidation by the Auger beam was found and minimized.

Data for two different maximum exposures ($1.05 \times 10^4\text{L}$ and $4.2 \times 10^3\text{L}$) were analyzed according to both the direct and inverse logarithmic rate laws. Pressure was 10^{-6} torr. In both cases, it was obvious that the direct log kinetics fit the data, while inverse did not. The former gave straight lines with good correlation coefficients (>0.99 , except for one 27°C curve, which was 0.867) while the latter produced L-shaped plots with poor correlation coefficients. No attempt was made to calculate values of W , N , and $|V|$ in view of this clearcut preference for direct log kinetics.

Discussion

The results of the above analyses are collected together in Table IV. The metals are arranged according to the cation group numbers of the periodic table. Values of N , W , and $|V|$ are included.

The first observation is that, in general, the results for the Group I and II metals appear impossible and should not be included in the table. For instance, the value of N for Cu is too large in one case, $|V|$ for Cu is too large in another, and N is too small for Na, beyond the limits of error which are estimated to be an order of magnitude for N . Beryllium is similar in that no values of N , W , or $|V|$ were even calculated. However, values of N , W , and $|V|$ for the other metals in Table IV are reasonable, and the applicability of the Cabrera-Mott model appears to be established.

Table IV. Values of N , W , and $|V|$ obtained from kinetic data for low temperature oxidation

Group no.	Element	Ref.	N (cm^{-2})	W (eV)	$ V $ (V)
IA	Na	(48)	1×10^{-8}	-0.2	0
IB	Cu	(44, 45)	1×10^{21}	1.9	?
IB	Cu	(47)	2×10^7	0.5	86
IIA	Be	(49)	?	?	?
IIIA	Al	(25, 26)	6×10^6	1.6	~ 0.6
IIIA	Al	(32)	2×10^3	-0.9	~ 3
IVA	Si	(6, 11, 12)	1×10^6	1.5	2.6
IVA	Ge	(8)	2×10^6	1.1	0.2
IVA	Pb	(19, 20)	7×10^2	0.4	1.5
VB	Ta	(3, 42)	3×10^{12}	1.6	1.5
VIB	Cr	(33)	5×10^{15}	1.8	2.8
VIII	Fe	(39)	5×10^8	0.8	?
VIII	Ni	(40)	3×10^{15}	1.6	2.3

A comparison of the various values of N (excluding Groups I and II) shows an interesting correlation. The values decrease from Group III to IV and then increase again for Groups V through VIII. Two exceptions are found, the second set of results for aluminum and the results for iron. Oxides of these metals are considered to be intermediate oxides in the sense that they can be incorporated into, as well as modify a network. Both anion and cation movement are expected in such oxides. This flexibility may allow such oxides to shift roles depending on the conditions of oxidation. Such a shift could affect the value of N .

The overall trend in N appears to correlate with ionic transport numbers for metal oxides, as listed in Table V, taken mainly from work on anodic oxides (58). Cation transport predominates for the Group I and II oxides, but quickly diminishes as the group number increases towards Group IV. Here, anion movement predominates. As the group number increases still further, cation movement again becomes significant.

Oxide structure is the key to understanding ion movement (2, 5). It is noteworthy that the oxides of Group I and II metals are classified as network modifiers, *i.e.*, they break up the three-dimensional network of a vitreous oxide. At room temperature and above, films of these oxides tend to be polycrystalline. The movement of small cations is favored by the presence of defects in the close-packed ionic solid.

The oxides of the elements in Group IV are classified as network formers. They are capable of bonding into a three-dimensional network which can change the mechanism of self-diffusion. The strong covalent bonding in the network promotes formation of holes and channels through which large anions or even oxygen molecules can pass. Cations, because of their high charge density, are less mobile in such a network structure.

Network-forming oxides tend to be vitreous at room temperature. The temperatures at which the oxide network remains stable to recrystallization are determined by the nature of the cation, the presence of impurities, and applied stresses. The best network forming oxide, SiO_2 , is stable even at 1200°C while growing on silicon.

Barr (59) studied the passivation in air of elemental metals using ESCA. His results could be divided into two general classes. In the first, passivation terminated with the outermost layer of metal oxide, *i.e.*, that exposed to air, in its highest oxidation state, but with the bulk of the metal oxide in a lower oxidation state. Such oxides were classed as modifiers.

The second class of oxides terminated in the same oxidation state throughout the oxide. These oxides were classed as network formers. The results were complicated by the presence of water, but the correlation with the present work is impressive. For example, his network formers were Si, Al, Zr, Sn, Mo, W, Y, La, and Rh while his modifiers were Ce, Pt, Pd, Fe, Co, Ni, and Cu. Intermediate oxides were not distinguished.

Fehlner and Mott (2) proposed that the Cabrera-Mott theory can be applied to low temperature oxidation where anions and/or cations are mobile in a uniform ox-

ide. It is noteworthy that in the case of cation movement, oxidation kinetics are affected much more by crystalline orientation of the metal substrate than by oxygen pressure. The converse is true for anion movement.

Let us turn once again to the results in Tables IV and V. The correlation based on N is significant, but the present work is only the first step in deriving values of N , W , and $|V|$ from curve fitting of data. The Ghez formulation of the Cabrera-Mott equation has been used to analyze all the results except the Al (25, 26) and Cr (33) cases. In these two examples, numerical analysis was used to directly fit the data to the Cabrera-Mott equation. This approach is expected to be at least as good as the approximations of Eq. [1]-[4]. However, the status of unknowns in the available experimental results, *e.g.*, the concentration of impurities such as water and the structure of the metal surface and oxide, argued against such detailed analysis at this time. Instead, the less rigorous Ghez integration of the Cabrera-Mott equation was favored so that results from a spectrum of metals could be compared.

The results for Group IV elements are particularly interesting. Given the network oxide structure and anion conductivity, it may not be surprising that N derived from the Cabrera-Mott expression is small. It is tempting to speculate that this is so because N no longer refers to the potentially mobile cation population at the metal-oxide interface. Instead, it refers to the number of potentially mobile anions at the oxide-gas interface, which in turn may relate to the number of paths available for ion movement through the oxide. It follows that where N is relatively small and W is > 1 eV, the rate of oxide growth is also small. Thus, the addition of alloying elements to base metals to promote network oxide formation can lead to protective oxide films and corrosion resistance, *e.g.*, Cr in stainless steel (60).

Conclusions

The present results are limited in scope, especially as regards modifying oxides. Nevertheless, it appears that oxidation according to the Cabrera-Mott theory occurs when a uniform, stable, three-dimensional oxide film is formed. This occurs at different temperatures dependent on the ability of the metal to form vitreous oxide.

Metals which form modifying oxides have a polycrystalline structure and do not appear to fit the Cabrera-Mott inverse logarithmic kinetics. No attempt has been made here to fit these results to another theory.

Values of W obtained from Cabrera-Mott analysis of data for network formers and intermediates are similar to values obtained from high temperature oxidation. This implies that a similar rate-limiting step, perhaps bond breaking, may control oxidation over the whole span of temperature.

Values of N appear to correlate with the structure and mode of ion transport in oxides. They are smallest for network formers, where anion movement predominates. A larger value is found for intermediates, where both anion and cation movement may occur.

Values of the absolute value of voltage V are reasonable for the network formers and intermediates. Comparison with values determined from surface potential measurements shows fairly good agreement.

Chemical Properties and Film Casting of Radiation-Grafted Ion Containing Polymers

Marilyn N. Szentirmay and Charles R. Martin*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

A series of radiation-grafted cation- and anion-exchange polymers have been studied with the intent of developing procedures for dissolving and film casting these polymers. Solvent swelling studies have shown that these polymers display two maxima in plots of solvent uptake *vs.* solvent solubility parameter. While similar behavior is shown by the ion-exchange polymer Nafion, the anion- and cation-exchange polymers studied here will not dissolve under conditions (developed by us) which dissolve Nafion. We believe that this insolubility results from covalent cross-links and/or enhanced crystallinity in the chain-material regions of these polymers. These polymers do, however, swell extensively in certain solvents at high temperatures, and suspensions may be prepared from the swollen polymer. We have cast films from these suspensions onto electrode surfaces and report initial results of electrochemical characterization of these films.

Ion containing polymer (ICP) (1, 2) membranes have been used as separators in chlor-alkali cells (3) and in cells for energy conversion (4, 5), and ICP film-based chemically modified electrodes show promise for use in electrochromics (6), electrocatalysis (7), photoelectro-

chemistry (8) and electroanalysis (9, 10). Further developments in these areas will require ICP's with better mechanical and dynamic properties (11) which can be produced at a lower price (12). Accordingly, this research group has been investigating the fundamental chemical and electrochemical properties of a variety of ICP's (13, 14) and studying possible new applications for these polymers (10, 15).

* Electrochemical Society Active Member.

Key words: ion containing polymers, film casting polymers, RAI pore membranes.

We report here results of studies of ICP's prepared by derivitizing, through radiation grafting, polyethylene (PE) and polytetrafluoroethylene (PFE) sheets (12, 16). Both cation-exchange polymers (sulfonated PE's and PFE's) and anion-exchange polymers (quaternized PE's and PFE's) were studied. These polymers are of interest because they may prove to have the desirable chemical and transport properties of Nafion, a highly successful perfluorosulfonate polymer (1, 13, 14), but can be produced at lower costs (12). The quaternized polymers are of particular interest to us because they may prove to be cationic versions of Nafion and thus be useful when anion exchange or transport is needed.

The purposes of the work described here were to use solvent swelling studies (12, 17) to develop procedures for film casting these radiation grafted ICP's and to use electrochemical methods for preliminary investigations of the physical and transport properties of the resulting films. Particular emphasis is placed on the quaternized polyethylene polymer.

Experimental

Materials.—The ICP's and polyethylene were obtained from RAI Research Corporation (Hauppauge, New York). The sulfonated polyethylene (PE-SS, 700 g/mol-SO₃H) and the sulfonated polytetrafluoroethylene (PFE-SS, 850 g/mol-SO₃H) are prepared by grafting styrene onto sheets of the polymer, followed by sulfonation of the styrene (12, 16). The quaternized polyethylene (PE-QA, 1100 g/mol N) and the quaternized polytetrafluoroethylene (PFE-QA, 1000 g/mol N) are prepared by grafting vinylbenzylchloride onto the polymers and quaternized with triethylamine (16). Membranes were converted to various counterionic forms by soaking in appropriate salt or acid solution.

Water was triply distilled or obtained from a Milli-Q water purification system (Millipore Corporation, Bedford, Massachusetts). 2-Ethylhexanol, 1-decanol, 2-ethylbutanol, 1-pentanol, ethylene glycol, sodium anthraquinone-2-sulfonate, disodium anthraquinone-2,6-disulfonate, and sodium hexafluorophosphate were obtained from Aldrich Chemical Company (Milwaukee, Wisconsin). Xylene was obtained from Center Chemical Company (Austin, Texas). Triethylamine was obtained from MCB (Cincinnati, Ohio). Hydroquinone was obtained from J. T. Baker Chemical Company (Phillipsburg, New Jersey). Trifluoroacetic acid (TFA) was obtained from Sigma Chemical Company (St. Louis, Missouri). Ru(NH₃)₆Cl₃ was obtained from Johnson Matthey, Incorporated (Winslow, New Jersey). 8-Hydroxy-1,3,6-pyrenetrisulfonic acid, trisodium salt was obtained from Eastman Kodak Company (Rochester, New York) and recrystallized twice from aqueous acetone. Ru(bpy)₃Cl₂ (bpy = 2,2'-bipyridine) was obtained from G. F. Smith. All other chemicals were reagent grade.

Solvent swelling measurements.—Studies similar to those described by Yeo *et al.* (12, 17) were done. The membranes (0.06-0.10g) were immersed in the desired solvent in a capped vial at room temperature for at least 2 days, then removed, blotted dry, and weighed immediately in a closed weighing bottle. The membranes were then replaced in the solvents and reweighed more than 1 day later to insure that no further solvent uptake had occurred. Each value of percentage increase in weight is the average of two or more experiments. In almost all cases, reproducibility was better than $\pm 5\%$.

Preparation of polymer suspensions.—Specific conditions used to soften the ion-exchange polymers are given in the Results and Discussion section. The pressure reactor (Parr Instrument Company, Moline, Illinois) was purged with N₂ before sealing. In some cases, N₂ was added after sealing to increase the pressure in the reactor. The contents of the reactor were stirred while heating. Prior to heating in the reactor, PFE-SS was ultrasonically cleaned in 50:50 ethanol-water to remove a pink color. The softened polymers were ground in a glass tissue

grinder driven by an overhead stirring motor. Titrations to check the manufacturer's listed value of the ion-exchange capacity of PE-QA (chloride form) were done by equilibrating a known weight of polymer with aqueous KNO₃ and titrating the Cl⁻ released with AgNO₃. Chlorofluorescein was used as the indicator.

Preparation of electrode films.—Glassy carbon (1/8 in. diam, Atomergic Chemetals Corporation, Plainview, New York) was polished as described previously (14). Films of PE-SS and PE-QA were cast onto glassy carbon electrodes from suspensions in propanol, PFE-QA from a suspension in 50:50 ethanol-water, and PFE-SS from a suspension in 50:50 ethylene glycol-ethanol. The electrodes were coated by syringing a measured amount of polymer suspension onto the electrode surface (14). After the solvent evaporated (in air), the polymer-coated electrodes were soaked at least 6h in supporting electrolyte before use. This served to both hydrate the film and wash out any residual solvent. Wet film thicknesses were measured with an Alpha-step surface profiler (Tencor Instruments, Mountain View, California).

Electrochemical measurements.—A PAR Model 173 potentiostat and Model 175 programmer (EG&G PAR, Princeton, New Jersey), an X-Y recorder (Houston Instruments, Austin, Texas), and a Nicolet 2090-3 digital oscilloscope (Nicolet Instrument Corporation, Madison, Wisconsin) were used for electrochemical experiments. A three-electrode cell with a saturated calomel reference electrode (SCE) and a Pt disk counterelectrode was employed. All electrochemical measurements were done in N₂-degassed solutions.

Results and Discussion

Solvent swelling studies.—Yeo *et al.* (12, 17) have found that Nafion and the sulfonated RAI membranes exhibit two maxima in plots of solvent uptake *vs.* solvent solubility parameter. We have shown that Nafion may be dissolved at high temperatures in binary solvent systems composed of a solvent which has a solubility parameter near the first swelling maximum and a solvent which has a solubility parameter near the second swelling maximum (13). It was of interest to us to see if a similar approach could be used to dissolve the various RAI membranes. If so, chemically modified electrodes based on films of these polymers could be prepared. Such electrodes allow for convenient evaluation of the charge transport properties (14) and the ion exchange thermodynamics (10) of ICP's.

Solvent swelling studies are also of interest because they can be used to deduce information about ICP morphology (*vide infra*). Solvent swelling data are already available for the sulfonated RAI polymers (12). We report results of swelling studies of PE-QA. Since the solvents used varied in hydrogen bonding ability, three component solubility parameters (δ) (18, 19) were used for these studies. The solvents and their solubility parameters are listed in Table I.

Results of the solvent swelling studies of PE-QA are shown in Fig. 1-3. In pure solvents, the Cl⁻ form of PE-QA exhibits two swelling maxima, one at approximately 10 Hb, the other a broad maximum in the range 15-20 Hb (Fig. 1). As noted above, similar results were obtained with Nafion (17), PFE-SS, and PE-SS (12). In propanol-water mixtures, PE-QA chloride exhibits solvent uptakes greater than those observed in either pure propanol or pure water (Fig. 2). Again, this type of behavior was also observed with Nafion (17). Finally, when PE-QA is converted from the Cl⁻ form to the PF₆⁻ form its solvent swelling characteristics change dramatically (Fig. 3). While nearly all of the solvents swell the PF₆⁻ form much less extensively, it is of particular interest to note that the low δ envelope is essentially completely wiped out.

It is now fairly well established that many ICP's are, on a microscopic level, biphasic (20). Yeo *et al.* (12, 17) have concluded that in Nafion, PFE-SS, and PE-SS, the high solubility parameter envelope results from interactions in

Fig. 1. Solvent uptake vs. solubility parameters of solvents for PE-QA, chloride form.

the ionic cluster phase (20) and the low solubility parameter envelope results from interactions with the organic chain-material phase or with the sidechains. The fact that two δ maxima are observed in PE-QA Cl⁻ suggests that this ICP is also biphasic. Because polyethylene (the chain material in PE-QA) has a δ of about 8 (21) and the first swelling maxima occurs at $\delta = 10$, it is reasonable to conclude that the low δ maximum in PE-QA results primarily from interactions with the sidechains. A comparison of solvent uptake data for PE-QA with data for the polyethylene used by RAI to make PE-QA (Table II) supports this conclusion. The solvents which produce the greatest swelling in PE-QA do not appreciably swell polyethylene.

That the low δ maximum is attributable to interactions with the sidechains is also supported by the PF₆⁻ swelling

data. It is generally accepted that counterions are localized in the ionic domains of ICP's and not in the surrounding chain material phase (20). Therefore, if the swelling maximum at 10 Hb were due primarily to interactions with the chain material, the tremendous sensitivity of swelling to the nature of the counterion would not be expected. Furthermore, by the same argument, since the sidechain interactions are very sensitive to counterion, it seems likely that the sidechains intrude into the ionic domains. This intrusion of organic sidechain explains why luminescence probe studies of these ICP's indicate that the cluster phase is rather hydrophobic (22, 23).

Polymer suspensions.—The swelling studies revealed several solvents and solvent systems which showed promise for dissolving PE-QA chloride (*e.g.*, 50:50 ethanol water and dimethylsulfoxide). However, PE-QA would not dissolve in any solvent or solvent system, even at high temperatures and pressures. The failure of PE-QA to dissolve is surprising, since a similar approach was successfully used to dissolve Nafion (13). Since cluster formation may be regarded as electrostatic cross-linking (24), it

Fig. 2. Solvent uptake of PE-QA, chloride form vs. solubility parameters, δ_{mix} , of propanol-water mixtures. $\delta_{\text{mix}} = V_{\text{PROH}} \delta_{\text{PROH}} + V_{\text{H}_2\text{O}} \delta_{\text{H}_2\text{O}}$ (17), where V_{PROH} and $V_{\text{H}_2\text{O}}$ are volume fractions, and δ_{PROH} and $\delta_{\text{H}_2\text{O}}$ are solubility parameters, of propanol and water, respectively.

Fig. 3. Solvent uptake vs. solubility parameters of solvents for PE-QA, PF_6^- form.

seemed possible that the clusters might be responsible for the insolubility. To test this possibility, PE-QA chloride membranes were immersed for several hours in boiling xylene. This caused the charged sites to cleave from the membrane.¹ The uncharged membranes were then boiled in fresh xylene for several more hours. While boiling xylene will dissolve the polyethylene used to prepare PE-QA, it did not dissolve the decharged PE-QA. This shows that the presence of the charged groups (and, therefore, cluster formation) is not responsible for the insolubility. We believe that covalent cross-links are introduced during the radiating grafting procedure; even a minute amount of cross-linking would render this polymer insoluble in any solvent.

We were also unable to dissolve PE-SS, PFE-QA, and PFE-SS. PE-SS is probably also covalently cross-linked, but tetrafluoroethylene polymers show little tendency to cross-link when bombarded with radiation (16). The insolubility of these polymers in solvent systems which will dissolve Nafion may result from higher degrees of crystallinity in the starting PFE's than in Nafion. The Nafions which we successfully dissolved (13) by heating to 250°C have melting points around 210°C (25). The melting points of the polytetrafluoroethylenes are around 350°C (26). While in principle this indicates that PFE-QA and PFE-SS could be dissolved at higher temperatures, we have found that in the solvents studied here the charged sites begin to cleave from PFE-QA at temperatures above about 150°C and from PFE-SS at temperatures above about 300°C.

¹ When as-received membranes are immersed in an aqueous solution of the fluorescent anion 8-hydroxy-1,3,6-pyrenetrisulfonate, strong fluorescence from the cationic membrane is observed. After treatment in boiling xylene, and reimmersion in the fluorophore solution, no fluorescence can be detected from the membrane.

Table II. Solvent uptake measurements for polyethylene and PE-QA

Solvent	Percentage increase in weight	
	Polyethylene	PE-QA
Xylene	13	17
Decanol	2	60
Butanol	<1	42
DMSO	0	52
H ₂ O	0	42

In spite of their insolubility, we were able to cast films of all of these ICP's. This was accomplished by using the solvent swelling experiments to identify strongly swelling solvents, using these solvents in the high temperature reactor to soften the polymers, and then grinding the wet, softened polymer in a ground glass tissue grinder. Suspensions of the polymers resulted; these suspensions were filtered to remove the larger particles and then used to cast films. The conditions required to soften each polymer are shown in Table III. As noted above, temperatures high enough to soften PFE-QA also cleaved the charged sites. For this reason, we were forced to use lower than optimal temperatures, and poor softening resulted.

A comparison of the ion-exchange capacities of PE-QA chloride before treatment and after suspension showed that charged sites are not destroyed during the softening and grinding process. The ion exchange capacities were 0.95 meq/g for the as-received membranes and 0.94 meq/g after suspension.

Polymer-coated electrodes.—Films cast from the ICP suspensions were examined with a surface profilometer. These studies showed that while the entire electrode surface was covered, the coatings were uneven, as might be expected for films composed of small adhering particles. Thickness measurements on wet PE-QA films gave densities of 0.69 g/cm³; the density of the dry, as-received membrane is 0.65 g/cm³ (27). Figure 4, curve A shows background currents observed at a bare glassy carbon electrode. Figures 4B through 4E show analogous background currents for electrodes coated with the various RAI polymers. As would be expected (13), background currents do not change appreciably after coating.

Table III. Summary of conditions used to suspend RAI polymers

Polymer	Counterion	Solvent	T (°C)	P (psi)	t (h)
PE-QA	Cl ⁻	50:50 Propanol-Water	150	100	4
PE-SS	Li ⁺	Methanol	150	250	4

^aVery little softening.

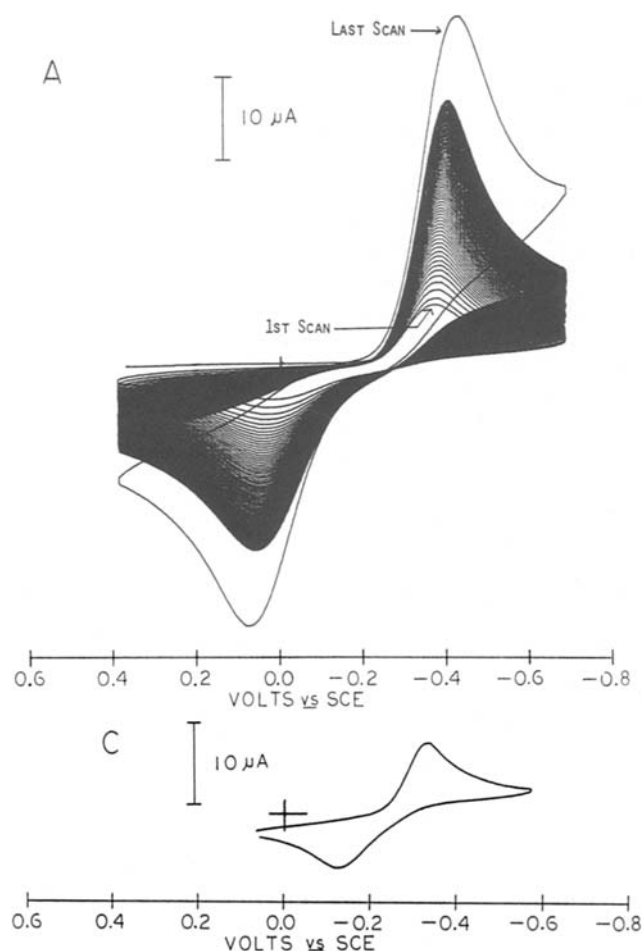

Fig. 4. Cyclic voltammograms recorded at 0.1 V/s. A. Uncoated glassy carbon electrode in 0.2M NaTFA, pH 3.0. Curves B to E are glassy carbon electrodes coated with the following. B: PFE-SS, $\sim 10^{-7}$ mol $\text{SO}_3^-/\text{cm}^2$ (0.2M NaTFA, pH 3.0). C: PE-SS, 4.5×10^{-7} mol $\text{SO}_3^-/\text{cm}^2$ (0.2M NaTFA, pH 3.0). D: PFE-QA, 6.3×10^{-7} mol quaternary ammonium sites/ cm^2 (0.1M TFA/0.1M NaTFA). E: PE-QA, 2.4×10^{-7} mol quaternary ammonium sites/ cm^2 (0.1M TFA/0.1M NaTFA).

As has been observed with other ICP-based chemically modified electrodes (13, 28, 29), the RAI films incorporate and retain electroactive counterions and allow for charge transport to and from these ions. For example, Fig. 5A shows a series of cyclic voltammograms recorded after a PE-QA-coated electrode was immersed in a solution of anthraquinone sulfonate (AQS). Current increased with time, eventually reaching a steady-state level (13, 28, 29). When the electrode was removed from solution, rinsed, and placed in supporting electrolyte, current due to the retained AQS was observed. The voltammogram in Fig. 5B was recorded 35 min after the coated electrode was placed in supporting electrolyte. While, when immersed in supporting electrolyte, AQS is slowly leached from the polymer, the film itself remained attached to the electrode and could be reloaded with AQS to the same voltammetric current level shown in the last scan in Fig. 5A. Analogous results were obtained with the other RAI polymers.

Preliminary investigations of the charge and mass-transport properties of PE-QA films at electrode surfaces were also carried out. Figure 6A shows that voltammetric peak currents, i_p , for polymer-bound AQS are proportional to the square root of scan rate. This is the expected (28) dependency in the thick (ca. 4 μm) films used here. Potential step chronocoulometry for AQS and anthraquinone-2,6-disulfonate (AQDS) in PE-QA films produced linear charge vs. $t^{1/2}$ plots (Fig. 6B). Apparent diffusion coefficients (14, 28) of about 1×10^{-9} cm^2/s were obtained, from such plots, for both the oxidized and reduced forms of AQS and AQDS.

Figures 5 and 6 show that PE-QA extracts and transports electroactive counterions. It was also of interest to evaluate the extent to which neutrals and coions permeate the film. We have found that small, neutral molecules (e.g., hydroquinone) readily penetrate films of PE-QA; in fact, peak currents for hydroquinone at coated electrodes are identical to those at uncoated electrodes. These molecules are not, however, retained by the film in that no trace of the hydroquinone voltammetric wave is observed when a PE-QA modified electrode is transferred from a hydroquinone solution to a solution containing only supporting electrolyte.

Coions (e.g., $\text{Ru}(\text{bpy})_3^{2+}$, $\text{Ru}(\text{NH}_3)_6^{3+}$) also penetrate PE-QA films. Peak currents for these ions are, however, reduced to less than about 25% of the peak currents observed for the same solution at an uncoated electrode. Coions are also not retained by these films. The ability of coions to penetrate the rather thick (4 μm) films used here suggests that there are pinholes or channels through the films. Again, this is not surprising, given the fact that these films are composed of adhering particles. We are

currently investigating the possibility of using annealing procedures to reduce the void volumes of these films.

Conclusions

Solvent swelling studies have provided a method for film casting the RAI ICP's. While these polymers show solvent swelling characteristics very similar to Nafion, they will not dissolve in solvents which dissolve Nafion [e.g., 50:50 ethanol-water (13), dimethylsulfoxide (29), or propylene carbonate (30)]. We suggest that cross-linking introduced during the grafting procedure or enhanced crystallinity cause this lack of solubility. The solvent swelling studies have also provided information about the polymer-solvent interactions which produce swelling and about the morphology of PE-QA. More importantly, these studies have shown that the chemical properties of the PE-QA ionomer are strongly dependent on the nature of the counterion.

Because of the ability to cast films, charge-transport properties and ion-exchange thermodynamics of these polymers may now be conveniently evaluated. In previous studies, we have shown that Nafion preferentially binds hydrophobic counterions (10, 15, 28) and that hydrophobic interactions can influence rates of diffusion in Nafion films at electrode surfaces (14). It will be of interest to see if hydrophobic interactions are of importance to ion exchange and charge transport in films of the RAI polymers.

Gas-Phase-Functionalized Plasma-Developed Resists: Initial Concepts and Results for Electron-Beam Exposure

G. N. Taylor,* L. E. Stillwagon, and T. Venkatesan

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A resist method involving gas phase functionalization of exposed or unexposed resist by volatile inorganic compounds followed by pattern development using oxygen reactive ion etching is described for use in ion, photo, electron, and x-ray lithography. Negative or positive tones can be obtained in theory from a single exposure by employing selective reaction of either the exposed or unexposed regions with volatile reactive inorganic compounds that form *in situ* masks during plasma development (usually as refractory metal oxides). Near surface functionalization (top several thousand angstroms) is seen as having resolution advantages for electron and photolithography. It is envisioned as being controlled by either limited permeation or by selective near-surface exposure (*i. e.*, low voltage ion or electron exposures). In electron lithography, this could reduce the proximity effect in backscatter-limited thick resist films on high Z substrates. Consequently, we have studied materials and functionalizing reagents for electron lithography at 10 keV. The radiation-initiated reactions studied in the resist were the creation and destruction of unsaturation (olefins, etc.). The inorganic functionalizing reagent was diborane. Pattern development was achieved using O₂ reactive ion etching. Thin ($\leq 2000\text{\AA}$) 1 μm line and space patterns were obtained at 10-50 $\mu\text{C}/\text{cm}^2$ doses for materials which afforded negative and positive tones. These include chlorinated polyacrylates, polyisoprene, and copolymers containing unsaturation and chlorine functionality.

Recently, a report from our laboratory described plasma-developed ion-implanted resists having at least 2500 \AA resolution (1). These resists used implanted metal ions acting as *in situ* etch masks during O₂ reactive ion etch removal of the unexposed regions. Organic polymers were typically employed as resists using oxygen as the etch gas, although thin SiO₂ also was used with fluorocarbon etch gases. In both cases, In⁺ ions were first implanted at low potentials. Features as small as 1500 \AA wide and 1 μm high were fabricated by this technique using a 20 keV focused beam of In⁺ ions (2). Presently, resolution appears limited mainly by the beam size and shape. One of the problems of the scanning ion beam systems is the low penetration ($\sim 200\text{\AA}$) of the heavy ions in most polymer resist (3). A resist that can be patterned with a near surface exposure would be attractive for such systems. Yet, the metal-implanted resists are impractical for present-day scanning ion exposure, since they require excessive dose (10^{16} ions/cm²) even though the implanted-metal layer mask is only 2-4 monolayers thick. Clearly, higher sensitivity is needed given present-day metal ion exposure systems. Thus, we sought new resist materials and processes. One method would involve making use of the many chemical events which occur when each ion is implanted in a resist film. This would amplify the implantation process and hopefully improve sensitivity.

In this report, we describe some initial results for one of the approaches derived from the above considerations. We call resists utilizing this methodology gas-phase-functionalized plasma-developed resists. They are applicable to all four lithographic processes (ion, photo, electron, and x-ray lithography), but would appear to have primary use for ion and photolithography. In the next section, we outline the particular resist methodology and the advantages (both realized and hypothesized) for each application. Finally, we describe some initial results for electron resists in which both positive and negative tone images are produced from the same exposure by various gaseous and subsequent plasma treatments.

Methodology

We envision gas-phase-functionalized plasma-developed resists to behave according to the two routes outlined in Fig. 1. There we depict a resist with reactive groups A which upon irradiation form product groups P at the expense of A, which is depleted in the exposed regions. Next the exposed film is treated with a reactive gas MR containing reactive groups R and inorganic atoms

* Electrochemical Society Active Member.

M capable of forming nonvolatile compounds MY which are resistant to removal under reactive ion etching conditions using gas Y. Several situations are now possible. (i) If the metal containing gas does not diffuse into the film and/or does not react with either the exposed or unexposed areas, no functionalization will occur and no amplification upon development is expected. (ii) Conversely, if the metal compound diffuses everywhere and reacts with both A and P, no etching is likely to occur upon RIE development. (iii) If, however, gas diffusion occurs and reaction with either A or P occurs, selective functionalization results. Subsequent plasma development then can produce either negative tone images when the inorganic compound bonds selectively to P or positive tone images when it selectively bonds to A. Tone is thus dependent upon both the actinically generated species (radiation chemistry) and selective functionalization (organometallic and inorganic chemistry).

Some further considerations would also appear to be of importance. Since the functionalizing step is a gas-solid reaction, surface layers of the resist would be expected to react first if the reaction rate were much greater than the diffusion rate or if the major portion of the incident radiation were absorbed in the topmost ($\sim 1000\text{-}2000\text{\AA}$) layer of resist. For the first case, a reactive gas diffusing into a polymer film, the concentration of gaseous species C at a depth x (in centimeters) into a film from the film surface can be estimated from Eq. [1] where C_0 is the continuous gas concentration at the surface, D is the diffusion coefficient in square centimeters per second, and t is the diffusion time in seconds

$$C = C_0 \operatorname{erfc} \left(\frac{x}{2\sqrt{Dt}} \right) \quad [1]$$

This is the simplified plane sheet solution to the one-dimensional diffusion problem. For the present purposes, it is analytically convenient to calculate C/C_0 as a function of the variables x , D , and t . Some results are given in Table I for two polymers chosen for their structural analogies to systems investigated in this report. In all cases, both inert (O₂, Ar) and interactive (SF₆) gases diffuse more readily into rubbery poly(isoprene) PI than into glassy poly(ethyl methacrylate) PEM. In fact, for PI after treatment for 1s, the gas concentration is expected to be higher in a 1 μm film than in the gas phase for each gas listed. Only for PEM and large molecules (Ar, SF₆) are C/C_0 values < 1.0 found. With SF₆, a significant interaction with PEM ester carbonyl is expected. Consequently, D is very low and no gas penetrates even 1 μm deep for treatment times as long as 10s. At shallower depths, a gra-

Fig. 1. Schematic representation of gas-phase-functionalized plasma developed resists showing (1) exposure of a material with reactive groups A (2) conversion of such groups to product groups P, and (3) selective functionalization of either A or P with metal containing reagent MR, where M is the metal and R are reactive or inert groups or atoms. (4) reactive ion etch development using gas Y forming nonvolatile compounds MY and volatile AY, PY, and host Y compounds.

dient of SF_6 is expected. Reaction in the near-surface top 2000Å region is clearly favored by short treatment times, low diffusion coefficients associated with large gas molecules, and glassy polymers. Figure 2 presents a representation of near-surface functionalization in this way.

Fig. 2. Schematic representation as in Fig. 1 for the negative tone showing near-surface functionalization of product P by metallic reagent MR. In this case, the gradient shown in Fig. 3 for P is not achieved because of low absorption cross section. Near-surface functionalization is achieved by limited permeation of MR during the sample treatment time.

An alternative to diffusion-controlled reactions in the near-surface region is exposure of the resist selectively in the near-surface region, followed by gas phase functionalization and RIE development as above. This is represented schematically in Fig. 3 for the negative tone case. In the limit of complete diffusion of inorganic reagent MR throughout the film, only negative tone can be achieved in theory. Functionalizing original species A in this instance would result in reaction of subsurface layers as well, thus preventing development. The consequence would only be relief-image formation upon development rather than complete development. In the limit of restricted gas permeation to the near-surface regions, positive tone could be formed with advantages being derived from the near-surface exposure.

For the four lithography types, surface exposure can be achieved most readily with ion beam lithography and photolithography. Use of low energy (~ 20 -50 keV) high atomic number (Z) ions permits exposure of only the top 100-250Å of any organic resist because of the very rapid stopping of the ionic species. For UV and visible photons, resists containing 10 weight percent (w/o) of compounds having $\epsilon \geq 50,000$ l/mol-cm at the exposing wavelength absorb $\geq 90\%$ of the incident light in the topmost 2500Å and $\geq 40\%$ in the first 1000Å. In the vacuum UV ($\lambda < 190$ nm), many polymers have $\epsilon_{\text{values}} > 10^5$ l/mol-cm, while highly conjugated aromatic materials have similar absorbances in 190-700 nm regions. Materials which meet the high absorbance criteria are, therefore, readily available for ion or photon exposures. In the photon case, improved resolution should result, whereas for ions sensitivity should be enhanced.

The situation is considerably different for electron and x-ray lithography in their present forms. For the former,

Fig. 3. Schematic representation as in Fig. 2, but only for negative tone showing a gradient of product P produced primarily in the near-surface region due to extremely high absorption cross section expected for ion beam and photon exposures.

high accelerating voltages (15-30 kV) are employed, and even higher ones are contemplated for production use in order to minimize the proximity effect caused by electrons backscattered from the substrate (3). At 20 kV, for example, with a typical low Z resist like PMMA, only about 5% of the incident dose is absorbed in a 1 μm film. The exposure contribution by electrons backscattered from the substrate is considerable and results in greater exposure near the substrate. Clearly, selective surface exposures are not achieved using present exposure voltages. However, if the permeation limited approach outlined in Fig. 2 were followed, one might expect improved resolution because surface functionalization would reduce the proximity effect normally encountered. Another alternative is to expose using very low energy electron beams (< 5 keV), the scheme shown in Fig. 3. These are being developed by Pease and his group at Stanford, but are only in the initial stages of investigation (4). Only permeation-limited functionalization would appear to have merit for electron lithography as we presently know it. However, since few exposure events occur in the near-surface region, such resists would appear to have very limited sensitivity.

X-ray lithography in its present forms likewise suffers from low absorption. For the Pd_L (4.37Å) to Cu_L (13.3Å) wavelength range generally in use today, a maximum of about 40% absorption per micrometer can be achieved using high Z absorbers in 1 μm thick polymeric films. Only about 5% absorption occurs in the top 1000Å. At much longer wavelengths, for which there are no currently available inexpensive high throughput exposure systems, high absorption in the top 1000Å can be achieved ($\lambda = 40 - 2000\text{Å}$). However, for the systems currently available, we again expect to be plagued by insensitivity.

We can now estimate the chances for this new type of resist for each of the lithographic technologies. Ion beam lithography appears to offer the best opportunity because

of extremely high absorbed doses in well-confined near-surface layers. But, for high resolution, conducting organic materials may be required (1). This would limit materials choices. Photolithography using very strong absorbers also is a very good candidate especially in the deep and vacuum UV regions. Use as an x-ray resist does not appear very promising, since sensitivity must be extremely high (weak sources), while absorbance is only moderate at best.

An analogous difficult application would be for E-beam resists. This results from an estimated operational dose range of 1-10 $\mu\text{C}/\text{cm}^2$ at 20 keV and 5% absorption in a 1 μm thick film. The near-surface (top 2000Å) absorbed dose would be less than 1% of the incident dose or about 4 mJ/cm^2 . For comparison, commercial photoresists require 40-100 mJ/cm^2 dose when used in microlithography. Sensitivity will once again be pushed to the limit in E-beam examples. Amplification upon development could help in achieving such a sensitivity.

In electron lithography important benefits may be realized. These could result if the proximity effect, which distorts pattern size as a function of geometry in the 1-0.1 μm range, could be reduced. The proposed resist scheme (Fig. 2) has such a potential if only the near-surface layers can be selectively functionalized by etch resistant inorganic groups. It is for this reason that we chose to work first on E-beam-exposed samples.

Results and Discussion

In analyzing chemical systems which would be reactive enough to provide adequate sensitivity as an E-beam resist, we decided to study olefin forming and olefin destroying reactions. The olefinic group could then react with an appropriate inorganic compound. In this regard, the reagent of choice would be nickel carbonyl (2)

which reacts readily with substituted olefins to give olefin-Ni complexes. However, its extreme toxicity makes its use unacceptable. Another gaseous reagent, diborane B_2H_6 , also reacts readily with olefins especially in the presence of ether compounds according to a well-researched mechanism pioneered by Brown (6). Complete reaction occurs according to Eq. [3]. However, in the solid state

one might expect incomplete reaction to give organoboron hydrides shown at the left side of Eq. [4]. Upon plasma oxidation, these boron compounds would be expected to form B_2O_3 , which has a bp of about 1860°C and should act as a good *in situ* mask for protecting underlying resist.

Initial experiments focused on functionalizing poly(isoprene) [5] with B_2H_6 generated by reaction of BF_3 with NaBH_4 in diglyme solution. The product

diborane was carried by argon into a reaction vessel containing a silicon wafer coated with poly(isoprene). After treatment, samples were etched in a reactive ion etcher

for various times at 30W power, -250V bias, 10μ O₂ pressure, and approximately 30 sccm flow. The treatment sequence was, first, a flush of the reaction vessel with inert gas, reaction for a given time, temperature, gas, and flow, and, finally, a postreaction treatment. The latter usually consisted of an inert gas flush for a specified time.

Results from the first functionalization experiments using 4900Å initial poly(isoprene) thickness are summarized in Table II. Two sets of experiments are listed. One utilized no flush after reaction and varied the temperature. The second kept temperature constant, used a flush after reaction, and varied treatment time. The former (runs 1-5) shows the importance of temperature on boron incorporation. The etching rate was slowed by nearly a factor of 2 after a 110°C treatment, while low temperature treatment produced only slight changes in developed thickness from the untreated control sample. The majority of the boron incorporated was only sorbed and not reacted. This is indicated by comparing runs 4 and 6 conducted at 80°C for 5 min. Run 6 used a flush after reaction and exhibits a six-fold reduction in NT_D (see Table II), compared to run 4, which did not use a flush. Thus, without a flush sorbed B₂H₆ appeared to be locked into the film by reaction with O₂ upon exposure to air. This may also occur with run no. 6 but to a much reduced extent. Runs 7 and 8 for longer times suggest that reaction may contribute to boron locking, as evidenced by the high normalized thickness values, where a maximum value of 1.0 can be attained. However, can conditions such as those in runs 4, 7, and 8 provide enough selectivity for image formation after exposure and processing?

We first tried a potential negative tone producing polymer, poly(vinyl chloride) PVC (5). This material is known to efficiently evolve HCl upon exposure to ionizing radiation with the generation of polyene sequences (7). However, both Ga⁺ exposures at 6.5 and 10 keV electron exposures at 100 μC/cm² failed to give any change in the slight negative tone images observed for PVC without B₂H₆ treatment. At the latter dose, 0.5 μm lines and spaces were visible in only very thin (< 500Å) resist.

Electron exposures at 10 keV also were conducted with poly(isoprene) using doses from 1-100 μC/cm². At 100 μC/cm² and after B₂H₆ treatment, faint 500Å thick positive tone images were obtained. This is the tone expected for boron reaction and masking. Control exposures at 100 μC/cm² without B₂H₆ treatment gave negative tone images (1100Å). Thus poly(isoprene) appeared to afford some selective functionalization and thus provided the first example of this type of resist. However, such images are not useful because of the very thin final resist, resist flow during reaction, and excessive dose.

In addition, other disadvantages were encountered. The tone inversion was dependent on reaction temperature, with 70°-80°C being optimum. At higher temperatures (> 100°C) no appreciable film removal was observed during

development, while at < 60°C, the final developed image thickness disappeared (no patterns). Also, surface texture was very rough and reproducibility was fair at best.

Poor reproducibility could result from a variety of factors. One is the chemical generation of B₂H₆, which occurs in spurts and is extremely difficult to control adequately. Consequently, we tried 1% B₂H₆ in nitrogen at 76°C and found no reaction with poly(isoprene) under a wide variety of conditions as judged from the O₂ reactive ion etch rates. This was further confirmed by ESCA analysis for B_{1s} at 186 eV, done by Schwartz and Gualtieri. Addition of dimethylether to the B₂H₆ gas stream had no effect, although Brown had claimed it accelerated gas phase reactions of B₂H₆ (6). Treatment at 107°C did show slight evidence of reaction. However, selectivity and flow as expected were adversely affected at this temperature.

It seemed likely that the B₂H₆ concentration was too low in the 1% mixture used above. So, we experimented with 14.6% B₂H₆ in N₂, the maximum percentage available commercially. The etch rate of a control sample, untreated poly(isoprene) of 5600Å thickness, was compared to a variety of samples treated at 75°C using a 5 min N₂ flush before and after treatment. The etch rates in an oxygen plasma relative to the control sample are given in Table III. From Table III we see that treatment with B₂H₆ reduces the etch rate and that the degree of reduction is fairly independent of treatment time. The addition of dimethylether to B₂H₆ increases the etch rate. This is the behavior expected for a noncatalytic diluent, even though it was thought to enhance B₂H₆ reactions, according to early studies by Brown and co-workers (6).

Poor etching selectivity can result from three sources: (i) inefficient destruction or creation of reactive double bonds during the exposure step, (ii) inefficient reaction of the functionalizing inorganic reagent, or (iii) inadequate etch resistance of the incorporated inorganic species. To probe the first possibility, we studied other polymers which may be expected to be more reactive to the incident radiation. It is known, for example, that a synergism exists between halogens and olefinic groups leading to the more facile destruction of unsaturation upon electron irradiation of polymers containing both groups (8). A likely candidate for examination would appear to be poly(chloroprene) [7], but it is quite unreactive

Table III. Relative O₂ RIE etch rates of poly(isoprene) reacted with 15% B₂H₆ in N₂ at various conditions

toward B_2H_6 because of the electron withdrawing properties of chlorine. As alternatives, we chose copolymers of 2, 3-dichloro-1-propyl acrylate [8] and 2, 2, 2-trichloroethyl acrylate [9] with

allyl acrylate [10] prepared by transesterifying the homopolymers of [8] and [9] with allyl alcohol. The copolymers designated at [8]-[10] and [9]-[10], respectively, contained 14.5 and 12.8 mole percent (m/o) allyl acrylate determined from elemental analysis. 0.5-1.1 μm thick films of the two copolymers were irradiated on EBES at 10 keV and five doses: 1, 5, 10, 50, and 100 $\mu\text{C}/\text{cm}^2$. Homopolymer films of monomers [8] and [9] were also irradiated and used as control materials. After exposure, the materials were either developed by O_2 RIE or treated with B_2H_6 under a variety of conditions and then developed as above. The baseline experiments for exposure only are summarized in Table IV. Here normalized thicknesses after development (NT_D) are listed at the five exposure doses. Since $NT_D = NT_{DE} - NT_{DU}$, where E and U designate the exposed and unexposed regions, negative values for NT_D imply positive tone. Samples were heated as indicated to mimic those heated later in a B_2H_6 atmosphere.

In each case, irradiation and plasma development gave weak positive tone images analogous to those found for poly(2, 3-dichloropropyl methacrylate) and poly(methyl methacrylate-co-oximinobutanedione methacrylate) by Taylor and Wolf (9). In those instances, lower doses were required, and the phenomenon was thought to result from cracking during exposure and post exposure heating. In the present instance, since most of the films were rubbery, cracking seemed unlikely. Rather, we believe the irradiated regions contract due to E-beam-induced cross-linking and gaseous product evolution. (All four materials behave as sensitive low contrast negative resists using solution development.) Even at the highest dose, none of the materials underwent enough chemical change

Table IV. NT_D Values as a function of dose for four chlorinated polymer films developed by O_2 RIE

to significantly influence the development (etch) rates. Thus, all give shallow positive tone images at doses > 10 $\mu\text{C}/\text{cm}^2$.

In contrast to this, samples reacted with B_2H_6 exhibit significant differences. The optimum results for each material are collected in Table V. In three of the four instances, addition of an equal amount of dimethyl ether gave better results than treatment with B_2H_6 alone. Treatments for times of less than 30 min were inferior, while longer times showed no additional improvement. Etching time to clear increased for all treated samples and was longer for longer treatment times (range of 4-11 min). For the two homopolymers treatment with B_2H_6 changed the resist tone from positive to negative (Fig. 4a, Table V). Best results were obtained with DCPA irradiated at 50 $\mu\text{C}/\text{cm}^2$ to give 0.21 normalized thickness at 1 μm line and space resolution. This is a change of 0.3 in normalized thickness from the control sample exhibiting positive tone. Note that a maximum was obtained at 50 $\mu\text{C}/\text{cm}^2$. Apparently, at higher doses the unsaturation generated by electron exposure is reduced by cross-linking processes. A similar but less dramatic trend was observed for TCEA. Both polymers exhibit the tone expected for reaction of B_2H_6 with unsaturation created in irradiated regions. Apparently either generation of olefinic unsaturation or reaction with B_2H_6 is less efficient for the glassy TCEA.

Results for the allyl acrylate copolymers show the opposite trend as expected for preferential B_2H_6 reaction in unirradiated regions (Fig. 4b, Table V). However, the changes are not as dramatic. The normalized thicknesses of the positive tone images in the control samples increased by a maximum of 0.13 for the [8]-[10] copolymer and only 0.08 for the [9]-[10] copolymer. High doses (50-100 $\mu\text{C}/\text{cm}^2$) were required, and final films were thin. This process is clearly less selective and less sensitive than the negative tone case using DCPA. All are inadequate for EBES and have not achieved the ideal condition of near-surface functionalization proposed in Fig. 2, since full resist thickness did not result. However, the effect has clearly been demonstrated, especially for DCPA, where the tone is inverted by gas phase reaction after exposure.

What factors are responsible for the low sensitivity and selectivity? Several could possibly contribute. The first is inefficient reaction of B_2H_6 with olefinic groups in the solid state. A second could be inefficient masking by boron due to facile sputtering of B_2O_3 (which seems unlikely) or removal during development as volatile organo-boron-oxygen compounds. A third possibility is too low

Table V. NT_D values as a function of B_2H_6 reaction and dose for four chlorinated polymer films

Fig. 4. Normalized thickness vs. log dose for: (a, top) DCPA (●) and TCEA (○) homopolymers treated (—) and untreated (---) with B_2H_6 and developed by O_2 RIE, and (b, bottom) analogously treated DCPA-co-AA (●) and TCEA-co-AA (○) samples which exhibit only positive tone.

conversion of unsaturated groups upon irradiation. A fourth is sorption outcompeting reaction and therefore minimizing etch rate differences.

Other reasons may undoubtedly contribute as well. The halving of removal rates by treatment with B_2H_6 for long times clearly suggests that boron incorporation reduces etch rates. But, how much is incorporated? From the work of Venkatesan and co-workers (1), we know that about four equivalent monolayers of metal forming a nonvolatile oxide are sufficient to reduce the etching rate by about a factor of 10. Assuming a linear relationship between metal content and relative etch rate, we would expect somewhat less than one monolayer of boron reacted preferentially in the film in the present case from the halved relative etch rate. But, it is dispersed throughout the film prior to O_2 RIE development. The latter would serve to concentrate the boron at the surface, much like SiO_2 is concentrated on the surface during O_2 RIE development of plasma-developed silicon containing x-ray resist (10).

To ascertain boron content, Schwartz and Gualtieri ran ESCA spectra of some of our samples before exposure and after B_2H_6 treatment and O_2 reactive ion etching. Rutherford backscattering analyses were not possible due to substrate interferences. In the case of the samples discussed in Tables IV and V, the chlorine present partially interferes with the boron 1s peak at 186 eV because of the strong Cl_{2p} absorption at 197.5 eV. Careful analysis, however, revealed no "boron shoulder" with the Cl_{2p} peak for untreated and boron-treated [8]-[10] copolymer. Other expected peaks (O_{1s} , C_{1s} , Cl_{2s} , and Cl_{1s}) also were observed. In the RIE-developed sample, a small shoulder on the low energy side of the Cl_{2p} peak was found; it seems likely that it is the B_{1s} peak. Comparison to other peaks and correction for differences in cross section provides a rough estimate that about 0.03 equivalent monolayers of boron were present. Since the film studied had 14.8 m/o unsaturation prior to irradiation (an ample amount for reaction), it seems likely that inefficient reaction with B_2H_6 in the solid state is partially responsible for the low sensitivity. Low normalized thickness after development, in spite of etch rates reduced by as much as a factor of 2, suggests that selectivity is poor and that sorbed material is not completely removed by flushing after reaction with B_2H_6 .

Fine patterns can nonetheless be obtained. Photomicrographs of positive and negative tone patterns are shown in Fig. 5. Figure 5a shows negative tone patterns obtained

Fig. 5. Photomicrographs of O_2 RIE-developed images in (a) DCPA exposed to $50 \mu C/cm^2$ at 10 keV and reacted with B_2H_6 (final thickness 1800\AA) negative tone. (b) Copolymer of TCEA and AA exposed at $10 \mu C/cm^2$ and reacted with B_2H_6 (final thickness $\sim 800\text{\AA}$) positive tone. Finest lines and spaces are 0.5, 1.0, 2.0, and 4.0 μm .

in DCPA after a $50 \mu C/cm^2$ exposure, B_2H_6 treatment, and O_2 RIE development. In this instance, the development endpoint was easy to detect since most of the resist was selectively removed. $0.5 \mu m$ lines and spaces $0.18 \mu m$ thick are evident along with the larger 1, 2, and 4 μm lines and spaces. In Fig. 5b, positive tone images 800\AA thick are shown for the copolymer of TCEA and AA after exposure at $10 \mu C/cm^2$, B_2H_6 treatment, and O_2 RIE development. In this case, clearing of fine features was very difficult to gauge during development, and all fine features were overetched. Nonetheless, remnants of the 0.5, 1.0, and 2.0 μm lines are evident in the micrograph along with a very rough granular texture which is not as noticeable in the negative tone example. In most cases, we see a granular texture which is very similar to that observed with plasma-developed negative x-ray resists (11). In the latter instance, the granularity arises from the Si containing component and appears as small ($< 500\text{\AA}$) SiO_2 granules (11). In the present instance, it appears uniformly in the exposed and unexposed regions and for both tones. We believe it results from sorbed B_2H_6 , which continues to desorb slowly upon removal from the treatment cell. Upon diffusion to the surface, it probably reacts with O_2 to give B_2O_3 in trace amounts, which would act as a partial discontinuous mask in the development process.

Conclusions and Final Remarks

In this paper, we have outlined the principles of functionalizing organic resists by gas phase reaction with

inorganic or organometallic reagents, which selectively bind inorganic atoms to either exposed or unexposed resist regions. The reactive selection is amplified by plasma development, which converts the metal into a nonvolatile *in situ* mask. Two additional examples are already present in the literature. The first is grafting of dichloromethylvinyl silane to plasma-polymerized methyl methacrylate selectively in electron exposed regions, followed by O₂ plasma development to give negative tone patterns (12). Negative tone patterns were also obtained with electron-irradiated PMMA treated with dimethyl dichlorosilane and then water and developed by O₂ RIE (13). In this latter instance, a permeation, water-induced polymerization model was proposed. It differs from that which we discuss here. The radiation grafting example is a good example of the model which we outline here.

We have tested this new resist technique using 10 keV electron lithographic exposures from 1 to 100 $\mu\text{C}/\text{cm}^2$ and treatment with diborane, which efficiently reacts with electron-rich C-C double bonds to form organoboranes in solution. Pattern development was achieved with O₂ RIE at 10 μ pressure. Formation of both positive and negative tone patterns was achieved using chloroacrylate homopolymers or copolymers with allyl acrylate containing 12-15% unsaturation. Comparison to control samples not treated with diborane demonstrates selective functionalization in both instances. A maximum change of 0.30 in normalized thickness was realized for DCPA irradiated at 50 $\mu\text{C}/\text{cm}^2$. High resolution but thin final developed patterns were obtained. Sensitivity and resolution do not appear to be as high with the copolymer positive tone resists.

While these materials and processes demonstrate the principles of the technique, they are far from practical use. First, both sensitivity (50 $\mu\text{C}/\text{cm}^2$) and final thickness ($\sim 1500\text{\AA}$) are inadequate. This appears to result from two factors, poor reaction of diborane with unsaturation in the resist and competition from sorbed material, which desorbs at a slow rate and which can presumably form a skin on the resist surface upon exposure to air. ESCA

measurements appear to indicate that inefficient functionalization is the primary limitation.

Acknowledgments

We are indebted to G. P. Schwartz and G. A. Gualtieri for their careful and patient ESCA analyses. Also, we thank J. Frackowiak and R. K. Watts for the electron beam exposures and M. P. Bohrer for helpful discussions.

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A new type of plasma-developed positive acting photo and electron-beam resist is described. It is based upon the difference in functionalization occurring when exposed resists such as Waycoat IC-43 and Selectilux N-60 are treated with gaseous inorganic halides. Unexposed areas etch slowly during O₂ reactive ion etching. In these areas, azide-inorganic halide complexes are readily converted to a masking metal oxide layer. In the exposed areas, inorganic amino halides are converted to volatile organic and inorganic compounds. Thicknesses in excess of 5000 \AA result for 8s contact photoexposures at 366 nm followed by treatment with SiCl₄ and O₂ reactive ion etching. In addition, 0.6 μm resolution is attained. Electron beam exposures indicate resolution capabilities of less than 0.3 μm , with sensitivity on the order of 10-20 $\mu\text{C}/\text{cm}^2$ at 20 keV. A mechanism consistent with UV, infrared, Rutherford backscattering, ESCA, and kinetic data is presented.

In a previous paper (1), Taylor and co-workers described a new resist technology involving gas phase functionalization of an exposed resist with inorganic compounds. They envisioned selective reaction of the gaseous inorganic compounds in either the exposed or the unexposed regions of the resist. This selective reaction would optimally occur at or near the surface of the resist and would be controlled by either the limited permeation of the inorganic compounds, the near-surface exposure, or both. The selectivity would be further enhanced during pattern development using reactive ion etching, during

which the inorganic compound would be converted into a nonvolatile product. This nonvolatile product would act as an *in situ* mask, a concept previously used for plasma-developed x-ray resists (2) and ion-implantation resists (3). In the present instance, positive or negative tones could be obtained by controlling either the gas phase functionalization process or the type of etchants employed during the development process. Whichever the case, it is conceivable that either tone could be generated from the same exposure using appropriate methods.

Although this technique is applicable for use in ion, photo, electron, and x-ray lithography, Taylor and co-workers studied the method using 10 keV electron expo-

* Electrochemical Society Active Member.

sure of chlorine containing acrylic polymers and copolymers containing allylic ester groups. B_2H_6 was used as the functionalizing agent. Exposed and functionalized resists were developed using O_2 reactive ion etching. High resolution patterns were obtained ($\sim 1.0 \mu m$), but the final patterns were too thin ($< 2000 \text{ \AA}$) and were obtained only at high doses ($\sim 50\text{-}100 \mu C/cm^2$).

Herein, we describe some initial results obtained in a study of the gas phase functionalization of two negative acting photoresists, Waycoat IC-43 (Phillip A. Hunt Company) and Selectilux N-60 (E. Merck Incorporated), with various inorganic halogen compounds. Our goal was the development of a low dose, high resolution gas phase functionalized photo or electron resist. We wanted to utilize the photochemistry of the sensitizers in the resist to effect a means to selectively sorb a volatile inorganic halide. We also wanted a very high absorbed concentration of the inorganic halide. This would insure the formation of a thick metal oxide protecting layer during O_2 reactive ion etching. High values of normalized developed thickness, NT_D , in excess of 5000 \AA , should result. We also envisioned the difference in selectivity to be large enough to enable one to achieve resolution less than $1.0 \mu m$.

Methodology

Waycoat IC-43 and Selectilux N-60 are two commercially available negative-acting photoresists whose radiation chemistry is well documented (4). The resists consist of a bis-azide sensitizer [1] in a partially cyclized poly(isoprene) host [2]

Upon UV irradiation, the sensitizer loses two molecules of nitrogen to give the dinitrene intermediate [3]

The dinitrene can add across a double bond to give an aziridine [4], or insert into a carbon-hydrogen bond to give a secondary amine [5]. The difunctionality of

the sensitizer affords cross-linking of the polymer host and the material functions as a negative solution-developed resist in conventional photolithography.

However, the transformation of the azide functionality to either an aziridine or amine can potentially be useful in the gas phase functionalization process. Inorganic halides, such as silicon tetrachloride ($SiCl_4$) and tin tetrachloride ($SnCl_4$), are known to react with secondary amines (5) to form tetrasubstituted silyl or stannyl amines [6]. On this basis we formulated

the lithographic process outlined in Fig. 1. Photolysis of the resist converts the azide A contained in the partially cyclized polyisoprene host into aziridines and amines B. Next, the exposed resist is treated with a gaseous inorganic halide MX. This is envisioned to functionalize the exposed areas via the reaction with the amines as depicted by BMX. Oxygen reactive ion etching would strip the unexposed, unfunctionalized areas. Etching would oxidize the inorganic-amine product to an inorganic oxide. This oxide would then act as an *in situ* masking layer, which would effectively prevent further etching in the exposed areas.

These processes were outlined (schematically) first by Taylor *et al.* (1) for negative resists. Since then, Follett and co-workers (6) and Hattori and co-workers (7) have described similar processes. Both used PMMA, which afforded negative tone patterns.

Both of these examples appear to be impractical. This paper describes materials and processes which bring gas phase functionalized plasma-developed resists closer to reality. In addition, a novel means for achieving positive tone is detailed.

Experimental

Prebaked $1 \mu m$ thick films of Waycoat IC-43 and Selectilux N-60 on Si were contact exposed on two different exposure tools. An Optical Associates Incorporated deep UV exposure light source (Model 29D) and intensity control system (Model 780) were employed using 250-300 nm optics. A Cobilt Model CA2020H Contact Printer at 366 nm was used for resolution studies.

The exposed coatings were functionalized using $SiCl_4$, $SnCl_4$, or Me_2SiCl_2 (Alfa Products). Gas phase functionalization took place in a reaction cell, the details of which will be discussed in a later paper. Treatment times were typically 1-60s.

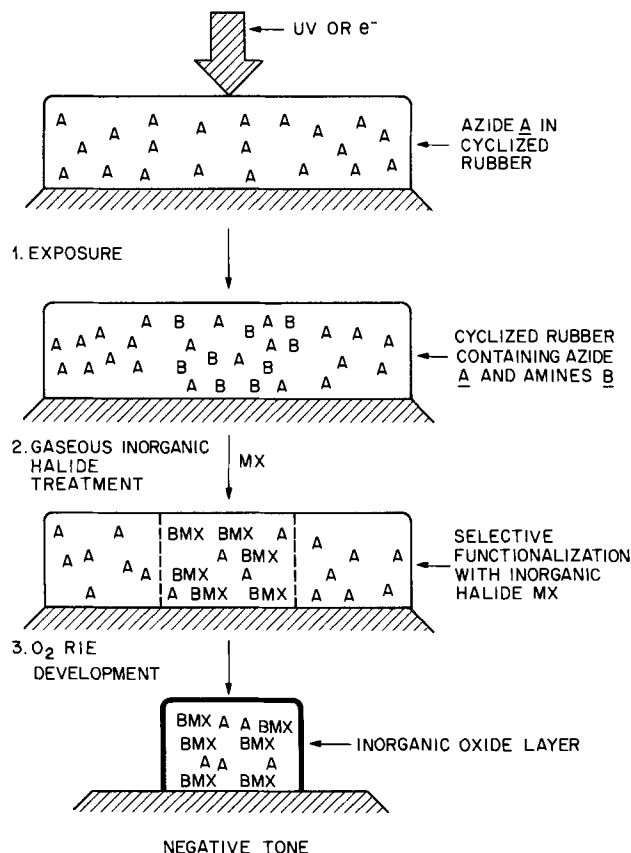

Fig. 1. Schematic showing the proposed mechanism for gas-phase functionalized resists. Azide A incorporated in a host polymer is radiologically converted to an amine B. Treatment with an inorganic halide MX gives an amine-inorganic halide BMX capable of conversion to a refractory nonvolatile oxide MO_2 during O_2 RIE.

Etching was done in a Cooke Vacuum Products reactive ion etcher, using oxygen as the sole etchant. The typical etching conditions were 20W, 10-20 mtorr, and an oxygen flow of 8-12 sccm.

Results and Discussion

The azide containing gas-phase-functionalized resists etched in a manner completely opposite the mechanism we envisioned (Fig. 1). The unexposed regions etched at a significantly lower rate than their exposed counterparts! Under the best processing conditions, a normalized developed thickness, NT_D , between 0.5 and 0.7 was obtained. Positive acting resist behavior resulted whenever we "successfully" functionalized the resist (Fig. 2). The term "successful" is used to indicate complete clearing of the substrate in the exposed areas upon reactive ion etching. Instances will be described later where only partial or even no clearing was obtained.

Waycoat IC-43 and Selectilux N-60 were successfully functionalized using SnCl_4 , SiCl_4 , and dimethyldichlorosilane $[(\text{CH}_3)_2\text{SiCl}_2]$. Figure 3 shows the results for the normalized developed thickness of SiCl_4 functionalized Selectilux N-60 as a function of exposure time and functionalization time. N-60 was contact exposed using the Cobilt CA2020H and then treated with SiCl_4 for various times. Two trends are noted. First, when SiCl_4 treatment time was varied (8, 16, or 32s) at constant exposure, NT_D passed through a maximum. At 3, 5, and 7s SiCl_4 treatments, patterns could be developed. However, at or above 10s treatment, neither the exposed nor the unexposed areas could be etched. Secondly, varying the exposure time while keeping the SiCl_4 treatment time constant (3, 5, 7, or 10s) afforded a maximum NT_D at a 16s exposure time. Coincident with decreasing NT_D at high doses or long treatment times was a decrease in the etch rate relative to the same etching rate for functionalized low dose exposures. A 10s SiCl_4 treatment always afforded resist films that could not be etched, regardless of exposure time.

These results indicate the possibility of two types of behavior depending on exposure and SiCl_4 treatment times.

Fig. 2. Schematic depicting the observed pathway of gas phase-functionalized negative photoresists treated with SiCl_4 or SnCl_4 .

Fig. 3. Plots of the normalized developed thickness vs. exposure time for Selectilux N-60 treated with SiCl_4 for various times.

At low doses and low SiCl_4 treatment times, one can easily develop patterns. Etch time to clear the exposed regions and etch rate are constant and equivalent to that of an unfunctionalized resist (1250 Å/min) used as a control. It appears as if SiCl_4 were present only in the unexposed areas, contrary to our expectations. During RIE, the silicon present there is converted to SiO_2 , thus reducing the etch rate.

However, a much different picture is evident from an analogous study using SnCl_4 as the volatile inorganic halide and Waycoat IC-43 resist. Waycoat IC-43 has nearly identical components and structures to those in Selectilux N-60. 1 μm thick films of IC-43 on Si wafers were exposed to 250-300 nm UV radiation for 1, 3, 5, 10, 30, and 60s using the OAI exposure tool. Each sample was treated with SnCl_4 for 1 min. An analogously treated but unexposed sample of IC-43 was used as a control. In this case, the use of SnCl_4 permits the analysis of the depth distribution of the reagents (Sn and Cl) using Rutherford backscattering spectroscopy (RBS) (8). Figure 4 shows the spectra obtained for 3 samples: an unexposed control, a 3s exposure, and a 30s exposure.

The control spectrum reveals that SnCl_4 was uniformly distributed (sorbed) within the resist. This simulates the unexposed areas on a patterned wafer that etch at a slower rate than the exposed areas. Incredibly, Sn was present in the photoexposed wafers as well. Both the 3 and the 30s samples show a Sn background comparable to the control; that is, they both show a uniform distribution of Sn in the resist (1.2×10^{17} Sn at./cm²). In addition, the appearance of a new peak in the vicinity of channel no. 400 shows a build-up of Sn (1.8×10^{17} Sn at./cm²) in the near-surface region (upper 2500Å) of the resist. Tables I and II summarize the amounts of Sn and Cl sorbed for each exposure dose. Figure 5 shows a plot of the additional Sn concentration vs. exposure time using the data

Fig. 4. Rutherford backscattering spectra for exposed and unexposed Waycoat IC-43 treated with SnCl_4 for 1 min showing the increase in Sn and Cl as a function of exposure time.

Table I. RBS results for photoexposed Waycoat IC-43 resist treated for 1 min with SnCl_4

Exposure time (s)	Sn (cts)	Cl (cts)	Cl/Sn ^a (total)	Cl/Sn ^a (excess)
0	23,365	8,561	3.17	0

given in Table II. There appears to be a first-order dependence of excess Sn with respect to exposure time. IC-43 coated wafers exposed for 30s and treated with SnCl_4 contain 50% more Sn than the control sample. Moreover, it is this high Sn concentration area that is etched away in preference to the unexposed, but treated, control!

An examination of the data in Table I shows that the ratio of Cl to Sn in the background of all the samples is approximately 3.2 and is lower than the value of 4.0 for SnCl_4 itself. But, in the regions that correspond to the Sn build-up, this ratio decreases to 1.4. Clearly, Sn appears to be present in different forms in the exposed and the unexposed regions. One of these may be an amino-tin compound, as outlined earlier in this paper. The other appears to be SnO_2 overlying a SnCl_4 -sensitizer complex of undetermined form.

ESCA analysis supports the above hypothesis. Substantial differences for the surfaces of the exposed and unexposed samples of IC-43 treated with SnCl_4 were seen in the ^{3d}Sn and ^{1s}O peaks of the ESCA spectra (Fig. 6). In the unexposed region the signals are like those observed for SnO_2 (this region does not etch rapidly, as would be expected if SnO_2 were present). The exposed regions exhibit a Sn composition that is more representative of either an organotin oxychloride or an organotin amino chloride.

UV-visible spectroscopy gives additional clues to the mechanism of the gas-phase-functionalization process.

Fig. 5. Plot of the additional Sn absorbed (taken from the RBS data) during gas phase functionalization of $1 \mu\text{m}$ of Waycoat IC-43 treated with SnCl_4 as a function of deep UV exposure time.

Fig. 6. ESCA spectra of $1 \mu\text{m}$ exposed and unexposed Waycoat IC-43 treated with SnCl_4 .

Figure 7 shows the spectra of an unexposed, $1 \mu\text{m}$ thick film of IC-43 before and after treatment with SnCl_4 . The original absorption band centered at 370 nm is slightly red shifted upon treatment. The intensity is also reduced. Unexposed Selectilux N-60 resist treated with SiCl_4 shows a similar behavior (Fig. 8). The changes in both these spectra suggest complexation of the inorganic halide with the azide sensitizer. However, for an exposed (60s) sample of N-60 treated with SiCl_4 , we see a complete disappearance of the 370 nm chromophore. This indicates the absence of this type of complexation and the occurrence of other chemical reactions in the exposed regions.

Complexation of the unexposed N-60 may occur with either of the three major functional groups present. These include the highly substituted double bonds of the host polymer (partially cyclized polyisoprene) and the azide ($-\text{N}_3$) and carbonyl ($-\text{C}=\text{O}$) groups of the sensitizer. A series of experiments was conducted to determine the complexing functionality. Various polymers were coated on Si wafers and treated with SiCl_4 . Then, they were reactive ion etched in oxygen along with an untreated control. Poly(*cis*-1,4-butadiene), poly(methyl methacrylate), and poly(methyl vinyl ketone) showed no difference in etch rate from the control. SiCl_4 complexation with the double bonds in poly(butadiene) or the carbonyl groups in the latter two polymers should have decreased the etch rate via the formation of an oxide layer. The carbonyl and olefinic groups do not appear to be involved in complexation.

The need for the azide group in the system is critical. It is further supported by another experiment. As we saw above, poly(*cis*-1,4-butadiene) was not functionalized. We

added 10 weight percent (w/o) 1-azido-4-bromo-naphthalene [7], which contains no carbonyl groups

[7]

to a solution of poly(cis-1,4-butadiene). The mixture was spun on a Si wafer, contact exposed with deep-UV radiation, and treated with SiCl_4 . Positive tone patterns ($NT_D \sim 0.2$) were obtained upon oxygen reactive ion etching, thus confirming azide complexation.

Mechanism.—The spectroscopic studies (RBS, ESCA, and UV-visible) and the previously described observations suggest the mechanism for gas-phase functionalization outlined in Fig. 9. Two types of inorganic halide functionalization appear to occur. In the unexposed regions, MCl_4 is quickly sorbed into the film. We presume the formation of an $\text{R-N}_3 \dots \text{MX}$ complex. In the presence of water this complex hydrolyzes to form inorganic oxide MO_2 . During O_2 RIE, some loss of MO_2 may occur due to sputtering of this protective masking layer. This metal oxide layer may be renewed during oxidative etching by converting unhydrolyzed inorganic compounds to MO_2 .

In the exposed regions, MX_4 also is sorbed quickly. From the infrared spectra, all azide groups having a strong absorbance at 2250 cm^{-1} disappear upon a 16s exposure at 366 nm with the formation of amine products. The inorganic halide then appears to react with the amine or aziridine groups generated during photo exposure.

These new products ($\text{R}'\text{-N-MCl}_x$) apparently hydrolyze more slowly than the complexed metal halides. Upon O_2 RIE, the compounds are removed as CO_2 , H_2O , NO_2 , and volatile inorganic compounds of unknown structure. At short MX treatment times, little oxide is formed to

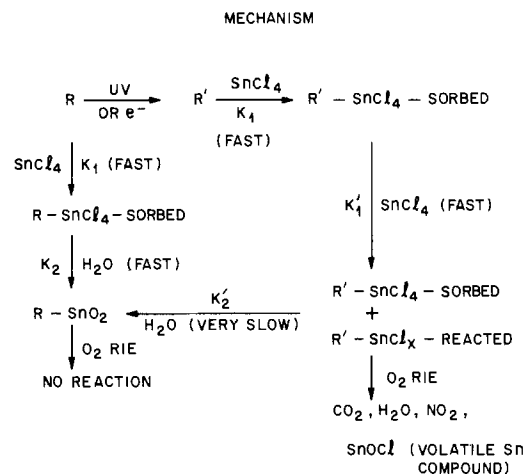

Fig. 9. Proposed mechanistic and kinetic scheme for the gas phase functionalization of negative azide containing photoresists with gaseous inorganic halides.

hinder removal of the exposed areas. However, a second mode of MX_4 sorption appears to occur at longer treatment times. MX_4 also is physically sorbed into the resist. The concentration of it quickly builds after all the photo-generated products have reacted. This second complex appears to be highly reactive toward water, thus forming a metal oxide layer which severely hinders removal of these areas during O_2 RIE. With very long MX treatment times, no etching is possible in either region.

This mechanism also is consistent with the failure to obtain patterned resists for films which were photoexposed and treated for short times ($< 8\text{s}$). Under these conditions, insufficient azide is photodecomposed, as evidenced by considerable residual IR absorbance at 2250 cm^{-1} . Substantial concentrations of $\text{R-N}_3\text{-MX}_4$ are present in both the exposed and unexposed areas of the resist. This highly reactive complex is readily converted to a metal oxide in the presence of water or during O_2 RIE. The net result is the inability to attain any significant differential etch rate during O_2 RIE. Complete photodecomposition of the bis-azide sensitizer appears to be necessary in order to optimize selectivity as judged from the IR analyses.

Pattern resolution.—The use of gas phase-functionalized IC-43 as an electron-beam resist gave us an indication of the resolution capabilities for this lithographic process and material. $1 \mu\text{m}$ of IC-43 was exposed to a 20 keV electron beam at doses of 1, 3, 6, 9, 12, 18, and $24 \mu\text{C}/\text{cm}^2$. The resist was then treated with SnCl_4 for 1 min. Figure 10 shows a scanning electron micrograph of underexposed $1 \mu\text{m}$ lines and spaces at $18 \mu\text{C}/\text{cm}^2$ developed using O_2 reactive ion etching. The exposed regions (represented by the trenches) contain a slight residue. A closer examination of the lines reveal that the field butting was misaligned by $\sim 0.15 \mu\text{m}$. This misalignment was resolved by the gas-phase-functionalized resist. The smallest gap width is about $0.3 \mu\text{m}$. Additional samples were not exposed by electron irradiation due to the low wafer throughput. Process development like that outlined below for contact photoexposures would be expected to afford improved E-beam images.

Cobilt contact exposures of N-60 reveal the resolution potential of these photolithographic gas phase-functionalized resists. A 16s photoexposed sample of N-60 was treated for 7s with SiCl_4 . Figure 11a shows the nominal $1 \mu\text{m}$ lines and spaces obtained after exposure, treatment, and O_2 RIE. The lines were $0.7 \mu\text{m}$ high and $0.6 \mu\text{m}$ wide; the spaces were $1.4 \mu\text{m}$ wide. This was independent of exposure from 3-16s. Thinner films were obtained at the shorter exposure times. A close examination of the mask used for these photoexposures revealed that the chrome lines measured about $0.6 \mu\text{m}$, with $1.4 \mu\text{m}$ gaps. It appears that in this exposure mode the mask dimensions were re-

Fig. 10. Scanning electron micrographs of O_2 RIE-developed Waycoat IC-43 irradiated at 20 keV and $18 \mu C/cm^2$ and treated with $SnCl_4$. Fig. 10a and 10b depict underexposed $1 \mu m$ and $0.75 \mu m$ lines and spaces, respectively, in $0.80 \mu m$ thick resist. The $0.15 \mu m$ misaligned address structure is clearly seen.

Fig. 11. Scanning electron micrographs of $0.6 \mu m$ lines and $1.4 \mu m$ spaces (Fig. 11a) and $1.4 \mu m$ lines and $2.6 \mu m$ spaces (Fig. 11b) obtained after O_2 RIE development of $1 \mu m$ Selectilux N-60 contact exposed for 16s with UV irradiation and treated with $SiCl_4$ for 7s. Final resist thickness is $0.7 \mu m$.

produced quite faithfully. In Fig. 11b, the $2.0 \mu m$ lines and spaces actually measured $1.4 \mu m$ and $2.6 \mu m$, respectively. These also correspond to the same dimensions found for corresponding features on the mask.

The presence of residue in the exposed regions of these samples and in the E-beam-exposed samples attests to the difficulties associated with excess $SiCl_4$ sorbed in the resist. This excess $SiCl_4$ may be hydrolyzed during handling to form traces of inorganic oxide. It also may be formed in the exposed area during O_2 RIE. The residue cannot be removed by sputtering during pattern development at high bias. If it is pure oxide, such as SiO_2 , it may be possible to remove it after development by brief RIE using CHF_3 gas or a freon-oxygen mixture similar to that used by Taylor and co-workers (9) for plasma-developed x-ray resists. These experiments are currently in progress.

Conclusions

A new type of plasma-developed, positive acting photo and electron-beam resist has been described. It is based upon the chemical differences induced by the gas-phase functionalization resulting when exposed samples of Waycoat IC-43 or Selectilux N-60 resists are treated with volatile inorganic halides such as $SiCl_4$ or $SnCl_4$. In the unexposed regions, the inorganic halide is uniformly distributed throughout the resist and complexes with the azide group of the sensitizer. This complex is readily con-

verted to a masking refractory oxide by either hydrolysis in the presence of water or by an oxidative process during oxygen reactive ion etching.

The functionalization that takes place in the exposed areas is quite different. The inorganic chloride-amino compounds that appear to be formed hydrolyze more slowly and are readily removed as volatile organic and inorganic compounds during O_2 reactive ion etching. These areas are removed at a much higher rate than their unexposed counterparts. Normalized developed thicknesses in excess of 5000 \AA can be obtained at 366 nm for Cobilt contact exposures between 8 and 24s upon O_2 RIE development.

Resolution in the vicinity of $0.6 \mu m$ can be obtained with $SiCl_4$ -functionalized contact photoexposure of Selectilux N-60. Smaller dimensions are possible with electron-beam exposures of Waycoat IC-43. With further development and extension to other materials and exposure sources, practical single-level plasma-developed gas phase-functionalized resists previously envisioned may be extended to H^+ ion beam and low voltage electron ($< 5 \text{ keV}$) and scanning metal ion beam ($< 4 \text{ keV}$). At a minimum, practical trilevel and perhaps even bilevel applications may be feasible, provided processes for residue removal are forthcoming.

Hydrogen Plasma Etching of Organics

F. Y. Robb*

Motorola, Incorporated, Process Technology Laboratory, SRDL, Phoenix, Arizona 85008

ABSTRACT

The use of hydrogen plasmas for reactive ion etching of organic films has been characterized. It was found that anisotropic etching could be easily achieved, but with relatively slow etch rates ($< 300\text{\AA}/\text{min}$). The effect of variables (such as pressure, temperature, and power) and chemistry changes (such as the addition of O_2 and N_2) were studied and discussed. In addition, the applications of contact-hole etching and trilevel resist processing are considered.

The increasing complexity of integrated circuits has demanded technological changes in the areas of materials, lithography, and processing. The need for an anisotropic etch process for organic films is a result of both material and lithographic advancements. One new dielectric/passivant material which has recently gained acceptance in the semiconductor world is polyimide (1). An anisotropic etch process for polyimide will clearly be needed as device geometries shrink to the submicron regime. In the lithography area, the trilevel resist process outlined by Moran and Maydan (2), extends lithographic capabilities by first planarizing the wafer's surface with a thick organic layer. That thick layer is then patterned using a thin inorganic intermediate masking layer and very thin top layer of resist. This trilevel process requires an anisotropic organic etch to maintain good dimensional control.

Oxygen plasma attack of organic films is well known, as "ashing" of photoresist is quite common in the microelectronics industry (3). In addition, the use of oxygen for reactive ion etching of organics has been widely studied and applied (4-6). In order to achieve anisotropic etching of organic films with oxygen reactive ion etching, however, relatively low pressures (< 0.02 torr) are required (5).

Hydrogen plasmas are also capable of removing organic films under the proper conditions (7-8). In those studies, temperatures between 150° and 200°C were needed to promote etching, although only mild ion bombardment was present. (One investigator utilized a high frequency barrel etcher, while the other immersed the sample in the positive column of a dc discharge.) The subject of this paper is the characterization of organic etching in hydrogen plasmas under low temperature/higher ion bombardment conditions. The principle motivation behind this study was to develop an anisotropic organic etch process (for both trilevel masking and preohmic applications) at operating pressures above 0.10 torr, making sophisticated and costly vacuum equipment unnecessary.

Experimental

Figure 1 shows a schematic diagram of the experimental apparatus. The RF electrodes and reactor baseplate

*Electrochemical Society Active Member.

Key words: plasma etching, hydrogen discharges, semiconductor processing, organics.

were constructed of aluminum, and a Pyrex bell jar comprised the remainder of the vacuum chamber. The wafers were placed on the smaller powered electrode which had a surface area of approximately 500 cm^2 .

The system was operated at a RF frequency of 13.56 MHz, with the power variable from less than 0.1 to $0.6\text{ W}/\text{cm}^2$. The operating pressure, which was measured with a capacitance manometer (MKS Baratron), was varied by changing the input flow of process gas to the chamber. The gas was injected into the chamber via a single hole in the reactor baseplate. Gas flow was measured via Tylan mass flowmeters, which allowed mixtures of gases to be made. Flow rate restrictions and the 0.01 torr system base pressure limited usable etching to the above 0.1 torr regime. Temperature was varied by resistance heaters and monitored via a thermocouple, both positioned within the electrode support structure.

Various cathode covers were investigated in order to eliminate metallic contamination of the etching wafers. Contamination-free etching resulted only when all reactor surfaces were covered with an organic film. Both conventional photoresist coatings and du Pont Kapton sheet polyimide (affixed with a resist "glue") were successfully used, although the lifetime of the sheet polyimide was considerably longer. The test sample etch rates with organic reactor coatings were approximately 40% lower than with the bare aluminum cathode, presumably because of loading. Both the trilevel resist and contact resistance applications utilized a polyimide reactor coating.

Fig. 1. Reactor utilized for organic etch studies

Oxidized silicon substrates, coated with from 1.0 to 2.0 μm of an organic film, were used. du Pont PI2545 polyimide was mainly used, although the etch rates of Hunt Chemical HR-100 negative and HPR-204 positive photoresists were also measured. The polyimide film was cured via multiple temperature bakes, ending with a 15 min 420°C N_2 bake. The HR-100 films were hardbaked for 30 min at 150°C in N_2 , while the HPR-204 films were given a 2h 200°C vacuum bake. For patterned samples, a thin intermediate masking layer of plasma nitride or oxide was next applied and patterned, with a resist mask, by reactive ion etching in CF_4 or CHF_3 .

Figures 2 through 6 plot the etch rates of PI2545, while Fig. 4 also includes the HR-100 and HPR-204 rates for comparison. In general, the photoresists' etch rates were virtually the same, with the polyimide etch rate being 10%-20% higher.

Etch data was measured for small loads with typically only one 3 in wafer per run. The etch uniformity (2σ) across a 3 in wafer was less than 5%. Error bars represent the maximum spread in etch rate measured over a several month period.

Various analysis techniques were used to characterize the etch process. Film-thickness and etch-depth measurements on patterned samples were made on the Tencor 10-00020 Alpha Step. For sheet organic films of HR-100 and HPR-204, the IBM 7840 Film Thickness Analyzer was used to make thickness measurements. The anisotropy of the etch and general etch quality were determined from scanning electron micrographs (SEM's) of samples given a 20% overetch.

The contact resistance measurements were made on p-type silicon to aluminum-Si contacts. The silicon substrates were BF_2 implanted with a thermal oxide mask, at $2 \times 10^{15}/\text{cm}^2$ and 40 keV. An 800°C , 10 min N_2 activation anneal followed the implant. A 6000\AA thick dielectric film of either du Pont's PI 2566 polyimide, fully cured to 450°C , or low pressure CVD phosphosilicate glass (PSG) was next applied/deposited, and preohmic holes patterned. All samples were given a 35s 75:1 HF (75 to 1 volume mixture of 49% HF and water) preclean before subsequent sputter deposition, at 150°C , of 8000\AA of aluminum-1.5% silicon. After a 30 min, 450°C N_2 anneal, the contact resistance was measured using a four-terminal Kelvin resistor test structure, which is more fully described elsewhere (9). The voltage was measured at two currents to confirm ohmic behavior. Contacts which showed diode-type behavior or opens were rejected. Specific contact resistance was calculated from SEM measurements of the etched preohmic openings.

Results and Discussions

Oxygen comparison study.—Since oxygen has become the industry standard for organic etching, a brief comparison of its etch characteristics to those of hydrogen was initially performed. The etch rate and anisotropy of polyimide films etched in both oxygen and hydrogen plasmas were characterized as function of pressure in the 0.1-0.5 torr range. Figure 2 shows that the etch rates in oxygen increased twofold, from about 500 $\text{\AA}/\text{min}$, as the pressure was lowered from 0.5 torr. The etch rate in hydrogen, however, varied little with pressure and was always less than 300 $\text{\AA}/\text{min}$. SEM's of patterned samples etched in oxygen with a 20% overetch showed definite undercutting at all pressures in this range. Samples patterned in hydrogen showed no undercutting, even when overetched more than 100%, when the etch pressure was below 0.4 torr.

The data suggest that both oxygen and hydrogen have two modes of etching. One mode, dominated by neutral radical etching, exists at high pressure and results in some horizontal etching. The second mode, one of ion-assisted etching, occurs at lower pressures and results in highly directional etching. The transition from the neutral to the ion-assisted etch mode occurs at different pressures for hydrogen and oxygen plasmas. The literature (4-6) suggests a transition pressure of about 0.02 torr for

Fig. 2. Hydrogen and oxygen etch rates for polyimide as a function of pressure.

oxygen, while this study defines a much higher hydrogen transition pressure of about 0.4 torr. Anisotropic organic etching in hydrogen, therefore, eliminates the need for sophisticated and costly vacuum equipment.

Because the etch rates in hydrogen are quite slow compared with oxygen, however, several methods for increasing the rate were investigated and are discussed below.

Hydrogen process studies.—As a first attempt to increase organic etch rates in hydrogen, elevated temperature was investigated. Studies of the oxygen ashing of organics have shown as much as tenfold increase in oxidation rate as the temperature was increased from 60° to 130°C (10, 11). Figure 3 shows that the etch rate in hydrogen, however, varies little as the temperature is increased from 30° to 125°C . An earlier study (7) of hydrogen "ashing" indicated that the organic etch rate will increase dramatically with temperature, but only if the temperature is raised above 150°C . In this application, flowing of the top resist limited the temperature to below 130°C . An Arrhenius plot of the hydrogen data in Fig. 3 yields an activation energy of less than 0.9 kcal/mol. This is less than the literature value of 2.8 kcal/mol reported for oxygen organic etching in the same pressure/temperature regime (5) and suggests that ions, which have larger kinetic energy than radicals and are thus less affected by temperature, are the primary etching species in the hydrogen plasma.

Figure 4 shows that organic etch rates in hydrogen do increase as the power density is increased. However, even at the maximum system power density, the rate was only 300 $\text{\AA}/\text{min}$. The increasing rate with increasing power may be attributed to increased reactive species production

Fig. 3. Temperature dependence of the polyimide etch rate in a hydrogen plasma.

Fig. 4. Power density dependence of various organic etch rates in a hydrogen plasma.

and/or enhanced ion bombardment energies as power is increased. From the etch rate at maximum power, and assuming a simple CH_4 etch product, it can be estimated that a hydrogen atom flux to the surface of $1.0 \times 10^{16}/\text{cm}^2 \text{ s}$ is needed to sustain etching. This should be compared to a calculated hydrogen ion flux of $6.3 \times 10^{15}/\text{cm}^2 \text{ s}$, which assumes a fairly typical hydrogen ion density of $10^{11}/\text{cm}^3$ and a flux of $1/4 n \bar{v}$. The good agreement is consistent with an ion-assisted etch mechanism.

Finally, the addition of oxygen and nitrogen to the hydrogen plasma was investigated as a means of increasing the etch rate. Figure 5 shows a linear increase in etch rate is produced as increasing amounts of oxygen are added. Unfortunately, however, the amount of undercutting also increased linearly as the oxygen percentage increased, with even samples etched in 8% oxygen displaying slight undercutting. It appears that the mixed H_2/O_2 plasmas simply produce an additive result. The faster etching, free radical-dominated oxygen etch mode is superimposed on the slower etching, ion-assisted hydrogen etch mode, with the exact results controlled by the percentage of oxygen added.

Figure 6 displays the polyimide etch rate as a function of the amount of nitrogen added to hydrogen. Interest-

ingly, the etch rate in a N_2/H_2 mixture is higher than in either constituent alone. Figure 7 compares the etch profiles for a pure hydrogen and a 17% N_2/H_2 mixed plasma. Although a straight-walled profile is observed for pure hydrogen, retrograde undercutting (where the width of the top hard mask opening is smaller than the base of the etched feature) results in the mixed N_2/H_2 plasmas. In addition, samples etched in pure nitrogen displayed straight-walled profiles, although severe etch residues made pure nitrogen etching unusable.

The reason for the retrograde profile is not well understood. Since pure nitrogen profiles showed no retrograde, the nitrogen species by themselves cannot be the cause. Scattering of the small hydrogen ion by the relatively large nitrogen species [via the model proposed by Zarowin and Gelatt (12)] also seems unlikely, since no profile changes were observed when comparable amounts of argon were added to the hydrogen plasma. The presence of a new retrograde undercutting species in these N_2/H_2 plasmas was investigated by comparing emission spectra from the various plasmas, but no new species could be identified.

Finally, surface recombination may be modified when nitrogen is added. A change in the surface recombination

Fig. 6. Polyimide etch rate as a function of the nitrogen concentration in hydrogen.

Fig. 7. Etch profiles of plasma oxide masked polyimide films patterned in a pure hydrogen (top) and 17% N_2/H_2 plasma (bottom). Both samples were given 50% overetch.

properties could result in higher surface concentrations and/or different surface diffusivities of etching species, producing retrograde undercutting. Similar "catalytic" effects, brought about by the addition of small amounts of impurities to hydrogen, have been previously reported (13).

Successful anisotropic organic etching with a hydrogen plasma involves several factors. Cathode-coupled wafer placement is essential because etching could not be initiated when substrates were placed on an anode surface. An organic coating must be placed over metallic reactor surfaces to eliminate contamination of the substrates. A pure hydrogen chemistry is required for nonretrograde anisotropic etch profiles. In the present study, 0.13 torr H_2 (which required 36 sccm) and 0.6 W/cm^2 (maximum power) gave the optimum results, yielding organic etch rates of approximately 300 \AA/min and selectivity over both thermal oxide and polysilicon of greater than 60/1. Under these conditions the etch rates of HR-100 negative and HPR-204 positive photoresist were virtually identical, with the PI2545 polyimide rate about 15% higher.

Applications.—Two applications of the hydrogen plasma etch process were investigated. In the first, a thin plasma oxide/thick polyimide (or HPR-204) structure was patterned, using an E-beam-sensitive top resist, to provide a thick organic mask for the subsequent etching of submicron polycide gate features. SEM measurements found linewidth changes of less than $0.1 \mu\text{m}$ between the top E-beam resist and the final polycide gates. No problems were encountered with the sequential etching processes themselves, although successful postetch mask removal required a brief wet etch for removal of sidewall

Table I. p-Type silicon to aluminum-Si contact resistance as a function of the interlayer dielectric and its etch technique. The total number of contacts possible on each wafer is 82

DIELECTRIC	DIELECTRIC ETCH	AFTER ETCH TREATMENT	R_s ($\Omega \mu\text{M}^2$)	STANDARD # DEVIATION	CONTACTS PER WAFER
PSG CONTROL	6:1 BHF	—	2.34	1.91	44

POLYIMIDE	H_2 PLASMA	IN SITU BACKSPUTTER	43.8	21.7	22

buildups. The sidewall build-up phenomenon is not unique to hydrogen organic etching; others have identified and similarly solved the problem for oxygen plasmas (14).

The second application involved the etching of preohmic openings in a polyimide dielectric and subsequent measurement of the silicon-to-aluminum contact resistance. Table I displays the specific contact resistance and number of ohmic contacts per wafer (out of 82 possible) for both hydrogen-etched polyimide and buffered HF-(BHF) etched PSG controls. It should be noted that alignment problems on the first PSG control accounted for its lower contact yield.

Although SEM inspection of the polyimide preohmic vias showed no obvious problems, Table I data show a definite degradation of these contacts. The contact resistance was an order of magnitude higher and the number of contacts much lower than for PSG control contacts. In addition, *in situ* premetal backspattering had little effect. The problem is a result of the polyimide dielectric rather than hydrogen plasma itself, as wet etched contacts exposed to the hydrogen plasma for 20 min (a typical overetch time) showed little degradation. Others (15, 16) have observed a similar problem for oxygen plasma etching of polyimide vias. The applicability of the oxygen-plasma solutions to hydrogen-etched contacts is currently being investigated.

Conclusions

The use of a hydrogen plasma for etching organic films has been investigated. Anisotropic etching was easily achieved, at pressures more than an order of magnitude higher than those required for equivalent anisotropic oxygen etching. A major drawback, however, is the relatively slow etch rate of less than 300 \AA/min . The hydrogen-etch temperature dependence, etch rate, and etch anisotropy are consistent with an ion-assisted etch mechanism. No unusual problems were encountered when using the hydrogen etch for trilevel patterning of a thick organic masking material. The specific contact resistance of test structures fabricated with hydrogen-etched polyimide vias, however, was much higher than wet-etched PSG controls.

The Effect of Various Encapsulants on the Electrical Properties of Implanted Layers in GaAs

V. B. Rao*,¹ and R. Y. Koyama

Tektronix, Incorporated, Semiconductor Research Department, Beaverton, Oregon 97077

ABSTRACT

Reactively sputtered silicon nitride, plasma-enhanced CVD silicon nitride, and silox have been investigated as dielectrics for the encapsulation of GaAs for the purpose of post-implantation anneal. The effect of several treatments on the GaAs surface prior to dielectric deposition was analyzed by Auger spectroscopy and ellipsometry to characterize the high temperature annealability of the encapsulated samples. An ammonium hydroxide-hydrogen peroxide etchant that leaves the surface clean and damage free was found to be the most suitable. After surface treatment and dielectric deposition, Van der Pauw devices were fabricated and carrier mobilities and sheet carrier concentrations for devices annealed at 800°C were compared. In specific cases, the electrical characteristics of devices annealed at higher temperatures (850° and 900°C) were also measured. Differences in the carrier mobilities and sheet carrier concentrations obtained, using the various dielectric films, have been explained in terms of the movement of a surface depletion layer edge closer to or away from the GaAs-dielectric interface.

Ion implantation is widely used for planar fabrication of a variety of gallium arsenide-integrated circuits (1, 2). The implantation process requires a high temperature anneal to restructure the lattice and electrically activate the implanted ions. However, the incongruent evaporation of Ga and As from GaAs at temperatures in excess of 600°C (3) makes it difficult to anneal without surface degradation. In order to inhibit decomposition of GaAs at high temperatures, it is necessary to encapsulate the GaAs samples in a suitable dielectric such as reactively sputtered silicon nitride (4), RF plasma CVD silicon nitride (5), or CVD silicon dioxide (6). Some investigations have shown that samples can also be annealed in a carefully controlled arsine overpressure (7), or by using a proximity cap (8).

Several investigations have compared the various dielectrics in terms of their effectiveness in the encapsulation of GaAs. It was found from backscattering measurements (9), low temperature photoluminescence and Auger electron spectroscopy (AES) measurements (10), and also from an XPS study on annealed SiO₂/GaAs interfaces (11) that SiO₂ films permit outdiffusion of Ga from GaAs. Such outdiffusion of Ga could result in nonstoichiometry near the GaAs-SiO₂ interface, and could significantly affect the activation of carriers during a post-implant anneal. It was also shown (9) that Ga outdiffusion through RF plasma-deposited CVD Si₃N₄ films was considerably lower than through SiO₂ films, provided that the Si₃N₄ films are relatively oxygen free. Thus, they concluded that oxygen contamination of the silicon nitride film was responsible for the pronounced Ga outdiffusion.

Most of these investigations reported on the effectiveness of the various dielectric films for encapsulation in order to maintain the chemical integrity of the GaAs substrates. However, relatively little has been reported on the

effect that these dielectrics have on the basic properties of carriers produced by the implanted ions, such as carrier mobilities (μ_n) and sheet carrier concentrations (N_s). In the present study, carrier concentrations and mobilities were measured on Van der Pauw devices, which were fabricated using reactively sputtered silicon nitride (sputtered nitride), plasma-enhanced CVD silicon nitride (plasma nitride), or CVD SiO₂ (silox). The properties of each dielectric film as an encapsulant and its influence on the activation and mobility of carriers are discussed.

The major limitation in the use of dielectric films for encapsulating GaAs is the temperature at which the samples can be annealed before they fail by cracking when the films are in tension, or blistering when they are in compression (12). During our initial annealing studies, it was observed that surface preparation of the GaAs substrates prior to plasma nitride deposition was extremely critical in preventing film failure. This suggested that, besides film stress, the high temperature annealability of these samples depended in some manner on the properties of the GaAs-dielectric interface. Therefore, a detailed characterization of several surface treatments was done using Auger spectroscopy and ellipsometry in conjunction with the annealing studies.

Experimental Procedures

Predielectric surface treatments.—The substrates used for the study were <100> oriented undoped semi-insulating LEC GaAs single-crystal wafers (2 in diam). All samples were initially degreased using trichloroethylene (boiling) and acetone, and followed by a light isopropyl alcohol scrub to dislodge any adhered particles. Each wafer was screened under an optical microscope (using dark field) for scratches and particles. They were then etched using either (i) 10 DIH₂O:1HCl followed by 100 DIH₂O:1HF; (ii) 10 DIH₂O:1NH₄OH; or (iii) 485DIH₂O:10 NH₄OH:3.5H₂O₂ as described in Table I. All etch cycles were followed by a 45s DIH₂O rinse.

Table I Different surface treatments studied

Sample	Surface treatment	Depth etched
A	1HCl:10 DIH ₂ O; 15s 1HF:100 DIH ₂ O; 15s DIH ₂ O rinse; 45s	<10Å (21)
B	1NH ₄ OH:10 DIH ₂ O; 30s DIH ₂ O rinse; 45s	<10Å (21)
C	1NH ₄ OH:10 DIH ₂ O; 60s DIH ₂ O rinse; 45s	≤10Å (21)
D	485DIH ₂ O:10 NH ₄ OH: 3.5H ₂ O ₂ ; 5s DIH ₂ O rinse; 45s	≈150Å
E	485DIH ₂ O:10 NH ₄ OH: 3.5H ₂ O ₂ ; 166s DIH ₂ O rinse; 45s	≈5000Å

The samples from one-third of the wafers that were treated as described in Table I were immediately taken for AES measurements. In all cases, survey scans were made to determine all contaminating elements. Depth profiles were then taken by using Ar sputter etching in combination with AES. The excitation voltage of 5 kV and emission current of 400 nA was maintained constant for all samples. The base pressure inside the chamber prior to Ar sputtering was 5×10^{-10} torr, and during Ar sputtering and data collection the pressure was 5×10^{-8} torr. For the depth profiles, data were collected for about 1 min prior to sputtering to ascertain that a stable situation existed.

Samples from the next third of the wafers were studied by ellipsometry using a Gaertner Model L119. Samples were etched and measured immediately so as to minimize contamination and oxide growth on the freshly etched samples. All ellipsometric measurements were made in the dark at an angle of incidence of 70° and using a wavelength of 5461Å. A photomultiplier was used as the detector, and extinction was measured at two settings of the analyzer and polarizer. ψ and δ are, respectively, the amplitude ratio and the phase difference between the incident and reflected elliptically polarized light; these are calculated from the analyzer and polarizer settings using the equations for nonideal compensators (13).

From the values of ψ and δ , the thickness of the contaminating layer over GaAs can be calculated (14) by assuming the imaginary part of the refractive index ($k = 0.304$) for GaAs and the refractive index of the film ($n = 1.90$); the film on GaAs exposed to air is believed to be gallium oxide (15) with a refractive index of 1.90. Several investigations have used the extinction coefficient (k) as a measure of the extent of crystal damage in Si (16, 17) and GaAs (18) substrates. In this study, ψ and δ values were also used to calculate the extinction coefficient and hence, imply the extent of crystal damage remaining in GaAs substrates after the various surface treatments. These calculations assume that the film thickness (over GaAs) is small and hence, can be assumed to be zero.

The remainder of the samples after being etched were immediately placed in a plasma nitride reactor for nitride deposition. Plasma Si₃N₄ films were deposited at 400°C by the RF plasma-enhanced reaction between SiH₄ and NH₃ with Ar as the carrier gas. The SiH₄/NH₃ ratio in the mixture was maintained at 0.425. The total flow rate for all gases was about 180 sccm with SiH₄ being about 5% of the total. Deposition was started when a base pressure of 2 mtorr was reached, and the pressure during deposition was about 350 mtorr; 1000Å of plasma nitride was deposited on all of these wafers at a deposition rate of 90 Å/min. The wafers were then annealed in a forming gas atmosphere (90% N₂, 10% H₂) at various temperatures between 800° and 950°C for 20 min. After annealing, the wafers were inspected for film failure using an optical microscope.

Van der Pauw device preparation and measurement.—From the results of the cleaning experiments (to be dis-

cussed later), it became evident that plasma nitride films could be annealed favorably at the elevated temperatures if a 485DIH₂O:10 NH₄OH:3.5H₂O₂ etch was used. As noted from Table I, the 166s etch removes about 5000Å of GaAs material. After degreasing (as described in the previous section), GaAs wafers were treated with this etchant prior to dielectric deposition. Either plasma nitride (1000Å), sputtered nitride (1000Å), or silox (1250Å) was deposited. Plasma nitride was deposited as described earlier. Deposition of sputtered nitride was accomplished by reactive sputtering from a pure silicon target in the presence of pure nitrogen gas. Wafers were placed on a water-cooled substrate table; the actual wafer temperature during sputter deposition was determined to be no higher than 300°C. The chamber was pumped down to a pressure of 2×10^{-6} torr or better before commencement of deposition. After admitting nitrogen gas and initiating the plasma, a 20 min presputter was done to allow the target composition to stabilize, and also to react and pump away some of the residual impurities from the chamber. The deposition rate was approximately 45 Å/min at a power density of 0.93 W/cm². CVD silox films were deposited by a reaction between SiH₄ and O₂ in the presence of N₂. The deposition rate is around 400 Å/min at a deposition temperature of 420°C.

The silox, plasma nitride, and sputtered nitride films were characterized by Auger spectroscopy and ellipsometry. It was observed that the CVD silox films are very nearly stoichiometric (*i.e.*, they are SiO₂). The index of refraction for silox is found to be 1.46 ± 0.02 . For the plasma and sputtered nitride films, the ratio of atomic concentration of Si to N is 0.90 ± 0.05 . The atomic concentration of oxygen throughout the film thickness is less than 2-3 atom percent (*a/o*) for the nitride films. The index of refraction for both the plasma and sputtered nitride films is found to be 2.01 ± 0.02 . This result shows that these nitride films are to be differentiated from silicon oxynitride, whose index of refraction is typically between 1.45 and 2.00, depending on the oxygen content (19).

Following dielectric deposition, ion implantation of ²⁸Si⁺ into the GaAs wafers was carried out at room temperature through the dielectric films, using patterned photoresist as the implant mask. The thicknesses of plasma and sputtered nitrides (1000Å), and silox (1250Å) were chosen to ensure about the same stopping power for Si ions through these films (20) and also to adequately encapsulate the wafer during the post-implant anneal. Implantation was graded in rows on any given wafer with doses that ranged from 8×10^{11} to 1×10^{13} cm⁻². The implant energy was 140 keV and the beam was incident at an angle of 7° from the normal to the wafer surface to minimize channeling effects. After implantation, the samples were annealed in a forming gas atmosphere. In most cases, annealing was carried out at 800°C for 20 min, but in two cases, annealing was performed at 850° and 900°C as well. Finally, alloyed Au-Ge-Ni was used for the ohmic contacts.

Fig. 1. Auger depth profile E (see Table I)

Sheet carrier concentrations (N_s) and Hall mobilities (μ_H) for the various implant doses were obtained from measurements made using a Hall apparatus, in which data collection and reduction was facilitated by computer control. The sheet carrier concentration (N_s), which is equal to the impurity concentration integrated over the depth of the impurity profile, was calculated from the sheet Hall coefficient. Hall mobilities were calculated from the sheet Hall coefficient and the sheet resistance. It should be pointed out that the Hall mobility measurement for an implanted layer results in an average mobility for the distributed profile. The strength of the magnetic field was 6000G. Each Van der Pauw die is 5 mm on a side, and on a 2 in. wafer there are between five and nine devices per row for each implant dose. This provides data for assessing the die-to-die uniformity of electrical properties across a wafer, for any given implant dose.

Results and Discussion

Cleaning procedures.—Table I shows the different surface preparation sequences performed on GaAs samples and the corresponding depth of material etched. The Auger spectroscopy, ellipsometry, and annealing results for each of these preparations are presented in Table II. From the Auger depth profiles for samples A through E, the a/o of C and O near the surface was obtained. It is seen from the table that the C concentration decreases consistently down the column to about 5 a/o for sample E. For sample E, the oxygen concentration near the surface was about 18 a/o. It was observed that the C on these samples was not present as a carbide, but was either elemental in nature or a hydrocarbon, as ascertained by the shape and position of the Auger peaks. In addition, this C may have been adsorbed on the surface from the atmosphere or from the cleaning solutions.

To confirm the above hypotheses, samples were exposed to an ultraviolet source (22) (in atmosphere) for about 3h, and quickly loaded into the Auger chamber. The Auger spectra did not show any traces of C. However, the oxygen concentration on the surface of these samples increased from between 17 and 20 a/o to about 37 a/o for all samples. This cleaning action by exposure to a UV source is believed to occur (22) by a complex reaction involving the interaction of surface species with photons and ozone. Certain wavelengths in the UV spectrum are absorbed by O (and causes the generation of ozone) and by hydrocarbons on the sample surface. When the C on the surface reacts and leaves, the surface becomes highly reactive and hence becomes oxidized. This explains the disappearance of C from the Auger spectra and the increase in the concentration of O. Hence, we conclude that C and O were present only on the surface of the wafers.

Figure 1 shows the Auger depth profile for the sample that had the lowest C and O concentrations on the surface (sample E). The rate of sputtering (of GaAs) for a sputtering voltage of 5 kV and an emission current density of $327 \mu\text{A}/\text{cm}^2$, was determined to be approximately $800 \text{ \AA}/\text{min}$. This rate is obviously too high to determine the thickness of the contaminating layer accurately. Since data collection was made between sputter intervals of 0.05 min, the first data point for C and O was at the surface and the next about 40 \AA below. Hence from Fig. 1, it is seen that the contaminating layer thickness is less than 40 \AA . Also, from this figure and from depth profiles for

samples A through D (not included here), the stoichiometry of GaAs near the surface of the sample is disturbed as a result of the surface treatments. There is excess As near the surface, consistent with previously reported data (23) on As "pile-up" at the interface due to HCl and NH_4OH cleaning solutions on GaAs. It should be noticed however, that below a depth of about 200 \AA , stoichiometry is again nearly restored.

From the ellipsometry data, the thickness of the contaminating film was determined as described earlier. From Table II, it is seen that the film thickness decreases consistently for samples A to E down to about 5 \AA for sample E. Although the thicknesses are approximate and could be in error (14) by $\pm 5 \text{ \AA}$, the errors are systematic. This means that the differences in the film thicknesses for the various samples are fairly precise. As noted earlier, the extinction coefficient (k) has been used as a measure of the surface damage in Si single-crystal substrates (16, 17), where the higher the extinction coefficient, the greater the degree of damage. It is seen from Table II that there is a systematic decrease in the value of the extinction coefficient for samples A through E. For sample E, the extinction coefficient of 0.329 is approaching the value of 0.304 for damage-free GaAs (24), measured at a wavelength of 5461 \AA . This is to be expected since the surface treatment used for sample E removes about $0.5 \mu\text{m}$ of material, and along with it, removes the surface damage remaining after the chem-mechanical polishing of the wafers.

From the annealing experiments, it is seen that only plasma nitride films deposited on sample E did not show any signs of failure by cracking or blistering in the temperature range of $800^\circ\text{--}950^\circ\text{C}$. All other films showed signs of failure (by blistering), although it was not possible to correlate the extent of failure with the various surface treatments. These results suggest that the combined effects of reduced surface contamination and an essentially damage-free surface (sample E) prior to plasma nitride deposition was responsible for its high temperature annealability.

Electrical measurements.—Annealing experiments on Si ion-implanted undoped semi-insulating GaAs wafers were carried out using different encapsulating dielectrics. This enabled a comparison of carrier mobilities and sheet carrier concentrations which resulted with the various dielectrics. For two specific cases, measurements were made with and without the dielectric present to understand what effect the dielectric had on the electrical properties of the devices.

Several experiments were performed with silox (1250 \AA), and plasma and sputtered nitride films (1000 \AA each) to compare the values of μ_H and N_s . As mentioned earlier, the film thickness was adjusted to achieve about the same stopping power with all films. Measurements were made with the dielectric layer remaining over the implanted layer. Figure 2 shows a comparison of the activation as a function of the implant dose for the various dielectrics. It should be pointed out that the actual scatter in the data was very small; the individual points shown in Fig. 2 average over five to nine devices for each implant dose. Also, these activations have neither been corrected for dose reduction due to implantation through the dielectric layer, nor for carrier loss due to the existence of

the depletion layer. Nevertheless, relative comparisons between the activations for the three dielectric films are still possible, and we notice from Fig. 2 that there is a significant difference in activations. The activation (for a dose of $1 \times 10^{13} \text{ cm}^{-2}$) for silox is about 40% whereas it is 22% for plasma nitride and 28% for sputtered nitride. Figure 3 shows a comparison of mobilities for the same devices. The two curves for each dielectric film bound the scatter in the mobility data. It is seen that the highest mobilities are obtained with the plasma nitride film (4300 cm^2/Vs) and the lowest with sputtered nitride (3800 cm^2/Vs), with silox being intermediate (4100 cm^2/Vs). This clearly demonstrates that the electrical properties of the implanted layers are strongly dependent on the type of dielectric used.

Onuma *et al.* (25) found that for Si implantation into Cr-doped GaAs substrates, the carrier concentration (cm^{-3}) profiles were identical for samples encapsulated with CVD SiO_2 and CVD Si_3N_4 , and annealed at 800°C. However, for higher annealing temperatures (850°-900°C), the diffusion coefficient of Si in GaAs was one or two orders of magnitude higher for SiO_2 encapsulated samples when compared to Si_3N_4 encapsulated samples. In the preceding comparison of the present study, since all samples were annealed at 800°C, we could assume that differences in N_s and μ_H for the three dielectrics may not be due to enhanced Si diffusion. A likely explanation for higher activations with silox films compared to silicon nitride could be the creation of excess Ga vacancies near the GaAs-dielectric interface. It was shown (10) that Ga outdiffusion through SiO_2 films was more pronounced than through oxygen-free silicon nitride films. As mentioned earlier, the silicon nitride films studied in the present investigation are relatively oxygen-free. Since implanted Si becomes a donor by occupying Ga sites, the higher activations for silox samples compared to silicon nitride is reasonable to expect. This would suggest (from Fig. 2) that outdiffusion of Ga from plasma nitride would be more than from sputtered nitride samples, although this has not been verified experimentally. Another possible explanation for the differences in N_s and μ_H for the three dielectric films is the difference in the stress induced by these films at the interface.

Fig. 3. A comparison of mobilities for Van der Pauw devices encapsulated and annealed at 800°C with plasma nitride, sputtered nitride, and silox.

Fig. 4. Mobility vs. sheet carrier concentration for Van der Pauw devices with and without a plasma nitride passivation.

A separate experiment was performed to compare the properties of Van der Pauw devices with and without the dielectric present. Figure 4 shows a comparison of the carrier mobilities as a function of sheet carrier concentration (and hence implant dose) for Van der Pauw devices before and after plasma nitride deposition. Only for this case, we started with devices that were fabricated by a slightly different procedure, such that there was no dielectric film present over the completed devices. Measurements were first made on these Van der Pauw devices. Then 1000Å of plasma nitride was deposited over the wafer and etched to expose only the ohmic contacts, and a second set of measurements were made. It is seen that there is an appreciable difference in mobilities, especially for the lower implant doses. The peak (average) mobility increases from about 3900 cm^2/Vs before nitride deposition to about 4200 cm^2/Vs after nitride deposition. There is also an appreciable improvement in the apparent activation of carriers as indicated by the systematic shift of the "after nitride" data points to the right. Next, the plasma nitride (from the same wafer) was carefully stripped in a parallel plate plasma etch system (0.08 W/ cm^2 , 200 mtorr, 400 Å/min), removing about 800Å, and then completely removed in 1HF:1DIH₂O. This would ensure that there is essentially no damage introduced due to the stripping process. It was observed that the mobilities and activations returned to their original values. This suggests that the mere presence of the plasma nitride over the implanted layer increases both N_s and μ_H . We believe that this behavior may be suitably explained by the movement of the surface depletion layer edge closer to or away from the interface with the addition or removal of the nitride, respectively.

A somewhat similar experiment was also performed with the sputtered nitride dielectric film. Unlike our plasma nitride deposition process (which is fairly gentle), sputtered nitride deposition introduces radiation damage. Hence, we started with devices already fabricated with sputtered nitride, which was annealed following deposition and ion implantation. When the sputtered nitride layer was carefully removed, (under conditions described earlier, but with an etch rate of 250 Å/min), there was a degradation in activations and mobilities (as it was observed for the case of plasma nitride), for all implant doses considered. However, when 1000Å of sputtered nitride was redeposited, there was a further decrease in the activations and mobilities. This latter behavior could be due to radiation damage introduced in the implanted layer due to the sputtering process and consequent movement of the surface depletion layer edge away from the dielectric interface. Because of the presence of the alloyed ohmic contacts, no attempt was made to anneal this radiation damage.

Higher temperature (850° and 900°C) annealing experiments were also performed with sputtered and plasma nitride. Figure 5 shows the activation vs. implant dose data for samples annealed at 800° and 900°C using a sputtered nitride encapsulant. It is observed that the activations are higher at the higher temperature for all implant doses considered. In Fig. 6, the mobility data for the samples

Fig. 5. A comparison of activations for Van der Pauw devices encapsulated with sputtered nitride and annealed at 800° and 900°C.

Fig. 6. A comparison of mobilities for Van der Pauw devices encapsulated with sputtered nitride and annealed at 800° and 900°C.

Fig. 7. A comparison of activations for Van der Pauw devices encapsulated with plasma nitride and annealed at 800° and 850°C.

are presented. Again, we see that the samples annealed at 900°C showed higher mobilities. The peak mobility increased from 3800 cm²/Vs at 800°C to about 4200 cm²/Vs at 900°C. When similar experiments were performed with plasma nitride, however, there was an opposite trend. From Fig. 7 we see that the activations were considerably lower for the 850°C anneal (compared to 800°C) and that for the lower implant doses (< 4 × 10¹² cm⁻²) there was no activation. There was very little difference in the mobility characteristics of the devices annealed at 800° and 850°C. When samples were annealed at 900°C, there was no activation even for the highest implant dose considered (1 × 10¹³ cm⁻²). This difference in behavior of the sputtered and plasma nitride encapsulants, it not clearly understood at the present time. However, a reasonable explanation could be based on outdiffusion of Ga or As from the interface at the elevated temperatures. In this case, the implanted Si ions could occupy either Ga or As sites, and this results in an increase or decrease in activation, respectively. Also, there may be differences in the stress induced by the dielectric films, which could lead to a difference in the enhanced diffusion of the implanted ions in the GaAs substrate.

Conclusions

It has been shown from AES and ellipsometry studies that surface preparation of GaAs samples prior to plasma nitride deposition is critical to their high temperature annealability, and that a clean and damage-free surface prior to deposition is essential. Hall measurements on devices which were encapsulated with plasma nitride, sputtered nitride, and silox, and annealed under the same con-

ditions resulted in different sheet carrier concentrations and mobilities for a given implant dose. This may be due to (i) interdiffusion of impurities, (ii) different stresses induced by the films, or (iii) different depletion layer thicknesses. A separate experiment and measurements show that the presence of plasma and sputtered nitride over the implanted layer improves the electrical characteristics of the devices. This behavior was explained in terms of the movement of a surface depletion layer edge closer to or away from the interface. Finally, we observed increased mobilities and activations with a sputtered nitride encapsulation at 900°C, when compared to 800°C. On the other hand, we saw decreased activations at 850°C for plasma nitride encapsulated samples and no activation at 900°C. This may be due to outdiffusion of Ga or As and excess compensation, or to differences in stresses.

Interface States and Fixed Charges in MNOS Structures with APCVD and Plasma Silicon Nitride

R. Hezel, K. Blumenstock, and R. Schörner

Institut für Werkstoffwissenschaften VI, Universität Erlangen-Nürnberg, D-8520 Erlangen, Germany

ABSTRACT

The net positive charge density Q_N/q and the interface state density D_{IT} of MNOS structures on p-Si (100) with APCVD and plasma silicon nitride is studied as a function of the nitride deposition temperature and the postdeposition annealing temperature. For APCVD silicon nitride, a decrease of Q_N/q is accompanied by an increase of D_{IT} with increasing deposition and annealing temperature. Electron irradiation (30 keV and 5×10^{-5} C/cm² dosage) did not affect Q_N/q , whereas D_{IT} was increased for nitride films deposited below 800°C. For plasma silicon nitride, both Q_N/q and D_{IT} decreased with deposition and annealing temperature up to 450°C. Very low interface state densities (8×10^9 cm⁻² eV⁻¹) could be achieved. These low D_{IT} values are due to the influence of hydrogen incorporated in the PECVD silicon nitride films. Very high positive charge densities ($>10^{13}$ cm⁻²) could be obtained by cesium contamination of the plasma nitride films.

Pyrolytic chemical vapor deposited (CVD) silicon nitride films are widely used as active layers in microelectronics, e.g., as gate dielectric in nonvolatile memory elements. The performance of these metal-nitride-oxide-silicon (MNOS) devices is strongly dependent on the density of fast interface states and fixed insulator charges (1-3).

Plasma enhanced CVD (PECVD) silicon nitride films are almost exclusively applied for final passivation of semiconductor devices. There is, however, growing interest in using plasma Si nitride as an electrically active layer. It appears to be promising as dielectric for high efficiency silicon inversion layer solar cells (4, 5), as well as for amorphous silicon thin film transistors for application as switching elements in large area displays and imaging arrays (6, 7). In both cases, the properties of the plasma Si nitride/silicon interface, such as the fixed nitride charges and the fast interface states, are of great importance. However, no data about these quantities are available in the literature up to now. For the case of inversion layer solar cells, a high density of fixed positive insulator charges in conjunction with a low interface state density is required in order to obtain a highly conductive inversion layer (8, 9). In contrast to MOS devices, where a correlation between the fixed oxide charges and the interface states was found (10), for MNOS structures with atmospheric pressure CVD (APCVD) Si nitride, some data pointing to an inverse behavior were already reported by us (11, 12).

In the present work the grown-in fixed charges (density Q_N/q) and the fast surface states (density D_{IT}^* at midgap) have been investigated as a function of the nitride deposition temperature and after postdeposition heat-treatment in nitrogen.

The studies were performed on Al/Si nitride/thin Si oxide/p-Si (100) structures with APCVD as well as with PECVD Si nitride; the different behavior of these dielectric films will be outlined. Particularly for the case of plasma Si nitride on silicon, where very low interface state densities could be achieved, the crucial role of hydrogen is discussed. The effect of cesium contamination of the plasma Si nitride films on the interface properties, as well as the influence of electron irradiation, was also studied in this work.

Experimental

The MNOS structures were fabricated in the following way. Chemically mechanically polished (CZ) p-Si (100) 2 Ω cm substrates were cleaned in trichlorethylene, acetone, 1% HF, NH₄OH-H₂O₂, and HCl-H₂O₂ solutions. The thin oxide preparation was performed at 525°C for 15 min in a dry O₂/N₂ atmosphere resulting in a thickness of 1-1.3 nm, as measured by ellipsometry ($\lambda = 632.8$ nm). Oxides

Key words: plasma silicon nitride, MNOS, interface states, insulator charges.

prepared in this way are also used by us for tunnel MIS diodes (5), and an extensive characterization of these films is given elsewhere (13). Immediately after the oxide formation, the silicon nitride films of 1000 nm thickness were deposited either by APCVD or PECVD. The gases used in both cases were 2% SiH₄ (diluted in Ar) and 100% NH₃. APCVD films were deposited in a hot-wall reactor with a SiH₄/NH₃ ratio of 1:500 at temperatures ranging from 620° to 900°C. A capacitively coupled parallel-plate reactor with radial gas flow was used for the fabrication of the plasma nitride films. The RF (30 kHz) power was 11W, and the SiH₄/NH₃ ratio was 1:25 at a pressure of 1.2 mbar. The deposition temperature ranged from 210° to 270°C. Finally, aluminum contacts were evaporated from a heated tungsten boat.

The refractive index, measured by ellipsometry, was $n = 1.90 \pm 0.03$ for the APCVD Si nitride films and $n = 1.88 \pm 0.02$ for the PECVD Si nitride films. Electron irradiations at 30 keV and a dose of 5×10^{-5} C/cm² of the capacitors with APCVD Si nitride were performed in a scanning electron microscope. The cesium contamination was accomplished by spinning an alcoholic solution of CsCl (10^{-4} mol CsCl/l) onto the wafer prior to the nitride deposition. Good uniformity of the charge density across the wafer was obtained in this way. No special oxide was grown before the CsCl deposition.

High frequency and quasistatic C-V measurements were performed in order to determine the density of fixed insulator charges and interface states. The high frequency (1 MHz) capacitance (C_{HF}) and the low frequency capacitance (C_{LF}) were recorded simultaneously with a measurement system described elsewhere (14). The rate of the linearly increasing voltage ramp was between 5 and 50 mV/s. In order to avoid possible effects of charge injection from silicon into the Si nitride on the interface state density D_{IT}^* at midgap, the curves were recorded starting from inversion towards accumulation, since charge injection occurs only at voltages smaller than the flatband voltage.

Results and Discussion

APCVD silicon nitride.—In Fig. 1, the fixed charge density (graph a) and the midgap interface state density (graph b) of MNOS structures prepared by depositing APCVD Si nitride on the thin oxide on silicon is shown as a function of the nitride deposition temperature. The results obtained after a postdeposition heat-treatment at 900°C for 30 min in nitrogen as well as after electron irradiation with a beam energy of 30 keV and a dose of 5×10^{-5} C/cm² are also included in Fig. 1. As can be seen from Fig. 1a, the fixed charge density Q_N/q decreases with increasing nitride deposition temperature from 4.3×10^{12} cm⁻² at 620°C down to 5×10^{11} cm⁻² at 900°C. Almost the same low value of Q_N/q is obtained after annealing at 900°C of a nitride film deposited at 650°C. The insensitiv-

Fig. 1. Fixed charge density (a) and midgap interface state density (b) of MNOS structures [Al/100 nm APCVD Si nitride/native oxide/p-Si (100)] as a function of the deposition temperature. The effects of annealing at 900°C and irradiation with 30 keV electrons (dose $D = 5 \times 10^{-5} \text{ C/cm}^2$) are also shown.

ity of the fixed nitride charges against electron irradiation is clearly demonstrated for the whole deposition temperature range. This confirms earlier results obtained by us (12, 15). For the decrease of Q_N/q with deposition and annealing temperature, a correlation with the decomposition of Si-H and N-H bonds was found (3, 11).

The values of the interface state density (Fig. 1b) range from 4×10^{11} to $6 \times 10^{11} \text{ cm}^{-2} \text{ eV}^{-1}$ in the deposition temperature range 620°–720°C, whereas a remarkable increase of D^*_{IT} occurs at higher deposition temperatures. A drastic increase of D^*_{IT} is obtained after annealing a nitride film at 900°C which was deposited at 650°C. A nearly constant high value of the interface state density ($D^*_{IT} \sim 2 \times 10^{12} \text{ cm}^{-2} \text{ eV}^{-1}$) resulted after electron-beam irradiation of the MNOS structures with nitride films grown at different temperatures. Thus, as a main result in Fig. 1b, the

same high value of the interface state density is obtained in MNOS structures with APCVD Si nitride either by depositing the films at temperatures above 800°C or by annealing at high temperatures as well as by electron irradiation.

It is known that Si-H bonding, particularly, in APCVD Si nitride decreases considerably with increasing deposition temperature (16). The observed variation of the interface state density with deposition temperature may therefore be attributed to a loss of chemically bound hydrogen creating unsaturated silicon bonds. A similar decomposition of Si-H and N-H bonds (17) and the formation of dangling silicon bonds is made responsible for the observed increase of D^*_{IT} after annealing. The increase of D^*_{IT} after electron irradiation is attributed to bond breaking at the silicon/insulator interface.

Pyrolytic CVD Si nitride, and particularly Si oxynitride, is known to be resistant against ionizing radiation (18, 19). According to our results, this fact must be restricted to nitrides deposited or annealed at temperatures above 800°C. It is not clearly understood why the interface states but not the fixed charges of the low temperature APCVD Si nitrides are affected by electron irradiation. It should be noted in this context that the fixed grown-in charges in MNOS structures are located some nanometers away from the silicon surface in a region of Si nitride or Si oxynitride (12).

It was clearly established by depth profiling of a MNOS structure using a combination of Auger electron spectroscopy and low energy electron energy loss spectroscopy in our laboratory that the Si oxide, originally present at the silicon surface, was transformed into Si oxynitride during the Si nitride deposition at 800°C (12, 20).

From Fig. 1, the general conclusion can be drawn that no correlation exists between the fixed charges and the fast interface states in MNOS structures with APCVD Si nitride.

PECVD silicon nitride.—In MNOS structures with plasma Si nitride in the as-deposited state, charge injection occurs already at voltages slightly more negative than the flatband voltage. This is demonstrated in Fig. 2a by the high and low frequency C-V curves obtained for capacitors with plasma Si nitride films 100 nm thick deposited at 270°C. Even after recording the C-V curves up to -8.5 V , which is only 3.5V below the flatband voltage, a hysteresis of 1V is observed. In contrast to MNOS structures with APCVD Si nitride, the very poor charge retention properties of as-deposited plasma Si nitride are reflected, particularly in the different shapes of both the C_{HF} and C_{LF} curves measured before (solid lines) and after (broken lines) accumulation was reached. The interface state density was in all cases determined from the initial C-V curves (solid lines in Fig. 2a).

Fig. 2. High and low frequency C-V curves of MNOS structures [Al/100 nm PECVD Si nitride/1.2 nm Si oxide/p-Si (100)] of the as-deposited state (Fig. 2a, left) and after annealing at 500°C in N₂ (Fig. 2b, right). The plasma Si nitride was deposited at $T_N = 270^{\circ}\text{C}$.

Drastic changes of the interface properties were obtained after annealing the plasma nitride films at temperatures above their deposition temperature. The hysteresis is strongly reduced after annealing the samples above 450°C. This is demonstrated in Fig. 2b by the C-V curves of a MNOS structure with plasma Si nitride deposited at 270°C and annealed at 500°C. Lowering of both the fixed charge density and the interface state density occurring by annealing can also be seen from Fig. 2b. This important behavior was studied in more detail, and the results are presented in Fig. 3. The charge density (Fig. 3a) and the interface state density (Fig. 3b) are plotted as a function of the postdeposition annealing temperature. The films were deposited at 210°, 240°, and 270°C, respectively. As can be seen from Fig. 3a, the fixed charge density Q_N/q drops from 6.6×10^{12} to 2.8×10^{12} cm⁻² by increasing the deposition temperature from 240° to 270°C. By postdeposition annealing, the Q_N/q values are reduced. For annealing temperatures above 430°C, a nearly constant fixed charge density of about 1×10^{12} cm⁻² was obtained for all deposition temperatures.

For the midgap interface state density D_{IT}^* of the as-grown films, as shown in Fig. 3b, the same value of 2×10^{12} cm⁻² eV⁻¹ was obtained at deposition temperatures of 210° and 240°C, whereas $D_{IT}^* = 1.7 \times 10^{11}$ cm⁻² eV⁻¹ resulted for films grown at 270°C. By annealing these films at temperatures up to 500°C, a decrease of the interface state density by about two orders of magnitude occurred. At annealing temperatures between 450° and 500°C, minimum values of D_{IT}^* were obtained which increase with decreasing deposition temperature. Very low midgap interface state densities of 8×10^9 cm⁻² eV⁻¹ could be achieved for films deposited at 270°C and annealed at 500°C. A strong increase of D_{IT}^* up to 7×10^{11} cm⁻² eV⁻¹ occurred by annealing the plasma nitride films at temperatures up to 700°C.

For comparison, the interface state density of the MNOS structure with a plasma nitride film deposited at 270°C and annealed at 500°C was measured by CC-DLTS (21). As shown in Fig. 3b, $D_{IT}^* = 9 \times 10^9$ cm⁻² eV⁻¹ was obtained, which is in good agreement with the value determined by the quasistatic technique. In Fig. 4, the

Fig. 3. Fixed charge density (a) and midgap interface-state density (b) of MNOS structures with plasma Si nitride as a function of the postdeposition annealing temperature. The nitride films were deposited at 210°, 240°, and 270°C. The midgap interface-state density of a MNOS sample ($T_N = 270^\circ\text{C}$, annealed at 500°C) was also determined by CC-DLTS.

Fig. 4. Interface state density of a MNOS structure with plasma Si nitride as a function of the bandgap energy determined by the quasistatic C-V technique and CC-DLTS. The corresponding C-V curves are shown in Fig. 2b.

interface state density of this sample is shown as a function of the energy in the silicon bandgap, determined by the quasistatic C-V technique, as well as by CC-DLTS. As can be seen, the results obtained by the two techniques are in good agreement.

In the following, the results presented in Fig. 3 will be discussed. The high interface-state density of PECVD Si nitride films in the as-grown state (Fig. 3b) is attributed to unsaturated bonds at the silicon/insulator interface, resulting from incomplete bonding, which may be enhanced by electron and ion bombardment during the plasma-deposition process. It is known that a high amount of hydrogen is incorporated into the plasma Si nitride films (22). It is further known that annealing of the films in nitrogen at temperatures up to 500°C leads to a decomposition of N-H bonds, whereas the amount of Si-H bonds increases slightly. By heat-treatments at temperatures above 500°C, however, both N-H and Si-H centers are lost (23). It is reported for the Si/SiO₂ system that the formation of silane groups at the interface at annealing temperatures ranging from 300° to 500°C is responsible for the passivation of the interface states (24). Hence the strong decrease of the interface state density at annealing temperatures up to 500°C is attributed to the saturation of unsaturated bonds at the silicon surface by hydrogen originating from N-H bonds in plasma Si nitride. The loss of chemically bound hydrogen at annealing temperatures above 500°C is assumed to be responsible for the observed increase of the interface state density. This latter behavior is in analogy to that of APCVD Si nitride films, as discussed above.

About the nature of the fixed positive charges in plasma Si nitride, no information is available in the literature. Whereas for APCVD Si nitride a correlation between the charges and hydrogen bonding in the films was suggested (3, 11), the data presented in Fig. 3a for plasma nitride do not clearly indicate such a correlation. Although the decrease in N-H bonding (23) parallels a decrease in the fixed charge density after annealing at temperatures up to 500°C, a correlation of these two quantities cannot be established in the present state.

From the common decrease of the fixed charge density and the midgap interface state density with annealing temperatures of up to 450°C, as demonstrated in Fig. 3, at least in this temperature region some relationship between Q_N/q and D_{IT}^* may exist.

Cesium contamination of PECVD silicon nitride films.—It was demonstrated recently for APCVD Si nitride on silicon that the density of positive nitride charges can be drastically increased by the incorporation of alkaline ions (25). In order to obtain very high and stable positive charge densities in plasma Si nitride on silicon

Fig. 5. Influence of cesium contamination of MNOS structures with plasma Si nitride upon the insulator charge density. The C-V curves before (curve a) and after (curve b) cesium contamination are shown in the insert.

in this work, the films were heavily contaminated with cesium by spinning an alcoholic solution of CsCl onto the native oxide on silicon prior to the nitride deposition. In Fig. 5, the nitride charge density is plotted as a function of the cesium concentration up to a level of $2 \times 10^{15} \text{ cm}^{-2}$. As can be seen, the insulator charge density increases with increasing cesium concentration until, at a contamination level of about $8 \times 10^{14} \text{ cm}^{-2}$, saturation is reached. In all cases, only a fraction of the amount of cesium deposited is electrically active as positive insulator charge. The saturation charge density was found to be dependent on the plasma-deposition parameters, but no systematic investigations have been performed. It could be shown that peak values of the nitride charge density up to $2.2 \times 10^{13} \text{ cm}^{-2}$ can be achieved for a cesium contamination level of $2 \times 10^{15} \text{ cm}^{-2}$.

In the insert in Fig. 5, the high frequency C-V curves of both the uncontaminated MNOS capacitor with plasma Si nitride (curve a, $V_{FB} = -7.7 \text{ V}$, $Q_N/q = 3.8 \times 10^{12} \text{ cm}^{-2}$, nitride thickness = 72 nm) and the corresponding one with a cesium contamination of $2 \times 10^{15} \text{ cm}^{-2}$ (curve b, $V_{FB} = -30.5 \text{ V}$, $Q_N/q = 1.5 \times 10^{13} \text{ cm}^{-2}$) are shown. No ion hysteresis was observed at room temperature for gate fields up to insulator breakdown, indicating that these charges are immobile in the nitride film. The interface state density of the Cs-doped samples could not be determined by the standard quasistatic C-V technique due to high leakage currents occurring as a consequence of the extremely high flatband voltages. However, it can be qualitatively deduced from the shape of the C-V curves that the additional charges introduced in the Si nitride film by the cesium contamination neither give rise to a significant amount of additional surface states nor cause large surface-potential fluctuations due to inhomogeneous charge distribution. This behavior is in contrast to that of alkaline ions in MOS structures. For comparison, corresponding samples with pyrolytic CVD Si oxide films deposited on silicon by the silane oxygen reaction at 650°C were coprocessed with the MNOS structures. Similar to the results obtained recently by us for sodium contamination (25), the C-V curves of the cesium-contaminated MOS samples were displaced towards negative voltages, and they were extremely distorted and showed a pronounced ion hysteresis at room temperature.

The thermal stability of the cesium-induced charges in plasma Si nitride was investigated by annealing the samples in a nitrogen ambient at temperatures up to 500°C . The results are shown in Fig. 6. At temperatures below the nitride deposition temperature of 260°C , no degradation of the charge density occurred. Above the

Fig. 6. Effect of N_2 annealing on the insulator charge density of plasma Si nitride MNOS structures contaminated with cesium.

deposition temperature, the charge density decreases with annealing time. Still, a charge density of about $8 \times 10^{12} \text{ cm}^{-2}$ was present in the contaminated structures after 1h annealing at 500°C . The shape of the C-V curves was not significantly changed by this heat-treatment.

It could be further verified that before and after annealing the charges were located near the silicon insulator interface and that no ion migration occurred during the heat-treatment (9). The charge decay is assumed to be either due to the neutralization of positive charges or to a partial compensation of the positive charges by the creation of negative charges (11).

Conclusions

In this work, MNOS structures with APCVD and plasma Si nitride have been investigated with respect to the fixed positive insulator charge density Q_N/q and the midgap interface state density D^*_{IT} . For APCVD Si nitride no correlation could be established between Q_N/q and D^*_{IT} , since with increasing nitride deposition temperature a decrease of Q_N/q and an increase of D^*_{IT} occurred. With plasma Si nitride for postdeposition annealing temperatures up to 450°C , a common decrease of Q_N/q and D^*_{IT} was found, whereas at higher temperatures D^*_{IT} increases again and Q_N/q remains constant. The origin of the fixed charges is unknown for both nitride films; only some correlations between Q_N/q and hydrogen bonding in these films are possible. The dependence of the interface state density upon deposition and annealing temperature, respectively, can be interpreted by the influence of hydrogen bonded to silicon and nitrogen. Due to hydrogen passivation of unsaturated silicon bonds, very low values of D^*_{IT} ($8 \times 10^6 \text{ cm}^{-2} \text{ eV}^{-1}$) could be achieved for plasma nitride films deposited at 270°C and annealed at 500°C . This low interface state density, together with a moderate fixed charge density, makes the low temperature plasma Si nitride films suitable for an application as active layers in semiconductor devices. For high efficiency inversion layer solar cells, extremely high charge densities can be obtained by cesium contamination of the plasma nitride layers.

ABSTRACT

Rice hulls are a relatively high-volume, low-cost by-product commodity which contains the two basic components needed to produce silicon: silica and carbon. Impurity analyses have indicated that rice hulls from various sources are compositionally similar and that they have low concentrations (10-20 ppmw) of aluminum and iron, the major impurities in conventional raw materials used to prepare metallurgical silicon. The levels of the major impurities (Ca, K, Mg, and Mn) in rice hulls can be reduced by about a factor of 100 to around 20 ppmw by hot hydrochloric acid leaching. The doping impurities boron and phosphorus, important in silicon intended for solar cells, were less affected by acid leaching. Their concentrations were found to be 1 and 40 ppmw, respectively, in leached hulls. Coking of unpurified rice hulls produced a material with a C:SiO₂ ratio of about 4:1. An increase in concentrations of some impurities was noted since coking results in about a 67% loss in sample weight. The coked hulls were extruded with sucrose as a binder to produce 5 mm diam pellets with an average bulk density of about 800 g/l. The pellets gave favorable changes in bulk density and compression strength with increasing percentage sucrose. The abrasiveness of silica caused die wear in the extruder, resulting in roughly a doubling of the original concentration of iron in the coked hulls. Coked rice hull pellets showed excellent reactivity for producing silicon. Laboratory tests employing the reaction of silicon monoxide with carbon in the pellet showed very high reactivities for both purified and unpurified materials. A test in a small arc furnace of unpurified material showed energy consumption per unit weight of silicon to be about 15%-30% lower than normal. Unpurified rice hulls were used for these tests. Although the silicon produced in the arc furnace test was contaminated, estimates of silicon purity attainable from coked hulls, unpurified and purified, indicate their potential as raw materials for the production of MG-Si and solar-grade silicon.

The impetus for this work arose from the need to produce a grade of silicon pure enough for fabrication into solar cells and low enough in cost so that photovoltaic energy can be competitive with conventional energy sources. Metallurgical-grade silicon (MG-Si) of about 99% purity is produced by an arc-furnace process in the western world at an annual rate of about 400,000 tons (1). Even though MG-Si can be upgraded considerably during a series of purification steps (2), the concentration of boron cannot be substantially reduced while maintaining silicon in its elemental form. Since boron in excess of about 0.4 part per million by weight (ppmw) results in an unacceptable decrease in the conversion efficiency of silicon solar cells (3), various research programs have focused on reducing the level of impurities introduced into the arc furnaces through use of higher purity raw materials (2, 4, 5, 6).

This paper discusses the potential use of rice hulls, or rice husks, as they are also called, as a raw material

source for preparing silicon. As will be seen later, raw rice hulls could be of interest for the production of MG-Si, while purified rice hulls might be suitable for producing a higher quality of silicon such as a solar grade.

Numerous reports on the composition, properties, and intended uses of rice hulls have appeared since 1871. References (7) and (8) summarize the status of this by-product commodity, for which new markets are still being sought to utilize the annual production capacity. Because of this excess supply, rice hulls can be purchased at a large-volume cost of around \$22/ton. It has been calculated that the yearly U.S. harvest of rice, 2% of the world total, generates sufficient hulls for potential recovery of about 100,000 tons of silicon (9).

Burning of rice hulls leaves an ash that consists mainly of silica with about 5% impurity oxides. Singh and Dhindaw reported that the silica structure is not quartz, but is rather an active form of silica that might be more easily reduced to silicon (10). They proposed use of the ash as the silicon feed stock for an arc-furnace process for producing solar-grade silicon. However, since the rice

* Electrochemical Society Active Member.

hull contains only about 20% silica ash, the ash is not cost competitive with quartzite sources used for MG-Si production.

The purification of rice hulls using various acid leaching solutions has been reported previously (9, 11). Purified hulls were pyrolyzed (coked) to produce a product containing an atomic-to-molecular ratio of C:SiO₂ of about 4:1. It was suggested that this material, together with pure quartz, be used as feedstock for the carbothermic reduction process to produce silicon. Since the rice hull contains 15% fixed carbon, it is cost competitive with commercial reductants used to produce MG-Si. A method for adjusting the C:SiO₂ ratio to lower values by controlled combustion was also detailed. The procedure can provide carbon-free silica or a mixture having a 2:1 C:SiO₂ ratio required by the reaction

This paper reports on the leaching of rice hulls, their conversion into pellets, and the reactivity of these pellets. Suggestions are made for further investigations.

Raw Rice Hulls

Samples of raw rice hulls from different parts of the world were analyzed to determine whether or not significant differences in impurity concentrations exist. Good agreement was found between the results of the two analytical techniques that were used: optical-emission and spark-source mass spectrometry. Table I shows that rice hull samples from the U.S. (Arkansas and Louisiana), Japan, and Malaysia¹ are very similar in composition. Low variation of impurity composition with source has also been observed for tree wood (12). The unusually high concentrations reported in one case each of Al, Fe, P, and S may be attributable to the analytical technique, since these high values were not observed in samples of the same rice hulls that had been processed as indicated below. Table I also gives the average rice hull analysis for later comparison.

Rice Hull Purification

Compositional analysis has been reported for rice hulls leached with boiling solutions of concentrated hydrochloric acid and deionized (DI) water in HCl/H₂O ratios of 1:1 and 1:3 (9, 11). Anticipating material-of-construction problems in a pilot plant; acid leaching tests were carried out at a lower temperature and in more dilute acid solution. Raw rice hulls, ground to -20 +80 mesh, were acid leached under conditions indicated in Table II. The samples were subsequently washed with DI water, dried, and analyzed.

Leaching for 15 min under boiling conditions at a 1:10 HCl:H₂O ratio was just as effective for purification as leaching with more concentrated acid solutions. However, leaching for 5h at 50°C with a 1:10 solution did not reduce impurity concentrations to levels as low as those attained under boiling conditions.

*Other impurities <1 ppmw.

Three of the raw rice hull samples from different sources (see Table I) were acid leached for 15 min in boiling 1:10 hydrochloric acid solution. As might be expected, the impurity levels in the acid leached hulls were similar (see Table III). Ca, K, Mg, and Mn were reduced by factors of 40-100 times, and Na, P, and S by factors of 3-8. Their average composition is given in Table III.

One commercial source of acid-leached rice hulls was investigated. Quaker Oats Company produces furfural by the acid extraction of rice hulls using H₃PO₄ and waste H₂SO₄. The waste by-products hulls, called "residue," are burned by Quaker Oats for their energy value. A sample of moist "residue" was washed with DI water, dried, and analyzed. The results in Table IV show that this product is more impure than the average leached hull sample listed in Table III. However, the impurities present at considerably higher concentrations are the ones that vaporize and are removed in exhaust gases during the arc-furnace production of silicon and its subsequent recrystallization. Therefore, this commercial by-product is a potential source of purified rice hulls for silicon production.

Rice Hull Coking

Ground rice hulls, unleached and leached, were coked in 1 liter (~400g) quantities in a quasifluidized-bed reac-

tor constructed from a 45 × 10 cm diam quartz tube. The reactor was continuously purged with nitrogen at ~1 l/min. The system was heated to 500°C until heavy smoke evolution, from the decomposition of organic compounds, began to decrease (~30 min). The reactor was then heated to 800°C, and coking was considered to be complete when smoke evolution was no longer visible (~15 min). A weight reduction to one-third of the original value was observed: approximately 65% of raw rice hulls are converted to volatiles during pyrolysis.

Samples of acid leached rice hulls from various sources (see Table I) were coked and analyzed. The results in Table V show that impurity concentrations in leached/coked hulls are, on the average, similar to those in their leached-only precursors. Five of the eleven measurable impurities increased in concentration (see Table VI for comparison). A three-fold increase is expected if all of an impurity remains, while the matrix weight decreases by a factor of three during coking. Of the only remaining impurities, the concentration of two remained the same (Ca and P), while that of B, Fe, and Ti actually decreased. When potassium is excluded from consideration, the maximum average of any impurity in the coked hulls does not exceed 50 ppmw. If one further excludes those impurities that are lost during subsequent high-temperature processing, the total impurity concentration is only about 100 ppmw. A further lowering of impurity concentrations has been reported when hydrogen chloride gas is used during coking (9, 11).

When no prior leaching was used, somewhat different results were obtained when comparing impurity concentrations of coked hulls to that of their precursor. Table VI shows that Al, Mg, and Mn concentrations increase by about the same amount as they did for the leached/coked hulls. However, an actual reversal was noted for B, Fe, and Ti, while a large decrease was observed for phosphorus. More in-depth investigations are required to explain these differences. It should be noted that raw rice hulls have a total impurity concentration about 30 times greater than that of leached hulls.

Table VI also provides a convenient comparison of the change in impurity concentrations going from raw → leached → coked rice hulls and from raw → coked hulls.

Pelletization of Coked Hulls

Raw materials used for the production of silicon in an arc furnace must have sufficient mass so as not to be entrained in the large by-product stream of gases leaving the surface of a furnace. Due to the small size and low bulk density of coked rice hulls, it is necessary to agglomerate them prior to smelting in an arc furnace.

Extrusion pelletization tests were carried out by California Pellet Mill Company in a Model CL Laboratory pellet mill with the goal of producing strong pellets of minimum density (Fig. 1). Strength is required to prevent premature pellet disintegration in an arc furnace, whereas low density is directly related to raw material reactivity for producing silicon. Coked rice hulls were mixed with water as a lubricant and sucrose as a binder. Sucrose was chosen because of its purity and its ability to enhance the reactivity of activated carbon and carbon black during smelting tests in a 100 kW arc furnace (4). Sucrose content of dry pellets was determined by heating them to 300°C under nitrogen and measuring the weight loss due to water evolution during the decomposition of sucrose. No change in pellet size due to sucrose decomposition could be measured. Table VII shows pellet density and relative strength as a function of sucrose content for 8 × 5 mm diam cylindrical pellets. Favorable changes in both physical properties occur with increasing sucrose content. Pellets containing 17% sucrose gave adequate strength at minimum sucrose cost. Bulk densities in the 800 g/l range were measured.

Pellet composition was measured to determine the effect of the abrasiveness of the silica in coked rice hulls upon the pelletizer die. Analysis showed an increase in iron concentration from 200 to 500 ppmw (see "Coked only" analysis in Table VI). No other change in impurity concentration was measurable.

Based upon the data above and upon laboratory reactivity measurements (see next section), approximately 100 kg of 13 × 10 mm diam pellets containing 17% sucrose were produced in a Model CM pellet mill at California Pellet Mill Company. Coked hulls were prepared by Exxon Enterprises, Materials Division (Greer, South Carolina) from -20 +80 mesh, unleached, Louisiana rice hulls. The reactivity of these pellets was tested in an arc furnace, as described in the next section.

Pellet Reactivity

Unleached/coked pellets, designated as CRP in Table VII, were tested by SINTEF (Trondheim, Norway) for their reactivity. The test, as originally devised, consists of passing a SiO/CO gas mixture of known composition through a bed of carbon and measuring the CO content of the exit gas (13). Reactivity of the carbon is measured in milliliters of SiO: a low volume of SiO exiting the bed implies that a large percentage of it reacted with the carbon reductant according to the reaction

Ti	8	2

Since the rice hull pellets contain both carbon and silica, it was necessary to prereact the silica at 1500°C in a graphite cylinder purged with argon. Treatment was discontinued when carbon monoxide evolution was no longer appreciable due to reaction $\text{SiO}_2 + 3\text{C} \rightarrow \text{SiC} + 2\text{CO}$. The reactivity of the remaining carbon was then measured in the usual manner, as described above.

The reactivity of samples CRP-1, CRP-2, and CRP-3 were 272, 206, and 255 ml SiO, respectively. These are the lowest values ever measured by SINTEF. Similar results were obtained for purified coked hulls. As a comparison, the reactivity of typical commercial reductants for the production of MG-Si lie within the range 850-1600 ml SiO, while that of reactive charcoals varies from 300-1000 ml SiO.

The 100 kg batch of pellets, described in the previous section, was smelted in a 50 kW, one-electrode arc furnace (14). Since the analyzed pellets had an atomic-to-molecular ratio of $\text{C}:\text{SiO}_2 = 3.7$, the balance of the SiO_2 was supplied by adding chunks of pure quartz in order to adjust the total raw material ratio close to its stoichiometric value of 2.0. Furnace operation was excellent during the short 23h test, which produced 35 kg of silicon. Energy consumption of 20.9 kWh/kg was very low for this furnace. Energy utilization in the 50 kW furnace is normally 25-30 kWh/kg for commercial raw materials used to prepare MG-Si.

The arc-furnace experiment was performed primarily to test the reactivity of the coked pellets. Pure smelting conditions could not be used. However, an estimate of an impurity concentration in silicon can be made from its published recovery factor, which is the fraction of the impurity in the raw materials that ends up in silicon (15). Recovery factors, obtained from commercial-scale operation, were applied to the "Coked only" and "Leached/coked" analyses in Table VI to project impurity level as listed in Table VIII for two grades of silicon. "Coked only" hulls have the potential of producing silicon with impurities 1-2 orders of magnitude lower than those in commercial MG-Si. "Leached/coked" hulls are definitely of interest for solar-grade silicon. Since the P/B ratio exceeds 10, however, eventual fabrication of n/p solar cells would require development of a process to substantially reduce the concentration of phosphorus.

Conclusions

Extruded pellets of coked rice hulls, with sucrose as a binder, were shown by two techniques to be very reactive

raw materials for the production of silicon using submerged-electrode, arc-furnace technology. A short duration arc-furnace experiment using these pellets resulted in the lowest energy consumption ever measured in this furnace. Silicon from the experiment was contaminated, but projections indicate that the purity should far exceed that of commercially available MG-Si.

The coked hulls were pelletized in pilot-scale equipment for which commercial-size equipment already exists.

Acid leaching of rice hulls was demonstrated to produce a much purer coked material than that used in the furnace test just described. Although sufficient raw material was not available to make a smelting test, it can be projected that an acid-leached and coked product is of interest as a raw material for the production of solar-grade silicon. A source of suitably acid-leached hulls may be available as a by-product from a commercial process used by Quaker Oats Company. Their by-product analyzed to have a purity approaching that demonstrated in our laboratory leaching experiments.

Acknowledgments

Special thanks are expressed to M. Pope of ER&E for the acid leaching experiments and for expediting many phases of this study. Gratitude is also extended to J. Cook, M. Gust, and H. Schleckser of Exxon Enterprises' Materials Division for providing hulls in their raw and coked forms and for pilot-plant concepts for leaching rice hulls; to R. Robinson and G. Wendelin of California Pellet Mill Company for laboratory and pilot plant pelletizations; and to O. Raaness of SINTEF for providing SiO reactivity analyses.

ABSTRACT

A novel process for fabricating planar low dark-current InP- and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}/\text{InP}$ -based photodetectors is described. The process utilizes a film of ZnF_2 as a source of Zn dopant and an encapsulating layer of either SiO_2 , borosilicate, or Al_2O_3 . Localized p-n junctions were fabricated using standard photolithography and diffusing in an open-tube air ambient. Dark currents as low as 5×10^{-12} and 3×10^{-10} A at 10V reverse bias voltage have been achieved in 75 μm diam unpassivated planar diodes of InP and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$, respectively.

Thermal diffusion of an acceptor such as Zn plays an important role in the formation of p-n junctions in III-V semiconductor devices, e.g., photodiodes for use in long-wavelength lightwave communication systems. In the fabrication of such devices, the p-n junctions may be formed by diffusion from the gas phase in sealed ampuls (1-4), ion implantation (5), or open-tube diffusion from films deposited (6, 7) or spun-on (8) the semiconductor wafers. The diffusion from the gas phase requires accurate control of the partial pressures of the species involved to be reproducible, and necessitates the use of a sealed ampul. In order to confine the diffusion to a localized region of the wafer, a dopant-impermeable mask like Si_3N_4 is required. Ion implantation causes compensation and irradiation damage (5). This technique requires a subsequent high-temperature sealed-ampul or open-tube annealing step to activate the implanted dopant and to remove the damage. CVD deposited films require elaborate deposition apparatus (6, 7), and spin-on films still require a sealed ampul for optimum diffusion (8).

In this paper, we report on a novel process for fabricating low dark-current planar-photodiodes of InP or $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. This process requires neither a sealed ampul nor a diffusion mask. The diffusion source consists of an initial film of ZnF_2 followed by a film of SiO_2 . These followed by a film of SiO_2 films are easily and reproducibly deposited by electron-beam evaporation. Standard photolithography and chemical etching is used to define the ZnF_2 film for planar photodiodes. After the $\text{ZnF}_2/\text{SiO}_2$ is defined, a layer of SiO_2 , borosilicate, or Al_2O_3 is deposited over the wafer surface to prevent loss of zinc and decomposition of the semiconductor surface during diffusion. The wafer is then annealed in an open tube to diffuse in the Zn.

Experimental

The $\langle 100 \rangle$ -oriented n-InP crystals used in this work were LEC grown. The crystals were chemical-mechanically polished to a mirror-like finish using a 1% Br_2 in CH_3OH solution. The carrier concentration ($N_D - N_A$) was in the range of $2\text{-}5 \times 10^{15} \text{ cm}^{-3}$. The $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ samples with $(N_D - N_A) \approx 1 \times 10^{16} \text{ cm}^{-3}$ were undoped n-type LPE layers ($\sim 4 \mu\text{m}$ thick) grown lattice matched to InP substrates.

Prior to the deposition of the films, the samples were degreased in chloroform, acetone, and methanol. They were then etched in a 1:1 solution of hydrofluoric acid (HF) in deionized water for 1 min, thoroughly rinsed in deionized water, and blown dry with nitrogen gas. The sample was then immediately transferred to an E-beam evaporator. To form full surface p-n junctions 150Å of ZnF_2 followed by 600Å of SiO_2 or borosilicate film (BSG), or 3000Å of Al_2O_3 film were deposited at $\sim 2 \times 10^{-6}$ torr pressure. The ZnF_2 film acts as a source of the Zn dopant. The encapsulant, SiO_2 , BSG, or Al_2O_3 , prevents any thermal degradation of the sample surface during diffusion and also protects the ZnF_2 film (which is slightly

*Electrochemical Society Active Member.

Key words: diffusion, p-n junctions, III-V compounds.

hygroscopic) from atmospheric humidity, thus allowing storage of wafers for long periods of time ($>24\text{h}$).

To demonstrate the ability to form localized p-n junctions 75 μm diam islands of the ZnF_2 encapsulant film were defined using conventional photolithographic techniques. The unwanted portions of ZnF_2 and the encapsulant were then removed using a CF_4 plasma and a buffered HF solution etch, respectively. A final protective layer of 1.2 kÅ thick SiO_2 or BSG film was then E-beam evaporated over the full surface of the wafer.

The samples were then annealed in an air-ambient, open-tube three-zone furnace at temperatures and durations which were chosen to yield a junction depth of $x_j \approx 2 \mu\text{m}$. As determined from C-V probing of the epitaxial layers, this junction depth is sufficient to fully deplete the remaining n-InGaAs layer in the bias voltage of -10V . The conditions for obtaining such junction depths were inferred from the diffusion profiles of active Zn in a number of InP and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ samples (of varying carrier concentrations $N_D - N_A$), diffused for various times at several temperatures. The diffusion temperatures used for InP and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ were 500° and 550°C , respectively. For all samples the junction depth x_j was found to vary with \sqrt{t} , where t is the diffusion time. Junction depth was measured on (110) surfaces of cleaved samples after staining with an aqueous solution of $\text{K}_3\text{Fe}(\text{CN})_6$ and KOH under illumination.

Upon completion of the diffusion process, the sample was quenched to room temperature in about 1 min by simply removing it from the furnace. The samples were then etched in concentrated HF to remove the films. The cleaned samples did not show any surface deterioration. Unpassivated planar devices thus formed were ready for metallization and electrical measurements. For purposes of comparison, mesa-type diodes were also fabricated from each wafer using conventional photolithographic and etching techniques.

Results and Discussion

Measurements of dark current (I_d) and capacitance (C) as a function of voltage were performed on 10-15 devices from four InP and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ wafers. Figure 1 shows the room temperature reverse I-V characteristics of some typical planar InP diodes. The diodes typically exhibited

Fig. 1. Dark current-voltage characteristics of planar InP photodiodes at room temperature.

Fig. 2. Dark current-voltage characteristics of planar $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ photodiodes at room temperature.

dark currents ranging from $\sim 3 \times 10^{-11}$ to 10^{-8} A at -10 V with very sharp breakdown voltages, V_b , varying between 70 and 150 V. The measurements repeated after a 30 s etch in 0.05% Br_2 in methanol solution showed slightly improved values of I_d and V_b , which now ranged from 5×10^{-12} to 10^{-8} A and 100 to 200 V, respectively. The capacitance for InP diodes was found to be < 0.1 pF at 0 V. (This was the lowest capacitance measurable in our measuring setup). The mesa-type devices yielded comparable electrical characteristics.

In Fig. 2, the dark current as a function of the reverse-bias voltage is shown for a number of planar $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ diodes. The leakage currents in these devices ranged from $\sim 3 \times 10^{-10}$ to 3×10^{-8} A at a 10 V reverse bias with soft breakdowns ranging from 45 to 70 V. The capacitance values were 0.7 and 0.2 pF at 0 and 10 V, respectively. Similar I-V and C-V characteristics were obtained with mesa devices formed on the same wafer. It was confirmed by the C-V data that the background doping density of the $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ wafer was indeed in the 10^{16} cm^{-3} range. Improved capacitance and possibly higher breakdown voltages can be expected from wafers with $N_b - N_A \leq 5 \times 10^{15} \text{ cm}^{-3}$.

The electrical performance of these p-n junctions formed by ZnF_2 diffusion is comparable state-of-the-art devices fabricated by other techniques (4, 8-10).

Summary and Conclusions

We have developed a novel process for p-n junction formation in the InP/InGaAs material system which overcomes some of the difficulties encountered in the more commonly employed p-n junction formation techniques, such as sealed-tube gas-phase diffusion, ion implantation, and diffusions from CVD-deposited or spun-on doped films. We have demonstrated the high selectivity and the simplicity with which the p-n junctions could be reproducibly formed. The devices thus fabricated exhibited state-of-the-art electrical performance (4, 8-10). Finally, the process shows the potential to be applicable to other material systems in which localized and reproducible p-n junctions are to be formed.

Acknowledgments

We are indebted to W. A. Bonner for supplying some of the InP substrates and D. D. Roccasceca for LPE $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. Thanks are due to P. B. O'Connor and W. H. Grodkiewicz for borosilicate material. We appreciate the help of H. Wade in making electrical measurements.

Stabilization of Mo-Gate MOS Structures Using H_2 Doping in Mo and High Temperature Forming Gas Annealing

Shin-ichi Ohfuji and Noboru Shiono

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, 1839, Ono, Atsugi-shi, Kanagawa Prefecture 243-01, Japan

ABSTRACT

Mobile ionic charge-related instability in Mo-gate MOS devices has been successfully prevented by high temperature forming gas annealing ($\text{H}_2/\text{N}_2 = 1/10$) above 900°C , combined with H_2 -doped Mo or H_2 -doped Ta-Mo alloy gate electrodes. H_2 -doped films were deposited by RF sputtering in a mixed H_2 and Ar ambient. It is concluded that sodium diffusion from Mo-gate metal into the gate SiO_2 is prevented by forming gas annealing above 900°C , and that its effect is enhanced by H_2 -doping in Mo films. It is also revealed that, when Ta-Mo (7 atom percent Ta) alloy gate structures are used, high temperature forming gas annealing does not degrade other MOS characteristics and maintains good stability under short-term bias-temperature stress aging.

A refractory metal gate, in place of a conventional polysilicon gate, has been studied extensively in order to improve the gate-level conductivity for realizing high density and high performance MOS LSI's (1). However,

Key words: metals, integrated circuits, contamination, sputtering.

one of the problems in refractory metal-gate MOS structures is poor reliability, compared with polysilicon-gate MOS structures. The reasons are that pure refractory metal materials are difficult to prepare in the present technology, especially for sputtering target materials, and refractory metals do not have self-passivation effects like phosphorus-doped polysilicon on ionic contamination.

Several approaches have been investigated to avoid ionic contamination for metal-gate MOS structures. Phosphosilicate glass (PSG) coating on top of the thermally grown SiO_2 layer (2) or gate oxide grown in a dilute mixture of HCl and dry O_2 at high temperature ($>1100^\circ\text{C}$) (3) are widely used. However, when these methods are used, it is not easy to form a thin gate oxide less than 50 nm thick, which is the typical gate-oxide thickness for high density MOS devices, with good controllability. Another approach is CVD PSG deposition on patterned-Mo films followed by high temperature annealing (4), which tends to getter mobile ions along the perimeter of Mo-gate electrodes. However, this method is not effective for large area gate MOS structures. Recently, forming gas annealing after Mo patterning has been reported to be effective in reducing ionic contamination (5, 6). However, this method is not so effective when contamination level is high. The mechanism is also not clear yet.

In this work, the effects of high temperature forming gas annealing for intentionally H_2 -doped Mo and Ta-Mo alloy films have been examined to reduce ionic contamination in the gate SiO_2 . H_2 doping in the films was realized by reactive sputtering in a mixed H_2 and Ar ambient. The authors have found that high temperature forming gas annealing above 900°C for H_2 -doped Mo, especially H_2 -doped Ta-Mo gate structures, is very effective to reduce ionic contamination in the gate SiO_2 . Also, the basic mechanism of this effect was analyzed, and the stability of these structures was examined through short-term bias-temperature stress aging.

Experimental

Mo-gate MOS capacitors were fabricated on p-type (100) silicon wafers with 4-6 Ωcm resistivity. Thin gate SiO_2 was grown in a dry O_2 ambient at 950°C to a 40 nm thickness. Mo film was deposited by an RF planar magnetron sputtering equipment in Ar gas at 1 Pa pressure. H_2 -doped Mo films were prepared by sputtering in a mixed H_2 and Ar ambient, with varying H_2 partial pressure. Ta-Mo alloy films were deposited by cosputtering using two targets, Mo and Ta. Ta concentration in the films was 7 atom percent (a/o), to maintain high conductivity ($<3 \times 10^{-5} \Omega\text{cm}$, after 1000°C annealing) and process compatibility of Mo gate process. H_2 -doped Ta-Mo films were prepared in a mixed H_2 and Ar ambient, like H_2 -doped Mo films. Gate metal film thickness was 0.33 μm for all samples. Purity for both Mo and Ta targets was 99.95%.

MOS gate electrodes of $500 \times 500 \mu\text{m}$ were defined by conventional photolithography and chemical etching using $\text{H}_3\text{PO}_4\text{-HNO}_3$ solution. After Mo patterning, annealing was carried out in N_2 ambient or forming gas ambient ($\text{H}_2/\text{N}_2 = 1/10$) at various temperatures between 600° and 1000°C for 30 min. Such high temperature annealing is necessary to activate implanted impurity ions. For some samples, forming gas annealing at 450°C for 30 min was performed to reduce the fixed oxide-charge density and interface trap density at the Si-SiO_2 interface.

Mobile ionic charge density in the MOS structures was measured by triangular voltage sweep method (TVS) (7) with a 50 mV/s ramp rate at 270°C . Depth distribution profiles for sodium in the MOS structures were measured directly by SIMS (CAMECA, IMS-3F). Bias-temperature (BT) stress aging was made in order to examine slow trapping instability, as well as mobile ionic charge-related flatband voltage instability.

Results and Discussion

Effects of annealing ambient and temperature.—Figure 1 shows mobile ionic charge density N_m vs. annealing temperature as a function of annealing ambient for various gate-metal structures. High temperature forming gas annealing above 900°C is found to be effective for reducing mobile ionic charge density, especially for H_2 -doped Mo and H_2 -doped Ta-Mo gate structures. However, mobile ionic charge density increases drastically after N_2 annealing for all samples, irrespective of gate metal structures.

Fig. 1. Mobile ionic charge density N_m vs. annealing temperature in N_2 or forming gas ($\text{H}_2 + \text{N}_2$) for various gate metal structures.

The effect of H_2 -doping in the Mo films on the reduction of mobile ionic charge density N_m is shown in Fig. 2. In this figure, N_m vs. H_2 partial pressure in a sputtering gas ambient is shown as a function of annealing ambient at 1000°C . The N_m for as-deposited samples increases with H_2 partial pressure. The reason for this increase is not clearly understood. After forming gas annealing, mobile ionic charge density decreases below 10^{10} cm^{-2} , when H_2 partial pressure is higher than $8 \times 10^{-2} \text{ Pa}$. This indicates that H_2 doping in the Mo films enhances the reduction effect on mobile ionic charge density in forming gas annealing, although, in N_2 annealing, H_2 -doping is not effective.

Fig. 2. Mobile ionic charge density N_m vs. H_2 partial pressure in sputtering gas ambient for as-deposited and annealed samples.

In the following sections, H_2 -doped Mo and H_2 -doped Ta-Mo films represent the films deposited in an H_2 partial pressure of 3×10^{-1} Pa.

Sodium concentration profiles in MOS structures.—A possible reduction mechanism for mobile ion contamination under high temperature forming gas annealing is sodium gettering in the SiO_2 , like PSG-coated gate SiO_2 or HCl oxides. To clarify this effect, sodium distribution profiles in the MOS structures were measured by SIMS. Figures 3, 4, and 5 show depth relative distribution profiles of sodium and silicon for as-deposited, annealed in N_2 , and annealed in forming gas at 1000°C samples, respectively. Ion intensities were normalized by $^{94}\text{Mo}^+$ ion intensities in gate electrodes. For as-deposited samples with Mo gate (Fig. 3a) and H_2 -doped Ta-Mo gate (Fig. 3c), sodium is detected only in the gate electrodes. The $^{23}\text{Na}^+$ ion intensity in the gate electrodes corresponds to the sodium concentration less than 1 ppm, which is quantitatively measured by a flameless atomic absorption analysis. At the metal- SiO_2 interface region, $^{23}\text{Na}^+$ ion intensity decreases rapidly. However, for as-deposited samples with H_2 -doped Mo gate (Fig. 3b), a slight increase in $^{23}\text{Na}^+$ intensity in the SiO_2 region is observed, which corresponds to the small amount of mobile ionic charge density measured by TVS, as shown in Fig. 1. In the case of N_2 annealing (Fig. 4), a clearly identified $^{23}\text{Na}^+$ intensity

peak in the SiO_2 region is detected for all samples. This indicates that sodium ions in the gate electrodes can diffuse into the gate SiO_2 layer during N_2 annealing and are responsible for the large amount of mobile ionic charge densities observed in the actual MOS structures. In the forming gas annealing (Fig. 5), the $^{23}\text{Na}^+$ intensity peak in the SiO_2 region almost disappears, and its intensity decreases abruptly, as it does for as-deposited samples. The decrease in $^{23}\text{Na}^+$ ion intensity in the SiO_2 region is drastic for H_2 -doped Mo and H_2 -doped Ta-Mo gate structures.

Figure 6 shows the correlation between ion intensity ratio $I(^{23}\text{Na}^+)/I(^{30}\text{Si}^+)$ in the gate SiO_2 region and the mobile ionic charge density N_m measured by TVS for Mo gate and H_2 -doped Mo gate capacitors. Here, $^{30}\text{Si}^+$ ion intensity in the gate SiO_2 region was chosen as the standard ion intensity. This result indicates that the SIMS-measured $^{23}\text{Na}^+$ ion intensities in the gate SiO_2 region correspond closely with the mobile ionic charge density measured by TVS.

These analytical results indicate that sodium diffusion from Mo films into the gate SiO_2 layer is enhanced by high temperature annealing in N_2 , whereas its diffusion is very slow or prevented in forming gas annealing above 900°C . The preventing effect under forming gas annealing is more apparent in H_2 -doped Mo and H_2 -doped Ta-Mo gate structures. This suggests that the H_2 doping into the Mo enhances the preventing effect on sodium diffusion

Fig. 4. Depth relative distribution profiles for sodium and silicon in 1000°C , N_2 -annealed MOS structures. a: with Mo gate. b: with H_2 -doped Mo gate. c: with H_2 -doped Ta-Mo gate.

Fig. 5. Depth relative distribution profiles for sodium and silicon in 1000°C, forming gas annealed MOS structures. a: with Mo gate. b: with H₂-doped Mo gate. c: with H₂-doped Ta-Mo gate.

into the gate SiO₂ layer. Since Ta film has about 10⁴ times higher hydrogen absorption property (8), compared to Mo film, H₂-doped Ta-Mo film may contain a larger amount of hydrogen atoms in the film than H₂-doped Mo film. This explains that H₂-doped Ta-Mo gate structure has a superior ability to prevent sodium diffusion into the gate SiO₂.

It has been known that sodium diffusion in the SiO₂ is very rapid. The diffusion constant is $D = 5 \exp(-1.5(eV)/kT) \text{ cm}^2/\text{s}$ (9). In fact, rapid diffusion is observed during N₂ annealing. However, sodium diffusion is prevented in forming gas annealing above 900°C, as described above. This leads to a conclusion that the sodium-diffusion constant decreases drastically in forming gas ambient above 900°C, although the physical origin remains uncertain.

Leakage current characteristics.—Although high temperature forming gas annealing is found to be very effective for reducing mobile ion contamination in the gate SiO₂, such high temperature annealing may degrade other MOS characteristics, such as leakage currents and stability at the Si-SiO₂ interface. MOS leakage current characteristics were measured, and short-term stability under BT stress aging was examined.

Figure 7 shows leakage current vs. applied field characteristics for MOS capacitors with various gate metal struc-

tures annealed in forming gas at 1000°C. This shows that high temperature forming gas annealing results in significant leakage current increases and decrease in breakdown field for H₂-doped Mo-gate MOS capacitors. A slight leakage current increase is also observed for Mo-gate MOS capacitors. Ta-Mo and H₂-doped Ta-Mo gate MOS capacitors, however, can maintain low leakage current without breakdown-field degradation.

The leakage current increase due to forming gas annealing is probably attributed to local oxide defect creation caused by molybdenum silicide formation at the Mo-SiO₂ interface with the deoxidizing reaction of SiO₂. However, a stable Ta-Mo-SiO₂ interface, due to the presence of tantalum oxides at the interface, probably prevents interface reaction during high temperature forming gas annealing, for Ta-Mo and H₂-doped Ta-Mo gate structures.

Fig. 6. SIMS-measured ion intensity ratio $I(^{23}\text{Na}^+)/I(^{30}\text{Si}^+)$ vs. TVS-measured mobile ionic charge density N_m for Mo-gate and H₂-doped Mo-gate capacitors.

Fig. 7. Variation in leakage current as a function of applied field for Mo-gate and Ta-Mo gate MOS capacitors. Samples were annealed in forming gas at 1000°C for 30 min.

Fig. 8. Typical changes in quasistatic C-V characteristics under positive and negative BT stress aging. a (top): for Mo-gate MOS capacitors. b (bottom): for H₂-doped Ta-Mo gate MOS capacitors.

Short-term stability at Si-SiO₂ interface.—Short-term positive and negative bias-temperature (BT) stress aging was made for H₂-doped Mo and H₂-doped Ta-Mo gate structures annealed in forming gas at 1000°C. BT stress conditions were ± 5 V and ± 10 V gate bias at 270°C for 30 min. Under negative BT, the flatband voltage (V_{FB}) shift was small, less than 0.1V for all samples. This indicates that slow trapping instability is negligible. Under positive BT, a negative V_{FB} shift was measured within 0.1V, which was almost the expected shift from TVS measurement. From this result, low mobile ionic charge density is confirmed.

In addition to the V_{FB} shift, interface trap generation was estimated by quasistatic C-V measurement. Figure 8 shows typical changes in quasistatic C-V characteristics under positive and negative BT stress aging for (a) Mo gate and (b) H₂-doped Ta-Mo gate MOS capacitors annealed in forming gas at 1000°C. Here, for H₂-doped Mo gate structures, the quasistatic C-V curve could not be obtained because of large leakage current, as shown in Fig. 7. Interface trap density D_{it} at midgap is less than 2×10^{10} cm⁻² eV⁻¹ for all samples in the initial state, i.e., the as-made state. Under negative BT, a negligible amount of D_{it} generation is observed in both gate structures. However,

a slightly large D_{it} , about 5×10^{10} cm⁻² eV⁻¹ at midgap, is generated for Mo-gate structures associated with negative V_{FB} shift under positive BT. It is also noticeable that D_{it} increases mainly from midgap toward the conduction band edge for Mo-gate structure, which is extracted from large distortion of the C-V curve from depletion to inversion region, as shown in Fig. 8a. For H₂-doped Ta-Mo gate structures (Fig. 8b), the C-V curve distortion is small. These results show that high temperature forming gas annealing does not degrade the Si-SiO₂ interface stability for H₂-doped Ta-Mo gate MOS structures.

Conclusion

High temperature forming gas annealing above 900°C was found to be very effective for reducing mobile ionic charge density for Mo-gate MOS structures. This effect is enhanced by H₂ doping in the films in the deposition process. Depth distribution profiles for sodium in the gate SiO₂ layer, analyzed by SIMS, lead to a conclusion that high temperature forming gas annealing prevents sodium diffusion from Mo-gate metal layer into the gate SiO₂, although the physical origin of this effect remains uncertain. A disadvantage of high temperature forming gas annealing is leakage-current increase in the MOS structures. However, an addition of several percent Ta in Mo films can prevent the leakage current increase and assure good stability at the Si-SiO₂ interface under BT stress aging. The H₂-doped Ta-Mo gate MOS structure, combined with high temperature forming gas annealing above 900°C, is very promising as regards highly reliable refractory metal-gate MOS devices.

Structural Perfection Testing of Films and Wafers by Means of Optical Scanner

E. F. Steigmeier and H. Auderset

Laboratories RCA Limited, CH-8048 Zurich, Switzerland

ABSTRACT

An alternative use of an optical scanner is presented for rapid structural perfection testing of films and wafers. Specific examples are given: (i) for silicon-on-sapphire quality, (ii) for structural perfection of low pressure chemical vapor deposited amorphous silicon, and (iii) for the distribution of precipitated oxygen in silicon wafers treated for internal gettering. Further, in phase transformable materials, the method permits the determination of the depositional phase (amorphous or crystalline) after film growth and after annealing.

In a previous paper, we reported on a laser scanner system for dust and defect detection on silicon wafers, thin films, and other surfaces (1).¹ The present work deals with an alternative and novel use of the above instrument, for testing the structural perfection of various materials and assessment of thin film quality (2). Specifically, we will describe the testing of silicon-on-sapphire (SOS) wafers, the qualification of low pressure chemical vapor deposited (LPCVD) amorphous silicon layers, and other materials. In addition to determining the structural quality of crystalline or amorphous material, a rapid acceptability characterization of phase-transformable material can be performed, *i.e.*, of a material which in a certain process can be deposited in either the amorphous or the crystalline phase, depending on the deposition conditions. This is exemplified for the case of as-deposited amorphous or crystalline LPCVD silicon. Moreover, the laser scanner system is capable of determining whether the film of subsequently annealed and thus crystallized material has resulted from an as-deposited amorphous layer, or from an as-deposited crystalline layer; this feature is important because silicon recrystallized from amorphous deposited films is found to be of superior quality in terms of device performance. Finally, it is shown that the method of structural perfection testing can be used to qualify the precipitated oxygen distribution in single-crystal silicon wafers in connection with treatment for internal gettering. In summary, the alternative use of the laser scanner in the quality-control mode is shown to be very effective in different fields of applications (IC technology, solar cells, thin films, and others).

Instrumental

The laser scanner used for this study has been described in detail elsewhere (1). As shown in Fig. 1, it consists of HeCd laser light (325 or 442 nm) of about 10 mW focused onto a spinning wafer while being translated. The scattered elastic light is collected in a coaxial arrangement, detected by a fast photodiode or a photomultiplier. After suitable amplification, the electrical signal is then mapped on a storage oscilloscope, making use of the polar-to-rectangular coordinate transformation sketched in the lower part of Fig. 1. The laser wavelength of 325 or 442 nm is selected according to the desired light penetration depth or film thickness. One laser scan takes about 6s for a 3 in. wafer.

In general, every material exhibits an intrinsic elastic light scattering due to temperature or entropy fluctuations (3). In addition, extrinsic elastic scattering is produced by all effects causing local changes of the dielectric constant or refractive index. These include all kinds of structural imperfections on a microscopic scale such as strain, mosaic misorientation of the lattice, stacking

Key words: semiconductor, crystallization, CVD, integrated circuits.

¹This laser scanner system is commercially available from Fluorocarbon Process Systems, Anaheim, California 92803, and is used in many places throughout the semiconductor industry.

faults, dislocations, twinning, grain boundaries, and, of course, microscopic variation of the material, as, for example, in an agglomerate. Surface irregularities (surface roughness, scratches, etc.) also contribute to this extrinsic light scattering. For all cases of practical relevance, however, and for the light wavelengths used here, the surfaces are sufficiently smooth that the volume effects dominate over the surface effects.

For the present paper, we limit ourselves to the "quality-control mode" use of the instrument (1). In this mode, all events originating from individual defects are disregarded. Instead, one deals with the large regions in between the individual events. These regions give rise to the background scattering level originating from the bulk. This is demonstrated in Fig. 2. For a good quality wafer (Fig. 2a), the background level of a signal, as taken along the spiral path, is very low, and a large dc shift is needed for the background level to reach the writing threshold of the storage scope. For a poor quality wafer (Fig. 2b), the background level is high, and a small dc shift is needed to reach the writing level. Thus, the dc shift can be used as a direct measure of structural quality. The scanner units, measuring the dc shift, can be considered as arbitrary rel-

Individual defects or dust, which are not considered here, are indicated by the spikes.

ative units of quality, a high value indicating high quality of perfection.

It should be noted that the coaxial arrangement (Fig. 1) is of particular importance in using the quality-control mode, since it is essential for the sensitivity uniformity across a larger wafer area (1).

Results and Discussion

General.—An example for the use of the quality-control mode to qualify a wafer is presented in Fig. 3. This shows scanner mappings taken at various threshold settings for

Fig. 3. Scanner mappings of a wafer exhibiting a structural quality variation along a vertical line. A (top): taken at threshold setting of 750 units. B (center): at 730 units. C (bottom): 680 units.

a wafer with a structural quality variation along a vertical line. Since the best material is found to produce full writing at the highest scanner unit setting (corresponding to largest dc shift), it is seen that point 1 is of the relative best, point 2 of medium, and point 3 of the poorest quality on this wafer.

Silicon-on-sapphire structural perfection testing.—For silicon-on-sapphire (SOS), it has been shown (4) that the crystalline perfection of the silicon layer is directly related to the final device performance. Imperfections may result (5) from the polishing quality of the sapphire substrate, from the thermal mismatch of sapphire and silicon lattice, and from details of the epitaxial deposition or growth process. It was shown (6) that the volume percentage (221) twins in the silicon layer is a good indicator of structural quality, since the microtwins represent the dominant crystallographic defect in SOS films (7). Several methods have been used (4, 8) to characterize the quality of near-surface SOS. Among them, UV reflectance measurement plays a particular role (9), since it is a most widely used simple method.² For this reason, the results of the scanner method can best be correlated (2) with the UV reflectance method, in addition to the (221) twinned density.

Figure 4 shows the result of the scanner method for SOS wafers plotted vs. UV reflectivity. The vertical scales show the scanner units, directly proportional to the dc offset, as mentioned above, for incident laser light of 325 nm. Note that a high number indicates good quality, i.e., a low elastic scattering background and vice versa. The horizontal scales give the UV reflectometer units R_{280} and R_{400} ; these units for 280 and 400 nm, respectively, represent the reflectance difference relative to the single-crystal standard. (One R_{280} unit corresponds to about 0.05% loss of absolute reflectance, and one R_{400} unit to 0.03% loss.) It is seen in Fig. 4 that the two measurements, elastic light scattering as determined by the scanner method and UV reflectivity, correlate extremely well. A typical high quality SOS wafer (category A) would be selected for a scanner threshold level of about 710 units or more.

It should be borne in mind that the light penetration depth varies considerably between 280 and 400 nm. Therefore, the UV reflectivity data plotted on the horizontal axis of Fig. 4, sample quite different near-surface regions of about 50Å for the left-hand part of Fig. 4, and of about 1000Å for the right-hand part. It is notable that the laser scanner results, sampling a surface depth of about 85Å, correlate with both of them.

Figure 5 shows the correlation of the laser scanner results with the UV reflectivity difference ΔR , defined by $R_{280} - R_{400}$, which is frequently used (9) to qualify the SOS wafers.

Also of interest, and shown in Fig. 6, is the correlation of the laser scanner units with the (221) twinning concentration as determined by x-ray (6). It is found that SOS films of category A, with a (221) twinning density of up to 4%, correspond to 710 laser scanner units and more, while films of category B, with a (221) density of 4 to 6.5%, are found between 680 and 710 laser scanner units.

To summarize the results on SOS:

1. The laser scanner used in the quality-control mode can determine the structural perfection of SOS films, in good correlation with UV reflectivity and twinning density.
2. The method permits one to continuously scan the whole SOS film and thus to provide a uniformity map of the structural perfection.
3. Due to its high speed, the optical-scanner method offers itself as an alternative for rapidly determining the structural perfection or acceptability of SOS films for device processing.

Quality characterization of amorphous silicon.—The scanner can also be used for determining the quality of

²The UV reflectometry method is presently used by all major manufacturers and users of SOS.

amorphous silicon. The term “amorphous” in this context of light scattering denotes material in which the narrow crystalline Raman line of 522 cm^{-1} is completely absent in the Raman spectrum. Instead, a broad line is observed. This peaks at about 490 cm^{-1} . This is the result of breakdown of perfect lattice periodicity, which relaxes the selection rules and permits a multitude or all lattice modes to be excited by the light. It is known that in amorphous silicon some short-range order still prevails; only the long-range order is missing. In this sense, the structural perfection in amorphous silicon might be connected with the degree of spatial short-range order fluctuations. We have found that amorphous silicon produced by the different methods to obtain solar cell material, *e.g.*, evaporation, glow discharge, sputtering, LPCVD, etc., results in elastic light scattering results of the corresponding films that vary over several orders of magnitude. In addition to

the deposition method, the substrate temperature, geometry, gas species present, and other factors play an important role on the resultant structural perfection.

To demonstrate the influence of the substrate on the structural perfection of amorphous silicon, and the application of the scanner in the quality control mode, we present here some results on multilevel polysilicon depositions as relevant in the charge-coupled device (CCD) processing. As Fig. 7 shows, we have, in a controlled experiment, inspected amorphous silicon (I) as deposited on a thermally oxidized single-crystal substrate and compared it with amorphous silicon (II) as deposited on the “same” oxide, which, however, had been formed on top of a previously deposited amorphous poly-A, which subsequently had been POCl_3 doped, and annealed at 900°C . Figure 7 (middle part) shows that the scanner results

Fig. 7. Testing the structural perfection of amorphous silicon by means of laser scanner (middle part) for 10 mW (442 nm) focused onto a spot of $50 \times 220 \mu\text{m}$, and static elastic light scattering (bottom part) for 100 mW (515 nm) focused onto a spot of $40 \mu\text{m} \times 2 \text{mm}$.

show excellent structural perfection for layer I and poor structural perfection for layer II. In fact, the latter is indeed below the acceptability limit which we have established after extensive work with amorphous silicon layers. It should be emphasized that the whole poly-B layer, resulting in the two different regions I and II, was deposited in one and the same LPCVD process ($T_d = 566^\circ\text{C}$). The bottom part of Fig. 7 shows that the scanner results are confirmed by an independent measurement of the elastic light scattering with a static method: again, layer I is found to be very good and layer II to be very poor and unacceptable.

Fig. 9. Raman peak intensity for as-grown LPCVD silicon layers vs. deposition temperature. ○: amorphous. x: crystalline. ⊗: mixed.

In order to understand the exact nature of the difference between these two layers, we had them analyzed by cross-sectional transmission electron microscopy (TEM). The results are given in Fig. 8 (courtesy of J. McGinn). It is seen that both layers are indeed amorphous for TEM, at least for the scale of the light penetration depth (for $\lambda = 442 \text{ nm}$) of about 1000\AA . There is one striking difference between them, however: for layer I, the oxide top surface is very smooth (arrow a), while for layer II, the oxide top surface is rather rough (arrow b). We speculate that it is this rough surface II which has influenced the degree of spatial short-range order fluctuations, and thus the local refractive index, and the light scattering a few thousand angstroms further up in the amorphous silicon layer II. In any case, the rough oxide-to-silicon interfaces of region II are very undesirable for many devices, because they might induce electrical breakdown at much lower electrical fields than desired. Such unwanted conditions can be

Fig. 8. Transmission electron microscopy (TEM) cross sections of layers I and II from Fig. 7 (courtesy of J. T. McGinn). Thickness of poly-B is 6600\AA in both region I and II, and thickness of poly-A is 5400\AA .

revealed nondestructively by using the scanner in the quality-control mode.

Determining the crystallographic phase of a deposited layer.—Films of LPCVD silicon can be deposited in either one of the two phases, depending on the deposition temperature (T_d): for $560 \leq T_d \leq 580^\circ\text{C}$, the films are amorphous, for $T_d \geq 620^\circ\text{C}$, they are crystalline. The simplest and most rapid method to determine the crystallinity is by Raman scattering, as shown in Fig. 9. For convenience, we have plotted here the peak intensity of the Raman spectrum in the $490\text{--}530 \text{ cm}^{-1}$ region. Since the broad amorphous peak is much weaker (≈ 25 counts/s) than the crystalline peak ($\approx 100\text{--}400$ counts/s), the degree of crystallinity can simply be determined from the peak Raman intensity. Recent work on undoped (10, 11) and *in situ* phosphorus-doped (12) LPCVD polysilicon has demonstrated that only films deposited in the amorphous phase and subsequently crystallized by annealing have the high quality, in terms of structural perfection and surface roughness, which is required for critical device applications. The laser scanner has played an important role in the structural perfection characterization of the corresponding films. In the following, it will be shown in detail how the scanner, once calibrated for

Fig. 11. Correlation between Raman peak intensity and laser scanner units for as-grown LPCVD silicon films, deposited at different deposition temperatures as indicated. \circ : amorphous. \times : crystalline. \otimes : mixed.

one system, e.g., LPCVD silicon, can be used very effectively for rapidly determining the crystallographic phase of a deposited film, a procedure for which x-ray measurements usually take at least 30 min. Moreover, it will be shown that even an annealed film can be identified whether it originates from a desirable, originally amorphous-deposited film or from a less desirable crystalline-deposited film. This permits rapid feedback in device processing.

Two detection methods have actually been used for testing with elastic light scattering: (i) the blue version of the laser scanner (442 nm) in the quality-control mode, and (ii) the static method (515 nm) with photomultiplier detection.

The former is more rapid and provides a map of the whole wafer area, while the latter is more sensitive. In principle, both methods give fully consistent results as will be seen.

Figure 10 shows the correlation between Raman peak intensity and elastic intensity, determined with the static method (b) for different deposition temperatures. It can be seen that the amorphous layers resulting from the LPCVD process always are of lowest elastic light scattering, the fully crystalline layers of highest, and the mixed amorphous-crystalline layers of intermediate. Figure 11 shows the corresponding results with the scanner method

Fig. 12. Correlation between elastic scattering by scanner method (a) and by static method (b) for LPCVD silicon films, as-grown and annealed.

in the quality-control mode (a). The highest scanner units are observed for the amorphous layers, and the lowest for the less-desirable crystalline layers. In Fig. 12, the two methods are correlated with each other. It is seen that the correspondence is very good. Of considerable importance is the finding in Fig. 12 that the annealed films coincide well with the as-grown LPCVD films, particularly the ones which had been deposited in amorphous form. This is shown in more detail in Fig. 13 by using the static method. Thus, the elastic scattering of the films does not change with annealing, and it is possible to determine with the scanner (or the static method) whether an annealed film had been produced in the desirable amorphous form or in the less-desirable crystalline form. Since the amorphous deposition is preferred more and more for device processing, the acceptability assessment by the scanner of as-grown or annealed polysilicon layers is quite useful.

Internal gettering.—As device processing moves towards larger wafer size, the warpage of silicon wafers due to plastic deformation at elevated temperatures represents a more and more important problem to the IC industry (13). It is known that oxygen in small complexes improves the mechanical strength of silicon due to dislocation pinning. However, for many devices, lifetime is a limiting factor, and careful internal gettering is required to remove any impurities from the active device zone. For this purpose, one presently uses wafers with an oxygen-denuded zone in a shallow surface region, and with oxygen precipitates in the lower lying bulk part. Much work remains to be done in this field to reach a full understanding. We have studied the applicability of light scattering techniques for quantitatively assessing the structural perfection status of such wafers. For this, we have looked at bevel-polished wafers of the above kind (courtesy of Wacker Chemitronics, Burghausen, Germany) by means of the scanner in the quality-control mode and the static elastic scattering technique. The results appear very encouraging: both techniques can easily discriminate between the two regions and also show the crossover. Figure 14 presents the results on a beveled wafer. In the top part, the scanner map is reproduced as obtained in a few seconds. In the bottom part, the results of the static elastic light scattering are given. The agreement is obvious. Since the scanner method produces a whole map of the wafer, one can easily see if there are any radial

uniformities in the oxygen distribution. Judging from the top part of Fig. 14, this appears to be the case. It has been verified independently with the static method by studying along different lines across the wafer. At the present time, it is still unclear how much of the effect originates from the wafer and how much from a possible imperfect even polish. However, effects of the former type, namely,

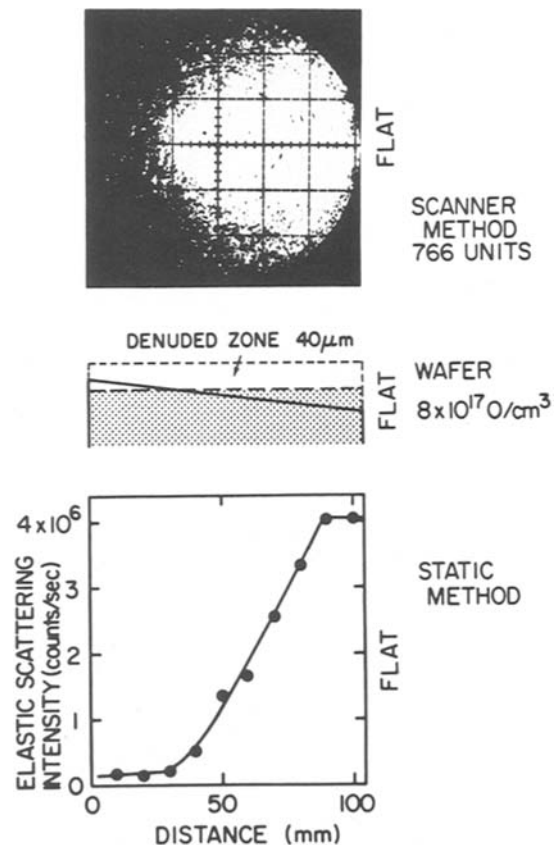

Fig. 14. Observation of transition from oxygen-denuded zone to precipitation zone on a beveled internal gettering silicon wafer. Top: Scanner method (442 nm), picture taken at 766 scanner units with 0 dB attenuation. Bottom: Static elastic scattering (515 nm).

a radial variation of the oxygen distribution, have been reported in the literature (14).

From these results, it appears that the scanner used in the quality-control mode can provide an important tool in studying the subtle details of oxygen distribution connected with internal gettering and warpage.

Thermal Pulse Diffusion of Zn in GaAs from an Elemental Source

D. Dobkin¹ and J. F. Gibbons

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

We have studied Zn diffusion from an electroplated elemental source, using rapid thermal annealing techniques to investigate a range of diffusion times from 3 to 30s. Improved surface morphology is obtained by exploiting the high vapor pressure of Zn to remove excess source material, leaving only one to two monolayers of Zn tightly bound to the substrate. Resultant diffusions form shallow (0.1-0.2 μm) heavily doped ($1 \times 10^{20}/\text{cm}^3$)p⁺ regions. Junction properties are almost independent of diffusion time and linear in temperature over the range investigated.

Zinc is a common p-type dopant for GaAs. Diffused Zn layers are typically formed using sealed ampuls with a Zn-As compound as a dopant source (1, 2) or in open-tube diffusions with Zn-doped SiO₂ cap (3). We have investigated the diffusion of Zn into GaAs from an elemental Zn layer for short times (3-30s) using the technology developed for rapid annealing of implanted material (4).

Experimental Results

The rapid thermal annealer is designed so that only the sample in process is heated; thus, the incorporation of the Zn source directly on the wafer is advantageous. As a diffusion source, we have used a layer of elemental Zn, $\approx 100\text{\AA}$ thick, deposited by electroplating directly onto a GaAs surface after a pretreatment in a RuCl₃ solution. This process is described in more detail elsewhere (5).

In our initial studies, plated samples were placed in the rapid thermal annealer and covered by a silicon wafer to form a proximity cap. The chamber was evacuated by a mechanical pump/LN₂ trap and backfilled with a 90% Ar:10% H₂ mixture. Diffusions were performed for temperatures from 700° to 850°C and at 800°C for times from 4 to 30s (risetime was typically 5-7s). Samples were then characterized by Hall measurements and chemical stripping.

¹Also with Watkins-Johnson Company, Palo Alto, California.
Key words: semiconductor, diffusion, junctions, electrodeposition.

The doping profiles were found to be flat with a very abrupt drop-off. The plateau doping was typically $\approx 10^{20}/\text{cm}^3$. SIMS measurements verified this picture of the diffused profile (Fig. 1). The junction depth was found to be linear in temperature and almost independent of diffusion time (Fig. 2).

A disadvantage of this process was a degradation of surface morphology in the plated regions, evidenced as a clearly visible discoloration which was verified to be due to surface roughening using SEM observations. We speculate that this roughening is due to dissolution of GaAs into the Zn film once the temperature exceeds the Zn melting point (1).

To avoid this problem, we have exploited the high vapor pressure of Zn at moderate temperatures to remove the majority of the film before diffusion. The samples are loaded into the annealer without a top Si wafer and the chamber evacuated. Initial work was performed at a pressure of 50-100 mtorr using a mechanical pump. An oil diffusion pump with LN₂ trap was later added to the system, enabling operation at $\approx 3 \times 10^{-4}$ torr. (This pressure is far above the ultimate base pressure of the system, but is a compromise value chosen to minimize cycle time.) The sample is then raised to a temperature of 440°-520°C in vacuum for times of from 15 to 45s (most frequently 30s). The chamber is vented with forming gas and the sample covered with a Si wafer. Diffusion then proceeds as before. The plated regions are visually indistinguishable, at-

Fig. 1. SIMS profile of Zn diffusion: 10 sec at 800°C. (Depth scale estimated from Dektak measurement of sputtered crater.)

testing to undegraded surface morphology. Samples were characterized by Van der Pauw/Hall and four-point probe measurements combined with chemical stripping.

Electrical results are summarized in Fig. 3-6. Here sheet conductance is plotted as the dependent variable. It is found that the doping profiles were again flat with an abrupt edge, and that the peak doping ($\approx 1 \times 10^{20}/\text{cm}^3$) did not vary much with the various parameters explored. Thus, the variation in sheet conductance primarily represents variations in junction depth. The total dose corresponds to roughly one to two monolayers of Zn (5×10^{14} - $1.5 \times 10^{15}/\text{cm}^2$).

The data show that the junction depth decreases roughly linearly with increasing evaporation temperature, and increases linearly with increasing diffusion temperature. On the other hand, the junction properties seem substantially independent of the times used in either process, within the range explored.

To verify the usability of this process for device fabrication, junction GaAs FET's were produced. The starting material was liquid-phase epitaxial n-GaAs (doping $\approx 1 \times 10^{17}/\text{cm}^3$) on Cr-doped substrate without a buffer layer. Plating and evaporation/diffusion were performed as above to create a uniform p^+ region about $0.2 \mu\text{m}$ thick. Devices were isolated by chemical etching of mesas. Aluminum metal was patterned on the wafer by lift-off to form gate lines, which also acted as a mask for chemical removal of the p^+ layer from the remainder of the wafer. AuGeNi ohmic contacts were then patterned by lift-off and alloyed to complete the structure. Current voltage characteristics were measured on a curve tracer, with and without illumination from a microscope lamp; the results are shown in Fig. 7. The devices are seen to be well-behaved with illumination, but display hysteresis in the dark.

This hysteretic behavior was tentatively attributed to traps at the epi-substrate interface, possibly due to outdif-

Fig. 2 (a, top) Junction depth vs. diffusion temperature (10s diffusion). The line is a least squares fit to the data; slope $1.0 \times 10^{-3} \mu\text{m}/^\circ\text{C}$; extrapolated to $x_j = 0$ at $T = 540$. (b, bottom) Junction depth vs. diffusion time (800°C).

fusion of impurities either during epitaxial growth or in the diffusion thermal processing. We found that a substrate bias of -50 to -60V would completely pinch off the device even at zero gate voltage; such behavior is considered to be due to deep impurities at the epi-substrate interface (6). To verify that this behavior was material-related rather than intrinsic to the Zn diffusion process, a second piece of the same wafer was processed in an identical fashion but without any zinc plating, to fabricate MESFET's of similar geometry. These devices displayed an identical "backgating" behavior.

Deep-level transient spectroscopy measurements were also made using a boxcar-integration scheme. A typical scan is shown in Fig. 8. The control sample was an aluminum Schottky barrier on n type ($10^{17}/\text{cm}^3$) bulk GaAs with a AuGe alloyed back contact; a second piece of the same wafer received an evaporation/diffusion to form a p^+ layer, followed by Al evaporation and chemical etching to form mesa diodes. The data show two electron trap levels in the control sample. The level of 150 K is completely absent in the diffused sample; the level at 370 K is just observable. (Hole traps were not investigated, as we do not at present have an optical DLTS capability.) The two

peaks are tentatively identified as EL7 and ET2, respectively (14), although due to the heavy doping and consequent high fields, precise characterization is difficult.

Discussion and Conclusions

The most interesting aspects of the dependence of p^+ region formation on the various experimental parameters are the weak (linear rather than exponential) dependence of junction depth on temperature of diffusion, the linear decrease of junction depth with increasing "evaporation" temperature, and the lack of any strong time dependence. These features contrast strongly with the typical behavior of diffusing species in semiconductors: diffusion constant $D \propto \exp[-E_a/kT]$ where E_a is several eV, and junction depth $x_j \propto \sqrt{t}$. The non-erfc/non-Gaussian diffusion profiles, on the other hand, are not surprising in view of the well-known concentration dependence of Zn diffusion (9).

The diffusion time independence of the p^+ region formation is reminiscent of the post-diffusion annealing results of Tuck and Houghton (10). In this work, junctions formed by conventional sealed ampul diffusion of Zn were annealed in a second Zn-free ampul at the same temperature as the diffusions. For temperatures less than 900°C , the anneal had essentially no effect on the diffused profiles. Zn diffusion is generally held to occur through either interstitial Zn (11) or interstitial Ga (12). The concentration of V_{Ga} , which controls the inclusion of Zn

atoms in the lattice, is calculated by assuming equilibrium with As pressure at the surface, implying that the relevant defects are generated primarily at the surface. We must thus speculate that when a Zn source is not present, the driving force for defect creation at the surface is removed and diffusion then proceeds by a very slow substitutional mechanism. We have previously found that after "evaporation" Al Schottky barrier heights are modified, suggesting the presence of a very thin layer containing Zn at the surface (5). This layer may act as the finite source of Zn required by the model sketched above.

The independence of evaporation time may be explained by considering evaporation rates. The equilibrium Zn vapor pressure at 500°C of about 1.5 torr (13) gives an evaporation rate of about 3×10^5 monolayers/s assuming detailed balance and a unity sticking coefficient. Thus, all bulk Zn evaporates away in a very short time (\ll 1s), if retarding effects such as oxidation are negligible. After this time, only Zn atoms in an especially stable state, e.g., tightly bound to the substrate, remain, and these may be only weakly affected by further heat-treatment.

At present, we have no explanation for the temperature dependence of the diffusion process.

In conclusion, we have explored a new regime of Zn diffusion using rapid thermal processing and a plated elemental Zn source. We have characterized the dependence of junction formation on several process parameters. The use of an "evaporation" step to remove excess Zn results in preservation of surface morphology and a process suitable for device fabrication. The high doping levels obtained may make the process of interest for contact layer formation.

Thermal Annealing of Proton-Bombarded GaAs and (Al, Ga)As

B. Schwartz,* L. A. Koszi,* P. J. Anthony,* and R. L. Hartman

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A study of the annealing of proton-bombarded, p-type GaAs and (Al,Ga)As revealed different electrical conductivity recovery effects, depending on the host crystal and the original dopant species and concentration level. It was found that the dopant dependence of the annealing temperatures was in the order $T_{Zn} < T_{Mg} < T_{Ge}$. In fact, whereas a Zn-doped binary system annealed completely at $\leq 570^\circ\text{C}$, Ge-doped samples, both binary and ternary, did not recover to better than within a factor of five of their original conductivities, even at temperatures as high as 700°C . The Mg-doped ternaries recovered at $\leq 570^\circ\text{C}$, while equivalently doped binaries acted similarly to the Ge cases in approaching only within a factor of five of their original values at 700°C . The ability to place juxtaposed regions of conducting and nonconducting layers in the "bulk" of a multilayered crystal structure was demonstrated. The potential for three-dimensional integration in compound semiconductors, utilizing these effects, is discussed.

The bombardment and penetration of a solid by an accelerated charged particle is an old field of study (1, 2) which became important in semiconductor technology with the fabrication of nuclear particle detectors by ion implantation (3). This technique has since become an integral part of silicon-integrated circuit fabrication (4) and is beginning to be used for the construction of compound semiconductor devices and circuits as well (5).

The recognition by Foyt *et al.* (6) that proton bombardment-induced damage in GaAs could be used to produce electrical isolation between adjacent devices, and the subsequent use of this technique by Dymant *et al.* (7) for the fabrication of stripe geometry double heterostructure lasers that would operate cw at 25°C , were two important steps in the development of optoelectronics. This technology depends on the ability to control the generation of regions of high resistivity material by bombardment-induced carrier removal (8). However, the use of this type of damage has been limited to the preparation of "tubs" (*i.e.*, regions from the near surface to the surface in restricted areas of the slice) of semi-insulating material. This is a direct consequence of the fact that the bombarding ions impinge on the surface from essentially a normal direction, with a patterned attenuator to define which areas of the semiconductor are exposed and which are protected. The result is a pseudo-three-dimensional technology.

We present observations that will enable the fabrication of more complex three-dimensional devices based on the interactive effects between the proton bombardment generation of high resistivity in GaAs and (Al, Ga)As, the dopants present in these materials, and a moderately high temperature anneal. We have found that proton-bombarded germanium-doped GaAs and/or (Al, Ga)As can be heated to 600°C and will maintain semi-insulating properties, while an identical treatment of Mg- or Zn-doped material will cause a return to a high conductivity state. In this paper, we shall show our preliminary results and mention a few of the many possible uses of this phenomenon in fabricating novel and improved devices.

Below is a description of the experimental procedures used in this study, followed by the experimental results and data analysis. Then we put this work in perspective and point out some possible technological applications, and we conclude with a summary.

Experimental Procedures

The experiment consisted of: (i) exposing the full surface of epitaxial samples of p-type GaAs and/or (Al, Ga)As to 300 keV protons at a dose of $3 \times 10^{15} \text{ cm}^{-2}$ [these bombardment conditions are known to render the surface region of this material semi-insulating to a depth of $\sim 3 \mu\text{m}$, with a resultant resistivity in the $10^5 \Omega\text{-cm}$ range (9)]; (ii) heating the samples at temperatures ranging from 450° to 700°C in an open-tube leaky-box "diffusion-type" furnace in a forming gas ambient for 30 min (estimated time at

maximum temperature being 15 min); and (iii) evaluation of the results using either a depth-profile conductance measurement (10) or a cleave-and-stain technique (11).

Two types of liquid phase epitaxial samples were prepared for this study. One set involved a single epitaxial layer containing the specific dopant of interest, and the other consisted of multiple epitaxial layers alternately doped with the impurity element of interest. Most of the single-layered samples were 1-2 μm thick GaAs or $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ($x = 0.3$ or 0.4 films), containing either Mg or Ge, with a free carrier concentration from 2×10^{17} to $1 \times 10^{18} \text{ cm}^{-3}$, and were grown on (100) oriented, 10^{18} cm^{-3} , Si-doped n-type substrates. The multilayered samples were also grown on n-type Si-doped substrates, but they contained juxtaposed Mg- and Ge-doped layers, each about 0.2-0.6 μm thick and doped in the mid 10^{17} to low 10^{18} range; the total thickness of the epitaxial layers was $\sim 2 \mu\text{m}$.

The electrical measurements were done on the single-layer samples exclusively. After the bombardment and annealing sequences were completed, ohmic contacts of Au-Zn were evaporated onto the bombarded surface of the sample in the circular geometry shown in Fig. 1, at a deposition temperature of 140°C . As controls, unannealed samples, identically bombarded, were similarly metalized.

Layer resistivity was evaluated by applying a fixed bias of 0.1V between the inner dot contact and the outer ring and measuring the voltage drop across a suitably adjusted series sampling resistor (10). By etching the exposed semiconductor material in the annular ring in care-

Fig. 1. The ring-dot configuration used to make the electrical measurements.

fully controlled steps, one can profile the conductivity of the bombarded regions; the sample resistivity is inversely proportional to the slope of the conductance *vs.* etching time plot. The low bias voltage limits the current to the p-type material above the n-type substrate. The current leakage across the junction and also through the $10^6 \Omega\text{-cm}$ deionized water used in the etching procedure places a $10^3 \Omega\text{-cm}$ upper bound on the resistivity that can ordinarily be measured.

Because of the large diffusion coefficient and high volatility of Zn, single epitaxial layers doped with Zn were not grown, and Zn-doped bulk GaAs was used instead. This altered the resistivity measurement geometry (*i.e.*, no p-n junction to isolate the measurements to the top 1-2 μm of material) and made interpretation of the measurements more difficult.

The cleave-and-stain measurements were done exclusively on LPE-grown multilayered samples containing alternately Ge and Mg as the p-dopants, in both the binary GaAs and the ternary (Al, Ga)As, also alternately juxtaposed. The epitaxial layers ranged in thickness from 0.15 to 0.6 μm , while the total of all layers was approximately 2 μm thick. The samples were not full surface bombarded with protons, but tungsten wire stripe masks were used to produce bombarded and unbombarded regions of the same slice. Subsequent to bombardment and anneal, the samples were cleaved on the (110) plane, stained in a solution of 5:1::H₂O:NH₄OH, and then photographed in a scanning electron microscope.

Experimental Results

Table I is a summary of the results of the electrical measurements performed on the bombarded and annealed single layer samples. All of the control samples examined without bombardment showed resistivities in the 10^{-2} to $10^{-1} \Omega\text{-cm}$ range. Because the evaluation technique used has an upper measurement limit of $10^4 \Omega\text{-cm}$, the largest normalized resistivity ratio (*i.e.*, the ratio of the resistivity after bombardment and anneal to that before bombardment) is listed as $> 10^4$; the value ~ 5 indicates that complete return to original resistivity was not achieved.

Samples 1-3 were Ge-doped epitaxial layers, samples 4-8 were Mg-doped epitaxial layers, and sample 9 was a Zn-doped bulk slice. As seen from column IV, the sample compositions ranged from the binary (samples 2, 3, 7-9) to 30 and 40% Al (samples 1, 4-6) in the ternary.

Three major trends can be discerned by examining the data in Table I. (i) In the ternary-based systems, proton-bombarded Mg-doped slices recovered their initial resistivity in the temperature range 575°-600°C, while the Ge-doped material continued to show high resistivity up to temperatures of 700°C. (ii) In the binary-based systems, except for the Zn-doped material, none of the samples completely annealed back to their original resistivity, coming only within a factor of about five of their initial value, even after annealing to temperatures of about 700°C. (iii) One can distinguish the influence of original dopant concentration on the recovery level by comparing the annealing results of samples 2 and 3, wherein a higher initial doping level yielded better recovery of conductivity.

Figure 2 is an example of the results of the cleave-and-stain experiments performed on the bombarded and annealed multilayered samples. The specimen displayed in Fig. 2 was a six-layered sample consisting of the following: starting with the n-type Si-doped substrate (layer 1), a 3-4 μm thick Te-doped buffer layer was grown first, then a thin (0.2 μm) Mg-doped, Al_{0.08}Ga_{0.92}As layer was grown (layer 3), then a 0.6 μm Ge-doped Al_{0.40}Ga_{0.60}As layer (layer 4), then a Mg-doped, 0.6 μm thick Al_{0.4}Ga_{0.6}As layer (layer 5), and finally a 0.15 μm heavily Ge-doped GaAs layer was deposited. A proton bombardment mask was used over the right-hand third of the sample shown, while the specimen was exposed to 300 keV protons at a dose of 3×10^{15} . The sample was annealed at 570°C for 15 min and then was metallized, cleaved, and stained in order to bring out the various layers.

Table I. Ratio of the sample resistivity after bombardment and anneal to resistivity before bombardment, at indicated temperatures

Sample	Dopant—	Approx. concentration	Epitaxial layer composition	Resistivity ratio	Anneal temp °C	Resistivity ratio	Anneal temp °C	Resistivity ratio	Anneal temp °C	Resistivity ratio	Anneal temp °C

Fig. 2. An SEM photomicrograph of a stained cross section of a proton-bombarded and -annealed multilayer sample.

A number of interesting observations can be made from this photograph. First, all of the Mg-doped layers stained the same as the unbombarded region, including the protected area of the Ge-doped layer. On the other hand, the exposed Ge-doped layer did not stain the same as the unbombarded region of the Ge-doped layer. Although the protons penetrated the n-type Si-doped substrate and, in fact, the "end of range" for the protons was well into the substrate, there was no evidence of an etching delineation to indicate a change in conductivity in the substrate. Lastly, although the p-type binary cap layer was Ge-doped, it was very heavily doped, and some magnesium might even have been incorporated by melt carry-over from the p-type (Al, Ga)As layer below it to provide for a substantial recovery of conductivity.

Discussion

In spite of the fact that a large literature exists on radiation damage in solids (12-15), and semiconductors in particular (16-18), the mechanisms involved in the generation of high resistivity in GaAs by proton bombardment are not well understood. Very little theoretical work has been done on this subject, and most of the experimental studies have revolved around two basic points: carrier removal effects (8, 9, 19) and optical absorption as a function of bombardment conditions followed by heat-treatments of various kinds (9, 20, 21). In a few cases, measurements have been made to show the influence of annealing on the recovery of electrical conductivity (8, 22-25), including that of proton-bombarded (Al, Ga)As (26).

Under the conditions defined by Sakurai *et al.* (24), it was found that a proton bombardment dose of $6 \times 10^{12}/\text{cm}^2$ into n-type (originally 10^{16} cm^{-3} , Te-doped) GaAs did not respond to annealing at a temperature of 435°C for 35h. Favennac *et al.* (26) found that equivalently doped and bombarded (Al, Ga)As annealed extensively after 15 min at 550°C . Steeples *et al.* (25) have shown that the temperature required for the onset of annealing effects was both proton-dose and n-type dopant concentration dependent. However, Donnelly *et al.* (27) claimed that a multiple energy proton bombardment sequence into 4×10^{18} Si-doped GaAs "... combined with a post bombardment anneal ... (of up to 500°C) ... is superior to a single energy bombardment in creating high resistivity layers in n⁺-GaAs ...". Dymant *et al.* (9) showed that annealing results of heavily (*i.e.*, $\geq 10^{18} \text{ cm}^{-3}$) Zn-doped p-type GaAs after proton bombardment was both dose and time-temperature dependent.

In almost all of these studies, the question of the "onset" of annealing appeared to be most important, and the conditions required to recover to the prebombardment value of conductivity were not stressed; in a few studies, however, continued annealing was performed. Whereas Foyt *et al.* (6) noted that "... an overnight anneal of 700°C ... removed the high resistance layer and the entire sample returned to the substrate carrier concentration,"

they also observed that "... contact alloying at 500°C without removing the high resistance layer" was achieved. Favennac *et al.* (26) presented the only direct data to show that the normalized resistivity ratio returned to unity for a 10^{16} cm^{-3} Te-doped (Al, Ga)As layer that was bombarded with a dose of 7×10^{12} protons/ cm^2 and then annealed at 550°C for 15 min.

The data presented in this paper differ in two ways from most of the information obtained in previous studies. From the beginning, we were interested in determining the conditions required for reaching, if at all possible, the original conductivity of the prebombarded samples, and we were also concerned with obtaining information on the influence of specific dopants and host crystals on these recovery conditions. From the data shown in Table I, and analyzed above, it is clear that there are strong influences pertaining to all of these parameters. The major observations were: (i) the recovery-anneal temperatures, as a function of dopant, were $\text{Zn} < \text{Mg} < \text{Ge}$; (ii) total recovery was achievable in the ternary more readily than in the binary host; and (iii) the higher the background doping, the lower the temperature at which recovery started. This last point is totally consistent with the previously reported concepts of requiring larger proton doses and/or lower annealing temperatures for increased background doping in the host crystal. However, the first two points noted above are new and are potentially of scientific as well as technological interest.

As was stated earlier in this paper, the fundamental understanding of the mechanisms involved in rapid generation after proton bombardment, subsequent anneal, and dopant activation is minimal at best. Because of this, it is not possible to provide a definitive explanation for the effects we have just noted. However, a strong diffusion mechanism involvement, possibly defect-enhanced, is clearly suggested. It is known (28), for example, that p-type dopants diffuse more readily in the ternary than in the binary, and the known diffusion coefficients are in the order, $\text{Zn} > \text{Mg} > \text{Ge}$. This would be consistent with the annealing temperature dependence observed in this work. It is difficult to be more quantitative in this discussion because dopant diffusion in the Al-Ga-As system is not well understood, and many parameters influence the mechanism of diffusion (29, 30) (*e.g.*, arsenic vapor pressure and control thereof, dopant concentration effects (31), etc.). Couple this with the complications introduced by dealing with a severely defected material resulting from ion bombardment, and one can begin to appreciate the magnitude of the problem.

To determine the amount of damage introduced by bombarding GaAs with protons, we have calculated that approximately 50 atomic sites are affected by each of the incoming 300 keV protons (see Appendix). The ion dose used in these experiments was $3 \times 10^{15} \text{ cm}^{-2}$, which results in an "area" damaging effect of approximately $1.5 \times 10^{17} \text{ cm}^{-2}$. Knowing that at 300 keV the projected range for

protons in GaAs (33) is approximately $2.5 \mu\text{m}$, and assuming, for simplicity, that all of the displaced atomic sites are uniformly distributed, one finds a "damage" concentration level in the mid 10^{20} cm^{-3} as a result of this specific set of bombardment conditions. This damage level is not far from the conditions described by Wang *et al.* (34) for making GaAs amorphous; they determined a critical proton dose of approximately 10^{16} cm^{-2} at bombardment energies comparable to those used in our study. This means that, under all of the background doping conditions used in our experiments, there were at least two orders of magnitude higher defect densities generated by ion bombardment than the electrically active dopant present to compensate for these defects during annealing. Therefore, the strong influence of defect-enhanced diffusion is a very real possibility.

From a technological point of view, some very interesting and potentially novel device possibilities arise from the observations made in this study. For example, when two layers of GaAs and/or (Al, Ga)As are placed side by side but doped with different dopants, one can visualize, if the sample is properly proton-bombarded and annealed (schematically shown as T_a in Fig. 3), that one of the layers could be maintained in a high resistance condition, while the other layer could be made conducting again. An example of this effect in a more complicated structure is clearly shown in Fig. 2, where just such a set of conditions was achieved with the p-type dopants Mg and Ge in the multilayer sample. From the limited data of Steeples *et al.* (25), one might infer that similar disparate annealing effects should occur with n-type dopants. This leads to the very interesting speculation that by a judicious choice of host crystal (epitaxial layer), dopants, and processing conditions (*i.e.*, bombardment and anneal), one should be able to control the juxtaposition of conducting and non-conducting layers and/or parts of layers, either of the same or different initial conductivity type and/or bandgap, buried within the solid. This kind of capability opens entirely new vistas in the potential for three-dimensional integrated circuits in compound semiconductors; for example, planar-buried interconnects, buried blocking layers, buried active devices, and buried optical wave guides.

Another very striking piece of information should be considered with regard to three-dimensional integration. Examining the dose dependencies of high resistivity generation in p- and n-type GaAs by Dymont *et al.* (9) and Pruniaux *et al.* (8), respectively, one obtains the data in Fig. 4 which show that p- and n-type GaAs become highly resistive at different proton doses. Coupling this information with the ability to grow juxtaposed layers either n- or

Fig. 3. A schematic showing annealing curves for two differently doped GaAs samples; T_A is a temperature where sample containing dopant A has recovered its conductivity and sample B is still highly resistive.

Fig. 4. Resistivity curves for proton-bombarded p- and n-type GaAs, as a function of proton dose, after Ref. (8, 9).

p-type with carefully chosen dopants, we see that countless possible permutations and combinations are available to the device designer for three-dimensional integrated optoelectronics.

Conclusion

It has been shown that the annealing characteristics of proton-bombarded p-type GaAs and (Al, Ga)As depend strongly on the dopant species and concentration, as well as on the host crystal used. Total recovery of electrical conductivity has been achieved more readily in the ternary than in the binary and with the higher diffusion coefficient dopants. Juxtaposing of buried conducting and nonconducting regions has been achieved by judiciously choosing the dopants, epitaxial layer compositions, and annealing conditions. On the basis of these observations, speculations have been presented about the possibilities of three-dimensional integration.

APPENDIX

From Gibbons (32)

$$N_t = \{P(E_0 - E_c) + bE_c\}/Ed \quad [A-1]$$

where N_t is the total number of displaced atoms per incident ion, P is the probability factor $\approx 10^{-3}$, E_0 is the initial energy of projectile = 300 keV, E_c is the energy at which nuclear stopping power equals electronic stopping power $\approx 1 \text{ keV}$, E_d is the displacement energy for target atom $\approx 15 \text{ eV}$, and $b = 1/2$ if $E_b > E_c$, and $1/4$ if $E_b < E_c$.

$$E_b = \frac{\gamma E_A^2}{4E_d} \quad [A-2]$$

$$\gamma = \frac{4M_1M_2}{(M_1 + M_2)^2} \quad [\text{A-3}]$$

$$E_A = 2E_R Z_1 Z_2 (Z_1^{2/3} + Z_2^{2/3})^{1/2} (M_1 + M_2) / M_2 \quad [\text{A-4}]$$

where Z_1 and M_1 are the atomic number and mass of the projectile, Z_2 and M_2 are the atomic number and mass of the single element target atom, and E_R is the energy of projectile at which it is equal to the Coulomb interaction potential of the two nuclei separated by the sum of the radii of their screening clouds ≈ 13.5 eV.

For protons as the projectile, assuming the average mass and atomic number for GaAs (the target) to be that of Ge (*i.e.*, 73 and 32, respectively) by putting in the appropriate values, one obtains: $E_A \approx 3$ keV, $\gamma \approx 0.05$, and $E_b \approx 8$ keV. Therefore, by substituting the proper values in Eq. [A-1], $N_i \approx 50$ displaced atoms/incident proton. Considering a proton dose of 3×10^{15} cm⁻², then $N_{\text{total}} = 3 \times 10^{15} \times 0.5 \times 10^2$, or total atomic displacement $\approx 1.5 \times 10^{17}$ cm⁻².

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173-0073

ABSTRACT

The principal topographic imperfections in Si films recrystallized on SiO₂ by the graphite-strip-heater technique have been examined. Wafer warpage has been reduced to less than 4 μm for 2 in. diam samples. The protrusion density decreases with finer sub-boundary spacing; this correlation can be understood in terms of the thermal gradient present at the liquid-solid interface.

In recent years, substantial efforts have been directed toward the development of a technology for producing high-quality single-crystal Si films on insulating substrates (1-4). These efforts have been motivated by the potential of thin film devices for achieving higher packing density, speed, and radiation resistance than bulk devices, and by the potential of Si-on-insulator (SOI) structures for accomplishing the three-dimensional integration of electronic circuits. Of the several SOI approaches currently under investigation (5), one of the most promising is zone melting recrystallization (ZMR), in which the grain size of a polycrystalline Si film on an insulating

*Electrochemical Society Active Member.

substrate is greatly increased by the passage of a narrow molten zone. We have developed ZMR using graphite-strip heaters to the point where 2 and 3 in. diam wafers can be recrystallized over their entire surface (6-8), and we have used the recrystallized SOI material to fabricate majority carrier devices and integrated circuit chips with properties comparable to those of analogous bulk devices (9, 10). However, before the full potential of SOI technology using graphite-strip heaters can be realized, techniques must be developed to eliminate or minimize the remaining material problems: wafer warpage, protrusions, and low angle grain boundaries. The first two of these are topographic imperfections. In this paper, we

Fig. 1. Schematic diagram of a graphite-strip heater used for zone melting recrystallization of encapsulated Si films. The inset shows a cross section through a typical sample.

present the results of our investigation of these imperfections and discuss their dependence on thermal profiles present during the recrystallization process (11). In addition, we will briefly discuss our observation of voids, which are occasionally formed in the crystallized films because of contamination during wafer preparation.

ZMR by the Graphite-Strip-Heater Technique

The configuration of the graphite-strip-heater oven we use for ZMR of Si on SiO₂ is shown schematically in Fig. 1 (8). The sample, which is placed on the stationary lower heater, consists of a fine-grained Si film on an insulating substrate or layer, together with an encapsulation layer over the Si film. The inset of Fig. 1 shows a schematic cross section of a typical sample, prepared by coating a Si wafer 10-20 mil thick with a 1.0 μm thick thermally grown SiO₂ layer, a 0.5 μm poly-Si layer formed by low pressure chemical vapor deposition (LPCVD), a 2 μm layer of CVD SiO₂, and a 30 nm layer of sputtered Si-rich Si₃N₄. The lower strip heater is used to heat the sample to a base temperature of 1100°-1300°C, generally in a flowing Ar gas ambient at atmospheric pressure. Additional radiant energy, provided by the movable upper strip heater, is used to produce a narrow molten zone in the poly-Si layer (mp of Si = 1410°C). The molten zone is then translated across the sample by scanning the upper heater, typically at 1/2 mm/s, leaving a recrystallized Si film (7). The thicknesses of the SiO₂ and Si layers, the composition of the encapsulation layer, the molten zone speed, and the shape of the upper heater and its position relative to the sample all have a strong effect on the morphology and crystallography of the recrystallized films.

Topographic Imperfections

Warpage.—Zone melting recrystallized Si films exhibit several types of topographic imperfections. One type is wafer warpage, which must be minimized because of the

stringent flatness requirements imposed by photolithographic processes used in VLSI fabrication. Warpage was measured with a laser interferometer flatness monitor which gives a fringe pattern that provides a topographic map of the sample surface, with each fringe corresponding to a constant height contour. Before recrystallization, the overall warp, peak to valley, of a 2 in. diam sample placed on a vacuum chuck is typically 2-4 μm, a value comparable to that for a bulk Si wafer after processing. To maintain this degree of flatness for recrystallized samples, well-controlled heating rates and temperature profiles are necessary.

Uniform thermal contact between the sample and lower heater and a constant separation between the sample and moving upper heater are essential for recrystallization to be accomplished over the entire surface of 2 and 3 in. diam samples. Because Si has a lower emissivity than graphite, a radial temperature gradient will result if an SOI sample is placed on a uniformly heated lower heater. One can compensate for this effect by making a circular depression in the surface of the lower heater in order to reduce the resistive heating directly beneath the sample¹. For example, we have found that a 0.010 in. deep 2 in. diam well in a 0.040 in. thick lower heater (8) minimizes the radial temperature variation and allows uniform recrystallization of the entire surface of a 2 in. diam. sample in an Ar ambient.

Figure 2a shows an interference pattern obtained for an as-recrystallized 0.013 in. thick, 2 in. diam SOI sample that was placed on a vacuum chuck for measurement. The pattern shows that the sample was relatively flat over a large portion of the surface, but had several high points. We have determined that such high points, which are characteristic of as-recrystallized samples, result from imperfections that protrude from the back side of the samples (see Fig. 3) and prevent them from conforming to the flat surface of the vacuum chuck. Auger analysis shows that these imperfections are Si mounds that are coated with a thin surface layer (~100Å) of carbon. They are most likely caused by local melting of the Si substrate at hot spots on the graphite heater. The molten Si breaks through the SiO₂ coating on the back side of the substrate and beads up because of surface tension before it solidifies. These imperfections are readily removed by lapping the back side of the sample with 40 μm abrasive for 30s. By using this procedure, the measured overall warp was dramatically reduced from ~30 to ~4 μm, as shown in Fig. 2b. To simulate the effects of high temperature device processing, recrystallized samples with a total warp of ~4 μm were heated at a maximum ramping rate of 80°C/min and then annealed for 1h at 1000°C and then for 1h at 1100°C in a N₂ ambient. The overall flatness was actually slightly improved, probably as the result of elimination of stress in the Si substrate by the annealing. Simi-

¹For a similar technique, but relying upon reduced thermal contact between the sample and lower heater, see Ref. (12).

Fig. 2. Interference patterns, with a sensitivity of 5 μm per fringe, for a 2 in. diam SOI sample (a) as recrystallized and (b) following back-side lapping.

Fig. 3. Scanning electron micrograph showing an imperfection on the back side of an SOI wafer.

lar results have been obtained for 0.015 in. thick, 3 in. diam wafers, with total warp typically $\sim 10 \mu\text{m}$ and in the best case $6 \mu\text{m}$. (Slip occurs in the Si substrate, but not in the Si film during ZMR. However, the annealing experiments show that slip does not adversely affect the overall wafer flatness during subsequent high temperature processing.)

Fig. 4. (a): Micrograph of a recrystallized Si film taken with a scanning electron microscope operated in the backscattering mode. The Si₃N₄/SiO₂ cap has been removed. (b): Magnified view of a small area of the film showing protrusions.

Protrusions.—Figure 4 shows scanning electron micrographs of a recrystallized SOI film containing protrusions. These imperfections are believed to result from the volume expansion occurring during the solidification of liquid Si pools which remain after the liquid-solid interface has passed. According to Auger microprobe analysis, the protrusions consist predominantly of Si, and they do not differ significantly from the surrounding Si film in their impurity content. As shown in Fig. 4, the protrusions generally lie along low angle grain boundaries (sub-boundaries), suggesting some correlation between the two types of imperfections. By evaluating a large number of SOI samples, we have established a direct relation between protrusion density and sub-boundary spacing. The relationship is illustrated in Fig. 5, which shows optical micrographs of two recrystallized SOI samples that were etched in Secco etch (13) and diluted with an equal volume of water to delineate the defects. The sample on the right, which has a wider sub-boundary spacing, has many protrusions; the sample on the left, with more closely spaced sub-boundaries, has very few. In Fig. 6, the sub-boundary spacing is plotted vs. protrusion density; 85% of the data points fall in the shaded region, which shows a systematic decrease in protrusion density with decreasing sub-boundary spacing. This correlation can be understood in terms of the model developed earlier to explain sub-boundary formation (14). According to this model, the sub-boundary spacing decreases as the thermal gradient in the scanning direction is increased. As this gradient increases, the protrusion density should also decrease, since the liquid-solid interface becomes more stable and hence less susceptible to small thermal fluctuations which would give rise to protrusions.

A number of experimental procedures can be followed to increase the temperature gradient at the liquid-solid interface². These include reducing the scan speed (7), decreasing the thickness of the Si film to reduce the total heat of fusion to be dissipated (7), replacing the Ar gas with He (which has a higher thermal conductivity) to increase the rate of heat dissipation to the ambient, and reducing the thickness of the underlying SiO₂ layer or the base temperature of the sample in order to increase the rate of heat dissipation to the substrate. In all cases when such procedures have been followed, the result (if any was detected) was to reduce the sub-boundary spacing and protrusion density as expected for an increase in the temperature gradient.

²For a theoretical analysis of the recrystallization process, see Ref. (15).

Fig. 5. Photomicrographs of recrystallized Si films illustrating the correlation between protrusion density and sub-boundary spacing.

The temperature gradient is also affected by the shape of the upper strip heater and its separation from the sample. We have carried out calculations to investigate the effect of these parameters on the geometrical distribution of power from the upper heater that is incident on the sample. The calculations were made for the two heater cross sections shown schematically in Fig. 7, where D is the heater-sample separation and x is the position on the sample surface along the scan direction, with $x = 0$ located beneath the center of the heater. The heater was assumed to be an infinitely long blackbody. To obtain the relative power distribution, the incremental power originating from a small segment of the heater surface and incident at a position x was calculated from the angle subtended by the segment and the angle of incidence at x . This incremental power was then integrated over the region of the heater visible from x , yielding the relative incident power profile, $P(x)$

$$P(x) = \begin{cases} P_1(x) & 0 \leq x \leq \frac{W}{2} \\ P_1(x) + P_2(x) & x \geq \frac{W}{2} \end{cases}$$

where $P_1(x)$ and $P_2(x)$ are respectively the contributions to P from the bottom and side of the heater, as given by

$$P_1(x) = N \left\{ \frac{x + \frac{W}{2}}{\left[\left(x + \frac{W}{2} \right)^2 + D^2 \right]^{1/2}} - \frac{x - \frac{W}{2}}{\left[\left(x - \frac{W}{2} \right)^2 + D^2 \right]^{1/2}} \right\}$$

$$P_2(x) = N \left(x - \frac{W}{2} \right) \left\{ \frac{1}{\left[\left(x - \frac{W}{2} \right)^2 + D^2 \right]^{1/2}} - \frac{1}{\left[\left(x - \frac{W}{2} \right)^2 + (D + H)^2 \right]^{1/2}} \right\}$$

W is the width and H the height of the heater, and N is a factor normalizing the distribution to unity at $x = 0$. Normalized incident power profiles for several values of D and for the two heater shapes are shown in Fig. 7. The incident power profiles (and thus the temperature gradients) become sharper with decreasing heater-sample separation. Consistent with this result, lower protrusion densities have been observed for reduced separations. To achieve sharp incident power profiles experimentally, care must be taken to control or eliminate the bowing of the SOI sample, and of the upper and lower strip heaters as a result of thermal expansion upon heating. Such bowing could significantly alter the upper heater-sample sep-

aration. Note also that the temperature gradient at the liquid-solid interface depends on the position of the interface with respect to the upper heater (*i.e.*, on the width of the molten zone), since the gradient as well as the incident power varies with x .

Voids.—From time to time, we have found that recrystallized Si films from a particular batch of SOI wafers contain voids with densities as high as $5/\text{mm}^2$. Figure

Fig. 6. Plot of sub-boundary spacing vs. protrusion density. Data points for 85% of the samples examined fall in the shaded region.

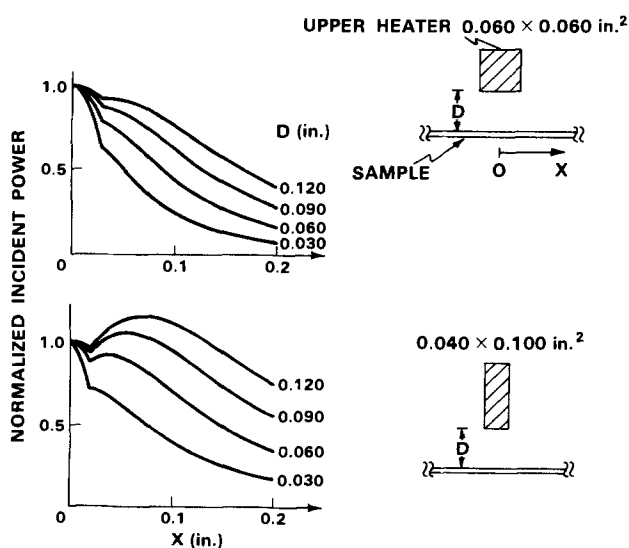

Fig. 7. Power incident on a sample from the upper strip heater as a function of position x along the sample surface. D is the heater-sample separation.

Fig. 8. Optical (Nomarski interference) and SEM micrographs of typical voids. The cross-section diagram shows the reduction in the thickness of the recrystallized Si film in the vicinity of the void.

8 shows optical and scanning electron microscope (SEM) micrographs of typical voids. The SEM cross-sectional view indicates that the voids result from the flow of molten Si, which leads to local thinning of the Si film, and in extreme cases to the absence of Si between the two oxide layers. Because void-free recrystallized Si films have often been produced immediately before and after the preparation of films with high void densities, these imperfections are believed to result from contamination introduced in the fabrication of the SOI structure. Although the precise mechanism of void formation is not known, we have found that reducing the scan speed from 1 mm/s to 0.5 mm/s significantly decreases the void density in films from contaminated batches. This improvement probably occurs because the lower rate produces a sharper temperature gradient, which stabilizes the liquid-solid interface.

Conclusion

We have discussed factors affecting the principal topographic imperfections in ZMR Si films. With suitable control of the heating rate and temperature profile, together with back-side lapping after recrystallization, total warp of less than 4 μm has been achieved for 2 in. diam SOI wafers on a vacuum chuck. This flatness approaches that needed for VLSI applications. Lower protrusion density has been correlated with finer sub-boundary spacing, and both can be attributed to a sharper thermal gradient at the growth front. Lower protrusion density can be achieved by reducing the thickness of the lower SiO₂ layer and the poly-Si film, the scan speed, and the upper heater-sample separation, and by using an ambient gas with higher thermal conductivity. 2 in. diam films nearly free of protrusions have been obtained. However, such films have a high density of sub-boundaries.

We are presently exploring two approaches to solve the problem of protrusions and sub-boundaries in recrystallized SOI films. First, we are investigating control of the sub-boundaries by means of entrainment (14). Second, we are attempting to suppress sub-boundary formation by

using sharper temperature gradients,³ repeated melting and regrowth, and periodic seeding (17). Because the protrusions lie along the sub-boundaries, success with either approach would yield SOI films with large areas free of both sub-boundaries and protrusions. We believe that the characteristics needed for employing large-area wafers will be achieved in the near future, making the ZMR process a practical technique for producing SOI materials for VLSI applications.

Massachusetts Institute of Technology assisted in meeting the publication costs of this article.

³As the temperature gradient increases, the sub-boundary density will also increase. However, if a sufficiently sharp gradient can be achieved, the formation of instabilities giving rise to sub-boundaries will be suppressed (16).

Characterization of RF Sputter-Deposited Ti-W Schottky Barrier Diodes in Boron-Doped Silicon

O. Paz,* F. D. Auret,¹ and J. F. White

IBM East Fishkill Laboratories, Hopewell Junction, New York 12533

ABSTRACT

The properties of defects introduced during RF sputter deposition of Ti-W contacts on p-Si were investigated using I-V, deep level transient spectroscopy (DLTS), and electron-beam-induced current (EBIC) techniques combined with isochronal and isothermal annealing. It was found that the barrier height decreased from 0.56V before annealing to 0.5V after isochronal annealing. DLTS measurements indicate the presence of several sputter-induced defect states. Annealing removed some of the defects, but second generation defects were still present after annealing at 500°C, now distributed deeper into the substrate. EBIC results showed that the diffusion length decreased with increasing annealing temperature. DLTS and EBIC results suggest that a hole trap at $E_v + 0.35$ eV is a strong recombination center. This hole trap is very likely the same defect as the one identified as the K center [V + O + C].

Sputtering, which allows deposition of both metals and insulators, is especially useful because of its ability to deposit compounds with good stoichiometric control. When sputtering metal contacts, they and the substrate underneath are subject to bombardment by energetic particles. These particles include low energy Ar ions from the plasma, sputtered metal atoms [with energies up to 20 eV (1)], high energy electrons, and neutral Ar atoms. It has been found that in silicon, the sputtering process creates an electrically active damaged layer in the substrate underneath the contact (2, 3).

Mullins and Brunnschweiler (2) suggested that during sputter deposition (on n-type silicon), high density donor-like traps are created near the surface. Berg *et al.* (3) proposed that the increasing surface-trap density causes electron tunneling through the barrier at an energy lower than the energy at the top. This leads to lowering of the effective barrier height. Not much has been published on the structural modification that this damage may cause in the surface layer. Ogilvie and Thomson (4) have shown that positive argon ions (at an energy of 130 eV) can introduce disoriented crystallites and stacking faults near the surface of single-crystal silver.

In this work, we investigate the damage induced in the substrate when Ti-W Schottky barrier diodes (SBD's) are RF sputter deposited. The effect of the damage on the properties of the rectifying junctions is obtained from I-V measurements, while the DLTS and EBIC techniques are employed to characterize the nature of the defects, and the extent to which they increase recombination.

Experimental

p-Type ($N_A = 1 \times 10^{16}$ cm⁻³), Czochralski-grown, <100> Si wafers (82 mm diam) were used. In order to form ohmic contacts, the wafers were chemically cleaned and Al deposited on their unpolished back sides. The wafers were subsequently annealed for 30 min at 450°C in forming gas. Prior to sputtering, the wafers were dipped in buffered HF for 10s to remove the residual surface oxide. After pumping the system to 10⁻⁶ torr, a 2000Å thick continuous layer of Ti-W (10% Ti, 90% W by weight) was sputter deposited at a power of 1 kW (800V) in an argon atmosphere of 8 × 10⁻³ torr. In order to define a dot pattern of SBD's, 0.5 mm Al dots were resistively deposited on the Ti-W film through a contact mask. The Ti-W film around the dots were then removed by chemical etching. This method of forming the SBD's prevented possible contamination of the wafer's surface due to contact with the contact mask.

I-V and DLTS measurements were taken on the devices without annealing them as well as after annealing for 10 min at 25° or 50°C intervals up to 500°C. EBIC measure-

ments were taken before annealing and after annealing for 20 min at 275° and 400°C. The longer annealing times approximately compensate for the fewer annealing cycles that were received by the latter devices. DLTS (5) analysis was performed by using the dual-gated, lock-in amplifier technique (6). Measurements were taken in the temperature range 83-300 K.

Diffusion lengths in the Si layer beneath the contact were determined using electron-beam excitation (EBIC mode). The diffusion lengths were measured at 18 kV and corrected for carriers generated by backscattered and secondary emitted electrons. In carrying out the correction due to backscattered electrons, the number of collected carriers at 8.6 kV (the energy spectrum of backscattered electrons with primary energy of 18 kV) was also measured. The model used to calculate the diffusion length is described in Ref. (7). Here we briefly outline some of the assumptions used in deriving it. Due to the normalization procedure (the collection current is divided by the specimen current (7), the diffusion length does not depend on the beam current (except for injection effects that can be reduced or taken into account). The acceleration voltage determines the generation volume and, therefore, the depth (we are using a one-dimensional model) of generation and collection. Because of the geometry, any variations in surface recombination velocity are not a problem. It is assumed that carriers are collected at the edge of the depletion layer with infinite collection velocity. In the depletion layer itself, no recombination is assumed. This constraint is less significant when the depletion layer depth is small compared to the generation volume.

When the beam electrons penetrate the metal layer, they lose part of their energy due to scattering, without generation of excess carriers. Therefore, the metal thickness, as well as the mass density and atomic weight, greatly influence charge collection. In order to correct the diffusion length readings for losses in the metal layer, charge collection *vs.* metal thickness was plotted for evaporated Mo contacts (on n-type wafers) in the thickness range 200-2700Å. For SEM beam energy of 18 kV, a linear fit produced the following relationship

[Loss of Excess Carriers]

(in carriers per incident electron) =

$$[0.919] \times [\text{layer thickness in angstroms of the Mo layer}] \quad [1]$$

For a Ti-W layer, the readings were further corrected by assuming that the effective layer thickness Y is proportional to the maximum penetration range R_{\max} [for R_{\max} , Kanaya and Okayama's (8) model was used]

$$\frac{Y_{\text{Mo}}}{Y_{\text{Ti-W}}} \approx \frac{R_{\max\text{Mo}}}{R_{\max\text{Ti-W}}} \quad [2]$$

Results

The barrier heights were extracted from the log (I)-V curves by using Beguwala and Crowell's three-point method (9). The influence of anneal temperature on these barrier heights is shown in Fig. 1. The devices were annealed for 10 min at 50°C intervals up to 500°C. A gradual decrease in the barrier height from 0.56V at room temperature to 0.5V at 500°C was observed. Isothermal annealing (400°C, 1h intervals) showed that the barrier height stabilized at 0.52V after 3h, and remained at that value even after 8h anneal at 400°C.

The activation energies and annealing characteristics of the DLTS defect states obtained from the DLTS spectra are summarized in Table I. Figure 2 shows typical DLTS spectra, taken before annealing and after 275°, 375°, and 450°C anneals. Before any annealing, three defect levels were observed: H(0.26), H(0.35), and H(0.45) (the H signifies that the defect is a hole trap and that the activation

H(0.48)	2×10^{-15}	261	400	>500

* The symbol RT means that the defect was observed after deposition and without any annealing.

energy is measured from the valence band). At 275°C, almost no defects can be observed; however, annealing at higher temperatures again increased the defect concentration, as well as introduced new defects. A similar disappearance of the defects after 250°C, and reappearance after annealing at higher temperatures, was observed by us in ion beam sputter-deposited Mo contacts on n- and p-type Si (10). Figure 3 summarizes the results of depth profiling that was achieved by the fixed-bias variable pulse method (5). As the figure shows, the most prominent defect level observed before annealing H(0.35) was located very close ($\leq 1600\text{\AA}$) to the interface. This defect level merits a detailed discussion. Figure 4 plots the DLTS signal (that is proportional to the concentration of the defect states) vs. the isochronal annealing temperature (10 min, 25°C interval). The figure shows that defect H(0.35) follows the same trends as defect H(0.35) that was analyzed after ion beam deposition of Mo on p-type silicon (10). After a 200°C anneal, H(0.35) disappeared almost completely. Upon increasing the anneal temperature to 300°C, it reappeared only to be distributed much deeper ($< 4000\text{\AA}$, see Fig. 3) in the substrate. Its concentration reached a maximum after 350°C annealing, and it finally annealed out at approximately 450°C. Above 300°C, more defects were introduced. The most significant defect in this temperature range H(0.38) started to appear as H(0.35)

Fig. 3. Depth concentration profiles of H(0.35) and H(0.38) taken before and after annealing.

Fig. 4. Isochronal (10 min) annealing behavior of RF sputter-induced damage. The defects represented by dark symbols were only present very close to the surface.

began to anneal at 400°C. It was still present after annealing at 500°C, now observed even deeper into the Si substrate ($\leq 6000\text{\AA}$) than H(0.35). Figure 5 illustrates that isothermal annealing (400°C, 1h intervals) showed a gradual increase in the defect concentrations, especially of H(0.38) and H(0.29). Annealing, therefore, did not remove the process-induced defects, but only caused them to move deeper into the Si substrate.

Another related conclusion was that the defect H(0.35) exhibited the same annealing behavior as H(0.35), observed after irradiating similar wafers with 2 MeV electrons (Fig. 6). For the latter case, SBD's were formed on the irradiated wafers by resistive evaporation of Ti. Furthermore, it was recently found that defects H(0.35) and H(0.38) are present after electron-beam deposition of Mo, Hf, and Ti on p-type silicon, and all exhibit a similar annealing behavior (11). As discussed in more detail in Ref. (11), H(0.35) is very likely the same (12, 13) defect as the one identified as the K center [V + O + C]. The defect H(0.38) appears after H(0.35) anneals out. This strongly suggests that H(0.38) is formed from the dissociates of H(0.35).

Figure 7 illustrates the diffusion length results. At 18 kV, electron-hole pairs are produced within a 4.5 μm generation volume. Generation of excess carriers in the substrate can be approximated as an exponential that decays with increasing depth. Therefore, more excess carriers are generated within the surface portion of the generation volume than in the bulk portion. This means that, at 18 kV, the diffusion lengths measured are more representative of the damaged layer beneath the contact than the bulk. As the figure shows, the diffusion length decreases gradually from about 4.5 to 1.2 μm after annealing the samples at 275° and 400°C, respectively.

Discussion

The decrease in barrier height that was observed in the present work after annealing is consistent with observations on ion beam sputter-deposited Mo contacts (on p-type silicon) (10). After RF or ion beam sputter deposition, the device barrier heights are modified: as reported for n-type silicon (10), the barrier heights are decreased, and they increase for p-type silicon. Mullins and Brunnschweiler (2) calculated the potential energy profile in n-type silicon assuming that donor-like traps are introduced due to the sputtering damage. They showed that, for traps that are distributed into the substrate as a decreasing exponential, the modified potential energy profile leads to narrowing of the barrier and increased tunneling. This is reflected in a lower effective barrier height. For p-type silicon, we can qualitatively reason out an increase in the effective barrier height as follows: if we assume donor-like traps, the positively charged traps will neutralize some of the negatively charged ionized acceptor impurities. This has the same effect as moving the Fermi level away from the valence band, which leads to widening of the barrier and a decrease in tunneling. Fonash *et al.* (14) suggested a similar effect for ion-beam-generated damage. The decrease in barrier height that we observed after annealing (Fig. 1) suggests that a decrease in defect concentration near the interface has taken place. However, the DLTS data suggests that as the defects mi-

Fig. 7. Variation of minority carrier diffusion length, measured below the Ti-W SBD, with annealing temperature.

grated deeper into the substrate, their concentration increased (even as close to the interface as can be determined given the spatial resolution of the method). This is illustrated for trap H(0.35) in Fig. 3. The concentration of H(0.35) and its replacement H(0.38) is higher at 350° and 475°C than before annealing.

A comparison of the DLTS spectrum and the diffusion length results suggest that H(0.35) is a strong recombination center. The significant increase in the concentration of H(0.35) seen after 375° or 400°C anneal is accompanied by a factor of three reduction in diffusion length. Based on the annealing behavior we postulated that H(0.35) is the same defect as the vacancy-carbon-oxygen complex [V + C + O] that was identified, using the EPR technique, in irradiated p-type silicon (15). A possible mechanism for the formation of this defect is the following (12)

where [V] represents the vacancy and [C_s + O_i] represents a complex consisting of substitutional carbon and interstitial oxygen. The concentration of the [V + O + C] complex can be determined from the concentration of its constituents. Both substitutional carbon and interstitial oxygen are present in Czochralski-grown silicon. The vacancies are introduced due to the bombardment by Ar ions or neutral Ar atoms. After annealing, the vacancies will migrate deeper into the substrate producing even more [V + O + C] complexes, as we observed from both the DLTS and the diffusion length data. An argument can be made that the [V + O + C] complex was observed by several investigators that reported slightly different energy levels (12). This conclusion is based on an agreement on the location of the levels and their annealing behavior. More recently, Benton and Kimerling (16) reported a hole trap at $E_v = 0.36$ eV that has the same DLTS peak temperature as we report, after correcting for the different instrumentation time constants, although anneal data were not given. In still another work, conducted at our laboratory, H(0.35) and H(0.38) were observed after electron-beam deposition of Mo and Ti on p-type silicon (11). The preponderance of this defect after several processes and in a wide range of samples suggests a major defect in boron-doped silicon. The annealing behavior reported here for the [V + O + C] is somewhat different than the annealing behavior reported previously for the [V + O + C] complex (12). This difference may be due to the substrates used. The disappearance of the [V + O + C] after 275°C does signify, in our opinion, not that the defects were removed, but rather that a change of state took place. This conclusion is based on the diffusion length's remaining low. The change of state can occur due to two reasons. First, it can be due to a Fermi level shift that may result from dopant compensation. However, the oxygen thermal donor is not sufficiently activated at 275°C to cause this compensation. Second, the [V + O + C] complex can react with a vacancy to form a new complex [X] that can either be electrically inactive or have a state in the upper bandgap and, therefore, undetectable to us

the subsequent reappearance of the [V + O + C] complex at higher temperatures may be due to production of new [V + O + C] complexes upon further vacancy migration.

A recent paper reports that complexes involving oxygen are lifetime limiting (17). Dislocation-free Czochralski-grown Si crystals were used, doped with boron or phosphorus. The interstitial oxygen concentration in their samples (about 10^{18} cm⁻³) is comparable to ours, and the carbon concentration is relatively high (10^{17} cm⁻³).

The crystals were measured as grown without any heat-treatment. Since defect energy levels were not measured, we can only speculate that the reported defects may have been [V + O + C] complexes.

Conclusions

We have demonstrated that RF sputtering of Ti-W contacts introduces defects near the semiconductor interface. Log (I) vs. V results confirm an earlier observation that sputtering induced damage increases the barrier height in p-type silicon. Log (I) vs. V and DLTS measurements, taken after isochronal annealing, suggest that the defects move deeper into the substrate at temperatures above 275°C. Also, new defects are introduced and defects are present even after 500°C anneal. Isothermal annealing indicated that the total defect concentration at 400°C increased with anneal time. EBIC results indicate that annealing lowers the lifetime in the surface layer of the substrate (up to a depth of 4 μm). It also shows that some of the defects observed by DLTS, in particular H(0.35), are recombination centers.

Two of the defects observed after Ti-W sputtering, H(0.35) and H(0.38), have the same anneal characteristics as H(0.35) and H(0.38) observed by us on unspattered wafers that received 2 MeV electron irradiation. This suggests that H(0.35) is the same defect as the one identified as the K center, also present in p-type wafers that received 1.5 MeV electron irradiation.

ABSTRACT

Raman scattering has been utilized to examine variations in the free-carrier concentration of S-, Sn-, and Ge-doped (100) InP and Si-doped (100) GaAs induced by vacuum annealing the wafers at 500°-550°C for periods ranging from 30 to 60 min. Corrections for the concentration dependence of the conduction electron effective mass have been incorporated analytically. After annealing, reduction of the free-carrier concentration is observed in all cases; for InP, the magnitude of the reduction varied from ~20% for S-doped material annealed at 550°C for 30 min to 20%-50% for Sn- and Ge-doped samples annealed at 500°C for 1h. A 1h anneal of Si-doped GaAs at 500°C reduced the net free-carrier density by roughly a factor of 4. Our measurements indicate that if annealing induced dopant "pile up" occurs at the surface because of gettering or the dynamics of surface evaporation, then the dopants either (i) are not electrically active, (ii) have been compensated by defects generated during annealing, or (iii) are piled up within the space-charge depletion region.

The net doping level in the near-surface region of most compound semiconductors is known to be sensitive to the thermal history experienced by the sample. Some of the factors known to alter the surface free-carrier density include (i) dopant redistribution induced by gettering to surface defects, (ii) direct dopant volatilization, and (iii) generation and diffusion of defects related to surface substrate evaporation. The latter consideration is particularly important for a material like InP because it incongruently evaporates *in vacuo* at temperatures above 360°C. Other parameters, such as the gas ambient, are also critical in influencing the type of defects generated during substrate volatilization. As a consequence, reports can be found in the literature concerning InP in which varying the annealing ambient can either reduce (1) or enhance (2) the near-surface doping level relative to bulk values:

The present study concerns alterations of the near-surface free-carrier concentration induced by uncapped vacuum annealing of InP and GaAs wafers at 500°-550°C for periods varying from 30 to 60 min. The substrates studied were all degenerately n-doped in the range $0.5\text{-}2 \times 10^{18} \text{ cm}^{-3}$. In degenerately n-doped zinc blende materials, it is possible to obtain the net free-carrier density from a Raman measurement of the coupled plasmon-phonon mode frequencies. The technique is both contactless and nondestructive, with a penetration depth which depends on the excitation wavelength and the absorption coefficient of the substrate. The current study has examined free-carrier variations within the first 2000Å of the surface.

The remaining sections of the paper are organized as follows. "Experimental and Results" contains details of the experiments and the Raman spectra of S-, Sn-, and Ge-doped InP and Si-doped GaAs before and after vacuum annealing. "Theory" in the "Discussion" section presents the details of calculations pertinent to converting plasmon-phonon mode frequencies into net free-carrier densities, and "Free-carrier concentration" contains a comparison of our results with data previously reported in the literature.

Experimental and Results

Wafers of S-, Sn-, and Ge-doped (100) InP and Si-doped (100) GaAs were bromine-methanol polished, rinsed in methanol, and blown dry, and then inserted into quartz ampuls which were evacuated to $\sim 5 \times 10^{-6}$ torr and sealed. The ampuls were placed in a preheated furnace at 500°-550°C and removed after periods varying from 30 to

* Electrochemical Society Active Member.

60 min. Table I records the thermal history of each sample.

Raman measurements were carried out using the 5145Å line of an argon ion laser for excitation and a 1m double monochromator with holographic gratings for analysis of the scattered light. The instrument resolution was set at $6\text{-}8 \text{ cm}^{-1}$, and the incident power was typically 100-300 mW, which was dispersed in a line source of approximate length 5 mm. All measurements were performed at room temperature with the samples mounted in an argon-purged cell.

The resulting Raman spectra taken before and after annealing are presented in Fig. 1-4 for S-, Sn-, and Ge-doped (100) InP and Si-doped (100) GaAs, respectively. The lower spectrum in each figure represents the sample prior to annealing. The primary features of interest are the coupled plasmon-phonon modes labeled as ω_+ and ω_- . Since ω_- is only weakly concentration dependent in the free-carrier density range of interest, our analysis will emphasize only the shifts observed in ω_+ . These are summarized in Table I. In addition to these two modes, one also sees scattering from longitudinal optic (LO) phonons originating from the carrier-depleted space-charge layer in which there are no conduction electrons available for screening. In (100) n-InP with a nominal 10-20Å native oxide, the upward band bending is roughly 0.5 eV (3), whereas on n-GaAs it is closer to 0.8 eV (4). In the carrier

Table I. Free-carrier concentration measurements

	Dopant	Anneal	ω_+ (cm ⁻¹)		N (carriers/cm ³)	
			No anneal	Annealed	No Anneal	Annealed
(100) InP	S	550°C 1/2h	431	407	1.0×10^{18}	7.8×10^{18}
	Sn	500°C 1h	376	358	0.47×10^{18}	0.25×10^{18}
	Ge	500°C 1h	555	481	2.2×10^{18}	1.5×10^{18}
(100) GaAs	Si	500°C 1h	511	332	1.7×10^{18}	0.43×10^{18}

concentration range between 5×10^{17} and 2×10^{18} cm⁻³, this represents a depletion zone of ~370-185Å for InP and 480-240Å for GaAs. The effective measurement depth in a surface reflection geometry for collection of 95% of the signal is $\approx 3 \times \lambda/4\pi k \times 1/2$ where λ is the excitation wavelength and k is the absorptive part of the index of refraction. These effective measurement depths are of order 1400 and 1700Å for InP and GaAs, respectively. The unscreened LO signal is fairly strong in our spectra because the space-charge depletion zone represents a sizable fraction of the effective measurement depth.

For frequencies lower than ω_- , additional structure is observed, which consists primarily of transverse acoustic overtones (5, 6). The three relatively strong peaks seen in the InP spectra between 600 and 700 cm⁻¹ are overtones and combination modes of the transverse and longitudinal optic phonons (2TO, LO + TO, 2LO in increasing cm⁻¹) (5, 6). Asterisks denote laser plasma lines at 116 and 520 cm⁻¹. These modes are peripheral to our interests and will not be considered further.

Discussion
Thermally induced variations in the net carrier concentration have been extensively studied by a variety of techniques including infrared reflectivity, capacitance-voltage profiling, sheet resistivity, etc. In this section, we present an outline of the theory necessary for converting the measured ω_+ frequency shifts into changes in free-carrier densities followed by a comparison and discussion of our results with other reports in the literature.

Theory.—The coupling of the conduction electron plasma oscillations to the vibrations of long wavelength longitudinal optic phonons in partially ionic semiconductors was treated theoretically in the early 1960's by Yokota (7) and later by Varga (8) and Singwi and Tosi (9). The zeroes of the dielectric response function for longitudinal waves yields the coupled plasmon-phonon modes ω_{\pm} , which are given in the long wavelength limit in the absence of phonon and plasmon damping by

$$\omega_{\pm}^2 = \frac{1}{2} (\omega_{LO}^2 + \omega_p^2) \pm \frac{1}{2} [(\omega_{LO}^2 + \omega_p^2)^2 - 4\omega_p^2\omega_{TO}^2]^{1/2} \quad [1]$$

In this expression ω_{LO} and ω_{TO} are the longitudinal and transverse optic phonon frequencies and ω_p is the bulk plasma frequency

$$\omega_p^2 = 4\pi N e^2/\epsilon_{\infty} m^* \quad [2]$$

N represents the net difference in donor and acceptor concentrations $N_d - N_a$, ϵ_{∞} is the high frequency dielectric constant, and m^* is the conduction electron effective mass. The plasma frequency in Eq. [2] must be corrected for finite values of the scattering wave vector q . The N - and q -dependent plasma frequency is given by (10)

$$\omega_p^2(N, q) = \omega_p^2(N) + \frac{3}{5} (qV_F)^2 \quad [3]$$

where V_F is the conduction electron Fermi velocity. The scattering q vector is determined from

$$q^2 = k_i^2 + k_s^2 - 2k_i k_s \cos \phi \quad [4]$$

I and S denote incident and scattered; k is the photon wave vector $2\pi n/\lambda$, where n is the real part of the substrate refractive index. Since the incident and scattered

Fig. 4. Raman spectra for Si-doped GaAs before (lower trace) and after (upper trace) a thermal anneal at 500°C for 1h.

frequencies are very close ($k_i \sim k_s$), Eq. [4] reduces to $q \sim 4\pi n/\lambda$ for the surface reflection geometry ($\phi \sim 180^\circ$) employed. Data from Ref. (11) were interpolated to obtain the real part of the refractive index n at 5145Å. We obtain $q = 0.87$ and $1.05 \times 10^6 \text{ cm}^{-1}$ for InP and GaAs, respectively.

At high carrier-concentration levels one also anticipates that m^* will be concentration dependent (12) because both InP and GaAs have nonparabolic conduction bands. The carrier concentration dependence of m^* is not typically corrected for because experimental data for m^* vs. N have not been fit to some simple analytic equation. The correction is far from negligible however, as demonstrated by Chandrasekhar and Ramdas (13) in analyzing infrared reflectivity data on GaAs.

In order to obtain an analytic function for incorporating m^* corrections, the following procedures were followed. For GaAs, 18 data points were scaled from the smoothed curves found in Fig. 3 of Ref. (13) in the carrier concentration range $10^{16} - 10^{19} \text{ cm}^{-3}$. These 18 points were then fit to an equation of the form

$$m^*/m_0 = \sum_{j=0}^4 B_j [\ln N - \ln N_0]^j \quad [5]$$

where $N_0 = 1.0 \times 10^{16}$. For InP, m^*/m_0 values were taken from the raw data of Kesmanly *et al.* (14), except that all data were uniformly increased by 0.009 m^*/m_0 units in order to obtain a room temperature value of $m^*/m_0 = 0.0781$ in undoped material consistent with the recent magneto-phonon measurements of Eaves *et al.* (15). These data were plotted and a smooth curve drawn through them from which 18 points were taken and fit to Eq. [5]. The fits to the m^*/m_0 plots for InP and GaAs are shown as solid lines in Fig. 5. It should be emphasized that the open symbols do not represent the original published data, but rather values extracted from curves visually fit to the original data. This was necessary because the density of original points was too low to fit satisfactorily to Eq. [5]. The values of the fitting parameters B_j are tabulated for InP and GaAs in the upper section of Table II.

The coupled plasmon-phonon mode frequencies denoted by ω_{\pm} in Eq. [1] can now be solved analytically incorporating both finite q vector and concentration dependent m^* corrections. Figures 6 and 7 show the results of such calculations for InP and GaAs in the carrier concentration range $10^{16} - 10^{19} \text{ cm}^{-3}$. The materials parameters ω_{LO} , ω_{TO} , $q(5145\text{\AA})$, and ϵ_{∞} used in the calculations are listed in the second part of Table II.

Free-carrier concentration.—The results of the calculations presented in graphical form in Fig. 6 and 7 allow us

to extract both the sign and magnitude of changes in the free-carrier density. From Table I, it is seen that the ω_{+} mode frequency decreases after annealing, *i. e.*, the free-carrier density is reduced relative to the unannealed sample in all cases. Two comments are in order. The first is that the observed sign (*i. e.*, free-carrier reduction rather than enhancement) is independent of whether one includes or excludes q vector and m^* corrections. The latter parameters influence the magnitude of the shift ΔN , but do not alter the sign of the shift. The second comment is that the measurements probe the region behind the space-charge depletion zone out to depths of $\sim 1400\text{\AA}$ for InP and 1700\AA for GaAs. The region examined in Raman scattering is similar to what is examined in C-V measurements, but it is not necessary to perform an extended analysis to account for the influence of deep traps (16). Other techniques such as sheet resistivity do not probe so sharply defined a spatial zone, nor is that technique easily applied to heavily doped materials (just as Raman scattering is not generally applicable at low carrier concentrations) (17).

The magnitude of the carrier density reduction ($\Delta N/N$) is $\sim 22\%$ for S-InP annealed at $550^\circ\text{C}/12\text{h}$, 47% for Sn-InP annealed at $500^\circ\text{C}/1\text{h}$, and 21% for Ge-InP annealed at $500^\circ\text{C}/1\text{h}$. The largest change occurred in the sample with the lowest initial doping, *i. e.*, Sn-doped InP with N initially around 4.7×10^{17} . The uncertainty in assigning a value to $\Delta N/N$ is larger in that case due to the small shift observed (18 cm^{-1}) and the intrinsic limitations associated with accurately locating the ω_{+} peak position. It is also likely that if carrier compensation related to drifting sur-

Fig. 7. Calculated plasmon-phonon mode frequencies ω_{\pm} vs. free-carrier concentration for Raman scattering from GaAs at 5145Å. The solid lines correspond to the bulk substrate LO and TO modes. The calculations have been corrected for finite q vector and concentration-dependent effective mass.

face generated defects is a dominant mechanism for free-carrier removal, then equivalent annealing conditions should affect the sample with the lowest initial carrier concentration the most. For Si-doped GaAs, we observe a reduction of $\sim 75\%$ in N after annealing. This value is similar to what was reported some years ago by Kung and Spitzer (18, 19) in their infrared reflectivity studies of Si-doped GaAs. They observed a reduction in N from ~ 8.5 to $4 \times 10^{18} \text{ cm}^{-3}$ after a 1h anneal at 600°C ($\Delta N/N \sim 53\%$). Our annealing cycles were not exactly comparable however because those authors subjected their samples to a 15 min preanneal at 1100°C in order to establish a common thermal history. Our results are qualitatively similar in view of these differences.

Thermally induced alterations of the free-carrier concentration in n-InP have been reported previously (1, 2, 20). The studies in Ref (1) and (2) involved low doped substrates ($N \sim 3 \times 10^{15} \text{ cm}^{-3}$) and annealing ambients of hydrogen or phosphorus vapor. Since their annealing ambients and doping levels differed from ours, a strict comparison of results is inappropriate.

The most comparable study has been the published results of Chin *et al.* (20), who examined vacuum-annealed (100) InP doped with S, Sn, Se, Zn, Mn, Fe, and undoped

annealed at 550°C for 1/2h. They interpreted their measurements (defect etching, cathodoluminescence, photoluminescence) in terms of rapid dopant out-diffusion for S, Sn, and Se, but they observed no measurable out-diffusion in Zn, Mn, Fe, and undoped materials. For S-doped InP, they estimated from the photoluminescence linewidth that the surface layer consisting of the top $5 \mu\text{m}$ was $\sim 50\%$ higher in carrier concentration relative to the bulk, whereas in an extended region ($\sim 200 \mu\text{m}$) behind this surface layer, the carrier concentration was approximately 10% lower than the bulk. Our own results show a reduction rather than an enhancement of the near-surface free-carrier density, but it should be noted that our reference point is the near-surface carrier density measured prior to annealing rather than the bulk density measured after annealing. Whether this difference in reference points is sufficient to account for the discrepancy in results remains to be seen.

Finally, it is probably worthwhile to comment that our observations of near-surface free-carrier reduction do not rule out the possibility that dopant redistribution with surface "pileup" has occurred. This phenomenon has been observed in secondary ion mass spectroscopy (SIMS) measurements of Fe- and Cr-doped InP (21) and

may well be a general artifact of thermal annealing due to surface gettering of impurities. The Raman measurements do not address the question of the actual dopant density; they only measure the net free-carrier concentration. SIMS measurements provide actual dopant profiles, but they do not specify whether the dopants are electrically active, *i.e.*, whether they contribute to the free-carrier density or not. It is not obvious *a priori* that dopants gettering at defects would be electrically active. In addition, if the dopant pileup were to occur sufficiently close to the surface that it was contained within the space-charge depletion zone, then Raman scattering would not detect any enhancement of the free-carrier density, since measurements of ω_+ only probe the region beyond the edge of the space-charge layer.

Summary

Raman scattering measurements of the coupled plasmon-phonon mode frequencies of S-, Sn-, and Ge-doped (100) InP and Si-doped (100) GaAs have been performed before and after vacuum anneals at 500°-550°C. A consistent reduction of the free-carrier density is observed in all cases within the near-surface region bounded by the edge of the depletion layer and a depth of 1400-1700Å. Numerical calculations of the ω_{\pm} frequencies incorporating an analytic correction for the carrier density dependence of m^* allow one to estimate the percentage reduction $\Delta N/N$ in the free-carrier density. For S- and Ge-doped ($1.2 \times 10^{18} \text{ cm}^{-3}$) InP, $\Delta N/N$ is $\sim 20\%$. For Sn-doped ($\sim 5 \times 10^{17} \text{ cm}^{-3}$) InP, $\Delta N/N \sim 50\%$. For Si-doped ($\sim 2 \times 10^{18} \text{ cm}^{-3}$) GaAs, $\Delta N/N \sim 75\%$.

Low Field Recombination of Self-Activated Centers in II-VI DCEL Cells

M. S. Waite*

School of Materials Science and Physics, Thames Polytechnic, London SE18 6PF, England

ABSTRACT

Excitation of formed dc electroluminescent powder cells containing ZnS:Cl or ZnSe:Cl(Br) phosphors gives two peaks of recombination luminescence with respect to the applied voltage pulse. Peak A coincides with the leading edge of the voltage pulse, while the luminescence of peak B rises to a maximum at approximately 10 μs from the end of the voltage pulse. In both cases, the luminescence arises from DAP transitions of self-activated centers, $V_{\text{Zn}} - \text{Cl}_{\text{(Se)}}$ in the phosphors. However, the origins are different. Temperature and electrical measurements suggest that peak A corresponds to recombination involving carriers released from traps of activation energy $\sim 0.3 \text{ eV}$, by the applied voltage pulse. The profile of peak B is strongly influenced by the time constant $C \times R$, where C is the capacitance of the formed layer and R is the resistance of the unformed region. Electroluminescent efficiencies of 0.01% (4% duty cycle) were found for 465 nm emission from ZnS:Cl cells with thin insulating films on the anode, but much lower efficiencies, $\sim 10^{-3}\%$ without the insulating film.

Zinc sulfide activated with Mn is well established as the standard material for DCEL powder displays, providing an emission centered at 580 nm with a bandwidth of 60 nm (1-3). To increase the range of colors available without using filters, it is possible to modify the lattice, as in Zn(S,Te):Mn(4), or choose different activators for ZnS, such as the rare earths, Tb, Er, or Tm (5). These modifications have been found to be less efficient ($10^{-2}\%$) than ZnS:Mn ($10^{-1}\%$), and more efficient displays based on alkaline sulfide phosphors have been developed (6, 7). A

common feature in these systems is the use of localized activators, Ce, Mn, and Tb, which are excited by impact with hot electrons rather than the use of donor-acceptor recombination processes as in powder DCEL devices based on Cu-doped ZnS.

During an investigation of the electroluminescence of undoped ZnS in conventional DCEL powder cells, it was noticed that under pulsed operation a narrow blue band at 467 nm replaced the very broad, relatively featureless emission seen with dc operation (8). The narrow band corresponded to the self-activated (SA) luminescence arising from the recombination of electrons on donor sites and holes localized at the A centers, $V_{\text{Zn}} - \text{Cl}_{\text{S}}$ complex centers

(9). The donor levels were presumed to be from chlorine present in the precipitated ZnS. Further preparation of ZnS phosphors with chlorine deliberately added also gave this emission band in a pulsed DCEL cell, while ZnS fired in H_2S and lacking the self-activated photoluminescence did not exhibit SA electroluminescence. In the following, the spectral and temperature dependence of emission from DCEL cells, made with zinc sulfide and zinc selenide self-activated phosphors, is described. The application of these processes to large screen displays technology in forming an alternative to impact excitation of characteristic activators is mentioned, with reference to parallel work being done on Ag-doped zinc cadmium sulfide phosphors (10).

Experimental

Preparation of phosphors.—Zinc sulfide, zinc selenide, and mixtures of the two were slurred with potassium chloride or bromide and fired in a stagnant atmosphere at 800°-950°C, depending on selenide content. The phosphor particles were washed in acetic acid to remove oxides and with sodium sulfite to dissolve excess selenium on the surface. A few samples of chloride slurred zinc sulfide were also fired in N_2 for comparison. These samples were also photoluminescent but have low intensities of SA electroluminescence. X-ray powder diffraction analysis of the phosphors indicated that both cubic and hexagonal phases were present in ZnS:Cl and the cubic phase in ZnSe:Br. Analysis of ZnS:Cl and ZnSe:Cl phosphors indicated a Cl content of 10 ppm, with less than 1 ppm of Cu, when prepared with an initial halide concentration of 1% w/w.

Construction of cells.—The phosphors were treated with $10^{-2}M$ $CuCl_2$ to provide the particles with a conducting Cu-rich surface and made into DCEL cells, as reported by Vecht *et al.* (1). After treatment in the copper solution, the phosphors were screened onto conducting glass substrates (Fig. 1), with thicknesses in the range 30-60 μm depending upon the particle size, phosphors with smaller particle size, ca. 2 μm diam, giving the thinner layers. The densities of the layers were in the range of $1.5-2.0 \times 10^3$ $kg\ m^{-3}$ compared to 4×10^3 $kg\ m^{-3}$ and 5.42×10^3 $kg\ m^{-3}$ for bulk ZnS and ZnSe, respectively. In addition to the electroluminescent cells prepared on conducting glass substrates, several were constructed using insulating layers 500-1000Å thick between the conducting substrate and

the layer of phosphor particles. Dielectrics used included SiO and YF_3 .

Forming and operation.—The cells were formed by the initial application of a dc field, and the spectra of the avalanche emission processes were obtained under dc operation at 100-150V. To observe the low field recombination emission, the cells are operated with short pulses (Fig. 2) for 5-500 μs , and at a frequency of 100 Hz-5 kHz. The recombination luminescence was also observed over a range of temperatures from room temperature to 100 K.

Results

Time dependence.—The emission from the formed panels appears at three characteristic points during the cycle of excitation and relaxation, as shown in Fig. 2 for the case of a self-activated phosphor, excited at the formed voltage with unipolar rectangular pulses at 100 Hz. Three separate features can be seen.

Peak A.—This appears on the leading edge of the voltage pulse. This leading edge has a slight slope to it, of 1 μs per 30V, as indicated in Fig. 2b and the maximum for peak A is seen before the pulse reaches the maximum or avalanche voltage at room temperature. This emission is only seen when pulsed excitation is used.

Peak B.—This follows the voltage pulse, rising to a maximum at a time interval from the end of the pulse of 10-50 μs , τ_B , depending upon the nature of the phosphor and the extent of forming. Typical values of τ_B at room temperature for formed panels are 5-20 μs .

Emission C.—This corresponds to the "on" phase of the rectangular pulse. The decay of this emission is rapid, ca. 200 ns, which is the limit of resolution of the present equipment. By analogy with similar emission in other semiconductors, this is termed "avalanche emission" and appears to have similar origins in intraband momentum loss and interband transfer. It has been investigated in electroluminescent diodes of II-VI materials under high fields (11) and in thin film and powder cells (12, 13). It is not directly useful in EL displays since the efficiency is low ($<10^{-6}$ photons/electron) even if the spectral characteristics of the emission were acceptable.

The luminescence of principal significance to displays is that represented by peaks A and B rather than the emission C, and it is the properties of peaks A and B which are of interest.

The values of τ_B have been found to be dependent on the forming process and can be related to the capacitance of the copper-depleted layer. Typically, values of 5-10 μs for ZnS:Cl are found in panels formed to voltages in the

Fig. 1. Structure of DCEL powder cells. A: Cu-depleted layer. B: Unformed Cu-coated ZnS particles. C: Tin oxide or ITO layer. D: Al back electrode.

Fig. 2. Emission under pulsed excitation. 1: 100 Hz, 100 μs pulse width. 2: 1 kHz, 20 μs pulse width.

range 80-100V, with a capacitance of ca. $25 \mu\text{F m}^{-2}$. In a progressive forming experiment, the variation of τ_B was followed as a ZnS:Cl panel was formed from 60-110V. After an initial rapid decrease in τ_B , there is a steady decline with increasing values of $1/C$ (Fig. 3). As forming proceeds and the width of the Cu depleted zone (proportional to $1/C$) increases, the intensities of the recombination peaks A and B increase relative to the change in current (Fig. 3). The overall luminescence efficiency thus increases. The capacitance of unformed panels has values of $100\text{-}500 \mu\text{F m}^{-2}$, determined mainly by thin oxide layers underlying the deposited Al. Once forming has started and a resistive Cu depleted layer has begun to grow at the anode, the majority of the field is dropped across this region and the capacitance exhibits the sharp initial decrease seen in Fig. 3. The slower decline in $1/C$ can be seen as representing the gradual increase in the thickness of the Cu depleted layer which also occurs continually during use and which constitutes one of the principal failure mechanisms of DCEL powder cells.

These observations suggest that the post field peak B is determined, at least in part, by rate processes which involve the geometry of the Cu depleted layer rather than merely the kinetics of thermal release of carriers from traps and radiative decay. This conclusion is also reached by observations of the temperature dependence of τ_B .

Spectra of peaks A and B.—The spectral characteristics of the recombination luminescence are shown in Fig. 4 and 5 for ZnS:Cl, ZnSe:Cl, and ZnSe:Br with the spectra of avalanche emission obtained by continuous dc excitation for comparison. For ZnS:Cl the emission characteristics: a peak maximum of 2.67 eV (465 nm) and a bandwidth of 0.45 eV, correspond to the self-activated luminescence, the recombination between electrons at Cl donor sites and holes on $V_{\text{Zn}} - \text{Cl}$ neutral acceptors (14).

For ZnSe:Cl and ZnSe:Br the emission maximum is located at 1.98 eV (623 nm), close to the emission maximum of 1.99 eV determined by a recent ODMR study of ZnSe:Cl (15). The 1.98 eV peak was obtained at an excitation intensity equivalent to an input power of $2.5 \times 10^3 \text{ Wm}^{-2}$ while at higher intensities, $7.5 \times 10^3 \text{ Wm}^{-2}$, ZnSe:Br devices exhibited a shift in emission maximum to lower energies 1.95 eV (Fig. 5). The shift is in the opposite direction from that expected from the characteristics of DAP luminescence, where the emission maximum moves to higher energies with increased excitation intensity as distant pairs become saturated (16). Furthermore, in the experiments by Shionoya and colleagues on DAP luminescence in

ZnS phosphors, the range of excitation intensity necessary to cause a significant spectral shift is much higher than that found here. There may, therefore, be two very broad emission bands in the ZnSe:Br spectrum whose relative intensity depends upon the excitation level. The obvious suspect is Cu contamination which has a broad emission band at 1.94 eV (17). DCEL cells with ZnSe:Cu (0.02) phosphors were prepared and after forming showed a recombination electroluminescence at 1.94 eV (640 nm) under pulsed excitation (Fig. 5). This suggests that the ZnSe:Cl,Br phosphors show both SA and Cu electroluminescence, with the relative contribution of the Cu emission increasing at higher excitation intensities.

Temperature dependence of recombination pulses.—The effect on peaks A and B of reducing the temperature has been examined for ZnS:Cl and ZnSe:Cl phosphors. The rise and decay times and the luminescent efficiencies are both affected. In particular, τ_B was seen to be strongly dependent on temperature, as seen in Fig. 6 for ZnS:Cl cell as the temperature is successively reduced from 300 to 100 K. From 300 to 220 K, τ_B fell from ca. $10 \mu\text{s}$ to ca. $4 \mu\text{s}$. In general, below 220 K the post-field emission is seen to consist of two components: (i) the broad peak for which the delay time τ_B gradually decreases and (ii) a fast rising spike (ca. $0.3 \mu\text{s}$) with a decay time of approximately $2 \mu\text{s}$. In some samples, the fast spike dominated the post-field emission at low temperatures (Fig. 7). The decay of this fast pulse should be compared with the values of 0.5 and $4 \mu\text{s}$ found by Shionoya and colleagues for the decay of

Fig. 6. Variation of τ_B with temperature: ZnS:Cl panel, P3/81: 100 μ s pulse width, 100 Hz excitation rate.

SA luminescence at 77 K (18). If the emission corresponding to peak B arises from the recombination of electrons thermally released from traps with holes at neutral acceptor centers, the emission might be expected to extend for a longer time at lower temperatures so that τ_B should increase. It may be that there are several closely overlapping components in the post-field recombination corresponding to different trap depths which are successively frozen in as the temperature is lowered. However, the change in τ_B seems to be too smooth for this explanation. The intensity of peak B does not appear to vary greatly with temperature.

The behavior of peak A with temperature is different from that of peak B. The intensity of peak A, as measured by the area of the oscilloscope trace and normalized to unit current densities, increases as the temperature is reduced and the delay time increases (Fig. 8). The variation in τ_A for ZnS:Cl is typically from 1.0 μ s at room temperature to ca. 4 μ s at 150 K. Since the time in which the field builds up to its maximum value is at least 3 μ s for applied voltages of 100V, the changes in τ_A indicate that a higher

Fig. 8. Variation in electroluminescent efficiency of peak A and thermoluminescence for ZnS:Cl, and ZnS:Ag, 100 μ s pulse width, 100 Hz excitation rate [after Ref. (10)]. Curves A and B: ZnS:Cl, (P3/81). Curves C and D: ZnS,Ag, (ZA6/7).

field is needed at lower temperatures to promote the recombination. This is analogous to the luminescence induced by field detrapping in photoconductors as analyzed by Haering (19). If the recombination for ZnS:Cl represented by peak A depends upon the release of trapped carriers, the temperature dependence of the normalized area of this peak should parallel that of the thermoluminescence of the SA luminescence. In Fig. 8 [from Ref. (10)], the glow curve for ZnS:Cl is illustrated together with the area of peak A, normalized to unit current density. There is an approximate agreement between the two maxima at 180-183 K, and both are shifted relative to the maxima for the Ag-blue emission from ZnS:Ag, which also appears in the figure from Ref. (10).

Effect of pulse width on recombination efficiency.—The charging and discharging times of the displacement current in the devices at room temperature are of the order of 2 μ s, as judged from the current signal. However, with pulse widths as small as this, the panels have a very low efficiency because the total of trapped carriers per cycle is low. The effect upon brightness of the pulse width for a ZnS:Cl phosphor is soon in Fig. 9, where the peak heights of A and B have been plotted against the total charge passed per cycle. Although the curves are not completely coincidental, they both show a continued increase in output with charge

Fig. 9. Variation in recombination efficiency with the total charge passed per cycle, ZnS:Cl, (P8/80).

passed per cycle. Thus the more carriers that pass through the cells, the greater the concentration of trapped charges and the greater the luminescence output. The quantum efficiencies, combining the output of both peaks A and B, are approximately 10^{-3} photons per electron, leading to power efficiencies in the range 10^{-2} – $10^{-3}\%$ for ZnS:Cl and ZnSe:Br. There is little evidence for saturation of the post field peak B at higher charges in the phosphors with deliberate addition of donor impurity, in contrast to a previous observation with lower Cl concentrations (8). τ_A and τ_B are independent of pulse width, provided the extent of forming does not change.

Effect of other impurities.—The presence of oxygen has been found to be particularly important for low field recombination. In phosphors prepared by firing in N_2 with exclusion of oxygen, peaks A and B are not seen even when the phosphor has strong self-activated photoluminescence. This suggests that the presence of oxygen provides conditions for producing the traps for the space charge, although the identity of the traps is not known at present. The glow curves in Fig. 8 indicate a trap depth of ca. 0.3 in ZnS:Cl compared with a value of 0.27 eV found by Hoogenstraaten for oxygen in ZnS (20). A minimum estimate of $4 \times 10^{20} m^{-3}$ has been made for the trap density in ZnS:Cl from the intensity of the low field recombination luminescence, based on the assumption of unit quantum efficiency for the self-activated luminescence.

Li and Cd reduced or eliminated low field recombinations at SA sites in ZnS:Cl, and Cu concentrations as low as 5 ppm were found to reduce the SA electroluminescence without introducing copper-related luminescence, acting in effect as nonradiative centers. Shallow hole traps, producing nonradiative pathways, have been found by Tabei and Shionoya (21) in ZnS:Cu and Al at 50–300 eV from the valency band edge, and similar shallow traps may be present in the ZnS:Cl phosphors with low Cu concentrations. In ZnSe:Br, the effect of Cu is to increase overall red electroluminescence by an increase in the 1.94 eV emission, which corresponds to recombination via the Cu centers. Recent work by Robbins and others has shown that the Cu has a different role in the individual II-VI compounds (22). The significance of this work on the low field electroluminescence is discussed below.

Discussion

The DAP transitions observed do not occur under high field conditions, where only avalanche emission or localized transitions are seen (8). There is some similarity between the cells described here and conventional ac powder cells in that luminescence is the result of electron-hole recombination processes involving donor and acceptor centers rather than localized states of characteristic activators excited by electron impact. However, there are sufficient differences to make it advisable not to consider the dc power cells as merely planar versions of the ac powder cells. Field emission of electrons and holes from the ends of copper sulfide inclusions is considered to be part of the mechanism of the powder ACEL cells in the generally accepted Fischer model (23). According to this interpretation, substitutional Cu_{Zn} centers bind holes to form neutral acceptors adjacent to the inclusions, while the more mobile electrons travel to the boundaries of the ZnS particle. The primary light peak obtained on field reversal occurs as electrons are field emitted into the region containing neutral acceptors, while a secondary peak is produced as the displaced electrons return. The practical brightness depends on the displaced charge, and therefore on the capacitance of the powder layer and the applied voltage. This capacitive coupling limits the applications; although the overall efficiency of a green emitting (ZnS:Cu,Cl) panel can be high, up to 19 lm/W, considerably greater than that obtained in a ZnS:Mn DCEL powder panel (ca. 1 lm/W),

even allowing for the smaller lumen equivalent of the Mn emission.

In DCEL powder panels, the field across the Cu-depleted layer is of the order of $10^8 V m^{-1}$ (3), where impact ionization of ZnS can occur. The primary electrons injected into this high field region can generate further electron-hole pairs in an avalanche process. There is some evidence for this in the form of negative resistance in current-voltage characteristics of powder panels (3), and in ACEL thin film cells, the multiplication gain in ZnS:Mn films operating at similar fields has been determined by Venghaus (24). Carrier multiplication rates of $10^6 m^{-1}$ were obtained in fields of 0.8 to $1.2 \times 10^8 V m^{-1}$, rising rapidly in the region 1.2 – $1.5 \times 10^8 V m^{-1}$, where the threshold field for strong light emission was found. In principle, there are opportunities in dc systems for overcoming the limited brightness per cycle of ac powder devices while taking advantage of the high radiant efficiency of DAP processes in ZnS and ZnSe. The recombination processes described here, however, were only observed under certain conditions. These were (i) the presence of oxygen during the preparative stage of the self-activated phosphors, and (ii) in ZnS, the absence of copper impurities which distinguished these cells from conventional ac powder cells.

Origin of post-field recombination peaks.—Oxygen is believed to produce deep traps, of at least 0.3 eV (20), in self-activated ZnS, trapping a proportion of the excess electrons produced during a dc pulse. An explanation of the profile and temperature dependence of peaks A and B in ZnS:Cl and ZnS:Ag,Cl, by assuming that these peaks represent the recombinations of Cl donor bound electrons with the $(V_{Zn} - Cl)_0$ and Ag neutral acceptor centers as electrons are released from traps, predicts the wrong temperature dependence for τ_B . The value for the delay would be expected to increase as the temperature falls and the rate of electron release from traps slows. In practice, τ_B is found to decrease from typically 10–15 μs at 300 K to ca. 2 μs at 100 K. This characteristic appears to be general for powder DCEL panels since it is seen in Ag-doped phosphors as well as self-activated phosphors. Another characteristic which needs to be explained is the lack of dependence of the rise and decay of peak B on the excitation intensity as the current or the pulse length is increased. This suggests that bimolecular kinetics are not followed in the early stages of the recombination, implying that in the recombination zone the concentration of neutral acceptors or electrons (free or in shallow donors) is effectively constant.

Electrons are the more mobile carriers in compensated ZnS and, in an alternative mode for peak B outlined in Ref. (10) following removal of the applied field electrons, are considered as diffusing back to positive donor sites from shallow traps or surface sites concentrated at the anode. However, in order to reconcile diffusion over a distance of $10^{-6} m$ (the formed layer) with a recombination maximum of ca. $10^{-5} s$, the electron mobility must be lower than the literature value of ca. $10^{-2} m^2 V s^{-1}$ (25) by several orders of magnitude. Such a trap-limited value would again result in the wrong temperature dependence of τ_B .

Recent measurements of the tail of the decay curve of peak B in some ZnS:Cl cells do show a $t^{-1/2}$ dependence over part of the decay curve (Fig. 10), but it also appears that other processes are rate determining at different regions of the decay. This area is now receiving further study.

The recombination maximum of peak B is more closely coincident with the discharged capacitance spike as measured by a test resistor in series with the cell. The decay time of the discharging spike is of the order of $10^{-6} s$, and Abdalla has pointed out that a DCEL powder cell has a discharge time given by $C \times R$, where C is the capacitance of the formed layer and R is the resistance of the unformed Cu-coated ZnS, which acts as a distributed series resistance (26). Values obtained for C and R for test areas

Fig. 10. Time dependence of the decay of electroluminescence in peak B, 100 μ s pulse width, ZnS:Cl, formed to 80V. Curve A: 65V applied voltage. Curve B: 80V applied voltage. Curve C: 100V applied voltage.

in ZnS:Cl and ZnSe:Br panels are typically 0.5-1.5 nF and 10^3 - $10^4\Omega$, respectively, giving capacitance spikes with decay times of the order of 0.5-15 μ s, so that the movement of shallow trapped electrons back to ionized donor levels as the polarization decays is dependent upon the distributed resistance of the unformed region of the cell. This gives better agreement with observed values of τ_B than the models given above. It would also explain the fall in τ_B as the capacitance of the Cu-depleted layer falls during the forming process. The formed zone gradually increases in width, reducing C , but without significantly affecting R , since the formed layer is only 3% of the total thickness of the powder layer. In Fig. 11, observed values τ_B are plotted against values of the product $C \times R$ taken from several ZnS:Cl and ZnSe:Br cells without anodic insulating films. This is a weak but apparent correlation with the $\tau_B = C \times R$ line acting as a boundary limit to the spread of results. The temperature dependence of R_s is complex,¹ but the initial decrease in R_s as the temperature is reduced below 300 K is consistent with the initial rapid fall shown in Fig. 6.

Peak A is not affected by the change in R_s and the temperature dependence observed, which is a move to greater τ_B values as T decreases, agrees with that expected if recombination follows the release of trapped carriers.

Role of copper centers.—The role of copper is also of interest for any eventual practical utilization of these effects. The low field recombination peaks, which are readily noticed in self-activated ZnS and ZnSe, are much less prominent in Cu-doped ZnS.

Another difference is that peak A is more prominent than peak B at room temperature in Cu-doped ZnS than in ZnSe:Cl. The efficiency of emission through the Cu center is much lower than that of the SA luminescence in ZnS, being $10^{-3}\%$ (power efficiency) compared to $2 \times 10^{-2}\%$ for the most efficient panels so far obtained with ZnS:Cl, whereas in ZnSe, recombination via Cu-red centers appears from preliminary observations to be more efficient than the self-activated luminescence. The resistivities of the unformed panels (corresponding to R_s) are generally lower for ZnS:Cu phosphor than for ZnS:Cl phosphor under the same processing conditions: this presumably accounts for the difference in τ_B . However, it does not explain directly the lower efficiency.

The nature of the deep Cu-related centers in II-VI's has

¹ The resistance of Cu-coated ZnS phosphor layers falls with decrease in temperature to reach a minimum at a temperature which varies between 150 K and room temperature, depending on the initial resistance and the degree of Cu uptake.

Fig. 11. τ_B as a function of the capacitance of the formed layer, C , and the small signal resistance of the informed layer, R . Results from several panels of ZnS:Cl and ZnSe:Br phosphors.

recently been the subject of several investigations (17, 22, 27), and Robbins (22) has pointed out differences in the Cu center among the various semiconductors of this group. For ZnS, the neutral acceptor involved in the G-Cu luminescence is the 2T_2 (d^9) state of Cu_{Zn}^{2+} with a shallow hole state at 0.35-0.4 eV from the vb edge due to the $^2E(d^9)$ state. In ZnSe, the Cu level in the gap has the configuration (d^{10})h, a hole bound to a filled d^{10} core. The lower efficiency of Cu-doped ZnS low field el compared to the SA el or the R-Cu luminescence of ZnSe may be related to the greater probability of electron recombination in ZnS via the $E(d^9)$ state. In ZnSe:Cu,Br the effect of copper is to increase overall red emission (620-650 nm) by recombination at the Cu center, and in these phosphors, the reported acceptor ionization energies of Cu and SA centers are similar, 0.6 eV (14, 28). The reduction in SA recombination luminescence by Li, which acts as a shallow acceptor in ZnS with an ionization energy of ca. 30 meV, may also involve a similar mechanism.

Practical output.—The highest power efficiency: $10^{-2}\%$, was found with Cl-doped ZnS, and corresponds to the lower range of efficiencies found in ZnS:Mn DCEL powder panels. In practical terms, a brightness of 20 Ft.L at 4% duty cycle for blue SA electroluminescence was found for a ZnS:Cl panel with a YF_3 insulating film on the anode. Generally, an improvement in efficiency was noted with the presence of an insulating film on the anode, but no systematic investigation has yet been carried out. In ac thin film panels, Marelllo and colleagues found that the blue luminescence of a ZnS:Ag film was much weaker than that of Mn emission (29), but it is not reported that the Ag-doped films were optimized. If the temporarily trapped charge can be held in the formed layer long enough for recombination to take place, then this type of excitation of phosphors should lead to multi-color el panels of similar design to the ZnS:Mn powder DCEL panels.

Technical Notes

Reproducible "Leaky Tube" Diffusion of Zinc into GaAs with Submicron Junction Depths

R. J. Roedel, J. L. Edwards, A. Righter, P. Holm, and H. Erkaya

Center for Solid State Electronics, Arizona State University, Tempe, Arizona 85287

The diffusion of zinc into GaAs and other III-V semiconductors to produce p-type layers remains a common procedure in compound semiconductor processing. It has been used in the fabrication of light-emitting diodes (1), injection lasers (2), optical waveguides (3), and other structures. In general, these devices require junction depths of the order of 1-5 μm , and the technique most often used to obtain these "deep" diffusions is the "closed tube" process, in which an evacuated quartz ampul containing the GaAs wafer and the zinc source is placed in the diffusion furnace. However, there are several applications in which very shallow ($<1 \mu\text{m}$) p⁺ layers are quite desirable. These include tunnel diode-transition regions in cascade solar cells, the emitter regions of GaAs photovoltaic devices, the gate regions of GaAs JFET structures, and ohmic contact areas. Ion implantation of Zn, Mg, or Be has been used to produce very shallow p-type layers in GaAs. Troeger *et al.* (4) have reported the fabrication of triply implanted E-JFET's in which both n-type implants and the p-type (Mg) implant are less than 1 μm deep. Kasahara *et al.* (5, 6) have used Zn ion implantation for the construction of shallow ($\sim 0.2 \mu\text{m}$) p-type gate regions of GaAs JFET's. However, problems have remained with p-type ion implantation into GaAs. The p-type implantation has been reported to produce p-i-n, rather than p-n, junctions by several authors (7, 8). Additional complications include low activation of the implanted species (5), drastic redistribution of the implanted ions during thermal annealing (6), and an incomplete knowledge of the residual lattice damage after annealing. However recent work by Taira *et al.* (9) and Kasahara *et al.* (10) shows that dual implantation of Zn and As can be used to produce Zn profiles that closely match those predicted by the LSS theory.

In this paper, we wish to report that thermal diffusion of Zn can be used to fabricate extremely shallow p⁺ layers in a very reproducible manner, with carrier concentrations as high as $1.8 \times 10^{20} \text{ cm}^{-3}$.

In our laboratory, we employ the so-called "leaky tube" diffusion technique, which is a variation of the the "box" diffusion process described by Tuck (11) and Springthorpe and Svilans (12). A schematic of the leaky tube diffusion system is shown in Fig. (1). The leaky tube apparatus consists of a normal open-tube furnace system that contains a quartz liner sealed at one end. Ultrapure helium can be passed through the outer open tube, or through the liner with the aid of a small purge tube. During diffusion, the He flow through the liner can be halted so that a stagnant, inert ambient can be established in the diffusion zone. The quartz boat holds GaAs samples horizontally and can accommodate four 2 in. wafers; in addition, it holds a quartz crucible containing 30g of elemental zinc of 6N purity. In the diffusion zone, a small temperature gradient ($\sim 4^\circ\text{C}$) is maintained along the boat to prevent Zn condensation on the wafers.

A series of n-type GaAs wafers [$N_D \sim 1 \times 10^{18} \text{ cm}^{-3}$, (001) orientation] were diffused for times varying between 5 and 30 min at a temperature of 600°C. Figure 2 shows the junction depth *vs.* square root time for these diffusions, and the linear form of this plot indicates that the diffusion is "well behaved," *i.e.*, predictable. The line does not go through the origin. This reflects an "incubation" period of approximately 1 min; before this time, diffusion does not take place. The junction depth was first determined by staining cleaved samples in a dilute solution of KOH and $\text{K}_3\text{Fe}(\text{CN})_6$ in water for 5s. None of the diffusion showed two diffusion "stain lines," but this was expected, as the intrinsic carrier concentration at the diffusion tem-

Fig. 1. Schematic of the leaky tube diffusion system.

Fig. 2. Junction depth vs. square root of diffusion time for the leaky tube diffusion of zinc into (001) GaAs at 600°C.

perature ($n_i \sim 1.4 \times 10^{16} \text{ cm}^{-3}$) is lower than the background doping. These junction depths were confirmed independently using electrochemical profiling techniques. All of the diffused samples were coated with a 50Å sputtered-SiO₂ film prior to diffusion. As described elsewhere (14), the thin SiO₂ coating prevents the thermal decomposition of the substrates during diffusion, but allows the zinc to diffuse without attenuation.

Figure 3 contains photomicrographs of three typical cleaved and stained samples diffused with Zn at 600°C for 5, 10, and 15 min. The junction depth of each is 0.22, 0.44, and 0.56 μm, respectively. The uniformity of the junctions is quite noteworthy; across a 1.5 cm wafer, the deviation from planarity is not measurable. In a series of ten diffusions for 5 min at 600°C, the average junction depth was 0.22 μm with a standard deviation of less than 4%. We attribute this remarkable reproducibility to the inherent stability and repeatability of the leaky tube diffusion apparatus. It should be noted that we also performed short duration diffusions at 600°C on GaAs wafers without the 50Å SiO₂ layer. The junction depths of the bare wafers were identical to their coated counterparts, but the bare wafers subjected to diffusions longer than 15 min began to show signs of surface erosion.

After optical examination of the diffused substrates, electrical characterization was carried out. With a four-point probe, the sheet resistance of the 5, 10, and 15 min diffused layers was found to be 95.8, 63.6, and 55.4 Ω/□, respectively. These values correspond to average resistivities of 2.21×10^{-3} , 2.80×10^{-3} , and 3.10×10^{-3} Ω-cm, respectively. A modified electrochemical profiler (manufactured by Polaron Instruments) was then used to mea-

sure the electrically active zinc diffusion profiles. Figure 4 shows the profiles of three samples diffused for 5, 10, and 15 min which did not have a SiO₂ coating. It is very interesting to note that the 10 and 15 min samples show a carrier concentration peak near the surface, followed by a plateau-like region, and finally a steep drop in concentration as the junction is approached. The 5 min sample, however, shows only the peak and the steep drop-off, with the plateau region conspicuously absent. In fact, the slopes of the peak region and the drop-off region for all three samples are virtually identical. The appearance of the plateau region for diffusions 10 min or longer (and its absence beforehand) may indicate that a fundamental change in the zinc diffusion mechanism takes place in the first few minutes of diffusion.

The formation of a peak in carrier concentration near the surface is almost certainly effected by the leaky tube diffusion technique. At the end of the diffusion cycle, the samples are not quenched and brought quickly to room temperature. Rather, the boat is pulled to the cold end of the diffusion furnace and is cooled slowly with an external fan. Thus, the wafers remain in contact with a warm boat for an extended period, and out-diffusion of the Zn from the surface occurs. The profiles in Fig. 5 corroborate this explanation. Both samples in this figure were diffused for 5 min at 600°C, but sample of curve a was covered with 50Å of SiO₂, and the sample of curve b was bare. Both show the near-surface peak (in different locations but with the same height), and nearly identical drop-off regions. The presence of the SiO₂ film on the sample of curve a effectively impedes the out-diffusion, and as a result the carrier peak is closer to the surface.

Fig. 3. Cleaved and stained GaAs samples after 600°C leaky tube Zn diffusion. A: 5 min, $x_j \approx 0.24 \mu\text{m}$. B: 10 min, $x_j \approx 0.44 \mu\text{m}$. C: 15 min, $x_j \approx 0.56 \mu\text{m}$.

The peak carrier concentration produced by our short diffusion cycles was as high as $1.8 \times 10^{20} \text{ cm}^{-3}$. To the authors' knowledge, this concentration is higher than any previously reported using either thermal diffusion or ion implantation. Although these high concentrations were not corroborated with another differential technique, such as differential Hall measurements, we have integrated the carrier concentrations from Fig. 4 in the formula

$$\bar{\rho} = \frac{x_j}{q \int_0^{x_j} p(x) \mu_p(x) dx}$$

to calculate the average resistivity. We find for these three samples, $\rho = 2.34 \times 10^{-3}$, 2.72×10^{-3} , and $3.06 \times 10^{-3} \Omega\text{-cm}$, for the 5, 10, and 15 min samples, respectively. These numbers are within 5% of the four-point probe measured values. We feel confident that the carrier con-

Fig. 4. Carrier concentration profiles for GaAs samples after Zn diffusion at 600°C. Curve a: 5 min. Curve b: 10 min. Curve c: 15 min. All samples were without an SiO_2 coating.

Fig. 5. Carrier concentration profiles for GaAs samples after 15 min Zn diffusion at 600°C. Curve a: with 50Å SiO₂ coating. Curve b: without SiO₂.

centrations, as measured by the Polaron apparatus, are accurate.

In summary, we report that the leaky tube diffusion technique can be utilized to produce very shallow, heavily doped p-type GaAs layers on an extremely reproducible basis. This repeatability is associated with the large quantity of source material and the stagnant ambient in the diffusion zone: a stable and consistent zinc vapor environment is readily achieved from run to run. We feel that even shallower diffusions are possible, but not by carrying out the diffusions at 600°C for durations less than 5 min. Rather, performing the diffusions at lower temperatures ($\approx 550^\circ\text{C}$) for short durations should restrict the Zn penetration to depths $\approx 0.1 \mu\text{m}$. Work is underway to examine the depths, profiles, and characteristics of these lower temperature Zn diffusions.

Acknowledgments

The authors would like to express their gratitude to S. Ageno for assistance with the diffusion, to G. Conrad for help with the doping profile determination, and to J. Marion and J. Martin for their able support in the laboratory. This work was supported in part by an Arizona State University Research Grant.

Structure of Silver (100) and (111) Single-Crystal Surfaces Obtained by Chemical Polishing

Radoslav R. Adzic,¹ Michael E. Hanson,* and Ernest B. Yeager**

Case Center for Electrochemical Sciences and the Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106

Interest has been increasing in the investigation of electrochemical reactions on single-crystal electrode surfaces [see, e.g., Ref. (1-7)]. Electrode processes having a pronounced dependence on the particular single-crystal surface include hydrogen adsorption (8-11), underpotential deposition of metals (4), oxidation of organic molecules (6), and oxygen reduction (7). Inadequately characterized single-crystal surfaces, however, may lead to misleading results. Atomically flat, well-ordered surfaces are needed in order to obtain meaningful data. Ultrahigh vacuum techniques such as low energy electron diffraction (LEED), Auger electron spectroscopy (AES), and x-ray photoelectron spectroscopy (XPS) can facilitate the characterization of such surfaces and verification of freedom from adsorbed impurities, but these techniques are *ex situ*. Elaborate systems (8-11) have been developed for preparing and characterizing single-crystal electrode surfaces in ultrahigh vacuum and then transferring them into the electrochemical environment and vice versa under conditions designed to minimize structural changes and contamination. Experiments with these transfer techniques, however, are very time consuming and impose substantial restraints on the types of electrochemical systems that can be studied because of factors such as the use of completely volatilizable electrolytic solutions and thin-layer cell configurations.

Some electrochemists, including one of the authors (R.A.), have prepared single-crystal surfaces of metals by chemical methods and then proceeded to examine the

electrochemical properties of these surfaces. This work, however, has left unanswered the question of the quality of the single-crystal surfaces. This paper presents results which demonstrate that chemical polishing in the instance of silver single-crystal electrodes can yield ordered (100) and (111) surfaces, as judged by LEED.

Single crystals of Ag, 99.99% pure, were obtained from Metal Crystals Limited, Cambridge, England. They were oriented to better than 1°, mechanically polished by standard metallographic techniques with diamond paste, gradually decreasing the size of the grit to 1 μm. The crystals were further polished chemically, using procedures similar to those already reported (12). An aqueous solution of 30 volume percent (v/o) of H₂O₂ and a solution of 21.5 g/l of NaCN were mixed in a 1:1 ratio for polishing the Ag(111) single-crystal surface. For the Ag(100) face, a lower concentration of 20 v/o of H₂O₂ was used. The crystals were held for 5s in these solutions, during which time vigorous gas evolution occurred. They were taken out, held in air for 3s, and transferred into a solution of 37.5 g/l NaCN, where gas evolution ceased. After washing, the procedure was repeated several times, in most instances in a fresh solution of H₂O₂ and NaCN until a highly reflecting surface was obtained. The electrode surface was then thoroughly washed in pure water. The surface obtained in this way was protected by a drop of pure water and transferred into the UHV preparation chamber of the LEED-AES-XPS system, which has been described in prior publications (8, 9). The water drop was then volatilized during the pump down.

Figure 1a shows the LEED pattern from the Ag(111) surface immediately after introduction into the UHV chamber at 10⁻¹⁰ torr. This LEED pattern was obtained without cleaning the surface in the vacuum chamber in any way. Neither argon-ion sputtering nor thermal an-

Key words: LEED, silver single crystals, chemical polishing.

Fig. 1. A (left): LEED pattern of chemically polished Ag (111) immediately after introduction to the vacuum chamber (no sputtering or thermal annealing). Primary beam energy: 47 eV. Exposure time: 3 min. F-stop: 1.4, Kodak Panatomic X film for all exposures. B (right): same as A after sputtering at 1.5 kV for 3 min and thermally annealing at 600°C. Primary beam energy: 45 eV. Exposure time: 30s.

Fig. 2. A (left): LEED pattern of chemically polished Ag (100) immediately after introduction to the vacuum chamber (no sputtering or thermal annealing). Curvature of the pattern is due to the sample's protruding inside the radius of the screen because of its unusually large size for the system. Primary beam energy: 48 eV. B (right): same as A after sputtering at 1.5 kV for 3 min and thermally annealing at 600°C. Primary beam energy: 60 eV. Exposure time: 30s.

nealing was used. Figure 1b shows the LEED pattern of chemically polished Ag(111) after a single sputtering with an argon-ion gun (Varian Model 981-2043) for 3 min at 1.5 kV and subsequent radiative thermal annealing at approximately 600°C. The crystal reached this temperature in approximately 5 min and was allowed to cool to room temperature, which required about 20 min in vacuum. Analogously, Fig. 2a and 2b show LEED patterns of chemically polished Ag(100) before and after, respectively, UHV sputtering and annealing.

For both the (111) and (100) crystal faces before UHV sputter cleaning, highly diffuse background and weak fractional-order spots are present in the LEED pattern, probably due to random and ordered impurity adsorption during transfer to the vacuum chamber. Auger electron spectra before sputtering indicate the main impurity to be carbonaceous. No nitrogen was detected in the AES, indicating no substantial amount of CN^- remained on the surface. The LEED spots are surprisingly well defined, indicating a high two-dimensional periodicity, although not as ordered as the UHV-cleaned and annealed surfaces. Voltammetry curves were also obtained in 0.1M HF in a thin-layer cell using a special transfer techniques (8, 9). Over the potential range $-0.1-0.45\text{V vs. RHE}$, voltammetry curves were generally featureless.

These data demonstrate that chemical polishing can yield silver single-crystal surfaces of high enough quality to produce LEED patterns. This is of great importance for studies of these surfaces outside UHV systems.

Redox Pathways

Applications in Catalysis

Thomas J. Meyer

Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514

ABSTRACT

Complex redox pathways, like H-atom transfer, hydride transfer, or O-atom transfer, appear in the chemistry of polypyridyl complexes of ruthenium and osmium. These pathways provide a basis for the known activities of the complexes as electrocatalysts in the oxidation of organics, the interconversion of nitrite and ammonia, the oxidation of water to oxygen, the oxidation of Cl^- to Cl_2 , and the interconversion of nitrate and nitrite.

One-electron transfer processes, whether to or from an electrode surface, or between two reactants in solution, are becoming well-defined processes chemically (1, 2). An extensive theoretical background is available based on the pioneering work of Marcus (3), Levich and Dogonadze (4), and Hush (5b), and more recently based on quantum mechanics and time-dependent perturbation theory (6-10). The theoretical work has been extended to optical electron transfer (5). The successful interplay between theory and experiment in this area promises to lead to a series of advances in other areas; for example, to an understanding of electron transfer in biological systems, to an understanding of and ability to control photochemical and photophysical events, and to the possible design of devices based on the electron transfer properties of chemical sites in films or in polymers.

Notwithstanding our success at comprehending and manipulating one-electron transfer events, there are additional classes of redox pathways—hydrogen atom transfer, hydride transfer, O-atom transfer, etc.—which are far more complex and which present formidable challenges both from the mechanistic and theoretical points of view. Although more difficult to study, the potential rewards in learning to control such pathways are considerable. They appear to lie at the heart of some significant redox transformations in both organic and inorganic chemistry, and knowledge of their details could lead to the systematic development of new families of catalytic reagents.

The themes here are to develop in preliminary detail some of the issues involved in complex redox pathways, to turn to identification of such pathways based on a closely related series of redox reagents, and, finally, to show how even at this early stage of development it is possible to use such findings to develop potentially useful catalytic reagents for carrying out redox transformations that are electrochemically driven.

Mechanistic Implications

In order to understand why complex redox pathways such as hydride transfer might appear and what factors could lead to the determination of which pathway provides the lowest energy alternative for a given transformation, it is useful to consider the energetics of two illustrative reactions, one organic and one inorganic. As summarized in Scheme 1, the first case considered is the oxidation of ethanol to acetaldehyde.

Scheme 1

Scheme 2

Four distinct pathways are considered in Scheme 1, and they are divided into one-electron (3 and 4) and two-electron (1 and 2) cases. Although other pathways could have been considered, the ones shown here have all been suggested to have an important role in the oxidation chemistry of ethanol, except perhaps for 1. Energetically, the most desirable pathways are those involving two-electron transfer steps and the immediate formation of the two-electron product. There is an additional advantage in that the two-electron pathways avoid high energy, one-electron intermediates. This is important from the synthetic point of view because one-electron, radical intermediates often have indiscriminate chemistries, which can lead to a lack of selectivity, and control of the reaction products can be lost if they appear.

From the mechanistic point of view, one-electron steps are appealing since the demands that they place on a chemical oxidant are relatively simple. The simplest case of all is outer-sphere electron transfer (reaction 4 in Scheme 1), which, although energetically costly, is relatively simple from the viewpoint of mechanistic demand. All that is required is electronic coupling between the chemical oxidant and the reducing agent and a reasona-

ble Boltzmann population of those vibrational levels which interconvert the reactant and product structures. Once formed, the ethanol radical cation would quickly undergo a series of proton-electron losses

to give the final product, acetaldehyde.

Although relatively easy to achieve from the mechanistic point of view, a simple one-electron transfer step has a costly energy demand. In order to achieve a significant reaction rate, a reasonably strong oxidizing agent is required because of the instability of the radical cationic intermediate.

Reaction 3 in Scheme 1 is a slightly more complex, but less energetically demanding pathway. It also involves one-electron transfer, but now with the simultaneous loss of both a proton and an electron from ethanol to give the intermediate radical with a proton complement fitting to the pH conditions of the medium. The mechanistic demands imposed by a hydrogen atom transfer pathway are more severe. Electronic coupling must occur between the reducing and oxidizing agents, and, in addition, there must be an acceptor site on the oxidant for the transferred proton. The combination of electronic and vibrational coupling needed to meet the demands of the pathway leads to a significant increase in molecular complexity.

The advantages of the two-electron steps are clear, but they are achieved at the cost of a further increase in molecular complexity. For the hydride transfer pathway, reaction 2 in Scheme 1, it is necessary to have not only an electron acceptor and a proton acceptor site on the oxidant at the same time, but, in addition, the acceptor must have a two-electron capability. The savings in energy and the gain in specificity can be had only at the cost of a greater challenge at the mechanistic level.

Perhaps the ideal pathway for carrying out the oxidation of ethanol is that shown in reaction 1 of Scheme 1, which involves a hybrid of both hydride transfer and proton transfer. The advantage of pathway 1 is that it creates the product in its equilibrium structure with regard to electron and proton content. However, the demands now placed on the oxidant are quite fancy indeed. In a concerted step, it must accept a coupled proton-electron pair (a hydride ion) and an additional proton. Impossible? We will, in a moment, find reagents which appear to come close.

The inorganic example shown in Scheme 2 is the reduction of nitrate ion to nitrite. Once again, there is a clear energetic advantage in favor of the two-electron step. However, as is often the case for inorganics when compared to organics, the advantage is far less dramatic because of a lesser relative instability for intermediate radicals. This is an important point mechanistically since facile one-electron pathways could appear for inorganic substrates: we will see just such a case later in the reduction of nitrite ion to ammonia.

Returning to Scheme 2, it is possible by inspection to begin to see mechanistic approaches for carrying out the reduction of nitrate. A traumatic change in structure must occur in that an oxide group must be lost on reduction. One approach to this problem mechanistically could involve an initial binding step

If the metal site has an accessible higher oxidation state, two electrons removed and stabilized by bonding to an oxo group, a concerted two-electron step could occur involving synchronous breakage of the MO-NO₂ bond and formation of the double bond component of the metal oxo link (M = O). The net two-electron reaction would be of the oxygen atom transfer type, as shown in Eq. [2]

Higher Oxidation States of Polypyridyl Complexes of Ru and Os

Having presented the case for the implied importance of multiple electron steps both mechanistically and in catalysis, the most difficult task remains: the identification of chemical systems having appropriate reactivity properties. A likely place to look is in the polypyridyl chemistry of Ru and Os. An extensive background synthetic chemistry exists for these complexes, based on the ligands, 2,2'-bipyridine, 1,10-phenanthroline, and their derivatives

(bpy)

(phen)

2,2'-bipyridine

1,10-phenanthroline

Typical complexes of ruthenium and osmium containing these ligands have a high stability toward loss of ligands in both oxidation states II and III, and it is interesting to note that complexes like Ru(bpy)₃²⁺ have found extensive use as photosensitizers in energy conversion applications (11-14).

A key feature in the redox chemistry of complexes of this type are cases where water is one of the bound ligands. For these complexes, the usual redox properties are complicated by the gain and loss of protons as shown by plots of $E_{1/2}$ vs. pH. As summarized in Scheme 3, the effect of oxidation of the aquo complex is enhanced acidity of the bound M-O-H protons, which accounts for the domains of pH-dependent redox behavior. Of more interest is the appearance in electrochemical

Scheme 3 (E° values in V vs. SCE at pH 7) (15, 16)

experiments of a higher oxidation state, Ru^{IV}. The potential of the Ru^{IV/III} couple also has a complex pH dependence, as suggested by Scheme 3. It is striking that the potentials for the Ru^{IV/III} and Ru^{III/II} couples are so close in value, since for related couples where there is no chance for proton gain or loss, e.g., Ru(bpy)₂Cl₂^{2+/+} - Ru(bpy)₂Cl₂⁺⁰, the difference in potentials exceeds 1.6V. Based on thermodynamic arguments, the key to the stabilization of the higher oxidation state is proton loss and donation of the freed p-II oxygen electron density to the metal to form the M = O double bond.

The accessibility of multiple higher oxidation states is a general feature of complexes of this type. It is important to realize that by making systematic variations in the ligands at the metal, a series of related redox reagents can be prepared and characterized where such features as reduction potentials can be varied systematically. An extreme example of such behavior is shown in Scheme 4, which is a

Scheme 4 (E° values in V vs. SCE at pH 4.0) (17)

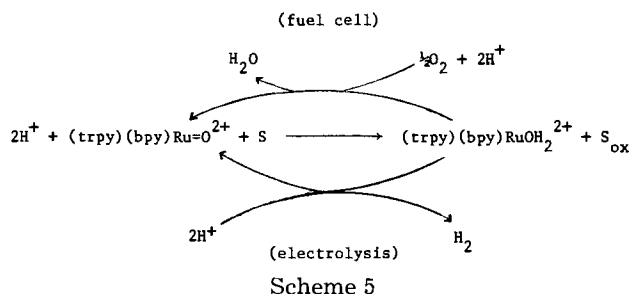

Latimer-type diagram interrelating oxidation states from Os(VI) to Os(II) in a coordination environment containing two bipyridine ligands. The redox potentials quoted in Scheme 4 are specified at pH 4 because there are complex variations in $E_{1/2}$ with pH for all of the couples. The data in Scheme 4 clearly open up the possibility of having a series of redox couples with an implied capacity for multiple electron changes. The importance of the oxo groups in stabilizing higher oxidation states is rather dramatic here, when it is realized that five different oxidation states of osmium, from II to VI, can exist over a potential range of ~ 0.6V.

The availability of higher oxidation states is striking in itself, but it also has important implications for mechanism and catalysis. The various oxidation states are reasonably stable; in fact, the Os(VI) dioxo complex, (bpy)₂Os(O)₂²⁺, has been isolated and characterized. The higher oxidation states also have some of the features that appear to be demanded by the mechanistic pathways mentioned above. One of these features is the existence of two-electron couples like the Ru(IV)/(II) couple in Scheme 3, which occur at potentials very near those for the component one-electron couples. The presence of the oxo group is important both in stabilizing higher oxidation states and mechanistically by providing an O atom transfer pathway, an initial lead-in site for attack on a substrate, or an acceptor site for a transferred proton in a hydride transfer.

Coordinative stability is essential for catalysis and for the Ru and Os complexes the primary coordination geometries stay intact in the different oxidation states. Critical structural changes occur only at the oxo "active site." This is in contrast to more typical oxidants like CrO₃ or MnO₄⁻, where reduction leads at some stage to changes in coordination number and composition (e.g., CrO₃/Cr(H₂O)₆³⁺), and it is usually quite difficult to make such systems catalytic.

Electrocatalysis

Before proceeding further into the chemical reactivity of the Ru and Os complexes, it is of value to consider how they might be used as catalysts in electrocatalytic applications. The principles involved are straightforward. They are illustrated in Scheme 5 for the hypothetical case where Ru(IV) is the active oxidant of a substrate S where the products of the reaction are S_{ox} and Ru(II)-OH₂. In the electrocatalytic schemes, the catalyst redox couple is oxidatively regenerated at the electrode in a net electrocatalytic "shuttle" mechanism. Two cases are shown in Scheme 5. One is an electrolysis cell, in which

the oxidation of the catalyst to its oxidized form is accompanied by reduction of water to hydrogen. From an energy balance point of view, it is important to note that H₂ is formed in the second cell compartment. Given the ready availability of oxygen in the air, electrocatalyses based on the Ru(IV)/Ru(II) couple in Scheme 5 occur with a near energy balance, assuming that the free energy stored in hydrogen as product could be recovered in an efficient hydrogen-oxygen fuel cell.

In the second approach, the catalytic regeneration is shown as running spontaneously by utilizing oxidizing equivalents from an O₂/H₂O electrode. Low overvoltage, high current density, practical O₂/H₂O electrodes are not available. If the technology does evolve, such cells could combine two functions and operate as chemical synthesis fuel cells, where either organic or inorganic transformations of interest could be carried out spontaneously with the production of an electrical current.

We have successfully operated electrolysis cells based on the shuttle mechanism, but an additional design feature must be taken into account. The shuttle mechanism has disadvantages arising from a requirement for relatively large amounts of catalytic material and from the difficulty of an added separation step at the end, one to recover the catalyst. A more sophisticated design feature involves the attachment of the redox sites directly to an electrode surface. In this configuration, catalyst demands

are greatly decreased and the possibility exists for flow-through design. There is an extensive background chemistry of this kind for the polypyridyl complexes, in which the electrode attachment is accomplished by adsorption of preformed polymers containing the redox sites, or by electropolymerization of appropriate complexes directly onto an electrode surface. This work has been reviewed elsewhere (18) and will not be of additional concern here.

Oxidation of Organics

The higher oxidation state oxo complexes of Ru mentioned above undergo rapid reactions with a variety of organic substrates. In some cases, the reactions have been investigated in detail either electrocatalytically or mechanistically, or both. A reaction which has been particularly well studied is the oxidation of isopropanol by Ru(IV)=O, as shown in Scheme 6. In the first step, a two-electron oxidation of isopropanol to acetone occurs along with the reduction of Ru(IV) to Ru(II) (19a). However, spectrophotometric studies show that (trpy)(bpy)-RuOH²⁺ is the initial product. It appears because the comproportionation reaction in Eq. [4] is rapid compared to the initial oxidation of isopropanol.

Scheme 6

Following oxidation by Ru(IV), a slower reaction is observed in which isopropanol is oxidized by Ru(III) (Eq. [5]). The oxidation by Ru(III) is slower by ~ 400 at room temperature and occurs by an initial one-electron step to give the intermediate organic radical.

A variety of experimental facts are available for the oxidation of isopropanol by Ru(IV)=O: (i) The rate law is first order in both Ru(IV) and alcohol over a broad pH range with $k(25^\circ) = 0.07 \text{ M}^{-1}\text{s}^{-1}$. (ii) An isotopic labeling experiment shows that the oxo group is not transferred from Ru(IV) to the alcohol in the redox step. This is an important point for catalytic design, since it suggests that the mechanistic details of the reaction involve a template step in which substitution at the metal is not required. The importance of this point is that for inert second- and third-row transition metal complexes, overall catalytic rates are often controlled by substitutional steps. A template mechanism avoids such pitfalls. (iii) Comparing rate constants between (CH₃)₂CHOH and its perdeutero analog, (CD₃)₂CDOD, shows that the H/D kinetic isotope effect is $(k_{\text{H}}/k_{\text{D}}) \sim 18$. The majority of the effect (~ 6) comes from the C-H bond adjacent to the hydroxyl group, which is not surprising, since it is the bond that is oxidized in the net reaction.

The results of a variety of experiments are consistent with the mechanism shown in Eq. [6], in which a concerted two-electron step occurs via a hydride transfer. It is interesting to note that even though Ru(IV)=O has apparently chosen to use a low energy, but complex, hydride transfer pathway, the initial products are formed with nonequilibrium proton contents, which is costly energetically. Following the redox step, proton equilibrium is achieved by rapid proton gain and loss steps to give the final products in their stable proton environments, which are determined by the pH of the solution. It is interesting to speculate that if an additional site were added to the complex as a proton acceptor site, at a structurally appropriate location, the proton composition dilemma might be

avoided, leading to the mechanism suggested by reaction [1] in Scheme 1, in which both two electrons and two protons are removed in a simultaneous step.

Without discussing the details, the oxidation of isopropanol by Ru^{III} also has some interesting features. From a combination of kinetic studies and kinetic isotope effects, it has been concluded that the oxidations occur by initial one-electron steps, as shown in Eq. [7] and [8], but that there is a change in mechanism between outer-sphere electron transfer in water to H atom transfer in acetonitrile

Detailed kinetic and mechanistic information is also available for the oxidation of C-H groups adjacent to aromatic rings by Ru(IV) = O. Typical reactions are shown in Eq. [9]-[11], where the examples shown are solubilized aromatic hydrocarbons, which were convenient for kinetic studies in water (19b). It is interesting to note that in contrast to Ru(IV)=O, Ru(III) no longer undergoes reactions at a measurable rate. This is not too surprising, since Ru^{III} is forced to behave as a one-electron oxidant, and the intermediate aromatic hydrocarbon radicals are far less stable than, for example, radicals of secondary alcohols. However, it clearly points out the value of the accessibility of two-electron pathways. Again, without elaborating on details, several interesting features have evolved from the aromatic oxidations: (i) the multiple electron reactions shown, for example, in Eq. [10] and [11] occur via a

series of consecutive two-electron steps. (ii) The example in Eq. [10] is illustrative of a clear element of selectivity in the preference for oxidation of C-H groups adjacent rather than remote to the aromatic ring. (iii) In the initial hydrocarbon oxidation step in Eq. [9], an oxygen atom must be derived from an external source in order to satisfy the compositional demands of the products. The results of kinetic and mechanistic studies suggest that the hydrocarbon oxidation occurs by a two-electron hydride transfer, Eq. [12], with the added feature that water or

another nucleophile (Br⁻, t-BuOH) enters the rate law in a first-order fashion in acetonitrile (19b).

Once again, it is worth noting that the oxo complex has chosen a relatively sophisticated pathway to carry out an oxidation, but the demands of the reaction products are not fully met in that the proton contents of the initial products are not those at equilibrium. Here again, an improvement in catalyst design might be achieved by including a proton acceptor group at an appropriate site structurally.

One of the striking features to arise from the oxidation of aromatic hydrocarbons is the suggestion of an implied

functional group selectivity based on rate-constant data. As an example, under equivalent conditions, oxidation of the hydrocarbon in Eq. [9] is faster by 200 than oxidation of isopropanol. This is a surprising turnabout in reactivity and suggests the possibility of developing selective oxidants based on kinetic selectivity.

The major theme of the paragraphs above has been a discussion of mechanistic detail, but the same redox systems have proven to be of value in electrocatalysis. Examples of electrocatalytic oxidations based on the complex (trpy)(bpy)RuO²⁺ in water or in mixed organic solvent/water mixtures are shown in Eq. [13]-[16]. Some of the important

features to emerge from this work are the following: (i) The reactions are all carried out at or slightly above room temperature using the electrochemical shuttle procedure in Scheme 5. (ii) The reactions are notable for the fact that they appear to be quantitative within experimental error without the appearance of side-products. (iii) In multiple electron reactions like Eq. [14]-[16], the net processes involve a series of two-electron steps and in favorable cases intermediates, e.g., acetaldehyde in Eq. [13], build up, and, in fact, procedures can be developed for carrying out the selective oxidation of ethanol to acetaldehyde (20).

The Ru(IV) complex is not a universal catalyst. Under the relatively mild conditions of the electrocatalytic procedure no, or at least slow, reactions occur with a number of organics including acetate ion, tertiary alcohols, alkanes, or aromatic hydrocarbons. Finding that there are unreactive substrates represents a challenge to catalyst design. By preparing catalysts which are stronger oxidants and/or using more forcing conditions, it should be possible to find the conditions needed to oxidize any organic.

Inorganics

The Ru and Os complexes dealt with here have an equally interesting and revealing chemistry, both mechanistically and catalytically, in a series of important inorganic redox reactions. As a first example, consider the oxidation of hydrogen peroxide by (bpy)₂(py)Ru = O²⁺. The steps that occur in the net reaction are shown in Eq. [17]. One reason

for studying the reaction was the possibility of finding a hydride transfer pathway for the oxidation of hydrogen peroxide to oxygen, Eq. [18], given the apparent propensity of Ru(IV)=O to undergo two-electron transfer steps. Although the reaction may not appear to be of consequence in its own right, it could have important implications for the

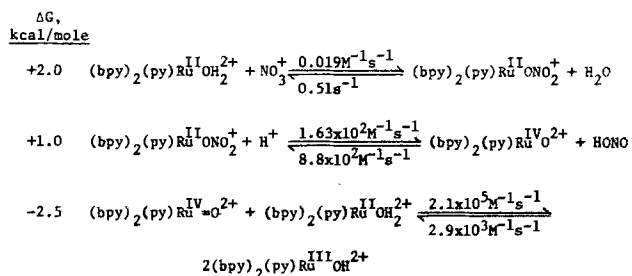

design of catalysts for the electrocatalytic reduction of oxygen to hydrogen peroxide based on microscopic reversibility. Nonetheless, it is clear from stopped-flow studies that the reaction occurs as shown in Eq. [17]-that is, through a series of two sequential one-electron steps. There is something quite extraordinary about the initial, relatively slow, one-electron step. At room temperature,

the rate constant for the reaction is $k = 2.1 M^{-1}s^{-1}$ (25° , $\mu = 0.1M$), and the H/D isotope effect is $(k_{H_2O}/k_{D_2O}) = 22.1 \pm 0.6$. The large H/D kinetic isotope effect indicates the existence of a complex pathway which can best be described as a hydrogen-atom transfer. The reason for the appearance of such an elaborate pathway in a reaction of this kind is obvious when one considers the possibilities shown below. One-electron

transfer by pathway 2, while mechanistically simple, necessarily gives the initial products with nonequilibrium proton compositions. The energetic demands associated with creating a Ru^{III} complex which is short a proton and a protonated perhydroxal radical are sufficient that this pathway is apparently noncompetitive. The large kinetic isotope effect signals the fact that pathway 2 is operative. The dilemma posed by proton composition in pathway 2 is avoided in pathway 1 by the simultaneous transferral of both an electron and a proton from hydrogen peroxide to the oxidizing agent in a net H-atom transfer.

Clear evidence has been obtained that the Ru redox couples can undergo multiple electron steps with inorganics. A case in point is the reversible interconversion of nitrate to nitrite. An initial experimental observation was that if $(bpy)_2(py)RuOH_2^{2+}$ is dissolved in nitric acid solution, it is unstable and with time is oxidized to $(bpy)_2(py)RuOH^{2+}$. The observation is remarkable when it is realized that a pH 1, $\Delta G^\circ \sim 0$ and that nitrate ion is commonly used as the anionic component of "inert electrolytes." Both the mechanistic and kinetic details of the interconversion between nitrate and nitrite have been investigated in detail and the facts as they are now known are presented in Scheme 7 (22).

Scheme 7. ($\mu = 0.1M$; pH 2.0)

In the overall mechanism, the initial step involves a substitution in which NO_3^- displaces a water molecule in the inner coordination sphere to give an intermediate nitrate complex. The second step is the key one from the redox point of view, since in it the ion is literally stripped apart to give as products HONO and the Ru(IV)-oxo complex. Once again, the advantage of a multiple electron capability clearly emerges. In this case the pathway is O atom transfer, and its existence depends upon the accessibility of a higher oxidation state at the metal as well as the metal's ability to bind the oxide ion as it is removed from the bound nitrate. It is ironic that by far the slowest process in the overall scheme is the initial substitution step, a situation which is quite common for second- and third-row transition metal ions. With regard to the redox step, the rate constant for reduction of nitrate once bound is $160 M^{-1}s^{-1}$, showing that if the proper reactivity features are built into the redox reagent, nitrate can be reduced in a facile manner.

The overall reduction of nitrate to ammonia is an important process in plants. The nitrate to nitrite step described above is a mimic for a class of enzymes called nitrate reductases. The next step in plant metabolism, reduction of nitrite to ammonia, is carried out by the nitrite reductase enzymes. The reduction of nitrite to ammonia is a net six-electron step (Eq. [19]), and the reaction

demands are sufficiently formidable that at first glance it would seem unreasonable to think that a simple chemical reagent could carry out the net transformation. In fact, when bound in Os and Ru complexes, the interconversion

between nitrite and ammonia can be made reversible, and the results of a series of electrochemical studies have shown that the mechanism involves the one-electron steps, shown in Scheme 8 (23).

Scheme 8

The existence of the series of reactions depends on a closely matched balance of redox levels between the metal and coordinated ligands. In the reductive sense, the initial step is the interconversion of a metal nitro complex to the corresponding nitrosyl, which is well known chemically (24). Once the nitrosyl complex is formed, an initial one-electron reduction occurs at levels largely $\pi^*(NO)$ in character. The second step also involves a one-electron reduction at the ligand but is irreversible because of the subsequent addition of a proton to give a new intermediate in which an NHO group is bound to the metal. In the scheme, the consequences of the addition of a third electron are notable. According to the scheme, at this point there is a crossing of the sense of the redox orbitals involved, and the redox chemistry is carried out by orbitals largely metal-based in character, to give a nitrido complex $M(V)=N$ as intermediate. The rest of the scheme and the nitrido ammonia conversion are relatively straightforward. The four-electron intermediate, $Ru(IV)=NH$, contains a metal imine group and is an analog of the corresponding $Ru(IV)$ -oxo complex. The intermediate has not been isolated because it is inherently unstable in water, and reacts to give the corresponding hydroxylamine complex, with $t_{1/2} \sim 100s$ at $25^\circ C$ (Eq. [20]). Further reduction of the $Ru(IV)$ -NH intermediate leads

to isolable Ru(III) and finally to Ru(II) complexes, both of which contain coordinated ammonia. As suggested by the scheme, the reactions shown are reversible, at least for the complex shown, and can be driven in either direction, depending on whether the complexes are exposed to oxidizing or reducing conditions.

The chemistry suggested by the reactions in Scheme 8 appears to have general features as shown by the reactions in Eq. [21] and [22]

However, the catalytic interconversion of ammonia and nitrite based on the Ru and Os complexes suffers from the disadvantage of their being substitutionally inert. Once the redox chemistry occurs, the redox product is firmly bound.

It is possible to make the nitrite-to-ammonia interconversion catalytic. The key is to turn to the first-row transition metal congener, iron. Electrolysis of an aqueous solution containing nitrite in the presence of the water soluble iron tetraphenylporphine derivative, Fe(TPPS)(H₂O)₂²⁺, which contains -SO₃⁻ groups on the phenyl groups of the ligand, results in the electrocatalytic production of ammonia (23a). Although detailed mechanistic information is not available for the catalyzed reaction, it seems reasonable to expect that the mechanism is related to that in Scheme 8 and involves initial binding of NO₂⁻, acid-base equilibrium to give the nitrosyl, and reduction of the bound ligand. The advantage of the iron porphyrin complex in catalytic applications is that at the end of the reduction process, the complex is labile and exchange of ammonia for nitrite can occur. It is interesting to note that it is thought that the active redox sites in the enzymatic systems for nitrite reduction are also based on iron porphyrin groups. It is conceivable that much of the enzyme function is a redox apparatus designed to bring redox equivalents to the active iron porphyrin site.

Oxidation of Water to Oxygen

It should be evident by now that the polypyridyl complexes of Ru and Os, with which we began, are extremely versatile in their redox properties. One of the most appealing features is the availability of varying redox potentials through systematic variations in structure. In the appropriate coordination environment, oxidizing complexes are accessible which have the thermodynamic ability to attack the problem of the electrocatalytic oxidation of water to oxygen or of chloride to chlorine. The problem of water oxidation is important to the possibility of developing photocatalytic systems for water splitting (H₂O → H₂ + 1/2 O₂) and also as the microscopic reverse of an extremely important fuel cell component, the reduction of O₂ to H₂O.

As can be seen from reaction [23], the mechanistic demands inherent in water oxidation are, once again, rather formidable. In order to

carry out the transformation at the thermodynamic potential for the H₂O/O₂ couple, a bond between two oxygens must be formed, and four protons and four electrons lost. There are severe energetic penalties if other pathways are chosen because of the instability of intermediate oxidation states of oxygen. For example, in 1M acid, the potential for the H₂O/OH couple is (25)

The approach we have taken to a water oxidation catalyst is to turn to a water oxidation catalytic dimeric structure, namely, (bpy)₂(H₂O)₂RuORu(H₂O)(bpy)₂⁴⁺. The structure of the dimer has been determined by x-ray crystallography. From the structure, the RuORu link is bent (165.4°) and the water molecules are slightly canted so that the water-water separation distance is ~ 4.7Å (26). The composition of the dimer is obviously promising for water oxidation in that it contains two linked metal sites and two bound water molecules held in close proximity. In fact, when more than four equivalents of a strong oxidant like Ce(IV) are added to aqueous solutions containing the dimer, the catalytic oxidation of water to oxygen occurs (Eq. [25] (27)). The system works effectively as a

catalyst through many turnovers, although over an extended period of time, the catalytic properties of the system can be lost under certain conditions.

The redox properties of the dimer have been investigated by electrochemical techniques and are summarized in Scheme 9 (26). The actual proton compositions of the various dimers which appear there depend on pH, and the reaction shown are those which occur at pH 1.

Scheme 9

In the initial step, one electron and one proton are lost to give a formally Ru(III)-Ru(IV) dimer. The actual description of oxidation state in the dimers is complicated by the existence of strong electronic coupling through the bridging oxo group (29). The next stage is a two-electron, two-proton step giving a Ru(IV)-Ru(V) dimer. The appearance of a two-electron step shows that the Ru(IV)-Ru(IV) dimer is near to being or is actually unstable with respect to disproportionation. Under some pH conditions, an additional one-electron oxidation wave can be observed. Oxidation past that wave delivers the system to a state where the dimer presumably contains two chemically linked Ru(V) = O groups. Although information past this point is not yet available, we suspect that the Ru(V)-Ru(V) form is the active catalyst in the oxidation of water, perhaps by the four-electron step shown in Eq. [29]

It is illuminating to trace how the dimeric system appears to carry out the oxidation of water to oxygen. The net effect of Eq. [26]-[28] is the loss of the requisite numbers of electrons and protons to arrive at the structure, O=Ru(V)ORu(V)=O. In the structure, two oxo groups are held in close proximity in a dimeric unit where four redox equivalents are stored between the two metal sites. The water-to-oxygen interconversion appears to be quite rapid under certain conditions. Once again, the telling point here is that if transition metal redox reagents can be designed with the needs of a target reaction in mind, even reactions as complex as water oxidation and nitrite reduction can be carried out in a facile and potentially useful way.

Oxidation of Chloride to Chlorine

The electrochemical oxidation of Cl⁻ to Cl₂ is a commercially important process which is carried out at carbon-based electrodes, which suffer from decomposition, or, more recently, at TiO₂ electrodes impregnated with Ru. RuO₂ containing electrodes are also efficient catalysts for the oxidation of water to oxygen, and given the structures of some of the metal complexes discussed here, extensions of the catalytic chemistry to the electrocatalytic oxidation of chloride to chlorine seem promising. In fact, we have found that a number of high oxidation state, Ru-oxo complexes do catalyze the oxidation of chloride to chlorine. Two such systems have been studied in detail: the dimeric system described in the previous section, and the Ru^{VI/IV} couple shown in Eq. [30] (28). The monomeric couple is part of a larger redox set, much like the one shown for the osmium analog in Scheme 4.

In the presence of either the Ru(IV) complex shown in Eq. [30] or the dimeric complex shown in Eq. [27], elec-

trollysis at carbon electrodes containing Cl^- leads to large catalytic currents and the production of chlorine, eq. [31]

or

The results of catalytic, electrochemical, and spectral experiments have revealed a number of details concerning the catalyzed oxidations and the way the catalysts operate: (i) for both catalysts, catalytic lifetimes are limited by slow replacement of water by chloride ion in the inner coordination spheres, Eq. [32], [33]. (ii) The monomeric

system has an additional instability arising from slow oxidation of water by $(\text{bpy})_2\text{Ru}(\text{O})_2^{2+}$, which occurs with the concomitant formation of an as-yet unidentified complex of Ru(III). (iii) It is clear from electrochemical studies that the active form of the dimer toward oxidation of chloride to chlorine is the Ru(IV)-Ru(V) dimer (Eq. [27]). This leads to an element of selectivity since electrolyses at potentials sufficient to oxidize the Ru(III)-Ru(IV) dimer to the Ru(IV)-Ru(V) dimer lead to the selective oxidation of Cl^- to Cl_2 without the appearance of oxygen. (iv) The catalyst couples are pH dependent in most pH regions, but the Cl_2/Cl^- couple is pH independent up to ~pH 3. As a consequence, it is possible to vary the overall driving force for the $\text{Cl}^- \rightarrow \text{Cl}_2$ oxidation by simply varying pH. (v) From pH variations, overvoltages for the catalyzed reactions are low since even when ΔG for the net reaction is as low as -0.07V , significant catalytic currents are still observed. (vi) A second point of note to arise from the pH dependence study is that in solutions more basic than pH 4, where chlorine exists largely as HOCl , or as OCl^- , the electrocatalytic reaction can be run in the reverse sense. Under these conditions, chlorine as HOCl rapidly oxidizes the Ru(III)-Ru(IV) dimer to Ru(IV)-Ru(V) or the Ru(IV) monomer to Ru(VI). For the dimer, this provides a route to use chlorine as the oxidant in the chemically catalyzed oxidation of water to oxygen.

Although the catalytic systems described here for the oxidation of chloride to chlorine have their faults, the net chemistry is successful. This appears to be a case where it should be possible to devise "ideal catalysts" which are reactive and long-lived and which can be attached to electrode surfaces.

A Mechanistic Summing-Up

Three interwoven themes have been developed here. The first was a consideration of complex redox events and the demands they place on a reagent if it is to be capable of carrying out complex redox transformations at reasonable rates. The second was the existence of complex redox pathways in real chemical systems, and the third was the incorporation of the chemical systems into operating electrocatalytic systems.

The chemical systems presented here are not, one would hope, the ultimate in catalyst design, but their properties are clearly encouraging. In the long run, these systems and others like them may fulfill a more important role in fundamental chemistry. They may allow a complete tally to be made of the reactivity patterns inherent in redox reactions. In the context of the speculations about chemical reactivity, it is interesting to note that even at this early stage at least six distinct redox pathways have been identified for the Ru complexes of interest here. Although the details of the various pathways may be debatable, all six are discernibly and

definably different based on H/D kinetic isotope effects, rate laws, activation parameters, etc. The six pathways and examples of them are illustrated in Scheme 10.

Scheme 10

It is without question that other redox pathways will appear for these reagents as additional substrates are investigated mechanistically. One of the most fascinating issues will be the attempt to unravel not only the details of the pathways, but to discover those factors leading to the most facile pathways for a given reaction. A combination of mechanistic studies with continued synthetic advances should lead to an extended family of catalysts for carrying out redox transformations in both organic and inorganic chemistry.

Molecular Ingredients of Heterogeneous Catalysis

G. A. Somorjai and R. C. Yeates

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemistry, University of California, Berkeley, California, 94720

ABSTRACT

The purpose of this paper is to present a review and status report of the rapidly developing surface science of heterogeneous catalysis. We describe the experimental results that identified three molecular ingredients of catalysis: (i) structure (ii) carbonaceous deposit, and (iii) the oxidation state of surface atoms. The hydrogenation of ethylene at both the gas-solid and liquid-solid interfaces is described.

The explosively rapid development in surface science over the past 15 yr was concentrated on studies of the solid-gas and solid-vacuum interfaces. Electron, atom, and ion scattering techniques revealed the atomic structure and composition at the surface (1). Many of these techniques that are frequently used in surface studies are listed in Table I. The same techniques could not be used to probe the solid-liquid interface. The high elastic and inelastic scattering cross sections that make these probes surface sensitive render them ineffective in studies of interfaces between two phases of high atomic densities. As a result, studies of solid-liquid interfaces were pursued by the use of an ultrahigh vacuum-liquid cell that permitted *in situ* investigations of electrochemical reactions and then the direct transfer of the electrode surface into ultrahigh vacuum for analysis of the surface structure and composition (2). These cells are similar in design to the low pressure-high pressure cells developed in our laboratory (3) for combined low pressure surface science and high pressure catalysis studies, and have been most valuable in studies of platinum electrodes and electrocatalysis. More recently, high intensity electromagnetic radiation emanating from lasers (4) or from the synchrotron (5) has been employed increasingly for studies of the solid-liquid interface. Laser Raman spectroscopy, infrared ellipsometry, grazing angle x-ray scattering, and Fourier transform infrared techniques are among those that hold great promise for *in situ*, molecular-level analysis of the solid-liquid interface.

In this paper, we shall review what has been learned about the atomic structure and composition of clean surfaces from surface science studies of the solid-vacuum interface. We shall show the surface structures of a few organic molecules that have been determined by combined LEED and HREELS studies. We shall then describe the model of the working metal catalyst surface as revealed by single-crystal studies primarily using platinum surfaces. We shall correlate what is known about the hydrogenation of ethylene, C_2H_4 , that was studied over the Pt(111) crystal face, both at the solid-liquid and solid-gas

interfaces. Finally, we shall review what needs to be done, in our estimation, to accelerate the development of solid-liquid interface studies which are clearly at the frontier of surface science.

The Structure of Miller-Index Surfaces

The atomic structure of clean low Miller-index surfaces.—Low energy electron diffraction studies have revealed two important features of atomic surface structure: (i) relaxation and (ii) reconstruction. It has been found that for most solid surfaces, the spacing between the first and second layers is shortened as compared to the spacing between the second and third, which in turn is shortened as compared to the third and fourth, and so on. This contraction is larger for more open surfaces, that is, for surfaces having lower atomic density. For example, the contraction for the (110) surface of face-centered cubic metals is greater than that of the higher density (111) surface. In the surface plane (X-Y plane) the atoms maintain the structure of the projection of the bulk unit cell onto the surface. The contraction occurs in the Z direction, perpendicular to the surface. This phenomenon may be understood by considering the surface as an intermediate between a diatomic molecule and bulk crystal. The interatomic distance in diatomic molecules is much shorter than the interatomic distance in the solid crystal. The surface atoms, having fewer nearest neighbors than atoms in the crystal, exhibit a lattice parameter somewhere between these two extremes in order to compensate for the anisotropy of the forces (*i.e.*, having atoms on one side and vacuum or atoms of another type on the other side).

Reconstruction is also a consequence of surface atom relaxation. When atoms are placed in an anisotropic environment, such as the surface, there are many dangling bonds that would like to pair up in order to maximize the binding energy between surface atoms. As a result, the atoms at the surface seek a new equilibrium position, not only in the Z direction, but also in the surface (X-Y) plane. This massive dislocation of surface atoms leads to reconstruction, the ap-

pearance of a new surface unit cell. Most semiconductors and many metal surfaces undergo these reconstructions (Fig. 1). Many of these structures have been analyzed by surface crystallography and the precise location of surface atoms has been determined (6).

The structure of high Miller-index surfaces.—Studies of high Miller-index surfaces by low energy electron diffraction have revealed that they are composed of low Miller-index surfaces in stepped and kinked configurations. Typical high Miller-index surfaces with various combinations of terraces and kinks are displayed in Fig. 2 and 3. By cutting crystals along a high Miller-index direction and suitable cleaning afterwards, one can obtain diffraction patterns from which the structure of these high Miller-index surfaces can be determined. Because of the periodicity of the steps and/or kinks, structure determination of diffraction is possible. Steps of monatomic height provide minimum surface free energies for these surfaces and therefore are prevalent on clean high Miller-index surfaces.

The Composition of Clean Surfaces

Because of differences in bonding at the surface and in the bulk, there is a considerable driving force for many impurities to segregate to the surface (7). Sulfur, carbon, boron, and silicon are often found to segregate to the surface upon heating. Although surface segregation of impurities is rather inconvenient when one would like to study the properties of clean surfaces, subsequent removal of the segregated impurity atoms provides a cleaning mechanism for many solids. For multicomponent systems, the surface free energy is minimized by placing that component which has the lowest free energy on the surface. As a

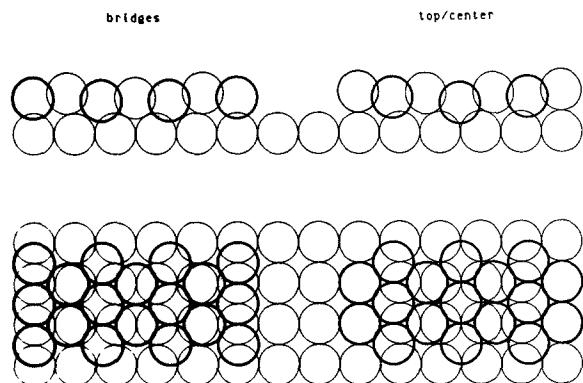

Fig. 1. Arrangement of atoms on the reconstructed (100) surface of platinum, gold, and iridium.

result, surface compositions are almost always different from the bulk composition for multicomponent systems (Fig. 4). This is particularly important for alloys because metals, having high surface energy in the range of thousands of ergs per square centimeter, provide a large thermodynamic driving force to segregate the component with the lowest surface energy to the surface, thus minimizing the total surface energy. Several thermodynamic models predict surface segregation in alloy surfaces (8).

It should be noted that the adsorption of gas atoms or molecules that form bonds of different strengths with a different alloy constituent can change the surface composition markedly. For example, copper is segregated to the surface of clean copper/nickel alloys (9). Upon adsorption of carbon monoxide, which forms a much stronger bond with nickel than with copper, nickel diffuses to the surface, altering the surface composition (10). When carbon monoxide is desorbed, the copper moves back onto the surface and provides a copper-rich alloy phase.

It should be noted that, in order to observe the surface segregation predicted by thermodynamic models, one needs to provide large enough diffusion rates to facilitate equilibration between the surface and bulk. At suffi-

Fig. 2. Structure of several high Miller-index stepped surfaces with different terrace widths and orientation.

Fig. 3. Structure of several high Miller-index surfaces with different kink concentrations.

ciently low temperatures, one may freeze in metastable surface compositions. The surface segregation is minimized when the bulk lattice forces are strong enough to overcome any change due to the introduction of a surface. As a general rule, if the heat of mixing or the heat of compound formation is much greater than the surface energy differences of the components, surface segregation may be unimportant.

Structure of Alkenes and Benzene on Metal Surfaces

Our low energy electron diffraction and high resolution energy loss spectroscopy studies have been directed toward the determination of the molecular structure and bonding of hydrocarbons on platinum and rhodium surfaces. Figure 5 shows the stable structures of ethylene, propylene, and butene adsorbed on platinum and rhodium surfaces in our laboratory (11) and on palladium and nickel surfaces in other laboratories. The carbon-carbon bond closest to the metal surface is perpendicular to the surface plane, and is elongated to a single bond, 1.5Å. The carbon closest to the metal sits in a three-fold hollow site with a carbon-metal distance of 2.0Å, considerably shorter than the 2.2Å covalent bond length expected. This indicates a very strong multiple carbon-metal bond of carbene- or carbyne-like character. The methyl group or ethyl groups are away from the surface and are rotating rather freely. Only at high coverages will these side groups order to form new surface structures. These structures are called alkylidyne because of their similarity to several organometallic cluster compounds. Benzene lies flat on the (111) crystal face of these transition metals with the center of the benzene ring above the threefold hollow site (Fig. 6). The surface structure is highly symmetrical, as determined by both LEED and HREELS

Fig. 4. Surface concentration of Au-Ag alloy plotted vs. the bulk concentration.

studies. As the temperature is increased, selective C-H and C-C bond breaking occurs and organic fragments, C_2 , C_2H , and CH , form on the surface. These fragments are very stable and seem to be present in the temperature range 140°-400°C (12), perhaps the most important temperatures for catalytic reactions. The hydrogen-deuterium exchange in these organic fragments is very facile. The

carbon atoms are strongly bound to the surface and stay on the surface for periods much longer than the turnover times of most catalytic reactions. The function of these fragments in a catalytic reaction appears to be one of hydrogen storage. They readily supply their hydrogen to incoming organic reactants and intermediates. Above 400°C, all the hydrogen desorbs and a graphitic overlayer forms. This layer poisons the transition metal surface for heterogeneous catalysis.

The Model of the Working Metal Catalyst during Hydrocarbon Conversion

Over the last ten years, studies of hydrocarbon conversion reactions using single-crystal surfaces have revealed the dominant molecular ingredients of hydrocarbon conversion catalysis. These are the atomic structure of the metal surface, its composition, and the oxidation state of the surface atoms. How does the reaction rate depend on the atomic structure of the catalyst surface? To answer this question, reaction rate studies using various flat, stepped and kinked single-crystal surfaces have been very useful indeed. For the important aromatization reaction of n-hexane to benzene and n-heptane to toluene, we discovered that the hexagonal platinum surface, where each surface atom is surrounded by six nearest neighbors, is three to seven times more active than the platinum surface with a square unit cell (13). Aromatization reaction rates increase further for stepped and kinked platinum surfaces (14). Reaction rate studies on more than ten different crystal surfaces with various terrace orientations and step and kink concentrations indicate that maximum aromatization activity is achieved on stepped surfaces with terraces of hexagonal orientation, about five atoms wide (Fig. 7).

The reactivity pattern of platinum crystal surfaces for alkane isomerization reactions is completely different than that for aromatization (15). Our studies revealed that maximum rates and selectivity (the rate of the desired reaction divided by the total rate) for butane isomerization reactions are obtained on the flat crystal face with the square unit cell. Isomerization rates for this surface are four to seven times higher than those for the hexagonal surface and are only increased slightly by surface irregularities (steps and kinks) on the platinum surface (Fig. 8). For the undesirable hydrogenolysis reactions that require C-C bond scission, we found that the two flat surfaces with the highest atomic density exhibit very similar reaction rates (15). However, the distribution of hydrogenolysis products varies sharply over these two surfaces. The hexagonal surface displays selectivity for scission of the terminal C-C bond, whereas the surface with the square unit cell always prefers cleavage of C-C bonds located in the center of the reactant molecule. The hydrogenolysis rate increases markedly (three- to fivefold) when kinks

Fig. 7. The dependence of dehydrocyclization selectivities as a function of surface structure ($P_{n\text{-heptane}} = 15$ torr, $P_{H_2} = 480$ torr, and $T = 573$ K).

Fig. 8. The dependence of isomerization rate of various alkanes as a function of surface structure.

are present in high concentrations on the platinum surfaces.

Since different reactions are sensitive to different structural features of the catalyst surface, one must prepare the catalyst with an appropriate structure to obtain maximum activity and selectivity. As indicated, H-H and C-H bond breaking processes are more facile on stepped surfaces than on the flat crystal faces, while C-C bond scission is aided by kink sites.

What is the composition of the working metal catalyst surface? When the surface of platinum was examined after carrying out any one of the hydrocarbon conversion reactions, it was always covered by a near monolayer amount of carbonaceous deposit. Studies of carbon 14-labeled organic molecules and thermal desorption spectroscopy revealed that the turnover time of the carbon fragments was longer than the turnover times of the catalytic reactions (17). Deuterium exchange studies indicate rapid exchange of the hydrogen atoms between the adsorbing reactant molecules and the active, but irreversibly adsorbed carbon fragment deposits. The carbon atoms in this layer do not exchange. One important property of the carbonaceous deposit is its ability to store and exchange hydrogen. 10% and 15% of the surface remains uncovered, while the rest of the metal surface is covered by the organic deposit. The fraction of uncovered metal sites decreases slowly with increasing temperature (17). The structure of these uncovered metal islands is not very different from the structure of the initially clean metal surface.

The result of our catalytic hydrocarbon conversion reaction studies on platinum crystal surfaces was to develop a model (18) for the working platinum and other transition metal catalysts and is shown in Fig. 9. Between 80% and 95% of the catalyst surface is covered with an irreversibly adsorbed carbonaceous deposit that stays on the surface for times much longer than the reaction turnover time. The structure of these carbonaceous deposits vary continuously from two-dimensional to three-dimensional with increasing reaction temperature, and there are platinum patches that are not covered by this deposit. These metal sites can accept the reacting molecules and are responsible for the observed structure sensitivity and turnover rates. While there is evidence that the carbona-

MODEL FOR THE WORKING PLATINUM CATALYST

Fig. 9. Model for the working surface composition of a platinum reforming catalyst.

aceous deposit participates in some of the reactions by hydrogen transfer and by providing sites for rearrangement and desorption while remaining inactive in other reactions, its chemical role requires further exploration.

In other catalytic reactions, such as the hydrogenation of carbon monoxide, the oxidation state of the transition metal ions at the surface plays an important role in reaction selectivity. It was found that, using rhodium metal, carbon monoxide and hydrogen proceed to form methane (19) and nothing else (Fig. 10). When rhodium was used in the 3+ formal oxidation state as lanthanum rhodate (20) or rhodium oxide (21), oxygenated molecules such as acetic acid, ethanol, acetaldehyde, and methanol were produced. Changing the nature of adsorbed molecules by changing the oxidation state of the transition metal can drastically alter the reaction selectivity. In the case of the hydrogenation of carbon monoxide, the insertion of a carbon monoxide molecule into the growing organic chain can only occur in the presence of higher oxidation-state transition metal ions. In the presence of the metallic state, hydrogenation and CO dissociation predominate to produce mostly methane.

Ethylene Hydrogenation at the Solid-Liquid and Solid-Gas Interfaces of Pt(111)

One of the few reactions that has been studied at both the solid-liquid and solid-gas interfaces using combined low pressure surface science techniques and high pressure catalytic techniques is the hydrogenation of eth-

ylene. The research at the solid-liquid interface is being carried out by Hubbard (22) and his co-workers, and the hydrogenation of ethylene at the solid-gas interface was carried out in our laboratory (23). In both cases, the reaction exhibited an insensitivity to the surface structure and only depended on the number of surface platinum atoms.

When a clean platinum single-crystal surface was exposed to ethylene in the gas phase, a saturation coverage of ethylidyne formed with the structure shown in Fig. 5. The rate of hydrogenation of the ethylidyne molecules was much slower than the observed hydrogenation rate, indicating that the ethylidyne molecule is not a direct intermediate. Since the ethylidyne molecules block the metal atoms and prevent the direct adsorption of ethylene on the metal surface, the ethylene molecules adsorb on top of the ethylidyne layer and are hydrogenated by hydrogen transfer from the ethylidyne. This mechanism explains the structure insensitivity of this reaction. The hydrogenation reaction has an activation barrier of 10.8 kcal/mol (Fig. 11) with a reaction order of 1.3 for hydrogen and -0.60 for ethylene (Fig. 12).

When a clean platinum single-crystal surface was exposed to an aqueous ethylene solution, a strongly adsorbed ethylene layer formed. The structure of this adsorbed ethylene has not yet been determined. Two mechanisms appear to be important in the hydrogenation of ethylene at the solid-liquid interface. The adsorbed ethylene molecule can accept two electrons from the platinum electrode and subsequently react with two hydrogen ions in solution. Also, hydrogen ions can be reduced at the platinum surface. These adsorbed hydrogen atoms can then react with reversibly adsorbed ethylene to form ethane. The dependence of the reaction on temperature has not yet been determined.

Needs for Accelerated Development of Atomic-Scale Studies at the Solid-Liquid Interface

There is no doubt that the chemistry that occurs at the solid-liquid interface is at the frontier of modern surface science. Our challenge is to determine the atomic structure at the solid-liquid interface and the surface composition under adsorption and various reaction conditions. A molecular level understanding of many phenomena in electrochemistry and in biology depends on closer scrutiny of the solid-liquid interface. There are many new techniques that promise to open up this interface to closer scrutiny. The new high intensity photon scattering techniques are certainly among those that are likely to be used in these studies. Techniques that use high intensity, tunable synchrotron radiation and laser techniques are at

the forefront of the promising technologies. It is our hope that the intensive use of these techniques and the development of new techniques will accelerate the understanding of solid-liquid interfaces at the atomic level.

We should emphasize the need for studies of chemisorption of the same atoms and molecules on the

same surface at both the solid-liquid and solid-gas interfaces. By detailed studies of both interfaces, one should be able to correlate the different phenomenon and perhaps use the tremendous amount of data available about solid-gas interfaces to aid in the understanding of the solid-liquid interface on the molecular scale.

It is equally important to study catalytic reactions at the solid-liquid and solid-gas interfaces on the same crystal face. Candidates, in addition to ethylene hydrogenation, are the oxidation of hydrogen and partial oxidation reactions of small molecules. It should be noted that, while temperature-dependence studies reveal kinetic parameters readily, temperature-dependent measurements are rarely made in solid-liquid interface studies.

Reduction of Voltage Delay in the Li/SOCl₂ System via Suitable Choice of Electrolyte Salts

N. A. Fleischer,^{*} S. M. Manske, and R. J. Ekern^{*}

RAYOVAC Corporation, Madison, Wisconsin 53711

ABSTRACT

New electrolyte salts based on the reaction between NbCl₅ and either Li₂S or Li₂O in SOCl₂ substantially reduce voltage delay in laboratory half-cells. The maximum effect was obtained with the NbCl₅/Li₂S combination. The conductivity of both electrolytes is 13.2×10^{-3} mho cm⁻¹ at 26°C. Observations with scanning electron microscopy (SEM) show that the anode film formed in the new electrolyte has a different morphology and appears less dense than the film formed in control LiAlCl₄ electrolyte. The anodic rate capability of Li is slightly greater, over a range of over-potentials, in the NbCl₅/Li₂S electrolyte than in LiAlCl₄. Atomic absorption, infrared, and x-ray photoelectron spectroscopy and electrochemical analysis suggest that the salt formed by reacting NbCl₅ with Li₂S in SOCl₂ is either Li₂Nb₂Cl₁₀S or Li₂Nb₂Cl₁₂. The mechanism for reducing voltage delay and affecting anode film morphology is thought to be associated with the nature of the salt's anion, or possibly the SO₂ produced when Li₂S is combined with the NbCl₅ in SOCl₂.

The Li/SOCl₂ system (1, 2) is attractive as a battery power source because of its high voltage and energy density, good shelf life, and broad operating temperature range. However, a major concern about its successful commercial application is voltage delay. Voltage delay is the excessive polarization of the anode (when a cell is first placed on load), which causes the cell voltage to temporarily drop below a predefined cutoff voltage.

According to the multilayer model of anodic film growth (3, 4), a primary passivating film of LiCl is rapidly formed upon contact of the Li with the SOCl₂ solvent. This primary film is dense and thin. Voltage delay is caused by the subsequent growth of a secondary, porous film on top of the primary film. The growth of the secondary film in LiAlCl₄ electrolytes is believed to be associated with the nature of the AlCl₄⁻ anion and its interaction with the primary film. LiAlCl₄ is widely used in cells as the electrolyte salt (5) because of its high conductivity. Other variables which might affect film growth include electrolyte purity, the chemical dissolution and ionic conductivity of the solid phase of the film, and temperature (3, 6).

Several different approaches have been developed for reducing voltage delay (7-12). The approach of this work is that voltage delay can be controlled by using an electrolyte salt which, as opposed to LiAlCl₄, would not appreciably interact with the primary LiCl film. However, the choice of alternate salts is limited by the low dielectric constant of SOCl₂ (9.25 at 20°C). Similar electrolyte approaches have been used by others. Schlaikjer (7) and Dey (13) have used clovoborate salts to successfully reduce voltage delay. These salts have very large anion structures which are considered to be inert towards the primary LiCl film. Gabano (8) and Bresson *et al.* (14) have studied various Lewis acid/base combinations as electrolytes.

In this paper, we report on the development of conductive, NbCl₅-based electrolytes (15). The effects of this electrolyte on voltage delay, anode film formation, and Li and SOCl₂ discharge were studied. A chemical analysis of the salt was performed.

Experimental

Electrolytes were prepared in an Ar-filled glove box (1-2 ppm H₂O, Vacuum Atmospheres Company). NbCl₅ (Aldrich, 99.8% Pure) was dissolved in distilled thionyl chloride at 70°C while being stirred for 60-90 min. The solution was allowed to cool and then was stirred for 1-2h. A secondary salt of Li₂S (98% Pure Anhydrous, Aldrich or 99% Pure Alfa), LiCl (Mallinckrodt AR Grade, dried under vacuum at 150°C), Li₂O (95% Pure, Alfa), or LiBr (Fisher certified, dried under vacuum at 178°C) was slowly added to the solution which was stirred for another 60 min. The electrolytes were decanted and filtered (Reeve Angel 934 AH, glass fiber). AlCl₃-(99% Pure, Fluka) based electrolytes were prepared with Li₂S or LiCl without heating.

The electrolyte concentration of Nb and Li were determined by atomic absorption analysis (Perkin-Elmer Model 603 Spectrophotometer). The concentration values have an accuracy of $\pm 0.05M$ for Nb and $\pm 0.012M$ for Li.

Conductance measurements were performed in the glove box with a Yellow Springs Instrument Model 31 Bridge at 1 kHz. The manufacturer states that the instrument has an accuracy of $\pm 1\%$. The conductivity cell with Pt electrodes was used in the inverted position, and the vent was sealed with Teflon tape.

Voltage delay measurements using galvanostatic steps were previously described in Ref. (25). The measurements and cell construction were performed inside the glove box. The cell apparatus consisted of a Teflon bottle with a Teflon screw cap. All electrodes were made from lithium (Foote Mineral Company). The working electrode was constructed by forcing a glass capillary tube (3 mm id) through 0.15 cm thick Li foil. The tube was then pulled from the lithium and excess material trimmed with a razor blade to form an electrode with a well-defined surface area. A Ni wire contacted the rear of the Li slug inside the tube for electrical contact. The other end of the Ni wire was force fitted through a small hole in the cell cap as a feed through. This construction prevented the Ni from contacting the electrolyte.

The counterelectrode was a flat Li ribbon positioned parallel to the face of the working electrode. The Li reference electrode was positioned close to the working electrode, but did not interfere with the current flow. Both the counter- and reference electrodes were connected to

Ni feed throughs well above the electrolyte level. The cyclic voltammetry experiments used the same instruments, but the working and counterelectrodes were both made from nickel foil. Tafel anodic polarization curves were run using the same instruments and used lithium as the working and counterelectrodes.

Scanning electron microscopy (SEM) of lithium anodes and x-ray photoelectron spectroscopy (ESCA) of dried salts were performed as in Ref. (26).

Infrared (IR) spectra of electrolyte samples were observed with a Perkin-Elmer 457A Grating IR Spectrophotometer. The IR cell has a path length of 0.025 mm and BaF₂ windows. Samples of evaporated electrolyte salt for IR analysis were prepared by forming them into KBr pellets.

Results

Solubility and conductivity.—The concentration and conductivities of various solutions are shown in Table I. The maximum solubility of NbCl₅ in SOCl₂ is 0.93-0.96M at room temperature. Heating the solution at 70°C for several hours or stirring at room temperature for several days in the presence of excess salt did not change this value. The conductivity of NbCl₅/SOCl₂ solution is very low. This has been noted for other Lewis acids in SOCl₂ (16). Li₂S, LiCl, LiBr, and Li₂O, which act as Lewis bases in SOCl₂, are basically insoluble in pure SOCl₂ (the maximum solubility of Li₂S was found to be 0.003M), but do dissolve in the NbCl₅ solution to form neutralized solutions with conductivities close to that of LiAlCl₄ electrolyte (Table I). 1.60M was used as the reference concentration for LiAlCl₄ electrolyte because at this concentration its conductivity is near its maximum (1).

The neutralization of the acid by a base with a single lithium ion is straightforward (*e.g.*, LiCl and AlCl₃ to form LiAlCl₄). The reaction is more complicated for bases with two lithiums in the stoichiometry such as Li₂S or Li₂O (8). We found that, in the case of the NbCl₅/Li₂S combination electrolyte, the concentration of the acid is equal to that of lithium, or, in other words, to twice that of the base. Reacting NbCl₅ in amounts ranging from 1.0 to 1.5M with Li₂S in the range 0.5-2.0M (these concentrations are assuming all of the amount added would have been soluble) yielded a constant concentration of 0.93-0.96M Nb and 0.94-1.00M Li (0.47-0.50M Li₂S). The reaction between NbCl₅ and Li₂S is discussed below in more detail.

The concentration and conductivity of the NbCl₅/Li₂S electrolyte can be increased by redissolving material from the evaporated solution. In this way, the concentration of Nb was raised to 1.42M with a corresponding increase in Li. The solution conductivity increased to 16.5 × 10⁻³ mho cm⁻¹ at 26°C.

Table I. Conductivities of electrolytes in SOCl₂ at the indicated concentration at 26°C and measured at 1 kHz

Electrolyte	Concentration (M)	Conductivity (mho cm ⁻¹ × 10 ³)
NbCl ₅	0.93	0.01
Li ₂ S + NbCl ₅	0.93	13.2
Li ₂ O + NbCl ₅	0.93	13.2
LiBr + NbCl ₅	0.93	13.9
LiCl + NbCl ₅	0.93	12.0
LiCl + AlCl ₃	1.60	19.7
Redissolved Li ₂ S + NbCl ₅	1.42	16.5

Voltage delay.—Figure 1 shows quite clearly that the NbCl₅/Li₂S combination electrolyte greatly reduced voltage delay in half-cells as compared to the control LiAlCl₄. Figure 2 shows that substituting Li₂O for Li₂S is also very effective in reducing voltage delay.

Anodes that were stored for 5 days at room temperature in an electrolyte of AlCl₃/Li₂S, as described in Ref. (8), had a maximum polarization in this type of experiment of almost three times the polarizations in the Nb-based electrolyte. Maximum polarization in the AlCl₃/Li₂S electrolyte (1M concentration) was typically about 0.930V *vs.* only 0.335V for the NbCl₅/Li₂S electrolyte.

NbCl₅ by itself does not reduce voltage delay. Anodes stored 5 days at room temperature in 0.93M NbCl₅/SOCl₂ had an average maximum polarization of 5.748V *vs.* 0.335V for the NbCl₅/Li₂S electrolyte. While the low conductivity of the NbCl₅/SOCl₂ electrolyte might affect its voltage delay polarization to some degree, it is clear from Fig. 6 that this electrolyte has a direct impact on the morphology of the anode passivating film.

The voltage delay polarization of anodes stored in 0.93M NbCl₅/LiCl and NbCl₅/LiBr electrolytes was excessive (maximum polarization greater than 9.530V after 5 days of room temperature storage) and did not show any improvements compared to the LiAlCl₄ control.

The magnitude of the polarization obtained in these tests for the LiAlCl₄ electrolyte is greater than expected, based on previous reports (27). Dey and Schlaikjer (27) report that a polarization maximum of about 6V *vs.* Li reference is obtained only after 11 days of storage at 55°C and at 15 mA/cm² anodic current. In this work, a polarization of almost 6V was obtained after 5 days of room temperature storage in the LiAlCl₄ electrolyte at 6 mA/cm². This difference might be due to a contaminant in the LiAlCl₄ electrolyte used here (even though it was carefully prepared and handled). The electrolyte typically contained less than 3 ppm Fe, and less than 130 ppm water, based on IR analysis of the OH absorption band. The data obtained with the Nb-based electrolytes is, of course, inde-

Fig. 1. Anode polarization at 6 mA/cm² after 5 days room temperature storage in various electrolytes.

Fig. 2. Anode polarization at 6 mA/cm² after 5 days room temperature storage in various electrolytes.

Fig. 3. Anode polarization at 6 mA/cm² after 5 days room temperature storage in various electrolytes.

pendent of the LiAlCl₄ measurements. The benefits of the Nb-based electrolyte are further illustrated in Fig. 3. NbCl₅/Li₂S used as a minor additive in the LiAlCl₄ electrolyte significantly reduces voltage delay. This occurs in spite of the greater than expected polarization found with the initial LiAlCl₄ electrolyte.

Extended storage of the Nb-based (and LiAlCl₄) electrolytes at room temperature did not alter their voltage delay polarization characteristics, concentration, or conductivity, indicating good solution stability.

Film morphology.—Anode film morphology was studied with SEM following immersion in various electrolytes for various times and temperatures. A comparison of Fig. 4 and 5 shows that the anode film formed in the NbCl₅/Li₂S electrolyte is less dense and of a different morphology than the one grown in LiAlCl₄. Figure 6 shows that the film formed in a solution of just NbCl₅/SOCl₂ under identical conditions is dense with bulky crystal growth. NbCl₅/Li₂S, as an additive to the LiAlCl₄ electrolyte, also changed the morphology of the anode film. The films in Fig. 4-6 all analyzed (SEM/EDAX) to be LiCl; essentially, no Nb was detected on the surface of the anodes stored in the Nb-based electrolytes.

These differences in LiCl film morphologies correlate very well with the corresponding half-cell polarization data of Fig. 1-3. The trend is for anodes covered by a dense, bulky appearing film to have greater voltage delay than those covered with less dense appearing films.

Rate capability.—The data in Table II show that the discharge rate of Li in the NbCl₅/Li₂S electrolyte is slightly greater over a range of overpotentials than in LiAlCl₄ solutions. The data were obtained by Tafel polarization curves at a 5 mV/s scan rate, and represent an average of four measurements. The half-cells were filled with electrolyte just prior to testing and were prepulsed at 6 mA/cm² for 5s to minimize film buildup.

Table II. Anodic rate capability of Li in various electrolytes at room temperature

Electrolyte	Current density (mA/cm ²)		
	400 mV vs. Li	200 mV vs. Li	50 mV vs. Li
1.60M LiAlCl ₄	13.48	6.41	1.03
0.93M NbCl ₅ /Li ₂ S	14.90	7.05	1.83

Fig. 6. Li sample stored in 0.93M NbCl₅ electrolyte for 5 days at 71°C. The white bar in the lower right corner represents a length of 10 μm.

Fig. 5. Li sample stored in 0.93M NbCl₅/Li₂S electrolyte for 5 days at 71°C. The white bar in the lower right corner represents a length of 10 μm.

Cyclic voltammetry.—Typical cyclic voltammograms (Fig. 7) on Ni working electrodes in the NbCl₅/Li₂S combination electrolyte are very similar to those in LiAlCl₄ electrolyte (17, 18). Since the potential at which the reactions occur is the same in both electrolytes, the use of the NbCl₅/Li₂S should not affect the operating voltage in battery cells. The use of a Ni working electrode shifted the cathodic peaks to potentials lower than would be found on carbon substrates (17, 18).

At the start of the cathodic scan, a small peak (marked "A" in Fig. 7) appears at about 2.85V vs. the Li reference.

This peak has been observed in previous studies (17-20) and has been attributed (20) to the first step of a two-step reduction of SOCl₂ or to the reduction of oxidation products of SOCl₂ such as Cl₂ (5, 17, 19). The peak marked "B," occurring at 2.14V, can be assigned to the main reduction reaction of SOCl₂ (17-20). The decrease in current at potentials immediately cathodic to peak B is due to the passivation of the electrode surface by LiCl produced in the reaction. A weak peak (marked "C") occurs at about 0.79V. It has been attributed by others to the reduction of SOCl₂ reduction products as in LiAlCl₄ solutions (17-20).

The current rise at the end of the cathodic scan is due to the plating of lithium onto the Ni working electrode. The composition of the deposit, as determined by atomic absorption for Li and Nb, was essentially Li. Since both counter- and working electrodes in this test were Ni, the only source of the Li is the NbCl₅/Li₂S electrolyte. On the return anodic scan, the Li deposit is stripped off of the Ni and no other anodic peaks are observed at this current sensitivity.

Infrared spectroscopy.—The IR spectrum for pure SOCl₂ is distinguished by its single S-O stretch frequency at about 1229 cm⁻¹ (17, 21). The spectrum of a NbCl₅/SOCl₂ solution (Fig. 8) has two additional S-O species, appearing as shoulders at 1150 and 1106 cm⁻¹ on the SOCl₂ peak. Based on literature (22) describing similar solutions of metal chlorides in SOCl₂, the 1106 cm⁻¹ peak represents the product of the following reaction

The most likely form of the product is the 1:1 undissociated complex. This conclusion is based on a detailed report of similar solutions of AlCl₃ in SOCl₂ by Long and Bailey (21). They were able to isolate the 1:1 complex of

Fig. 7. Cyclic voltammogram of 0.93M NbCl₅/Li₂S in SOCl₂ on a Ni electrode. Scan rate is 10 mV/s.

SOCl₂, AlCl₃ in solid form and obtain its Raman spectrum. That spectrum was basically identical to the spectrum of the solution species. IR analysis of the same AlCl₃ solution in this lab yielded an absorption peak at a similar wave number of 1110 cm⁻¹. Thus, the analogy for solutions of NbCl₅ in SOCl₂ points to the existence of the 1:1 undissociated complex. However, Abraham and Mank (17) interpreted this and other data to mean that the product is in the ionic form.

NbCl₅ has a strong affinity for oxygen, and so a lengthening of the S-O bond in thionyl chloride due to the attached NbCl₅ would lower the S-O stretch frequency from 1229 to 1106 wave numbers. The other shoulder, the 1160 peak, is probably due to a 2:1 NbCl₅-SOCl₂ complex with the second NbCl₅ loosely attached to the first. Similar 2:1 complexes were also found in AlCl₃/SOCl₂ solutions (21). This second molecule of NbCl₅ would not decrease the primary S-O stretch frequency as much as the first, and so an intermediate peak between 1106 and 1229 wave numbers, the 1160 peak, is obtained. Since two peaks are observed, it may indicate that the 1:1 and 2:1 complexes are both present and in some sort of equilibrium.

Adding Li₂S to the NbCl₅/SOCl₂ solution to form the NbCl₅/Li₂S electrolyte eliminates the 1106 and 1160 cm⁻¹ peaks. A peak at 1332 cm⁻¹ representing SO₂ (23) appears, as shown in Fig. 9. Adding excess Li₂S to the NbCl₅/SOCl₂ did not increase the SO₂ peak height. No SO₂ peak was observed in the original SOCl₂ solvent, nor was one in the NbCl₅/SOCl₂ solution. Adding Li₂S alone to SOCl₂ does not produce an SO₂ peak either. The SO₂ peak also appears in spectra of solutions made by redissolving in pure SOCl₂ the evaporated material of the NbCl₅/Li₂S combination electrolyte. IR spectra in this lab of a previously reported electrolyte formulation (8) of AlCl₃/Li₂S also contained the SO₂ peak.

SO₂ dissolved in the electrolyte has been reported to reduce voltage delay (9). However, the optimum concentration cited was 5 weight percent (w/o). The amount of SO₂ produced here according to Eq. [2a] and [4] (see below) would be less than 1 w/o.

The IR spectra of powder samples of the evaporated material of the NbCl₅/Li₂S electrolyte showed peaks at 1595 and 812 wave numbers. The 1595 peak probably represents a Nb-Cl bond (24). The Nb-Cl bond was also indicated in ESCA measurements of the material. The ESCA results also suggest that the Nb is in the +5 oxidation state. The 812 cm⁻¹ peak could not be identified. Nb-S, Li-S, Nb-O, Li-O, Li-Cl, and S-Cl bonds all absorb at wave numbers other than 1595 and 812 cm⁻¹ (24).

Discussion

The analytical evidence for the composition of the NbCl₅/Li₂S electrolyte salt consists of several items: (i) the measured concentration of Nb and Li show that the stoichiometric balance of the two elements are the same, (ii) the cyclic voltammetry plating experiment determined that Li was the cation of the salt, (iii) IR spectroscopy and ESCA qualitatively identified Cl in the salt, that it was attached to the Nb, and that Nb was in the +5 oxidation state, and (iv) SO₂ is produced in the neutralization of NbCl₅/SOCl₂ solutions with Li₂S. A number of attempts to analyze for the sulfur content of the salt via a variety of analytical methods were all unsuccessful. The dried salt is very hygroscopic.

Based on the cited analytical evidence, possible reaction schemes for the neutralized electrolyte can be narrowed down to at least three possibilities. In Eq. [2], the 2:1 NbCl₅-SOCl₂ complex reacts with Li₂S. No SO₂ is produced, and S, a possible constituent, is contained in the neutralized electrolyte salt

Another possible reaction (which would produce SO₂), involving the 2:1 NbCl₅-SOCl₂ complex, has been suggested by one of the reviewers of this paper

Fig. 8. Infrared spectra of NbCl₅ in SOCl₂ (—) and SOCl₂ alone (· · ·)

Fig. 9. Infrared spectrum of NbCl₅/Li₂S in SOCl₂

In the next scheme, Eq. [3] and [4], the 1:1 complex reacts to form the neutralized salt. The product does not contain any sulfur, but SO₂, as detected in the IR work, is produced

(The product Li₂Nb₂Cl₁₂ in Eq. [2a] and [3] could also conceivably be represented as 2LiNbCl₆.)

A definite test for S in the neutralized salt would help identify the correct scheme.

The anion of either of the products formed in Eq. [2] and [3] is quite different than tetrachloroaluminate, AlCl₄⁻. Some of the properties of the neutralized electrolyte can be explained in terms of the postulated anions. The large size of either anion, even with its divalent charge, would lead to a reduced anionic charge density. This would tend to favor dissociation of the salt, and

could lead to the higher electrolyte conductivity relative to that of plain $\text{NbCl}_5/\text{SOCl}_2$ solutions. However, these same factors could decrease the mobility of the anion relative to Li^+ or AlCl_4^- and so explain the lower overall electrolyte conductivity relative to LiAlCl_4 . Similar reasoning was applied to explain conductivity behavior of clovoborate electrolytes (7).

The growth of the LiCl anode film in LiAlCl_4 electrolyte is promoted by the relative instability of LiAlCl_4 in SOCl_2 and can be represented as

The dissociated LiAlCl_4 electrolyte in Eq. [6] can exchange with the LiCl anode film. But because of the nature of the anions postulated in Eq. [2] and [3], it is felt that no such exchange equilibrium exists between these anions and the LiCl film formed in the NbCl_5 -based electrolytes. Thus, growth of the voltage delay causing film is reduced.

Conclusions

1. Voltage delay in half-cells was reduced by using electrolyte formed by the neutralization in SOCl_2 of NbCl_5 with Li_2S , or NbCl_5 with Li_2O . The use of the $\text{NbCl}_5/\text{Li}_2\text{S}$ electrolyte as a minor additive to LiAlCl_4 was also effective in reducing voltage delay.

2. The conductivity of $\text{NbCl}_5/\text{Li}_2\text{X}$ ($\text{X} = \text{S}$ or O) electrolytes in SOCl_2 is slightly less than the corresponding LiAlCl_4 solutions.

3. The anode film formed in the $\text{NbCl}_5/\text{Li}_2\text{S}$ electrolyte has a different morphology and appears less dense than the film formed in LiAlCl_4 . The mechanism for the effect is thought to be due to the nature of the anion in $\text{NbCl}_5/\text{Li}_2\text{S}$ electrolyte and/or the SO_2 produced by the neutralization of NbCl_5 with Li_2S .

4. Anode rate capability is slightly higher in the $\text{NbCl}_5/\text{Li}_2\text{S}$ electrolyte than in LiAlCl_4 . The $\text{NbCl}_5/\text{Li}_2\text{S}$ electrolyte does not affect the cathodic discharge characteristics of SOCl_2 .

5. NbCl_5 by itself in SOCl_2 has low conductivity and promotes voltage delay.

Manuscript submitted Dec. 14, 1983; revised manuscript received Feb. 13, 1984. This was Paper 32 presented at the Washington, DC, Meeting of the Society, Oct. 9-14, 1983.

Thermogravimetry-Evolved Gas Analysis of Silver Oxide Cathode Material

W. A. Parkhurst,* S. Dallek,* and B. F. Larrick

Naval Surface Weapons Center, Electrochemistry Branch, Silver Spring, Maryland 20910

ABSTRACT

A new, rapid, and precise thermogravimetry-evolved gas analysis (TG-EGA) method has been developed for the determination of the AgO, Ag₂O, Ag, and Ag₂CO₃ content of silver oxide cathodes. Cathode samples were analyzed by the present method and by the commonly used wet chemical method. The analysis is being used to study the rates of change in chemical composition during storage of cathodes prepared by various manufacturers. The analysis results can be used to correlate the compositional changes with degradation in battery performance.

Batteries employing silver oxide cathodes are used in numerous military and commercial applications. The electrochemically prepared cathodes, used in high rate battery applications, contain various amounts of silver (II) oxide, silver (I) oxide, silver, and silver carbonate impurity. The change in chemical composition of these cathodes during storage remains a problem of serious concern. For example, AgO is thermodynamically unstable and decomposes to form an Ag₂O phase, having higher ohmic resistance (1), resulting in a voltage regulation problem. Ag₂O is also found to be formed (2) when solid AgO contacts solid Ag. In silver oxide/zinc cells, the zinc anode is a getter for the evolved O₂ from the AgO decomposition, resulting in a film of ZnO that can cause increased polarization after activation (3). Clearly, the capacity and performance of silver oxide batteries can be adversely affected by the degradation of the cathode material (4). Therefore, the need to determine the chemical composition of silver oxide cathodes after preparation and during storage under various conditions is of considerable importance. Methods reported for the analysis of this material involve lengthy gravimetric and titrimetric (5) or gasometric (6) procedures. An obvious need exists for a better analytical procedure for silver oxide electrodes.

Thermogravimetry (TG) techniques have been employed for a wide range of analytical determinations (7). Complex mixtures of substances can be rapidly analyzed by TG, provided that the substances decompose independently of one another, thus permitting the establishment of separate, measurable mass plateaus. Evolved gas analysis (EGA) is frequently used as a simultaneous complementary technique to TG. Attempts to analyze silver oxide cathodes by thermal analysis techniques have been reported (8, 9).

We report here the development and employment of a new, extremely rapid, precise thermogravimetry-evolved gas analysis (TG-EGA) analytical method for the determination of the AgO, Ag₂O, Ag, and Ag₂CO₃ content of silver oxide cathode material.

Experimental

Apparatus.—The TG studies were performed with a du Pont 1090 Thermal Analysis System and a 951 Thermogravimetric Analyzer (TGA). TG samples were run in platinum boats over a temperature range of 298 to 753 K (25°–550°C) at a heating rate of 20 K/min in a flowing atmosphere (50 cm³/min) of dry argon. Because the decomposition temperatures of AgO and Ag₂CO₃ overlap, neither can be determined in the presence of the other by TG alone (10, 11); therefore, an EGA method using a Hewlett-Packard 5710-A Gas Chromatograph (GC) was developed for determination of the evolved CO₂ from the Ag₂CO₃ decomposition. Samples for GC analysis were

placed in a specially designed Pyrex vessel (Fig. 1) fitted with a Teflon valve. The vessel was first evacuated ($p \leq 20\mu$ Hg), placed in the TGA furnace, heated over the same temperature range as in the TG run, and then connected to the GC for determination of the amount of evolved CO₂. The GC employed a thermal conductivity detector and a Carbosieve column. Pressures were measured with a Validyne Model DM56A digital manometer system with an AP10 absolute pressure transducer. The GC furnace temperature was maintained at 468 K. Helium purge gas was employed for maximum sensitivity. The tightness of all valves and connections was checked by monitoring the constancy of the digital manometer readings while the system was under vacuum and when pressurized.

The AgO, Ag₂O, Ag, and Ag₂CO₃ content of the cathode sample was determined from the TG mass loss plateaus and from the GC analysis of the evolved CO₂.

Samples.—Commercially obtained AgO (99.5%, Rayovac Corporation) (12), Ag₂O (99.6%, Metz Metallurgical Corporation), Ag (99.98%, Fischer Scientific Company), and Ag₂CO₃ (99.7%, Alfa Products) were studied initially to determine their thermal transition temperatures. Samples of active cathode material were obtained from several battery manufacturers either as powders or on silver current collectors from which the material was removed and powdered. Typically, a 100 mg sample was used for each TG and GC run.

Results

During the development of the present method, numerous TG experiments were run on chemically and electrochemically prepared silver oxide cathode material and on the individual components to establish the validity of the technique. Typical TG curves and their derivatives for pure AgO, Ag₂O, Ag₂CO₃, and silver oxide cathode material are shown in Fig. 2. In Fig. 2a, the three main decom-

Fig. 1. Gas collection vessel for CO₂ analysis.

Fig. 2. TG curves of AgO, Ag₂O, Ag₂CO₃, and silver oxide cathode material. Heating rate: 20 K/min. Atmosphere: Ar, 50 cm³/min.

position processes of AgO can be seen: (i) an initial rapid decomposition of AgO to Ag₂O, (ii) a slow continuing decomposition of AgO, and (iii) a rapid decomposition of Ag₂O to Ag. The structure of AgO was established by neutron diffraction to be Ag₂O₃ · Ag₂O (13). X-ray photoelectron spectroscopy (XPS) studies (14) confirmed this structure and showed that the mass loss in process B (Fig. 2a) is caused by the decomposition of the Ag₂O₃ component of AgO. The decomposition curve of Ag₂O is shown in Fig. 2b. As seen in Fig. 2, there is the possibility that the decomposition of Ag₂O (Fig. 2b) may be initiated just prior to the completion of the AgO decomposition process near the very end of region (B) in Fig. 2a. However, as seen in the derivative curves in Fig. 2a and 2b, the rates of decomposition in this region are very small. We have determined that any overlap in this region has a negligible effect on the precision of the calculated composition. The shoulder on the derivative curve in Fig. 2a and the small derivative peak in Fig. 2b at about 433 K (160°C) are caused by the slight contamination of these samples by Ag₂CO₃. The decomposition curve of Ag₂CO₃ is shown in Fig. 2c. The evolution of CO₂ from the two "forms" of Ag₂CO₃ beginning at about 433 K (160°C) and 593 K (320°C) in Fig. 2c agrees with previously reported temperatures (15). Mass spectrometric analysis (14) of the evolved gas confirmed it to be CO₂ during both mass losses. The final mass loss on this curve is caused by the decomposi-

tion of the Ag₂O, as seen above. In Fig. 2d, a TG curve of a cathode sample containing a considerable amount of Ag₂CO₃ is shown.

The equations used to evaluate the TG-EGA data for silver oxide cathode material were derived, as follows, on the assumption that the sample initially consists of only Ag₂CO₃, AgO, Ag, and Ag₂O, having weight fractions A, B, C, and D, respectively.

The decomposition reactions are

Let W_1 equal the weight fraction remaining after reaction [1], W_2 equal the weight fraction remaining after reactions [1] and [2], and W_3 equal the weight fraction remaining after reactions [1], [2], and [3]. Using the appropriate gravimetric factors, the weight balance equations are

$$1 = A + B + C + D$$

$$W_1 = 0.8404A + B + C + D$$

$$W_2 = 0.8404A + 0.9354B + C + D$$

$$W_3 = 0.7824A + 0.8708B + C + 0.9310 D$$

The weight loss equations are

$$1 - W_1 = 0.1596A$$

$$W_1 - W_2 = 0.06458B$$

$$W_2 - W_3 = 0.07416 (W_3 - C)$$

Rearranging

$$A = 6.2657 (1 - W_1) = \text{weight fraction Ag}_2\text{CO}_3$$

$$B = 15.4838 (W_1 - W_2) = \text{weight fraction AgO}$$

$$C = W_3 - 13.4838 (W_2 - W_3) = \text{weight fraction Ag}$$

$$D = 1 - A - B - C = \text{weight fraction Ag}_2\text{O}$$

W_2 and W_3 are determined from the TG curves. W_1 is obtained from the GC analysis of the evolved CO₂ as follows

$$F = \frac{g \text{ CO}_2/44.011 \text{ g/mol}}{g \text{ CO}_2/44.011 \text{ g/mol} + g \text{ O}_2/32.00 \text{ g/mol}} = \text{mole fraction CO}_2 \text{ in the evolved gas}$$

$$g \text{ CO}_2 = (1 - W_1) (S) \text{ and } g \text{ O}_2 = [(1 - W_3) - (1 - W_1)] (S)$$

where S = total sample weight.

$$F = \frac{(1 - W_1)2.7507}{(1 - W_1)2.7507 + [(1 - W_3) - (1 - W_1)]/2}$$

$$W_1 = 1 - (2.7507)(1 - W_3)F/(0.7507F + 2)$$

In Fig. 3, the TG curve of the cathode sample shown in Fig. 2d has been enlarged and labeled with points W_2 and W_3 . The value of W_2 , at which point the decompositions of Ag₂CO₃ and AgO into Ag₂O are complete but prior to the onset of the decomposition of Ag₂O, is determined from the intersections of the extrapolated completion of the AgO decomposition and the onset of the Ag₂O decomposition processes. The derivative curve is used to locate the point more precisely. At the point W_3 , the sample is completely decomposed into Ag. The weight fraction, W_1 , remaining after the two-step loss of CO₂ from the decomposition of Ag₂CO₃ is determined by GC, as described above. Repeated CO₂ analyses, used in determining W_1 , resulted in Ag₂CO₃ determinations that agreed to within 0.01%.

Several cathode samples were analyzed by the present TG-GC method and by the commonly used Wagner method (5) combined with a standard gravimetric determination of the CO₂ from the Ag₂CO₃ component. The results are shown in Table I. Reasonable agreement was achieved between the two methods.

During the course of this work, samples of very pure, stable, chemically prepared AgO (99.5%, Rayovac Corpo-

Fig. 3. TG curves of silver oxide cathode material showing points W_2 and W_3 . (W_1 is obtained from the GC analysis.)

ration) were run periodically to check the calibration of the TGA by determining the final mass plateau, W_3 . The results are given in Table II. The theoretical value of W_3 for the pure AgO is 0.8708, as compared with the average measured value of 0.8701 for these runs. The lower experimental values are a result of the slight contamination of the AgO with Ag_2CO_3 . GC analyses of the evolved CO_2 from this AgO material gave an average Ag_2CO_3 content of 0.75%. Using the average measured value of $W_3 = 0.8701$ and setting $B = (1 - A)$, $C = 0$, and $D = 0$, the derivation

equation may be solved to give $A = 0.0079$ (0.79% Ag_2CO_3), in excellent agreement with the 0.75% from the GC analysis. This result and the results shown in Table II demonstrate, respectively, the accuracy and precision obtained using the TG-EGA technique on this AgO material. The lack of suitable standard materials and analytical methods precluded the determination of accuracy for typical cathode material mixtures containing AgO, Ag_2O , Ag, and Ag_2CO_3 .

Discussion

A new, extremely rapid, precise analytical method has been developed using a combined TG-EGA technique to analyze the components of silver oxide cathode material. At a heating rate of 20 K/min, a TG run takes only about 20 min; a concurrent GC analysis is performed during the TG run on a separate sample. This analysis method requires minimal sample manipulation and eliminates the need to prepare and standardize chemical reagents. It relies only on the measurement of mass loss by an extremely accurate electrobalance coupled with a high speed microprocessor analyzer and on the analysis of the evolved CO_2 in the $CO_2 + O_2$ mixture by GC. In addition, the TG curve of a silver oxide sample provides a "fingerprint" that can be compared to subsequent curves to immediately discern aging trends.

This new analysis technique is being used to study rates of change in chemical composition during storage of silver oxide cathodes; in addition, correlations are possible between the compositional changes and the degradation in battery performance. The present technique is being developed further so that a simultaneous, rather than concurrent, TG-EGA determination can be performed on a single sample.

The Corrosion of Carbon Black Anodes in Alkaline Electrolyte

I. Acetylene Black and the Effect of Cobalt Catalyzation

Philip N. Ross* and Harvey Sokol

Lawrence Berkeley Laboratory, Materials and Molecular Research Division, Berkeley, California 94720

ABSTRACT

¹⁴C labeling of acetylene black was used together with mass spectroscopic analysis of the gas evolved to determine the current efficiencies for oxygen evolution, carbon dissolution, and carbon gasification (to carbon monoxide). The current efficiencies were found to depend dramatically on potential, temperature, and the presence of an evolution catalyst like Co₃O₄. On uncatalyzed black, three regimes could be distinguished: (i) at potentials below 500 mV vs. Hg/HgO and temperatures below 50°C, carbon dissolution is the primary anodic process, (ii) at 500-600 mV and 50°C or lower, carbon dissolution and oxygen evolution occur at equivalent rates, and (iii) above ca. 600 mV or above ca. 60°C, oxygen evolution and gasification of the carbon to carbon monoxide are the dominant processes. Catalyzation with Co₃O₄ collapsed these regimes so that all three anodic processes are concurrent throughout the potential region of interest, and the overall rate of corrosion increased significantly. In addition, Co₃O₄ catalyzation caused the production of organic products (ca. 5% current efficiency) in a potential region where none is produced from acetylene black alone. The mechanism of action of Co₃O₄ on the acetylene black corrosion is not yet understood, but there is evidence that direct physical contact between the Co₃O₄ particles and carbon particles is not required to produce accelerated corrosion of the carbon.

With the advent of dimensionally stable metal oxide anodes for chlor-alkali cells, technological interest in the oxidation of carbon anodes (usually graphite) in caustic solution has waned. In the years when diaphragm cells with graphite anodes were the leading technology, there was a substantial body of literature produced concerning the corrosion of graphite accompanying chlorine evolution. This literature is reviewed in several places (1-4), the most recent being in the compilation of the electrochemistry of carbon by Randin (4). The literature on the corrosion of graphite anodes during oxygen evolution in chloride-free electrolyte is, in comparison, almost nonexistent. Most of the work on graphite anodes for oxygen evolution has been in acid solution, and it is known that the corrosion processes for graphite change as a function of pH (5). Current technological interest in the use of graphite and/or carbon blacks in alkaline battery positives has revived interest in the corrosion processes of these materials in strongly alkaline chloride-free solutions. Graphite powder is used as a current collector and dispersion substrate for nickel electrodes (6), and various types of carbon blacks are of interest for use as catalyst substrates for bifunctional air electrodes (7). Acetylene black is widely used in primary batteries of both the alkaline and nonaqueous type, and is being examined as a catalyst substrate for air electrodes for a number of fuel cell and metal-air battery technologies. In none of these battery applications is the acetylene black intended to act as an active material for oxygen evolution, and in the primary batteries oxygen evolution does not occur in normal use, so it is not surprising that very little research has been published on the corrosion of acetylene black in oxygen evolving electrodes. Yet the use of acetylene black in a bifunctional air electrode is technologically attractive because of its very low cost relative to metal oxide materi-

als. The principal question concerning its use is the corrosion resistance.

It is a difficult matter to measure corrosion rates accurately in gas evolving electrodes. Standard electrochemical methods are not useful by themselves because the gas evolution is generally the predominant anodic process; so, the observed current is not representative of the corrosion processes. Electrochemical methods must be combined with other analytical tools which discriminate between the different anodic processes, at the least between oxygen evolution and all other processes, and, ultimately, each anodic process is measured independently. Historically, analysis of the anode gas composition for oxygen, carbon monoxide, and carbon dioxide has been used together with standard electrochemical methods to obtain relative current yields for O₂, CO, and CO₂. Examples of this approach are seen in the reports by Kristalik *et al.* (8) on the corrosion of graphite anodes of the type used in chlor-alkali cells. The gas analysis method does not account for corrosion processes that produce solution-phase species (soluble or insoluble), surface oxides, or intercalation compounds like "graphite oxide" (9). Other work (10) on graphite anodes reported that the formation of water soluble products can be 30%-40% of the current yield, and the total current yield of all reaction products (solution plus gas phase) was less than 100%, leading to the conclusion that some current (10%-20%) passed in the formation of "graphite oxide." It is clear that if one is to determine the rate of corrosion processes by the rate of appearance of products the inventory of products must be complete. The prior work on graphite anodes suggests quantitative solution analysis is imperative, including organic compounds that are not well established. The approach we have taken in this work was to use ¹⁴C acetylene black and quantitative radiochemical techniques for analyzing the products in solution and a

* Electrochemical Society Active Member.

quadrupole mass spectrometer for analyzing products in the gas evolved. The ^{14}C technique has several advantages over conventional methods for the quantitative analysis of carbon in water: (i) the lower limit of detection is ppb vs. ppm, (ii) the quantitative determination is absolute and relatively free of matrix or solvent effects, (iii) different types of carbon in the electrode can be discriminated against. The ability to label certain physical parts of a carbon electrode with ^{14}C was particularly useful in examining corrosion in the presence of evolution catalysts. The disadvantage of the ^{14}C labeling technique is that acetylene black is probably the only industrial carbon black that is made from a relatively pure feedstock (acetylene) that can be labeled, so the technique cannot be extended to furnace blacks of technological interest. In order to make quantitative discriminations of inorganic (carbonate) from organic carbon in solution, we did develop a chromatographic procedure based on complete oxidation of organic to CO_2 . Our experience with this procedure indicated that with further development it is capable of making the quantitative determinations of the rate of production of carbonate ion and organics at the levels likely to be observed with industrial carbon blacks in future studies.

Experimental

^{14}C radiotracer.— ^{14}C labeled acetylene black was supplied by Nuclear Research Chemicals with a specific radioactivity of 1.625 mCi/mg. The ^{14}C acetylene black was produced using the same commercial procedure for Shawinigan Acetylene Black (Shawinigan Products Department, Gulf Oil Chemicals Company), but reduced to laboratory scale. Shawinigan Acetylene Black is made by continuous thermal decomposition of acetylene at 800°C in a retort. The retort is first heated to the decomposition temperature by burning the acetylene on introduction, then burning is discontinued, and the acetylene continues to flow into the retort in the absence of air. Thermal decomposition occurs resulting in a flocculent black with a bulk density of ca. 0.019 g/cm^3 . ^{14}C labeled acetylene black was produced by Nuclear Research Chemicals using the same procedure with ^{14}C labeled acetylene gas. Since the quantity of ^{14}C labeled acetylene black was quite small (2.59 mg), owing to its high cost and the fact that only a small amount is needed for radiotracer work, all the physical properties of the ^{14}C acetylene black could not be compared to those of commercial Shawinigan black. Examination of the particle size, aggregate morphology, and microstructure by transmission electron microscopy (TEM) was the principal tool used to determine that the ^{14}C labeled acetylene black was similar to Shawinigan acetylene black in its physical and chemical properties. The ^{14}C black was blended with Shawinigan black using a two-stage procedure. First, 0.59 mg ^{14}C was liquid blended with 100 mg of Shawinigan using isopropanol and ultrasonic agitation. Second, 10 mg of that blend was liquid blended with 100 mg of Shawinigan. The specific activity of the resulting blend was determined using an oxidizer method (Packard Model 306 Oxidizer) to be $1.4 \pm 0.05\text{ dpm/mg}$.

Catalyzation procedure.—Both the ^{14}C blend and the unlabeled Shawinigan black were catalyzed with cobalt oxide using an impregnation procedure. The cobalt content was prepared at a 20 weight percent (w/o) level assuming Co_3O_4 as the final form. $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ was dissolved in 1:1 methanol:water; the carbon black was dispersed into the solution with ultrasonic agitation; ammonium hydroxide was added to pH 11 to precipitate cobalt hydroxide into the carbon black. The impregnated carbon black was filtered from solution and air dried at 120°C for 24h. Conversion of the cobalt to Co_3O_4 was confirmed by x-ray diffraction analysis, which showed only lines for this phase.

Cell and electrode design.—The electrochemical cell used in these studies is depicted in Fig. 1. It was essentially a standard glass H-cell modified for both gas

Fig. 1. Three-chambered corrosion cell. 1: test. 2: Ni counter-electrode. 3: Hg/HgO reference electrode. 4: Nafion membrane. 5: septum for liquid sampling. 6: gas sampling bulb.

and solution sampling and solution sampling. The solution in the working electrode compartment was isolated from exchange with solution in the counterelectrode compartment by cation-exchange membrane (du Pont Nafion 117) and from the solution in the reference by a thick ultrafine porous ceramic. Solution samples were drawn from the working electrode compartment through the rubber septum using a $100\ \mu\text{l}$ syringe. The reference electrode was Hg/HgO and the solution was 30 w/o KOH + 2 w/o LiOH. Some experiments were done without the lithium addition, and the presence of lithium did have an effect (increased precipitation of corrosion product within the pores of the electrode due to reduced solubility), so all the results reported here were obtained with the mixed electrolyte. The working electrode consisted of a carbon black-PTFE paste impregnated into a gold-plated tantalum mesh acting as the current collector. The paste contained 5 w/o PTFE solids (du Pont TFE-30B dispersion) mixed into the carbon black with 1:1 isopropanol:water, and was applied to the mesh by spatula followed by air curing at 320°C for 10 min. The typical loading of a working electrode was 40 mg (ca. 10 mg/cm^2) of carbon black or catalyzed black. The working electrodes were vacuum filled with electrolyte at room temperature prior to use in the cell. The internal electrolyte volume in the working electrode was determined gravimetrically after emersion

of the electrode and wiping the surface free of bulk electrolyte. The internal electrolyte volume was typically 2-3 $\mu\text{l}/\text{mg}$ initially, with an increase by as much as 100%-200% on use in the cell (after extensive oxidation).

Solution analysis.—100 μl aliquots were withdrawn from the working electrode compartment at periodic intervals (usually 30 min) and put immediately into 5 ml of scintillation solution (New England Nuclear Atomlight NEF-968) and counted in a commercial scintillation counter (Tracor). Stirring of the solution in the compartment was accomplished by bubbling with argon; results from stirred and unstirred solution did not agree when the corrosion rate was above a certain level, so all the results reported here are for stirred solutions. Because of the requirement for gas flow, gas sampling and solution sampling were not simultaneous. Conventional (*i.e.*, nonradiochemical) qualitative analysis of the solution was conducted to distinguish inorganic (carbonate) from organic corrosion products. The complete analysis procedure, shown in Fig. 2, was initially carried out in an apparatus built in our laboratory. However, it was found that the solutions did not contain any purgeable organic carbon, so the volatilization step was eliminated. Subsequently, the organic/inorganic determinations were made in a single apparatus, a Dohrmann DC-80 Total Carbon Analyzer. Under certain conditions, the KOH solution became colored, and these solutions were analyzed colorimetrically with a UV/VIS spectrophotometer. Attempts were made to isolate and to analyze the colored product by GC-MS and proton NMR, but, as described later in the text, these were largely unsuccessful.

Gas analysis.—Purified argon was used as the diluent gas. The gas evolving from the electrode was accumulated in the space over the KOH solution, then sampled into a 10 ml gas sampling bulb using vacuum withdrawal. The sampling bulb was then isolated and transferred to a quadrupole mass spectrometer (Balzers QMG112) for analysis. Quantitative determinations of the composition of the gas (absolute partial pressures) were made using the calibration procedures described in the Appendix. The only gases observed evolving from the solution were oxygen and carbon monoxide. All the carbon dioxide created anodically was apparently trapped in the electrolyte. The time required to accumulate an analyzable quantity of gas varied with potential, temperature, and whether the cobalt catalyst was present, *e.g.*, from as much as 15h to as little as 30 min. During this time, the electrode potential was controlled, and the total charge passed was measured using a digital coulometer (PAR 179). The rate of gas evolution was calculated as an average quantity from the total moles of gas evolved and the collection time.

Fig. 3. TEM of cobalt oxide catalyzed acetylene black

Results

Microstructure analysis by TEM.—Classical texts (11, 12) on carbon chemistry refer to acetylene as having a "chainlike" structure and as more "crystalline" than most carbon blacks. At relatively low magnification, as shown in Fig. 3, acetylene black does appear to have a "chainlike" structure in that prime particles appear joined together in chainlike fashion so as to give a three-dimensional "fishnet" structure. However, at much higher magnification in a high resolution (<0.25 nm) TEM, the microstructure of acetylene black was seen to be very heterogeneous, and it is apparent that graphitic "chains" or "ribbons" characterize only a portion of the total structure present. Therefore, while the characterization of acetylene black as being more crystalline (graphitic) than most carbon blacks is essentially correct, it is also the case that acetylene black has a significant

ANALYSIS OF SOLUBLE CORROSION PRODUCTS

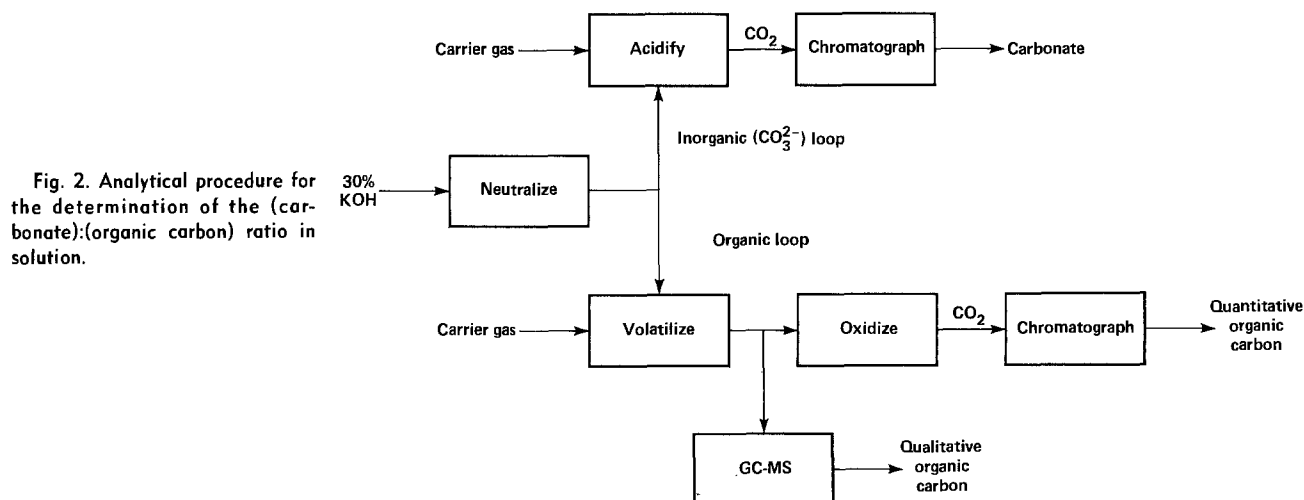

Fig. 2. Analytical procedure for the determination of the (carbonate):(organic carbon) ratio in solution.

portion of the carbon present in a disordered (lacking microcrystallinity) microstructure.

The ^{14}C labeled carbon black was indistinguishable from the Shawinigan acetylene black in terms of the microstructure observed by TEM.

TEM analysis also showed that the catalyzation of the acetylene black with Co_3O_4 resulted in macroscopically uniform dispersion of the oxide in the black, but there was evidence of microscopic "clustering" of the oxide. A typical illustration of this "clustering" is shown by Fig. 3, in which the oxide prime particles (200-300Å) have aggregated into certain regions of the black, leaving other regions of black without Co_3O_4 . The characteristic dimensions of the catalyzed and uncatalyzed regions of black are ca. $0.1\ \mu\text{m}$, so that on the scale of $1\ \mu\text{m}$ or more, the catalyzed black can be considered to be a homogeneous composite material.

Corrosion rates for acetylene black.—A characteristic curve for the amount of carbon lost from the electrode into KOH solution as a function of time and potential is shown in Fig. 4. These data were always obtained in the direction of increasing potential following an initial (new electrode) "aging" period of 48h at 45°C , 450 mV vs. Hg/HgO.¹ After obtaining data at one potential, the solution was drained and replaced with fresh solution before stepping the potential. The rate of weight loss to solution was calculated from the slope of the linear least squares fit of the data. In some cases, such as at higher temperatures, or with Co_3O_4 present, there was clear evidence of an "induction period," as seen from the data in Fig. 5. These induction periods appear to represent a memory in the carbon, as after a step to either higher potential or higher temperature the dissolution² rate remains for a period at the lower rate. Tafel plots of the dissolution rates are shown in Fig. 6. For the purposes of these plots, the dissolution rate was obtained from the steeper slope observed after the induction period. These data illustrate a further memory effect of much longer duration. The one set of rates was taken in the order of increasing potential and increasing temperature, then the temperature was reduced from 65° to 25°C , and the sequence was repeated. The second set of data showed a lasting displacement to higher dissolution rates for the same potential and temperature. These memory effects show clearly how sensitive the dissolution rate of acetylene black is to the pretreatment history, and makes it essentially impossible to determine an absolute (single-valued) dissolution rate

¹ All potentials in this paper are given vs. an Hg/HgO in the same electrolyte at room temperature.

² For compactness, the term "dissolution" refers to the oxidation of carbon to form dissolved species, or partially soluble or insoluble products which are solvent-extracted from within the electrode.

Fig. 4. Quantity of carbon appearing in solution, expressed as a percentage of carbon initially in the electrode, vs. time at a fixed potential.

Fig. 5. Same plot as Fig. 4 at 45°C

for a particular potential and temperature. Therefore, the Tafel slopes in the plots in Fig. 6 probably do not have any significance relative to the mechanism for acetylene black dissolution. Rather, the potential dependence shown is the effect of increasing the potential on the quasi-steady-state dissolution rate.

The data shown in Fig. 6 are for the dissolution of the acetylene black into the bulk solution and do not contain the contributions from insoluble species or from partially soluble species that precipitate in the pores of the electrode, or from gaseous oxidation products. An extraction procedure was developed to analyze for precipitated product. After a run like that in Fig. 4 or 5, the cell was drained of KOH, replaced with an extraction solution, and left at open-circuit potential while sampling from the solution. Extraction of precipitated carbonate was obtained using 1M KOH solution, while extraction of organic was obtained using ethanol-water. Very little precipitated organic was extracted at any of the conditions in Fig. 6. Using the known solubility of $\text{KHCO}_3\text{-K}_2\text{CO}_3$ in KOH (13) and the measured internal electrolyte volume in

Fig. 6. Rate of appearance of carbon in solution as a function of potential and temperature for (curves 1) ascending temperature and (curves 2) descending temperature.

the electrode, one can calculate the amount of corrosion (as carbonate) required to cause precipitation in the electrode assuming no carbonate ion diffusion out of the internal region. The amount is surprisingly high: ca. 1 w/o loss is required to cause carbonate precipitation to occur, even in the absence of diffusion into bulk solution. Since the typical data collection time for the rates given in Fig. 6 was ca. 5h, only at the very highest dissolution rates ($>0.1\% \text{ h}^{-1}$) would one expect to see any precipitated product in the electrode, and this was in fact the case. The extraction analyses did indicate that there was precipitated carbonate internal to the electrode in the 45° and 65°C runs. The corrections to the dissolution rates for this contribution is shown in Fig. 7. Internal precipitation appears to account for the flattening of the potential dependence of dissolution rate in the 550-600 mV potential region at 45°C. It does not, however, entirely account for the negative potential dependence of the rates at 65°C.

Mass spectrometer analyses of the gas above the electrode indicated that only two gases were produced in significant quantity: oxygen and carbon monoxide. The CO_2 in equilibrium with the KOH solution in these experiments was at too low a partial pressure to be detected by our analyzer. There was no detectable evolution of CO at 25°C, but at 45°C, CO evolution was evident, and at 65°C, it was substantial, as shown by the data reported in Fig. 7. Above ca. 600 mV at 45°C, CO becomes the majority corrosion product, which accounts for the apparent maximum in the dissolution rate observed by analysis of the solution. At 65°C, CO becomes the majority corrosion product at about 100 mV lower potential than at 45°C. When the gas-phase and internal precipitate contributions are added to the solution-phase analysis, the resulting Tafel plot at 45°C from 550 to 625 mV continues with approximately the same slope (ca. 130 mV per decade) as the low potential portion where carbonate was the only product. Above 625 mV, the slope changes sharply due to the very different potential dependence for oxidation to CO than for dissolution to carbonate. The Tafel plot at 65°C after the gas phase and internal volume correction still shows behavior unlike that seen in the low temperature data. The relatively flat potential dependence of the total corrosion rate in the potential region of 400-500 mV may represent transport limitations, e.g., limiting diffusion of dissolved corrosion products out of the electrode and internal pH

Fig. 7. Contribution of carbon monoxide production and pore volume precipitate to the total corrosion rate at 45° (closed symbols) and 65°C (open symbols). Dashed curves represent the total corrosion rates calculated from the gaseous and solution product rates.

change, rather than nearly potential independent kinetics.

Qualitative analysis of the solution by the procedures in Fig. 2 indicated there was no measurable quantity ($<10 \text{ ppm}$) of organic carbon in the solution at temperatures below 65°C. At 65°C, traces of organic carbon appeared at 550 and 575 mV, but the current efficiency for producing organic species was extremely low ($<<1\%$).

In the potential region of this study, there are three anodic processing occurring: oxygen evolution, carbon dissolution, and carbon surface oxide formation. The latter is a pseudocapacitance, while the former two are faradaic processes, so that, in principle, one can separate out the surface oxide formation from the other two by analysis of time dependence of the current response. The ¹⁴C labeling and the mass spectrometer analysis enable the carbon dissolution and oxygen evolution rates to be determined independently, and from the simultaneous measurement of the total anodic current the current efficiencies for each anodic process can be calculated. The results at 45°C are shown in Fig. 8 and in Table I. The anodic current equivalent to a given rate of appearance of carbon product was calculated from Faraday's law, assuming $4e^-$ per g-mol carbonate ion, $2e^-$ /g-mol carbon monoxide, and $1.5e^-$ /g-mol carbon in organic form. The latter assumes that mellitic acid is the model for organic carbon in solution. Under the potentiostatic conditions used, when the potential was stepped to a higher potential, the current increased sharply, then decreased to a steady-state potential and temperature. The time dependent current probably represents the surface oxidation process. Generally, the sum of the partial currents due to CO evolution, O₂ evolution, and carbon dissolution was very close to the steady-state current, so that the contribution of the oxide formation process to the steady-state current was usually very small ($<10\%$).

Corrosion rates for catalyzed acetylene black.—The effect of cobalt catalyzation on all the anodic partial currents was dramatic. The Tafel plots for the carbon dissolution rates are shown in Fig. 9. In comparison to the uncatalyzed results in Fig. 6, several changes due to catalyzation are apparent: (i) the rate of dissolution was much greater (factor of 2-3), (ii) the potential depend-

Fig. 8. Partial anodic currents for oxygen evolution, carbon monoxide evolution, and carbonate ion formation and the total anodic current at 45°C.

Table I. Current efficiencies* at 45°C

Potential	Acetylene black		O ₂	Organic
	CO	CO ₂ (CO ₃ ²⁻)		
480	≈8	80	13	≈0
550	10	55	35	0
600	10	10	80	0
Co ₃ O ₄ -catalyzed acetylene black

550	6	15	74	5

* Based on the sum of the partial currents and not the observed total current.

ence at 25° and 45°C was about the same, and (iii) the potential dependence at 65°C was very different. The change in potential dependence at 65°C reflects the preferential acceleration by Co₃O₄ of carbon dissolution processes that produced highly soluble organic species, as observed by the organic/inorganic qualitative analysis of the solution. The increase in organic product was even intuitively apparent by dramatic coloration of the solution, producing deeply colored reddish-brown solutions. At 65°C with fresh KOH solution in the cell, dark brown streaks could be seen streaming from the electrode upon the imposition of a potential of 550 mV! Gas evolution rates from the electrode were also increased, as seen by a comparison of the curves in Fig. 10. The oxygen evolution rates increased by more than an order of magnitude; the lower potential dependence probably reflects oxygen transport limitations at these higher evolution rates. The rate of CO evolution at lower potentials (ca. 450 mV) was also increased by about an order of magnitude, but the rate at high potential (650 mV) was about the same. The nearly flat potential dependence of the CO evolution rate cannot be due entirely to transport limitations: the transport limitations on oxygen evolution (which is evolving at a higher rate than CO) did not produce such a flat potential dependence. It is more likely that there was a change in the distribution of

Fig. 9. Cobalt oxide-catalyzed acetylene black dissolution rate as a function of potential and temperature. Open symbols: ¹⁴C mixed into Co-impregnated ¹²C acetylene black. Closed symbols: Co-impregnated ¹⁴C acetylene black mixed into ¹²C acetylene black.

anodic processes that occurred with increasing potential. In particular, the dissolution of carbon to soluble organic products was found to increase suddenly when the potential was increased from 450 to 550 mV. This is reflected in the current efficiencies reported in Table I; at 450 mV there was essentially zero organic product, but at 550 mV the rate of dissolution to organic was nearly equal to the rate of oxidation to carbon monoxide.

The characterization studies of the structure of the catalyzed acetylene black had indicated that there was some clustering of the Co₃O₄ phase so that there are significant regions of the carbon that are not in contact with Co₃O₄. To learn more about the degree of direct contact between Co₃O₄ and carbon black required for the catalyzation of the carbon corrosion processes, an electrode was fabricated from a mechanical blend of uncatalyzed ¹⁴C acetylene black and unlabeled catalyzed acetylene black. Mechanical blending is unlikely to produce the degree of physical contact between the ¹⁴C aggregates and the Co₃O₄ clusters achieved by solution phase impregnation. Therefore, if direct physical contact between Co₃O₄ and the carbon black particles were required for catalyzed corrosion, the mechanical blend should yield lower dissolution rates as measured by the ¹⁴C method. As the comparison of results made in Fig. 9 indicates, this was not observed, since the dissolution rates observed with the mechanical blend were the same (within the ±50% deviation of values observed for identical electrodes) as with the solution impregnated electrode. It appears then that direct physical contact between the oxide phase and the carbon black aggregates is not required for enhancement of the corrosion process to occur.

Discussion

One of the objectives of this study was to determine the individual rates of all the anodic processes occurring in an acetylene black electrode in the 450-650 mV potential region. The approach was to measure the rate of appearance of products of the anodic processes using a variety of techniques, and there remains the question as to whether all the anodic processes occurring in the electrode were accounted for. Techniques were developed to analyze for gaseous products, soluble products in the KOH solution, and partially soluble or solvent extractable products within the electrode. There are well-known anodic processes which do not produce products that

Fig. 10. Rates of gas evolution at 45°C as a function of potential for (open symbols) catalyzed acetylene black and (closed symbols) acetylene black. Error bars represent the range of values observed with repetitions with nominally identical electrodes.

would be seen by these techniques, in particular, the oxidation processes that form surface oxides or intercalation compounds like "graphite oxide" (14). An approximate measure of these processes can be obtained by comparison of the sum of the measured partial rates (as partial currents) with the observed total anodic current. This procedure has an inherent inaccuracy as the product evolution rates require a finite sampling time, whereas the anodic current is instantaneous and is changing during the sampling period. The resulting sums of the measured partial rates of oxygen evolution, carbon monoxide evolution, and carbon dissolution were generally less (ca. 90% of the total current) than the average values of the anodic currents observed over the time period for the partial rate determinations. But there are sufficient inaccuracies in the partial rate determinations that the relatively small differentials are probably not reliable measures of anodic processes like surface oxidation or "graphite oxide" formation. One can, however, reasonably conclude that these latter processes make a relatively minor (ca. 10%) contribution of the time-averaged anodic current observed under potentiostatic conditions.

Due to the different potential dependence of each anodic process, the predominant anodic process changes as a function of potential (at constant temperature) and, due to different activation energies, the predominant process changes as a function of temperature at any given potential. For uncatalyzed acetylene black at low (<50°C) temperature, three regimes can be distinguished: (i) in the low potential region (450-500 mV) the predominant process is dissolution of the acetylene black to carbonate ion, (ii) in the 500-600 mV region oxygen evolution and carbon dissolution occur at equivalent rates, and (iii) above 600 mV, oxygen evolution and carbon monoxide evolution are the dominant processes. Elevation of the temperature to 65°C, or catalyzation with Co_3O_4 preferentially accelerates the gas evolution reactions (for O_2 and CO) such that all three anodic processes occur at nearly equivalent rates even at low potential. Carbon monoxide production was always commensurate with oxygen evolution and was never observed in the absence of oxygen evolution, indicating that there is a good possibility that chemical oxidation of the carbon by evolving oxygen (or intermediates) may be occurring in addition to direct electrochemical oxidation. This was also indicated by the effect of Co_3O_4 on the CO evolution rate, particularly the results that showed that physical contact between Co_3O_4 and carbon was not necessary for enhanced oxidation. The results with the cobalt catalyzed acetylene black also suggest that CO evolution and organic formation are competing, and not parallel, reaction paths. This was evident from the observation that the appearance of significant quantities of organic product was always at conditions (potential and temperature) where the current efficiency for CO evolution was the lowest, e.g., Table I. It is not mechanistically obvious why oxidation to CO and dissolution to organic would be competing reacting paths.

While the anodic processes of oxygen and carbon monoxide evolution appear to be coupled, there is no apparent coupling between oxygen evolution and dissolution to organic products. This is clear by comparison of the data in Table I, where high current efficiency for oxygen was not accompanied by measurable organic dissolution product. Also, in the case of the 65°C experiments with uncatalyzed acetylene blacks, the absolute oxygen evolution rates were about the same as with the catalyzed black at 45°C, yet no measurable quantity of organic appeared in the absence of catalyst. It seems clear that oxygen evolution is not a sufficient condition for organic product formation, and that cobalt oxide has a selective catalytic effect for the dissolution process to organics. We did not perform experiments designed to determine whether physical contact of Co_3O_4 and carbon aggregates is required for this catalysis as we did for the carbonate ion reaction. This determination could have been made by using ^{14}C detectors on the chromatographs in the organic carbon analysis, but our apparatus was not equipped with

these detectors. Unfortunately, there are no results in this work that would help to elucidate the mechanism of the selective catalyzation of the dissolution of carbon to organic products.

We attempted some experiments designed to explore the relationship between the acetylene black microstructure and the corrosion rate, but these have not yet yielded definitive results. Because of the heterogeneous nature of the acetylene black microstructure, it might be expected that the corrosion rate might change (go down) with time as the more easily oxidized sites are used up. Also, if the different types of carbon in the black are removed at different rates, one might expect to see the microstructure change by TEM analysis of corroded samples. However, it was clear from the TEM analysis that the scale of heterogeneity is fairly large, and that the amount of carbon loss required to see a significant change in either the structure or the overall corrosion rate could be as much as 30%-40%. A ^{14}C acetylene black electrode was potentiostated in KOH solution at 550 mV, 45°C for 500h, which resulted in a total weight loss (determined gravimetrically) of ca. 30%. This electrode was placed in the corrosion cell of Fig. 1, and the rates of the anodic processes were measured. The absolute rates of all anodic processes were increased by factors of 1.5-2 times those for "new" acetylene black, but the current efficiencies were significantly changed, with the corrosion rates reduced relative to oxygen evolution. The TEM analysis on the corroded black was inconclusive in that we could not distinguish regions of the carbon that had been attacked preferentially. Apparently, the increase in surface area with carbon loss more than offsets the decrease in the rate per unit area, resulting in a net increase in corrosion rate. The same effect was seen in the temperature cycling experiments shown in Fig. 6. After the measurements at 65°C, which resulted in a weight loss of about 20%, the dissolution rates at the lower temperatures were about a factor of 2 higher than before the 65°C measurements. It would seem that the difference in corrosion rate (per unit area) between the different forms of carbon in acetylene black cannot be very large, perhaps only factors of 2-3.

We were not able to identify the organic products of acetylene black corrosion, and, in particular, the nature of the deep reddish-brown coloration of the KOH solution. There is a long and interesting history related to the observation and analysis of colored caustic solutions from the oxidation of graphite anodes in chlor-alkaline cells. Thiele (15) reviewed observations made in the 1930's on the oxidation of graphite in caustic solutions, and reported that a brown discoloration of the solution was observed with graphite oxidation, that "lampblack" carbon-colored solutions more intensely than graphite, and that the brown product was probably humic acid. In the early 1940's, Heller (16) did a thorough analytical study to identify the source of color in caustic from chlor-alkali diaphragm cells. He found that when graphite anodes from these cells were soaked in water a yellowish coloration developed, which left a dark brown residue upon drying. From this brown residue, Heller extracted a bright yellow crystalline compound which he concluded, from various property measurements, was pyromellitic acid chloroquinone. Janes and co-workers (17-18) at Union Carbide reported that caustic solutions prepared from the yellow crystalline material isolated by Heller had the same UV-Vis spectrophotometer spectra as chlor-alkali cell effluent, and concurred with Heller that this material was the source of color in caustic from diaphragm cells. They also reported that less graphitic raw materials for the anode like "lampblack" or "charcoal" gave increased coloration in cell effluent. However, further analytical study of Heller's yellow material by Wawzonek and Eftax (19) indicated this material was not a single compound but a mixture of mellitic acid, pentacarboxylchlorobenzene, tetracarboxylchlorobenzene, and a material of unknown structure that is actually the source of color! Since this active period sparked by Heller's work, there has been very little further work on this subject. Some Russian

work (10) reported isolating mellitic acid as one of the organic products from graphite anode oxidation in 0.01N Na_2SO_4 , but mellitic acid constituted only a fraction of the total organic product which was not otherwise identified. There appears to be no precedent in the literature for the specific catalyzation of the dissolution process to organic products, as we have observed in this work.

The practical consequences of the determinations of the partial rates of the anodic processes occurring in acetylene black electrodes made in this work could be significant with regard to the use of this material in alkaline batteries, but care must be taken in applying these partial rates directly to practical electrodes. The rates of oxygen evolution, the current efficiencies in Table I, and the total anodic currents measured at any potential are influenced by the rate of transport of products from within the porous mass of the electrode. The rates measured here were for fully submerged electrodes containing only enough PTFE to bind the acetylene black together. Experiments done with a floating electrode containing ca. 20% PTFE so as to approximate the practical "gas diffusion" type structure (20) indicated the rate of oxygen evolution from catalyzed acetylene black increased severalfold over that observed with the same material in a submerged electrode. This means the concentration of dissolved oxygen inside the submerged electrode was probably severalfold higher than in the high transport rate gas diffusion electrode, so that the corroding action of evolved oxygen may be accentuated due to the transport effect. Also, in PTFE-bonded gas diffusion electrodes, it is usually the case that all of the carbon is not wetted by electrolyte, so that the direct electrochemical corrosion rate will not be as high as for fully wetted carbon, but the oxygen evolved can react homogeneously with the dry catalyst to form gaseous carbon dioxide that may diffuse out of the electrode without being trapped in the electrolyte. The gas diffusion electrode might, therefore, be expected to give higher gaseous product to dissolved product ratios than reported here. However, due to the complexity of the interactions and the potentially compensating nature of some of these interactions, it is difficult to predict what the differences in the partial rates might be between a practical gas diffusion electrode and the fully submerged electrode used here.

Conclusions

1. Carbon dissolution to carbonate ion, gasification of carbon to carbon monoxide, and oxygen evolution are the predominant anodic processes in uncatalyzed acetylene black at 450-600 mV vs. Hg/HgO in concentrated KOH. No evidence for the formation of a "graphite oxide" intercalation compound was found. The potential and temperature dependence of these anodic processes is different, so that there are various combinations of the three processes that are dominant at different conditions: (i) at potentials below 500 mV and temperatures below 50°C, carbon dissolution is the primary anodic process, (ii) at 500-600 mV and 50°C or lower, carbon dissolution and oxygen evolution occur at equivalent rates, and (iii) above ca. 600 mV or above ca. 60°C at any potential above 450 mV, oxygen evolution and carbon gasification are the dominant anodic processes.

2. Below 500 mV and 50°C, the current efficiency for oxygen evolution from acetylene black is sufficiently small that the total anodic current is essentially the corrosion current.

3. In a cobalt oxide-catalyzed acetylene black electrode, the current efficiency for oxygen evolution is increased severalfold, but the rates of the corrosion processes are also accelerated relative to those for the uncatalyzed black. In addition, cobalt oxide causes organic products to form at significant rates at conditions where only trace amounts are observed for uncatalyzed black.

APPENDIX

Mass Spectrometer Calibration

The calibration procedure was based on the electrolytic generation of oxygen from KOH solution into the gas space above the solution, whose volume is maintained at a constant value. A nickel Exmet® working electrode was used to evolve oxygen at a constant rate by use of a constant current power supply. The quantity of oxygen in the argon is therefore known precisely, and a calibration curve of mass spectrometer peak ratio (oxygen to argon) vs. quantity of oxygen (in coulombs) can be prepared, as shown in Fig. 11. Because oxygen is always present in low concentration relative to the argon, we chose the $M/e = 36$ peak of argon (the natural abundance of the 36 isotope is 0.337%) as the normalization factor. Water vapor in equilibrium with the KOH solution is present at partial pressures of 20-200 torr depending on temperature, so that the total pressure of the argon above the solution is a function of the solution temperature. A different calibration curve was therefore required for each solution temperature. The absolute calibration for carbon monoxide was obtained using the absolute oxygen calibration and observing the $M/e-28:M/e-32$ peak ratios for calibrated mixtures of oxygen and carbon monoxide (purchased from Matheson). As a check on this calibration, we computed the expected $M/e-28:M/e-32$ peak ratios from the quadrupole analyzer transmission function supplied by the manufacturer and tabulated ionization probabilities for O_2 and CO and found them to be in reasonable agreement ($\pm 5\%$) with the observed values.

ABSTRACT

The cycling efficiency of a lithium-aluminum electrode has been studied in a variety of aprotic systems and compared with that of pure lithium. It is shown that the efficiency of the alloy electrode is virtually independent of the nature of the electrolyte solution but that it depends somewhat on the amount of alloy deposited per unit area and current density used in the charging and discharging processes. The roles of the β - and α -phases of the alloy system in the operation of the electrode and in cracking and disintegration of the electrode are considered in detail. It is shown that the cycling efficiency could be improved significantly by mechanically stabilizing the alloy material on the surface of the electrode.

In recent years, substantial research effort has been directed to the development of rechargeable lithium and lithium alloy electrodes for batteries operating at room temperature in nonaqueous media (1, 2). In this connection, it has been shown that the charging efficiency of pure lithium electrodes can reach 96%-98% in a few carefully selected electrolyte solutions (3, 4). However, in order to achieve high efficiencies, complex and costly methods of solvent and electrolyte purification are necessary. The major problem limiting cycle life in experimental cells was found to be short circuits caused by the growth of lithium dendrites through the separator (2). One way of overcoming this problem is to alloy the lithium with aluminum. β -LiAl deposited on aluminum does not grow dendrites (5, 6) and exhibits high rechargeability in many aprotic solvents (5-7). The major disadvantages of the lithium-aluminum electrode are that the atomic weight of LiAl is 4.9 times greater than that of Li, and that the equilibrium potential is 0.38V more positive. If one estimates the change in energy density in a cell using a TiS_2 intercalation cathode with nature of the anode, one finds that the theoretical energy density of the LiAl/ TiS_2 system is only about 33% lower than that of the Li/ TiS_2 system. Thus, if higher cycle life is achieved, the lithium-aluminum anode is an attractive alternative for use in ambient temperature high energy density batteries. In a previous paper (8), a study of charge and mass-transfer processes occurring at a lithium-aluminum electrode in propylene carbonate (PC) was reported. The present paper is concerned with cycling studies in other media. In addition, the factors affecting the cycling efficiency have been examined in more detail, with a view to finding methods of improving the electrode's performance.

Experimental

The apparatus and electrochemical methods were the same as those used in the previous study (8). The active

material of the working electrode was electrodeposited at high purity aluminum or nickel wires, 2 mm diam, which were mounted in Teflon tubes. Electrodes of higher surface area used in some experiments were prepared from aluminum foil 0.4 mm thick. The counter- and reference electrodes were made of pure lithium, as described earlier (8). The experiments were carried out in a controlled atmosphere chamber under an atmosphere of purified argon.

Tetrahydrofuran (THF), 2-methyl-tetrahydrofuran (MTHF), and bis-(2-ethoxyethyl) ether (EEE), used as solvents, were purified by drying with LiAlH_4 and distilled under argon from a Vigreux column 1m high, only the middle fraction (60%) being collected. THF and MTHF were then distilled a second time under reduced pressure and temperature. N,N -dimethylformamide (DMF) and 1-methyl-2-pyrrolidone (MP) were dried over CaH_2 and then distilled under reduced pressure. In the case of PC and dimethylsulfoxide (DMSO), drying was carried out over 4Å molecular sieves for 24h before distilling at reduced pressure. The water content of the purified solvents was $\leq 0.01\%$. Three lithium salts were used to prepare the electrolyte solutions. Commercial LiAsF_6 from U.S. Agri-chemicals was used without drying or other purification. Reagent grade LiClO_4 and LiI were dried under vacuum at 120°C for 48h before use. The electrolyte solutions were prepared at low temperature in the controlled-atmosphere chamber.

Results and Discussion

A comparison of the cycling efficiencies of lithium-aluminum electrodes in various media.—In order to improve understanding of the influence of the medium on the rechargeability of lithium-aluminum anodes, experiments were performed in which the cycling efficiency of the lithium-aluminum was measured and compared with that for pure lithium. The lithium electrode (Li/Ni) was formed by electrodepositing lithium on a nickel wire, 2 mm diam, at a constant current density of 2.5 mA cm^{-2} for 1000s. Then, the deposit was completely oxidized at the same current density. This cycle was repeated five

¹ Present address: Department of Chemistry, University of California, Davis, California 95616

times, and the ratio of the charge involved in the oxidation process for the last three cycles, Q_o , to that for the reduction process, Q_R , was used to estimate the average cycling efficiency. The lithium-aluminum electrode (LiAl/Al) was formed under the same conditions at an aluminum wire; the cycling conditions and method of estimating cycling efficiency were the same as for those for the Li/Ni system. Data for nine different electrolyte solutions are presented in Table I. The striking result is that the cycling efficiency of the Li/Ni system changes from 5% to 94% when the electrolyte solution is changed, whereas that of the LiAl/Al system is virtually constant and high (91%-95%) in all solutions. In other experiments, the influence of corrosive additives, namely, I_2 , H_2O , and SO_2 , on the cycling efficiency was examined (Table II). Again, it was found that the LiAl/Al electrode is much less sensitive to corrosion than the Li/Ni electrode. It is obvious that the major factors affecting the cycling efficiency of these systems are quite different. According to the generally accepted view, metallic lithium can be plated from many aprotic solvents with close to 100% coulombic efficiency (2). However, subsequent oxidation is much less efficient. Two models have been proposed to explain this result. According to Rauh and Brummer (2, 9), the surface grains on the lithium deposit react with the electrolyte solution, and are undercut by corrosion. Some of the grains become partially or completely isolated from the substrate. Thus, subsequent oxidation is not 100% efficient. The morphology of the residual lithium is seriously distorted in subsequent platings, and, cycle by cycle, the deposit becomes increasingly dendritic. In addition, as the deposit becomes more dendritic, it is more vulnerable to the corrosion and isolation process. An alternative model has been described by Peled (10), who interpreted the poor stripping efficiencies of alkali and alkaline earth metals in terms of the formation of a solid electrolyte interphase in which Li^+ ion is conductive. Excessive local heating and the high local electric field result in the formation of a short circuit through the solid interphase during the charging cycle. As a result, a parcel of lithium metal forms within the solid electrolyte out of

direct electrical contact with the substrate. The short circuit disappears after plating ceases, and, on subsequent discharge, the encapsulated parcel of lithium is unavailable for electro-oxidation.

In the case of the lithium-aluminum electrode, neither of the above mechanisms is applicable. For this system, four steps can be distinguished in the reduction process: (i) migration of Li^+ ions through the solid/electrolyte interphase, (ii) charge transfer, (iii) diffusion of lithium in β -LiAl, and (iv) reaction of lithium with aluminum. Because the mobility of aluminum in β -LiAl is negligible in comparison with that of lithium (11), the lithium-aluminum deposit is never dendritic, and, therefore, much less vulnerable to corrosion. The nondendritic character of the deposit was confirmed by scanning electron microscopy. However, even if the solution reacts efficiently with the grain boundaries of the alloy phase, one of the products, aluminum, may provide good electrical contact between the grains. Peled's model (10) does not apply to the LiAl/Al electrode because formation of the alloy occurs at a more positive potential than the potential necessary for deposition of metallic lithium. These differences explain why the cycling efficiency of the LiAl/Al electrode is relatively high and virtually independent of electrolyte nature. In addition, lithium-aluminum is thermodynamically less reactive than lithium. This factor seems to be less important because of the high cycling efficiency of the LiAl/Al electrode, even in the presence of sulfur dioxide.¹

On the basis of the present results, it is concluded that the cycling efficiency of the LiAl/Al electrode is much more determined by the properties of the alloy itself rather than by those of the electrolyte. It follows that changing the composition of the electrolyte or the method of purification is unlikely to improve cycling efficiency. In any case, the majority of experiments were conducted in THF and MTHF solutions of $LiAsF_6$, electrolyte solutions which are believed to be last reactive with lithium (3, 12).

Factors affecting the cycling efficiency of the lithium-aluminum electrode.—In order to determine the influence of various factors on the cycling efficiency of the LiAl/Al electrode, extensive galvanostatic cycling experiments were carried out in THF and MTHF solutions containing 1.5M $LiAsF_6$. In the first stage of the cycle, Li^+ ions were reduced at the electrode for a precisely measured period of time; then the direction of the current was changed and oxidation of Li from the previously formed alloy was carried out. During this procedure, the electrode potential was recorded. The final sharp rise of electrode potential to greater than + 2.0V was considered an indication that lithium was exhausted from the electrode. Since the absolute value of the current during the experiment was constant, the ratio of the oxidation time (τ_o) to the reduction time (τ_R) is equal to the cycling efficiency with respect to lithium, η_{Li} (8). In the first type of cycling experiment, the electrical charge involved in the reduction process, Q_R , was kept constant at 0.25 C cm^{-2} , and the current density was varied from 0.04 mA cm^{-2} to 25 mA cm^{-2} . Ten cycles were recorded at each current density, and the average cycling efficiency was calculated. From the dependence of average efficiency on current density (Fig. 1), the maximum efficiency is obtained for current densities in the range 1-5 mA cm^{-2} .

In other experiments, the current density was kept constant at 5 mA cm^{-2} and the charge density involved in one cycle varied from 0.1-50 C cm^{-2} . The results showing the average efficiency of ten identical cycles are shown in Fig. 2. A sharp decrease in efficiency for charge densities greater than 8 C cm^{-2} was observed in both THF and MTHF. It is important to notice that identical results were obtained earlier in PC (8). The influence of temperature on cycling efficiency was also studied in a 1.5M $LiAsF_6$ solution in MTHF. In agreement with results obtained in

¹ The standard potential for the reaction $2SO_2 + 2Li^+ + 2e \rightleftharpoons Li_2S_2O_4$ is 2.6V more positive than that for the reaction $Li^+ + Al + e \rightleftharpoons \beta$ -LiAl.

PC (8), the efficiency decreases with decrease in temperature, the effect of temperature being greater at larger charge densities and currents (Table III). These results are further indication that the cycling efficiency of the lithium-aluminum electrode is more affected by the properties of the alloy phase than by the nature of the electrolyte or solvent. The reasons why the efficiency for this system is less than 100% are now considered in detail.

One reason for the observed efficiencies for the LiAl/Al could be the slow diffusion of lithium into the bulk of the aluminum phase. On the basis of the phase diagram for Li-Al(13), lithium can dissolve in aluminum to form the α -phase which contains up to 7 atom percent (a/o) Li and has a density close to that of pure aluminum. The loss of active lithium due to this process can be described by an integrated form of the Cottrell equation

Table III. Temperature dependence of the cycling efficiency of the lithium-aluminum electrode*

Temp (°C)	Efficiency (%)

* The electrolyte solution contained 1.5M LiAsF₆ in MTHF.

$$\Delta Q = 2F c_{\alpha m} D_{\alpha}^{1/2} t^{1/2} / \pi^{1/2} \quad [1]$$

where ΔQ is the loss in charge density due to active lithium, $c_{\alpha m}$ the maximum concentration of lithium in the α -phase at the boundary with the β -phase ($c_{\alpha m} = 7 \times 10^{-3}$ mol cm⁻³), D_{α} the diffusion coefficient of lithium in the α -phase, t the time after formation of the β -phase by reduction of Li⁺ at aluminum, and the other symbols have their usual meanings. In order to assess the role of this process, a known amount of β -LiAl was deposited on an aluminum electrode, and the electrode was dried and stored under an argon atmosphere for varying periods of time. Then, the active lithium was electrochemically oxidized, and the loss in charge density due to storage determined. A plot of ΔQ against $t^{1/2}$ for two series of experiments is shown in Fig. 3. The value of D_{α} determined from the slope is 1.4×10^{-12} cm²s⁻¹. Melendres *et al.* (14) reported a value of 4×10^{-10} cm²s⁻¹ for D_{α} at 450°C, but no other values of this parameter were found in the literature. It is noted that D_{α} is much smaller than D_{β} , the diffusion coefficient of lithium in β -LiAl [$D_{\beta} = 7.7 \times 10^{-8}$ cm²s⁻¹ at 25°C (8)]. The diffusion of lithium from β -LiAl into pure aluminum may explain the decrease in cycling efficiency observed when small current and charge densities are involved (see Fig. 1), but this process has a negligible effect on observed efficiencies when the current density $i > 1 \text{ mA cm}^{-2}$ and $Q > 1 \text{ C cm}^{-2}$.

The decrease in efficiency observed at high current densities (Fig. 1) is probably due to blocking of the β -LiAl phase by rapidly formed α -phase. If this conclusion is correct, one may expect that when the deposit is oxidized under controlled-potential conditions instead of galvanostatic conditions, the blocking process will affect the current density, but the charge efficiency of the oxidation process will remain high, provided that the oxidation is carried out for a sufficiently long period of time. Current-

Fig. 3. The dependence of the decrease in oxidizable lithium, ΔQ on the square root of time $t^{1/2}$ for a lithium-aluminum electrode formed in THF.

Fig. 4. Current density against time curves for the potentiostated oxidation of lithium from a LiAl/Al electrode covered with 1.5 C cm^{-2} of electrodeposited lithium in THF solution containing 1 M LiAsF_6 . The potentials at which oxidation was carried out against a Li/Li⁺ reference electrode were (a) 1.0V, (b) 1.2V, (c) 1.4V, (d) 1.7V, and (e) 2.0V.

time curves for the potentiostatic oxidation of the alloy electrode are shown in Fig. 4. By integrating these curves, it was shown that the charge efficiency of the oxidation process is about 95%, independent of the initial current density even when this exceeds 100 mA cm^{-2} . The blocking of β -LiAl by rapidly formed α -phase is likely to be more efficient at low temperature due to the decrease in the rate of diffusion. This fact may account for the decrease in cycling efficiency with decrease in temperature (Table III).

Conversion of the β -phase containing 47-56 a/o lithium to the α -phase containing up to 7 a/o lithium during oxidation of the active material of the electrode has additional significance with respect to cycling efficiency. Because of the low value of D_α , the lithium in the α -phase is not oxidized during the time scale of our experiments. The efficiency of the first cycle with respect to lithium at a fresh aluminum electrode may be estimated on the basis of the following argument. Assuming that the composition of the β -phase is 56 a/o Li, and that n_β mol of Li are deposited in m mol of Al on the surface of the electrode, then $n_\beta = 0.56m/0.44$. If the α -phase remaining on the surface after the oxidation step contains 7 a/o Li and n_α moles of Li are present in the same amount of Al, $n_\alpha = 0.07m/0.93$. It follows that the efficiency at the fresh electrode is $\eta_{Li} = 100 \cdot 100n_\beta/n_\alpha = 94\%$. In subsequent cycles, the efficiency rises according to the relationship

$$\eta_{Li} = 100 \left[1 - \left(\frac{7 \times 44}{93 \times 56} \right)^N \right] \quad [2]$$

where N is the number of cycles. Thus, one may account for the increase in efficiency observed with increase in number of cycles. However, η_{Li} should approach 100% according to Eq. [2]. This is not observed experimentally after long cycling.

Structural changes in the lithium-aluminum electrode during cycling.—According to the literature (6) and previous work in this laboratory (8), the main reason for the loss in efficiency of the lithium-aluminum system is cracking and disintegration of the electrode during cycling. Since the molar volume of the β -phase is 1.3 times greater than that of the α -phase, the aluminum lattice is destroyed when β -LiAl is formed, and particles of the β - and α -phases lose contact with one another. The development of cracks on the surface of the electrode with cycling was

Fig. 5. Dependence of the specific double layer capacity at the lithium-aluminum electrode/solution interface on (a) the number of cycles and (b) time after lithium had been deposited. The electrolyte solution was 1 M LiAsF_6 in THF, the current density for cycling, 5 mA cm^{-2} , and the charge density due to deposited lithium, 3 C cm^{-2} . The specific capacity was estimated on the basis of the apparent electrode area.

clearly visible in electron micrographs. The disintegration process was studied at an aluminum electrode in a THF solution containing 1 M LiAsF_6 using the ac impedance technique. The electrode was charged and discharged with a lithium charge density of 3 C cm^{-2} at a current density of 2.5 mA cm^{-2} . After each charging cycle, the in-phase and out-of-phase components of the cell impedance were measured at various frequencies in the range 5-20,000 Hz. The double layer capacity C_{dl} was calculated as described previously (8) using the measured components of the impedance and solution resistance. This quantity calculated at 20 Hz is shown in Fig. 5 as a function of the number of cycles. A large increase in C_{dl} , almost by a factor of 1000, is apparent when the electrode is cycled 25 times. This is clearly connected with an increase in the active surface area of the electrode caused by cracking of the deposit. The change in C_{dl} with time for a free standing alloy electrode not involved in either the charging or discharging process is also shown in Fig. 5. The slight drop in C_{dl} over a period of several hours is probably due to an increase in the thickness of a passivation layer on the electrode.

The increase in the surface area of the electrode is also responsible for the appearance of new waves on the potential against time curves recorded during galvanostatic cycling. Curves for the first and fourteenth cycles at an alloy electrode are shown in Fig. 6. It is probable that the wave near +0.8V with respect to a Li/Li⁺ reference electrode is due to the process

The transition time associated with this wave is given by the equation

$$\tau_\alpha^{1/2} = \frac{\pi^{1/2} F A D_\alpha^{1/2} c_{\text{om}}}{2I} \quad [4]$$

where A is the true surface area of the electrode, and I the current. The change in electrode surface area estimated from Eq. [4] indicates that the area increased by a factor

Fig. 6. Potential against time curves recorded galvanostatically during 5 min of reduction of Li^+ at a lithium-aluminum electrode and subsequent oxidation in THF solutions containing 1M LiAsF_6 . Curve a is for the first cycle, and curve b for the fourteenth.

of 10 after 12 cycles. This is much less than the area increase estimated on the basis of the double layer capacity (Fig. 5). However, one should keep in mind that the estimates of area changes based on C_{dl} or Eq. [4] are only qualitative, since the relationships used are not really applicable to very rough surfaces composed of particles with small grain size.

In another experiment, lithium was repeatedly transferred from one LiAl/Al electrode to another in a THF solution containing 1M LiAsF_6 . The initial amount of electrodeposited lithium corresponded to 5 C cm^{-2} and the apparent surface area was 20 cm^2 . Because the cycle efficiency is less than 100%, the active charge on the system decreased with the number of cycles, and, at the same time, a black powder fell off of the electrodes and accumulated on the bottom of the cell. When the charge dropped to 1% of its initial value, the experiment was stopped. The black deposit and the electrodes were separately dissolved in HCl, and the resulting solution analyzed

for Li^+ ion using atomic absorption spectroscopy. On the basis of three experiments, it was concluded that 20%-30% of the lithium lost during the cycling experiment remained on the electrodes in a nonactive form, presumably, as the α -phase, or as β - LiAl in particles which had lost electrical contact with the substrate. The remaining lithium was found in the black deposit.

It should be emphasized that the proposed mechanism in which β -phase particles are isolated from the electrode is different from the mechanism of lithium encapsulation proposed by Rauh and Brummer (9). The low efficiency observed with the lithium-aluminum electrode is a result of mechanical problems rather than chemical corrosion. It follows that the performance of the alloy electrode can be improved using mechanical methods.

Methods of improving the cycling efficiency of the alloy electrode.—On the basis of the above results, it was decided to attempt to improve the cycling efficiency of the

Fig. 7. The coverage of the alloy electrode with active lithium expressed as charge density Q against the number of cycles for (a) a LiAl/Al electrode pressed against a polypropylene separator soaked with a PC solution containing 1M LiAsF_6 , and (b) a free standing LiAl/Al electrode in the same electrolyte.

alloy system by pressing a separator against the electrode. By applying pressure, electrical contact between the grains should be improved and separation from the substrate prevented. In addition, since the LiAl deposit is not dendritic, shorting of the battery electrodes through the separator should not occur. To test the effect of pressure, two aluminum electrodes, one of which was covered with a known amount of alloy, were separated by two layers of polypropylene separator material (Kendall E-1452) soaked with a PC solution containing 1M LiAsF₆. The total system was compressed under a weight to achieve a pressure of 2.5 kg cm⁻². The active lithium was repeatedly cycled from one electrode to the other under galvanostatic conditions with a current of 1 mA cm⁻², and the charge associated with each cycle recorded. In a parallel experiment, the same initial amount of active lithium was cycled between two free standing electrodes in the same electrolyte. On the basis of the results presented in Fig. 7, it is clear that the performance of the system under pressure is much better than that for free standing electrodes; in the former case, the cycling efficiency over 40 cycles averaged 97%; in the latter, it averaged 94%. This aspect of the lithium-aluminum system certainly merits further investigation.

Conclusions

The results presented above demonstrate that the factors affecting rechargeability of the lithium-aluminum electrodes in nonaqueous media are different than those affecting the rechargeability of pure lithium. The cycling efficiency of the alloy electrode is much more determined by the properties of the alloy itself rather than by the properties of the electrolyte solution.

At the beginning of the cycling experiment, the charging efficiency of the LiAl/Al electrode is limited mostly by conversion of the β -phase into the less active α -phase either electrochemically in the oxidation cycle or as a result of reaction of the β -phase with the aluminum substrate. In addition, in the oxidation portion of the cycle, blocking of the β -phase by rapidly formed α -phase occurs, especially if large current or charge densities are involved. With increase in the number of cycles, these two effects become less important. However, due to the large difference in molar volumes between the β - and α -phases,

a process of disintegration of the electrode develops. The surface area of the alloy electrode increases, the deposit cracks and falls off the electrode, or remains on the electrode without electrical contact. Finally, the cycling efficiency can be significantly improved by pressing a separator against the electrode in order to prevent separation of the alloy phase and improve electrical contact between grains of the alloy phase.

Structural Changes of Positive Active Material in Lead-Acid Batteries in Deep-Discharge Cycling

T. G. Chang*

Cominco Limited, Product Research Centre, Sheridan Park, Mississauga, Ontario, Canada L5K 1B4

ABSTRACT

The positive active material of lead-acid cells under deep-discharge cycling conditions was studied. Morphological transformation and changes in surface area, density, pore-size distribution, and composition were recorded. The relationship of these parameters to discharge capacity and ultimate failure are discussed. It was found that pores can be classified in two categories, namely, macropores with diameters larger than 0.5 μm and micropores with smaller diameters. Macropores are responsible for mass transport to and from the reaction surface provided by the micropores. In order to sustain high capacity discharge performance, an optimum structure of active material must contain both kinds of pores appropriately distributed.

The utilization of the active material in the positive plates of lead-acid batteries is quite low, about 35% for traction and 50% for SLI batteries at 100% depth of discharge at the 5h rate.

In the course of our investigation (1) of positive active material made from various oxides, we found positive plates prepared from a finely divided oxide, Fume Lith-

arge (produced by NL Industries, Incorporated), gave a very high utilization of up to 65% at the 5h rate. However, this high utilization declined rapidly in the first ten deep-discharge cycles. After 24 cycles, the utilization was lowered to the level of active materials prepared from coarser oxides under similar conditions. A subsequent investigation was undertaken to identify and characterize the active material structures which contribute to high discharge capacity and the structural transformations which take place during deep-discharge cycling.

The morphology of the active material in positive plates has been widely and quite intensively investigated (2-33). However, the failure of active material in deep cycling is not yet well understood. Simon *et al.* (12) found an association between the presence of a coralloid structure and active material failure. Although the advent of the coralloid structure was accompanied by a loss of capacity, they pointed out, on the basis of theoretical considerations, that the structure appeared ideal for a porous electrode. The structure has a dense PbO_2 core, which should provide strength and conductivity. The large voids in the convolutions should provide a free flow of electrolyte from the bulk to the reacting surface. Burrows and Giess (17) suggested that a decrease in surface area of the active material in cycling might be partly responsible for the loss of capacity. It was also suggested that failure of active material was associated with an increasing amount of amorphous lead dioxide (26) and "inactive" lead dioxide (34, 35). In this paper, we also explore the cause of active material failure.

Experimental

Lead oxides were made into pastes with the addition of water and sulfuric acid, and pasted on a $47 \times 75 \times 1.9$ mm book-mold grid (Pb-3%Sb alloy). The oxides were Fume Litharge (NL Industries, Incorporated), a finely divided orthorhombic lead monoxide, and Grenox (Canada Metal Company, Limited), a Barton pot leady oxide. The plates (3 mm thick) were cured at 40°C , formed in 1.05 sp gr H_2SO_4 for Fume Litharge plates (wet paste density 4.0 g/cm^3) and 1.10 sp gr H_2SO_4 for Grenox plates (wet paste density 4.4 g/cm^3). They were cycled in 600 ml beaker cells containing excess 1.25 sp gr H_2SO_4 at 30°C . Each cell contained a test (positive) plate with one counterelectrode on each side and a reference electrode capillary (connected to a room temperature reference electrode in a side compartment) within 1 mm of the test plate. No separator or other supports were used. The plates were discharged in successive cycles at 600, 900, 1200, 1200, 900, and 600 mA for the first through sixth cycles, respectively. This discharge pattern was repeated for subsequent cycles. The discharge was terminated when the potential of the test plate fell to 995 mV *vs.* $\text{Hg/Hg}_2\text{SO}_4$ (in 1.25 sp gr H_2SO_4). The plate was then charged at a constant potential of 1295 mV with a maximum current of 2A until the current fell to 150 mA, whereupon the plate was charged at this current until 115% of the ampere-hour capacity of the previous discharge was returned.

The surface area measurements were made by Micromeritics Instrument Corporation, Norcross, Georgia,

using the BET gas adsorption method. Pore volumes and pore-size distributions were determined by Micromeritics and by Quantachrome, Syosset, New York, using mercury porosimetry. The pore volumes and densities of active material were also determined in our laboratory using the water uptake and displacement method described by Fleischmann (36).

Specimens for optical or scanning electron microscopic examination were prepared by grinding and polishing samples impregnated with a polyester resin or by saturating the sample with water, which was then frozen, and microtomed. The second method has some advantage over the first: the sample preparation is much simpler and faster, and a much better view of the plate can be obtained where it is not obstructed by mounting material. This simple and convenient method to investigate active material in lead-acid batteries does not appear to have been used previously.

Results

The average discharge capacities for the positive plates prepared from the two oxides are presented in Fig. 1. In the first cycle, Fume Litharge plates gave a high utilization (over 60%) compared with Grenox plates (45%). However, the capacity of the Fume Litharge plates declined at a high rate, especially in the first ten cycles. After 24 cycles, it was on a level which was no longer extraordinarily high, considering the low density paste used in these plates. In contrast, plates prepared from Grenox did not have a high discharge capacity. The capacity only declined slightly in the first few cycles, and increased slowly to a maximum of 46% theoretical at the fiftieth cycle. The plates prepared from Fume Litharge failed at about the eighty-fifth cycle, whereas the plates from Grenox failed at about the one-hundred-fifth cycle.

Data for surface area, porosity, and density of the active materials are given in Table I. Some of the pore size distribution curves are presented in Fig. 2.

Morphological Changes in Cycling

Grenox was a rather coarse leady oxide which had a median particle size of about $4 \mu\text{m}$ diam, whereas the median size for Fume Litharge was about $1 \mu\text{m}$. After curing, all pastes were a mixture of residual oxide and tribasic lead sulfate ($3\text{PbO} \cdot \text{PbSO}_4 \cdot \text{H}_2\text{O}$) crystals. However, the tribasic crystals in Grenox plates had dimensions of about $0.5 \times 0.5 \times 2.5 \mu\text{m}$, whereas those in Fume Litharge plates were about $0.3 \times 0.3 \times 0.5 \mu\text{m}$.

As-formed active material.—In the surface layer of both types of formed plates (100-200 μm thick) the particles

were arranged in a whorl-like manner, as shown in Fig. 3. The same structure has been described by Simon and Caulder (11). This structure was also observed on the sides of cracks in the plates, but not elsewhere, suggesting that it was formed at locations which were heavily sulfated during soaking and forming. The active materials in the interior were very different, comparing plates prepared from the two oxides. The active material prepared from Grenox had mainly two types of particles: irregularly shaped ones formed from the residual oxide and cigar-shaped ones from tribasic sulfate crystals, as shown in Fig. 4. The interior active material prepared from Fume Litharge had a fine brain-coral structure, as shown in Fig. 5, in which lobes and branches had a diameter about 2-5 μm . The interlobar channels were very evenly distributed. The lobes were made up of submicron particles and were porous.

Active material after one cycle.—The structure of most of the active material was drastically changed by the first cycle. In the plates prepared from Grenox, the cigar-shaped particles were hollowed out; thus, a cellular network was formed, as shown in Fig. 6. The same process occurred in the plates prepared from Fume Litharge. The particles in the lobes were also hollowed out, and the material was redeposited over a larger volume. As shown in Fig. 7, the lobes and branches expanded and merged into one another. The interlobar channel nearly disappeared. The active material in the center of all plates, however, remained basically unchanged from their as-formed structure.

Active material after 12 cycles.—The surface layer containing the whorl-like structure had been completely transformed to a coralloid structure (12, 13) after 12 cycles. Under this surface layer, active material started to consolidate to form coralloid structure, which, in the initial stage (Fig. 8), had porous lobes with small interlobar channels of about 5-10 μm diam. In the center of the plate, 1/4 of the total thickness for Fume Litharge plates, and more than 1/3 of the total for Grenox plates, the fine-network structure predominated.

Active material after 24 cycles.—The active material in the surface layer had begun to disintegrate by 24 cycles.

Under it, the coralloid structure had spread inward. The active material at the center of the Fume Litharge plate entered the initial stage of coralloid structure development, characterized by porous lobes and small interlobar channels. The coralloid structure closest to the surface experienced a further consolidation: the lobes became much more densely packed, and the interlobar channels were enlarged to 10-20 μm diam, as shown in Fig. 9. In contrast, the coralloid structure in the Grenox plates was less well developed, and the network structure still dominated the center of the plates (about 1/3 of the total thickness).

Active material after 50 cycles.—The coralloid structure became completely established by 50 cycles, even in the center of Fume Litharge plates. Big pores with diameters larger than 25 μm were formed in the outer part of the plate (Fig. 10a). They had smooth walls and apparently were the result of the coalescence of smaller pores. The lobes associated with big pores were densely packed. In the center of the plate the coralloid structure was not in an advanced stage, *i.e.*, the lobes were still quite porous and interlobar channels were small. Big pores on the side of a grid wire facing the bulk electrolyte coalesced to form a gap of several hundred micrometers in length. The disintegration of the active material in this part was noticeable. Similar development, but to a lesser degree, also occurred in Grenox plates. In the center part, about 1/4-1/3 of the total thickness, the cellular-like network structure still dominated.

Active material cycled to failure.—The average cycle life of Fume Litharge plates was about 85 cycles, and that of Grenox plates about 110 cycles. The cross section of a failed Fume Litharge plate is presented in Fig. 10b. Big pores of diameters of up to 100 μm permeated the whole plate. The cross section of a failed Grenox plate was very similar to that of a Fume Litharge plate, showing no more of the network structure. Typical cross sections of coralloid structure in charged and discharged plates are shown in Fig. 11 and 12, respectively. In a discharged plate the lobes were surrounded by PbSO_4 crystals. Their cores appeared black under polarized light illumination, and the

x-ray diffractometric analysis showed that they were mainly β - PbO_2 with some PbSO_4 , i.e., the lobe interiors were not discharged. Figure 13 shows that little difference could be found between the active material inside a lobe of a discharged plate and that of a charged one. They all consisted of crystalline particles with dimensions of 0.2-0.5 μm .

As the coralloid structure became established at the core of the plate and large pores formed and grew, a dendritic growth was observed adjacent to the corrosion layer around the grid wire, as shown in Fig. 14. In a failed plate, the thickness of this dendritic layer could be as large as 100 μm . X-ray diffractometric analysis determined the dendrites to be β - PbO_2 in a charged plate and PbSO_4 in a discharged plate.

Discussion

Active material transformation.—The pore-size distribution curve for the as-formed active material retained the as-cured shape, but was displaced toward larger diameters, as shown in Fig. 2. This indicates that the structure in the cured plate was essentially unchanged by formation, as confirmed by the morphological study. The external forms of the basic lead sulfate crystals in the cured

Fig. 10. Microtomed cross section of plates prepared from Fume Litharge. a: 50 cycles. b: 104 cycles (failed).

plate were preserved after their conversion to PbO_2 (shown in Fig. 4 and 5), in agreement with previous findings (2, 6, 12). Thus, uniformly sized fine particles in the cured plate prepared from finely divided Fume Litharge result in the fine brain-coral structure of the formed plate. In subsequent cycling, particles are hollowed out, leaving a cell-like form. Like the interlocking columnar basic sulfate crystals, these interconnected cells form a three-dimensional network. Further cycling consolidates the active material into a coralloid structure. Initially, the lobes and branches are porous, and the interlobar channels small. With further cycling, the lobes and branches

Fig. 13. Active material inside a lobe in a failed plate. a: charged. b: discharged.

become more densely packed and the pores grow to a diameter of 5-20 μm . More cycling brings about the coalescence of these pores to form pores with diameters as large as 100 μm . With the formation of large pores, the active material begins to disintegrate. When the large pores permeate the core, the plate fails.

The morphological changes do not occur uniformly throughout the plate. There is always a gradient in structure. During the initial period of cycling, the active material closer to the surface is discharged deeply, while that further inside the plate is less utilized. However, on further cycling, the active material in the outer part consolidates into the coralloid structure with large densely packed lobes and big interlobar pores, and its utilization decreases. This process does, however, open up the structure in the outer part, making the active material deeper inside the plate more accessible to the electrolyte and thereby increasing its utilization. This process continues until the active material in the core is transformed to the coralloid structure. From then on, the capacity of the plate must decrease with cycling, as there is no further reserve of high capacity active material to replace that with decreasing utilization.

Gas generation and the coralloid structure.—In 1971, Simon and Caulder (11) advanced a hypothesis that the formation of the coralloid structure was caused by the physical effect of gas generation within the structure during charging periods. Later, in 1975, they (12) modified this hypothesis, suggesting that the coralloid structure was not the result of gas action.

Our observations suggest that gas action is a major factor governing the development of the coralloid structure. With or without gas action, active material is bound to

Fig. 14. The dendritic growth around a grid wire in a plate being cycled to failure.

consolidate under deep-discharge cycling. In the initial consolidation stage, there is little contribution from gas action. Once the framework has formed, gas action becomes more important. During the charging period, especially towards its end, a large quantity of oxygen is generated, both on and inside the plate. To escape to the plate surface, the oxygen bubbles would follow the larger pores with the least resistance, and the escaping bubbles, which exert considerable pressure on the pore walls, would break off and carry out loosened particles. This may explain why the walls of bigger pores are so smooth. Furthermore, at high potential and low pH, PbO_2 may dissolve in the solution to form tetravalent ions (37, 38). The dissolved Pb^{4+} ions may be transported out of the plate and reprecipitate as a very fine PbO_2 .

Some existing walls between channels are broken down as the result of the bubble action. This is clearly shown by the microscopy. As the coralloid structure develops, pores coalesce forming bigger pores with smooth walls. As bigger pores, with dimensions larger than 50 μm , become more numerous and larger, the structure is evidently weakened, and disintegration is the final result. The gaps between the grid members and the active material, observed after prolonged cycling, may also be due to gas action.

It is generally known that by placing pressure on a plate, the cycle life of the plate is extended. Ando *et al.* (39) put a pressure of 40 kg/dm^2 on their plates with active material of low apparent density and achieved a lifetime of 1000 cycles (75% DOD at 5h rate). It is possible that pressure on the active material impedes the formation and growth of the large pores caused by gas action and thereby delays deterioration of the active material.

In summary, although gas generation does not initially create the coralloid structure, it plays an important role in its evolution and, finally, its destruction.

Density of active materials.—Dittman and Sams (40) found the apparent density of positive active material always decreases during service, especially if it is subjected to deep-discharge cycling. Fleischmann (36), using the water uptake and displacement method, found that the solid portion of a fully charged positive active material had a "true" density of $7.8 \pm 0.6 \text{ g}/\text{cm}^3$. By using gas pycnometry, he got a higher value, $8.5 \pm 0.4 \text{ g}/\text{cm}^3$. Micka *et al.* (41) measured the active material density in cycled positive plates pycnometrically in toluene, and obtained a mean value of $8.65 \text{ g}/\text{cm}^3$. Since these values are less than that for PbO_2 of $9.37 \text{ g}/\text{cm}^3$ (42), they postulated the existence of amorphous lead dioxide. More recently, Constable *et al.* (26), employing x-ray diffractometry, claimed to have found an increase in amorphous material after cycling and they suggested that this amorphous lead dioxide was electrochemically inactive.

In this work, using the water method, we also found that the active material expanded with cycling. The apparent density decreased with cycling (Table I), as the pore volume increased. The calculated true density also declined with cycling. For Grenox plates this density was $9.2 \text{ g}/\text{cm}^3$ in the as-formed plate and decreased to about $7.7 \text{ g}/\text{cm}^3$ after 50 cycles. The corresponding values for Fume Litharge plates were 8.8 and $7.3 \text{ g}/\text{cm}^3$. The data obtained by mercury porosimetry (Table I) were in very good agreement with those from the water method. The density of the active material from the failed Grenox plate was $5.4 \text{ g}/\text{cm}^3$ (126 cycles) and that with Fume Litharge $6.8 \text{ g}/\text{cm}^3$ (102 cycles). These data cannot be accounted for by the PbSO_4 content. Even in failed plates, the PbO_2 content determined titrimetrically was 92%-95%. Microscopy, both optical and electron, had also failed to reveal any appreciable amount of PbSO_4 crystals, which are usually easy to detect.

The existence of amorphous PbO_2 , the density of which is very low, and the hypothesis that the amount of this amorphous phase increases with cycling are not supported by microscopy or x-ray diffractometry. SEM microscopy showed that at the beginning of the cycling test

the crystal size was not uniform. The outlines of a large amount of the primary particles could not be clearly defined (at up to 10,000 \times magnification). As the cycling progressed, the crystal sizes became larger and more uniform. In the failed plates, the crystals were clearly seen to be polyhedral and had a diameter ranging from 0.2 to 0.5 μm (Fig. 13). X-ray diffractometry showed that the lines for α - and β - PbO_2 in the as-formed plates were broad, indicating small crystal size and/or crystals with defective structure, *i.e.*, lattice distortions. As the cycling proceeded, the α - PbO_2 / β - PbO_2 ratio became smaller, and the lines for both of them narrower, indicating higher crystallinity and/or larger crystal size. This was consistent with the evidence provided by the microscopy.

The evidence from x-ray diffractometry and other measurements suggests that the amount of amorphous PbO_2 (or crystals with lattice distortions) also decreases with cycling and may practically disappear within 24 cycles. Meanwhile, the coralloid structure is forming and developing with cycling. Within the lobes and branches of this structure, the pores become smaller, and the tortuosity factor larger. Consequently, it becomes difficult for mercury (at less than 60,000 psi, *i.e.*, $4.14 \times 10^6 \text{ kPa}$) and water (1 atm, *i.e.*, 101 kPa) to fill up all the micropores. Therefore, the measured density of the active material gradually decreases with cycling. The gas is able to penetrate all the pores, no matter how small they are. Therefore, the values obtained by gas pycnometry are higher than those obtained by mercury and water methods. In addition, there may be noncommunicating pores in the active material, which will lower the measured density.

Cause of failure of positive active material.—The loss of active material through sludging has been suggested as the reason for loss of capacity. Ikari and Yoshizawa (43) have shown that the loss of capacity exactly parallels the loss of active material due to sludging. The microscopy done in this investigation revealed that, in the first couple of cycles, the active material in the center of the plate, which constituted nearly 1/3 of the total, did not take part in the cycling. In later cycles, active material in this part did participate, as the outlying active material consolidated and opened up the plate. This did not increase the plate capacity, because unfavorable structural changes took place in the outlying active material and lowered its dischargeability. This means that the loss of at least 1/4 of the amount of active material (under the experimental conditions) should not have caused a loss in capacity, although the two may have occurred in parallel because of the structural degradation.

It has also been assumed that the loss of capacity is related to a decrease in total surface area due to consolidation of active material in cycling (17). This explanation of capacity loss is not borne out by our experimental data. The as-formed Grenox plate had a surface area of $2.6 \text{ m}^2/\text{g}$. After one cycle, the surface area increased markedly, to $3.7 \text{ m}^2/\text{g}$. Correspondingly, the capacity did not increase; actually, it decreased. In the 24-cycle plate, the surface area was found to be $2.9 \text{ m}^2/\text{g}$, but the capacity at that cycle was higher than in the previous cycles. The surface area remained at $3.0 \text{ m}^2/\text{g}$ for the rest of the cycling. Even plate failure did not reduce the surface area. Similarly, with Fume Litharge plates, there appeared to be no simple correlation between surface area and discharge capacity. The results from this work suggest that not only is a large surface area needed for the discharge process, but an appropriate surface area distribution is also necessary.

After all the active material has been transformed into the coralloid structure, the capacity declines at a higher rate. The enlargement of the pores on further cycling promotes electrolyte communication between the bulk and the lobe surfaces and the enlarged pores themselves are able to store more electrolyte. This, however, creates an optimum condition for deposits of PbSO_4 at the opening of the micropores. In a discharge, the sulfate ions in a micropore are quickly consumed, and the acidity in the pore is lowered, which in turn increases the solubility of

PbSO₄ and produces a higher Pb²⁺ concentration in the micropore. However, outside of the micropore, the acid concentration is still high, owing to the large diameters of the interlobar channels. This results in a fast deposition of PbSO₄ at the pore openings (44, 45) and consequent blocking of the pores. An alternative hypothesis is that advanced by Winsel *et al.* (46), who proposed that if the pores are very small, the reaction product PbSO₄ will fill the pores completely, thus limiting the discharge capacity. This is in accordance with our microscopic observation that in a discharged plate, on the walls of pores with a diameter larger than 50 μm, fewer and smaller PbSO₄ crystals were present. Furthermore, in a discharged plate, there were lobes and branches surrounded by light colored PbSO₄ crystals, but the cores still remained unconverted PbO₂. All the above appears to support the hypothesis that the loss of capacity is caused by the formation and development of the coralloid structure. The plates prepared from Fume Litharge had a higher initial capacity than those from Grenox. However, coralloid structure formed and developed in the former at a much higher rate, which caused a higher rate of capacity loss and a shorter cycle life.

Recently, some researchers have found that when plates were cycled towards failure, there was a buildup of PbSO₄ crystals around the grid member. This was found in plates of Pb-Sb grids (33, 47) and in nonantimonial grids (48-50). As discussed previously, we have observed the same buildup. The evidence obtained from our investigation suggests that the buildup of PbSO₄ crystals may be the result of the development of the coralloid structure. At the beginning of cycling, the active material is evenly distributed, and the pores are small. The active material at the center of the plate does not participate in the charge-discharge process. As the cycling proceeds, the coralloid structure forms and spreads inward. As the coralloid structure ages, the active material in it becomes less available for discharge. At the same time, the structure becomes more open due to enlarged interlobar channels, making the electrolyte much more available to the active material in the inner part of the plate, which includes the active material and the corrosion product around the grid members. Thus, towards the end of a plate's cycle life, the corrosion product around a grid member and the active material around it are subjected to a discharge of increasing depth. This is indicated by the growth of dendrites around the grid members. These rings of dendrites are fully converted to PbSO₄ crystals in the discharge period. In the process, the resistance around the grid members increases and finally insulates them from the active material. This, of course, lowers the utilization of the more distant active material. The appearance of the rings of dendrites foretold, and might also have contributed to, the final failure of the plate, but it should be emphasized that they were the result of the deterioration of the active material and, therefore, not the primary cause of failure.

Optimal active material structure for high discharge capacity.—It has been shown in the previous discussion that the unusually high discharge capacity of plates prepared from Fume Litharge disappeared with the disappearance of the fine brain-coral structures in cycling. The transformation of this structure began in the active material close to the plate surface and then advanced inward with cycling. After about ten cycles, this kind of structure was eliminated from the plate and a 10% capacity loss was recorded. There was no decrease in apparent density or in surface area accompanying the decrease in capacity (Table I). Therefore, the reasons for the capacity drop must be found in the structural changes.

The pores in the fine brain-coral structure in the as-formed plate can be divided into two classes: macropores and micropores. Macropores have a diameter larger than 0.5 μm and are essential for mass transport from the plate surface to the interior of the plate. Micropores are pores with diameters smaller than 0.5 μm; most were actually

much smaller. Although the volume of the micropores is only a fraction of the total void volume, the surface area contributed by them is larger than 90% of the total.

When mass transport is not the limiting factor, discharge capacity is proportional to the second power of the internal surface of the active material (46). As the surface area in the micropores accounts for almost all the total surface area of the active material, the mass transfer to and from them is critical in maintaining the discharge process.

If we assume that the depth of discharge is 60% of the theoretical value, the volume increase due to the conversion of PbO₂ to PbSO₄ is 0.120 cm³ per gram of active material. If this were spread evenly over the surface, it would be 0.0165 μm in thickness and the diameter of the pores would decrease by 0.033 μm. This rough calculation shows that, in order to keep the mass-transport channels open, the macropores which are responsible for it should have a minimum diameter of about 0.05 μm. Smaller pores would be plugged or filled during discharge, and, consequently, the mass transport through them would cease. The discharge of a plate usually starts in the active material closer to the plate surface and proceeds inward. Generally, the active material in the outer part of the plate is discharged to a greater depth than that in the interior. Thus, to make the active material in the interior accessible to the electrolyte, the pores responsible for mass transport must have a diameter much larger than 0.05 μm: perhaps, about 0.5 μm.

In the as-formed active material, the volume of the macropores, with diameters ranging from 0.5 to 2.0 μm, was 0.10 cm³ per gram of active material. After one cycle, this dropped to 0.077 cm³/g, a 23% decrease, equivalent to a 23% decrease in the number of macropores. After 12 cycles, the fine brain-coral structure had disappeared, and the volume of the macropores with diameters ranging from 0.5 to 2.0 μm had shrunk to 0.056 cm³/g, a 44% decrease. Although there was some (0.03 cm³) increase in pores with diameters larger than 3 μm, the length of the additional bigger macropores was less than 1% that of the smaller macropores they replaced.

In the first few cycles, the major change is the transformation of the fine brain-coral structure to a fine network structure with much fewer macropores. The loss of capacity may be mainly due to the increased hindrance in mass transport from the plate surface to the active material inside. After about eight cycles, the coralloid structure started to form, and pores with diameters larger than 5 μm became more numerous. As the big pores increased in number, the mass transport between the bulk electrolyte and the active material in the core was expedited such that it was no longer a capacity limiting factor. However, as the total length of the macropores was reduced, the distance between the active material in the micropores and a macropore became longer. As their diameters were so small, the micropores could be easily plugged and filled by the discharge product PbSO₄. Therefore, later in cycling, the mass transport between macropores and the active surface in the micropores became a capacity limiting step. This is clearly illustrated by the micrographs of the as-formed active material (Fig. 5) and that of a 24-cycle plate (Fig. 9). The longest distance between any PbO₂ in the as-formed plate to the nearest macropore was about 2 μm; the corresponding distance in the 24-cycle plate was about 10 μm.

In summary, not only are pore volume and surface area important in obtaining a high discharge capacity, but pore-size distribution is of equal importance. If the former two are constant, the latter becomes the determining factor. The unusually high initial capacity of the Fume Litharge plate came from the optimal pore-size distribution. There were adequate amounts of macropores for mass transport, which would not be plugged or filled by the discharge product during discharge. Besides facilitating the communication between bulk electrolyte and the inner parts of the plate and enhancing the utilization of the active material which resided deeper in the plate, a

larger number of macropores also shortens the length of individual micropores, promoting higher utilization for the active material around the micropores.

There are two necessary conditions for obtaining a very high utilization. First, there should be a sufficient amount of micropores to provide an adequate amount of specific surface area, e.g., 3.5 m²/g, for electrochemical reactions. Secondly, the length of each micropore should be sufficiently short. In other words, there should be an adequate number of macropores per unit volume of active material to furnish an unimpeded mass transport between the bulk electrolyte and the reacting surface. Therefore, using a coarser oxide than Fume Litharge, higher utilization can also be obtained. To achieve that, a low density paste (lower than 4 g/cm³) should be prepared to provide an adequate amount of macropores. Due to the larger particle size of the oxide, the specific area might still be too low after formation, i.e., the amount of micropores may still be too small. Therefore, the utilization in the first cycle could still be low. However, the following recharge will open up the structure, generating a cellular-like network structure with a much larger micropore density, and, hence, a much larger surface area. Therefore, in the subsequent cycles, the utilization should be high (about 60% theoretical at the 5h rate). This achievement would be lost, however, in the ensuing cycles as the coralloid structure forms and develops. This hypothesis has actually been demonstrated in this laboratory.

Preparation and Open-Circuit Potentials of Silver-Intercalated 2H-TaS₂ and 1T-TiS₂

G. A. Scholz and R. F. Frindt

Physics Department, Simon Fraser University, Burnaby, British Columbia, Canada V5A 1S6

ABSTRACT

If 2H-TaS₂ or 1T-TiS₂ crystals are placed into an aqueous AgNO₃ electrolyte, a spontaneous intercalation/corrosion reaction of the host dichalcogenide is observed. The intercalation/corrosion reaction can be greatly reduced, or even eliminated, by using a dilute electrolyte or, even better, an organic solvent. The EMF of the Ag_xTaS₂/Ag⁺(glycerol)/Ag and Ag_xTiS₂/Ag⁺(glycerol)/Ag electrochemical cells are reported as a function of *x*, and the features observed are shown to correspond to the structural changes induced in the host lattice by the intercalating silver ions.

In a recent series of papers (1-7), we have reported some of the physical, structural, electronic, and optical properties observed in the Ag_xTaS₂ and Ag_xTiS₂ intercalation compounds. In this publication, we describe in detail their method of preparation and the EMF dependence of Ag_xTaS₂/Ag and Ag_xTiS₂/Ag electrochemical cells on the intercalated silver concentration.

Sample Preparation

Intercalation compounds can be prepared via thermal, electrochemical, or chemical methods. The Ag_xTaS₂ and Ag_xTiS₂ compounds have been prepared using all of these methods, depending on whichever method was more appropriate to the given experimental situation. X-ray diffraction studies (1) revealed no structural differences in the samples using the above methods of preparation.

Thermally, the intercalated dichalcogenides were prepared in a standard way (8) by placing the appropriate amounts of prereacted 2H-TaS₂ or 1T-TiS₂ and silver powders, including about 1 mg/cm³ of iodine to facilitate crystal growth, in one end of a well cleaned and evacuated 750 cm³ quartz transport tube. The tube was heated in a three zone furnace to about 1050 K, with a gradient of about 50 K in the central zone, for approximately 100h. Before removing the transport tube from the oven, it was first cooled slowly (about one day) to near 400 K. It was found that the intercalation process was severely impeded if traces of water vapor were present, and particular care in this regard was exercised. Thermally prepared Ag_xTaS₂ and Ag_xTiS₂ samples have the advantage of being homogeneously intercalated with a minimum of multiple phases.

The electrochemical intercalation cell is quite straightforward and consists of a silver anode in conjunction with either a 2H-TaS₂ or 1T-TiS₂ crystal (MCh₂) as the cathode. By completing the external circuit the anodic and cathodic half-cells

are able to proceed to give the desired net reaction

Since the EMF of the Ag/TaS₂ and Ag/TiS₂ cells is about +0.2 and +0.1V, respectively, if measured with respect to the silver anode (Ag/Ag⁺ ~ -0.8V), it implies that the intercalation half-cell (Eq. [2]) must have an EMF of about +1.0 and +0.9V, respectively. The increase in the negative free energy, which enables the intercalation reaction (Eq. [3]) to proceed spontaneously, is therefore provided by the intercalation of the silver ions into the host dichalcogenide (Eq. [2]). This is in marked contrast to other intercalation systems, such as Li/TiS₂, where it is the ionization of the lithium anode that provides the driving force for the intercalation reaction to proceed.

Uniform intercalation of the silver ions is an area of concern when the dichalcogenides are electrochemically intercalated and the use of small crystallites is a neces-

sity. It was found that crystallites up to a few millimeters in diameter and about 100 μm in thickness appear to intercalate quite well. Whereas the choice of salt used for the electrolyte fell naturally on AgNO₃, since it is one of the few soluble silver salts readily available, the solvent needs to be chosen with some care. The reason is that 2H-TaS₂ and 1T-TiS₂ will spontaneously intercalate silver by chemically reacting with the electrolyte if the solvent is aqueous. The vigor of the reaction is much more pronounced for 2H-TaS₂ than for 1T-TiS₂, and appears to be primarily controlled by both the AgNO₃ concentration and the crystal thickness. For example, after mixing about 30g of very fine 2H-TaS₂ powder with an aqueous solution saturated with AgNO₃, an extremely vigorous and exothermic reaction, during which the glass container became hot to touch, can be observed. The reaction is much less vigorous with 1T-TiS₂. After this reaction is complete, the 2H-TaS₂ and 1T-TiS₂ crystals have changed appearance from metallic looking platelets, having, respectively, a steel-blue and gold luster, to a material which, although still having the platelet shape, is now green-yellow in color and that will completely disintegrate when touched. Furthermore, the formation of some elemental sulfur and silver was observed, but sulfide odors were not noticed. Finally, in both cases it was observed that the electrolyte changed from being only slightly acidic to extremely acidic. For 2H-TaS₂, one could in addition to the above also observe the formation of a gelatinous substance which is slightly milky in color and is very likely tantalic acid, that is Ta₂O₅ · xH₂O. The creation of this hydrous pentoxide will likely correspond to the reaction shown in Eq. [4] below

The observed large decrease in the pH is strong evidence that 2H-TaS₂ undergoes a hydrolysis reaction and suggests that the similar, although less vigorous, reaction observed for 1T-TiS₂ is also a hydrolysis. After washing either of the green-yellow substances in distilled water, they changed their color to black. X-ray diffraction powder patterns revealed only a few weak lines, most of which were quite fuzzy, that did not correspond to any of the known structures, or simple variations thereof, of the silver intercalation compounds reported in previous work (1). Microprobe x-ray fluorescence analysis of the black powders were quite variable, but often indicated the presence of a large silver to tantalum or titanium ratios (in the order of 4:1). Consequently, the bulk of this new amorphous material likely corresponds to the complete decomposition of the dichalcogenides into a random mixture of a series of hydrated oxides of the transition metal along with Ag₂S plus elemental sulfur and silver (Eq. [4]).

If the aqueous AgNO₃ electrolyte is made more dilute, no vigorous reaction is observed with the dichalcogenide powders but, instead, we now find that silver intercalates. The degree of intercalation appears to be primarily controlled by the AgNO₃ concentration. For example, in a

0.1N aqueous AgNO_3 electrolyte the intercalation of silver into 2H-TaS_2 will proceed to a maximum mole fraction of $x \approx 1/3$ (i.e., $\text{Ag}_{1/3}\text{TaS}_2$) as determined from the lattice parameters (1), and for lower AgNO_3 concentrations, the degree of intercalation is correspondingly lower. If the AgNO_3 concentration is reduced to 0.1N when intercalating 1T-TiS_2 , which is generally much less reactive, no corrosion/intercalation reaction was observed. Judging from the x-ray powder patterns, the silver intercalation compounds prepared in this manner, that is by simply placing the dichalcogenide crystals into an aqueous AgNO_3 solutions, are indistinguishable from the thermally intercalated materials. Therefore, this chemical intercalation method provides a convenient means by which the host dichalcogenide can be intercalated to various degrees. This chemical intercalation of the host dichalcogenide must be accompanied by a simultaneous oxidation reaction so that a ready source of electrons is provided to balance the positive charge of the intercalating silver ions. One of the likely candidates for this oxidation reaction is the hydrolysis of the host dichalcogenide, as was readily observable when the dichalcogenides were placed into an aqueous solution saturated with AgNO_3 (Eq. [4]). In short, the chemical intercalation of the host dichalcogenide appears to be made possible by the simultaneous decomposition of part of the host crystal. In an effort to see if the effects of the self-intercalation of $\sim 1/3$ mole fraction of silver can be directly observed, an optically thin crystal of 2H-TaS_2 was observed under the microscope before and after 0.1N Ag^+ aqueous electrolyte was added. Even though the bulk of the dichalcogenide was relatively small, and a relatively large amount ($\sim 1/3$ mole fraction) of it should have corroded away (Eq. [4]), no obvious signs of corrosion (e.g., decrease in the crystal size, changes in color, dendrites, etc.) could be seen at the crystal edges where, one would think, the chemically active sites are likely to be. Therefore, since the corrosion of the host crystal is the only possible mechanism for supplying electrons to the intercalation process, it would appear that the basal planes are corroding away.

The problem of the parallel intercalation/corrosion reactions can be avoided altogether by using nonaqueous electrolytes. Although several choices for such a solvent exist, judging from experience, acetonitrile or glycerol appear to be best. Glycerol became the solvent of choice because it is much more convenient to use in practice. However, problems still exist when trying to restrict the intercalation/corrosion reactions to mole fractions below about $1/10$ for Ag_xTaS_2 unless special precautions, such as preparing the electrolyte and sample in a dry box, are taken. If any silver should precipitate and come into contact with the dichalcogenide, intercalation will of course occur. Therefore, in addition to the electrochemical cell having to be scrupulously clean and free of any reducing substances which might cause silver to precipitate, the electrolyte should also not be exposed to any intense light because of the photochemical nature of AgNO_3 . Using a solution of AgNO_3 in glycerol as electrolyte will allow the quantitative use of coulometry, as a parallel method to weighing, for measuring the intercalated mole fraction of silver ions.

In all of our work on the Ag_xTaS_2 and Ag_xTiS_2 systems, we have always used as electrolyte a solution of AgNO_3 in glycerol, which was often renewed, to avoid the corrosion/intercalation reactions described above. Furthermore, for reasons of standardization and convenience, the AgNO_3 /glycerol electrolyte was consistently made 0.1N for all measurements and crystal preparations. Note that Butz *et al.*'s (14) criticism of "massive self-intercalation" invalidating our optical measurements of the intercalation rate of silver into 2H-TaS_2 (2) is not valid because self-intercalation in 0.1N aqueous electrolyte is limited to $x < 1/3$, and it was the stage 1 front, which occurs reversibly for $x > 0.4$, that was monitored. Furthermore, as was pointed out in Ref. (2), these optical measurements were mostly performed with glycerol as the solvent.

EMF Measurements

The EMF of the $\text{Ag}_x\text{TaS}_2/\text{Ag}$ cells were determined by using thermally prepared powder samples of known composition, and by intercalating single 2H-TaS_2 crystals electrochemically. Both methods have drawbacks, but tend to be somewhat complementary. For reasons of convenience, the Ag_xTiS_2 samples for the EMF measurements were only prepared electrochemically. All EMF measurements were carried out with a PAR 173 potentiostat.

If the electrodes are thermally prepared, the EMF measurements of the $\text{Ag}_x\text{TaS}_2/\text{Ag}$ cells are sometimes hampered because the surface of the crystallites is easily contaminated with iodine, sulfur, silver, etc. Therefore, under the zero net current conditions at which EMF's are measured, various other equilibrium reactions can exist and will contribute to the net EMF. The degree to which the EMF's of the other equilibrium reactions are important is determined by the magnitude of their respective exchange current as compared to the exchange current for the equilibrium intercalation reaction. For the Ag_xTaS_2 samples, it was found by experience that whereas consistent EMF values could be obtained for thermally intercalated samples with $x \approx 1/3$, for samples with $x \geq 1/3$ the EMF's were sometimes erratic and often close to the Ag/Ag^+ potential. Closer inspection of these samples usually showed that not all of the silver had intercalated and that elemental silver was deposited on the crystal surface, thus making it possible for a large (EMF determining) Ag/Ag^+ exchange current to be established. The electrode construction for measuring the EMF of the thermally prepared powders is shown in Fig. 1. Quartz tubing was drawn to a very fine capillary at one end, the intercalated dichalcogenide powder along with a length of gold wire was inserted, tapped tight until good electrical contact resulted, and the whole assembly was then epoxied at the top for mechanical rigidity.

Electrochemically intercalated samples for EMF measurements were prepared by intercalating thin single crystals of the dichalcogenides in the standard 0.1N AgNO_3 /glycerol electrolyte, and x was determined via weighing and coulometry. The problem now often arising is that the intercalate is likely to be more concentrated at the crystal edges, as compared to the bulk, unless the sample is allowed to equilibrate properly, but this could at times take weeks at room temperature. Therefore, since the EMF of a crystal is determined by the silver ion concentration at the crystal edges, the correlation established between the total mole fraction of silver intercalated and the corresponding EMF may at times be misleading. On the other hand, a long equilibration time can cause other problems such as the corrosion/intercalation reactions initiated by water contamination. Since equilib-

Fig. 1. Cathode construction for measuring the open-circuit potential of thermally prepared Ag_xTaS_2 or Ag_xTiS_2 powders.

rium is achieved much more quickly in thin samples, we also measured the EMF of optically transparent (<2000Å thick) single-crystals which, because they could not be handled, had to be intercalated or deintercalated *in situ*. The drawback now was that the degree of intercalation was known only relatively poorly because the amount of the host dichalcogenide present could not be directly determined. In this case, the intercalated mole fraction had to be estimated via coulometry by knowing the number of coulombs passed when intercalation appeared complete, that is, x could then be assumed to be $2/3$ mole fraction [see also Ref. (6)]. For optically transparent electrodes, equilibration times at room temperature, after partial intercalation or deintercalation, was reduced from days or even weeks to a few hours. All samples were judged to be essentially in equilibrium if the EMF drift was less than about $1 \text{ mV} \cdot \text{h}^{-1}$.

Results

Ag_xTaS₂/Ag EMF.—The experimental results for the open-circuit voltage of the Ag_xTaS₂/0.1N Ag⁺(glycerol)/Ag cell as a function of x is given in Fig. 2. The voltages are measured directly against the silver anode and each data point corresponds to an individually prepared sample. Even though there is some scatter in the data, the line drawn through the data points is thought to be the best fit. Some samples had radically different EMF's, but when they were checked for uniformity of intercalation (*e.g.*, using x-ray diffraction and x-ray fluorescence) they inevitably proved to be of poor quality, or had elemental silver deposits on their surfaces. The large scatter in the data was of particular concern in region C ($1/3 \leq x \leq 1/2$) so that a series of five samples were very carefully prepared within this concentration range, and their open-circuit potentials monitored over a period of a few months. The open-circuit potentials were all initially near 40 mV, but then gradually rose to those indicated in Fig. 2 (*i.e.*, 80-120 mV) and remained constant there.

To determine the reversibility of this electrochemical cell, an optically transparent single crystal, which allows relatively rapid measurements to be made, was used as the electrode. The open-circuit voltage was measured, after resting the cell, following partial intercalation or deintercalation, and it became quickly apparent that the cell would cycle reversibly since the open-circuit voltage could be returned to above about 190 mV following complete intercalation. Considering all the structural changes involved when a Ag_xTaS₂ electrode is cycled (1), it was very surprising to discover this reversible behavior. Therefore, to verify this reversibility more completely, x-ray powder patterns were taken of part of an Ag_xTaS₂ electrode after it was completely discharged and then recharged to $x = 1/3$, $1/6$, and zero mole fractions. The resulting powder diffraction patterns confirmed the complete reversibility in the structural changes.

Ag_xTiS₂/Ag EMF.—In Fig. 3, the EMF dependence of the Ag_xTiS₂/0.1N Ag⁺(glycerol)/Ag electrochemical cell is shown as a function of x , and the voltages are again measured directly against the silver anode. The data points were all obtained using *in situ* intercalation of a series of 1T-TiS₂ single crystals which were typically about 500Å thick. There is very little random scatter in the data points compared to the Ag_xTaS₂ results and is undoubtedly a consequence of the corrosion/intercalation side reactions being only minimally present, as previously mentioned. For $0.08 \leq x \leq 0.18$ mole fractions, the line drawn in Fig. 3 to indicate the EMF dependence on x does not follow the data points closely, but is nevertheless thought to be closer to the ideal relation. The reason for this belief is that the data indicated by the squares were taken after waiting in excess of 8h for the cell to come to equilibrium, and clearly indicates that the Ag_xTiS₂ electrodes are slow in equilibrating in this concentration range. One possible explanation will be presented later.

Attempting to deintercalate the Ag_xTiS₂ electrodes immediately showed that they were only partially reversible at room temperature since it was impossible to recover an

Fig. 2. The EMF of a Ag_xTaS₂/0.1N AgNO₃, glycerol/Ag electrochemical cell as a function of x . Above the data points, the phases observed in x-ray and electron diffraction studies (1, 3) are indicated. The error bars are typical of all data points and are specifically drawn on all thermally intercalated samples.

open-circuit voltage above about 50 mV. Therefore, in contrast to the Ag_xTaS₂ electrodes, the Ag_xTiS₂ electrodes will only cycle reversibly for mole fractions above about $x = 1/5$, that is, stage 1. When the electrochemical cell was heated above about 450 K, the Ag_xTiS₂ electrode did become somewhat more reversible, and open-circuit voltages near 70 mV could be observed. However, cycling the cell at elevated temperatures enhanced the deterioration of the electrolyte, in particular silver precipitated more readily, and the cell's behavior at elevated temperatures was therefore not further pursued other than by simply noting that the cell's reversibility will improve with increasing temperature.

Discussion

Plateaus in the open-circuit voltage separated by relatively sudden decreases in the EMF are observed in both the Ag_xTaS₂ and Ag_xTiS₂ intercalation systems. These features can be attributed to the dichalcogenide cathode since the free energy of the silver anode does not change. Similar features, although less pronounced, have also been observed in other intercalation systems (9, 10). As already pointed out by Berlinsky *et al.* (11), the plateaus should signal the coexistence of two or more phases, and the relatively sudden drops in the EMF, signaling corresponding increases in the free energy of the dichalcogenide electrodes, are the free energy costs to initiate a new phase. These considerations appear to apply to the Ag_xTaS₂ and Ag_xTiS₂ intercalation systems, and there is an excellent correlation between the features in the cell EMF's and the structural changes in the host as established in our previously published x-ray and electron diffraction work (1, 3, 4). Coulomb interactions of the silver ions, viewed as a lattice gas, as discussed in Ref. (11) are probably not of any significance here because, judging by the Li_xTiS₂ system (10), their influence on the cell EMF is on a much smaller scale.

Ag_xTaS₂.—In region A of Fig. 2 the initial voltage drop signals the formation of a stage 2 Ag_{1/6}TaS₂ phase [Fig. 9

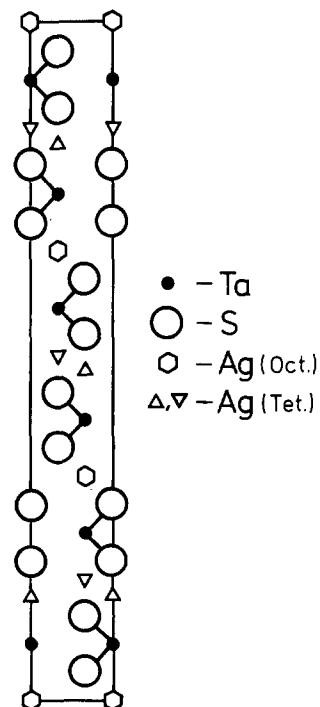

Fig. 3. The EMF of a $\text{Ag}_x\text{TiS}_2/0.1\text{N AgNO}_3$, glycerol/Ag electrochemical cell as a function of x . Above the data points are the phases determined from x-ray diffraction studies (1). The squares corresponds to data points obtained after equilibrating the electrode in excess of 8h.

in Ref. (4)] where the silver ions reside in octahedral sites with a local concentration of $x' \approx 1/3$ ($x' \approx nx$; n = stage number). It should be pointed out that so far the stacking sequence of the host layers has not changed. This stage 2 phase will grow at the expense of pure 2H-TaS₂, with increasing x , until it ideally comes to completion for $x = 1/6$. The dilute stage 1 phase (1), observed in thermally intercalated samples, is not observed and may only exist for very small concentrations, if at all, for electrochemically prepared samples as already previously observed (4). The small voltage step in the beginning of region B coincides with the appearance of $2a_0$, in addition to the $\sqrt{3}a_0$, superlattice satellites (4) and therefore suggests that some of the host layers are beginning to shift with respect to one another to form the stage 2 $\text{Ag}_{1/3}\text{TaS}_2$ phase [Fig. 4 in Ref. (1)]. This stacking rearrangement, which allows a larger local silver ion concentration ($x' \approx 2/3$) comes to completion near $x = 1/3$. As x continues to increase, stage 1 develops (1) and this is signaled by a large drop in the open-circuit voltage above $x \approx 1/3$. The large decrease indicates that a significant increase in the electrodes free energy is associated with the formation of stage 1, as might be expected. In region C, as was initially the case for stage 2, the silver ions above $x = 1/3$ are expected to reside in the octahedral sites of the empty stage 2 regions so that for $x = 1/2$ mole fraction, the idealized stage 1 structure shown in Fig. 4 may be expected, although it has not yet been confirmed. In short, the structure would be based on the $\text{Ag}_{1/3}\text{TaS}_2$ structure with, however, the octahedral sites in the empty regions now also intercalated to $x' = 1/3$ as in $\text{Ag}_{1/6}\text{TaS}_2$. There is some evidence that this structure is correct because the electron diffraction patterns in this concentration range show weak $\sqrt{3}a_0$, superlattice satellites (3) which may originate in those crystal layers similarly intercalated to those in $\text{Ag}_{1/6}\text{TaS}_2$. The especially large scatter in the data within region C, prompting the extra careful preparation of the five samples already mentioned, may in part be due to the co-existence of $\text{Ag}_{1/3}\text{TaS}_2$ and $\text{Ag}_{2/3}\text{TaS}_2$ in addition to $\text{Ag}_{1/2}\text{TaS}_2$ regions. If this is correct, it would naturally explain the tendency of the EMF's in region C to be near the $\text{Ag}_{2/3}\text{TaS}_2$ voltage plateau because this structure would be expected at the crystal edges where the sample's EMF is established. Finally, in region D the $\text{Ag}_{2/3}\text{TaS}_2$ structure

[Fig. 3 in Ref. (1)] is established and the voltage drop near $x = 1/2$ signals when the final shifting of the layers occurs (those having not yet shifted with respect to one another) in order to produce the so-called 2H-MoS₂ structure that $\text{Ag}_{2/3}\text{TaS}_2$ possesses (1).

Ag_xTiS_2 .—As can be seen in Fig. 3 for the $\text{Ag}_x\text{TiS}_2/\text{Ag}$ electrochemical cell, the variation in the open-circuit potential as a function of x is much simpler than that observed in the $\text{Ag}_x\text{TaS}_2/\text{Ag}$ cell. This is in agreement with the simpler structural changes that are observed for the Ag_xTiS_2 intercalation system (1). There are two drops in the open-circuit voltage signaling the formation of two phases, first stage 2 and then stage 1, in agreement with x-ray diffraction results (1). As was also the case for the

Fig. 4. Anticipated $\text{Ag}_{1/2}\text{TaS}_2$ stage 1 structure having $x = 1/3$ of the silver ions in the tetrahedral sites of alternative layers, and $x = 1/6$ of the silver ions in the octahedral sites of the remaining layers.

Ag_xTaS₂ system, the dilute stage 1 phase, found when the Ag_xTiS₂ samples are thermally prepared (1), is not observed in the EMF measurements of the electrochemically intercalated samples, and it appears that stage 2 coexists immediately with pure 1T-TiS₂. Then, with increasing x , the relative amount of stage 2 increases until, judging from Fig. 3, stage 2 is complete for $x \approx 0.18$. A limit of $x \approx 0.18$ for stage 2 would agree with the $x \approx 1/6$ ($x' \approx 1/3$) concentration suggested by the presence of the $\sqrt{3}a_0$ silver superlattice (12). However, it would be contrary to the x-ray work (1) which did not indicate the presence of any stage 1 material until $x \approx 1/4$ for the thermally prepared samples. This apparent discrepancy is likely associated with the different temperatures at which the samples were prepared, and, as predicted by Safran (13), formation of stage 1 is observed to be delayed to higher x for samples prepared at higher temperatures.

The irreversible intercalation of silver into 1T-TiS₂ below $x \approx 0.18$ is surprising because no structural changes, which might have large activation energies, other than a simple expansion of the host are observed up to the maximum mole fraction of $x \approx 0.42$ that we could intercalate (1). Therefore, although the cause is not clear, it would appear that this irreversible behavior may be chemical in nature.

This irreversible behavior may also explain why it is difficult to achieve equilibrium open-circuit potentials when $0.08 \leq x \leq 0.18$ (Fig. 3). Once the silver ions enter a crystal edge, thereby forming stage 2 regions (very stable), their further diffusion into the unintercalated interior crystal regions will be slow and, instead, intercalation will continue at the edges to higher concentrations including stage 1. The higher silver ion concentration at the edges, up to the creation of stage 1, will of course result in measuring a spuriously low open-circuit potential.

When increasing x above about 0.20 mole fraction, the EMF plateau results from the growth of stage 1 at the expense of stage 2 regions. Stage 1, as suggested by the $\sqrt{3}a_0$ silver superlattice (12), should ideally be complete for $x = 1/3$ ($x = 2/3$ appears unlikely). Therefore, since intercalation proceeds to 0.42 mole fraction, it will become necessary for the "excess" ions to occupy energetically less favorable sites which should decrease the cell EMF above $x = 1/3$, as can in fact be observed in Fig. 3.

Conclusions

When preparing Ag_xTaS₂ or Ag_xTiS₂ samples electrolytically using an aqueous AgNO₃ electrolyte, a spontaneous corrosion/intercalation reaction appears to occur. Even though this corrosion/intercalation process can be minimized by keeping the AgNO₃ concentration low (for 1T-TiS₂ it appears to be essentially eliminated at $\sim 0.1N$), one should not use weighing or coulometry as methods for determining the intercalated silver concentration. If an organic solvent such as glycerol or acetonitrile is used for the electrolyte, no problems should be encountered when preparing Ag_xTiS₂ samples. However, when preparing Ag_xTaS₂ samples, great care should still be ex-

ercised if x is to be determined via weighing or coulometry because, unless a dry box is used, the organic electrolyte will inevitably absorb some water.

There is good agreement in the Ag_xTaS₂ and Ag_xTiS₂ intercalation systems between changes in their structure and features in their open-circuit voltage. In the Ag_xTaS₂ system, additional phase changes, caused by stacking rearrangements, occur and are clearly evidenced by features in the cell EMF.

It is not clear why in Ag_xTiS₂ the silver ions will not deintercalate completely at room temperature, especially considering that this is the case in Ag_xTaS₂, where a series of structural changes occur. One might argue that the greater structural damage that Ag_xTaS₂ undoubtedly suffers may enhance its deintercalation process. However, this reasoning can be discounted because previous optical work (6) on thin ($\approx 1000\text{\AA}$) single crystals of Ag_xTaS₂ and Ag_xTiS₂, which do not suffer structural damage on intercalation, has also indicated that whereas the former intercalates reversibly the latter does not.

New Electrolyte Salts for Li/SOCl₂ Cells

W. L. Bowden,* J. S. Miller, D. Cubbison, and A. N. Dey*

Duracell, Incorporated, Duracell Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The high energy density electrochemical system Li/SOCl₂ has inherently good volumetric energy density and current capability. The currently used electrolytes of LiAlCl₄ and Li₂B₁₀Cl₁₀ possess objectionable features, and therefore new electrolyte salts were evaluated. Two promising electrolytes were discovered, LiGaCl₄ and Li₂O · 2GaCl₃. In SOCl₂, both salts had solubilities and conductivities similar to LiAlCl₄ at temperatures down to -30°C. Both electrolytes were evaluated in spirally wound D cells. At currents of 1A (approximately C/12) or below, the voltages and capacities were closely comparable to those recorded for LiAlCl₄. At higher currents of 3 or 4A, the gallium-based electrolytes delivered capacities as much as 60% greater than LiAlCl₄. This dramatic increase in high current capacity probably is due to reduced cathode passivation. Suggestions are made as to the cause of the increase in capacity.

The lithium/thionyl chloride cell is a high voltage, high energy density power source which has been shown to deliver energy densities around 300 Wh/lb and 1.2 Wh/cm³ (1-3). This cell consists of a lithium metal anode, a catalytic cathode (usually carbon), and an electrolyte composed of SOCl₂ with a salt to provide electrolytic conductivity. The salt provides an important function in SOCl₂ cells since it appears to affect growth of the passivating film on the anode which slows self-discharge and can introduce a start up problem "voltage delay" on extended storage (4-6). Electrolyte variables have also been found to effect cathode passivation and hence the cell capacity.

A number of salts have been used with SOCl₂ to form battery electrolytes, such as LiAlCl₄ (3) and Li₂B₁₀Cl₁₀ (7), as well as other lithium salts, such as LiBCL₄. LiAlCl₄ is both inexpensive and highly conductive, but is prone to developing a substantial voltage delay. The extremely expensive salts Li₂B₁₀Cl₁₀ and Li₂B₁₂Cl₁₂ are not so soluble and are partly oxidized in SOCl₂ solutions, although they give very good start-up performance (7).

We decided to examine other lithium salts to see if any electrolyte with attractive properties of improved performance and/or reduced voltage delay could be found. Our hypothesis was that a good electrolyte could be obtained by reacting a chloride source with a chloride acceptor. Thionyl chloride itself is weak chloride donor solvent (8). In such a solvent, an acid is a chloride acceptor, while a base is a chloride donor. With SOCl₂, we are then forming an electrolyte by reacting a strong acid with the conjugate base, Cl⁻

Thionyl chloride can also form oxygen-bound complexes with acids such as AlCl₃ (Eq. [3]) to give a product which can be isolated by distillation (9)

For reaction of Lewis acids with SOCl₂, we might then expect a variety of products, ranging from a halometallate anion to a solvent complex. Reaction of halide with LiCl would then be competitive with formation of the oxygen-bound solvent complex. This competition suggests that a stronger chloride acceptor would give the simpler solution chemistry of reaction [2] rather than a mixture of reactions [2] and [3]. For example, the weak Cl⁻ acceptor PCl₅ would be expected to react as in reaction [4], while the strong Cl⁻ acceptor SbCl₅ would be expected to react as in reaction [5]

*Electrochemical Society Active Member.

To test this hypothesis that good chloride acceptors should form useful electrolyte anions, we reacted a series of chloride acceptors with lithium bases in SOCl₂. These salts were tested in SOCl₂ cells.

The reactions above say comparatively little about the kinetic stability of the electrolyte to lithium metal, although one would expect the anion in reaction [2] to be less easily reduced than an oxo complex (reaction [3]).

Experimental

Generally, halides were used as received. GaCl₃, FeCl₃, InCl₃, PCl₅, TiCl₄, SnCl₄, and LiCl were purchased from Alfa Chemicals. Li₂O was purchased from Cerac. Lithium chloride was vacuum dried at 160°C before use. In some cases the extremely hygroscopic GaCl₃ was sublimed under vacuum before use. Sublimation appeared to have little or no effect on electrolyte appearance. Thionyl chloride (M & B) was refluxed over lithium strips under Ar and then slowly distilled through a three-foot column packed with saddles. The resulting SOCl₂ was colorless or extremely light yellow in color. Electrolyte solutions were routinely refluxed over lithium strips under Ar and filtered before use. The lithium strips were replaced if the lithium became discolored, and the reflux continued until the lithium strips stayed shiny.

Electrolyte salts were generally prepared by adding 0.5 mol of the halide to 0.5 liters of distilled thionyl chloride. To this was added (0.52 or 1.04 mol for dilithio salts) freshly dried LiCl. The solution was stirred overnight under Ar. If a substantial amount of undissolved material was present, the solution was refluxed overnight. Solutions with a substantial amount of precipitate remaining were discarded. The salt LiGaCl₄ was also prepared by a fusion technique, which gave an electrolyte with somewhat less yellow color.

LiGaCl₄.—Gallium chloride (88g), finely divided, was weighed into a clean, dry 1 liter round-bottom flask in an argon-filled glove box. To this was added freshly dried LiCl (22g) (4% excess). The flask was loosely stoppered and shaken to give a reasonably intimate mixture. The flask was then carefully warmed with a heating mantle. At about 70°C, a liquid began to form. At 97°C, the entire mixture melted to form a dark liquid. The liquid was shaken to give a homogeneous mixture and quickly cooled to give dirty gray solid. The gray color appears to be due to extremely small droplets of elemental Ga present in the GaCl₃. The resulting solid was then carefully dissolved in SOCl₂ and refluxed under Ar over Li strips to remove residual water.

Li₂O · 2GaCl₃.—Gallium chloride (88g) was dissolved in 500 ml SOCl₂. To this was added Li₂O (7.5g). The Li₂O remained solid. The mixture was refluxed under Ar for several days, with the Li₂O slowly dissolving. When solution was complete, lithium strips were added and the solution refluxed under Ar.

Conductivity measurements were taken with Genrad 1657 and 1658 Digibridge conductivity bridges with the

Fig. 1. Discharge curves of Li/SOCl₂ cells with 1.0M LiGaCl₄-SOCl₂ after 2 months storage at 25°C.

samples thermostated in Frigomix 1495 and 1496 constant temperature baths.

Test electrolytes were evaluated in spirally wound cells with hermetic glass to metal seals of conventional design. The nickel cans and tops were TIG welded. The tops had low pressure vents (9). The D cells were cathode limited by the carbon present and were of a variety of designs. The flat cells were of familiar design (12). Test cells were discharged through Kepco power supplies with data collection by strip-chart recorders.

Results

The donor and acceptor materials were mixed in SOCl₂ and stirred for several days in a closed container. A small excess of the appropriate base was used (LiCl or Li₂O). The Li₂O/GaCl₃ solution had to be refluxed before the Li₂O would dissolve. Results of these experiments are shown in Table I. Mixtures which gave a solution in SOCl₂ were first stirred and then refluxed over Li strips to remove the unreacted Lewis acid and hydrolysis products present. After these procedures were complete, the electrolytes which were obviously not compatible with lithium were eliminated. This left three electrolytes

Table I. Lewis acid-base combinations in SOCl₂

Acid	Base	Salt	Result	After Li reflux
GaCl ₃	LiCl	LiGaCl ₄	Light yellow solid	Light yellow solid

which were considered for further evaluation: LiGaCl₄, LiSbCl₆, and Li₂O · 2GaCl₃.

Spirally wound, hermetically sealed D cells were filled with 1M LiSbCl₆, 1M LiGaCl₄, and Li₂O · 2GaCl₃ electrolytes. The cells were discharged fresh and after 2 months of storage at room temperature. Discharge curves of typical cells with 1M LiGaCl₄ in SOCl₂ two months after filling are shown in Fig. 1, while discharge of typical fresh Li₂O · 2GaCl₃ cells is shown in Fig. 2. The Li₂O · 2GaCl₃ electrolyte proved extremely reactive and difficult to handle due to its extremely hygroscopic character, so testing was concentrated on cells containing LiGaCl₄. Capacities realized at lower rates were typical of those for identical LiAlCl₄/SOCl₂ cells of similar design. At the 3A (7.5 mA/cm²) rate, this was no longer true, since the LiGaCl₄ cells were substantially higher in capacity. Capacities of 11 Ah or more were realized to a 2V cutoff, where the equivalent LiAlCl₄ cell gave only 8 Ah. A capacity-rate plot for the LiGaCl₄ and LiAlCl₄ cells with 1M electrolytes is shown in Fig. 3. Figure 3 graphically shows the advantage of LiGaCl₄. Our finding of the high current capability of the LiGaCl₄ electrolyte was a bit surprising, so we built some more D cells, filled them with 1.8M electrolytes, and tested them at 4A (10 mA/cm²). On this high current, the LiAlCl₄ cell gave only 6.7 Ah, while LiGaCl₄ gave 11.0 Ah and Li₂O · 2GaCl₃ gave 10.6 Ah, a 60% improvement with the Ga electrolytes. In contrast, D cells filled with 1M LiSbCl₆ electrolyte gave very disappointing performance, with a capacity of only 1.4 Ah at 0.1A.

The LiGaCl₄ electrolyte was also tested in an extremely high rate flat cell described elsewhere (12). The cell was

Fig. 2. Performance of D cells with Li₂O · 2GaCl₃ electrolyte.

Fig. 3. Capacity-rate curve of 1M LiAlCl₄ and 1M LiGaCl₄-SOCl₂ in D cells.

tested on a pulse regime of 20 and 3.2A pulses (12), with the results shown in Fig. 4. Both the wall temperature and internal pressure were also monitored. As shown in the figure, the internal pressure rises smoothly during the discharge, in contrast to the work of Marincic *et al.* (14), where SO₂ was found to evolve only near the end of discharge in cells with SOCl₂/LiAlCl₄ electrolytes.

Even at 30 mA/cm², the 1M LiGaCl₄ electrolyte will support reasonable capacities. For a cell approximately 2/3 AA size with approximately 50 cm² electrode, discharge on a 2Ω load (approximately 30 mA/cm²) gives over 0.6h service with steady voltage, as shown in Fig. 5.

Capacity increases due to substitution of LiGaCl₄ for LiAlCl₄ can be appreciable at lower current densities as well. Comparative performances of wound AA cells with 1M LiAlCl₄ and 1M LiGaCl₄ are shown in Fig. 6. Cells with LiAlCl₄ averaged 1.31 Ah on 12.5Ω load (approximately 3.5 mA/cm²), while the cells with LiGaCl₄ delivered 1.62 Ah on identical load, a 23% improvement. Even on 3.9Ω, the wound AA cells gave 1.5 Ah. As shown in Fig. 6, the cell voltages are essentially equal for both electrolytes, while the start-up voltages are slightly lower for LiGaCl₄.

Samples of Li were stored at 72°C with 1M LiGaCl₄ in SOCl₂ and 1M LiSbCl₆ in SOCl₂. The samples stored with

Fig. 5. Discharge of 2/3AA cell with 1M LiGaCl₄ in SOCl₂ at 30 mA/cm².

LiSbCl₆ had extremely large, regular crystals covering the lithium which showed the presence of antimony on EDAX analysis. Possibly the poor performance of cells with SbCl₆⁻/SOCl₂ electrolyte is due to deposition of Sb on the Li, passivating it. Similar samples with the Ga electrolytes gave indistinct pictures with a "smudged" appearance, which allowed no careful examination of the character of the lithium film. The gallium electrolytes were extremely hygroscopic, as expected from GaCl₃ and GaOCl (15-17). Voltage delay measurements gave extraordinarily variable results, ranging from 2 min to 3V at 1A after 5 months storage at room temperatures to 45 min at 50 mA to 2V after 2 months. It is therefore clear that voltage delay in LiGaCl₄ electrolytes is irregular and may be sensitive to relatively minor details of the cell filling operation. We suspect that momentary air exposure of the cell before filling or during the filling operation may be the root of this substantial variation in anode passivation.

Conductivities of LiGaCl₄ and Li₂O · 2GaCl₃ in SOCl₂ were measured at a variety of temperatures and concentrations. Plots of conductivity *vs.* concentration at various temperatures are shown in Fig. 7 and 8. Concentration and conductance at 25°C are listed for LiGaCl₄, Li₂O · 2GaCl₃, Li₂B₁₀Cl₁₀, and LiAlCl₄ in Table II for comparison. From the data in the table it is clear that both of the GaCl₃-based electrolytes are highly conducting in SOCl₂

Fig. 4. Flat cell with 1.8M LiGaCl₄ on 20 and 3.2A pulses.

Fig. 6. Voltage vs. capacity for wound AA cells on 12.5Ω load. Al: 1M LiAlCl₄, Ga: 1M LiGaCl₄.

and show promise for evaluation in cells. Comparative conductivities at 25°C for these electrolytes are shown in Fig. 9. It should be noted that the conductivity of the Li₂O · 2GaCl₃ electrolyte is very similar to LiAlCl₄ and LiGaCl₄, while Li₂B₁₀Cl₁₀ shows rather lower limiting conductivities.

Discussion

Our original hypothesis, that extremely good chloride acceptors would give good electrolytes in the weak chloride donor SOCl₂, is clearly untenable. Of our three strong Cl⁻ acceptors, GaCl₃, FeCl₃, and SbCl₃, only GaCl₃ gave a usable electrolyte with LiCl or Li₂O. While LiGaCl₄ appears to be an excellent electrolyte for SOCl₂, cells with substantial increases (up to 60%) in delivered energy from unoptimized cell designs, the reasons for this improvement are not self-evident.

The relatively minor differences in conductivity between LiAlCl₄ and the LiGaCl₄ and Li₂Ga₂Cl₆O electrolytes are clearly inadequate to account for this increase in capacity. The D cells used in this study were "carbon limited." That is, both lithium anode and SOCl₂ catholyte were present substantially in excess of the cell capacity and the cell capacity is established by passivation of the porous carbon catalytic cathode. The low current capacities of cells with LiAlCl₄ and LiGaCl₄ are similar, so, at these relatively high rates (2.5-125h rates), self-discharge processes exert a minimal effect on cell capacity. The increase in capacity at high currents with the GaCl₃ electrolytes is therefore due to decreased cathode passivation.

Fig. 7. Conductivity of LiGaCl₄ in SOCl₂.

Fig. 8. Conductivity of Li₂O · 2GaCl₃ in SOCl₂.

This cathode passivation has been attributed to blocking pores in the porous carbon electrode by S and LiCl.

In earlier work using cyclic voltammetry, we found that an intermediate species with delayed formation of S and SO₂ was formed when SOCl₂ was reduced at platinum in a ClO₄⁻ electrolyte (19, 20). Other workers have also concluded that these sulfur oxygen intermediates are present (21, 22). Very limited data from the flat cell suggests that this intermediate(s) is not so stable in LiGaCl₄ electrolytes. We suggest that the lowered stability of these intermediates may modify sulfur generation and thus change the morphology of both S and LiCl deposition in the cathode to reduce pore blockage. This may perhaps be due to the lessened affinity of Ga(III) for O compared to Al(III) and the greater stability of GaCl₄⁻ and GaCl₃ to oxygen species compared to AlCl₄⁻ and AlCl₃.

An alternative hypothesis for the change in pattern of LiCl deposition in the cathode is the formation of a higher octahedral chloride of Ga in the reduction process [6], while the AlCl₄⁻

cannot act as a halide acceptor (reaction [7])

Even transitory existence of the species GaCl₆³⁻ would result in some Cl⁻ transport from the site of reduction. There seems little reason to suspect the reduction of Ga(III)Cl₄ to Ga₂Cl₄(Ga(I), Ga(III)Cl₄), since the greater capacity occurs at over 3V vs. Li, well above the Ga(III) reduction potential of 2.27V.

The very similar conductivity and cell performance of the electrolyte Li₂O · 2GaCl₃ to LiGaCl₄ is worth some comment. The analogous Al electrolytes LiAlCl₄ and Li₂O · 2AlCl₃ show (13, 14) differences in cell performance. The specific conductivity of Li₂O · 2AlCl₃ is reported (11, 12) at 6 × 10⁻³ Ω⁻¹ cm⁻¹. At 1A, LiAlCl₄ cells gave 8 Ah, while Li₂O · 2AlCl₃ cells of similar Li⁺ content gave only 6 Ah.

Table II. Conductivities of electrolyte salts in SOCl₂ at 25°C

Conc. (M/l)	Salt conductivity × 10 ³ Ω ⁻¹ cm ⁻¹			
	LiGaCl ₄	Li ₂ O · 2GaCl ₃	LiAlCl ₄	Li ₂ B ₁₀ Cl ₁₀

1.8	21.0		20.0	
2.0		18.9	20.0	6.7

Fig. 9. Conductivities of various Li salts in SOCl_2 at 25°C

The conductivity vs. concentration of Gabano's electrolyte is very similar to the dilithium salts $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ and $\text{Li}_2\text{B}_{12}\text{Cl}_{12}$. This lends support to the hypothesis that the $\text{Li}_2\text{O} \cdot 2\text{AlCl}_3$ species should be formulated as in reaction [8]

However, the electrolyte $\text{Li}_2\text{O} \cdot 2\text{GaCl}_3$ shows conductivity nearly superimposable on LiAlCl_4 and LiGaCl_4 , as well as performance in cells similar to LiGaCl_4 . This suggests that the dimeric formulation of the salt $\text{Li}_2\text{O} \cdot 2\text{GaCl}_3$ is incorrect.

Perhaps the Li_2O reacts with SOCl_2 to form SO_2 and LiCl (23), as has been suggested, although other possible structures can be envisioned.

Gallium oxyhalides have been reported previously, although description of their properties are contradictory (17, 18). Like GaCl_3 and LiGaCl_4 , the mixture $\text{Li}_2\text{O} \cdot 2\text{GaCl}_3$ is extremely hygroscopic. Evaporation of SOCl_2 solution of this electrolyte gave extremely hygroscopic white crystals, which reacted with atmospheric moisture too quickly for satisfactory elemental analysis.

Conclusion

Both LiGaCl_4 and the oxide salt $\text{Li}_2\text{O} \cdot 2\text{GaCl}_3$ have been shown to form high conducting electrolyte solutions in SOCl_2 . In practical cell performance tests, the Ga elec-

trolytes displayed capacities similar to other electrolytes at low rates and substantially superior capacities on high rate discharges.

ABSTRACT

Selective dissolution behavior and concomitant changes in surface composition have been elucidated by combined γ -spectrometry and ESCA studies of a passive stainless steel immersed in an artificial saliva solution. Quantitative γ -spectrometry data show that there is a selective dissolution of iron during all times of exposure. Quantitative ESCA data suggest that all expected surface accumulation of chromium occurs in the passive film formed. Under present conditions, the chromium content of the film increases with time of immersion, having its highest values at the outermost surface region and exhibiting a decrease when approaching the film/alloy interface.

The existing knowledge of passive film behavior on stainless steels is with almost no exclusion based on the use of experimental techniques which are capable of directly observing various properties of the passive film such as its thickness, structure, chemical composition, or semiconducting properties. See, for instance, Ref. (1), which is a recent review of the stainless steel surface. From these studies, it has become evident that the origin of the protective ability can be associated with an enrichment of chromium in the passive film (2, 3), the passivation presumably taking place by the formation of hydrated chromium oxy-hydroxide (4). It has been suggested that the buildup of the passive film on iron-based alloys and the possible surface accumulation of various alloying elements, such as chromium and molybdenum, is primarily due to a selective dissolution of iron during passive-state conditions (5, 6). However, in view of the importance of the concept of selective dissolution of iron, there exist only a small amount of quantitative data on dissolution rates of iron and its main alloying constituents as based on measurements of the chemical composition of the solution.

This work presents quantitative results of both passive film composition (as obtained by ESCA) and of dissolution rates of iron, chromium, and molybdenum (as obtained by γ -spectrometry) of a commercial ferritic stainless steel studied under passive-state conditions in an artificial saliva solution. The elemental release from biomaterials, such as stainless steels, in biological environments is an important property when evaluating these materials from a clinical point of view. By combining results obtained by ESCA as well as by γ -spectrometry, it has been possible to gain insight into the actual accumulation and in-depth distribution of, primarily, chromium in the investigated surface-alloy region.

Experimental

Material, sample configuration, and solution.—A ferritic stainless steel with chemical composition shown in Table I was mechanically polished to 1000 mesh on paper of silicon carbide and with distilled water as coolant. The sample configurations used in the radiochemical analysis are presented in Table II, and the composition of the artificial saliva solution used is found in Table III.

Radioactivation, exposure to solution, and γ -spectrometry measurements.—After mechanical polishing but prior

to exposure to solution, the samples were irradiated together with standards of chromium, iron, and molybdenum consisting of $\text{CrNO}_3 \times 9\text{H}_2\text{O}$, $\text{FeCl}_3 \times 6\text{H}_2\text{O}$, and MoO_2Br_2 in milligram quantities. The irradiation was accomplished at a thermal neutron flux of $5 \times 10^{12} \text{ n} \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$ for 1 day.

Each set of two samples (Table II) was exposed in 200 ml of the solution (Table III) for subsequent periods of 24.5, 48, and 24h, respectively. Thus the total period of exposure was 96.5h. In the beginning of each exposure period, fresh solutions were introduced into the vials. The solution was kept at 37°C in limited air contact resulting in a pH 5-6. The samples were under conditions of free corrosion, *i.e.*, without any external potentiostatic control.

The radiochemical analysis was accomplished by means of the following nuclides: ^{51}Cr ($t_{1/2} = 28\text{d}$), ^{59}Fe ($t_{1/2} = 46\text{d}$), and ^{99}Mo ($t_{1/2} = 67\text{h}$). The γ -ray spectrometric measurements were conducted by a multichannel analyzer, Canberra, connected to a Ge(Li) detector. The 200 ml solutions were measured for periods up to ~ 15h.

Surface analysis.—Electron spectroscopy for chemical analysis (ESCA) in a spectrometer, LH 2000, was con-

ducted for surface analysis. Immersion of the (nonactivated) ESCA samples in the artificial saliva solution was made under identical conditions as for the (activated) γ -spectrometry samples to evaluate the influence of the immersion on the chemical composition in the steel surface. Samples with dimensions $10 \times 10 \times 1$ mm for ESCA measurements were exposed together with additional steel samples in order to reach a ratio of solution-to-sample area $\approx 5 \text{ ml} \cdot \text{cm}^{-2}$ as being the ratio in the γ -spectrometry measurements. After exposure to the solution, the samples were rinsed in distilled water for a few seconds, dried in hot air, and transferred within 2 min into the vacuum chamber for ESCA measurements.

AlK α radiation was used for excitation of the photoelectrons. Cr2p $_{3/2}$, Fe2p $_{3/2}$, and Mo3d $_{5/2}$ photoelectron lines were studied. Pure iron-sputtered foils of these elements, together with naturally formed passive films on the same foils, as well as thicker (~ 20 nm) thermally grown oxides, were analyzed as standards. A quantitative evaluation of ESCA spectra was performed by measuring the signal amplitudes of photoelectron peaks and comparing them with corresponding oxide and metal peaks of the standard samples. When taking all possible sources of errors into consideration, the accuracy of the quantitative ESCA evaluation is estimated to approximately $\pm 15\%$ (6). A free mean path of 1.4 nm is assumed for both the chromium and iron photoelectrons analyzed (7). In order to somewhat alter the surface sensitivity of the ESCA method, the take-off angle of the detected photoelectrons was varied between 90° and 20° in a plane where the angle of acceptance by the electron analyzer was $\sim 10^\circ$.

Results

γ -spectrometry.—When the alloy is immersed in the electrolyte without potentiostatic control, the total dissolution rate decreases with time in a way which is representative of stainless steel in a passive state (2). Table IV gives the accumulated amount of dissolved chromium, iron, and molybdenum (in $\mu\text{g}/\text{cm}^2$) after various times of exposure in the solution. From Table IV, it is concluded that the most intensive dissolution for all investigated elements occurs during the first 24h and decreases during further exposure, suggesting that the protective ability of the steel increases as a result of changes in surface composition. In order to possibly distinguish the dissolution behavior of flat surfaces from that of sharp sample edges, the whole samples, including sharp edges, were immersed in the saliva solution during γ -spectroscopy measurements. By varying the sample geometry and hence the ratio of the total length of sharp edges to the total area of flat surfaces, it was possible to separate both contributions from each other. Although not further discussed in this work, Table IV shows the estimated accumulated amount of chromium, iron, and molybdenum (in $\mu\text{g}/\text{cm}$ sample edge) which has dissolved from sharp sample edges. The results suggest that selective dissolution also occurs from these parts of the sample but are less pronounced than from flat sample surfaces.

The selective dissolution behavior is illustrated by introducing selectivity coefficients, Z_{Cr} and Z_{Mo} , which show by how many times the ratios of chromium or molybdenum concentration to iron concentration in dissolving species differ from the same ratios in the bulk steel (6). Hence

and

$$Z_{\text{Mo}} = \frac{\left[\frac{m(\text{Mo})}{m(\text{Fe})} \right]_{\text{solution}}}{\left[\frac{m(\text{Mo})}{m(\text{Fe})} \right]_{\text{alloy}}} \quad [2]$$

with $m(\text{Cr})$, $m(\text{Fe})$, and $m(\text{Mo})$ in the solution being amounts of dissolved chromium, iron, and molybdenum in micrograms per square centimeter of exposed area and with measured values according to Table IV. The corresponding values in the alloy represent the weight content of the elements according to Table I.

Table V shows the variation in time of the selectivity coefficients both of chromium and of molybdenum and clearly indicates values significantly below 1 at all times of immersion. From the observed depletion of chromium and molybdenum detected in the solution follows an expected accumulation of the same elements in the alloy surface.

ESCA.—Figure 1 shows the observed surface content of both chromium and molybdenum after various times of immersion of the stainless steel in the solution. In accordance with γ -spectrometry results (Table V), there is observed a surface enrichment of both chromium and molybdenum which increases with time of immersion. The results in Fig. 1 for Cr/Cr + Fe and Mo/Mo + Fe atomic ratios are based on studies of the main peaks of chromium (2p $_{3/2}$), iron (2p $_{3/2}$), and molybdenum (3d $_{5/2}$) as obtained in survey ESCA spectra in which no deconvolution of metal and oxide peaks of the investigated elements could be made. Hence, atomic ratios given in Fig. 1 represent values of total surface accumulation of chromium and molybdenum, with no distinction being made of the elements in their metallic or oxidized state.

Figure 2 contains spectra of chromium (2p $_{3/2}$) and iron (2p $_{3/2}$) peaks before immersion and after 96.5h of immersion. It is possible to deconvolute these peaks into their metallic and oxidized states, as has been shown elsewhere (8). Because of too-low amplitudes, this was not possible for the Mo (3d $_{5/2}$) photoelectron peak. Quantitative evaluation of the metal and oxide peaks, respectively, yields the variation in exposure time of Cr/Cr + Fe ratios for the metallic as well as the oxidized state (Fig. 3). It can be concluded that a majority of chromium surface accu-

accumulation occurs with chromium being in the oxidized state, whereas no significant accumulation occurs with chromium being in the metal state.

Comparison of γ -spectrometry and ESCA.—In what follows, a comparison is made between the quantitative results as obtained by γ -spectrometry and by ESCA. This is done by estimating the expected number of chromium ions accumulated in the surface region according to both methods (6).

From γ -spectrometry data of accumulated amounts of dissolved chromium and iron, $m(Cr)$ and $m(Fe)$, (see Table IV for numerical values), the excess amounts of chromium $[\Delta m(Cr)]$ after various times of exposure are presented in Table VI after calculations using the formula

$$\Delta m(Cr) = \frac{0.184}{0.775} m(Fe) - m(Cr) \quad [3]$$

Here, $\Delta m(Cr)$, $m(Fe)$, and $m(Cr)$ are expressed in micrograms per centimeter, and 0.184 and 0.775 are the weight percents (w/o) of Cr and Fe in the stainless steel studied. From ESCA data, the accumulated amount of chromium

Table VI. Accumulated amounts of chromium and of molybdenum in the surface region according to γ -spectrometry

Time (h)	$\Delta m(Cr)$ ($\mu g/cm^2$)	$\Delta N(Cr)$ ($10^{15}/cm^2$)	$\Delta m(Mo)$ ($\mu g/cm^2$)	$\Delta N(Mo)$ ($10^{15}/cm^2$)
24.5	0.096	1.11	0.012	0.07
72.5	0.117	1.36	0.015	0.09
96.5	0.129	1.49	0.016	0.10

ions $[\Delta N(Cr)]$ in the alloy surface has been estimated using the formula

$$\Delta N(Cr) = (X_{Cr} - 0.20) \cdot \frac{t}{v} \quad [4]$$

Here $(X_{Cr} - 0.20)$ represents the increase in chromium surface content ($Cr/Cr + Fe$ values taken in Fig. 3) at different times of immersion relative to a $Cr/Cr + Fe$ ratio equal to 0.20, which represents the bulk value of the steel. t is the thickness of the surface layer in which accumulation of chromium occurs. v is the assumed value of the cation volume in the passive film which, according to electron diffraction data (9), has been estimated to be equal to 28 ± 3 ($nm \pm 0.1$)³; see Ref. (6) for further details. The thickness t can be estimated by a procedure outlined elsewhere (10), which uses the fact that the intensity of photoelectrons decays exponentially with depth from where they originate. Hence, Table VII presents estimated values of thicknesses and the accumulated amount of chromium after various times of exposure using the ESCA data of Fig. 1 and 3.

A comparison of the estimated accumulated number of chromium ions according to data obtained by γ -spectrometry (Table VI) and by ESCA (Table VII) shows that the estimates are close, the numbers as obtained by γ -spectrometry being slightly smaller.

Discussion

The coincidence between estimated excess surface chromium according to γ -spectrometry and ESCA is very close when considering various sources of errors which all may have an influence on the reliability of the results. Of such sources should be mentioned the procedure for quantitative evaluation of ESCA data, the separation of dissolution from sample edges and sample surfaces, respectively, and the procedure for estimating the thickness of the region with excess chromium.

The coincidence in results based on γ -spectrometry and ESCA measurements suggests that selective dissolution of iron results in changes in chemical composition of a surface layer which is thinner than the information depth of ESCA. Table VII reveals that after 3-96h of immersion the thickness of the surface layer with excess chromium is around 1.0 nm and with an average chromium content ($Cr/Cr + Fe$) slowly increasing with time of exposure from

Table VII. Thickness (t) of surface layer in which accumulation of chromium occurs, average chromium content (X_{Cr}), and amount of accumulated chromium $[N'(Cr), N(Cr)]$ in the surface layer according to ESCA. $\Delta N(Cr) = N'(Cr) - N'(Cr)_{t=0}$ is accumulation due to immersion

96.5	1.1	0.82	2.5	2.0

Fig. 4. Variation in overall chromium content, $\frac{\text{Cr}}{\text{Cr} + \text{Fe}}$, with take-off angle of photoelectrons detected.

0.7 to 0.8. Since all excess chromium is in an oxidized state (Fig. 3), it can be assumed that a majority of excess chromium is in the passive film of the stainless steel rather than in the alloy region adjacent to the film. A previous combined γ -spectrometry and ESCA study of passivated Fe18Cr and Fe18Cr3Mo alloys under potentiostatic control revealed much larger estimates of accumulated amounts of chromium according to γ -spectrometry measurements than according to ESCA measurements (6). This was interpreted as being due to an enrichment of chromium in a surface region thicker than the passive film itself. This suggests that selective dissolution of iron under potentiostatic polarization may result in a surface layer enriched in chromium which is significantly thicker than when selective dissolution of iron occurs under nonpotentiostatic conditions.

Although the results presented until now only have given the average chromium content of the passive film, it is of interest also to discuss the possible in-depth distribution of chromium within the film. For this purpose, the take-off angle of photoelectrons detected was varied by changing the orientation of the sample with respect to the entrance slit of the ESCA analyzer. With this procedure, it is possible to alter the surface sensitivity allowing the chemical composition to be studied at various depths in a nondestructive way (11).

Figure 4 illustrates the variation in overall chromium content, $\text{Cr}/\text{Cr} + \text{Fe}$, from lower surface sensitivity (high take-off angle) to higher surface sensitivity (low take-off angle). Because of too low ESCA amplitudes at take-off angles lower than 20° , the $\text{Cr}/\text{Cr} + \text{Fe}$ ratio in the outermost surface region cannot be measured; it can only be estimated from extrapolation of ratio values at higher

take-off angles. The results after 72.5h of immersion in Fig. 4 indicate that the $\text{Cr}/\text{Cr} + \text{Fe}$ ratio may approach 1.0 in the outermost surface region and decreases with depth. Similarly, the results after 3h of immersion indicate the highest $\text{Cr}/\text{Cr} + \text{Fe}$ ratio at the outermost surface region and a decrease in $\text{Cr}/\text{Cr} + \text{Fe}$ ratio towards increasing information depth (higher angles in Fig. 4).

The beneficial effect of enrichment of chromium in the passive film can be illustrated by inspecting the actual dissolution rates at various times of immersion. During the first 24h of immersion—characterized by lower chromium film contents—the total release of dissolving species was $\sim 0.49 \mu\text{g}/\text{cm}^2$ (Table VI), corresponding to an average current density of $\sim 0.03 \mu\text{A}/\text{cm}^2$, whereas during the final 24h of immersion—characterized by higher chromium film contents—the total release of dissolving species was approximately 10 times smaller (Table VI) corresponding to an average current density of $\sim 0.003 \mu\text{A}/\text{cm}^2$.

γ -spectrometry as well as ESCA data have furthermore shown that molybdenum is accumulated in the surface region of the stainless steel. However, because of too low intensities, it was not possible to deconvolute the Mo ($3d_{5/2}$) photoelectron peaks into their metallic and oxidized parts. For this reason, estimates of surface accumulation of molybdenum could only be made by γ -spectrometry; they are shown in Table VI.

Conclusions

Combined γ -spectrometry and ESCA studies of a ferritic stainless steel immersed in an artificial saliva solution under nonpotentiostatic conditions show that the observed selective dissolution of iron results in a surface enrichment of both chromium and molybdenum. After immersion times up to 96h the quantitative treatment of γ -spectrometry and ESCA data show that all accumulation of chromium occurs in the naturally formed passive film. During the same time interval, the average chromium content $\text{Cr}/\text{Cr} + \text{Fe}$ of the surface layer in which an accumulation of chromium is observed increases from around 0.3 to 0.8. The chromium content can be as high as 1.0 at the outermost surface region and decreases rapidly towards the film/alloy interface after immersion of the steel surface for a few hours in the solution.

The Characterization of Doped Iron Oxide Electrodes for the Photodissociation of Water

Stability, Optical, and Electronic Properties

J. E. Turner, M. Hendewerk,* J. Parmeter, D. Neiman, and G. A. Somorjai

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemistry, University of California, Berkeley, California 94720

ABSTRACT

A characterization of optical and electronic properties is presented for p-type (Mg-doped) and n-type (Si-doped) iron oxides used in the photoelectrolysis of water. Photocurrent *vs.* wavelength spectra for these electrodes indicate that α -Fe₂O₃ is the active optical component for both p-type and n-type materials. Band-edge locations for p-type and n-type iron oxides in sodium hydroxide aqueous solution are determined from differential capacitance measurements. The thermodynamic feasibility of the catalytic photodissociation of water without external potential is demonstrated for a short-circuited p/n diode assembly on an energy level diagram of the electrode/electrolyte interfaces. The open-circuit voltage (V_{oc}) and short-circuit current (I_{sc}) generated by the p/n assembly as a function of the intensity of laser irradiation indicate that these doped iron oxides are low mobility, high carrier density semiconductors. Photo-oxidation of water at the n-type anode is verified through oxygen detection. Gas evolution is monitored from an operating diode assembly using mass spectrometry and isotopically labeled water (H₂¹⁸O). Photocurrents from these p/n assemblies show excellent long-term stability in aqueous solution and Auger analysis of the semiconductor surfaces indicates no evidence of electrode dissolution.

The photoelectrolysis of water over semiconductors has received considerable attention as an alternative means of harnessing solar energy. Since the first report by Fujishima and Honda (1) of the photodissociation of water over TiO₂ electrodes, much of the theoretical basis for semiconductor photoelectrolysis has been developed by Gerischer (2).

To date, the photoelectrochemical generation of hydrogen and oxygen from water has been achieved in two different cell configurations. In the first, an illuminated (n-type) photoanode or (p-type) photocathode semiconductor is immersed in solution against a metal counter-electrode (3-8). In most cases, an external bias is applied between the electrodes. The second configuration, first investigated by Nozik (8), uses two illuminated semiconductors, a p-type photocathode and n-type photoanode. Such p/n assemblies have been used for water photoelectrolysis usually without an applied potential.

The majority of systems studied have required expensive single-crystal semiconducting electrodes to achieve high efficiency for solar conversion. However, several recent reports have found that transition metal oxide semiconductors may be a less costly alternative (11-15). The Mg-doped (p-type) iron oxide/Si-doped (n-type) iron oxide photochemical diode as described by recent reports from our laboratory (16) is an interesting and economical possibility.

Iron oxide satisfies most of the requirements for an excellent solar energy conversion material. It has a bandgap of 2.3 eV (17) which allows utilization of 40% of the incident solar radiation. It also exhibits excellent stability in both acidic and alkaline electrolyte solutions. Most attractively, it has been shown that in a short-circuited configuration, a Mg-doped p-type iron oxide cathode against a Si-doped n-type anode can photodissociate water with no applied external bias (16).

In this work, an electronic and optical characterization of the Mg-doped and Si-doped iron oxide electrodes is described. The photocurrent response was obtained as a function of wavelength. Depletion layer capacitance measurements were carried out to determine band-edge locations, carrier types and concentrations. The open-circuit voltage and short-circuit current were measured as a function of light intensity. The catalytic production of oxygen was detected using labeled water (H₂¹⁸O). In addition, we present advances in the operation and stability of the p/n diode assembly.

Experimental

Preparation of doped iron oxide electrodes.—The procedure for preparing p-type and n-type doped iron oxide electrodes has been presented in detail previously (16). Powders of MgO or SiO₂ are mixed with a α -Fe₂O₃ to produce p-type or n-type doped iron oxide semiconductors, respectively. These mixed powders are pressed into pellets, sintered, and rapidly cooled in water. Finally, the doped iron oxide disks are mounted on a conductive backing of silver epoxy.

Characterization of both Mg- and Si-doped electrodes with scanning electron microscopy (SEM) and scanning auger microprobe (SAM) showed the surfaces to be heterogeneous with several phases (16). Silicon-doped samples showed some diffusion of the silicon into the Fe₂O₃ matrix, and also the presence of silicon-rich precipitates. Magnesium-doped samples showed Mg in an iron oxide matrix, as well as MgO. It is evident from these results, as well as measurements of carrier density presented later, that only a small proportion of either dopant atom actually enters the iron oxide lattice substitutionally.

Photocurrent spectra.—Quantum efficiencies of these doped polycrystalline iron oxides were measured individually as a function of wavelength over the range 300 < λ < 700 nm. Photocurrent spectra were determined at several different electrode biases using a 500W tungsten halogen source, Heath monochromator, and a Pine RDE potentiostat. Correcting for the spectral output of the lamp/monochromator assembly, absolute quantum efficiencies were obtained using a Gamma Scientific 2000 Telephotometer and calibrated thermopile detector. Tests were performed in 0.01N NaOH on undoped samples as well as those doped with Mg or Si.

Depletion layer capacitance measurements.—To determine band-edge locations, capacitances of the space charge layer (C_{sc}) of each semiconductor electrode were determined as a function of applied voltage for both the p-type and n-type electrodes. The electrode configuration consisted of a standard three-electrode electrochemical cell containing a mercury oxide reference electrode, a platinum counterelectrode, and a doped iron oxide anode or cathode immersed in 0.01N NaOH solution. An ac voltage (amplitude 10 mV) with frequency 300 Hz < f < 3 kHz was superposed on the dc voltage applied to the working electrode from a Pine RDE potentiostat. Tests were performed both in the dark and under illumination of 35 mW/cm² intensity focused from a tungsten-halogen

*Electrochemical Society Student Member.

lamp. Depletion layer capacitances were extracted from the phase shift of the ac current out relative to the ac voltage in by use of a PAR Model 124A lock-in amplifier. Corrections were included to eliminate phase shifts introduced by the potentiostat and line impedances.

Open-circuit voltage (V_{oc}) and short-circuit current (I_{sc}).—Two important parameters of the operating p-type/n-type iron oxide assembly are the open-circuit voltage generated by the diode (V_{oc}) and the short-circuit current (I_{sc}). To investigate electron/hole production in these materials, V_{oc} and I_{sc} were measured as a function of the illumination intensity from a CW Kr⁺ laser (Spectra Physics). Iron oxide electrodes containing 10 atomic percent (a/o) Si and 5 a/o Mg were immersed in 0.01N NaOH and either separated by a high impedance voltmeter or connected through an ammeter. The laser supplied several discrete wavelengths centered at approximately 411 nm (violet) and 544 nm (green). Using a lens assembly and beam splitter, the single 1.5 mm diam beam was defocused to illuminate the entire surface of both electrodes with uniform intensity. The total intensity of illumination could be varied from 20 mW to 4W covering two electrodes of ~0.6 cm² area each.

Oxygen detection from the unbiased p/n diode assembly.—To detect the production of oxygen from the unbiased p-type/n-type iron oxide assembly, a stainless steel cell (Fig. 1) was used with two quartz windows for the simultaneous illumination of both iron oxide electrodes. Tungsten-halogen illumination of approximately 5 mW/cm² intensity was focused with quartz optics and passed through a 5 cm water filter to absorb IR radiation before entering the cell. A 0.01N NaOH/H₂O solution containing 6% isotopically enriched H₂¹⁸O (Alpha Ventron Distributors) was used as the electrolyte solution. Gases produced from the water dissociation process were circulated with a small mechanical pump in a closed stainless steel loop containing Ar carrier gas which passed over the electrolyte solution. Gas samples were extracted from the loop at 24h intervals and injected into a UHV chamber for mass spectral analysis. Photoproduced oxygen was detected as ³⁴O₂.

Results and Discussion

Photocurrent spectra.—Ferric oxide (α -Fe₂O₃) is known to be an intrinsic n-type semiconductor (17) with an indirect bandgap of approximately 2.3 eV. Since the electrodes as fabricated were shown to be multiphase, it was important to establish that the active optical component is in fact α -Fe₂O₃.

The quantum efficiency, η , defined as the number of chemically active electron/hole pairs produced per incident photon, was measured as a function of wavelength over the visible range. Figure 2 shows these results for

undoped Fe₂O₃ (Fig. 2a), silicon-doped (Fig. 2b), and magnesium-doped (Fig. 2c) electrodes.

Quantum efficiencies for undoped α -Fe₂O₃ were measured as photoanodic currents at a bias of 1250 mV RHE, yielding a maximum of $\eta = 0.03$ at 3800Å. A decrease in this efficiency at higher wavelengths occurs near the Fe₂O₃ bandgap of approximately 5500Å. Since the absorption coefficient for Fe₂O₃ increases with decreasing wavelength over the visible range, shorter wavelengths produce electron/hole pairs near the surface of the semiconductor. We believe that surface defects in this near surface region increase electron/hole recombination and result in the low quantum efficiencies observed at the lowest wavelengths.

The addition of Si is believed to enhance the n-type behavior of Fe₂O₃ by improving the electron mobility in this semiconductor (18). As seen in Fig. 2b, the addition of 10% Si in Fe₂O₃ resulted in a ten-fold increase in quantum efficiency over undoped samples for the same electrode bias (1250 mV, RHE). In separate measurements, the operating potential of an unbiased p/n assembly was found to be 750 mV, RHE. To determine the characteristics of the individual electrodes in this configuration, photocurrent spectra were measured at this bias. As seen from Fig. 2b, the n-type spectral features remain essentially the same at 750 mV, RHE as at 1250 mV, RHE, while quantum efficiencies at a given wavelength are reduced by greater than an order of magnitude. This behavior is expected since the 750 mV bias results in a lesser degree of band bending and increased electron/hole recombination.

Similar measurements on the Mg-doped samples (Fig. 2c) showed photocathodic currents (indicative of p-type behavior). Despite the change in sign of the photocurrent, the spectral features of the Mg-doped Fe₂O₃ were similar to the Si-doped and undoped Fe₂O₃ electrodes. For a bias of 750 mV, RHE (the operating potential of the assembly) the p-type iron oxide yielded a maximum quantum efficiency of $\eta = 5 \times 10^{-3}$ at 3800Å. By changing the bias to 250 mV, RHE, band bending near the electrode surface was increased by 500 mV, and quantum efficiencies were enhanced by a factor of five.

From the near bandgap region of these plots, one can determine the nature of electron/hole production in these materials (19). For a direct gap semiconductor

$$I_{ph} \propto (A/h\nu) (h\nu - E_g)^{1/2} \quad [1]$$

while for an indirect gap semiconductor

$$I_{ph} \propto (A/h\nu) (h\nu - E_g)^2 \quad [2]$$

where I_{ph} is the photocurrent, $h\nu$ is the energy of illumination, E_g is the bandgap, and A is a constant dependent upon applied bias.

Fig. 1. Schematic diagram of the apparatus for oxygen detection from the operating p/n diode assembly.

Fig. 2. Quantum efficiency vs. wavelength plots for (a, left) undoped Fe_2O_3 , (b, middle) 10% Si in Fe_2O_3 , and (c, right) 5% Mg in Fe_2O_3

Following these arguments, the data of Fig. 2b and 2c at 1250 mV bias are replotted in Fig. 3 as $(I_{ph}h\nu)^{1/2}$ vs. $h\nu$. The linear fit near the band edge confirms that both Mg- and Si-doped Fe_2O_3 are indirect bandgap semiconductors. In addition, the intercepts with the photon energy axis yield bandgaps of approximately 2.3 eV for both p-type and n-type materials. These values agree well with published values for the bandgap of undoped Fe_2O_3 (17), indicating that $\alpha\text{-Fe}_2\text{O}_3$ is most likely the photoelectrochemically active phase in these multiphase materials.

Differential capacitance measurements.—Previously, we reported the photodissociation of water in an unbiased p-type/n-type iron oxide assembly (16). In this assembly, the Mg-doped (p-type) electrode acted as a photo-

cathode and the Si-doped electrode acted as a photoanode for the generation of H_2 and O_2 from water. The spontaneous occurrence of both processes under illumination is thermodynamically feasible only with the proper positioning of the conduction and valence band-edges with respect to the redox couples in the electrolyte solution. To establish band-edge locations for the doped iron oxides, space charge capacitances of these electrodes were determined.

Differential capacitances of the semiconductor space charge layer (C_{sc}) with applied potential (V_a) were measured independently for both the p-type and n-type electrodes. Following the Mott-Schottky relation (20, 21)

$$1/C_{sc}^2 = 2(q\epsilon\epsilon_0 A^2 N)^{-1}(V_a - V_{FB}) \quad [3]$$

flatband potentials (V_{FB}) were extracted from the intercept on a plot of the reciprocal capacitance squared ($1/C_{sc}^2$) against applied voltage (V_a). Typical Mott-Schottky plots are shown in Fig. 4. These measurements were performed at 1500 Hz on a 10 a/o Si-doped and 5 a/o Mg-doped iron oxide electrode. All potentials are given relative to the reversible hydrogen electrode (RHE) which shifts 59 mV/pH unit, so that the hydrogen redox couple remains at 0.0V, RHE and the oxygen redox couple at 1.23V, RHE, independent of the pH of the electrolyte solution.

From these plots, the flatband potentials for the n-type and p-type electrodes are 200 and 2300 mV, RHE, respectively. Similar capacitance measurements performed over the frequency range 300 Hz $< f <$ 3000 Hz showed no shift in flatband potential. In addition, measurements made in the darkness and under illumination showed no appreciable variation within the accuracy of the measurement (± 200 mV).

In addition to values of the flatband potential, donor or acceptor concentrations, N , can be obtained from the Mott-Schottky plots of Fig. 4. The slope of the linear region in which relation [3] is obeyed is given by $S = 2(q\epsilon\epsilon_0 A^2 N)^{-1}$ where q is the charge on an electron, ϵ_0 is the permittivity of free space, ϵ is the dielectric constant for the sample, A is the electrode surface area, and N is the donor or acceptor concentration. Surfaces of the doped iron oxide electrodes have a roughness factor of approximately ten as measured in a krypton-helium BET apparatus (22) (Quantasorb Surface Area Analyzer, Quantachrome Corporation). From the value of $A = 6 \text{ cm}^2$ and the dielectric constant for pure $\alpha\text{-Fe}_2\text{O}_3$ ($\epsilon = 100$) (23), the acceptor or donor concentrations are calculated to be $N_A = 5 \times 10^{16} \text{ cm}^{-3}$ for the Mg-doped samples and $N_D = 2 \times 10^{18} \text{ cm}^{-3}$ for the Si-doped electrodes. Due to uncertainties in the dielectric constants for the doped iron oxides and in surface area determinations, carrier densities are correct only to within an order of magnitude.

Fig. 3. Plots of $(I_{ph}h\nu)^{1/2}$ vs. $h\nu$ over the near bandgap region for (a, top) 10% Si in Fe_2O_3 , and (b, bottom) 5% Mg in Fe_2O_3 . The linear fit of this function suggests that both Si- and Mg-doped Fe_2O_3 are indirect bandgap semiconductors, with bandgaps of approximately 2.3 eV.

Fig. 4. Mott-Schottky plots of the inverse square of space charge capacitance $(1/C_{sc})^2$ vs. applied potential (V_a) for (a, top) 10% Si in Fe_2O_3 and (b, bottom) 5% Mg in Fe_2O_3 electrodes. Performed at 1500 Hz frequency in 0.01N NaOH against a Pt counterelectrode.

Homogeneous acceptor and donor distributions in both the p-type and n-type semiconductors may produce samples with more consistent photocurrents in a p/n diode assembly. Observed curvatures in the Mott-Schottky plots may be due to inhomogeneous doping concentration (24), particularly for the p-type electrodes. Another difficulty in sample preparation is diffusion of dopant atoms into the Fe_2O_3 matrix. A comparison of carrier densities from Mott-Schottky plots with the proportion of Mg or Si in our electrodes shows that only a small amount of either dopant enters the lattice. For the p-type electrodes with 5 a/o Mg, only about 0.002% of the Mg atoms enter the iron oxide lattice substitutionally. The vast majority of the Mg probably remains in its original oxide form (MgO). Similar calculations for the n-type electrodes show that only 0.05% of the Si contributes to donor levels. As mentioned earlier, SAM has shown that much of the Si aggregates in silicon rich precipitates, particularly at the surface (2). Thus, it might be beneficial to explore

alternative methods of incorporating ions into the iron oxide lattice rather than sintering at high temperatures.

Energy level diagram.—To understand the energetics of a short-circuited p/n assembly, information on the flat-band potentials and bandgaps may be incorporated into an energy level diagram. Such a diagram will demonstrate both the operating principles and thermodynamic feasibility of water photodissociation by the p/n assembly.

From the Mott-Schottky plots of Fig. 4, the flatband potentials for n-type and p-type electrodes were 200 and 2300 mV, RHE, respectively. For heavily doped semiconductors, the Fermi level is nearly coincident with the band containing the majority charge carriers. Thus, in the n-type iron oxide, the flatband potential designates the location of the conduction bandedge ($E_{cb}^n \cong V_{FB}^n = 200$ mV, RHE). A measured bandgap of 2.3 eV places the valence bandedge of the n-type electrode at $E_{vb}^n = 2500$ mV, RHE. Similar arguments may be made for the p-type electrode. Equating the valence bandedge to the flatband potential of the p-type ($E_{vb}^p \cong V_{FB}^p = 2300$ mV, RHE) and subsequently subtracting the bandgap energy (2.3 eV) places the conduction band at $E_{cb}^p = 0$ mV, RHE.

To derive a complete description of the unbiased p/n assembly energetics, the Fermi level of the short-circuited assembly is also needed. This was obtained by placing a connected p-type/n-type assembly in 0.01N NaOH solution and measuring the operating potential against a mercury oxide reference electrode with a high impedance voltmeter. The Fermi level of the connected assembly was thus found to be 750 mV, RHE.

Figure 5 is a representation of the electrode/electrolyte interfaces for the connected p-type/n-type iron oxide assembly in solution. In addition to the Fermi level and bandedges, we include the energy of redox potentials for hydrogen and oxygen evolution. From this diagram, the means by which water photoelectrolysis occurs in the iron oxide p/n diode is apparent. Upon illumination of both electrodes in solution, electron/hole pairs are produced near the surface of the semiconductors. Depletion layer band bending drives minority carriers to the solution interface while majority carriers diffuse away from the surface in both p-type and n-type electrodes. Electrons at the surface of the p-type photocathode mediate the conversion of hydronium ions to hydrogen gas, while electron vacancies oxidize hydroxyl species to oxygen at the n-type photoanode.

The alignment of semiconductor bandedges relative to gas evolution redox potentials is critical. Electrons must arrive at the p-type/electrolyte interface at a potential equal to or cathodic of the H^+/H_2 redox couple. Figure 5 shows that within the accuracy of our measurements, electrons reach the solution with exactly enough energy to drive this half-reaction. Conversely, holes at the n-type

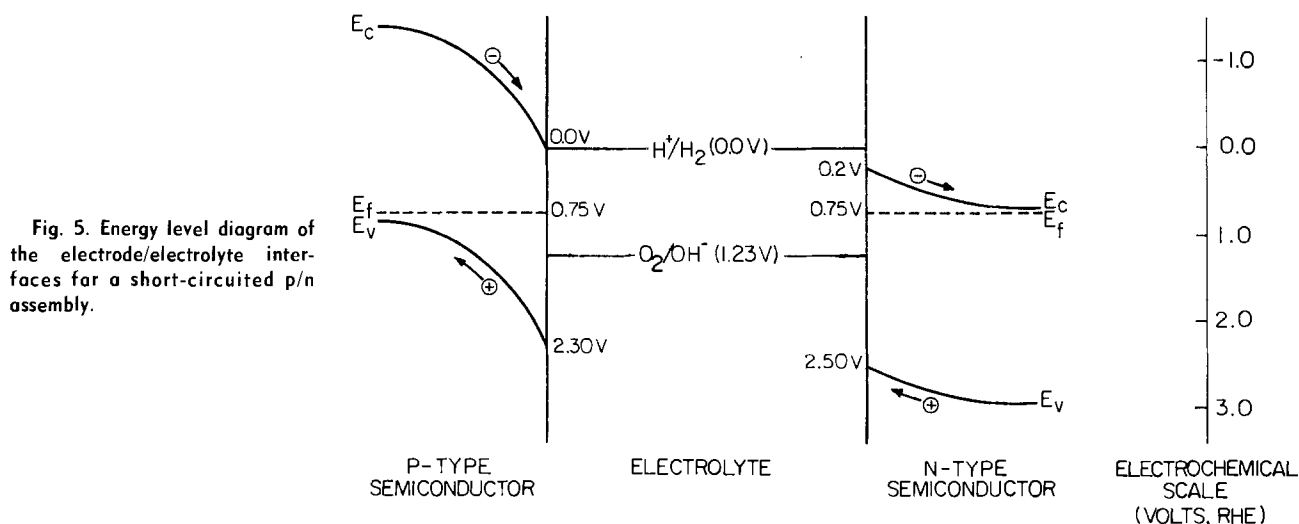

Fig. 5. Energy level diagram of the electrode/electrolyte interfaces for a short-circuited p/n assembly.

interface must arrive at a potential anodic of the O_2/OH^- half-reaction. As seen from the figure, this energy requirement is satisfied with more than 1.2 eV to spare. By meeting these basic thermodynamic criteria, it is evident that an illuminated and short-circuited p/n iron oxide assembly can photodissociate water without an external bias.

Figure 5 also shows that band-edge locations of the electrodes shift according to the dopant. The 200 mV cathodic shift of the conduction and valence bandedges of the p-type iron oxide relative to the n-type electrode may be due to the effect of introducing Mg into the iron oxide lattice. Butler and Ginley (25) have proposed a model in which the electron affinity of a composite system can be calculated using the geometric mean of the electron affinities of the constituent atoms. Thus, substitution of Mg dopant atoms ($EA = 1.2$ eV) with an electron affinity less than that of the iron atoms ($EA = 1.7$ eV) in the iron oxide lattice would lower the effective electron affinity of the semiconductor and shift the bandedges toward more cathodic potentials. Doping with Si, on the other hand, should not shift the bandedges of Fe_2O_3 since the electron affinities of silicon ($EA = 1.8$ eV) and iron are very similar.

With charge carrier concentrations from the Mott Schottky plots and band bending values (V_{bb}) from Fig. 5, depletion layer widths can also be calculated. With $W_D = (2\epsilon\epsilon_0 V_{bb}/qN)^{1/2}$, the depletion layer widths in an operating p/n assembly for the p-type and n-type electrodes are approximately 500 and 5000 Å, respectively. These results are tabulated in Table I along with a summary of flatband potentials, charge carrier concentrations, and band-edge locations for our Mg-doped and Si-doped iron oxide electrodes.

Open-circuit voltage (V_{oc}) and short-circuit current (I_{sc}) measurements.—In normal operation, the p-type/n-type iron oxide photodiode would be operated without external bias in a short-circuit configuration. As shown in the previous section (Fig. 5), pinning the Fermi levels at the same energy for p-type and n-type materials results in substantial band bending at both electrodes. Important information on electronic transport and production may be obtained, however, by allowing these Fermi levels to vary independently. The difference in the p-type and n-type electrode Fermi levels under illumination is measured as the open-circuit voltage

$$V_{oc} = E_{Fp} - E_{Fn} \quad [4]$$

In general, a positive V_{oc} under illumination indicates a spontaneous photoinduced process at one or both of the electrode/electrolyte interfaces.

Illumination of the p-type/n-type assembly in 0.01N NaOH was supplied by a CW Kr^+ laser as described earlier. Measurements of V_{oc} generated by the assembly were performed at two different wavelengths as a function of illumination intensity (I). Two important features are apparent in Fig. 6, in which the open-circuit voltage is plotted vs. $\log(I)$.

First, at a given intensity, illumination of 411 nm results in a larger open-circuit voltage than illumination by 544 nm. For example, at 100 mW intensity $V_{oc} = 290$ mV at 411 nm, while $V_{oc} = 120$ mV at 544 nm. Qualitatively, this difference may be understood in terms of the higher quan-

Fig. 6. Open-circuit voltage (V_{oc}) generated by the p/n assembly vs. illumination intensity. Performed under illumination from a CW Kr^+ laser in an electrolyte of 0.01N NaOH.

tum efficiency of photoconversion at 411 nm. Photo-induced carriers shift the Fermi levels in the p-type and n-type iron oxide apart towards their respective flatband conditions. The larger number of carriers generated at 411 nm shifts the Fermi levels to a greater degree and results in larger observed open-circuit voltages.

A second feature of interest in Fig. 6 is the linearity of the V_{oc} vs. $\log(I)$ plots. For both 411 and 544 nm illumination, the open-circuit voltage increases 118 mV per decade increase in light intensity. This behavior may be explained in terms of simple semiconductor theory. For an ideal photovoltaic device (26)

$$V_{oc} = \frac{kT}{q} \log \left(\frac{I}{I_0} + 1 \right) \quad [5]$$

where k , T , and q have their usual meanings, and I_0 is characteristic of the semiconductor material. This relation predicts that the open-circuit voltage will increase 59 mV for every decade increase in I as the semiconductor is driven toward flatband conditions. If the bandedges at a semiconductor/electrolyte interface remain fixed, this result may be generalized to a photoelectrochemical cell as well (27). Since a shift of $2 \times 59 = 118$ mV/decade is observed for the p/n assembly, the Fermi levels of the p-type and n-type iron oxide electrodes are shifting equally in opposite directions. This result confirms that Schottky barriers are present at both electrode/electrolyte interfaces, and the assembly is operating as a true p/n diode. The constant 118 mV/decade increase in V_{oc} up to very high intensities (>4 W/cm²) suggests that carrier production does not saturate for either the p-type or n-type iron oxides.

Unfortunately, the efficiency of the p/n diode is not determined only by the open-circuit voltage and the production of carriers. Instead, the actual photoconversion efficiency depends on the short-circuit current (I_{sc}), which reflects recombination losses of carriers before photoelectrolysis can take place. Figure 7 shows the current flow between the p-type and n-type electrodes as a function of laser illumination intensity. Due to a higher quantum efficiency for the violet beam (Fig. 2), larger currents are observed for 411 nm illumination than for 544 nm. Further, while the photogenerated currents are linear in photon flux for the 544 nm illumination, some saturation occurs at the higher current densities generated by the 411 nm beam.

The combined results of the open-circuit voltage and short-circuit current measurements suggest that these materials have high carrier densities and also high recombination rates. Experiments are currently underway to determine whether this recombination occurs in the bulk, at grain boundaries, or at the surface of these electrodes.

Detection of gases from the p/n assembly.—We have presented data on relevant optical and electronic properties

Table I. Values obtained from the Mott-Schottky plots and the energy level diagram

	p-Type iron oxide	n-Type iron oxide
Conduction band-edge	~0 mV	~200 mV
Valence bandedge	~2300 mV	~2500 mV
Band bending	~1550 mV	~550 mV
Majority carrier concentration	$\sim 5 \times 10^{16}$ cm ⁻³	$\sim 2 \times 10^{18}$ cm ⁻³
Depletion layer width	~5000 Å	~500 Å

Fig. 7. Short-circuit current (I_{sc}) generated by the p/n assembly vs. illumination intensity. Performed under illumination from a CW Kr^+ laser in 0.01N NaOH.

of the Mg- and Si-doped iron oxide electrodes. In addition, we have shown that upon connecting these electrodes in an unbiased short-circuit configuration, the photodissociation of water is thermodynamically feasible. In this section, evidence is presented to show that observed photocurrents correspond to gas evolution from the cell.

In previous work, hydrogen was detected by gas chromatography from an illuminated unbiased iron oxide p/n diode assembly (16). Predicted hydrogen production from integrated photocurrents correlated with detected amounts of hydrogen gas. Unfortunately, detection of oxygen by the same method was not possible due to the presence of additional sources of oxygen, both dissolved in the electrolyte solution and entering the closed loop system through small leaks. However, as described earlier, the use of isotopically labeled water ($H_2^{18}O$) and mass spectrometry has permitted the detection of photo-produced oxygen as $^{34}O_2$.

Initial analysis of the gases in the closed loop system (Fig. 1) showed no measurable traces of $^{34}O_2$. Constant illumination was provided to the cell to prevent variations in solution temperature and spurious gas production from outgassing. Instead, oxygen production was initiated by closing the circuit between the two electrodes and stopped by opening the circuit. Figure 8 shows the $^{34}O_2$ partial pressure as a function of time for a p/n assembly giving an average photocurrent of $2 \mu A$. As seen in this figure, the $^{34}O_2$ partial pressure increased during those periods in which the circuit was closed and the current was flowing. During the open-circuit intervals, the concentration of $^{34}O_2$ decreased slightly and then remained constant.

Due to leaks from the system, a direct comparison of oxygen production and integrated photocurrents was not possible. Instead, correspondence between oxygen yield and photocurrent was determined by the ratio $^{34}O_2/^{32}O_2$. Calculation of the relative oxygen ($^{34}O_2$ and $^{32}O_2$) yields involved two assumptions. First, no spontaneous water dissociation occurred, so that the oxygen initially dissolved in solution consisted only of $^{32}O_2$ and no $^{34}O_2$. Secondly, under equilibrium conditions, the ratio of $^{34}O_2/^{32}O_2$ in the gas phase above the electrolyte solution was equal to that in solution. This equilibrium was assumed to be established rapidly as compared to sampling frequency (once every 24h). The relative amounts of $^{34}O_2$ and $^{32}O_2$ produced depended on the relative probabilities of $^{18}OH^-$ and $^{16}OH^-$ oxidation at the anode. From a solution containing 6% isotopically labeled $H_2^{18}O$, the detectable concentrations of oxygen isotopes present at any time (t) were

$$[^{32}O_2] = C_0 + 0.88rt \quad [^{34}O_2] = 0.12rt$$

where r is the rate of oxygen production for all isotopes. The concentration of $^{32}O_2$ initially saturating the solution,

Fig. 8. Oxygen production from an operating p/n assembly. Mass spectrometry was used to monitor $^{34}O_2$ production from water enriched with isotopically labeled $H_2^{18}O$.

C_0 , was calculated from Henry's law to be 4×10^{18} molecules in 15 ml H_2O .

With these calculations, the observed total oxygen production showed good correspondence (within 20%) with the predicted value. After 340h of intermittent gas production, the predicted value for the ratio of $^{34}O_2/^{32}O_2$ was 0.059. The measured value was $^{34}O_2/^{32}O_2 = 0.047$.

Stability of the p/n assembly.—Other important factors governing the viability of the iron oxide p/n diode assembly for solar energy conversion are the long-term stability of the system and the catalytic nature of the photo-dissociation process. In the past, we found that the photocurrents from our iron oxide-based assemblies gradually declined over an 8h period until finally reaching zero. The iron oxide electrodes could be regenerated by purging the electrolyte solution with pure oxygen gas. Auger analysis of the poisoned electrode surfaces revealed large amounts of carbon, possibly originating from organic contaminants in the electrochemical cell or other parts of the system.

To determine if poisoning could be avoided, an active p/n diode assembly was illuminated in solution while the photocurrent from the production of H_2 and O_2 gases was monitored as a function of time. While an all-glass cell was used as in previous experiments, the use of stopcock grease was eliminated. As in all experiments reported here, conductive leads were isolated by silicon rubber sealant from the electrolyte solution prepared with doubly distilled water ($\rho > 2 \times 10^6 \Omega cm^{-1}$). In this stability test, shown in Fig. 9, no electrode poisoning was observed.

Fig. 9. Photocurrent stability for the unbiased p/n assembly. Measured at 35 mW/cm^2 illumination for two electrodes of 0.6 cm^2 area each.

At first exposure to the solution, a photocurrent of 3 μA was measured. During the succeeding 80h, the photocurrent steadily increased until it reached 15 μA . Dark currents throughout the test were $\leq 0.01 \mu\text{A}$. The p/n assembly was continuously illuminated for another 240h during which time a steady photocurrent of 15 μA persisted. Even after extended operation, no visible corrosion of the electrodes occurred. If the doped iron oxide electrodes were being reduced, operation of the p/n diode assembly for 320h at the photocurrents found here would result in the dissolution of approximately one-tenth of the electrode. However, comparison of the surface compositions of the electrodes with Auger electron spectroscopy (AES) before and after extended operation showed no change. These results support our contention that photocurrents are not a result of electrode degradation.

The 80h induction period described above is perhaps a result of a gradual modification of surface states on the electrodes. ESCA studies are underway to probe the possibility of the formation of hydroxylated intermediates or the reduction of iron in near surface layers as possible explanations.

Summary/Conclusions

The major results of this study may be summarized as follows:

1. Iron oxide powder mixed with MgO or SiO₂ and sintered at high temperatures produced semiconductors with p-type or n-type behavior, respectively.

2. Magnesium-doped electrodes show photocathodic currents at 250 mV, RHE bias with a maximum quantum efficiency of $\eta = 0.03$ for illumination at 3800Å. Silicon-doped Fe₂O₃ yields photoanodic currents with $\eta = 0.2$ at 3800Å and 1250 mV, RHE bias. Both electrodes show behavior characteristic of indirect bandgap materials with $E_g \approx 2.3 \text{ eV}$.

3. Mott-Schottky measurements were used to determine conduction and valence bandedges separately for the p-type and n-type iron oxide electrodes in 0.01N NaOH. The thermodynamic feasibility of water photodissociation is verified for the unbiased short-circuited p/n assembly.

4. Open-circuit voltage and short-circuit current generated by a p/n assembly is monitored as a function of laser illumination intensity. Results indicated that the assembly operates as a true p/n diode, and that, as fabricated, these doped iron oxides are high carrier density low mobility semiconductors.

5. Oxygen evolution is detected from an unbiased p/n assembly using a mass spectrometer and isotopically labeled water (H₂¹⁸O).

6. The assembly demonstrates excellent long-term stability and shows no decrease in photocurrents after 320h of continuous operation. Integration of the total current flux through the assembly in this test indicates that water photodissociation in this system is clearly catalytic.

The sintered and doped iron oxide photoelectrochemical diode assembly at present has a low conversion efficiency ($\eta = 0.05\%$) for solar energy to H₂ and O₂ gas. Uniformity of doping, control of the surface composition and surface states, the use of catalysts to accelerate atom recombination, and more desirable electrode configurations can all improve the degree of power conversion. Calculations using idealized models (2) indicate that power conversion efficiencies up to 7% may be attained for assemblies of this type. If the physical-chemical param-

eters currently limiting this efficiency can be understood and controlled, the doped iron oxide assembly may supply hydrogen economically in a simple passive electrochemical cell.

Film Thickness and Distribution of Electrolyte in Porous Fuel Cell Components

Joshua Mitteldorf and Gerald Wilemski*

Physical Sciences, Inc., Andover, Massachusetts 01810

ABSTRACT

The DLVO theory of liquid film stability is used to estimate the thickness of electrolyte films that may be present in molten carbonate fuel cell cathodes. Our result is $\approx 30\text{\AA}$, which is 2 orders of magnitude thinner than the values postulated in thin film models of cathode performance. We also examine carefully the thermodynamic basis of an equation governing the equilibrium of electrolyte among the different porous components of the fuel cell. We show that the validity of this equation is more general than previously recognized in that its derivation does not depend on the assumption of cylindrical or spherical pore geometry.

A molten carbonate fuel cell can be pictured as a sandwich of three distinct porous media, two electrodes and an electrolyte structure. Liquid electrolyte forms an ionic pathway between the two electrodes, but its volume is insufficient to fill the pores of all three components. How then does the electrolyte distribute itself among and within the components? Which pores are flooded; which are empty? Which pore walls are covered with liquid films, and what is the film thickness?

These questions are of interest because the electrolyte distribution affects cell performance. There are two principal effects. First, electrochemical reactions take place only where gaseous reactants have access to solid electrode and liquid electrolyte. Second, ions produced in one electrode must flow via connected liquid paths through the electrolyte structure into the opposite electrode. This conduction process may be enhanced by increasing the fraction of pore volume filled by electrolyte in each component. But in view of the first requirement, it is essential to have gas-filled volume thoroughly permeating each electrode. In practice, a compromise is reached by appropriately tailoring the pore-size distributions of the three components and by restricting the electrolyte volume to lie below the total pore volume. Electrolyte then partially fills each electrode while leaving the electrolyte structure full (or nearly so).

Based on prior work (1-3) and our own results, the following picture of the wetting physics may be constructed:

1. If the contact angle in a given component is less than 90° (as it must be for unpressurized fluid to enter the component at all), then the fluid fills all pores in that component whose diameter is smaller than a certain value D_i . Pores with larger diameters are left empty.

2. If the contact angle in any component is 0° , then all of the internal area of the component that is not flooded will be covered with thin liquid films. The film thickness δ can be estimated by equating the capillary pressure of the largest flooded pore to the disjoining pressure $\pi(\delta)$, which for given materials is a specific function of δ . The resulting equation is then solved for δ .

3. At thermodynamic equilibrium, the diameters of the largest flooded pores in the components are related (for constant ambient pressure) by

$$\gamma_1 \cos \theta_1 / D_1 = \gamma_2 \cos \theta_2 / D_2 = \dots = \gamma_i \cos \theta_i / D_i$$

where γ_i and θ_i are, respectively, the gas-liquid surface tension and contact angle of the electrolyte in the i th component, appropriate to the local gas environment.

A reasonable estimate of the volume distribution of electrolyte among the cell components can be obtained (1) using measured pore volume distribution curves and the above relationship for the D_i . This equation has been derived previously from both mechanical (2) and thermodynamic (3) considerations, but in each case idealized

cylindrical (2, 3) or spherical (3) pore geometries were assumed to simplify the analysis.

In this paper, we present a general thermodynamic derivation of this result, avoiding assumptions about pore shape, and we find a general definition for D that allows us to relate it to the pore diameter inferred from Hg-intrusion porosimetry. Our conclusion is that the diameter of the largest pores filled by electrolyte (*i.e.*, D) can be equated to the pore diameter found by porosimetry provided three conditions are met: (i) the contact angles of the wetting fluid (the electrolyte) and the nonwetting fluid (*e.g.*, Hg) are supplements, (ii) the pores of the component are sufficiently interconnected to allow both fluids to have access to all pores of each range during filling, and (iii) if (wetting) fluid films are present, they occupy negligible volume.

Besides bearing on the distribution of electrolyte, the question of film thickness also has direct implications for the electrochemical performance of a porous electrode. Therefore, we briefly consider in the next section the equilibrium thickness of molten carbonate films on a NiO substrate (the material currently used for cathodes). A more detailed presentation will be given in another article (4). Our theoretical estimate of the film thickness is $\approx 30\text{\AA}$. This is too thin for films to occupy a significant volume given typical internal electrode areas.

Following our discussion of film thickness, we develop the thermodynamics of electrolyte distribution and establish the above-noted connection with porosimetry measurements. Practical implications of our results for fuel cell design and operation will be only briefly mentioned, as many of these points have been nicely treated by Arendt (3). Also, in an earlier report (5) we used these results to analyze a limited number of fuel cell electrolyte inventory data obtained at Energy Research Corporation (6).

Estimate of Film Thickness

In this section, we estimate the maximum equilibrium thickness of molten carbonate films on NiO using the Derjaguin-Landau-Verwey-Overbeek (DLVO) theory of liquid film stability. The DLVO theory has been presented and reviewed extensively [for example, in Ref. (4, 7, 8, 9)], so we will only briefly sketch the considerations involved.

A thin liquid film can be stable on a solid surface when, relative to the bulk liquid, its chemical potential receives an additional negative contribution $\Delta\mu$. The magnitude of $\Delta\mu$ is determined by the interactions between film molecules and substrate molecules and is a function of the film thickness δ . Discussions of film stability are often made in terms of another quantity, the disjoining pressure π . The disjoining pressure can be thought of as an excess normal pressure in the film stabilizing the film from thinning. For an incompressible liquid with number density ρ , π , and $\Delta\mu$ are related by $\pi = -\rho\Delta\mu$. (The chemical potential is the derivative of the free energy with respect to number of particles N ; pressure is the negative

* Electrochemical Society Active Member

Key words: surfaces, cathode, thermodynamics, porosimetry.

derivative of the free energy with respect to volume V . Since $N = \rho V$, it follows that $\rho \Delta \mu = -\pi$.) In the DLVO theory, two contributions to π are identified: one from attractive van der Waals forces, the other from electrical double layer interactions. The two contributions are assumed to be additive.

Neglecting retardation effects, the van der Waals-London potential for a pair of atoms is $-\lambda/r^6$, where r is the distance between the atoms. It is found that the constant λ ($\approx 10^{-59}$ erg cm⁶) ranges over less than an order of magnitude for a broad range of materials. The interaction energy for the film is obtained by summing the contributions from all pairs of atoms in the film-solid system and subtracting the corresponding result for a thin liquid layer lying atop bulk liquid. For a flat film of thickness δ in contact with a semi-infinite slab, we find

$$\pi_{\text{vdw}} = A/(6\pi\delta^3) \quad [1]$$

With the atomic number densities for NiO and a 62/38 mole percent (m/o) Li/K carbonate melt and the above value of λ , the Hamaker constant A can be estimated (7, 8) to be about 1.1×10^{-12} ergs or, in more convenient units, about 7×10^6 atm (\AA)³.

Electrical double layer interactions arise when the film is thin enough to permit overlap of the ion distributions associated with the double layer at each film "surface." In a dense ionic melt, only a short-ranged, compact double layer is present. So, unless the film thickness is on the order of a few angstroms (which is not the case here), double layer interactions will not be important in an ionic melt.

A film in equilibrium with bulk liquid has adjusted its thickness until its disjoining pressure π just compensates for the mechanical pressure difference between the film and the bulk (7). For a partially-flooded porous solid, this mechanical pressure difference is due to the Laplace pressure drop across the curved meniscus of the flooded pore. Thus we have

$$\pi \approx \frac{\gamma}{R} \quad [2]$$

where γ is the liquid surface tension and R may be equated to the radius of the largest flooded pore (see next section). Typically, this radius is approximately $1 \mu\text{m}$. The surface tension of the carbonate melt is about 200 dyn/cm, hence $\pi = 2$ atm. From Eq. [1] we see that $\pi = 2$ atm corresponds to a film thickness of approximately 30\AA .

This thickness is substantially less than the values (1000-5000 \AA) used in earlier "thin film" models (10-12) of molten carbonate electrodes and assumed without physical justification. Our value of 30\AA is not very sensitive to the parameter values used to estimate it. The van der Waals contribution relies on atom densities and London potential force constants. The former are easy to evaluate and uncontroversial. The latter are also straightforward to estimate and do not vary in order of magnitude from material to material. By comparison with experiment and more accurate theory, the Hamaker approach for calculating π_{vdw} is known to be accurate to within a factor of 5. Thus, we might err, at most, by a factor of $5^{1/3}$ in estimating δ . Of greater uncertainty is what effect the ionic nature of the melt has on the van der Waals interactions. The work done to date (9) on this problem relies in part on the linearized Poisson-Boltzmann equation, and therefore would not be expected, *a priori*, to be relevant to a concentrated ionic melt. We also do not include the effects of so-called structural forces (13) that may arise from, roughly put, differences in the packing of ions in the film compared to the bulk fluid. However, because of their short range, the structural forces, if present, cannot alter the order of magnitude of our estimate.

The small estimated film thickness has two consequences for the analysis presented in the rest of this paper. First, by comparing δ with the radius of the largest flooded pore ($\approx 1 \mu\text{m}$), it is clear that films account for a negligible fraction of the pore volume occupied by elec-

trolyte. Second, the contribution of the disjoining pressure to the film surface tension is seen to be small: $\pi\delta/\gamma \approx 3 \times 10^{-3}$. Thus the film surface tension may safely be set equal to the sum of the bulk gas-liquid and solid-liquid surface tensions (14).

Equilibrium Thermodynamics of Electrolyte Distribution

The three porous components of a fuel cell are made of different materials that usually vary in their wettability by the electrolyte. They are also characterized by different pore size distributions. These two factors, the pore structure and the wettability, will determine the equilibrium electrolyte distribution among the three cell components. Electrolyte sufficient to fill some but not all of the total pore volume is infused in the cell as it is manufactured. When the cell is brought to operating temperature, the electrolyte melts and redistributes itself among and within the three components. Some pores may remain empty, some may be flooded, and others may be empty save for a thin film which coats the walls. We assume that the final electrolyte distribution will be at equilibrium, *i.e.*, that its free energy is a minimum. We then derive an equation for the equilibrium distribution by requiring that an infinitesimal volume transfer of electrolyte from any region of the cell to any other region where electrolyte is present incurs no first-order change in free energy.

Our derivation and results apply to a system with any number of porous media in contact. Although the fuel cell has three principal porous components, there are circumstances for which it may be necessary to consider more than three. For example, corrosion of originally non-porous hardware, such as a current collector, can result in a new porous component whose presence may affect the electrolyte distribution. There are also conditions, as discussed below, under which the electrolyte structure should be regarded as two components.

We treat a closed isothermal system consisting of a pure liquid phase at pressure P_i^l in each porous cell component i ($i = 1, \dots, N$) and a gas phase at pressure P_i^g in contact with the liquid in each component. The gases in contact with the two electrodes have intrinsically different compositions, and gas transport through the electrolyte structure is assumed to be negligible. In principle, the two gas streams may also be at different pressures, but this condition occurs normally only when testing for gas crossover. During routine operation, pressure differences are limited to small fluctuations in the gas supply system, but accidental upsets can lead to large imbalances.

If the electrolyte structure is partially empty, the anode and cathode sides of the structure will see different gas environments. If the variation of surface tension and contact angle with gas composition is significant, the electrolyte structure should then be treated as two components divided by a boundary surface lying wholly within the remaining flooded portion of the structure. We assume there are no connected paths of empty pores traversing the electrolyte structure.

A pressure difference exists between the gas and liquid phases because of the curvature of the gas-liquid interface in the pores. This consideration points to the Helmholtz free energy (denoted here as F) as a natural choice for describing the thermodynamics (15). The basic thermodynamics of interfacial phenomena has been developed many times [*e.g.*, by Adamson (16), Sanfeld (17), and Morrow (18)], so we proceed directly to write an expression for the free energy change dF occurring when an infinitesimal volume of liquid is redistributed among the porous components

$$dF = \sum_{i=1}^N dF_i \quad [3]$$

where, in the absence of films

$$dF_i = -P_i^g dV_i^g - P_i^l dV_i^l + \gamma_i^{lg} dA_i^{lg} + \gamma_i^{sg} dA_i^{sg} + \gamma_i^{sl} dA_i^{sl} + \mu_i^l dn_i^l \quad [4]$$

and, in the presence of films

$$dF_i = -P_i^g dV_i^g - P_i^l dV_i^l + (\gamma_i^{lg} + \gamma_i^{sl}) dA_i^{film} + \gamma_i^{sl} dA_i^{sl} + \gamma_i^{lg} dA_i^{lg} + \mu_i^l dn_i^l \quad [5]$$

Here, superscripts s, g, and l refer to the solid, gas, and liquid phases, respectively, present in each porous component. Curvature terms are absent in Eq. [4] and [5] because the Gibbs dividing surface between each pair of phases is taken to lie at the appropriate surface of tension (17). Although the entire system is closed, the number of moles of liquid n_i^l in a component may change. Thus, we include in Eq. [4] and [5] the term $\mu_i^l dn_i^l$ where μ_i is the chemical potential of the liquid. As noted above, each component is assumed to be closed to gas transfer, so terms accounting for this are absent in Eq. [4] and [5]. The PdV terms constitute the mechanical work of displacing gas and liquid volumes at their respective pressures. The γdA terms represent the work accompanying the formation of new interfacial area between the indicated phases. The γ 's are surface free energies per unit area of interface between the pair of indicated phases evaluated at the surface of tension. For fluid phases, they are commonly referred to as surface tensions. They should not be confused with specific (17) or superficial (18) surface free energies per unit area, from which they differ in (chemically) multicomponent systems. Thus, $\gamma^{lg} dA^{lg}$ is the free energy change resulting from variations in the total meniscus area within a porous component; $\gamma^{sl} dA^{sl} + \gamma^{sg} dA^{sg}$ represents the free energy change accompanying the replacement of bare solid area by wet area in flooded pores: and $(\gamma_i^{lg} + \gamma_i^{sl}) dA_i^{film} + \gamma_i^{sl} dA_i^{sl}$ denotes the free energy of forming new gas-liquid film area by withdrawing liquid from a previously filled pore. (Films, if they are present at all, are presumed to cover all surfaces in a given component that are not associated with flooded pores.) We have also assumed that the film surface tension is equal to the sum $\gamma_i^{lg} + \gamma_i^{sl}$. As discussed in the previous section, this is a good approximation.

Equations [4] and [5] can be simplified and unified by noting the following points. First, total pore volume is conserved, so that $-dV_i^g = dV_i^l = dV_i$. Next, in unfilled components new solid-liquid interface is created from an equal amount of solid-gas area, so that $dA_i^{sl} = -dA_i^{sg}$. Third, because the film thickness is much smaller than a typical radius of curvature for a pore wall, we may put $dA_i^{film} = -dA_i^{sl}$. Finally, we replace $\gamma^{sl} - \gamma^{sg}$ by means of Young's equation [14], which relates the equilibrium contact angle θ to the three γ 's.

$$\gamma^{sg} - \gamma^{sl} = \gamma^{lg} \cos \theta \quad [6]$$

If $\gamma^{lg} = \gamma^{sg} - \gamma^{sl}$, then the contact angle becomes 0° , and the formation of a film becomes energetically favorable. Upon making the indicated substitutions, we find for Eq. [4] (i.e., in the absence of films) the result

$$dF_i = (P_i^g - P_i^l) dV_i - \gamma_i^{lg} (\cos \theta_i dA_i^{sl} - dA_i^{lg}) + \mu_i^l dn_i^l \quad [7]$$

and for Eq. [5] (i.e., in the presence of films) the form

$$dF_i = (P_i^g - P_i^l) dV_i - \gamma_i^{lg} (dA_i^{sl} - dA_i^{lg}) + \mu_i^l dn_i^l \quad [8]$$

It is apparent that Eq. [8] is a special case of Eq. [7] for $\theta = 0^\circ$, which, we have remarked, is a necessary criterion for films to exist. It follows that Eq. [7] can be taken as a general result for filmed and unfilmed components.

Restricting consideration to variations such that $A_i = A_i(V_i)$, we take the incremental changes dV_i as the independent variables and rewrite Eq. [3] as

$$dF = \sum_i f_i dV_i \quad [9]$$

where

$$f_i = P_i^g - P_i^l - \gamma_i^{lg} (dA_i/dV_i) + \mu_i^l/v^l \quad [10]$$

$$dA_i/dV_i = \cos \theta_i (dA_i^{sl}/dV_i) - dA_i^{lg}/dV_i \quad [11]$$

and v^l is the molar volume of the liquid. The condition for capillary equilibrium among the porous components, filmed or unfilmed, can now be obtained by setting dF equal to zero, subject to the related constraints of constant electrolyte volume and mole number

$$0 = \sum_i dV_i = v^l \sum_i dn_i^l$$

From Eq. [9] and [10], we find

$$0 = \sum_i \mu_i^l dn_i^l - \sum_i P_i^l dV_i + \sum_i [P_i^g - \gamma_i^{lg} (dA_i/dV_i)] dV_i \quad [12]$$

At equilibrium, the chemical potential and the liquid phase pressure will be the same in each component, so, because of the volume-mole number constraint, the first two terms on the right-hand side of Eq. [12] will be zero. (Hydrostatic pressure differences are unimportant in fuel cells because of the small dimensions involved. When hydrostatic effects are big, the term $\rho^l g h_i$ must be added to the term in square brackets in Eq. [12], and the results below must be correspondingly modified; ρ^l is the liquid density, g the gravitational acceleration, and h_i the vertical distance from the level at which the pressures P_i^l are measured.)

After applying the volume constraint to the remainder of Eq. [12], we find

$$0 = \sum_{i \neq 1} \{ [P_i^g - \gamma_i^{lg} (dA_i/dV_i)] - [P_1^g - \gamma_1^{lg} (dA_1/dV_1)] \} dV_i$$

Because the remaining $N-1$ volume transfers are independent, this equation can be satisfied only when the following equality holds

$$P_1^g - \gamma_1^{lg} (dA_1/dV_1) = P_2^g - \gamma_2^{lg} (dA_2/dV_2) = \dots \quad [13]$$

Furthermore, each dF_i must separately be zero at equilibrium since an infinitesimal volume transfer wholly within a component cannot produce a change in the free energy. Thus, from Eq. [7] for a single closed component ($dn_i^l = 0$), we also have

$$P_i^g - P_i^l = \gamma_i^{lg} (dA_i/dV_i) \quad [14]$$

which is a disguised version of the Laplace equation (16) for the pressure drop across a curved interface. The quantity dA/dV defined in Eq. [11] was, in fact, shown by Gauss (19, 20) in 1830 to be equal to the curvature C^{lg} of the gas-liquid interface.

Equation [13] governs the electrolyte distribution among the porous components. Its significance can be appreciated by imagining what happens as liquid fills a porous medium. Different microscopic regions of the medium are characterized by different geometries, so that adding an infinitesimal volume of electrolyte at different points will result in different area changes, dA^{sl} and dA^{lg} . However, the liquid distributes itself in the partially filled medium, so that at equilibrium the boundary between filled and unfilled volume is a surface for which the derivative (Eq. [11]) is a constant; that is, it is a surface of constant curvature. All regions where this derivative has a value larger than that specified by Eq. [13] are full, and all regions where it has a smaller value are empty. Thus, dA/dV is a well-defined quantity (barring hysteresis effects) that characterizes the filling level of the porous medium. One may think of dA/dV as inversely proportional to an effective pore diameter; in which case small pores are flooded and large pores are empty. For example, for a solid whose pores consist of (connected) cylindrical pores of varying diameter D , we find $dA/dV = 4 \cos \theta/D$ exactly. This type of correspondence can be found for other idealized pore geometries, although the proportionality constant varies with the model.

Relation to Porosimetry: a Complementarity Theorem

Using, for example, mercury porosimetry, it is possible to measure the quantity (dA/dV) as a function of partial filling volume. In fact, under the right conditions, there

is an exact correspondence between the pore diameter D measured by porosimetry and the quantity dA/dV defined by Eq. [11]

$$\sec \theta_w (dA_w/dV_w) = dA_n^{sl}/dV_n - \sec \theta_n (dA_n^{ls}/dV_n) \equiv 4/D_1 \quad [15]$$

Furthermore, when this relationship holds, it is independent of assumptions about pore geometry. The conditions for which Eq. [15] holds are (i) that the contact angle of the wetting fluid be the supplement of the contact angle of the fluid used to measure the porosimetry curve (and hence D), (ii) that the porous material be sufficiently interconnected to allow both fluids to have access to all the pores of each size range during the filling, and (iii) that if the wetting fluid forms thin films, the films must occupy a negligible fraction of the pore volume. After using these conditions to establish the validity of Eq. [15], we will briefly discuss their applicability to molten carbonate fuel cell components.

To prove Eq. [15], consider two identical porous bodies, one partly filled with a wetting fluid (w) that has contact angle θ_w , and the other with a nonwetting fluid (n) with a contact angle $\theta_n = 180^\circ - \theta_w$. The wetting fluid will be at a pressure less than the ambient gas pressure, while the pressure in the nonwetting fluid will be greater than the gas pressure in its environs. Adjusting the pressure difference adjusts the filling level of each according to Eq. [14]. During filling, the wetting fluid will start in the small pores and work its way into the large pores, while the nonwetting fluid will first enter the large pores and eventually be forced into the small ones. For each partly filled body, there will be some pressure difference for which the fillings will be exactly complementary. That is, the wetted surface of the first sample will correspond to unwetted surface in the second, and vice versa (see Fig. 1). Furthermore, the free menisci will also be identical in shape. This is because (i) both free surfaces satisfy the "constant curvature" equation

$$|C^{lg}| = \left| \frac{1}{R_1} + \frac{1}{R_2} \right| = \text{const.}$$

where R_1 and R_2 are the principle radii of curvature at any point on the surfaces and (ii) both obey the same boundary conditions, since by assumption they meet the solid surfaces at the same angle (strictly, at supplementary angles).

For the case of 0° and 180° respective contact angles, the wetting fluid also forms films along the walls of the pores that would be filled by the nonwetting fluid—an exception to complementary filling. However, except for the case of very dilute ionic solutions, it is expected that films are only a few tens of angstroms thick (see the second section above), which makes their volume negligible for many applications, including the present one.

From the above considerations, we then have

$$dA_w^{ls}/dV_w = dA_n^{ls}/dV_n$$

and

$$dA_w^{lg}/dV_w = -dA_n^{lg}/dV_n$$

from which it follows that the equation

$$\frac{dA_w^{lg}}{dV_w} - \sec \theta_w \frac{dA_w^{ls}}{dV_w} = \frac{dA_n^{ls}}{dV_n} - \sec \theta_n \frac{dA_n^{lg}}{dV_n} \quad [16]$$

is also true, given our interconnectivity assumption.

Porosimetry curves are measured by forcing the nonwetting fluid into the sample at high pressures. The equation governing this process is Eq. [14]

$$P^g - P_n^l = \gamma_n^{lg} \cos \theta_n [dA_n^{sl}/dV_n - \sec \theta_n dA_n^{ls}/dV_n]$$

The bracketed quantity is measured by varying the pressure, but data are conventionally reported in terms of a cylindrical pore diameter D using the defining equation.

$$P^g - P_n^l = 4\gamma_n^{lg} \cos \theta_n / D \quad [17]$$

The point is that the geometric quantity (dA/dV) being

Fig. 1. Complementary filling of a pore by a wetting and a nonwetting fluid. A: Small pore filled with wetting fluid to a given level. B: Same small pore filled to complementary level with nonwetting fluid.

measured is actually the quantity that we need to solve electrolyte inventory problems. The fact that it has been reported in terms of cylindrical pore diameters via Eq. [15] and [17] has really introduced no geometric assumption, since we undo the assumption to use the data.

Thus, provided the measured pore diameters D_1 are properly interpreted, we may simplify the writing of Eq. [13] and still have an exact result

$$P_1^g - 4\gamma_1^{lg} \cos \theta_1 / D_1 = P_2^g - 4\gamma_2^{lg} \cos \theta_2 / D_2 = \dots \quad [18]$$

This equation has been obtained previously under more restrictive assumptions by Maru and Marianowski (2) and by Arendt (3), who also used constant pressure conditions.

A few comments on how well fuel cell components satisfy the three conditions governing Eq. [15] are now provided. Mercury, the most commonly used fluid in porosimetry, has a nominal contact angle of 140° on many materials. Thus, condition (i) requires that the contact angle of the wetting fluid be 40° . This is quite close to the 33° contact angle of Na/K/Li/CO₃ eutectic melt on Ni (21), a common anode material. Other fuel cell materials such as lithiated NiO (cathode) or LiAlO₂ (electrolyte structure) appear to be well wetted by molten alkali carbonates (contact angle of 0°), and, for these, condition (i) is violated. However, this mismatch in contact angles is probably not important because in the pore-size range of importance for the wetting of fuel cell components ($D < 2 \mu\text{m}$), the dA^{sl} terms of Eq. [15] should predominate.

Condition (ii) is probably the most important of the three. Judging from SEM's of cell components, large pores ($D > 2 \mu\text{m}$) are well connected, so mercury should have no trouble gaining access to all the pore volume in a monotonic fashion. However, the wetting fluid fills the smallest pores first. In a component with a broad pore-size spectrum, there should be sufficient overlap or contact between regions containing small pores to permit filling to proceed monotonically. In a component with a narrow spectrum, small pores, *i.e.*, regions in which the liquid would have a small radius of curvature, are much less likely to form a connected network. In this type of component, a liquid that cannot form a film can fill all the small pores only via the indirect and slow route of evaporation/condensation unless larger, better connected pores are also filled. So for low fill levels, condition (ii) would be violated in this component. In general, the applicability of condition (ii) will have to be decided separately for each component, taking into account specific features of its pore structure. It is likely that much more theoretical work and model construction will be necessary in order to ascertain the applicability of condition (ii) in all cases of interest.

As noted above, based on the results of the second section (above), condition (iii) appears to be satisfied for all highly concentrated electrolytes used in practice.

Summary

The equilibrium thickness of molten carbonate films in a porous NiO cathode has been estimated, and the equilibrium thermodynamics of electrolyte distribution among several porous media in contact has been developed.

In terms of the DLVO theory of liquid film stability, van der Waals forces are responsible for film formation

and double layer interactions (which are important for less concentrated electrolyte solutions) play a negligible role. Films of molten carbonate in NiO cathodes are estimated to be only $\approx 30\text{\AA}$ thick. This figure is 2 orders of magnitude too thin to contribute substantially to ionic conduction, and casts doubt on the physical basis for previous thin film models (10-12) of electrode performance that have postulated $\approx 1/2\ \mu\text{m}$ films.

The thermodynamic basis of the equilibrium distribution of bulk liquid electrolyte has been developed, and a connection has been made with porosimetry measurements. Within each porous component, small pores are flooded, and large pores are either empty or empty with filmed walls. The effective diameters of the largest filled pores in each component of a cell are mutually related as given by Eq. [18]. The analysis shows that the validity of this result is not dependent on the assumption of cylindrical (or other idealized) pore geometry. Equation [18] can be used with the porosimetry curves of the cell components to determine the equilibrium distribution of a given total electrolyte volume (1).

Properties of the Interface Between Two Immiscible Electrolytes in the Presence of Proteins

Petr Vanýsek,¹ Jonathan D. Reid, Mark A. Craven, and Richard P. Buck*

Department of Chemistry, The University of North Carolina, Chapel Hill, North Carolina, 27514

ABSTRACT

The influence of adsorbed proteins on electrochemical properties of the nitrobenzene-aqueous interface has been investigated using cyclic voltammetric and impedance techniques. Upon addition of $4\ \mu\text{g/ml}$ ovalbumin cyclic voltammetric ΔE_p values for Cs^+ transfer shifted from nearly temperature independent reversible values to more temperature-dependent irreversible values. These effects were especially pronounced at lower temperatures and suggested formation of a surface film. The cyclic voltammetry of a wide range of concentrations of bovine serum albumin (BSA) in base L/L electrolytes was also studied. Interfacial ac impedance measurements indicated an increase in diffuse layer capacitance accompanied initial BSA adsorption. At high protein concentrations, an adsorbed phase was formed which facilitates faradaic transfer of ions across an otherwise blocked interface.

The interface of two immiscible electrolytes [for reviews see Ref. (1, 2)] can be treated and experimentally investigated in ways similar to an electrode/electrolyte interface. Among many properties of the interface recently studied, the adsorption of species on the interface is of fundamental interest. Recent findings (3), showing a general effect of adsorption on irreversibility of ion transfers,

call for a more thorough investigation of adsorption properties.

Koryta *et al.* (4) studied transfer of a few ions across the interface in the presence of lecithin. Lecithin is known to form adsorbed interfacial layers. These authors carried out experiments at different temperatures and found that transfer of metallic ions across the interface was highly temperature dependent. At higher temperatures, up to 65°C , no influence of lecithin was observed. As the temperature decreased, the transfer of ions became more difficult; the interface became blocked. The change of in-

¹ On leave from J. Heyrovský Institute of Physical Chemistry and Electrochemistry, Czechoslovak Academy of Sciences, Prague, Czechoslovakia.

* Electrochemical Society Active Member.

terfacial properties, which was quite sudden at 42°C, can be related to the crystalline transition temperature of this particular lecithin.

The blocking or decreasing permeability of the interface for ion transfer results in irreversible cyclic voltammograms. These are normally characterized by an increase of the peak voltage difference (ΔE_p) from the ideal reversible value of 58 mV.

In addition, interfacial ac measurements are well-suited for revealing irreversibility and adsorption effects over a wide applied interfacial potential range (5). Cyclic voltammetry [based on Ref. (6)] and impedance measurements were used to study the influence of ovalbumin, colicine E_3 , and BSA on the nitrobenzene/aqueous interface.

Ovalbumin is a water soluble protein with molecular weight of about 45,000. The molecule consists of a simple polypeptide chain of about 400 residues, of which about half are hydrophobic (7). BSA is a water soluble protein with molecular weight of about 69,000 (7). Colicines are water soluble antibiotic proteins or polypeptides produced by a strain of *Enterobacteriaceae* (8). Colicine E_3 , used in these experiments, has a molecular weight of about 60,000.

Experimental

A custom-made four electrode potentiostat (6), based on principles described earlier (9, 10), was used for the cyclic voltammetry experiments. The experimental cell is shown in Fig. 1. Both counterelectrodes were platinum spiral wires. The aqueous phase reference electrode was Ag/AgCl wire in the aqueous base electrolyte (LiCl) solution. The reference electrode for the nitrobenzene phase was Ag/AgCl wire dipped in aqueous solution of tetrabutylammonium chloride (TBACl). This solution was in contact with a tetrabutylammonium tetraphenylborate (TBATPB) solution in nitrobenzene. This interface maintains a constant potential difference.

All routinely used chemicals were of analytical purity and were used as received. Base electrolytes for the nonaqueous phase were obtained by precipitation of suit-

able salts. TBATPB was obtained by mixing aqueous solutions of tetrabutylammonium iodide and sodium tetraphenylborate according to Ref. (11). Tetrabutylammonium dicarbollycobaltate was obtained from the Institute of Nuclear Research, Řež near Prague, Czechoslovakia. Colicines were a gift of Dr. J. Šmarda, J. E. Purkyně University, Brno, Czechoslovakia. The base electrolytes of aqueous and nonaqueous phase were brought into contact prior to measurement to bring the two phases into partition equilibrium.

Real and imaginary impedances of the L/L system were measured as previously described (5) using a Solartron 1250A frequency response analyzer interfaced with a Princeton Applied Research 173 potentiostat and a HP85A computer. Potentials were applied across the interface using the 1250A bias control. The cell, though of a somewhat different design, was principally the same as in Fig. 1. The aqueous/nitrobenzene interface of 0.18 cm² area lay in between 2 cm² Ag/AgCl electrodes connected by Pt wire to the impedance measurement system.

Results

Cyclic voltammetry.—The influence of ovalbumin on the transfer of probe Cs^+ ion was investigated using LiCl base electrolytes in water and TBATPB in nitrobenzene. CsCl was dissolved in the aqueous phase. Cyclic voltammograms were recorded at temperatures of 6° (Fig. 2), 10°, and 20°C. In the absence of ovalbumin, the transfer of Cs^+ was reversible at all temperatures according to the cyclic voltammetry, with the positive to negative peak difference being 59–62 mV.

A solution with a typical ovalbumin concentration of 4 $\mu\text{g/ml}$ in base electrolyte was used as a blank experiment to observe the influence of protein on the blocked interface. The transfer of ions of base electrolytes in the presence of ovalbumin occurred at smaller applied potentials, and narrowed the potential window of interfacial blockage by approximately 20 mV.

Upon addition of ovalbumin to the Cs^+ -containing solution (Fig. 2), the positive and negative peaks were both shifted to more extreme potentials by about 35 and 30 mV, respectively. At the same time, the peak current values decreased. The most pronounced effect on the peak-peak shift was observed at low temperatures (Fig. 3). In the course of the experiment it was possible to observe the formation of a white layer on the interface. The same effect (in absence of current) was experimentally produced on interfaces between aqueous ovalbumin solutions and other solvents (benzene, ether, chloroform,

Fig. 2. Influence of ovalbumin on the transfer of Cs^+ . A, cyclic voltammogram of base electrolytes 10^{-2} mol liter⁻¹ LiCl in water, 0.025 mol liter⁻¹ TBATPB in nitrobenzene; B, transfer of Cs^+ [$c(CsCl) = 9.2 \times 10^{-4}$ mol liter⁻¹]; and C, the same case as in B in the presence of $4 \mu\text{g ml}^{-1}$ ovalbumin in the aqueous phase. The rate of polarization was 26.3 mV s⁻¹, at temperature 6°C.

Fig. 3. The potential difference of the positive and negative peak of Cs^+ in the presence of ovalbumin as a function of temperature.

tetrachloromethane, and dichloroethane). This type of denaturation is typical for proteins and is known as a contact denaturation.

Similar experiments were done with colicine E_3 in base electrolytes of $0.01 \text{ mol liter}^{-1}$ LiCl in water and $0.017 \text{ mol liter}^{-1}$ tetrabutylammonium dicarbollycobaltate. Again, the protein in the base electrolyte alone narrowed the potential window. Addition of colicine E_3 to the systems with Cs^+ also resulted in the separation of positive and negative peaks from a reversible value of 60 mV toward 120 mV, and indicated irreversible Cs^+ transfer (Fig. 4). The degree of the shift depends on the temperature, being highest at low temperatures.

The greatest effect of both ovalbumin and colicine on the transfer of Cs^+ across the interface was observed at 6°C , the lowest usable temperature (the freezing point of the nitrobenzene solution is about 5.7°C). The character of transfer at this temperature was irreversible. The hindrance of Cs^+ transport can be explained by formation of a packed layer of insoluble peptide on the interface. Proteins are known to undergo contact denaturation when brought into contact with nitrobenzene. The denaturated protein is less soluble in water and precipitates on the interface. It is also possible that at low temperatures the denaturated protein undergoes structural rearrangements. With increasing temperature, the solubility of the deposited protein increases and diminishes the structural arrangement of the layer.

Fig. 4. Influence of colicine E_3 on the transfer of Cs^+ . A, cyclic voltammogram of the base electrolytes $0.01 \text{ mol liter}^{-1}$ LiCl in water and $0.017 \text{ mol liter}^{-1}$ tetrabutylammonium dicarbollycobaltate in nitrobenzene; B, curve of Cs^+ transfer [$c(\text{CsCl}) = 1.1 \times 10^{-3} \text{ mol liter}^{-1}$]; and C, the same case as in B, in the presence of $75 \mu\text{g ml}^{-1}$ colicine E_3 in water. The temperature was 6°C , at polarization rate 26.3 mV s^{-1} .

As described above, the precipitated protein can, due to its thickness, hinder the transfer of ions across the interface. At the same time, one can expect that the layer can be so thick that it can act as another phase with properties between those of water and nitrobenzene. An intermediate phase will thus change the ionic partition coefficients, generally narrowing the potential window of base electrolytes. At high concentrations of protein in the aqueous phase the base electrolytes lose their potential window controlling properties and the voltammetric curve becomes ohmic: a straight line indicating the current is governed by film resistance.

A set of cyclic voltammetry measurements of the base electrolytes in the presence of various BSA concentrations were obtained. The BSA concentration in aqueous phase ranged from 1 to 10,000 ppm. Figure 5 shows typical cyclic voltammograms obtained from the measurement. The width of the base electrolyte potential window decreased upon addition of the low (~ 1 ppm) amount of BSA. Upon further BSA concentration increase, the width of the base electrolyte potential window again increased. A decrease of the width was then observed upon further addition of BSA. The dependence of the potential window width on the BSA concentration is shown in Fig. 6. The width was determined as the difference between the potentials at which the base electrolyte current exceeded $90 \mu\text{A}$.

The pattern of potential width behavior strongly resembles that of the impedance measurement (5) described below.

Impedance characteristics.—Impedance characteristics of blocked and unblocked nitrobenzene/aqueous interfaces have been investigated as a function of BSA concentration and applied dc potential. Figure 7 shows the dependence of 1.0 Hz total interfacial impedance and

Fig. 5. Typical voltammetric curves in the presence of BSA. A, base electrolytes $0.1 \text{ mol liter}^{-1}$ TBATPB in nitrobenzene, $0.1 \text{ mol liter}^{-1}$ LiCl in water; B, addition of 3 ppm of BSA into the aqueous phase; and C, addition of 1% of BSA into the aqueous phase. The scan rate was 5 mV/s .

Fig. 6. The dependence of the potential window width on the BSA concentration. Base electrolytes: $0.1 \text{ mol liter}^{-1}$ LiCl in water and $0.1 \text{ mol liter}^{-1}$ TBATPB in nitrobenzene. The scan rate of the voltammogram was 5 mV/s .

Fig. 7. Dependence of 1.0 Hz total interfacial impedance (●) and phase angle (○) upon aqueous BSA concentration at applied potential of -10 mV. Phase angles at (□) -100 mV and (◇) -125 mV.

phase angle upon aqueous BSA concentration at an applied interfacial potential of -10 mV. Phase angles at -100 and -125 mV are also indicated.

The general behavior shown for -10 mV was observed between applied interfacial potentials of -70 and $+85$ mV. Note that the phase angle remains constant and near 90° up to 250 ppm BSA. This reflects nearly ideal capacitive behavior within this potential region. A constant phase angle requires that changes in total impedance correspond to proportional changes in the imaginary impedance which is inversely proportional to capacitance ($Z_i = 1/\omega C$) for a blocked interface. The decrease in total impedance up to about 10 ppm BSA therefore corresponds to an increase of the total system capacitance. As the concentration of BSA is increased beyond 10 ppm, impedances begin to increase, indicating a decrease in total capacitance.

The initial increase of capacitance is attributed to the initial adsorption of BSA (5-10 ppm) and an associated increase in interfacial charge density or dielectric constant. This effect is modeled by a capacitor in parallel with the initial double layer capacitance. Further adsorption increases the physical thickness of the interface region. The

adsorbed film may be considered as a capacitor in series with the capacitor representing increased interfacial charge density. The total interfacial capacitance of this array decreases until film thickness reaches a saturation value.

The decreasing total impedance at even higher BSA concentrations reflects facile film-solution ion transfer which was already described for the case of ovalbumin in the voltammetry section. Phase angles at -100 and -125 mV approached 45° as BSA concentrations were increased. At these potentials, where the interface is not ideally blocked, ion transfer is increasingly facilitated by further BSA additions.

Properties of the Interface of Two Immiscible Electrolytes Mediated by Molecules of Biological Importance

A Literature Review

Petr Vanýsek¹ and Richard P. Buck*

Department of Chemistry, The University of North Carolina, Chapel Hill, North Carolina, 27514

ABSTRACT

It has been shown in the past few years that the interface formed between two immiscible solutions of electrolytes can be treated, from an electrochemical point of view, in the same manner as the solution/electrode interface, and essentially the same techniques of electrochemical investigation can be used. A review of the methods pertaining to biologically important materials is given. Specifically, the following groups of experiments are treated: direct transport measurement of certain ionic species (choline, acetylcholine, and dodecylsulfate), transport of probe ions across the adsorbed material (lecithin and several proteins), impedance measurements in the presence of adsorbed bovine serum albumin, and transport across the interface facilitated by antibiotics (valinomycin and monensin).

Investigations of the electrochemical properties of interfaces between two immiscible solutions containing dissolved electrolytes have attracted an increasing number of scientists in the past years. Although the first paper dealing with this matter appeared in 1902 (1), the subject was dormant until about ten years ago when the properties of this interface were recognized to parallel those of metal/solution interfaces (2). The electrochemical phenomena of the L/L interface were reviewed quite deeply by Koryta and Vanýsek (3) in 1981. An updated version (4) and a literature review (5) have been published recently. For thorough theoretical treatments and experimental setups, the reader is referred to these works.

The purpose of this paper is to emphasize the possible advantages of the L/L electrical phenomena study for biologically important systems. The general aspect of the liquid/liquid interface is that it can serve, within certain limits, as a model for half of a biological membrane. However distant this model may be, it might prove useful. The present state-of-the-art of L/L electrochemistry of biologically important molecules is of more analytical interest.

The Basic Principle of L/L Electrochemistry

Assume the contact of two immiscible liquid phases α and β containing one common ion, i , in thermodynamic equilibrium. An interfacial potential will be established across this interface; its value is given by the Nernst-Donnan equation

$$\Delta\phi^{\alpha\rightarrow\beta} = \Delta\phi^{\circ,\alpha\rightarrow\beta} + \frac{RT}{nF} \ln \frac{a_i(\alpha)}{a_i(\beta)} \quad [1]$$

The fraction in the logarithmic function represents the partition equilibrium for ion i between the two phases. When the interfacial potential is changed from outside the system by applying a voltage from some source, the standard value $\Delta\phi^{\circ,\alpha\rightarrow\beta}$ remains constant, and, therefore, the ratio $a_i(\alpha)/a_i(\beta)$ will have to change. A portion of the equilibrated ions will be transferred to the other side of the interface, and is manifested by the passage of electric current through the interface.

The choice of nonaqueous solvents is determined by the requirement that the mutual solubility with water be limited, and the dielectric constant be quite high such that dissolved salt can be dissociated. The most commonly used solvent is nitrobenzene and, in some cases, dichloroethane is useful.

By using salts of very hydrophobic ions as a base electrolyte for nonaqueous phase and very hydrophilic ions as a base electrolyte for water, one can obtain a fairly broad potential window in which practically no faradaic

current passes through the interface. Under these conditions, the interface behaves as an ideally polarizable electrode. The typical electrolyte for water is LiCl and, for nitrobenzene, tetrabutylammonium tetraphenylborate (TBATPB) or tetraphenylarsonium tetraphenylborate (TPATPB). The potential window limits are determined by the transfer of base electrolytes. Measurements within the limits enable observation of ion transfer whose hydrophobic properties are between those of the base electrolytes. The potential at which this transfer is observed can be correlated with the standard energy and standard potential of transfer for the given ion

$$\Delta G^\circ = -RT \ln K_{w\rightarrow o}^\circ = -nF\Delta\phi_{w\rightarrow o}^\circ \quad [2]$$

Experimental Methods

L/L interfaces may be treated and investigated in manners similar to the solid electrode. Two different voltammetric methods of electrode kinetics were used for

Fig. 1. Electrolyte dropping electrode assembly. 1, aqueous electrolyte reservoir; 2, Teflon orifice attachment; 3, nitrobenzene electrolyte; 4, waste aqueous electrolyte; 5, glass frit; 6, overflow; RE₁ and RE₂, reference electrodes; and CE₁ and CE₂, counter-electrodes.

this investigation: cyclic voltammetry and polarography with a dropping electrode. The practical problem of eliminating the resistances of both phases, causing IR drops, was solved by using a four electrode potentiostat (6), preferably with a positive feedback elimination of the residual ohmic drop between the two reference electrodes (7). The potential difference across the interface was sensed by the reference electrodes, one in each phase. The electrode in the aqueous phase is an ordinary electrode of the second kind, usually Ag/AgCl. The reference electrode in the organic phase is essentially an ion selective electrode responding to the ion of the base electrolyte nonaqueous solution. It consists of an electrode of the second kind immersed in aqueous solution containing the same ion as the base electrolyte of the organic phase. Under these conditions, a reproducible (though not necessarily known) Nernst potential is established at the junction.

For polarographic studies an electrolyte dropping electrode was developed. The type with a Teflon capillary designed by Samec *et al.* (8) is shown in Fig. 1. The aqueous solution drops upward into the heavy organic phase. An improvement of the sensitivity for analytical purposes was achieved by using differential pulse stripping voltammetry in which the analytical ion is accumulated in the electrolyte hanging drop electrode (Fig. 2) (9, 10).

Chronopotentiometry, voltammetry, or impedance measurements used a cell of the type shown in Fig 3.

Impedance properties of the L/L interface are measured using an impedance bridge (11). The bridge is essentially a cross correlator which determines in-phase and 90° out-of-phase components of the response with respect to the perturbing sine wave signal.

Results

A direct study of selected ionic species of biological importance can be performed in liquid/liquid systems. Examples include choline and acetylcholine (10, 12, 13) and dodecylsulfate (14). Vanýsek and Behrendt (12) used multisweep cyclic voltammetry for the determination of standard potentials of transfer. A typical curve from this experiment is shown in Fig. 4. Mareček and Samec (10) used the hanging electrolyte dropping electrode and differential pulse stripping voltammetry (Fig. 2). The method for acetylcholine determination proved to be very sensitive. Figure 5 shows a set of differential pulse stripping voltammograms for different acetylcholine concentrations. It has also been shown that a good linear response can be obtained down to 0.5 ppm (2.75×10^{-6} mol/liter) acetylcholine. Samec *et al.* (13) used the method of convolution potential sweep voltammetry for determination of kinetic and thermodynamic parameters of cho-

Fig. 4. Voltammogram of acetylcholine transfer. 1, base electrolytes 1 mol liter⁻¹ LiCl in water and 0.025 mol liter⁻¹ TBATPB in nitrobenzene; and 2, addition of acetylcholine (1.1×10^{-2} mol liter⁻¹). The scan rate was 12.5 mV s⁻¹.

line and acetylcholine. The standard values for the dodecylsulfate were determined by the means of electrolyte dropping electrode (14). The standard values for the above ions are given in Table I.

Another group of results deals with the electrical properties of the interface in the presence of adsorbed material. The basic approach was to study the transfer of a well-characterized probe ion in the presence and absence of adsorbed species. Koryta *et al.* (15) studied voltammetric transfer of semihydrophobic ions and ionophore-facilitated alkali metal ion transfer across the water/nitrobenzene interface covered with a lecithin monolayer. The transfer processes were slowed down particularly at low (6°C) temperatures. Figure 6 shows the effect of addition of lecithin on the transfer of the Cs⁺ probe ion.

Fig. 5. Differential pulse stripping voltammetry of acetylcholine at hanging electrolyte drop electrode. The bold numbers show ppm concentrations of acetylcholine chloride in water.

Fig. 6. Cyclic voltammogram of the transfer of 5×10^{-4} mol liter $^{-1}$ Cs $^{+}$ (as CsCl) from water to nitrobenzene and back at 6°C. Base electrolytes 0.01 mol liter $^{-1}$ LiCl in water, 0.017 mol liter $^{-1}$ TBA dicarbollyl cobaltate in nitrobenzene. 1, base electrolytes only; 2, after addition of CsCl to the aqueous phase; 3, base electrolyte with the lecithin monolayer; and 4, 3 after addition of CsCl to the aqueous phase.

The alkali metal ion transfer in the presence of an ionophore, such as a crown polyether, is considerably easier than in its absence. Figure 7 shows a dependence of the difference of cyclic voltammetry peak potentials (for positive and negative currents), ΔE_p , of sodium ion in the presence of 0.5 mol liter $^{-1}$ dibenzo-18-crown-6 on temperature with a lecithin monolayer. Similar experiments were carried out with ovalbumin and other proteins dissolved in the aqueous phase (16-18). The formation of films on the interface was observed. The transfer of alkali metal ions was retarded by the presence of protein on the aqueous side of the interface.

Another method for investigation of the properties of an interface with adsorbed material is an impedance technique. Reid *et al.* (18, 19) measured impedance characteristics of water/nitrobenzene interface in the presence of

Fig. 7. Dependence of ΔE_p of Na $^{+}$ in the presence of dibenzo-18-crown-6 and lecithin monolayer on temperature.

Fig. 8. 1.5 Hz real (solid symbols) and imaginary (unfilled symbols) impedances as a function of aqueous BSA concentration. Applied interfacial potentials: +35 (■ and □), -15 (● and ○), and -65 mV (◆ and ◇).

bovine serum albumin (BSA). Figure 8 (19) shows one of the impedance plots. The results indicated three phenomena occurring at the interface: an increased interfacial charge density upon initial BSA adsorption, formation of an adsorbed dielectric film, and an enhancement of faradaic base electrolyte ion leakage at high BSA concentrations.

As mentioned in the case of lecithin monolayer studies (15), the transfer of ions across the interface can be influenced by the presence of suitable ionophores. This phenomena can be used for investigation of certain biologically important molecules which have the ionophoric (translocator) properties. This is the case of valinomycin (20-22), nonactin (21, 23), and monensin (24-26) (Fig. 9). Vanýsek *et al.* (22) studied the valinomycin mediated transfer of K $^{+}$ ions across water/nitrobenzene interface by potential-sweep voltammetry. A curve for this transfer is given in Fig. 10.

Monensin, which has a practical application in veterinary pharmacology, can be determined by voltammetry at L/L interface in the concentration range between 0.05 mmol/liter and 3 mmol/liter (25). The principle which allows this determination is the facilitated transfer of sodium and hydrogen ions across the nitrobenzene/water

Table I. Standard values for selected ionic species of biological importance

interface. A sodium monensin molecular functional group (Fig. 9) can serve both as a sodium carrier (NaX) and a proton carrier (NaHX^+). The particle being transferred is, in both cases, NaHX^+ . This species is formed in nitrobenzene by either the reaction

with equilibrium constant $\log K_1 = 5.63$, or by the reaction

Fig. 10. Cyclic voltammogram of K^+ ($c = 5 \times 10^{-5}$ mol liter $^{-1}$) transfer facilitated by valinomycin ($c = 5 \times 10^{-4}$ mol liter $^{-1}$). Base electrolytes 10^{-3} mol liter $^{-1}$ LiCl in water, 10^{-3} mol liter $^{-1}$ TPATPB in nitrobenzene. The scan rate was 16.3 mV s $^{-1}$.

Fig. 11. Cyclic voltammogram of monensin. A, base electrolytes 0.5 mol liter $^{-1}$ sodium acetate, 0.5 mol liter $^{-1}$ acetic acid, and 10^{-3} mol liter $^{-1}$ NaCl. B, 1.12×10^{-3} mol liter $^{-1}$ monensin dissolved in nitrobenzene.

with equilibrium constant $\log K_2 = 9.88$. The principal electrochemical process is the exchange reaction

(w—water, o—nitrobenzene) with the exchange equilibrium constant $\log K_{\text{exchng}} = -3.96$. A cyclic voltammogram for this example is shown in Fig. 11.

Summary

Transport of ions across a single L/L interface can be observed without recourse to whole membrane transport studies. This new technology has begun to be applied to species of biological importance: species that adsorb and modify (usually inhibit) transport of small probe ions, and finally ionophore species that aid in transport of simple inorganic ions. Results include principally kinetic effects that are difficult to measure by other techniques.

Electrochemical Reduction of Benzoyl Chloride and Benzoyl Fluoride

Graham T. Cheek* and Pamela A. Horine

Department of Chemistry, U.S. Naval Academy, Annapolis, Maryland 21402

ABSTRACT

Voltammetric studies of the cathodic reduction of benzoyl chloride and benzoyl fluoride at vitreous carbon and platinum in AN/TEAP have shown that reduction occurs at potentials (E_p) of -1.82 and $-2.29V$, respectively, vs. Ag/AgNO₃ (0.1M). Reduction of benzoyl chloride involves one electron per molecule, forming a 2:1 mixture of *trans*- and *cis*-stilbenediol dibenzoate. Electrochemical reductions of both product isomers produce good yields of diphenylacetylene. Evidence for the formation of the benzoyl radical, as opposed to the benzoyl anion, was obtained from experiments in which benzoyl chloride was reduced in the presence of another, less easily reducible acyl chloride (*p*-anisoyl chloride). The involvement of benzil as an intermediate in benzoyl chloride reduction is supported by voltammetric data for benzil reduction. An n value of 1.1-1.2 was observed for benzoyl fluoride reduction, which led to the formation of benzyl benzoate, diphenylacetylene, and stilbenol benzoate (total yield: approximately 35%) as identifiable products, the remainder of the product being material of higher molecular weight. The greater stability of the anion radical produced from reduction of benzoyl fluoride (compared to that of benzoyl chloride) is evidenced by observation of a reversible system at cyclic voltammetric sweep rates above 50 V/s, and is thought to reflect the fact that fluoride is generally not as good a leaving group as is chloride.

As a general pathway in the electrochemical reduction of organic compounds, cathodic dehalogenation has been found to be particularly interesting because the radicals formed upon elimination of halide in this process are usually fairly reactive and can couple to produce compounds with rather remarkable structures (1-5). Continued interest in this area has involved investigations of the effect of temperature upon the polarographic reduction of alkyl halides, as well as the general mechanism of organohalogen compound reduction (7-10).

In a literature survey of cathodic dehalogenation, it is apparent that the cathodic reduction pathways of acyl halides have not been thoroughly studied. An early study (11) revealed a diffusion-controlled polarographic response for the reduction of benzoyl chloride in acetone/LiClO₄, the slope of the wave indicating a one-electron process, although no preparative studies were carried out. Similar results were obtained in later work at mercury in DMSO/TEAP (12). The reduction in buffered 50% dioxane/water mixtures at pH 9.3, in which the hydrolysis of benzoyl chloride is rather slow, was found to involve four electrons, leading to the formation of benzaldehyde (13). Recently, a preparative electrolysis of benzoyl chloride at mercury in acetone/LiClO₄ has been carried out, and, although little voltammetric information was given, the products were found to be *cis*- and *trans*-stilbenediol dibenzoate (14).

The present work, carried out in acetonitrile/TEAP at both glassy carbon and platinum electrodes, was undertaken to determine the reduction mechanism for benzoyl chloride as well as benzoyl fluoride in a com-

monly employed medium. The results have allowed an assessment of the generality of the reduction mechanism for benzoyl chloride in various systems, as well as an interesting insight into the effect of the halogen atom upon the reduction pathway.

Experimental

Chemicals, preparation, and purification.—Acetonitrile (Fisher Scientific Company, ACS reagent grade) was stored for several days over CaH₂ prior to fractional distillation from P₂O₅ through a double-pass column, the middle 70% being retained for use as solvent. This solvent, freshly distilled, was transferred under nitrogen to a flask containing CaH₂ for introduction into the electrochemical cell (see below). Tetraethylammonium perchlorate (Southwestern Analytical Chemical Company, electrochromic grade) was dried *in vacuo* at 70°C for approximately 1 day before use. Nitrogen (Linde purified grade) was passed through an oxygen removal tower (BTS Catalyst) and through a desiccant (Drierite) for removal of traces of oxygen and moisture present.

Benzoyl chloride (99%) and benzoyl fluoride (95%, Aldrich Chemical Company) were purified by reduced-pressure distillation, producing clear liquids. Infrared spectra of these compounds confirmed their identity, and liquid chromatographic analyses showed the presence of only one peak in each case. These compounds were stored under nitrogen in tightly stoppered round-bottom flasks, kept inside a nitrogen-flushed desiccator over calcium sulfate. *Cis*- and *trans*-stilbenediol dibenzoate were synthesized and purified according to the procedure of Trisler and Frye (15), except that further

* Electrochemical Society Active Member.

purification of the *cis* isomer by two-fold recrystallization from 75:25 hexane:benzene was required for complete removal of the *trans* isomer. Identity and purity of these compounds were established by melting point (uncorrected) [*cis* isomer, 158°-159°C; literature 159°C (15); *trans* isomer, 188°-189°C; literature 188.5°-189°C (15)], infrared spectra, and liquid chromatographic analysis. Stilbenol benzoate was prepared according to the method of Beringer *et al.* (16). Benzyl benzoate (99+%) was used as received from Aldrich Chemical Company.

Electrochemical apparatus and techniques.—Voltammetric experiments were carried out using vacuum line/inert gas line techniques. A PAR Model K60/K66 electrochemical cell, fitted with $\frac{3}{8}$ 14/20 O-ring seal joints (Ace Glass Company), was used in these studies, with the electrode connections made by means of O-ring seals (Ace-Threds, Ace Glass Company) for the working electrodes and reference electrode, and sealed-through tungsten wires for the auxiliary electrode. The cell, together with electrodes and supporting electrolyte, was placed under vacuum ($\sim 5 \mu\text{m}$) for several hours in order to ensure anhydrous conditions. Acetonitrile, previously purified as described above, was distilled by means of a current of dry nitrogen into a volumetric receiver, connected to the cell by means of an O-ring connection and vacuum stopcock, immediately before backfilling of the cell with nitrogen. After introduction of the solvent, this receiver was left in place throughout the experiments, thereby serving as a source of nitrogen for bubbling through or sweeping over the solution in the cell, these functions being selected by means of a stopcock in a pressure equalizing tube on the receiver. Working electrode materials used in this work were vitreous carbon (3 mm diam vitreous carbon rod, Atomergic, sealed in Pyrex tubing) and platinum (5 mm diam disk). The auxiliary electrode was a platinum spiral, enclosed in a fritted glass tube (porosity E, 5-8 μm , Ace Glass Company). Potentials were referenced to a Ag/0.1M AgNO₃ [in acetonitrile; 0.336V *vs.* aqueous SCE in 0.1M AN/TEAP (17)] reference electrode, separated from the solution by a double fritted junction, the outer part of which was filled with solvent/supporting electrolyte. Transfers of benzoyl chloride from the storage vessel to the electrochemical cell were made under a stream of dry nitrogen by means of a 10 μl syringe.

Preparative electrolyses were carried out in a cell larger than that described above, the usual solution volume being 150 ml. The cell was constructed from 75 mm diam O-ring Pyrex tubing, the top section being fitted with O-ring seal ports for electrodes, vacuum line connection, and solvent delivery tube of the distillation reservoir described above. Working electrodes for these preparative electrolyses were a platinum gauze electrode (50 mm diam \times 55 mm height) and a vitreous carbon crucible (35 mm diam \times 35 mm height) placed in the electrolysis cell. The auxiliary electrode was concentrically located in the cell, and consisted of a carbon rod placed inside a porous clay cup, which in turn was placed in a fine porosity fritted glass tube. Solvent introduction procedure was the same as described for the smaller cell. Electrolyses typically involved 200-300 μl of benzoyl chloride or benzoyl fluoride.

Electrochemical experiments were carried out using a PAR Model 170 Electrochemistry System, with some cyclic voltammetric experiments utilizing a function generator based on the design of Bruckenstein (18). A digital coulometer (Model 640, The Electrosynthesis Company) was employed for current integration. A Biomation Model 1010 transient recorder was used to obtain chronoamperometric data on a short (10-200 ms) time scale.

Product isolation and analytical techniques.—Electrolysis mixtures were flushed from the cell by nitrogen pressure into receiving flasks and the solvent removed either on the vacuum line or by a nitrogen stream. The residues were then extracted with hexane, benzene, or hexane/THF mixtures (anhydrous conditions) or parti-

tioned between water and benzene, these conditions usually giving equivalent results. Electrolysis products were identified by comparison of spectroscopic, voltammetric, and chromatographic characteristics for components of electrolysis mixtures with those of authentic samples.

Liquid chromatographic analyses were carried out with a Varian 8500 Liquid Chromatograph using a UV absorption detector (254 nm), a CN bonded column, and 85% hexane: 15% methylene chloride mobile phase at a flow rate of 2.00 ml/min.

A Hewlett-Packard Model 5992 gas chromatograph/mass spectrometer, using a column of 2% OV 101/20% Carbowax 20M on Chromosorb WHP, was employed in this work. Typical conditions for analysis of products from benzoyl chloride electrolyses were a column temperature of 200°C and a flow rate of 30 ml/min, whereas those for analysis of benzoyl fluoride electrolysis products involved a temperature program of 110°C (5.0 min), 110°-175°C (in 6.5 min), and 170°C (13.5 min). An LKB 9000 GC/MS instrument was also used to characterize the electrolysis product isolated from benzene extraction of the benzoyl fluoride electrolysis mixture (after evaporation of acetonitrile), this compound having the following mass spectrum: *m/z* 554 (2.6%), 478 (9.6%), 390 (22%), 298 (26%), 283 (13%), 195 (25%), and 105 (100%).

Results and Discussion

Voltammetric studies of benzoyl chloride.—As shown in Fig. 1, the reduction of benzoyl chloride in acetonitrile/TEAP at vitreous carbon occurs at -1.82V (E_p , *vs.* Ag/0.10M AgNO₃ reference electrode), with the peaks at more negative potentials corresponding to reduction of products formed in the initial benzoyl chloride reduction (see below). On the return sweep, a rather large peak at $+0.8\text{V}$ indicates oxidation of chloride released upon benzoyl chloride reduction, as confirmed by addition of tetramethylammonium chloride to an acetonitrile/TEAP solution (19). A study of peak current (i_p) for the main reduction process over the concentration range 2-10 mM revealed a linear relationship between i_p and concentration, showing that benzoyl chloride reduction proceeds rather cleanly at vitreous carbon (that is, without serious filming effects). Variation of scan rate (v) from 5 to 200 mV/s produced a linear i_p *vs.* $v^{1/2}$ plot, indicating diffusion-controlled behavior.

Cyclic voltammetric characteristics for benzoyl chloride reduction at platinum appeared qualitatively similar to those at vitreous carbon. The main reduction process occurred at -2.00V with the same further reduction processes being observed, although the cathodic background process at platinum appeared at a somewhat more positive potential (-2.8V) than at vitreous carbon.

Preparative electrolyses and reaction mechanism.—Integration of current passed during preparative electrolyses and coulometric experiments produced an n value of 1.0 for benzoyl chloride reduction at platinum and vitreous carbon. The infrared spectra of isolated electrolysis products contained very strong bands at 1740 and 1600 cm^{-1} , characteristic of an ester carbonyl group and aromatic rings, respectively. Liquid chromatographic analysis of the electrolysis products showed that only two major products were formed in the electrolysis, with other products observed at shorter retention times. By comparison of chromatographic (LC and GC/MS) and voltammetric characteristics, the major products were identified as *cis*- and *trans*-stilbenediol dibenzoate (SDDDB), the *cis:trans* ratio being 1.0:2.0 with a combined yield of 85%-90%. The voltammetric responses for these products, shown in Fig. 2b and 2c, clearly indicate their formation upon reduction of benzoyl chloride (Fig. 2a).

It is interesting to note that the reduction of benzoyl chloride in acetone at mercury (14) produces similar results, indicating that, in this case, the electrochemical reaction pathway is apparently largely independent of solvent and electrode material. In this regard, the initial reduction of benzoyl chloride is pictured as a one-electron

Fig. 1. Cyclic voltammogram of 8.3 mM benzoyl chloride. $v = 100$ mV/s, at vitreous carbon.

process which produces an acyl radical, two of which quickly couple to produce benzil. Cyclic voltammetry of benzil (Fig. 3) indicates that reduction of benzil to its anion radical can occur at the potential employed in the benzoyl chloride electrolysis (-1.80 V). This reduction is envisioned as the first step in an ECEC mechanism involving benzil reduction, as given by the following sequence

Coupling of the intermediate anions with benzoyl chloride produces the observed product mixture, although only the *trans* isomer formation is shown for clarity. This scheme differs from that given for the reduction at mercury in involving an initial one-electron rather than a two-electron reduction of benzil following its formation. Both mechanisms, however, account for the coulometric n value of 1.0 observed for benzoyl chloride reduction according to the overall mechanism

Another possible mechanism for benzoyl chloride reduction involves the initial formation of the benzoyl anion by two-electron reduction of benzoyl chloride, followed by chloride displacement from benzoyl chloride by this anion to form benzil. In order to determine the extent to which this benzoyl anion is involved in benzoyl chloride reduction, a cross-coupling experiment in which benzoyl chloride ($E_p = -1.82$ V) is electrolyzed in the presence of an equal concentration of *p*-anisoyl chloride (*p*-meth-

oxybenzoyl chloride, $E_p = -1.92$ V) was carried out. Electrolysis at -1.82 V (at which potential *p*-anisoyl chloride is not reducible) consumed 1.2 electrons per molecule of benzoyl chloride, at which point the concentration of *p*-anisoyl chloride was approximately 80% of its initial value. Liquid chromatographic analysis of the product mixture revealed peaks due to *cis*- and *trans*-SDDDB ($k = \{t_R - t_M\}/t_M = 2.84$ and 3.06 , respectively; combined yield 45%) as well as others having $k = 5.25$, 5.62 , and 9.40 . These same products, with an additional peak at $k = 6.52$, were obtained in an electrolysis of an equimolar mixture of benzil, benzoyl chloride, and *p*-anisoyl chloride at the first reduction potential of benzil, the peaks at longer retention times being relatively more abundant than those produced in the benzoyl chloride/*p*-anisoyl chloride electrolysis. The latter two peaks ($k = 6.52$ and 9.40) were also produced in a similar electrolysis of a 1:2 mixture of benzil:*p*-anisoyl chloride. From these results, it appears that benzoyl chloride reduction in the presence of *p*-anisoyl chloride involves the initial formation of benzil, the reduction of which leads to coupling between the benzil anion radical and the acyl chlorides present in the solution. In addition to *cis*- and *trans*-SDDDB, four more

Fig. 2. Cyclic voltammograms of (curve a) benzoyl chloride, 8.2 mM, (curve b) *trans*-stilbenediol dibenzoate, 2.5 mM, (curve c) *cis*-stilbenediol dibenzoate, 2.2 mM, and (curve d) diphenylacetylene, 5.2 mM. All scans recorded at 100 mV/s.

stilbenediol diesters (*cis* and *trans* isomers of stilbenediol anisoate benzoate and stilbenediol dianisoate) are apparently formed in this process and give rise to the liquid chromatographic peaks having longer retention times than those for the SDDB isomers. The similarity of the products formed in the benzoyl chloride/*p*-anisoyl chloride and the benzil/benzoyl chloride/*p*-anisoyl chloride electrolyses supports the initial formation of benzil in the benzoyl chloride electrolysis, indicating that benzoyl radicals are involved in the initial coupling reaction to form benzil. (It is expected that attack of the benzoyl anion upon *p*-anisoyl chloride in the cross-coupling experiment would lead to the initial formation of *p*-methoxy benzil and, hence, to different ultimate products than those observed above.)

Recognizing the importance of benzil as an intermediate in the above mechanism, a brief investigation of the electrochemical properties of this molecule in the presence of benzoyl chloride was carried out. At a potential of -1.70 V, reduction of benzil to its anion radical occurs, whereas benzoyl chloride is not reduced, thereby allowing the ECEC sequence mentioned earlier to be studied. As seen in Fig. 4, the cyclic voltammetric peak height parameter $i_p/\nu^{1/2}$ for reduction of benzil at -1.70 V under these conditions increases considerably at lower scan rates, indicating the importance of the chemical reactions in the sequence (20). In this regard, the intermediate produced in the first EC step is evidently more easily reducible than is benzil itself, and its reduction contributes increasingly to the total reduction process as the scan rate decreases and its extent of formation increases. The effect of benzoyl chloride concentration on

this process is clearly shown in Fig. 4, which shows voltammetric data for benzil:benzoyl chloride ratios of 1.0:0.5, 1.0:1.0, and 1.0:2.0. In this sequence, the rate of the chemical step increases with increasing benzoyl chloride concentration, producing a noticeable effect at 200 mV/s at higher benzoyl chloride concentrations. A pseudo-first-order rate constant for this chemical step of 6.9 ± 0.5 s $^{-1}$ was obtained by treatment of chronoamperometric data for reduction of benzil (3 mM) in the presence of a large excess (60 mM) of benzoyl chloride according to the method of Alberts and Shain (21). A preparative electrolysis of a 1:2 benzil:benzoyl chloride mixture at -1.70 V produced essentially the same results as those found for benzoyl chloride reduction (2:1 *trans:cis* SDDB). At mercury (14), this electrolysis produces a 1:2 *trans:cis* SDDB ratio, and apparently involves the adsorption of benzil at the mercury electrode (14).

As can be seen in Fig. 2, the reduction of the esters formed in the reduction of benzoyl chloride leads to further products. Preparative electrolyses of *cis*- and *trans*-SDDB at vitreous carbon and platinum were found to produce diphenylacetylene in 75%-80% yield, as measured voltammetrically after positive identification by GC/MS and liquid chromatography. The n values observed (2.0-2.1) are consistent with a two-electron reduction, evidently involving the elimination of benzoate anions with the consequent formation of diphenylacetylene. The cyclic voltammogram of diphenylacetylene (Fig. 2d) illustrates its terminal position in the sequence benzoyl chloride \rightarrow *cis/trans*-SDDB \rightarrow diphenylacetylene.

Fig. 4. Plot of peak current function $i_p/\nu^{1/2}$ for first reduction process of 4.8 mM benzil, showing effect of benzoyl chloride additions. Curve a: no benzoyl chloride added. Curve b: 1.0:0.5 benzil:benzoyl chloride molar ratio. Curve c: 1.0:1.0 benzil:benzoyl chloride molar ratio. Curve d: 1.0:2.0 benzil:benzoyl chloride molar ratio.

Fig. 5. Cyclic voltammograms of (curve a) benzoyl fluoride, 2.8 mM and (curve b) benzyl benzoate, 2.8 mM. Both scans recorded at 100 mV/s.

Voltammetric studies of benzoyl fluoride.—The cyclic voltammogram of benzoyl fluoride in acetonitrile at vitreous carbon (Fig. 5a) shows that it is considerably more difficult to reduce than is benzoyl chloride, in accord with the usually observed order of ease of organohalogen reduction (1, 2). A product peak is evident at -2.55V in addition to smaller processes in the voltammogram. These results indicate that the electrochemical reduction pathway of benzoyl fluoride is quite different from that of benzoyl chloride.

The benzoyl fluoride reduction process, when observed by cyclic voltammetry at a scan rate of 50 V/s, was found to be reversible, in contrast to behavior observed for benzoyl chloride reduction. AC voltammetric measurements confirmed these observations, showing that elimination of fluoride upon reduction occurs much more slowly than the elimination of chloride in the corresponding benzoyl chloride reduction. The fact that chloride is generally a better leaving group than fluoride (22) seems to account for the greater stability of the benzoyl fluoride anion radical.

Coulometric investigations of benzoyl fluoride reduction produced an n value of 1.1-1.2, indicating that the process is not so well defined as that of benzoyl chloride reduction. Analysis of products from a preparative electrolysis carried out at -2.30V showed that the major products formed in the electrolysis are benzyl benzoate and diphenylacetylene (15% and 10%-15%, respectively, based upon voltammetric measurements in the electrolysis mixture) with variable yields of stilbenol benzoate (5%-15%) also being obtained. These products were found in a hexane extract (3-75 ml portions) of the evaporated electrolysis mixture. A similar extraction with benzene produced an orange oil which, upon dissolution in 50:50 methylene chloride:hexane and passage through an alumina column, led to the isolation of a light-yellow compound (10% yield) having the mass spectral characteristics given in the Experimental section. It is evident that this product involves rather extensive coupling of intermediates formed upon benzoyl fluoride reduction, since its molecular weight (554) is much higher than that of the other products isolated. The base peak (m/z 105) indicates the presence of the benzoyl group in the product, and the peak at m/z 298 suggests that the product may be the result of further reduction and coupling of stilbenol benzoate. Further extraction with refluxing benzene gave more of the orange oil noted above (total yield, 60%) which produced no well-defined peaks in liquid chromatographic analysis and is presumably polymeric material formed in the electrolysis. The infrared spectrum of this oil contains

bands at 1740 and 1600 cm^{-1} , indicating that ester carbonyl bonds, as well as phenyl groups, are present, and that the material has some structural similarity to the lower molecular weight products formed in the benzoyl fluoride electrolysis.

The product analysis of the benzoyl fluoride electrolysis mixture indicates that the reaction pathway is very fragmented. One of the directions taken apparently involves initial stilbenediol dibenzoate formation, as in benzoyl chloride reduction, followed by reduction to diphenylacetylene and stilbenol benzoate. Benzyl benzoate may arise from reductive cleavage of the stilbenediol dibenzoate double bond, although the results on stilbenediol dibenzoate reduction seem to indicate otherwise. A more likely route for benzyl benzoate formation involves a displacement of fluoride from benzoyl fluoride by the benzoyl fluoride anion radical following benzoyl fluoride reduction. Although the concentration of benzoyl fluoride at the electrode is very low under these conditions, the lifetime of the anion radical should be long enough to permit diffusion into solution where unelectrolyzed benzoyl fluoride would be encountered. Following the displacement reaction, the pathway is not as clear, but evidently involves further reduction, corresponding to loss of fluoride, and hydrogen abstraction from solvent and/or supporting electrolyte. The remainder of the product mixture consists of the compound of molecular weight 554 and polymeric materials, evidently involving extensive coupling of benzoyl radicals formed by decay of the benzoyl fluoride anion radical, the extent of the coupling being sufficient to produce the large yield of polymeric (high molecular weight) product observed.

In an attempt to measure the rate of decay of the benzoyl fluoride anion radical, double potential-step chronoamperometric experiments (23) involving the main benzoyl fluoride reduction process were carried out at vitreous carbon on a 3 mM benzoyl fluoride solution. A rate constant of $60 \pm 15\text{ s}^{-1}$ for the first-order decay process [as specified in this treatment (23)] was obtained. Although this value is in fairly good agreement with the cyclic voltammetric results observed at higher scan rates, it must be regarded with some caution because of the multitude of products formed in subsequent radical reactions. The proposed pathway for benzyl benzoate formation (coupling of benzoyl fluoride anion radical with benzoyl fluoride), if followed, would affect the above rate constant since it does not correspond to the assumed reaction (initial decay followed by subsequent reactions); however, the amount of benzyl benzoate formed is relatively small and therefore may

not greatly alter the above finding. Further work on the mode of benzyl benzoate formation, as well as on the benzoyl fluoride reduction process in general, is in progress and is expected to clarify the role of the benzoyl fluoride anion radical in the reduction pathway.

Conclusions

It would appear, from the results of this study and that of Guirado *et al.* (14), that the mechanism of benzoyl chloride reduction is essentially the same in these two media. This similarity evidently reflects the fact that the coupling of acyl radicals is much more favorable than reactions of these radicals with the various components in either of the systems employed. Chemical reductions of benzoyl chloride by hexaphenylditin (24) and in the presence of pentacarbonyliron (25) have also been found to produce a mixture of *cis*- and *trans*-stilbenediol dibenzoate, indicating that the reaction pathway is rather general.

As studied in the present work, the effect of the halogen atom on the reduction pathway can be seen in the difference of reduction potentials for benzoyl chloride and benzoyl fluoride, as well as in the nature of the products obtained. The difference in reduction mechanisms can be attributed to the greater stability of the benzoyl fluoride anion radical formed initially in the reduction process, as well as to the more negative potential required for its reduction.

ABSTRACT

The electrochemical behaviour of a variety of *para*-substituted *n*-phenylpyrrole monomers and their corresponding polymers was analyzed. The electron-attractive or electron-repulsive nature of each *para* group substituent was perceived in the pyrrole unit through the phenyl ring and manifested in their E_{pa} values. Good linear correlations with Hammett σ^+ constants were obtained for both the monomer E_{pa} values and the electroactive polymer E_o values.

In our continuous search for new polypyrrole conducting polymers (1), it was found that functional group substitution on the phenyl ring on *n*-phenylpyrrole provides an excellent way to obtain a wide selection of chemically modified polymer films. In addition, some of these functional groups, such as $-\text{NO}_2$, $-\text{OH}$, $-\text{COOH}$, and $-\text{COCH}_3$, are able to be modified chemically before or after the electropolymerization, affording an alternative route to modify the polymer.

The chemical synthesis and anodic oxidation of 15 *para*-substituted *n*-phenylpyrrole monomers and the electrosynthesis of their polymers offers the opportunity to study the substituent electromeric effect upon their electrochemical properties.

Earlier (2) results reveal that a wide variety of *n*-phenylpyrrole polymers are potentially usable as electrodes which contain a particular chemical composition, or physical or electrochemical properties.

Materials and Procedure

The *para*-substituted *n*-phenylpyrrole monomers were synthesized from 2,5-dimethoxytetrahydrofuran and the appropriate amine refluxed in acetic acid. The pyrrole derivatives were purified by column chromatography silica gel using as eluent ethylacetate/hexane. After crystallization or vacuum distillation, the pure pyrrole monomers were identified by $^1\text{H-NMR}$, IR, and MS and compared with reported data (3).

Electrochemical experiments were performed with a PAR 173 Potentiostat with a PAR 175 Universal Programmer. The working electrode was a button of Pt (0.5 cm^2) or a thin layer of Pt (0.5 cm^2) deposited on a glass plate. A gold wire was used as counterelectrode. All potentials were measured with respect to a calomel reference electrode saturated with KCl in H_2O . Acetonitrile (J. T. Baker) distilled from phosphorous pentoxide was used as solvent in all the experiments. The redox potentials and E_o values for monomers and polymers were obtained directly from the cyclic voltammograms. The anodic, cathodic, and E_o potentials listed were measured at 100 mV/s .

Results and Discussion

A comparative overview of the *n*-substituted pyrrole monomers and their electrosynthesized polymers showed that the oxidation potentials increase gradually to anodic

values in the order pyrrole < *n*-alkylpyrrole < *n*-phenylpyrrole. The chemical modification of the pyrrole unit by introduction of alkyl substituent in the nitrogen permits one to obtain a series of *n*-alkyl-substituted pyrrole polymers with different chemical and physical properties (4). However, the electropolymerization reaction of *n*-alkylpyrroles substituted with bulky groups (tert-butyl, cyclohexyl) is inhibited by steric interactions. In the series, the anodic oxidation potential of monomers and polymers is shifted as the substituent size, and steric hindrance increases. Therefore, the oxidation of the pyrrole nucleus is affected very little by the electron donating effects of the *N*-alkyl groups.

Fig. 1. Pyrrole electropolymerization mechanism.

Fig. 2. Cyclic voltammograms of 20 mC/cm² thin films of poly-n-phenylpyrroles substituted with *p*-COCH₃ (curve a) and *p*-OCH₃ (curve b) at 100 mV/s in CH₃CN containing 0.1M Et₄NBF₄.

In the N-phenylpyrrole series, *ortho*-electroactive substituents showed electronic and steric effects (5), whereas in *para*-substituted n-phenylpyrroles, which will be discussed here, only electromeric effects were observed.

Therefore, the electron-attractive or electron-repulsive nature of groups was transmitted through the n-phenyl ring into the pyrrole moiety (6). According to this, the group effects were reflected in the anodic oxidation E_{pa}

values of monomers as well as in the E_{pa} , E_{pc} , and E_o values of polymers, as shown in Table I.

The first electrochemical oxidation step of n-phenyl-substituted pyrrole monomers (Fig. 1) produces a very reactive radical-cation at the anode, which initiates the chain propagation, forming oligomers (7). The polymerization process continues by reaction of the oligomer radical-cation with others or with the radical-cation of the monomer present in high concentration in the anode region.

The poly n-phenylpyrrole formed on the electrode surface as a smooth film contains the phenyl substituent, which modifies the cyclic voltammogram shape and the redox values. Also in the cyclic voltammograms of *p*-NO₂(3), *p*-COCH₃, *p*-Br, and *p*-Cl, an additional small peak appears before the pyrrole oxidation loop between 0.5-0.6V (Fig. 2). These peaks of unknown origin were not assigned.

In order to measure the substituent effect in a quantitative way and to explain some electrochemical properties of the studied pyrroles, the E_{pa} and E_o values of monomers and polymers were related with the available Hammett-Brown (8) substituent constants σ^+ listed in Table II.

When least squares regression techniques were used and these values plotted against one another, a satisfactory linear relationship was obtained.

The correlation coefficient for the pyrrole monomer series in Fig. 3, is: $r = 0.960$ and $r = 0.927$ for the polymer set Fig. 4. These values are good enough to satisfy the Jaffe's standard (9) and exemplifies for the first time a parallel substituent effect on both the monomer and their polymers on the positive charged reaction center.

Also, monomers and polymers are in accordance with a linear relationship given by Eq. [1] and [2]

$$E_{pa} = 0.16\sigma^+ + 1.49 \text{ (monomer)} \quad [1]$$

$$E_o = 0.18\sigma^+ + 0.695 \text{ (polymer)} \quad [2]$$

Fig. 3. Relationship of oxidation (E_{pa}) of *p*-N-phenylpyrrole monomers vs. σ^+ values of substituents.

Fig. 4. Hammett-Brown plot of the E_0 values of *p*-N-phenylpyrrole polymers.

According to the slope values, the lines are almost parallel lines, and consequently we can infer that the substituent supports the same environment in monomer and polymer and the influence is transmitted through the phenyl ring into the pyrrole reaction center, producing the same effect. Therefore, torsional angle or conformation between the two aromatic rings of *n*-phenylpyrroles before and after polymerization should be very similar.

The preliminary studies to evaluate some of the formed polymers as electrodes, showed the substituent influence on the quality of the films (5) and on the changes in the film electron-transport rate (10).

Finally, polymerization was totally inhibited when the phenyl substituents were groups such as $-\text{N}(\text{CH}_3)_2$ and $-\text{OH}$, which are easier to oxidize than the pyrrole group. When NO_2 was the substituent, only thin films and oligomers were produced (11), whereas $-\text{C}(\text{F})_3$ yielded a powdery black deposit on the electrode. Thus, it appears that *N-p*-phenylpyrroles with strongly attracting or electron inductor substituents which have large positive or negative σ^+ values will present difficulties for polymerization.

Impedance Measurements in Nonaqueous Media: Measurements of an Electron-Transfer Rate Constant in the Presence of Adsorption

Xiang-Qin Lin,* Tadeusz Malinski,*¹ and Karl M. Kadish*

Department of Chemistry, University of Houston, Houston, Texas 77004

ABSTRACT

Equations are derived for the calculation of heterogeneous electron-transfer rate constants in nonaqueous media using the ac impedance method. These equations are modifications of equations in the literature and are specifically applicable for direct semiautomatic ac impedance measurements using a four-electrode system and a small ac perturbation signal. An example of combined faradaic and adsorption processes is given by the reduction of bis(N-R-2,6-pyridinedicarboxaldimine)Co(II). This compound shows adsorption at a Pt electrode in acetone, 0.1M TBAP which is not detected by cyclic voltammetry. Applications of modified ac impedance methods allowed the calculation of a $k^0 = 8.0 \times 10^{-2}$ cm/s and an $\alpha = 0.4$ in the presence of adsorption.

A well-established application of impedance measurements is in the study of adsorption and electrode kinetics. When accurate impedance measurements are required, ac bridges (1-3) have long been considered superior to direct measuring, phase-sensitive devices (4-10). However, the manual operation of an ac bridge is tedious and time consuming. It is therefore understandable that much effort has recently been devoted to designing more or less automatically operating, direct measuring devices (11-13). A great improvement in this direction was suggested by Smith *et al.* (14-17), who used a computer to control measurements and to acquire data with aid of a Fast Fourier transform algorithm. The only alternative to this Fast Fourier approach is still the direct measuring, phase-sensitive detector (11). However, nonbridge instruments are complicated and often expensive.

Recently, the design of an instrument which could be used for direct measurements of ac impedance and which could be constructed from relatively low cost commercially available components was reported (18, 19). With this device, we were able to decrease the ac perturbation signal below 0.5 μ A. In addition, by using a four-electrode system (the standard three-electrode system plus an ac counterelectrode), the frequency could be changed automatically and a complex plane spectrum could be obtained in the time that is usually needed for the obtaining of a single ac sinusoidal polarogram.

We now present an experimental and theoretical treatment of impedance data obtained from this device in order to calculate a heterogeneous electron-transfer rate constant for a redox process which occurs in nonaqueous media in the presence of adsorption. We have chosen for our investigation the six-coordinate bis(N-R-2, 6-pyridinedicarboxaldimine)Co(II) complex with substituent R = CH₂Ph. This complex was shown to exhibit an ²E(1s) \rightleftharpoons ⁴T(1s) spin-equilibrium process in both the solid and solution states (20). In nonaqueous media, the cobalt(II) complex can be reduced to a cobalt(I) species and has a rate constant of 3.7×10^{-2} cm/s when measured by cyclic voltammetry. No trend between spin state and k^0 was observed in this study (21). However, a number of other effects besides spin transition can influence the measured rate constant. One such effect is adsorption. The weak adsorption of bis(N-R-2,6-pyridinedicarboxaldimine)Co(II) on a platinum electrode could not be detected by cyclic voltammetry, but is quite evident from the impedance measurements. Thus, with this latter electrochemical technique, the characteristic of the "surface" reaction can be investigated.

Experimental

Bis(N-R-2,6-pyridinedicarboxaldimine)Co(II) where R = CH₂Ph was used for determining the heterogeneous rate

* Electrochemical Society Active Member

¹ Present address: Department of Chemistry, Oakland University, Rochester, Michigan 48063.

Key words: heterogeneous kinetics, bis(N-R-2,6-pyridinedicarboxaldimine) Co(II), four-electrode system.

constant for the Co(II)/Co(I) reaction. This compound, which we will abbreviate as LCo(II), was synthesized by the method of Simmons and Wilson (20) and was generously provided by Dr. L. J. Wilson. Impedance measurements were made with a home-built instrument whose design has been described previously (18, 19). A four-electrode system was used. This consisted of a platinum button (area = 0.08 cm²) working electrode and a Pt wire dc counterelectrode. The utilized Pt button electrode was well constructed by a competent glass-blower: a 1 mm diam commercial Pt wire was sealed into "cobalt-glass," which was sealed into Pyrex tubing to form a vacuum-tight Pt electrode. The electrode surface was polished by fine sandpaper and then a polishing agent to form a flat shiny surface. This electrode was investigated by cyclic voltammetric measurements and shows an excellent behavior without edge effects (The solution does not creep between the glass and the platinum). A 2 cm² platinum mesh served as an independent ac counterelectrode, and a saturated calomel electrode was used as the reference electrode. The latter was separated from the organic solvent by a glass frit. A constant 0.5 μ A testing alternating current flow through the cell (between the working electrode and ac counterelectrode) produced a signal measured from the in-phase output and quadrature output lock-in analyzer. A signal from the in-phase output corresponded to the sum of \dot{R}_{sol} and \dot{Z}_{Rs} and the signal from the quadrature output corresponded to the \dot{Z}_{Cs} (see Fig. 2a). The potential scan rate was 2 mV/s, and 200 and 50 kHz frequencies were applied for low and high frequency measurements, respectively.

Results and Discussion

The measurable parameters obtained from our ac impedance device can be represented by the in-series equivalent circuit shown in Fig. 1a. In this circuit \dot{Z}_{Rs} and \dot{Z}_{Cs} are the resistive and capacitive components of impedance, and R_{sol} is the resistance of the solution. The term c_1 indicates a concentration of i redox species.

The interface between a working electrode and solution where no redox species are present in solution can be represented by the parallel equivalent circuit shown in Fig. 1b, where R_L and C_L are the leaking resistance and leaking capacitance, respectively. In aqueous media at $c_1 = 0$, only the adsorption process influences C_L . In this case, R_L is assumed to be quite large and may be omitted, so the C_L represents the double layer capacitance C_{dl} . This is not the case in nonaqueous media, where C_L and R_L may be of comparable magnitude. For example, in freshly distilled acetone containing 0.1M TBAP, the values of R_L and $1/\omega C_L$ were calculated as 8 and 3 k Ω at 200 Hz frequency (both R_L and C_L were frequency dependent), and R_{sol} was measured as 450 Ω (19). This corresponds with a phase angle of the interfacial impedance of about 70°. In polar organic solvents, the phase angle should not be expected to be 90° due to the existence of adsorption and the relaxation time effect of the organic solvent molecules.

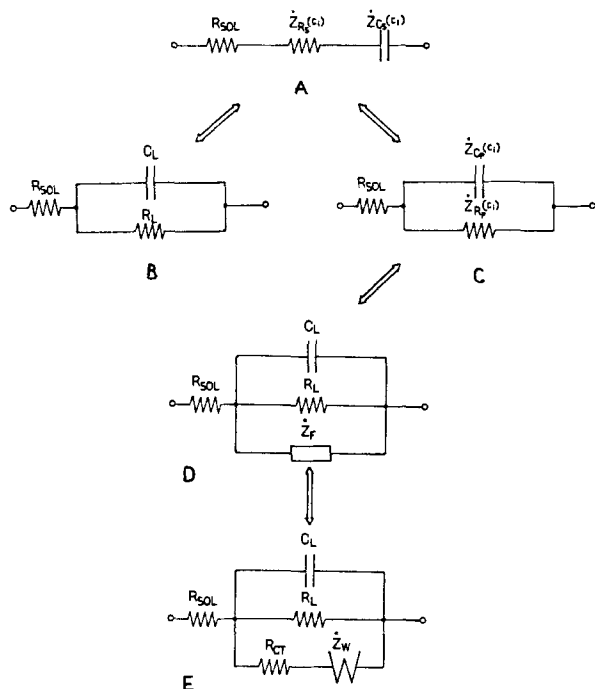

Fig. 1. A: in-series equivalent circuit of an electrochemical cell where Z_{Rs} is the resistive component of impedance, Z_{Cs} the capacitive component of impedance, and R_{sol} the solution resistance. B: parallel equivalent circuit of an electrochemical cell with solvent and supporting electrolyte (no faradaic process occurs). C_L is the leaking capacitance and R_L the leaking resistance. C, D, and E: interconversion of parallel equivalent circuit of the electrochemical cell in the case of pure faradaic process: Z_{Cp} = capacitive component of impedance, Z_{Rp} = resistive component of impedance, Z_F = faradaic impedance, R_{ct} = charge transfer resistance, Z_W = Warburg impedance. The sub "s" and "p" represent the in-series and parallel circuit, and C_i (concentration of a redox sample).

Plots of the resistive and capacitive components of impedance vs. potential for different concentrations of LCo(II) in acetone are shown in Fig. 2. The capacitive component of the impedance, Z_C , decreased with increasing concentration of LCo(II) (Fig. 2a). The resistive component, Z_R , also decreased with increasing concentration of the sample, but below a concentration of $6.5 \times 10^{-4}M$, Z_R was higher than that observed for the blank solution (Fig. 2b). In order to analyze these data, we will consider two limiting cases. These are pure faradaic processes and faradaic processes combined with adsorption.

Faradaic processes.—The half-cell equivalent circuit for a pure faradaic process is shown in Fig. 1d. In the absence of coupled reactions, the faradaic component of the first-order electrode process can be represented as a sum of the charge transfer resistance, R_{ct} , and the Warburg impedance, Z_W (22, 23) (see Fig. 1e)

$$\dot{Z}_F = R_{ct} + \dot{Z}_W \quad [1]$$

The Warburg impedance has been described as

$$\dot{Z}_W = \zeta R_{ct} (1 - j) \quad [2]$$

where ζ is the dimensionless rate parameter, which is given by the following equation (22, 23)

$$\zeta = \frac{k_R}{(2\omega D_R)^{1/2}} + \frac{k_O}{(2\omega D_O)^{1/2}} \quad [3]$$

k_R and k_O are the heterogeneous electron transfer rate constants and D_R and D_O are the diffusion coefficients for the reduced and oxidized species, respectively. The charge transfer resistance R_{ct} is dependent on the rate constants and can be described by Eq. [4]

$$\frac{1}{R_{ct}} = nFA \left(c_R \frac{\partial k_R}{\partial E} - c_O \frac{\partial k_O}{\partial E} \right) \quad [4]$$

Fig. 2. (a): Capacitive (Z_C). (b): Resistive (Z_R) component of impedance-potential dependence for the reduction bis(N-R-2,6 pyridinedicarboxaldimine)Co(II) in 0.1M TBAP, acetone. Concentrations of bis(N-R-2,6 pyridinedicarboxaldimine)Co(II) were: (1) 0.0; (2) $1.4 \times 10^{-4}M$; (3) $6.5 \times 10^{-4}M$; (4) $1.3 \times 10^{-3}M$; and (5) $2.5 \times 10^{-3}M$. The dotted line indicates R_{sol} .

where c_R and c_O are the concentrations of the reduced and oxidized forms on the electrode surface, A. The other symbols have their usual meanings.

The resistance of the solution R_{sol} can be measured for a blank solution and subtracted from the value of the total impedance. The in-series circuit shown in Fig. 1a can be transformed to the parallel circuit illustrated in Fig. 1b or 1c. Equations [5] and [6] describe the impedance for the in-series (\dot{Z}_s) and parallel (\dot{Z}_p) circuit, respectively (24), and Eq. [7] and [8] describe the transformation of the in-series circuit to the parallel circuit (24)

$$\dot{Z}_s = R_s + \frac{1}{\omega C_s j} \quad [5]$$

$$\dot{Z}_p = \frac{R_p}{1 + \omega C_p R_p j} \quad [6]$$

$$Z_{Rp} = Z_{Rs} \left[1 + \left(\frac{Z_{Cs}}{Z_{Rs}} \right)^2 \right] \quad [7]$$

$$Z_{Cp} = Z_{Cs} \left[1 + \left(\frac{Z_{Rs}}{Z_{Cs}} \right)^2 \right] \quad [8]$$

Combining Eq. [1] and [2] gives

$$\dot{Z}_F = R_{ct} (1 + \zeta) - \zeta R_{ct} j \quad [9]$$

and a further transformation from the in-series circuit represented by Eq. [9] to the parallel circuit represented by Eq. [7] and [8] yields the resistive impedance, $(Z_{Rp})_F$, and the capacitive impedance, $(Z_{Cp})_F$, for the faradaic contribution

$$(Z_{Rp})_F = \frac{R_{ct}}{1 + \zeta} (1 + 2\zeta + 2\zeta^2) \quad [10]$$

$$(Z_{Cp})_F = \frac{R_{ct}}{\zeta} (1 + 2\zeta + 2\zeta^2) \quad [11]$$

Finally, the ratio $(Z_{Cp})_F / (Z_{Rp})_F$ is only a function of ζ

$$\frac{(Z_{CD})_F}{(Z_{Rp})_F} = 1 + \frac{1}{\zeta} \quad [12]$$

Thus, the impedance of a blank solution provides $Z_{Rs}(c_0)$ and $Z_{Cs}(c_0)$, from which the C_L and R_L can be calculated (see Fig. 1b). The impedance is then measured for a solution containing an electroactive species, and values of $Z_{Rs}(c_1)$ and $Z_{Cs}(c_1)$ obtained from which the $Z_{Cp}(c_1)$ and $Z_{Rp}(c_1)$ can be calculated (see Fig. 1c). R_L and C_L can then be subtracted from the total impedance (see Fig. 1d). This pure faradaic contribution can be treated using Eq. [12] to get the ζ value.

The rate parameter ζ can be calculated as shown in Eq. [13]

$$\zeta = \left[\frac{Z_{Rs}(c_1) - Z_{Rs}(c_0) \cdot \eta}{Z_{Cs}(c_1) - Z_{Cs}(c_0) \cdot \eta} - 1 \right]^{-1} \quad [13]$$

where η is a conversion factor

$$\eta = \frac{[Z_{Cs}(c_1)]^2 + [Z_{Rs}(c_1)]^2}{[Z_{Cs}(c_0)]^2 + [Z_{Rs}(c_0)]^2} \quad [14]$$

If we assume that $D_R = D_O = D$ and $k_r + k_o = k$, then Eq. [3] can be written more compactly as

$$k = \zeta(2\omega D)^{1/2} \quad [15]$$

The standard heterogeneous rate constant k^0 can be obtained from the plot of $\log k$ vs. potential (25).

Calculated k values for LCo(II) in the potential range of -0.3 to -0.45 V are presented in Fig. 3. These values were calculated using a measured diffusion coefficient of 1.3×10^{-5} cm²/s. As seen in this figure, the shape of the $\log k$ potential plot for the lowest concentration of sample (1.4×10^{-4} M) is distorted. The maximum of the plot increases with higher sample concentration, and the potential of the maximum is shifted in a negative direction. This indicates that the measured impedance is due to a faradaic process which is influenced by adsorption (25).

Combined faradaic and adsorption processes.—AC admittance measurements for combined faradaic and adsorption processes have been described by several authors (23, 25-28). Theoretical representations of the cell admittance or impedance are quite complicated and cannot be simply solved without some limiting assumptions. A general form of the half-cell equivalent circuit for the case of adsorption of the reactant and the product can be

represented as shown in Fig. 4a, where Z_K and Z_F are the desorption-adsorption impedance (a kinetic impedance) and faradaic impedance, respectively.

The representation of faradaic and adsorption processes as shown in Fig. 4a is possible only with the assumption that there is no coupling between the faradaic and the adsorption process. The coupling would be a consequence of competition by different mechanisms (redox and adsorption-desorption) for the same species, but is negligible under conditions where the ac impedance measurement is performed at a surface completely covered by electroactive species (*i. e.*, at the plateau of the isotherm where the surface concentration Γ is close to unity). In this case, the contribution of the impedance due to adsorption will be constant and can be considered as the background.

The charge transfer resistance and Warburg impedance are proportional to the bulk concentration of the electroactive species (Eq. [1], [2], and [4]). Therefore, further increasing of the concentration will only effect the faradaic component of the impedance Z_F . In this special case, we can use Eq. [13] - [15] for calculation of the heterogeneous electron-transfer rate constant on an electrode surface which is completely covered by adsorbed species. The presented treatment eliminates measurements of double layer capacity. Using as a background the value of impedance measured for 6.5×10^{-4} M LCo(II) enabled calculation of the rate constant and the $\log k$ potential plot shown in Fig. 4b. A graphical extrapolation gave $k^0 = 8 \times 10^{-2}$ cm/s and α coefficients 0.4 and 0.6. No differences were observed for the $\log k$ potential plot if the impedance of the solution with the concentration of LCo(II) larger than 6.5×10^{-4} M was assumed to be the background.

A Cyclic Voltammetric Study of the Gold-Oxygen System

James P. Hoare*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090-9055

ABSTRACT

Cyclic voltammograms were obtained on gold bead microelectrodes in N_2 -stirred 1M H_2SO_4 and 1M HF solutions as a function of the sweep rate and the potential range scanned. It is found that H_2 and O_2 are very slightly absorbed on Au and that neither is dissolved in the bulk metal. As a result, Au makes a more stable indicator electrode than Pt, which does dissolve oxygen. It is the formation of this Pt-O alloy that necessitates a prepolarization of Pt before a steady-state cyclic voltammogram is obtained. It is noted that all contamination of Au with noble metals must be rigorously avoided.

In the literature, there is a growing body of evidence to support the conclusion that oxygen may be dissolved in Pt during anodic polarization (1-14) and with passivation in concentrated HNO_3 (15-17). To obtain a steady-state cyclic voltammogram on Pt in acid solutions, up to 20 cycles of polarization (18-22) are required, and it has been proposed that this preparation is required to free the Pt surface from absorbable, electroactive impurities even in highly purified solutions (20). From a cyclic voltammetric study of Pt in H_2SO_4 and HF solutions, it was concluded (23) that in purified solutions the predominant cause for the necessary 20 cycle prepolarization is the charging of Pt with dissolved oxygen. As oxygen is dissolved in the Pt metal, the catalytic activity of the Pt surface is modified for various electrochemical processes, and, until the surface or dermasorption layers of the metal are saturated with dissolved oxygen, a constant catalytic surface cannot be realized. Thus, a steady-state cyclic voltammogram cannot be obtained.

If such a study were carried out on gold, which does not dissolve gases (24, 25), the steady state would be expected to be established relatively quickly in purified systems. This report describes a cyclic voltammetric study of gold microelectrodes in purified H_2SO_4 and HF electrolytes.

Experimental

Test electrodes were in the form of small beads (about 0.13 cm diam) melted at the end of pure (99.9+%) gold wires (0.038 cm diam) in an oxygen torch. These gold beads were cleaned in hot concentrated HNO_3 and in a burning H_2 -jet, as described elsewhere (23), and were pot-

ted in molten polyethylene. As before (23), three test electrodes were mounted in the dual-compartmented Teflon cell, which had been leached in triply distilled water from an all-quartz still, for at least 2 weeks after having been soaked in concentrated HNO_3 for 48h. All counter- and auxiliary electrodes were made from electroformed gold gauze.

After the cell had been filled with 1M H_2SO_4 made from triply distilled water and analytical grade H_2SO_4 , the system was pre-electrolyzed with all-gold test and auxiliary electrodes connected together against gold wire pre-electrolysis electrodes. A pre-electrolysis current of 3 mA was allowed to flow for 48h before breaking the circuit by removing the gold wires.

At no point in the experimental procedure was the system permitted to come in contact with Pt. It has been shown (26-28) that the presence of only a very few Pt sites on the Au surface drastically modifies the electrochemistry of Au.

Once the pre-electrolysis electrodes were removed, the solution was stirred with purified hydrogen gas until all gold electrodes registered 0V between one another. This procedure removed the oxides and peroxides generated during pre-electrolysis, but it required a longer time to reduce the Au oxides on Au than the Pt oxides on Pt (23).

In a separate clean, Teflon cell, the α Pd-H reference electrode (29) was made. A small palladium bead was melted at the end of a Pd wire and potted in molten polyethylene. This bead was anodized in 1M H_2SO_4 against Pt for 48h, after which H_2 was bubbled around the Pd until its potential came to 50 mV vs. Pt/ H_2 gauze electrodes in the same solution. After continuing the H_2 bubbling for an additional 2h, the Pd bead was removed from the sec-

* Electrochemical Society Active Member.

ond cell, rinsed in triply distilled water, and sealed in the reference compartment of the first cell in the H_2 -saturated acid solution. In this way, contamination of the Au test electrodes with adsorbed or deposited Pd was minimized, if not prevented entirely.

The procedure for obtaining the cyclic voltammetric data in purified N_2 -saturated electrolyte was virtually the same as presented earlier (23).

For those experiments using 1M HF, the electrolyte was prepared in Teflon labware and the glass frit connecting the reference and test compartments was removed.

Unless otherwise noted, all potentials are recorded vs. $\alpha Pd-H$ (50 mV vs. NHE at pH = 0) at ambient temperatures, $25^\circ \pm 1^\circ C$.

Results and Discussion

On gold in N_2 -stirred 1M H_2SO_4 , it required about ten cycles of polarization to reach a steady-state voltammogram, as shown in Fig. 1. On Pt in N_2 -stirred 1M H_2SO_4 , as shown in Fig. 2, it required many more cycles of polarization than on Au to reach a steady state, and the changes from the initial trace to the steady state are much greater on Pt than on Au. The family of cyclic voltammograms presented in Fig. 3 was obtained on Au by varying the sweep rate from 100 to 17 mV/s. The major peaks are

identified with Roman numerals. For the hydrogen region, a subscript H, is used, and in the oxygen region, O is used. The peaks on the cathodic going sweep are distinguished from those on the anodic going sweep by a prime. Since the peak heights are linearly dependent on the sweep rate, it is concluded (30) that the electrode processes responsible for the peaks are surface processes and not diffusion of some electroactive species from the solution. The shape of the traces in Fig. 3 is similar to that reported on Au in the literature (31-36).

To relate peaks appearing on the anodic going trace with those on the cathodic going trace, one may vary the range of potentials over which the electrode is scanned. In Fig. 4, a family of voltammograms is obtained by initiating the anodic sweep at successively more anodic potentials. As the beginning of the anodic sweep is shifted from -200 to 500 mV, a small reduction in the II_o , III_o , and IV_o peak heights is observed. If the anodic sweep is begun at 1000 mV, II_o is reduced, but III_o and IV_o are maintained; if at 1100 mV, II_o disappears; and if at 1200 mV, III_o and IV_o disappear.

When the cathodic sweep is begun at successively more cathodic potentials, the family of voltammograms in Fig. 5 is obtained. As one progresses from 1700 to 1400 mV, I'_o diminishes until after about 1350 mV, and both I'_o and II'_o

Fig. 1. Cyclic voltammograms obtained on Au in N_2 -stirred 1M H_2SO_4 showing change in pattern from initial trace to the steady-state trace. Sweep rate: 100 mV. Sweep range: -200 to 1700 mV. Initial trace indicated by arabic numeral one.

Fig. 2. Cyclic voltammograms obtained on Pt in N_2 -stirred 1M H_2SO_4 showing change in pattern from initial to the steady-state trace. Sweep rate: 100 mV/s. Sweep range: 0-1500 mV. Initial trace indicated by arabic numeral one.

Fig. 3. Family of cyclic voltammograms obtained on Au in N_2 -stirred 1M H_2SO_4 at sweep rates of 100, 83, 67, 50, 33, and 17 mV/s from -200 to 1700 mV. 100 mV/s sweep is outside trace. Roman numerals identify major peaks.

Fig. 4. Family of cyclic voltammograms obtained on Au in N_2 -stirred 1M H_2SO_4 swept at 100 mV/s by reducing the range of potentials scanned from the cathodic end in 100 mV steps. Potential at start of trace is indicated by potential value.

disappear. On the 1400 mV trace, a shoulder on I'_o appears and is designated as II'_o . Changes in II'_H as the potential range is reduced, the largest changes occurring between 1300 and 600 mV.

From these data, one associates II_o , III_o , and IV_o with I'_o , but, apparently, II_o also contains the species reduced in II'_o . In addition, I_o is related to III'_o and I_H to I'_H .

In N_2 -stirred 1M HF, the steady-state voltammogram on Au is reached relatively quickly (in about five cycles of polarization), as demonstrated in Fig. 6. The linear dependence on sweep rate shown in Fig. 7 indicates that the electrode processes involved are surface reactions. The overall shape of the traces in Fig. 7 are very similar to those on Au in 2N H_2SO_4 (Fig. 3) except that I_o and III'_o are not present and I_H and I'_H have also vanished. At about 1100 mV, an additional peak, designated VI_o , appears. Traces similar to these have been reported by Hamelin *et al.* (36) for Au in NaF solutions.

As one reduces the potential range by initiating the anodic sweep at increasingly positive potentials (Fig. 8), little or no changes occur until the sweep is begun at 900 mV, where II_o is reduced. At 1000 mV, the structure in the oxygen region is reduced to a single broad peak, which disappears at potentials above 1100 mV. Figure 9 contains the data for reduction of the potential range by initiating the cathodic sweep at increasingly greater cathodic values. Between 1700 and 1300 mV, I'_o is reduced; the shoulder II'_o appears at potentials below 1300 mV. As be-

fore, we associate II_o , III_o , and IV_o with I'_o , noting that II_o is also associated with II'_o .

It is now possible to assign electrode processes to the peaks observed on the cyclic voltammograms. As discussed in the literature (28, 35, 37), the oxide layers on Au are formed by the discharge of adsorbed water molecules to form precursor species, such as hydrated Au_2O or hydrated adsorbed oxygen (Au-O). Such species are oxidized with continued polarization to hydrated Au_2O_3 or $AuOOH$. This oxide may be formed through a place-change mechanism (38) as discussed by Schultze and Vetter (37). However, oxygen atoms remain only in the first surface layer of gold atoms and do not penetrate into the bulk metal.

In Fig. 1 and 6, the first anodic sweep on gold exhibits peaks III_o and IV_o but not II_o . With each succeeding cycle of polarization, II_o becomes more prominent at the expense of III_o and IV_o until the steady-state pattern is formed (Fig. 3 and 7). This behavior is viewed as the oxidation of the hydrated oxide precursors to a steady-state layer of hydrated Au_2O_3 . According to the literature, the oxide film on Au is a porous, poorly adherent layer of hydrated Au_2O_3 (39) that grows continuously with polarization (40-42) by the place-change mechanism at the metal-oxide interface (37). The increase in area of the reduction peak I'_o in Fig. 3 and 6 reflects the growth of the Au_2O_3 layer during the anodic going sweep until the oxide formed during anodization is just reduced during cathodization at steady state.

Fig. 5. Family of cyclic voltammograms obtained on Au in N_2 -stirred 1M H_2SO_4 swept at 100 mV/s by reducing the potential range scanned from the anodic end in 100 mV steps. Potential at start of trace is indicated by potential value.

Fig. 6. Cyclic voltammograms obtained on Au in N_2 -stirred 1M HF swept at 100 mV/s from -200 to 1700 mV showing the change in pattern from the initial to the steady-state trace. Initial trace indicated by arabic numeral one.

Fig. 7. Family of cyclic voltammograms obtained on Au in N_2 -stirred 1M HF swept from -200 to 1700 mV as a function of the sweep rate (100, 83, 67, 50, 33, 17 mV/s). 100 mV/s trace is the outside curve.

From the data in Fig. 5 and 9, there appears to be two kinds of oxide, a strongly bound and weakly bound form. Most of the oxide is present as relatively thick patches of

weakly bound hydrated Au_2O_3 . Under these patches or clusters of hydrated Au_2O_3 at the metal-oxide interface is a strongly bound (probably monolayer) film of Au_2O_3 in-

Fig. 8. Family of cyclic voltammograms obtained on Au in N_2 -stirred 1M HF swept at 100 mV/s by reducing the potential range scanned from the cathodic end in 100 mV steps. Potential at start of trace is indicated by potential value.

Fig. 9. Family of cyclic voltammograms obtained on Au in N_2 -stirred 1M HF swept at 100 mV/s by reducing the potential range scanned from the anodic end in 100 mV steps. Potential at start of trace is indicated by potential value.

timately tied to the surface layers of the gold metal (similar to dermasorbed Au_2O_3). The reduction of this tightly bound Au_2O_3 appears in II'_0 . In the steady-state scan (Fig. 3 and 6), II_0 , III_0 , and IV_0 may represent the formation of Au_2O_3 with different degrees of hydration.

Since peaks I_0 and III'_0 appear on voltammograms obtained on Au in H_2SO_4 solutions but not on those in HF solution, it is concluded that the adsorption of HSO_4^- ions on Au produce I_0 , and their desorption III'_0 . It is noted that VI_0 appears on scans in HF but not on those in H_2SO_4 . If it is assumed that oxygen begins to adsorb on Au at VI_0 , then the absence of VI_0 in H_2SO_4 may be traced to the interference of adsorbed HSO_4^- ions which delay the adsorption of oxygen to higher potentials. Such behavior was noted (23) on cyclic voltammograms obtained on Pt electrodes in 1M H_2SO_4 and in 1M HF solutions. This interference of adsorbed HSO_4^- ion on Au may also account for the larger number of cycles of polarization required to reach steady state in H_2SO_4 (Fig. 1) than in HF (Fig. 6).

Evolution of oxygen leads to V_0 , and evolution of hydrogen to II'_H . In HF solutions, hydrogen is virtually not adsorbed. However Fig. 8 and 9 indicate that there is some relationship between the surface reaction at low values of the polarization and that at high values of the polarization. This behavior may be accounted for by area changes during oxide formation and reduction. In H_2SO_4 solutions, this effect is exaggerated to the point that I_H

and I'_H were assigned to this region. It may be possible that HSO_4^- ion adsorption may contribute to the enhancement of the area effects in H_2SO_4 solution.

Once a steady-state cyclic voltammogram is obtained on gold in 1N HF (SS in Fig. 10), the electrode was cycled for about 20 cycles between -200 and 500 mV. When the potential range scanned was increased to 1700 mV, the steady-state curve was virtually recovered with the first cycle of polarization. For the sake of comparison, this same procedure was repeated on Pt in 1M H_2SO_4 cycled between 0 and 1500 mV. The steady-state trace is indicated by SS in Fig. 11. When the potential range was narrowed to $0-500$ mV and cycled for about 20 cycles, large changes took place in the hydrogen peaks I_H , I'_H , IV_H , and II'_H , and III_H disappeared. Upon returning the sweep range to $0-1500$ mV, one observes that it required at least five (numbered in Fig. 11) cycles of polarization to recover the steady state.

Such behavior in the case of Pt has been accounted for (23) by the dissolution of oxygen in bulk Pt at potentials above $1V$ to form a Pt-O alloy. The alloy is a better catalyst for the O_2 and H_2 reactions than is oxygen-free Pt. As shown in Fig. 2, it requires many cycles of polarization to charge up the Pt so that a steady-state Pt-O alloy surface with a stable catalytic activity can be obtained. When the system was cycled between 0 and 500 mV (Fig. 11), oxygen was removed from the Pt surface by reaction with adsorbed hydrogen, and although this hydrogen is replaced

Fig. 10. Once the steady-state cyclic voltammogram had been obtained from -200 to 1700 mV at 100 mV/s on Au in $1M$ HF, the electrode was cycled between -200 and 500 mV for about 20 cycles. When the electrode was cycled again between -200 and 1700 mV, the steady-state scan (ss) was retraced on the first cycle.

Fig. 11. Once the steady-state cyclic voltammogram was obtained on Pt in $1M$ H_2SO_4 from 0 to 1500 mV at 100 mV/s, the electrode was cycled from 0 to 500 mV for about 20 cycles. When the electrode was cycled again between -200 and 1700 mV, it required at least 5 cycles (numbered on figure) to retrace the steady-state scan (ss).

by dissolved oxygen in the metal diffusing to the surface, the catalytic activity of the Pt surface changes with each cycle because the concentration of dissolved oxygen in Pt is being continually reduced. When the anodic end of the sweep is returned to 1500 mV, the steady-state Pt-O alloy surface can be regenerated with the replacement of the lost dissolved oxygen with five cycles of polarization.

In the case of Au, only a few cycles of polarization are required to reach to steady state (Fig. 1 and 6). When cycled to 500 mV (Fig. 10), relatively little change is observed, and the steady state is reached rapidly once the sweep is returned to 1500 mV. Since Au does not dissolve oxygen, anodization or cathodization does not modify the catalytic activity of the Au surface for H_2 or O_2 reactions (Fig. 10) and a steady-state voltammogram is obtained quickly.¹

To demonstrate the effect of noble metal poisoning of the Au surface, the α -Pd-H reference electrode was pre-

pared (preanodized and charged with hydrogen) in the same solution with the Au electrodes. The family of cyclic voltammograms obtained on the poisoned Au in $1M$ HF solution scanned between -200 and 1700 mV as a function of sweep speed is presented in Fig. 12. A prominent hydrogen desorption peak, I_H , is evident and the potential at which oxygen is first adsorbed VI_0 is shifted far to the left. Here, VI_0 appears at a potential coincident with the value for the beginning of oxygen adsorption on Pt (Fig. 13). Not only is II_0 much sharper in Fig. 12 than in Fig. 3 and 7, but it is also shifted to the left by at least 100 mV. Peaks III_0 and IV_0 (evident in Fig. 7) become indistinct in Fig. 12. The oxygen reduction peak I'_0 becomes much sharper and narrower in Fig. 12 than in Fig. 7. From the data in Fig. 12, it is evident that noble metal contamination of a Au surface can severely modify the electrochemistry of the noble metal-free Au surface. Since Pt or Pd sites are much more active than Au sites, only a very few noble metal sites present on an Au surface can give it a strong noble metal character.

From these studies, it is concluded that hydrogen is only slightly adsorbed (if at all) on Au, and much less than a monolayer of oxygen ($\theta < 0.01$) is adsorbed below 1350 mV. Above 1350 mV, hydrated Au_2O_3 is formed by the place-change mechanism between Au surface atoms

¹ One of the reviewers suggested that these data could be interpreted in terms of gold's not adsorbing impurities as easily as Pt, which could account for the shorter times required to reach the steady state on Au than on Pt. Another possibility is the suggestion that the deposition of oxygen rearranges the surface Au atoms more rapidly than on Pt. Both of these mechanisms have been rejected in favor of the one proposed in the body of this report.

Fig. 12. Family of cyclic voltammograms obtained on Pd-contaminated Au in N_2 -stirred 1M HF from -200 to 1700 mV/s as a function of the sweep rate (100, 83, 67, 50, 33, 17 mV/s). 100 mV/s sweep is outside trace.

Fig. 13. Family of cyclic voltammograms obtained on Pt in N_2 -stirred 1M H_2SO_4 from 0 to 1500 mV as a function of the sweep rate (100, 83, 67, 50, 33, 17 mV/s). 100 mV/s sweep is outside trace.

and adsorbed oxygen atoms generated by the discharge of water. There are two kinds of adsorbed Au_2O_3 on the Au surface, a strongly bound, thin layer at the Au surface lying beneath a relatively thick, weakly bound layer. Oxygen does not dissolve in the bulk gold metal, nor do other gases. Consequently, Au presents a stable catalytic surface in many electrochemical systems and can make an excellent indicator electrode. Bisulfate ions can adsorb on Au and interfere somewhat with hydrogen and oxygen reactions taking place at the Au surface. For investigations of the electrochemistry of Au, one must rigorously exclude contact with noble metals.

These data also support the conclusion (23) that prepolarization of Pt is required to produce a stable catalytic surface by forming a Pt-O alloy. In this way, a reproducible and stable indicator electrode may be obtained. Although desorption of impurities (21, 22, 30) and possible dissolution of Pt (43, 44) may contribute to the need for prepolarizing Pt, the major contribution to this treatment is the formation of a Pt-O alloy with a stable catalytic surface. This work on Au supports this viewpoint because pure clean Au, which does not dissolve oxygen, does not

need this intense prepolarization to achieve a stable catalytic surface in the same purified electrolytes.

Manuscript submitted Nov. 4, 1983; revised manuscript received Jan. 23, 1984. This was Paper 408 presented at the Cincinnati, OH, Meeting of the Society, May 6-11, 1984.

Membrane-Covered Oxygen Sensors: An Exact Treatment of the Switch-on Transient

Janice C. Myland and Keith B. Oldham*

Department of Chemistry, Trent University, Peterborough, Ontario, Canada K9J 7B8

ABSTRACT

Equations are derived that exactly describe the current-time behavior of a membrane-covered oxygen sensor, following the imposition of a polarizing potential to the previously equilibrated cell. The role of the various geometric, transport, and solubility factors is evaluated without any restriction being placed upon the magnitudes of these factors. The equations are analyzed to predict the duration of Cottrellian behavior, and the interval before the onset of the steady state, for sensors of practical importance.

The membrane-covered electrochemical oxygen sensor was invented by Clark (1); its principles are comprehensively described in the monograph by Hitchman (2). The geometry of the device is as shown in Fig. 1. The medium being analyzed, which may be a gas, a water body, or an aqueous solution, contains oxygen at a uniform partial pressure p_w . An inlaid disk electrode is separated from this medium by a layer of aqueous electrolyte and a layer of a plastic membrane. The diameter $(4A/\pi)^{1/2}$ of the electrode is very large compared with the thicknesses a and b of the two layers so that oxygen effectively reaches the electrode solely by diffusion along the dimension marked y in Fig. 1.

In operation, the electrode is polarized sufficiently negative that the reaction

proceeds under diffusion controlled conditions. When the polarizing potential is applied to a previously equilibrated cell, a transient current flows that declines towards an ultimate steady-state value. Both the initial transient current and the final steady-state current are proportional to p_w , and both currents have been used analytically. The form of the current vs. time relationship depends in a complicated fashion on the geometric, transport, and solubility properties of the two layers. Previous derivations (2-4) of this relationship have imposed restrictions on

these properties. The object of the present discussion is to remove these restrictions.

Solubility and Transport Properties

The concentration of oxygen at any plane y in the electrolyte is related to the oxygen partial pressure there by Henry's law

$$c = H_e p \quad 0 \leq y \leq a \quad [2]$$

Here, H_e is the Henry's law constant for oxygen in the electrolyte solution. It is a few percent smaller than H_w , the Henry's law constant for pure water, because of the "salting out" of oxygen by the electrolyte. A similar relationship

Fig. 1. The geometry of the membrane-covered oxygen sensor. The thicknesses a and b are small in comparison with the electrode radius $(4A/\pi)^{1/2}$.

*Electrochemical Society Active Member.

$$c = H_m p \quad a \leq y \leq a + b \quad [3]$$

holds in the membrane, but with a different Henry's law constant H_m .

Equilibrium may be assumed to exist at the outer and inner faces of the membrane, so that

$$p(y = a + b -) = p(y = a + b +) = p_w \quad [4]$$

and

$$p(y = a +) = p(y = a -) \quad [5]$$

Moreover, the fluxes of oxygen on each side of the membrane/electrolyte interface must be identical, *i.e.*

$$J(y = a +) = J(y = a -) \quad [6]$$

Because we assume oxygen transport to be wholly diffusive, Fick's first law

$$J = -D_e \frac{\partial c}{\partial y} = -D_e H_e \frac{\partial p}{\partial y} \quad 0 \leq y \leq a \quad [7]$$

applies, where D_e is the diffusion coefficient of oxygen in the electrolyte solution. A similar relationship

$$J = -D_m H_m \frac{\partial p}{\partial y} \quad a \leq y \leq a + b \quad [8]$$

holds within the membrane. As with his first law, Fick's second law may also be written in terms of oxygen partial pressures

$$\frac{\partial p}{\partial t} = D_e \frac{\partial^2 p}{\partial y^2} \quad 0 \leq y \leq a \quad [9]$$

and

$$\frac{\partial p}{\partial t} = D_m \frac{\partial^2 p}{\partial y^2} \quad a \leq y \leq a + b \quad [10]$$

The diffusion coefficient of oxygen in aqueous electrolyte solution is a mild function of temperature and of the nature and concentration of the electrolyte. We shall use the value (5)

$$D_e = 2.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1} \quad [11]$$

throughout this article. There is a paucity of information on the diffusion coefficients of oxygen in membrane materials but Hitchman (2) reports

$$D_m = 1.14 \times 10^{-11} \text{ m}^2 \text{ s}^{-1} \quad [12]$$

for polytetrafluoroethene (Teflon), which is commonly used for sensor membranes. Experiments in these laboratories (6) suggest that D_m approximates $3 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ for polydimethylsiloxane (silastic rubber).

Whereas there are few diffusion coefficient data, some compilations exist of the product $D_m H_m$, which is known as the "permeability" of the membrane material. However, as Table I shows, there is poor agreement among the reported values. The related quantity

$$P_m = D_m H_m / H_w \quad [13]$$

Table I. Permeabilities of two polymers to oxygen

Polymer	$D_m H_m$ mol m ⁻¹ s ⁻¹ atm ⁻¹	Method	Ref.

Polydimethyl- siloxane	2.3×10^{-8}	Volumetric using gas/	(7)
	1.7×10^{-8}	membrane/gas system	(8)
	1.4×10^{-7}	Volumetric using water/	(7)
		membrane/water system	(7)

is known as the "permeability coefficient" of the membrane. Hitchman (2) reports the experimental value

$$P_m = 8.2 \times 10^{-11} \text{ m}^2 \text{ s}^{-1} \quad [14]$$

for polytetrafluoroethene.

The Henry's law constant for pure water may be calculated from oxygen solubility data [Ref. (2), Appendix B] as about

$$H_w = 1.33 \text{ mol m}^{-3} \text{ atm}^{-1} \quad [15]$$

at room temperature. For aqueous 1:1 electrolytes at tenth-molar concentration

$$H_e \approx 1.28 \text{ mol m}^{-3} \text{ atm}^{-1} \quad [16]$$

for solutions typically used to fill membrane-covered sensors. The Henry's law constant for polytetrafluoroethene can be obtained as

$$H_m = 9.6 \text{ mol m}^{-3} \text{ atm}^{-1} \quad [17]$$

from Eq. [12]-[15]. Notice that oxygen is significantly more soluble in this polymer than in water or aqueous solutions.

A dimensionless grouping of terms that repeatedly occurs in the following theory is

$$\Lambda = \frac{D_e^{1/2} H_e - D_m^{1/2} H_m}{D_e^{1/2} H_e + D_m^{1/2} H_m} \quad [18]$$

This definition of Λ ensures that its value lies between -1 and +1. The constants in Eq. [11], [12], [16], and [17] lead to the representative value

$$\Lambda = 0.29 \quad [19]$$

when the sensor membrane is polytetrafluoroethene. This value will be used in numerical examples below.

There is a characteristic time associated with transport through each of the layers, namely

$$T_e = a^2 / D_e \quad [20]$$

and

$$T_m = b^2 / D_m \quad [21]$$

Probably the single most common membrane in present day use is a 0.001 in. thick film of polytetrafluoroethene. For such a membrane, one calculates, using Eq. [12]

$$T_m = 57 \text{ s} \quad [22]$$

The characteristic electrolyte time T_e may be either shorter or longer than this, according to the sensor design. Thus, a classical Clark cell has an electrolyte film of about 20 μm thickness, which gives

$$T_e = 0.19 \text{ s} \ll T_m \quad \text{Clark conditions} \quad [23]$$

when combined with the value in Eq. [11]. On the other hand, Fowler and Oldham (5) used an electrolyte solution layer of 2 mm thickness, which translates to

$$T_e = 1900 \text{ s} \gg T_m \quad \text{Fowler conditions} \quad [24]$$

Mancy and co-workers (4) considered a cell in which the two characteristic times are equal, *i.e.*

$$T_e = 57 \text{ s} = T_m \quad \text{Mancy conditions} \quad [25]$$

For brevity, we will find the definitions of a sum and difference

$$T_s^{1/2} = T_e^{1/2} + T_m^{1/2} = (a/D_e^{1/2}) + (b/D_m^{1/2}) \quad [26]$$

and

$$T_d^{1/2} = T_e^{1/2} - T_m^{1/2} = (a/D_e^{1/2}) - (b/D_m^{1/2}) \quad [27]$$

useful. The ratio $T_d^{1/2}/T_s^{1/2}$ is close to ± 1 respectively for the Fowler and Clark cells, while it is zero for the cell treated by Mancy.

General Expression for the Sensor Current Transform

We consider equilibrium to exist prior to the instant, $t = 0$, at which the electrode is polarized; therefore

$$p = p_w \quad y > 0 \quad t < 0 \quad [28]$$

Thereafter, polarization is complete at the electrode surface

$$p = 0 \quad y = 0 \quad t > 0 \quad [29]$$

and the current is given by Faraday's law applied to reaction [1]

$$i = -4AFJ \quad y = 0 \quad t > 0 \quad [30]$$

where J is the time-dependent oxygen flux along the Y-axis (Fig. 1). Combining this with Eq. [7], one obtains

$$i = 4AFH_e D_e (\partial p / \partial y) \quad y = 0 \quad t > 0 \quad [31]$$

We need to solve Eq. [9], Fick's second law for the electrolyte layer, subject to initial condition [28] and boundary condition [29]. The solution is aided by the Laplace transformation of Eq. [9] into

$$\frac{\partial^2 \bar{p}}{\partial y^2} - \frac{s\bar{p}}{D_e} = -\frac{p_w}{D_e} \quad 0 \leq y \leq a \quad [32]$$

which incorporates condition [28] and in which \bar{p} is the transform of the local oxygen partial pressure and s is the dummy variable of Laplace transformation with respect to time. Standard methods (9) permit a general solution to Eq. [32] to be written as

$$\bar{p} = \frac{p_w}{s} + G_e \cosh\left(\frac{ys^{1/2}}{D_e^{1/2}}\right) + g_e \sinh\left(\frac{ys^{1/2}}{D_e^{1/2}}\right) \quad 0 \leq y \leq a \quad [33]$$

where G_e and g_e are y -independent terms that depend on the boundary conditions. Condition [29] shows \bar{p} to be zero at $y = 0$, which requires G_e to equal $-p_w/s$ and leads to

$$\bar{p} = \frac{p_w}{s} \left[1 - \cosh\left(\frac{ys^{1/2}}{D_e^{1/2}}\right) \right] + g_e \sinh\left(\frac{ys^{1/2}}{D_e^{1/2}}\right) \quad 0 \leq y \leq a \quad [34]$$

On differentiation with respect to distance, one obtains

$$\frac{\partial \bar{p}}{\partial y} = \frac{-p_w}{s^{1/2} D_e^{1/2}} \sinh\left(\frac{ys^{1/2}}{D_e^{1/2}}\right) + \frac{g_e s^{1/2}}{D_e^{1/2}} \cosh\left(\frac{ys^{1/2}}{D_e^{1/2}}\right) \quad 0 \leq y \leq a \quad [35]$$

The membrane phase may be treated similarly, but it is more convenient to write the analog of Eq. [33] as

$$\bar{p} = \frac{p_w}{s} + G_m \cosh\left(\frac{(a+b-y)s^{1/2}}{D_m^{1/2}}\right) + g_m \sinh\left(\frac{(a+b-y)s^{1/2}}{D_m^{1/2}}\right) \quad a \leq y \leq a+b \quad [36]$$

The transform of boundary condition [4] shows \bar{p} to equal p_w/s at $y = a+b$, which requires G_m to be zero and leads to

$$\bar{p} = \frac{p_w}{s} + g_m \sinh\left(\frac{(a+b-y)s^{1/2}}{D_m^{1/2}}\right) \quad a \leq y \leq a+b \quad [37]$$

directly and

$$\frac{\partial \bar{p}}{\partial y} = \frac{-g_m s^{1/2}}{D_m^{1/2}} \cosh\left(\frac{(a+b-y)s^{1/2}}{D_m^{1/2}}\right) \quad a \leq y \leq a+b \quad [38]$$

on differentiation with respect to distance.

The remaining unknown functions of s , g_e , and g_m may be determined by using Eq. [5]-[8] to solve the $y = a$ specializations of Eq. [34], [35], [37], and [38] simultaneously. Omitting the detailed algebra, one finds

$$g_m = \frac{-p_w[1-\Lambda]}{s[\sinh(sT_s)^{1/2} - \Lambda \sinh(sT_d)^{1/2}]} \quad [39]$$

and

$$g_e = \frac{p_w[\cosh(sT_s)^{1/2} - \Lambda \cosh(sT_d)^{1/2}]}{s[\sinh(sT_s)^{1/2} - \Lambda \sinh(sT_d)^{1/2}]} \quad [40]$$

where abbreviations [18], [26], and [27] have been utilized.

To obtain the final expression

$$\bar{i} = \frac{4AFp_w H_e D_e^{1/2}}{s^{1/2}} \left[\frac{\cosh(sT_s)^{1/2} - \Lambda \cosh(sT_d)^{1/2}}{\sinh(sT_s)^{1/2} - \Lambda \sinh(sT_d)^{1/2}} \right] \quad [41]$$

for the transform of the current, one specializes Eq. [35] to $y = 0$ and combines it with Eq. [40] and the transform of Eq. [31]. The Laplace inversion of Eq. [41] is by no means trivial, and we shall consider limiting and simplifying circumstances before tackling the general case. It may bear emphasis that no assumptions about the sizes or materials of construction of the membrane or electrolyte are incorporated into transform [41] nor, therefore, into the equations of the "General Solution: First Inversion" and "General Solution: Second Inversion" sections below that result from its general Laplace inversion.

Initial Response

As $t \rightarrow 0$ only large values of s become important and the arguments of the hyperbolic terms in Eq. [41] tend towards infinity. The hyperbolic sines and cosines of infinitely large arguments are indistinguishable and, therefore, Eq. [41] collapses to

$$\bar{i} = 4AFp_w H_e D_e^{1/2} / s^{1/2} \quad s \rightarrow \infty \quad [42]$$

which inverts to

$$i = 4AFp_w H_e D_e^{1/2} / \pi^{1/2} t^{1/2} \quad t \rightarrow 0 \quad [43]$$

Equation [43], which is essentially the Cottrell equation (10), shows that the $it^{1/2}$ product is initially a constant [that we shall subsequently denote $(it^{1/2})_0$], proportional to p_w but independent of any membrane parameters. It is this independence from the membrane that provides the attraction for the pulse-after-equilibration mode of operation of the membrane-covered oxygen sensor (5).

Steady-State Current

Only small values of s are important as $t \rightarrow \infty$. In this circumstance, the hyperbolic cosine terms in Eq. [41] may be replaced by unities, and the hyperbolic sine terms by their arguments. Simplification to

$$\bar{i} = \frac{4AFp_w H_e D_e^{1/2} (1-\Lambda)}{s(T_s^{1/2} - \Lambda T_d^{1/2})} \quad s \rightarrow 0 \quad [44]$$

follows. Inversion is now straightforward and leads to

$$i = 4AFp_w / [(a/D_e H_e) + (b/D_m H_m)] \equiv i_\infty \quad t \rightarrow \infty \quad [45]$$

after some algebra.

Equation [45] for the steady-state current i_∞ has been known, in a less symmetrical form, for some time [Ref. (2), Appendix H]. Not surprisingly, this equation has the form of a current flowing through two resistors in series, one arising from the membrane and the other from the electrolyte. Depending on the details, either one of these resistors may be dominant.

It is useful to relate i_∞ to the Cottrell constant $(it^{1/2})_0$ given by Eq. [43]. The ratio of these quantities turns out to be

$$\frac{(it^{1/2})_0}{i_\infty} = \frac{T_s^{1/2} - \Lambda T_d^{1/2}}{\pi^{1/2}(1-\Lambda)} = \frac{T_e^{1/2}}{\pi^{1/2}} + \frac{1 + \Lambda T_m^{1/2}}{1 - \Lambda \pi^{1/2}} \quad [46]$$

in terms of the parameters defined previously.

Clark Simplification

Inequality [23], valid for classical Clark cells, implies that $T_s^{1/2}$ closely approximates $T_m^{1/2}$ and that $T_d^{1/2} \approx -T_m^{1/2}$. In these circumstances, Eq. [41] reduces to

$$\bar{i} = \frac{4AFp_w H_e D_e^{1/2} (1-\Lambda)}{s^{1/2} (1+\Lambda)} \coth(sT_m) \quad T_e \ll T_m \quad [47]$$

which may be inverted to either of the equivalent forms¹

$$i = \frac{4AFp_w H_m D_m^{1/2}}{\pi^{1/2} t^{1/2}} \sum_{j=-\infty}^{+\infty} \exp\left(\frac{j^2 b^2}{D_m t}\right) \quad \frac{a^2}{D_e} \ll \frac{b^2}{D_m} \quad [48]$$

or

$$i = \frac{4AFp_w H_m D_m}{b} \sum_{j=-\infty}^{+\infty} \exp\left(\frac{-j^2 \pi^2 D_m t}{b^2}\right) \quad \frac{a^2}{D_e} \ll \frac{b^2}{D_m} \quad [49]$$

via theta function identities (11).

Since all the parameters relating to the electrolyte disappeared during our Clark approximation, Eq. [48] does not correctly reduce, as $t \rightarrow 0$, to the Cottrell Eq. [43]. Likewise, the $a/D_e H_e$ term is missing from the $t \rightarrow \infty$ limit of Eq. [49]. Apart from these aberrations, the second of which will usually be very minor, Eq. [48] and [49] correctly describe the behavior of the Clark cell.

Provided that t is not too small in comparison with T_m , only the $j = 0, \pm 1$ terms in expansion [49] are of significance. In this event, the expansion can be simplified to

$$i - i_\infty \approx 2i_\infty \exp(-\pi^2 t/T_m) \quad 3\pi^2 t > T_m \ln(1/\epsilon) \quad [50]$$

where ϵ is the fractional error permissible in the approximation. (For example, when $\epsilon = 0.02$, [50] is obeyed to better than 98%.) This may be usefully recast as

$$\ln \frac{2i_\infty}{i - i_\infty} = \frac{\pi^2 t}{T_m} \quad i_\infty < i < (2\epsilon^{1/3} + 1) i_\infty \quad [51]$$

which shows that a plot of the logarithm of $2i_\infty/(i - i_\infty)$ should give a straight line through the origin when plotted against time; its gradient is $\pi^2 D_m/b^2$. Hale and Hitchman (3) essentially used this method to determine D_m for polytetrafluoroethene, and Myland (6) used it to measure D_m for polydimethylsiloxane.

Fowler Simplification

Inequality [24], appropriate to the conditions used by Fowler and Oldham (5), implies that both T_s and T_d closely approximate to T_e . Equation [41] then reduces to

$$\bar{i} = \frac{4AFp_w H_e D_e^{1/2}}{s^{1/2}} \coth(sT_e)^{1/2} \quad T_e \gg T_m \quad [52]$$

which inverts, by a similar theta function technique as before, to either

$$i = \frac{4AFp_w H_e D_e^{1/2}}{\pi^{1/2} t^{1/2}} \sum_{j=-\infty}^{+\infty} \exp\left(\frac{-j^2 a^2}{D_e t}\right) \quad \frac{a^2}{D_e} \gg \frac{b^2}{D_m} \quad [53]$$

or

$$i = \frac{4AFp_w H_e D_e}{a} \sum_{j=-\infty}^{+\infty} \exp\left(\frac{-j^2 \pi^2 D_e t}{a^2}\right) \quad \frac{a^2}{D_e} \gg \frac{b^2}{D_m} \quad [54]$$

In this case, all membrane parameters have disappeared, but no serious error is thereby likely to be introduced, even as $t \rightarrow \infty$ for cells constructed to meet the objectives of Fowler and Oldham.

At short enough times, only the $j = 0, \pm 1$ terms are important in expansion [53]. A development paralleling that in the final paragraph of the previous section can be carried out, leading to the result

¹The summations of form $\sum_{j=-\infty}^{\infty} \exp(j^2 x)$ in Eq. [48], [49], [53],

and [54] may be replaced by terms $1 + 2 \sum_{j=1}^{\infty} \exp(j^2 x)$.

$$\ln \frac{2(it^{1/2})_0}{(it^{1/2})_0 - it^{1/2}} = \frac{T_e}{t} \quad (it^{1/2})_0 \leq it^{1/2} \leq (2\epsilon^{1/3} + 1)(it^{1/2})_0 \quad [55]$$

This shows that a plot of the left member of [55] vs. $1/t$ will give a straight line of gradient T_e passing through the origin.

Mancy Simplification

If T_e and T_m are equal as Mancy and co-workers (4) assumed, T_d is zero and Eq. [41] simplified to

$$\bar{i} = \frac{4AFp_w H_e D_e^{1/2}}{s^{1/2}} [\coth(sT_s)^{1/2} - \Lambda \operatorname{csch}(sT_s)^{1/2}] \quad T_e = T_m \quad [56]$$

which inverts to

$$i = \frac{2AFp_w H_e D_e^{1/2}}{\pi^{1/2} t^{1/2}} \sum_{j=-\infty}^{+\infty} [1 - \Lambda + (-)^j (1 + \Lambda)] \exp\left(\frac{-j^2 T}{t}\right) \quad \frac{a^2}{D_e} = \frac{b^2}{D_m} \quad [57]$$

where T is the common value of a^2/D_e and b^2/D_m . An alternative inversion of Eq. [56] leads to the equation

$$i = \frac{2AFp_w H_e D_e^{1/2}}{T^{1/2}} \sum_{j=-\infty}^{+\infty} [1 - (-)^j \Lambda] \exp\left(\frac{-j^2 \pi^2 t}{4T}\right) \quad \frac{a^2}{D_e} = \frac{b^2}{D_m} = T \quad [58]$$

which is more useful than Eq. [57] at longer times.

The Mancy assumption is valuable in leading to a massive simplification of the current-time relationship. However, it seems unlikely that accidental equality of T_e and T_m would often occur in practice. Nevertheless, when rewritten as

$$it^{1/2} = (it^{1/2})_0 \left[1 + 2 \sum_{j=1}^{\infty} \exp\left(\frac{-4j^2 T}{t}\right) - \Lambda \exp\left(\frac{-(2j-1)^2 T}{t}\right) \right] \quad [59]$$

and

$$i = i_\infty \left[1 + 2 \sum_{j=1}^{\infty} \exp\left(\frac{-j^2 \pi^2 t}{T}\right) + \frac{1 + \Lambda}{1 - \Lambda} \exp\left(\frac{-(2j-1)^2 \pi^2 t}{4T}\right) \right] \quad [60]$$

Eq. [57] and [58] provide useful benchmarks against which to compare the more elaborate solutions that hold when T_m and T_e are unequal.

General Solution: First Inversion

In many designs of membrane-covered oxygen sensors, the characteristic times T_e and T_m are of comparable, but unequal, magnitudes so that none of the equations of the last three sections apply. Unless one's interest is solely in the $t \rightarrow 0$ or $t \rightarrow \infty$ limit, the task of predicting the current vs. time relationship is formidable. Nevertheless, a solution is possible in two alternative forms, as will be demonstrated in this section and in the "General Solution: Second Inversion" section.

If the abbreviations

$$M = \Lambda \exp(-2T_m^{1/2} s^{1/2}) = \Lambda \exp(-2bs^{1/2}/D_m^{1/2}) \quad [61]$$

$$E = \Lambda \exp(-2T_e^{1/2} s^{1/2}) = \Lambda \exp(-2as^{1/2}/D_e^{1/2}) \quad [62]$$

and

$$S = (1 - \Lambda^2)^{1/2} \exp(-T_s^{1/2} s^{1/2}) = (1 - \Lambda^2)^{1/2}$$

$$\exp\left[-s^{1/2} \left(\frac{a}{D_e^{1/2}} + \frac{b}{D_m^{1/2}}\right)\right] = \frac{(1 - \Lambda^2)^{1/2} M^{1/2} E^{1/2}}{\Lambda} \quad [63]$$

are adopted, Eq. [41] may be expressed as

$$\bar{i} = \frac{8AFp_w H_e D_e^{1/2}}{s^{1/2}} \left[\left(1 + E - \frac{S^2}{1-M} \right)^{-1} - \frac{1}{2} \right] \quad [64]$$

The terms $E - (S^2/1 - M)$ and M are less than unity and therefore, first $[1 + E - (S^2/1 - M)]^{-1}$ and then $1/(1 - M)$ may be expanded binomially. This leads to the series

$$\bar{i} = 8AFp_w H_e D_e^{1/2} s^{-1/2} [1/2 - E + (S^2 + E^2) + (MS^2 - 2ES^2 - E^3) + (S^4 + M^2S^2 - 2MES^2 + 3E^2S^2 + E^4) + \dots] \quad [65]$$

for which it is not possible to write a simple general term. Equation [65] involves only terms of the form $M^\mu E^\eta S^\sigma / s^{1/2}$ where μ , η , and σ are positive integers or zero. The Laplace invert of such a term is

$$\left(\begin{matrix} \mu \\ \eta \\ \sigma \end{matrix} \right) / \pi^{1/2} t^{1/2}$$

where we use the special symbol

$$\left(\begin{matrix} \mu \\ \eta \\ \sigma \end{matrix} \right) = \Lambda^{\mu+\eta} (1 - \Lambda^2)^{\sigma/2} \exp \left\{ \frac{-1}{4t} [2\mu T_m^{1/2} + 2\eta T_e^{1/2} + \sigma T_s^{1/2}]^2 \right\} = \Lambda^{\mu+\eta} (1 - \Lambda^2)^{\sigma/2} \exp \left\{ \frac{-1}{t} \left[\frac{(\mu + \sigma/2)b}{D_m^{1/2}} + \frac{(\eta + \sigma/2)\alpha}{D_e^{1/2}} \right]^2 \right\} \quad [66]$$

In terms of this symbol, Eq. [65] may be inverted to

$$i = \frac{8AFp_w H_e D_e^{1/2}}{\pi^{1/2} t^{1/2}} \left[\frac{1}{2} - \binom{0}{1} + \binom{0}{2} + \binom{0}{2} + \binom{1}{0} - 2 \binom{0}{1} - \binom{0}{3} + \binom{0}{4} + \binom{2}{0} - 2 \binom{1}{2} + \dots \right] \quad [67]$$

At short times, the terms in expansion [67] converge very rapidly and in practice few will be needed. With the first four terms written out explicitly, the full solution is

$$i = \frac{4AFp_w H_e D_e^{1/2}}{\pi^{1/2} t^{1/2}} \left[1 - 2\Lambda \exp \left\{ \frac{-a^2}{D_e t} \right\} + 2(1 - \Lambda^2) \exp \left\{ \frac{-1}{t} \left(\frac{a}{D_e^{1/2}} + \frac{b}{D_m^{1/2}} \right)^2 \right\} + 2\Lambda^2 \exp \left\{ \frac{-4a^2}{D_e t} \right\} + \dots \right] \quad [68]$$

Comparison of this result with Eq. [53] shows some striking differences. Perhaps the most interesting is that the departure from cottrellian behavior may well be in the negative direction, whereas it is invariably positive for a Fowler cell.

As an example of the convergence of Eq. [68], let us consider the case when $T_e = 4T_m$. Then we find

$$i = \frac{(it^{1/2})_0}{t^{1/2}} \left[1 - 2\Lambda \exp \left(\frac{-4T_m}{t} \right) + 2(1 - \Lambda^2) \exp \left(\frac{-9T_m}{t} \right) + 2\Lambda(1 + \Lambda - \Lambda^2) \exp \left(\frac{-16T_m}{t} \right) - 2\Lambda(2 - \Lambda - 2\Lambda^2 + \Lambda^3) \exp \left(\frac{-25T_m}{t} \right) + \dots \right] \quad T_e = 4T_m \quad [69]$$

Figure 2 was derived, in part, from this equation, the points being based on only the first four terms. Evidently, even with so few terms, accuracy is maintained to better than 98% for times as long as $10 T_m$.

Returning to the general solution, note that Eq. [68] can be rewritten as

$$it^{1/2} = (it^{1/2})_0 \left[1 + 2 \left\{ \exp \left(\frac{-(T_e^{1/2} + T_m^{1/2})^2}{t} \right) - \Lambda \exp \left(\frac{-T_e}{t} \right) + \Lambda^2 \exp \left(\frac{-4T_e}{t} \right) - \Lambda^2 \exp \left(\frac{-(T_e^{1/2} + T_m^{1/2})^2}{t} \right) + \dots \right\} \right] \quad [70]$$

and that, when $T_e = T_m = T$, the explicit terms in Eq. [70] exactly match the Mancy Eq. [59] as far as the $j = 1$ terms.

Duration of Cottrellian Behavior

At short enough times, Eq. [68] may be well approximated by

$$it^{1/2} = (it^{1/2})_0 [1 - 2\Lambda \exp(-a^2/D_e t)] \quad [71]$$

which shows that $2\Lambda \exp(-a^2/D_e t)$ is the fractional departure from cottrellian behavior after polarization for a length of time t . It therefore follows that, if a fractional er-

ror not exceeding ϵ is permissible, then during the interval

$$0 < t < \frac{a^2}{D_e \ln(2\Lambda/\epsilon)} = \frac{T_e}{\ln(2\Lambda/\epsilon)} \quad [72]$$

the Cottrell equation is effectively obeyed. Thus, for example, if $\epsilon = 0.02$ (98% obedience is acceptable) then cottrellian behavior is observed up to $0.30 T_e$, for the Λ value given in Eq. [19].

The fact that the third term in expansion [68] is of opposite sign to, and will normally have a pre-exponential

Fig. 2. Short-time response of a sensor for which $\Lambda = 0.29$ and $T_e = 4 T_m$. The line is exact, being based on Eq. [69] for $t < 2.5 T_m$ and on [86] for $t > 2.5 T_m$. The points are calculated from Eq. [69] retaining only terms up to $2\Lambda(1 + \Lambda - \Lambda^2) \exp(-16T_m/t)$.

coefficient of greater magnitude than, the second term, offers the possibility of utilizing the competition between these terms to prolong effective cottrellian behavior. This is brought out in Fig. 3 which shows a graph of $i t^{1/2}$ vs. t for four values of the T_m/T_e ratio. Note that with the judicious choice $T_m/T_e = 0.087$ cottrellian behavior (to within $\pm 2\%$) is prolonged until about $t = 0.67T_e$.

The results of the last paragraph can be generalized as follows. Cottrellian behavior to within a fractional error of $\pm \epsilon$ is observed over the time interval $0 \leq t \leq T_c$, where

$$\frac{2\Lambda(T_s - T_e)}{T_s} \left[\frac{(1 - \Lambda^2)T_s}{\Lambda T_e} \right]^{-T_e/(T_s - T_e)} = \epsilon \quad [73]$$

and T_c satisfies the equation

$$(1 - \Lambda^2) \exp\left(\frac{-T_s}{T_c}\right) - \Lambda \exp\left(\frac{-T_e}{T_c}\right) = \frac{\epsilon}{2} \quad [74]$$

General Solution: Second Inversion

Though Eq. [67] is valid at all times, its utility is greater for smaller values of t , for then few terms are needed. In this section, we will derive the complementary expression: one that is of greater utility for longer times.

The transform Eq. [41] can be written $i = U(s)/L(s)$ where $U(s)$ and $L(s)$ are the following functions of the dummy variable

$$U(s) = 4AFp_w H_e D_e^{1/2} [\cosh(sT_s)^{1/2} - \Lambda \cosh(sT_d)^{1/2}] \quad [75]$$

and

$$L(s) = s^{1/2} [\sinh(sT_s)^{1/2} - \Lambda \sinh(sT_d)^{1/2}] \quad [76]$$

Both these functions are analytic functions of s [i.e., each can be written in the form $k_0 + k_1s + k_2s^2 + \dots$ where the k 's are independent of s] and $L(s)$ is of higher order than $U(s)$ [in the sense that the ratio $U(s)/L(s) \rightarrow 0$ as $s \rightarrow \infty$]. Heaviside's expansion theorem (12) permits the inversion of such a ratio to

$$i = \sum_j U(s_j) \exp(s_j t) / \frac{dL}{ds}(s_j) \quad [77]$$

where each s_j is a root of the equation $L(s) = 0$, that is

Fig. 3. Departures from cottrellian behavior for a sensor for which $\Lambda = 0.29$ and the T_m/T_e ratio has the values associated with each of the four curves.

$$s^{1/2} [\sinh(sT_s)^{1/2} - \Lambda \sinh(sT_d)^{1/2}] = 0$$

$$s = s_0, s_1, s_2, \dots \quad [78]$$

Differentiation of Eq. [76] shows that

$$\frac{dL}{ds} = \frac{L(s)}{2s} + \frac{T_s^{1/2}}{2} \cosh(sT_s)^{1/2} - \frac{\Lambda T_d^{1/2}}{2} \cosh(sT_d)^{1/2} \quad [79]$$

and therefore

$$i = 8AFp_w H_e D_e^{1/2} \sum_{j=0,1}^{\infty} \frac{[\cosh(s_j T_s)^{1/2} - \Lambda \cosh(s_j T_d)^{1/2}] \exp(s_j t)}{\frac{L(s_j)}{s_j} + T_s^{1/2} \cosh(s_j T_s)^{1/2} - \Lambda T_d^{1/2} \cosh(s_j T_d)^{1/2}} \quad [80]$$

It remains to determine the roots s_j .

One root of Eq. [78], say s_0 , is clearly zero. The others turn out to be negative; so let us replace s_j by $-\tau_j^2$ where τ_j is restricted to be positive. Using the identity $\sinh(-z^2)^{1/2} = (-z^2)^{1/2} \sin z$ then reduces Eq. [78] to

$$\sin(\tau T_s^{1/2}) = \Lambda \sin(\tau T_d^{1/2}) \quad \tau = \tau_1, \tau_2, \tau_3, \dots \quad [81]$$

or equivalently

$$\tan\left(\frac{\tau b}{D_m^{1/2}}\right) = \frac{1 - \Lambda}{1 + \Lambda} \tan\left(\frac{\tau a}{D_e^{1/2}}\right) \quad \tau = \tau_1, \tau_2, \tau_3, \dots \quad [82]$$

where τ is the continuum along which the values τ_j are located. Figure 4 clarifies the first of these relationships.

If the s_0 root is detached from the summation in Eq. [80], this equation may be rearranged, with the help of Eq. [45], to

$$i = i_\infty \left[1 + \frac{2(T_s^{1/2} - \Lambda T_d^{1/2})}{1 - \Lambda} \sum_{j=1}^{\infty} \frac{[\cos(\tau_j T_s^{1/2}) - \Lambda \cos(\tau_j T_d^{1/2})] \exp(-\tau_j^2 t)}{T_s^{1/2} \cos(\tau_j T_s^{1/2}) - \Lambda T_d^{1/2} \cos(\tau_j T_d^{1/2})} \right] \quad [83]$$

Use of Eq. [81] to replace Λ from within the summation leads to the simpler

$$i = i_\infty + 2i_\infty \left[\frac{a D_m^{1/2}}{b D_e^{1/2}} + \frac{1 + \Lambda}{1 - \Lambda} \right] \sum_{j=1}^{\infty} \frac{\exp(-\tau_j^2 t)}{a D_m^{1/2} / (b D_e^{1/2}) - \sin(2\tau_j a / D_e^{1/2}) \csc(2\tau_j b / D_m^{1/2})} \quad [84]$$

after considerable algebra.

In general, numerical methods will be needed to solve Eq. [81] and so find values for τ_1, τ_2 , etc. However, analytic solutions may be possible when the T_s/T_d ratio is an integer. For example, when this ratio is 9, [i.e., when $T_e = 4T_m$ or $a^2 D_m = 4b^2 D_e$], Eq. [82] can be solved to

$$\tau_j = \left[(j-1)\pi - (-)^j \arctan\left(\frac{3 - \Lambda}{1 + \Lambda}\right)^{1/2} \right] D_m^{1/2} / b \quad j = 1, 2, 3, \dots \quad [85]$$

and Eq. [84] then gives

$$i = i_\infty \left[1 + \frac{2}{1 - \Lambda} \sum_{j=1}^{\infty} \exp\left\{ \frac{-t D_m}{b} \left((j-1)\pi - (-)^j \arcsin\left(\frac{3 - \Lambda}{2}\right)^{1/2} \right)^2 \right\} \right] \quad T_e = 4T_m \quad [86]$$

Figure 5 is a test of Eq. [86], the points being calculated using terms to $j = 2$. It shows that, apart from minor discrepancies at short times, this number of terms is perfectly adequate. The full line in Fig. 5 was constructed for

Fig. 4. Graphs vs. r of the two functions $\sin(rT_s^{1/2})$ and $\Lambda \sin(rT_d^{1/2})$. The values r_0, r_1, r_2, \dots lie at the points of intersection of the two sinusoidal curves.

$t \leq 2.5T_m$ from Eq. [69] and for $t \geq 2.5T_m$ from Eq. [86]. The perfect concordance of the two segments is evidence

Fig. 5. The approach to a steady state for a membrane-covered oxygen sensor for which $\Lambda = 0.29$ and $T_e = 4T_m$. This line is exact, being based on Eq. [69] for $t < 2.5T_m$ and on Eq. [86] for $t > 2.5T_m$. The points are from Eq. [86] truncated after $j = 2$.

that both equations are correct and speaks to the validity of the general results, Eq. [70] and [84].

Another check is provided by inserting the Mancy condition $T_e = T_m = T$. This renders Eq. [84] indeterminate, but the equivalent relationship Eq. [83] can be shown to reduce, under these conditions, to Eq. [60].

If we return to the general case in which there is no simple relation between T_e and T_m , we are forced to determine r_1, r_2, \dots by iterative methods. From Fig. 4, which illustrates Eq. [81], it is apparent that $j\pi/T_s^{1/2}$ provides an approximate value for r_j . The algorithm shown in Fig. 6 can then be used to determine the value of a root, usually r_j .

Duration of the Transient Phase

As $t \rightarrow \infty$, the summed terms in Eq. [83] approach zero as $i \rightarrow i_\infty$. For sufficiently large t , only the first term in the summation is important and Eq. [82] reduces to

$$\frac{i}{i_\infty} = 1 + 2 \frac{(T_s^{1/2} - \Lambda T_d^{1/2}) [\cos(r_1 T_s^{1/2}) - \Lambda \cos(r_1 T_d^{1/2})]}{(1 - \Lambda)[T_s^{1/2} \cos(r_1 T_s^{1/2}) - \Lambda T_d^{1/2} \cos(r_1 T_d^{1/2})]} \exp(-r_1^2 t) \tag{87}$$

Within a fractional error of ϵ , this equation shows that i has reached i_∞ after an interval T_t given by

$$T_t = \frac{1}{r_1^2} \ln \frac{2[1 - (\Lambda T_d^{1/2}/T_s^{1/2})] [\cos(r_1 T_s^{1/2}) - \Lambda \cos(r_1 T_d^{1/2})]}{\epsilon[1 - \Lambda] [\cos(r_1 T_s^{1/2}) - (\Lambda T_d^{1/2}/T_s^{1/2}) \cos(r_1 T_d^{1/2})]} \tag{88}$$

$$T_t = \frac{1}{r_1^2} \left[\ln \left(\frac{aD_m^{1/2}}{bD_e^{1/2}} + \frac{1 + \Lambda}{1 - \Lambda} \right) - \ln \left(\frac{aD_m^{1/2}}{bD_e^{1/2}} - \frac{\sin(2r_1 a/D_e^{1/2})}{\sin(2r_1 b/D_m^{1/2})} \right) + \ln \left(\frac{2}{\epsilon} \right) \right] \tag{89}$$

Detailed calculations show that, under conditions of practical importance, Eq. [88] or [89] is more than adequate to predict the duration of the transient phase.

Application to Practical Sensors

As we stated in the "Solubility and Transport Properties" section, the most commonly adopted membrane for oxygen sensors is polytetrafluoroethene, and the most common membrane thickness is 0.001 in. or 2.54×10^{-5} m. Hence, using the diffusion coefficient data of Hitchman, Eq. [12], one calculates that the characteristic time for the membrane has a square root given by

$$T_m^{1/2} = \frac{b}{D_e^{1/2}} = 7.52s^{1/2} \tag{90}$$

As reported previously, the values of $\Lambda = 0.29$ and $D_e^{1/2} = 45.8 \mu\text{m s}^{-1/2}$ are appropriate for the most frequently used filling solutions, aqueous solutions of close to decimolar concentration.

Few analysts would claim a precision for membrane-covered oxygen sensors in excess of 2%. Hence, we can use $\epsilon = 0.02$ as a conservative estimate for the fractional error that can be tolerated in a sensor measurement.

With these values of T_m, D_e, Λ , and ϵ prescribed, a is the only adjustable parameter. We are thus in a position to determine, for any arbitrary value of the electrolyte thickness a , how long cottrellian behavior will last and how soon the steady state will be achieved. The results of calculations, using Eq. [68] and [89], are presented in Fig. 7. This diagram shows, for example, that a cell with an electrolyte thickness of 0.5 mm will obey the Cottrell equation

$$\frac{it^{1/2}}{Ap_w} \approx \frac{4FH_e D_e^{1/2}}{\pi^{1/2}} = 12.8 \text{ A s}^{1/2} \text{ m}^{-2} \text{ atm}^{-1} \tag{91}$$

$$t \leq 70s, a = 0.5 \text{ mm}$$

Fig. 6. Illustration of the iterative procedure used to solve Eq. [81].

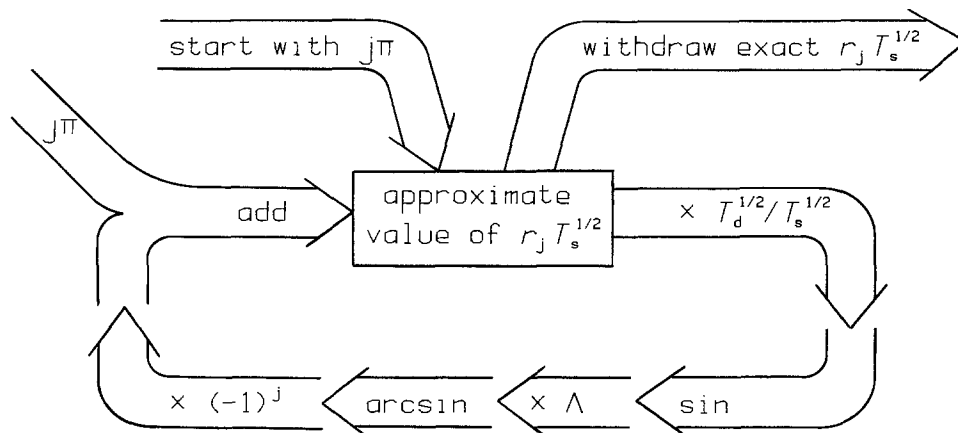

Fig. 7. The durations of cottrellian and transient behaviors for membrane-covered oxygen sensors of usual design, as a function of electrolyte thickness. When conditions fall in the top left-hand corner of this diagram, the Cottrell equation is obeyed to within 2%. In the bottom right-hand corner, the departure from a steady state is less than 2%.

for 70s. There will then be a transitional interval, until about 3 min after switch-on, before the cell assumes its steady state. In this steady state, the current has the constant value

$$\frac{i}{Ap_w} \approx \frac{4F}{\frac{a}{D_e H_e} + \frac{b}{D_m H_m}} = 0.92 \text{ A m}^{-2} \text{ atm}^{-1} \quad t \geq 190\text{s}, a = 0.5 \text{ mm} \quad [92]$$

Note that the cottrellian constant Eq. [91], is independent of the electrolyte thickness a , though the duration of obedience to the Cottrell equation is strongly dependent on a . On the other hand, the steady-state constant Eq. [92] does depend on a , unless a is less than $12 \mu\text{m}$, whereupon (to within our 2% precision specification) the steady-state constant becomes

$$\frac{i}{Ap_w} \approx \frac{4FD_m H_m}{b} = 1.66 \text{ A m}^{-2} \text{ atm}^{-1} \quad t \geq 27\text{s}, a \leq 12 \mu\text{m} \quad [93]$$

and independent of the electrolyte thickness.

The discontinuity in the T_c curve of Fig. 7 reflects the feature noted in the "Cottrellian Behavior" section: the competition between the signs of the second and third terms in the expansion of $it^{1/2}$. It shows that a decided advantage may be reaped, for a cottrellian-based sensor, in making the electrolyte thickness larger than about $400 \mu\text{m}$.

Thermodynamics of Lithium Intercalation from High Resolution Electrochemical Measurements

J. R. Dahn and W. R. McKinnon

National Research Council of Canada, Division of Solid State Chemistry, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

We discuss the importance of high resolution measurements of dx/dV , the inverse derivative of the voltage (V) vs. intercalant concentration (x) relation for intercalation-based electrochemical cells. The results of experiments on $\text{Li}/2\text{H-Li}_x\text{TaS}_2$ cells demonstrate the use of high resolution measurements of dx/dV to determine a partial phase diagram for the lithium order-disorder transition near $x = 2/3$. We stress the reproducibility of our results, which were obtained using derivative constant current chronopotentiometry.

The voltage of a lithium intercalation battery varies with its state of discharge. Early experimental studies of this variation (1) were often made to determine the suitability of a particular intercalation compound as a cathode in a reversible lithium battery. These studies were intended to show the overall variation of the cell voltage (V) with intercalant composition (x). Subsequently, more careful experiments have shown fine structure in $V(x)$ for many intercalation systems (2-8). This structure, seen clearly in plots of dx/dV vs. x or V , can be caused by a variety of physical mechanisms, such as the interactions between intercalated atoms within the host or intercalation-induced structural phase transitions in the host. Therefore, careful measurements of dx/dV can be used to study the physics and chemistry of the intercalation process. Attempts have been made to explain theoretically (9-13) the features in dx/dV , especially for Li_xTiS_2 . To be convincing, any such calculation must reproduce the fine structure in dx/dV . The overall variation of $V(x)$ can often be approximated by very simple mean-field solutions to lattice gas models (9); however, these simple solutions often give results for dx/dV much different from experiment. The theories should also be able to predict other thermodynamic quantities, for example $(\partial V/\partial T)_x$, the change in cell voltage with temperature at constant intercalant concentration (14, 15).

To test the theories at a quantitative level, high resolution measurements of $V(x)$ and $-dx/dV$ of intercalation batteries are needed. In this paper, we present high resolution electrochemical measurements on $2\text{H-Li}_x\text{TaS}_2$ [the 2H and 1T polytypes of TaS_2 are described in Ref. (1)], which allow a detailed comparison between experiment and theory. Our results illustrate the wealth of information contained in dx/dV , as well as the resolution required in the measurements. Our data were obtained using derivative constant current chronopotentiometry, in which the cell voltage is measured as a function of time at constant charge or discharge current and then differentiated numerically. We present results obtained with different cells, to show the reproducibility of the method, and at different currents to illustrate the reversibility of the intercalation process and the effects of kinetics on our measurements. We also present a partial phase diagram of the order-disorder transition in $2\text{H-Li}_x\text{TaS}_2$ (16), which is in good agreement with theoretical calculations.

Basic Considerations

Many of the transition metal dichalcogenides (MX_2) can be intercalated electrochemically with alkali metals (A) to

Key words: battery, electrode, phase transformation.

form intercalation compounds A_xMX_2 (1). An electrochemical cell based on intercalation is constructed in the following general way

A/Organic electrolyte containing A^+ ions/ A_xMX_2

The voltage, V , of such a cell varies with x in A_xMX_2 except when the intercalation electrode exists as a mixture of two phases (17). In a two-phase region V is constant and $-dx/dV$ is infinite. Two phase mixtures for large coexistence ranges are easily seen in $V(x)$ (18, 19), but to observe smaller coexistence ranges it may be necessary to look at $(\partial x/\partial V)_T$. Continuous or higher order phase transitions, where derivatives of the Gibb's free energy exhibit singularities (20), should also be observable in $(\partial x/\partial V)_T$. Theoretical predictions of $-dx/dV$ at an intercalant order-disorder transition which is continuous, show a sharp peak at the voltage and composition of the transition (9, 12). Even when there are no phase transitions, measurements of $-dx/dV$ serve to characterize the intercalation system more precisely than $V(x)$. This suggestion was advanced by Balewski and Brenet (22) for electrochemical cells in general.

Measurements of $(-dx/dV)_T$ have been used to study phase transitions in Li_xVS_2 (5), Na_xTiS_2 (7), $1\text{T-Li}_x\text{TaS}_2$ (4), and Li_xNbSe_2 (6). These measurements have been made using linear sweep voltammetry (5, 7), electrochemical potential spectroscopy (4), and a constant current method (6) similar to the one we will describe below. Discussions of the interpretation of $-dx/dV$ from linear sweep voltammetry data can be found in Ref. (5) and (8). Experimental details of electrochemical potential spectroscopy are given in Ref. (3) and (23).

When a cell based on intercalation is charged or discharged at constant current, the rate of change of cell voltage with time is

$$\frac{dV}{dt} = \frac{dV}{dQ} \frac{dQ}{dt} = \frac{I}{Q_0} \frac{dV}{dx} \quad [1]$$

In Eq. [1], V is the cell voltage, I the constant current, Q_0 the charge corresponding to a change, $\Delta x = 1$, in the intercalation electrode, and t the time. By monitoring the cell voltage as a function of time, one can obtain dx/dV since

$$dx/dV = \frac{I}{Q_0} \frac{dt}{dV} \quad [2]$$

To measure dx/dV with high resolution in V and x , we monitor the voltage of the cell as a function of time with a computer-controlled voltmeter. In the standard terminology, this method of measuring dx/dV is called derivative

constant current chronopotentiometry. Equations [1] and [2] assume that the integral of the current can be directly related to the stoichiometric changes occurring within the intercalation electrode. The validity of this assumption has been best demonstrated in the case of Li_xTiS_2 where *in situ* x-ray diffraction studies (24) (using electrochemical cells with x-ray windows) have monitored the changes in crystal lattice parameters as a function of transferred charge. The lattice parameter data obtained in this way agree to within experimental error with the data obtained from chemically prepared samples (25). Equations [1] and [2] are exact only in the absence of internal impedances and overvoltages of all kinds, and are only approximate at nonzero current. For reversible electrode materials, the effect of the deviation from equilibrium can be determined from the difference between dx/dV measured on charge and discharge (8, 23). For example, an internal resistance, R , will cause a deviation of $\pm IR$ in the measured voltages from the equilibrium voltages on charge and discharge. The solid-state diffusion of the intercalant within the cathode particles in a constant current experiment also produces an overvoltage that is proportional to the magnitude of the applied current (17, 26). By examining dx/dV measured at different currents, one can usually determine the effects of the finite rate and obtain the equilibrium dx/dV . Similar studies as a function of voltage sweep rate using linear sweep voltammetry to obtain the equilibrium dx/dV for $\text{Li}/\text{Li}_x\text{Ti}_{1.05}\text{S}_2$ cells have been made (8).

Experimental Methods

2H-TaS₂ was prepared by reacting stoichiometric mixtures at Ta and S powders at 900°C for 48h, followed by cooling to room temperature at 100°C per day to ensure production of the 2H polytype. The resulting crystallites were hexagonal with $a = 3.315\text{\AA}$ and $c = 12.077\text{\AA}$, in good agreement with published values (27). X-ray diffraction profiles showed no evidence of other polytypes of TaS₂, although our material showed a high density of stacking faults like that prepared elsewhere (28).

Intercalation cathodes were prepared by spreading a slurry of 2H-TaS₂ and propylene glycol in a thin layer (=

10 mg/cm²) on a 2.5 × 2.5 cm nickel substrate, which was then baked under flowing argon until dry. Cathodes were then flattened between a set of rollers, which promotes good mechanical adhesion of the powder to the nickel substrate and results in cathode utilizations near 100%. The cathode mass was determined to ±0.1 mg. Cells with two electrodes were constructed using these cathodes and lithium metal foil, as described elsewhere (6).

The computer-controlled system used to perform constant current chronopotentiometry is based on a HP85 microcomputer, which controls a HP3478A voltmeter switched alternately between up to 20 cells by an HP3495A scanner. The computer monitors the voltage of each cell once every 100s. During each monitoring period, the cell voltage and the time are measured N times ($N = 5$ typically) and averaged to produce an average voltage, \bar{V} , and average time \bar{T} . \bar{V} is then compared to the last stored voltage, V_n , for the same cell. If $|\bar{V} - V_n| > \Delta V$ ($\Delta V = 2.5$ mV typically), \bar{V} and \bar{T} are stored as V_{n+1} and T_{n+1} ; otherwise, \bar{V} and \bar{T} are ignored. ΔV sets the resolution of the measurement and helps to limit the number of data points collected. Increasing N can sometimes help to reduce the noise in data taken with $\Delta V < 1$ mV. Constant current battery cyclers with presettable high and low voltage trip points are used to provide the currents. The current is stable to one part in 10⁴ for currents greater than 100 μA and to ±30 nA for currents less than 100 μA . Cells under test are placed in temperature-controlled environments with a stability of ±0.01 K. Experiments on intercalation electrodes usually involve cycle times ranging from 5 to 1000h; hence, examining each cell every 100s is sufficient. The scheme allows for the testing of many cells at relatively low cost.

Results and Discussion

Figure 1 shows $V(x)$ and $-dx/dV$ vs. x for $\text{Li}/1\text{M LiAsF}_6$, PC/2H-Li_xTaS₂ cell JD-19 above 1.60V. These data were measured for the second charge and third discharge of the cell at a 100h rate. (We specify the rate of charge or discharge by the time required to change the composition x by $\Delta x = 1$, based on the current and the cathode mass. For this particular cell, the cathode mass was 42.9 mg, so a 100h rate corresponds to 47.2 μA .) As there are about 300 individual data points measured for charge and discharge ($\Delta V = 2.5$ mV), we have not plotted the individual points but have joined them with a continuous curve. The value of x does not return to $x = 0$ at 2.80V, indicating that some lithium remains in the host at these rates of deintercalation. This is a real effect, as has been confirmed by *in situ* x-ray diffraction results using the techniques described in Ref. (24), and is not an artifact caused by impurities in the cell reacting with lithium on the first discharge. The *in situ* x-ray experiments at an 800h rate of charge show $x = 0.04$ at 2.80V. Except in the region of slow kinetics near $x = 0$, the data on charging and discharging in Fig. 1 are nearly identical, indicating near-equilibrium conditions for $x > 0.3$.

The first discharge of this cell (JD-19) was made at a 1h rate to a voltage cutoff of 1.6V resulting in a transfer of $\Delta x = 0.71$. Then the cell was allowed to stand at open circuit for about 0.5h while the voltage recovered to near 2.0V. The cell was given a further discharge at a 25h rate to a cutoff of 1.60V, with the total charge transfer for the two discharges corresponding to $\Delta x = 0.920$. The cell was cycled once at a 25h rate (the first charge is shown in Fig. 2) and then the data of Fig. 1 were collected. The data in Fig. 1 have not been adjusted in any way; in particular, the values of x represent those inferred from the charge transfer and the cathode mass. The rapid initial discharge was made to avoid solvent intercalation, which can occur on the first discharge of $\text{Li}/2\text{H-Li}_x\text{TaS}_2$ cells using propylene carbonate (PC), when the intercalation rate is slow. Similar effects have been observed in $\text{Li}/\text{Li}_x\text{TiS}_2$ cells (8, 24, 29) with PC. PC cointercalation, which increases the distance between adjacent host layers from ≈6 to ≈18 \AA , is probably kinetically slower than lithium

Fig. 1. (a) Cell voltage $V(x)$ and (b) inverse derivative dx/dV for the second charge and third discharge of $\text{Li}/2\text{H-Li}_x\text{TaS}_2$ cell JD-19. The discharge curve in (b) has been offset by 0.5 V^{-1} for clarity.

Fig. 2. $-\partial x/\partial V$ vs. x for the first charge (c1) of Li/2H-Li_xTaS₂ cells JD-17, JD-19, and JD-21 and the second charge (c2) of cell JD-17. The data has been offset successively by 0.5 V⁻¹ for clarity. —: JD-19 (c1), - - -: JD-17 (c1), . . . : JD-17 (c2), — — —: JD-21 (c1).

intercalation. By discharging rapidly, the interlayer sites are filled with lithium first, and electrolyte cointercalation is inhibited because lithium increases the bonding between adjacent layers. This prevents the large lattice expansion needed to accommodate the PC molecules. *In situ* x-ray examinations of the cathodes of cells initially discharged at 1h rates show no evidence for solvent cointercalation. In addition, if all the lithium is not removed on subsequent cycling, very little cointercalation occurs. A more detailed discussion of solvent cointercalation will appear elsewhere.

Basu *et al.* (30) measured the voltage of Li/2H-Li_xTaS₂ cells at ten values of x ($x = 0.0, 0.1, 0.2, \dots, 0.9$) and hence did not observe the structure evident in our $V(x)$ and $-\partial x/\partial V$ data. Thompson (4) studied lithium intercalation in 2H-TaS₂ and also found that $x \approx 0.92$ in Li/Li_xTaS₂ cells with a voltage of 1.600V. Thompson's $-\partial x/\partial V$ data were measured with a resolution of 20 mV and showed a single large peak for $0 < x < 1/3$, which is resolved into several peaks in our higher resolution data. Thompson's data also showed structure for $x > 1/3$ which he suggested might be due to ordering effects (4). However, no effort was made to analyze the data or to demonstrate the reproducibility of the results.

In the small x region in Fig. 1b where $-\partial x/\partial V$ is large, the crystal lattice expands rapidly with x (1), which is known to lead to peaks in $-\partial x/\partial V$ (10, 11). The behavior at low x may be associated with staging as in Li_xNbSe₂ (6) and Na_xTiS₂ (7). Also evident in Fig. 1b are minima in $-\partial x/\partial V$ near $x = 1/3$ and $x = 2/3$ with peaks on either side. Such features have been predicted (9, 12, 16, 21) to occur near an order-disorder transition involving the intercalated lithium. The peaks correspond to the phase transitions between the ordered and disordered states as x varies, and the minima occur at the compositions of the ordered structures. The values $x = 1/3$ and $x = 2/3$ suggest that the ordered state is a preferred occupation by lithium

Table I. Measured position of the minimum in $-\partial x/\partial V$ near $x = 2/3$ for several Li/2H-Li_xTaS₂ cells made in the same way

Cell	Cycle	Minimum position
JD-17	Charge 1	$x = 0.654$
JD-17	Charge 2	$x = 0.670$
JD-19	Charge 1	$x = 0.637$
JD-21	Charge 1	$x = 0.652$
RM-22	Discharge 2	$x = 0.676$

of one or two of the three interpenetrating $\sqrt{3}a \times \sqrt{3}a$ triangular superlattices of octahedral sites in the van der Waals gap. In what follows, we will concentrate on the feature near $x = 2/3$. The features at $x = 1/3$ exhibit similar behavior, but are distorted by the large peaks near $x = 0.2$.

In Fig. 2 we show $-\partial x/\partial V$ vs. x for cells JD-19, JD-17, and JD-21 to demonstrate the reproducibility of the minima in $-\partial x/\partial V$ near $x = 1/3$ and $x = 2/3$. These data were collected in a manner similar to the data in Fig. 1 except at a 25h rate. The data shown were obtained from the first charge of all three cells and the second charge of JD-17. Each of these cells reached $x = 0.93 \pm 0.01$ at 1.6V. In Table I, the position of the minimum near $x = 2/3$ is tabulated for several cells made in the same way. In Fig. 3, we show $-\partial x/\partial V$ measured from the second and third charge of cell JD-17 at a 25h rate plotted as a function of voltage to demonstrate the reproducibility of the results on different charge-discharge cycles for the same cell.

Figure 4 shows $-\partial x/\partial V$ vs. V measured from a 100h rate charge and discharge of cell RM-21 between 2.00 and 2.30V limits. Small differences in the charge and discharge data are due to the resistive and diffusive overvoltages caused by the constant current (the shift, 5 mV, is

Fig. 3. $-\partial x/\partial V$ vs. V for the second (solid curve) and third (dashed curve) charge of Li/2H-Li_xTaS₂ cell JD-17. The third charge has been plotted twice, once shifted by 0.5 V⁻¹ for clarity.

Fig. 4. $-\partial x/\partial V$ vs. V measured on discharge (solid) and charge (dashed) for Li/2H- Li_xTaS_2 cell RM-21 between 2.00 and 2.30V.

consistent with a resistance of 100 Ω). It takes several hours after the change in current direction to establish the steady-state diffusion overpotential (17, 26). This is why $-\text{d}x/\text{d}V$ appears smaller when measured on discharge near the 2.30V trip point than when measured on charge and conversely near 2.00V. These data demonstrate how cycles over a limited range of V and x can be used to study a particular feature in $-\text{d}x/\text{d}V$, provided the voltage trip points are set far enough from the feature. The sharp peaks in Fig. 4 have a width of about 10 mV and therefore were not observed clearly in Thompson's measurements (4) with 20 mV resolution.

Figure 5 compares the individual data points of Fig. 4 between 2.13 and 2.20V with $-\text{d}x/\text{d}V$ measurements on the same cell at 200 and 400h rates to show the effects of changes in intercalation rate on one of the peaks in $-\text{d}x/\text{d}V$ due to the order-disorder transition. As the current is lowered the IR losses and diffusion overvoltages decrease, and the peak becomes sharper. A cycle at an 870h rate was indistinguishable from the 400h rate data,

Fig. 5. $-\partial x/\partial V$ vs. V for cell RM-21 measured on charge and discharge at 100, 200, and 400h rates. 100h rate, \circ -charge, \square -discharge; 200h rate $+$ -charge, Δ -discharge; 400h rate, \diamond -charge, \times -discharge. The 200 and 400h rate data have been offset by 0.35 V^{-1} and 0.70 V^{-1} , respectively, for clarity.

Fig. 6. Inverse derivative $-\partial x/\partial V$ vs. V for a series of discharges near $x = 2/3$. Temperatures in degrees centigrade are indicated. The currents used correspond to a change $\Delta x = 1$ in the following times: 10°C, 400h; 20°C, 200h; 28°-45°C, 100h; 50°C, 50h.

which indicates near equilibrium conditions at these slow rates. The 870h rate experiment took 90h for the cycle over the limited voltage range of Fig. 5.

Theoretical calculations of $-\text{d}x/\text{d}V$ near the order-disorder transition (9, 16, 21) predict that the phase transition occurs at the peak in $-\text{d}x/\text{d}V$; hence, by examining the peak positions as a function of x and V at different temperatures, it is possible to determine the phase diagram. Figure 6 shows $-\text{d}x/\text{d}V$ vs. V near $x = 2/3$ for a series of discharges at temperatures between 10° and 50°C. The features in $-\text{d}x/\text{d}V$ are highly temperature dependent, as expected (16) near an order-disorder transition. As the temperature is lowered, the minimum in $-\text{d}x/\text{d}V$ is enhanced and the peaks at either side move apart and grow. At higher T , the peaks disappear completely, leaving only a shallow minimum in $-\text{d}x/\text{d}V$. The feature near $x = 1/3$ shows a similar temperature dependence. The data of Fig. 6 are in good agreement with Monte Carlo calculations of $-\text{d}x/\text{d}V$ based on a two-dimensional

Fig. 7. Phase diagram (T vs. x) for the lithium order-disorder transition in 2H- Li_xTaS_2 . The solid curve through the data (\circ) is a guide to the eye. The Monte Carlo results of Ref. (16) (\square) are also shown.

Fig. 8. Phase diagram (T vs. V) for the lithium order-disorder transition in $2H-Li_xTaS_2$. The transition occurs at the voltages and temperatures indicated in $Li/2H-Li_xTaS_2$ cells. The solid curve through the data (○) is a guide to the eye. The Monte Carlo results of Ref. (16) (□) are also shown.

triangular lattice gas model of lithium intercalation (16). Figures 7 and 8 demonstrate the agreement between the phase diagram determined from the peak positions of the data of Fig. 6 and the predictions of the Monte Carlo calculations. Possible reasons for the small discrepancies between the data and the theory are discussed in Ref. (16). Finally, Fig. 9 shows $V(x)$ for the data of Fig. 6. Figures 6 and 9 demonstrate that quantitative analysis of this phase transition is far easier when $V(x)$ is differentiated and $-dx/dV$ examined.

As has been noted before (9), ordered lithium states produce minima in $-dx/dV$ as shown by our data near $x = 1/3$ and $x = 2/3$ (Fig. 1, 2, 4, 6). This suggests that the structure in $-dx/dV$ for Li/Li_xTiS_2 cells (2, 3, 8) does not arise from lithium ordering, due to the absence of features of the type observed in Li/Li_xTaS_2 cells near the order-disorder

Fig. 9. Voltage as a function of x for the series of discharges shown in Fig. 6. The temperatures in degrees centigrade are indicated. Data for $20^\circ C$ and above are shifted successively by -25 mV.

transition. The $-dx/dV$ data for Li/Li_xTiS_2 cells have been qualitatively explained using a lattice gas model which includes the effects of elastic strains produced upon intercalation (10). This model indicates that the peaks in $-dx/dV$ for $x < 0.3$ in Li/Li_xTiS_2 cells arise from the formation of a disordered stage-two structure near $x = 0.14$. Other data (14, 29, 31) support this interpretation.

Conclusions

We have demonstrated how measurements of dx/dV using high resolution constant current techniques are highly reproducible and can allow quantitative analysis of phase transitions in intercalation electrodes. Our measurements on $2H-Li_xTaS_2$ determined the phase diagram of the lithium order-disorder transition near $x = 2/3$, which was shown to be in good agreement with theoretical predictions (16) based on a two-dimensional triangular-lattice-gas model of intercalation. The quality of the data obtained permit comparison with the theory at a high level of accuracy. We suggest that similar studies on other lithium intercalation systems may reveal structure in $-dx/dV$ which was not observed in earlier, lower resolution studies.

Hydrodynamics and Mass Transfer in a Porous-Wall Channel

Philip Lessner* and John Newman**

Applied Science Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The hydrodynamics and mass-transfer equations for a porous-wall flow channel have been solved over a large range of Re and Sc. Jorne has analyzed the low Re, high Sc case. For the high Re, high Sc case we find that $\tau_{xy}h^2/\mu xv_w = 2.43 \text{Re}^{0.5}$ and $\text{Nu} = 0.8277 \text{Re}^{0.5}\text{Sc}^{1/3}$ at the solid wall. The intermediate range is treated by numerical methods.

A flow channel with flow entering through a porous wall may find use in practical electrochemical cells (1). When the end of the channel is closed off, the mass-transfer boundary layer that forms on the solid electrode opposite the porous wall is of constant thickness. Only a few other electrodes (e.g., the rotating disk and the impinging jet) show a uniformly accessible surface. Therefore, this arrangement is of theoretical as well as practical interest.

Other authors have considered this specific problem and related problems. Berman (2) presented the first complete analysis of the porous wall channel. His channel had two porous walls. He derived the proper form of the equations of motion and stream function for a viscous, incompressible fluid and constant wall velocity. He presented a regular perturbation solution of these equations.

Sellars (3) and Yuan (4) considered the high Reynolds number solution for a channel with two porous walls. Both presented some form of a perturbation solution. White (5) obtained a series solution for this problem that was uniformly valid at all Reynolds numbers. He also obtained limiting solutions for high and low Reynolds numbers for both suction and injection. Terrill (6) presented a singular perturbation solution for the high Reynolds number case. He obtained the first three terms in the outer solution and an approximate form for some of the terms in the inner solution.

White (7) obtained an exact series solution for developed inlet flow for a channel with one solid and one porous wall. He ran into numerical convergence problems using his series solution to solve for injection Reynolds numbers greater than ten. Jorne (8) recently reworked this problem along the lines that Berman (2) had used: a low Reynolds number perturbation approach. In that work, Jorne pointed out that, if the end of the channel was closed off, a mass transfer boundary layer of constant thickness would form. Jorne solved for the low Reynolds number, high Schmidt number mass-transfer case in that work.

In this work, we consider the high Reynolds number case of a channel with one porous and one solid wall with the end closed off. Our method of attack is to develop a high Reynolds number singular perturbation expansion. This method complements White's series solution, making it easier to obtain solutions for high injection Reynolds numbers. We also obtain a numerical solution to show the limits of validity of our solution and Jorne's low Reynolds number perturbation expansion. By combining these results, we are able to picture the flow over the entire range of Reynolds number.

A similar analysis is done for mass transfer. However, we have confined our theoretical work to high Sc, which

is the region of most interest in liquid phase mass transfer. Our numerical results show where the high Sc asymptote is valid.

Hydrodynamics

We take the origin of the coordinates to be at the solid wall, at the end of a flow channel which is closed off (Fig. 1). The flow is two dimensional and is described by the Navier-Stokes equations

$$v_x \frac{\partial v_x}{\partial x} + v_y \frac{\partial v_x}{\partial y} = \frac{-1}{\rho} \frac{\partial P}{\partial x} + \nu \left(\frac{\partial^2 v_x}{\partial x^2} + \frac{\partial^2 v_x}{\partial y^2} \right) \quad [1]$$

$$v_x \frac{\partial v_y}{\partial x} + v_y \frac{\partial v_y}{\partial y} = \frac{-1}{\rho} \frac{\partial P}{\partial y} + \nu \left(\frac{\partial^2 v_y}{\partial x^2} + \frac{\partial^2 v_y}{\partial y^2} \right) \quad [2]$$

and the equation of continuity

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} = 0 \quad [3]$$

The boundary conditions are

$$\text{at } y = 0, v_x = 0 \text{ and } v_y = 0 \quad [4a]$$

$$\text{at } y = h, v_x = 0 \text{ and } v_y = -v_w \quad [4b]$$

$$\text{at } x = 0, v_x = 0 \quad [4c]$$

The boundary conditions and the equation of continuity suggest the following form for the velocity components

$$v_y = Q(y) \quad [5a]$$

$$v_x = -xQ'(y) \quad [5b]$$

After substituting Eq. [5a] and [5b] into Eq. [1] and [2] and taking the curl to eliminate pressure, Berman (2) obtained the following equation for Q

$$Q'Q'' - QQ''' = -\nu Q^{iv} \quad [6]$$

with the boundary conditions

$$\text{at } y = 0, Q' = 0 \text{ and } Q = 0 \quad [7a]$$

$$\text{at } y = h, Q' = 0 \text{ and } Q = -v_w \quad [7b]$$

It is convenient to put Eq. [6] and [7] into dimensionless form by introducing the following dimensionless quantities

$$R = \frac{Q}{v_w} \quad [8]$$

$$\text{Re} = \frac{v_w h}{\nu} \quad [9]$$

$$\gamma = \frac{y}{h} \quad [10]$$

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

Key words: electrode, kinetics, battery, electrodeposition.

Fig. 1. Schematic of channel and coordinate axes

Then we obtain

$$R'R'' - RR''' = \frac{-1}{Re} R^{1\nu} \quad [11]$$

with boundary conditions

$$\text{at } \gamma = 0, R' = 0 \text{ and } R = 0 \quad [12a]$$

$$\text{at } \gamma = 1, R' = 0 \text{ and } R = -1 \quad [12b]$$

At low Re, Berman (2) showed that there is a regular perturbation problem. The first few terms in the expansion for the single porous wall channel have been obtained by Jorne (8). In the limit as Re becomes infinite, we lose the fourth derivative, and the problem becomes singular. Perturbation expansions need to be developed for both inner and outer regions. In the region of intermediate Re, neither the low nor high Re expansions is adequate, and we need to obtain a numerical solution of the complete equation.

The full equation is a nonlinear, two-point boundary value problem. It has been solved by reducing it to two second-order equations and linearizing them about a trial solution. The linearized equations were solved by BAND, a subroutine developed by Newman (9, 10). Figure 2a shows the velocity profile at a high Re.

Terrill (6) has considered the related singular perturbation problem in the two porous wall channel. The outer solution for the two porous wall channel is the same as for our problem. In this region our variable is denoted by

$$\bar{y} = y \quad [13]$$

The outer solution can be written as an expansion in 1/Re

$$\tilde{R} = \tilde{R}_0 + \frac{1}{Re} \tilde{R}_1 + \frac{1}{Re^2} \tilde{R}_2 + \dots \quad [14]$$

The differential equation for the first term in the outer region is

$$\tilde{R}'_0 \tilde{R}''_0 = \tilde{R}_0 \tilde{R}'''_0 \quad [15]$$

with the boundary conditions

$$\text{at } \gamma = 0, \tilde{R}_0 = 0 \quad [16a]$$

$$\text{at } \gamma = 1, \tilde{R}'_0 = 0 \text{ and } \tilde{R}_0 = -1 \quad [16b]$$

The solution to this nonlinear problem, first given by White (5), turns out to be

$$\tilde{R}_0 = -\sin\left(\frac{\pi\gamma}{2}\right) \quad [17]$$

The interested reader is referred to Terrill's work (6) for the rather more complicated solutions for the next two terms in the outer expansion.

At high Re, order of magnitude analysis shows that the proper form of the stretched distance in the inner region is

$$\bar{y} = \frac{y\sqrt{Re}}{h} \quad [18]$$

The inner flow variable is

$$\bar{R} = \frac{Q\sqrt{Re}}{v_w} \quad [19]$$

Terrill (6) suggested that the inner expansion should take the form

$$\bar{R} = Re^{1/2} \bar{R}_0 + Re^{3/2} \bar{R}_1 + Re^{5/2} (\log Re) \bar{R}_2 + Re^{5/2} \bar{R}_3 + \dots \quad [20]$$

This leads to the following differential equation for the first term in the inner solution

$$-\bar{R}'_0 \bar{R}''_0 + \bar{R}_0 \bar{R}'''_0 = -\bar{R}_0^{1\nu} \quad [21]$$

with the boundary conditions

$$\text{at } \bar{y} = 0, \bar{R}_0 = 0 \text{ and } \bar{R}'_0 = 0 \quad [22]$$

By requiring that

$$\lim_{\bar{y} \rightarrow \infty} \bar{R} = \lim_{\bar{y} \rightarrow 0} \tilde{R} \quad [23]$$

we can determine the matching conditions as \bar{y} tends toward infinity

$$\bar{y} \rightarrow \infty, \bar{R}'_0 \rightarrow -\frac{\pi}{2}, \bar{R}_0 \rightarrow 0 \quad [24]$$

The method of solution of Eq. [21] subject to boundary conditions [22] and matching condition [24] is similar to

Fig. 2. a(left): Shape of y velocity profile at Re = 50,000. b(right): Detail of boundary layer region at Re = 50,000.

Fig. 3. Function $G(Re)$ defined by Eq. [25]

that of the full equation. Figure 2b shows the boundary layer in more detail.

The shear stress at the solid wall can be written as a function of Re

$$\frac{\tau_{xy}h^2}{\mu x v_w} = G(Re) \tag{25}$$

Our boundary layer solution yields

$$G(Re) = 2.43Re^{0.5} \tag{26}$$

Jorne's low Re perturbation solution yields the following

$$G(Re) = 6 + \frac{16Re}{35} \tag{27}$$

Figure 3 shows a plot of $G(Re)$ vs. Re as determined by the full numerical solution. The low and high Re asymptotes are also plotted. For $Re < 1$, the low Re asymptote is a good approximation to the shear stress, while for $Re > 500$ the high Re line fits the data well. Reynolds numbers between 1 and 500 are in the intermediate region.

Mass Transfer

Since v_y is a function of y only, the equation of convective diffusion can be written as

$$v_y \frac{dc_1}{dy} = D_1 \frac{d^2c_1}{dy^2} \tag{28}$$

For our problem, the boundary conditions take the form

$$\text{at } y = 0, c_1 = c_0 \tag{29a}$$

$$\text{at } y = h, c_1 = c_b \tag{29b}$$

Equations [28] and [29] can be put in dimensionless form by introducing a dimensionless concentration

$$\Theta = \frac{c_1 - c_0}{c_b - c_0} \tag{30}$$

Then

$$\frac{d^2\Theta}{d\gamma^2} - PeR(\gamma) \frac{d\Theta}{d\gamma} = 0 \tag{31}$$

with boundary conditions

$$\text{at } \gamma = 0, \Theta = 0 \tag{32a}$$

$$\text{at } \gamma = 1, \Theta = 1 \tag{32b}$$

The solution to this equation can be represented as an integral

$$\Theta = \frac{\int_0^\gamma e^{Pe \int_0^\alpha R(\alpha) d\alpha} d\beta}{\int_0^1 e^{Pe \int_0^\alpha R(\alpha) d\alpha} d\beta} \tag{33}$$

The Nusselt number is simply

$$Nu = \left. \frac{d\Theta}{d\gamma} \right|_{\gamma=0} = \frac{1}{\int_0^1 e^{Pe \int_0^\alpha R(\alpha) d\alpha} d\gamma} \tag{34}$$

The number of points in the integration is dependent on the number of intervals used in the hydrodynamic solution. A finer mesh would be appropriate for the mass-transfer problem at high Pe , but this is limited by computer memory size. At high Pe , the exponential in the integral of Eq. [34] will change rapidly. We need to interpolate between grid points.

To do this interpolation we first stretch the distance with Sc

$$\xi = \gamma Sc^{1/3} \tag{35}$$

Then Eq. [33] takes the form

Fig. 4. Correction to high Schmidt number asymptote for (a, left) moderate and large Reynolds number and (b, right) moderate and small Reynolds number.

$$\text{Nu} = \frac{\text{Sc}^{1/3}}{\int_0^{\text{Sc}^{1/3}} e^{\text{ReSc}^{2/3} \gamma} R(\xi) d\xi} d\gamma' \quad [36]$$

At distances close to the solid wall we can write v_x in the form of a truncated Taylor series

$$v_x = \beta(x)y \quad [37]$$

$$\beta(x) = -\frac{\tau_{xy}}{\mu} \Big|_{y=0} \quad [38]$$

From Eq. [3] v_y becomes

$$v_y = -1/2 \beta'(x)y^2 \quad [39]$$

This form for the y velocity suggests that we interpolate quadratically between grid points.

At high Sc a mass-transfer boundary layer forms. Then the concentration can be represented as

$$\Theta = \int_0^\eta e^{-x^3} dx \quad [40]$$

where

$$\eta = y \frac{\sqrt{\beta}}{(9D_1 \int_0^x \sqrt{\beta} dx)^{1/3}} \quad [41]$$

Due to the functional form of $\beta(x)$, η is a function of y only. The high Schmidt number asymptote can be constructed with a knowledge of $G(\text{Re})$ from Fig. 3. Thus

$$\text{Nu}_{\text{Sc} \rightarrow \infty} = 0.6160(G(\text{Re}))^{1/3} \text{Pe}^{1/3} \quad [42]$$

Using this representation, Jorne (8) obtained for low Re, high Sc cases

$$\text{Nu} = 1.12 \left(1 + \frac{8}{108} \text{Re} \right)^{1/3} \text{Pe}^{1/3} \quad [43]$$

In the limit as $\text{Re} \rightarrow 0$, this yields

$$\text{Nu} = 1.12 \text{Re}^{1/3} \text{Sc}^{1/3} \quad [44]$$

Using our results for the hydrodynamics at high Re we obtain for the high Re, high Sc asymptote

$$\text{Nu} = 0.8277 \sqrt{\text{ReSc}^{1/3}} \quad [45]$$

The high Sc asymptote over the whole range of Re can be constructed from Eq. [42] and Fig. 3. At finite Sc, the actual value of Nu will deviate from this asymptote. Figure 4 shows the correction to be applied to the asymptote at finite Sc.

ABSTRACT

General formulas of the rearrangement energy for the electron transfer at a semiconductor/electrolyte interface are derived by using the dielectric continuum theory. The rearrangement energy of orientational and intramolecular vibrations of solvent and lattice vibration of the semiconductor depends not only on the distance between the electrode surface and redox ions, but also on dielectric constant of the semiconductor. Theoretical values of the rearrangement energy are compared with experimental values.

Nonradiative electron transfer in a polar solvent occurs accompanying the thermal excitation and emission of many phonons and is called a multiphonon process (1). The electron transfer rate in the multiphonon process is governed by the electronic matrix element coupling the initial and the final states of the electron transfer, and by phonon-state density, which is the Franck-Condon factor statistically averaged over the initial state of phonons. The phonon-state density is responsible for the temperature dependence of the electron transfer rate, and it increases with the decrease in the rearrangement energy of various vibrations participating in the electron transfer. The rearrangement energy of orientational vibration of a solvent, $E_s(o_s)$, is one of the important factors determining the phonon-state density for the electron transfer in a polar solvent. The $E_s(o_s)$ values have been estimated from the electron transfer rate constants by assuming the transmission coefficient to be unity (2). This assumption is plausible for an adiabatic electron transfer in which the electronic matrix element is very large. On the contrary, nonadiabatic electron transfer was experimentally found in the electrochemical reductions of Fe^{3+} at the organic crystal electrode (3) and in homogeneous electron transfer reactions including europium ions (4). In the case of the nonadiabatic electron transfer, information about the transmission coefficient or the electronic matrix element is necessary to determine the accurate $E_s(o_s)$ value from the electron transfer rate. The formal application of the adiabatic electron transfer may lead to the overestimation of the $E_s(o_s)$ value by a term of the transmission coefficient. On the other hand, it was reported (5-8) that the $E_s(o_s)$ values can be determined directly from current-voltage characteristics at a semiconductor/electrolyte interface. The advantage of the above method is that, since the phonon-state density can be obtained separately from the electronic matrix element, the estimated $E_s(o_s)$ values do not involve the uncertainty of the transmission coefficient. Such experimentally obtained $E_s(o_s)$ values have been compared with the theoretical $E_s(o_s)$ values for the electron transfer at a metal electrode. The $E_s(o_s)$ values in electrochemical reactions, however, depend on the mirror image force between an electrode and an electron transferred into the oxidant ion (9). This mirror image force is related to the difference in the dielectric constants of the electrode and the solvent. Since the dielectric constant of a metal is infinite, the electric field is everywhere zero in a metal electrode, while there is a nonzero electric field inside a semiconductor. Thus, an $E_s(o_s)$ value obtained at a semiconductor electrode with a small dielectric constant may deviate from that at a metal electrode. The semiconductor is polarized by the electron transferred into the oxidant ion, and thus the

rearrangement energy of lattice vibrations of the semiconductor electrode should be taken into account. In the present paper, we derived formulas for the rearrangement energy of several vibrations governing the electron transfer rate at the semiconductor/electrolyte interface.

Theory

Model of electron transfer at semiconductor/electrolyte interface.—We are concerned with one-electron transfer from the occupied conduction band of a semiconductor to an oxidant ion, or from a reductant ion to the empty conduction band: $Ox + e \rightleftharpoons Re$, where Ox denotes an oxidant ion with the charge $m+$, Re denotes a reductant ion with the charge $(m - 1)+$, and e is an electron in the conduction band. The spatial arrangement at the interface of the semiconductor and electrolyte is schematically shown in Fig. 1. The shape of the oxidant and reductant ions is approximated as a sphere, and the center of the reductant and oxidant ions is located apart from the semiconductor surface by $R/2$. No solvent penetrates inside of the ion sphere r_b . The ion possesses intramolecular vibration of frequency $\omega \approx 10^{13} \text{ s}^{-1}$. A polar solvent such as water possesses not only orientational vibration of a permanent dipole moment but also stretching or deformation vibrations (10). The energy of the orientational vibration of the solvent is about 10^{-4} eV ($\omega \approx 10^{11} \text{ s}^{-1}$), while the energy of the deformation or stretching vibration of the solvent ranges from 0.01 to 0.1 eV ($\omega \approx 10^{13} \sim 10^{14} \text{ s}^{-1}$). For simplicity, we assume that one mode among the intramolecular vibrations of the solvent contributes to electron transfer. Self-trapping of an electron observed in ionic semiconductors is the result of the strong interaction of an electron with the lattice vibration. The electron in the reductant ion located near the ionic semiconductor surface can also interact with the lattice vibration. Since for covalent semiconductors the electron-phonon interaction is weak in comparison with that in ionic semiconductors (11), hereafter we consider only ionic semiconductors. Accordingly, the vibrations taking part in the electron transfer at the semiconductor/electrolyte interface consist of the orientational vibration of the solvent, the intramolecular vibrations of the oxidant ion and of the solvent, and the optical phonons of the lattice vibration in the ionic semiconductor. In the cathodic process, at the final state an electron has been transferred into the oxidant ion and interacts strongly with the orientational vibration of the solvent, the intramolecular vibrations of the ion and of the solvent, and the optical phonons in the ionic semiconductor. At the initial state, an electron in the conduction band is delocalized over the semiconductor, so that its interaction with the said vibrations is negligible. The difference in this electron-phonon interaction results in the shift of the equilibrium coordinate of the interaction

Key words: rearrangement energy, electron transfer, semiconductor electrode.

Fig. 1. Geometry in determining the dielectric displacement by an electron transferred into the oxidant ion and the mirror image charge in a semiconductor electrode.

modes of various vibrations, *e. g.*, the ion radius is varied from r_a (oxidant) to r_b (reductant) after electron transfer from the semiconductor to the oxidant ion. The orientational vibration of the solvent with the slow relaxation time cannot respond to the fast change of the ionic radius after the electron transfer and cannot follow the thermal fluctuation of the ionic radius. However, the intramolecular vibration of the solvent can follow the thermal fluctuation of the ionic radius. This indicates that the interaction energy of the electron with the intramolecular vibration of the solvent depends on the coordinate of the intramolecular vibration of the ion (12). For simplicity, in the calculation of the rearrangement energy due to the intramolecular vibration of the solvent, the ionic radius is assumed to be frozen at r_b of the reductant ion.

Electric potential inside semiconductor, solvent, and reductant ion.—A solvent and a semiconductor are treated as dielectrics, which are uniform, isotropic, and unsaturated. The electrostatic potential at any point (r, ϑ, φ) inside the sphere r_b is given by (13)

$$V_1(r, \vartheta, \varphi) = \int_{r'=0}^{\infty} \frac{e |\Psi(r', \vartheta', \varphi')|^2}{\epsilon_1 |\mathbf{r} - \mathbf{r}'|} d v' + \sum_{n=0}^{\infty} \sum_{m=-n}^n B_{nm} r^n P_n^m(\cos \vartheta) e^{im\varphi} \quad [1]$$

where e is the charge of an electron, $\Psi(r', \vartheta', \varphi')$ is the electronic wavefunction in the reductant ion at point $(r', \vartheta', \varphi')$, the $P_n^m(\cos \vartheta)$ are the associated Legendre functions, and ϵ_1 is the dielectric constant inside the sphere r_b . The second term in Eq. [1] is the result of the charge distribution outside the sphere r_b . For simplicity, we assume that $|\Psi|^2$ has the spherical symmetry and no probability outside sphere r_b . Under this condition, Eq. [1] reduces to

$$V_1(r, \vartheta, \varphi) = \frac{e}{\epsilon_1 r} \int_{r'=0}^{r=r} |\Psi(r', \vartheta', \varphi')|^2 4\pi r'^2 dr' + \sum_{n=0}^{\infty} \sum_{m=-n}^n B_{nm} r^n P_n^m(\cos \vartheta) e^{im\varphi} \quad [2]$$

The electrostatic potential inside the semiconductor having the dielectric constant ϵ_3 satisfies Laplace's equation and is taken to be zero at $r \rightarrow \infty$. Thus, we have

$$V_3 = \sum_{n=0}^{\infty} \sum_{m=-n}^n \frac{D_{nm}}{r^{n+1}} P_n^m(\cos \vartheta) e^{im\varphi} \quad [3]$$

The electrostatic potential inside the solvent having the dielectric constant ϵ_2 is written as

$$V_2 = \sum_{n=0}^{\infty} \sum_{m=-n}^n \frac{G_{nm}}{r^{n+1}} P_n^m(\cos \varphi) e^{im\varphi} + \sum_{n=0}^{\infty} \sum_{m=-n}^n \frac{C_{nm}}{(r^*)^{n+1}} P_n^m(\cos \vartheta^*) e^{im\varphi^*} \quad [4]$$

where the coordinate $(r^*, \vartheta^*, \varphi^*)$ is related to the coordinate (r, ϑ, φ) as follows

$$r^* = (x^2 + y^2 + (z - R)^2)^{1/2} = (r^2 + R^2 - 2rR \cos \vartheta)^{1/2} \\ \cos \vartheta^* = (R - r \cos \vartheta) / (r^2 + R^2 - 2rR \cos \vartheta)^{1/2} \\ \varphi^* = \varphi \quad [5]$$

At the interface of semiconductor/electrolyte ($z = R/2$), V_2 and V_3 , and the normal component of the dielectric displacement, $-\epsilon_2 dV_2/dz$ and $-\epsilon_3 dV_3/dz$, shall be equal to each other. Thus, for the component of $n = m = 0$, one gets

$$\frac{G_{00}}{[x^2 + y^2 + (R/2)^2]^{1/2}} + \frac{C_{00}}{[x^2 + y^2 + (R/2 - R)^2]^{1/2}} = \frac{D_{00}}{[x^2 + y^2 + (R/2)^2]^{1/2}} \quad [6]$$

and

$$-\epsilon_2 \left\{ \frac{R/2 G_{00}}{[x^2 + y^2 + (R/2)^2]^{3/2}} + \frac{(R/2 - R) C_{00}}{[x^2 + y^2 + (R/2 - R)^2]^{3/2}} \right\} = \frac{-\epsilon_3 R/2 D_{00}}{[x^2 + y^2 + (R/2)^2]^{3/2}} \quad [7]$$

Then, it follows that

$$G_{00} = \frac{\epsilon_2 + \epsilon_3}{2\epsilon_2} D_{00}, \text{ and } C_{00} = \frac{\epsilon_2 - \epsilon_3}{2\epsilon_2} D_{00} \quad [8]$$

In order to get the boundary condition on the surface of sphere r_b , we expand V_2 in powers of $\cos \vartheta$ in the following form

$$V_2 = \sum_{n=0}^{\infty} \sum_{m=-n}^n \frac{G_{nm}}{r^{n+1}} P_n^m(\cos \vartheta) e^{im\varphi} + \sum_{n=0}^{\infty} \sum_{m=-n}^n \frac{C_{nm} P_n^m(\cos \vartheta^*)}{(r^2 + R^2)^{(n+1)/2}} e^{im\varphi} \left[1 + \sum_{k=1}^{\infty} (-1)^k \frac{(n+1)(n+3) \cdots (n+2k-1)}{2^k} \frac{1}{k!} \left(\frac{2Rr \cos \vartheta}{r^2 + R^2} \right)^k \right] \quad [9]$$

where

$$\cos \vartheta^* = (R - r \cos \vartheta) (r^2 + R^2)^{-1/2} \left\{ 1 + \sum_j (-1)^j \frac{1}{2} \frac{3}{2} \cdots \frac{(2j-1)}{2} \frac{1}{j!} \left(\frac{2Rr \cos \vartheta}{r^2 + R^2} \right)^j \right\}$$

From the boundary condition of $V_1 = V_2$ and $-\epsilon_1 dV_1/dr = -\epsilon_2 dV_2/dr$ at $r = r_b$, we have

$$\frac{e}{\epsilon_1 r_b} + B_{00} = \frac{C_{00}}{(r_b^2 + R^2)^{1/2}} + \frac{G_{00}}{r_b} + \frac{C_{10} R}{(r_b^2 + R^2)^{3/2}} + O(h) \quad [10]$$

and

$$e^2/r_b^2 = \frac{r_b \epsilon_2^2 C_{00}}{(r_b^2 + R^2)^{3/2}} + \frac{\epsilon_2 G_{00}}{r_b^2} + \frac{3 \epsilon_2 C_{10} R r_b}{(r_b^2 + R^2)^{5/2}} + Q(h) \quad [11]$$

where $O(h)$ and $Q(h)$ are the high order terms arising from C_{n0} ($n \geq 2$). We neglect the multipole potential arising from the terms of $n \geq 1$ in V_1 , V_2 and V_3 . Under this approximation, the work for charging the sphere r_b is given by

$$\frac{eB_{00}}{2} = -\frac{e^2}{2\epsilon_1 r_b} + \frac{eC_{00}}{2(r_b^2 + R^2)^{1/2}} + \frac{eG_{00}}{2r_b} \quad [12]$$

From Eq. [10] and [11], we have

$$D_{00} = e \left\{ \frac{\epsilon_2 + \epsilon_3}{2} + \frac{\epsilon_2 - \epsilon_3}{2} \frac{r_b^3}{(r_b^2 + R^2)^{3/2}} \right\}^{-1} \quad [13]$$

We take into account only the term of $n = m = 0$, so that the subscript, 00, in G , C , D , are omitted hereafter for simplifying the description. As seen in Eq. [2], the multipole potential is not the result of the charge distribution inside the sphere r_b , but of the mirror image effect (14): the electron in the reductant ion induces the charge at the semiconductor/electrolyte interface if there is the difference in the dielectric constants between the semiconductor and the solvent. The charge induced at the semiconductor/electrolyte interface polarizes the sphere, and, in consequence, the induced dipole moment appears at the surface of the sphere r_b . The multipole potential is generated in the same manner.

Interaction of an electron with dielectrics.—The polarization of the solvent \mathbf{P}_2 consists of the electronic polarization \mathbf{P}_{2e} , the ionic polarization due to the intramolecular vibration \mathbf{P}_{2i} , and the orientational polarization of the permanent dipole moment of the solvent \mathbf{P}_{2d} . When the distribution of the electron is changed slowly, the polarization induced inside the solvent is written as

$$\mathbf{P}_2 = \mathbf{P}_{2e} + \mathbf{P}_{2i} + \mathbf{P}_{2d} = \chi_{2s} \mathbf{E}_{2s} = \frac{\epsilon_{2s} - 1}{4\pi} \mathbf{E}_{2s} \quad [14]$$

where χ_{2s} is the dielectric susceptibility of the solvent and \mathbf{E}_{2s} is the static electric field inside the solvent. Similarly, for the slow fluctuation of the electron distribution, the polarization induced inside the semiconductor is written as

$$\mathbf{P}_3 = \mathbf{P}_{3e} + \mathbf{P}_{3i} = \chi_{3s} \mathbf{E}_{3s} = \frac{\epsilon_{3s} - 1}{4\pi} \mathbf{E}_{3s} \quad [15]$$

where χ_{3s} is the dielectric susceptibility of the semiconductor and \mathbf{E}_{3s} is the electric field inside the semiconductor. The static electric field inside the solvent \mathbf{E}_{2s} is given by

$$\mathbf{E}_{2s} = G_s \frac{\mathbf{r}}{|\mathbf{r}|^3} + C_s \frac{\mathbf{r}^*}{|\mathbf{r}^*|^3} \quad [16]$$

Similarly, the static electric field inside the semiconductor is

$$\mathbf{E}_{3s} = D_s \frac{\mathbf{r}}{|\mathbf{r}|^3} \quad [17]$$

where the coefficients, G_s , C_s , and D_s , are obtained by substituting the static dielectric constant of the solvent ϵ_{2s} and that of the semiconductor ϵ_{3s} into Eq. [8] and [13], instead of ϵ_2 and ϵ_3 , respectively. When the change in the distribution of the electron is so fast that the orientational vibration of the solvent cannot follow but both the lattice vibration of the semiconductor and the intramolecular vibration of the solvent can follow, the polarization induced inside the solvent is

$$\mathbf{P}_2 = \mathbf{P}_{2i} + \mathbf{P}_{2e} = \chi_{2r} \mathbf{E}_{2r} = \frac{\epsilon_{2r} - 1}{4\pi} \mathbf{E}_{2r} \quad [18]$$

and that inside the semiconductor is

$$\mathbf{P}_3 = \mathbf{P}_{3i} + \mathbf{P}_{3e} = \chi_{3r} \mathbf{E}_{3r} = \frac{\epsilon_{3r} - 1}{4\pi} \mathbf{E}_{3r} \quad [19]$$

where ϵ_{2r} and ϵ_{3r} are the dielectric constants of the solvent and the semiconductor in the infrared region, respectively. The electric field \mathbf{E}_{2r} or \mathbf{E}_{3r} is given by replacing G_s , C_s , and D_s by G_r , C_r , and D_r , in which the dielectric constants in the infrared region are used instead of the static dielectric constants. For the very fast change in the distribution of the electron, the electronic polarization of the solvent

$$\mathbf{P}_{2e} = \chi_{20} \mathbf{E}_{20} = \frac{\epsilon_{20} - 1}{4\pi} \mathbf{E}_{20} \quad [20]$$

and the electronic polarization of the semiconductor

$$\mathbf{P}_{3e} = \chi_{30} \mathbf{E}_{30} = \frac{\epsilon_{30} - 1}{4\pi} \mathbf{E}_{30} \quad [21]$$

can follow the change. In Eq. [20] and [21], ϵ_{20} and ϵ_{30} denote the optical dielectric constants of the solvent and the semiconductor, and in the expression of \mathbf{E}_{20} and \mathbf{E}_{30} the coefficient, G_o , C_o , and D_o , are written with the optical dielectric constants.

The total Hamiltonian for the electron and the polarization of dielectrics is written as (15)

$$\mathbf{H} = \mathbf{H}_e + \mathbf{H}_p \quad [22]$$

The Hamiltonian for the electron, \mathbf{H}_e , is the sum of the interaction of the electron with the polarization, \mathbf{H}_{ep} , and another term independent of the polarization \mathbf{H}_e'

$$\mathbf{H} = \mathbf{H}_{ep} + \mathbf{H}_e' \quad [23]$$

The Hamiltonian for the polarization inside the dielectrics, \mathbf{H}_p , is written as (15)

$$\mathbf{H}_p = \sum_{n=2}^3 \int \frac{\gamma_{ni}}{2} \dot{\mathbf{P}}_{ni}^2(\mathbf{r}') d^3\mathbf{r}' + \sum_{n=2}^3 \int \frac{\gamma_{ni}}{2} \omega_{ni}^2 \mathbf{P}_{ni}^2(\mathbf{r}') d^3\mathbf{r}' + \int \frac{\gamma_{2d}}{2} \dot{\mathbf{P}}_{2d}^2(\mathbf{r}') d^3\mathbf{r}' + \int \frac{\gamma_{2d}}{2} \omega_{2d}^2 \mathbf{P}_{2d}^2(\mathbf{r}') d^3\mathbf{r}' \quad [24]$$

where the coefficient γ has been determined from Lagrange's equation of the polarization (12). In Eq. [24], the first and second terms denoted by the subscript, $n = 2$ and $n = 3$, are the kinetic and potential energy of the ionic polarization of the solvent, and those of the semiconductor, respectively. The third and fourth terms in Eq. [24] are the kinetic and potential energy of the orientational vibration of the solvent. The interaction of an electron with the polarization is given by

$$\mathbf{H}_{ep} = \int \int \Psi(\mathbf{r}^*) \Psi(\mathbf{r}) \frac{e(\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} \cdot \mathbf{P}(\mathbf{r}') d^3\mathbf{r} d^3\mathbf{r}' \quad [25]$$

In the previous section, we assumed that the distribution of an electron has the spherical symmetry with respect to the center of the reductant ion, and that the probability of the electron outside the sphere r_b is zero. Under these conditions, Eq. [25] reduces to

$$\begin{aligned} \mathbf{H}_{ep} &= - \int \frac{e \mathbf{r}'}{|\mathbf{r}'|^3} \cdot \mathbf{P}(\mathbf{r}') d^3\mathbf{r}' \\ &= - \int \mathbf{E}_v(\mathbf{r}') \cdot \mathbf{P}(\mathbf{r}') d^3\mathbf{r}' \quad [26] \end{aligned}$$

where \mathbf{E}_v is the electric field originating from the electron in the reductant ion in the vacuum.

The electric field at \mathbf{r} induces the polarization $\mathbf{P}(\mathbf{r})$ inside the dielectrics, and thus the dielectric is attracted by the force

$$\mathbf{F} = (\mathbf{P} \cdot \nabla) \mathbf{E}_v \quad [27]$$

The work done against this electrical force in carrying the dielectrics from $|\mathbf{r}'| = \infty$ to $|\mathbf{r}'|$ is $-\int_{r=\infty}^{r'} \mathbf{F}(\mathbf{r}') \cdot d\mathbf{r}'$. Thus, the total energy provided from external system is (13)

$$W = - \int d^3\mathbf{r}' \int_{r=\infty}^{r'} \mathbf{F}(\mathbf{r}') \cdot d\mathbf{r}' = - \int d^3\mathbf{r}' \int \mathbf{P} \cdot d\mathbf{E}_v \quad [28]$$

This energy W is also obtained by calculating the difference between the field energy inside the dielectrics and

that in the vacuum (16)

$$W = \frac{1}{4\pi} \int d^3\mathbf{r}' \int \mathbf{E} \cdot d\mathbf{E}_v - \frac{1}{8\pi} \int \mathbf{E}_v^2 d^3\mathbf{r}' \quad [29]$$

The field energy is the work for charging the sphere r_b . Consequently, the subtraction of $eB/2$ in the vacuum from $eB/2$ in the dielectrics

$$eG/2r_b + \frac{eC}{2(r_b^2 + R^2)^{1/2}} - e^2/2r_b \quad [30]$$

must accord with W in Eq. [29]. But in the zero order approximation, $n = m = 0$, there is a small deviation between the work W in Eq. [29] and W in Eq. [30], because the electric field in Eq. [16] includes the high order terms of $\cos \vartheta$, while those terms are neglected in $eB/2$ in Eq. [12]. The work given by Eq. [28] or [29] is converted to both the interaction energy of the electron with the dielectrics, H_{ep} , and the work to polarize the dielectrics, W_p . From Eq. [26] and [28], W_p is written as

$$W_p = - \int d^3\mathbf{r}' \int \mathbf{P} \cdot d\mathbf{E}_v + \int \mathbf{P} \cdot \mathbf{E}_v d^3\mathbf{r}' = \int d^3\mathbf{r}' \int \mathbf{E}_v \cdot d\mathbf{P} \quad [31]$$

Substituting \mathbf{E}_v and \mathbf{P} into Eq. [31], we have

$$W_p = -W = -\frac{1}{2} H_{ep} \quad [32]$$

The relation of $W_p = -W$ leads to

$$W_p = e^2/2r_b - \frac{1}{8\pi} \int \mathbf{E}_{2s} \cdot \mathbf{E}_v dv_2 - \frac{1}{8\pi} \int \mathbf{E}_{3s} \cdot \mathbf{E}_v dv_3 \quad [33]$$

and the relation of $W_p = -1/2 H_{ep}$ yields to

$$W_p = \frac{1}{2} \int \mathbf{P}_{2s} \cdot \mathbf{E}_v dv_2 + \frac{1}{2} \int \mathbf{P}_{3s} \cdot \mathbf{E}_v dv_3 \quad [34]$$

where the volume elements dv_2 and dv_3 indicate that the volume integral must be taken over the space where the solvent is present, and over the space where the semiconductor is present, respectively. Substituting the relations of Eq. [16] and [17] into Eq. [33] or [34], we have

$$W_p = e^2/2r_b - \frac{1}{8\pi} \int (G_s \frac{\mathbf{r}}{|\mathbf{r}|^3} + C_s \frac{\mathbf{r}^*}{|\mathbf{r}^*|^3}) \cdot \frac{e\mathbf{r}}{|\mathbf{r}|^3} dv_2 - \frac{1}{8\pi} \int D_s \frac{\mathbf{r}}{|\mathbf{r}|^3} \cdot \frac{e\mathbf{r}}{|\mathbf{r}|^3} dv_3 \quad [35]$$

$$W_p = \frac{\epsilon_{2s} - 1}{8\pi} \int (G_s \frac{\mathbf{r}}{|\mathbf{r}|^3} + C_s \frac{\mathbf{r}^*}{|\mathbf{r}^*|^3}) \cdot \frac{e\mathbf{r}}{|\mathbf{r}|^3} dv_2 + \frac{\epsilon_{3s} - 1}{8\pi} \int D_s \frac{\mathbf{r}}{|\mathbf{r}|^3} \cdot \frac{e\mathbf{r}}{|\mathbf{r}|^3} dv_3 \quad [36]$$

The volume integrals in Eq. [35] and [36] are carried out by the variable change as follows (see Fig. 2 and 3)

$$\int \frac{\mathbf{r}}{|\mathbf{r}|^3} \cdot \frac{\mathbf{r}}{|\mathbf{r}|^3} dv_2 = \int_{r>r_b} \frac{4\pi r^2}{r^4} dr - \int_{z=R/2}^{\infty} \int_{y=0}^{\infty} \frac{2\pi y dy dz}{(z^2 + y^2)^2} = 4\pi/r_b - 2\pi/R \quad [37]$$

$$\int \frac{\mathbf{r}}{|\mathbf{r}|^3} \cdot \frac{\mathbf{r}^*}{|\mathbf{r}^*|^3} dv_2 = \int_{r=r_b}^{\infty} \int_{\vartheta=0}^{\pi} \frac{(r^2 - Rr \cos \vartheta) 2\pi r^2 \sin \vartheta d\vartheta dr}{2r^3 (r^2 + R^2 - 2Rr \cos \vartheta)^{3/2}} - \int_{r=r_b}^{\infty} \int_{\vartheta=0}^{\pi} \frac{(r^2 - Rr \cos \vartheta) 2\pi r^2 \sin \vartheta d\vartheta dr}{2r^3 (r^2 + R^2 - 2Rr \cos \vartheta)^{3/2}} = 2\pi/R \quad [38]$$

$$\int \frac{\mathbf{r}}{|\mathbf{r}|^3} \cdot \frac{\mathbf{r}}{|\mathbf{r}|^3} dv_3 = \int_{z=R/2}^{\infty} \int_{y=0}^{\infty} \frac{2\pi y dy dz}{(z^2 + y^2)^2} = 2\pi/R \quad [39]$$

Accordingly, the work W_p is written as

$$W_p = e^2/2r_b - eG_s/2r_b - eC_s/2R \quad [40]$$

or

$$W_p = e \epsilon_{2s} G_s/2r_b - eG_s/2r_b - eC_s/2R \quad [41]$$

But W_p in Eq. [41] deviates from W_p in Eq. [40] by the small term of $2^{-1}e^2b^2 (b^2 + R^2)^{-3/2} (\epsilon_{2s} - \epsilon_{3s}) (\epsilon_{2s} + \epsilon_{3s})^{-1}$, which disappears when the distance R is larger than r_b . This deviation is ascribed to the inaccuracy of the zero order approximation of the coefficient G , C , and D . The rearrangement energy for one vibrational mode is defined as the energy required to attain the new equilibrium of the interaction mode after electron transfer. Except for the electronic polarization, the ionic and orientational polarization can be related to the characteristic vibrations. The rearrangement energy due to one vibrational mode can be defined as the work required to induce the polarization arising from such vibrational mode. The polarization of the solvent, \mathbf{P}_{2e} , \mathbf{P}_{2i} , and \mathbf{P}_{2d} is independently determined by using the response time to the fluctuation of the electron distribution. The energy W_p in Eq. [40] is the total work to induce the electronic, ionic, and orientational polarization inside the dielectrics. Since the semiconductor has no low energy vibration such as the orientational vibration of the solvent, the rearrangement energy due to the orientational vibration of the solvent

Fig. 2. Volume element considered for determining the volume integral in Eq. [37].

Fig. 3. Volume element considered for determining the volume integral in Eq. [38].

can be obtained by subtracting the work required to induce the polarization in the infrared region, $W_p(\text{IR})$ from the total work W_p

$$E_s(\text{os}) = \frac{e}{2r_b} (G_r - G_s) + \frac{e}{2R} (C_r - C_s) \quad [42]$$

The rearrangement energy for the high energy vibration $E_s(\text{IR})$ is

$$E_s(\text{IR}) = \frac{e}{2r_b} (G_o - G_r) + \frac{e}{2R} (C_o - G_r) \quad [43]$$

The response time of the lattice vibration is similar to that of the intramolecular vibration of the solvent, so that the rearrangement energy due to the lattice vibration cannot be separated from that for the intramolecular vibrations of the solvent. The residual term due to the electronic polarization modifying the electronic energy has been usually included in H_e' (15).

For comparison, we show the formulas of $E_s(\text{os})$ and $E_s(\text{IR})$ for the electron transfer at the metal/electrolyte interface. Dielectric constant of a metal is infinite, because the electric field inside a metal is screened by free electrons. By introducing the relation of $\epsilon_{3s} = \epsilon_{3r} = \epsilon_{3o} = \infty$ into Eq. [42] and [43], we have

$$E_s(\text{os}) = e^2 (1/\epsilon_{2r} - 1/\epsilon_{2s}) (1/2 r_b - 1/2 R) (1 - r_b^3 (r_b^2 + R^2)^{-3/2})^{-1} \quad [44]$$

$$E_s(\text{IR}) = e^2 (1/\epsilon_{3o} - 1/\epsilon_{2r}) (1/2 r_b - 1/2 R) (1 - r_b^3 (r_b^2 + R^2)^{-3/2})^{-1} \quad [45]$$

When the distance R is large enough compared with r_b , Eq. [44] and [45] coincide with Marcus formulas for $E_s(\text{os})$ and $E_s(\text{IR})$ at a metal electrode. That is, Marcus formulas for $E_s(\text{os})$ for heterogeneous electron transfer reactions are valid for the limiting case of $R \geq r_b$ (17). In the practical case that the distance R is at least larger than $2r_b$, the correction due to the term $1/[1 - b^3 (b^2 + R^2)^{-3/2}]^{-1}$ is less than 8%.

The rearrangement energy due to the interaction between an electron and the intramolecular vibration in an ion, $E_s(\text{intra})$, is written as (2, 9)

$$E_s(\text{intra}) = \sum_j \frac{f_j \times f_j^*}{f_j + f_j^*} (\Delta q_j)^2 \quad [46]$$

where f_j and f_j^* are the force constants of the j th interaction mode in the oxidant and reductant ions, respectively, and Δq_j is the change in the equilibrium coordinate of the interaction mode before and after electron transfer.

Results and Discussion

The experimental $E_s(\text{os})$ values have been estimated from the electron transfer rate constants by using Marcus formula (9), or from the I-V characteristics (5-8). In order to compare theoretical $E_s(\text{os})$ and $E_s(\text{IR})$ values with experimental values, we consider the role of the rearrangement energy on the electron transfer rate. When the non-adiabatic electron transfer occurs from the occupied conduction band to the oxidant ion, the cathodic current density is given by (19)

$$i = \frac{4 \pi e}{\hbar} \int C_o(x) dx \int | \langle \Psi_i(E) | U(x, E) | \Psi_f(x, E) \rangle |^2 \rho_D(x, E) \rho_{sc}(E) dE \quad [47]$$

where C_o is the concentration of the oxidant ion, Ψ_i is the wavefunction of the electron in the conduction band, Ψ_f is the wavefunction of the electron in the reductant ion, ρ_D represents the state density of phonons, ρ_{sc} represents the state density of the conduction band, U is the perturbation causing the electron transfer, x is the distance between the semiconductor surface and the center of the reductant ion, and E is the energy of the transferring electron. The phonon-state density depends on the dis-

tance between the electrode surface and the center of the ion, because the phonon-state density is dependent on the rearrangement energy, which is a function of the distance x . Since the square of the matrix element in Eq. [47] decreases quickly with the increase in the distance, Eq. [47] can be approximated as follows (20)

$$i = \frac{4 \pi e}{\hbar} C_o d \int | \langle \Psi_i(E) | U(d, E) | \Psi_f(d, E) \rangle |^2 \rho_D(d, E) \rho_{sc}(E) dE \quad [48]$$

where d is nearly the sum of the ion radius r_b and the thickness of the Helmholtz layer d_H . The current density, which is observed experimentally at a metal or a semiconductor/electrolyte interface, may provide information about $E_s(\text{os})$ and $E_s(\text{IR})$ values at $R/2 = r_b + d_H$. For the comparison of theoretical $E_s(\text{os})$ and $E_s(\text{IR})$ values with experimental values we calculated the theoretical $E_s(\text{os})$ and $E_s(\text{IR})$ values at $R/2 = b + d_H$. The calculated $E_s(\text{os})$ and $E_s(\text{IR})$ values for some redox species are listed in Table I.

As is seen in Table I, the theoretical $E_s(\text{os})$ values at two semiconductor electrodes are larger than that at metal electrodes. The variation of the theoretical $E_s(\text{os})$ values among electrodes arises from the difference in the magnitude of the induced mirror image charge. Besides theoretical $E_s(\text{os})$ values, the large theoretical $E_s(\text{IR})$ values due to the intramolecular vibration of the solvent and the lattice vibrations in ionic semiconductors were evaluated for $\text{Fe}^{2+/3+}$, $\text{Ce}^{3+/4+}$, and $\text{Fe}(\text{bpy})_3^{2+/3+}$ at the SnO_2 and TiO_2 electrodes. Further, the appreciable $E_s(\text{intra})$ values due to the symmetric breathing mode of metal-ligand stretching vibration in the first coordinational sphere (M-L vibration) have been obtained experimentally for $\text{Fe}^{2+/3+}$ and $\text{Ce}^{3+/4+}$. This result implies that the electron transfer at an ionic semiconductor/electrolyte interface occurs with accompanying the excitation and emission of multiphonons in these high energy vibrations. The role of M-L vibration on the electron transfer in polar solvents was first considered classically by Hush and Marcus (2, 21). Subsequently, quantum treatment of M-L vibration was carried out by Kestner *et al.* (18), who gave the phonon-state density as

$$\rho_D(d, E) = \left(\frac{1}{4 \pi K T E_s(\text{os})} \right)^{1/2} \sum_{m=-\infty}^{\infty} \exp [- (E - E^\circ - E_s(\text{os}) - m \hbar \omega_c)^2 / 4 K T E_s(\text{os})] \times \exp [- Z_c \cosh(\hbar \omega_c / 2 K T) + m \hbar \omega_c / 2 K T] I_m(Z_c) \quad [49]$$

where $Z_c = E_s(\text{intra})/\hbar \omega_c \times \text{cosech}(\hbar \omega_c / 2 K T)$, and $I_m(Z_c) =$

$(Z_c/2)^m \sum_{k=0}^{\infty} (Z_c/2)^{2k} / [k!(m+k)!]$. In Eq. [49], E° is the electronic

energy corresponding to the standard redox potential, $\hbar \omega_c$ is the energy of the M-L vibration. High energy vibrations in the initial state are not sufficiently excited at room temperature. For endothermic or small exothermic reactions, the phonon state density arising from these high energy vibrations accords approximately with the Franck-Condon factor between the ground vibrational state at the initial state and that at the final state, and is independent of the free energy difference. In such case, only $E_s(\text{os})$ values can be determined from the free energy relationship of the electron transfer rate (17). For large exothermic reactions, since electron transfer can occur via excited vibrational states in the final state and the phonon-state density is influenced by high energy vibrations, the electron transfer rate is prompted. In order to evaluate quantitatively the effect of the high energy vibrations on the phonon-state density, we quote experimental values of the rearrangement energy estimated from the electrochemical rate constants at the zero overvoltage, or values from the isotropic exchange rate. If the exponential term of the phonon-state density at zero-free energy difference, $\Delta E = E - E^\circ = 0$, is formally written as $\exp(-E_s/4kT)$, the total rearrangement energy E_s at room temperature is approximately given by (18, 19, 22)

$$E_s = E_s(o_s) + \frac{4KTE_s(IR)}{\hbar\omega_r} [\coth(\hbar\omega_r/2kT) - \operatorname{cosech}(\hbar\omega_r/2kT)] + \frac{4KT E_s(intra)}{\hbar\omega_c} [\coth(\hbar\omega_c/2kT) - \operatorname{cosech}(\hbar\omega_c/2kT)] \quad [50]$$

where $\hbar\omega_c$ is the M-L vibrational energy and $\hbar\omega_r$ is the energy of the lattice vibration or the intramolecular vibration of the solvent. In the calculation of the E_s values in Table I, the vibrational energy $\hbar\omega_r$ was assumed to be about 0.01 eV, which is the intramolecular vibrational energy of H₂O (10). The experimental E_s values at metal electrodes in Table I were estimated not only from the electrochemical reaction rate constants at metal electrodes, but also from the isotropic exchange rate constants, by using Marcus' formulas (9).

For Fe(bpy)₃^{2+/3+}, the theoretical $E_s(o_s)$ value at the SnO₂ electrode is consistent with the experimental value of 0.15 eV (23). Furthermore, theoretical E_s value is also close to the experimental E_s values. The good agreement between theory and experiment for the E_s values is attributable to the validity of the application of the adiabatic electron transfer to Fe(bpy)₃^{2+/3+}. In the reductant ion, Fe(bpy)₃²⁺, appreciable 3d electron density is found in the ligand π^* orbitals by virtue of the back-donation interaction. Similarly, in the oxidant ion, Fe(bpy)₃³⁺, the acceptor d orbital extends to the ligands. Thus, for the isotropic reaction of Fe(bpy)₃²⁺ - Fe(bpy)₃³⁺ and the electrochemical reaction of Fe(bpy)₃^{2+/3+} at a metal electrode, the electronic matrix element coupling the initial and final states of the electron transfer is expected to be large, leading to the adiabatic electron transfer (24).

The rearrangement energy for Fe^{2+/3+} and Ce^{3+/4+} reported by Memming and Möller (5) may be close to E_s

values rather than $E_s(o_s)$ values, because I-V curves at the SnO₂ electrode were measured at the high overvoltage region. Though the experimental $E_s(o_s)$ values for Fe^{2+/3+} were not obtained for two semiconductor electrodes listed in Table I, the $E_s(o_s) = 0.5$ eV was estimated at the organic crystal electrodes (3). The variation of the theoretical $E_s(o_s)$ values at the two semiconductor electrodes in Table I is not so large that the experimental $E_s(o_s)$ value for Fe^{2+/3+} at a semiconductor electrode may not be different significantly from 0.5 eV. The theoretical $E_s(o_s)$ values for Fe^{3+/4+} and Ce^{3+/4+} are smaller than the experimental values. Concerning the E_s values of Fe^{2+/3+} and Ce^{3+/4+}, the agreement between theory and experiment is very poor. This discrepancy was ascribed to the nonadiabaticity of the electron transfer (24). In fact, the transmission coefficient smaller than unity ($\kappa = 0.012$) was obtained for the reduction of Fe³⁺ by Willig *et al.* (3). For cerium ions, the accurate transmission coefficient has not been determined. Balzani *et al.* (4) reported that, from the consideration of the intensity of spectroscopic transition, the transmission coefficient is about 10⁻⁵ for the electron transfer reactions between Eu²⁺ or Eu³⁺ and an adiabatic-type partner, and that $\kappa = 10^{-10}$ for Eu²⁺-Eu³⁺ exchange reaction. Such a nonadiabatic behavior observed for lanthanide ions such as cerium or europium was interpreted in terms of the strong shield of the 4f orbitals by the 5s and 5p orbitals (4, 25). Consequently, a small transmission coefficient may be expected for the electron transfer including Ce³⁺ or Ce⁴⁺.

Kestner *et al.* (17) derived first the formula of $E_s(o_s)$ for homogeneous electron transfer, in which the ionic radius is changed after electron transfer. In their paper, the electric displacement was expressed by the charge of the oxidant or reductant ions, and the obtained formula of $E_s(o_s)$ gave the same representation of $E_s(o_s)$ as Marcus' formula if no variation of the ionic radius occurs after electron

transfer. If the ionic radius is changed, the formula of $E_s(o_s)$ derived by Kestner *et al.* increases with the increase in the charge of the oxidant ion. In principle, the formula of $E_s(o_s)$, which reflects the interaction of the electron in the reductant ion with the solvent, is independent of the charge of the oxidant ion (26). The conflicting result can be explained as follows: the ionic radius of the reductant ion, r_b , is larger than that of the oxidant ion r_a . Thus, the vacant space with the shell structure is generated by the contraction of the ionic radius after the electron transfer from the reductant ion to the electrode. The generated vacant space is filled with the solvent surrounding the ion. The solvent in the vacant space is not polarized by the transferring electron, but is polarized by the charge of the oxidant ion. According to the description of the electric displacement by Kestner *et al.*, this polarization energy of the solvent by the charge of the oxidant ion was necessarily included in the formula of $E_s(o_s)$. This polarization energy should be taken into the total adiabatic potential energy (the total free energy) rather than the rearrangement energy of the orientational vibration of the solvent, $E_s(o_s)$.

A New Miniature Lithium-Iron Sulfide Battery

W. E. Aker,^{*1} N. Margalit,^{*2} D. P. Johnson,^{*3} R. J. Ekern,^{*} N. A. Fleischer,^{*} and R. J. Brodd,^{*4}

The present market for button cells which power low drain microelectronic devices is served mainly by aqueous silver-zinc and mercury-zinc cells. The mercury cell seems to be of declining interest because of the potential environmental hazards associated with mercury as evidenced by their ban or control in Sweden and Japan. Silver-zinc cells, while totally acceptable for performance, are susceptible to the market price for silver. Lithium cells, as an alternative to both systems, can deliver essentially the same hours of service as silver cells, have less costly components, and are less prone to leakage. Present lithium organic electrolyte cells, however, are for low drain applications only, such as analog watches or LCD watches without backlight or alarm.

Lithium-metal sulfide couples have been explored extensively for high temperature molten salt battery systems (1). Extensive work has been carried out on the Li-TiS₂ system at room temperature (2). Kegelman (3), Kronenberg (4), and Uetani *et al.* (5) have suggested the lithium-iron sulfide system for room temperature operation, but present limited data to substantiate cell performance.

A lithium-iron sulfide cell system is described below which gives performance essentially equivalent to commercial silver cells. Based on the cell reaction

the system has a theoretical voltage of about 1.78V and a theoretical energy density of about 2.14 Wh/cm³ based on the above reaction and the volume of reactants. The reaction product may involve the formation of a compound of the type LiFeS

If this is the case, the theoretical cell voltage could fall in the range 1.55-1.65V.

Experimental

In order to make meaningful comparisons of performance with the existing silver system, all experiments were carried out in a commercial cell construction (IEC designation SR-55). The cell casing material is 316 stainless steel and the sealing insulating grommet is polypropylene. Figure 1 shows the construction of the test cells. All cells were constructed in a dry room with <2% relative humidity. Exposure of lithium and electrolyte to the atmosphere was minimized to prevent contamination. Also, since one of the solvents in the electrolyte mixture, dimethoxyethane (DME), has a high vapor pressure, it evaporates rapidly, and the solvent ratio can change significantly if left exposed for even a short period of time.

The electrolyte solvent, a mixture of propylene carbonate (PC) and DME, was examined at various ratios with

three solutes, lithium perchlorate (LiClO₄), lithium hexafluoroarsenate (LiAsF₆), and lithium trifluoromethyl sulfonate (LiCF₃SO₃). The PC, obtained from Burdick & Johnson, was dried over Linde 3A molecular sieves. The DME was obtained from Ansul Chemical and redistilled

using a spinning band column. The LiClO₄, from Foote Mineral Company, was specially dried to 25-50 ppm of water. The LiCF₃SO₃ from Minnesota Mining and Manufacturing Company, called Fluorad 124, was dried overnight at 110°C under 10⁻² torr. The LiAsF₆ from USS Agrichemicals was used as received.

A Karl Fisher analysis of the electrolyte prior to cell assembly gave total water concentrations of less than 200 ppm for electrolytes used in cell assembly. A gas chromatographic analysis on the electrolyte extracted from cells after assembly was used to establish the solvent ratio (PC/DME) in the cell.

The anode was 0.014g of pure lithium (99.8% min.) ribbon obtained from Foote Mineral Company. At anode assembly, the lithium is cut to fit inside the cell top and the mating surface was prepared by scraping or buffing. The cell top interior was also scratched just before applying the prepared lithium surface to ensure a good cold weld connection. Lithium alloy anodes were constructed by placing a clean aluminum foil (0.008 cm) in contact with the lithium surface adjacent to the electrolyte. This relates to an alloy composition of approximately 40% aluminum overall. Alloying occurs spontaneously on contact with the electrolyte. This process is very similar to that described by Rao (6). Alloying occurred in this instance after cell closure, *i.e.*, an *in situ* process.

Various iron sulfide (FeS) cathode materials were evaluated in experimental cells. The analytical grade FeS materials obtained from J. T. Baker Chemical Company, Fisher Scientific Company, and Cerac, Incorporated were heated to 910°C. The treated powder was pressed into cathode pellets, reheated to 250°C, and stored at <2% RH for assembly into cells. A particularly active FeS material was prepared by mixing and heating iron powder (Cerac, 100 mesh, 99.6% pure) and sulfur powder (Mallinckrodt, precipitated, UPS) in 1:1.1 weight ratio. The powders were ground in a mortar until a light green homogeneous color developed. This mixture was heated in a mullite tube furnace for 5h at 910° ± 5°C in an argon atmosphere in porcelain boats. This material is referred to as synthesis 4 iron sulfide. An examination of the iron-sulfur phase diagram shows that after heating to 910°C, all materials should be in the iron-rich position of the phase diagram. An x-ray diffraction pattern of the material also indicated some spinel formation. Margalit *et al.* (7) suggested the use of iron-rich sulfide in primary cells.

In cathode assembly, the 0.125g FeS pellets are vacuum-filled with electrolyte and placed in the cathode cup on top of a nickel mesh spacer and current collector. A lithium strip under the nickel mesh served as the voltage reducer. This reduces about 1% of the FeS in the cathode. A Reeve Angel glass matte separator was then placed on the pellet and wetted with a drop (0.02 cm³) of

Fig. 1. Cross section of the Li/FeS organic electrolyte cell, with OCV reducer and nickel mesh spacer.

electrolyte. The completed cathode assembly had a 316 stainless steel load bearing ring placed between pellet and separator.

Cell assembly was completed by crimp closing the anode and cathode assemblies in a cell closing die. This operation forms the plastic compression seal common to button cell construction. The cells were stored for a minimum of 72h prior to discharge and exhibited a stable open-circuit voltage (OCV) of about 1.7-1.8V at that time.

The cells were discharged on various regimes of load, time, and temperature, as described below. Low temperature discharges were conducted using a Neslab Endocal RTE-8 refrigerated circulating bath. Measurements of the ohmic drop for the complete cell were made at various stages of discharge. Specific test regimes used to determine cell performance were:

1. Continuous discharge at room temperature on various loads to 1.2V end point (EP) to ascertain cell capacity, rate capability, and voltage level on discharge.

2. Continuous discharge at low temperature (-10°C) to 1.1V EP.

3. Pulse measurements at -10°C on 1 M Ω quiescent load (QL) and 2000 Ω pulse load (PL) for 8 ms/s at selected progressive depths of discharge (DOD). This accelerated test is designed to simulate performance requirements of the electronics for an analog watch.

4. Pulse measurements at room temperature on 300 k Ω QL, 200 Ω PL for 5s duration at 20s intervals, three pulses at selected progressive DOD. This accelerated test is designed to simulate the requirements of the electronics and backlight for a digital liquid crystal watch.

5. Accelerated storage at 60°C for 40 days followed by cell discharge on selected loads to determine capacity retention. A constant temperature laboratory oven was used for 60°C storage. The cells were weighed periodically to determine leakage. This storage condition is thought to correspond to 2 years storage at ambient temperature.

Results and Discussion

Most lithium organic electrolyte cells have a spurious high OCV just after cell assembly. The cells in this study were no exception. This voltage is thought to be associated with absorbed water or active oxygen species on the surface of the cathode powders and, in this case, free sulfur species as well. Several approaches were used to eliminate or reduce this high OCV effect (6-9). These included: (i) pulse discharge after cell assembly, (ii) reducing with an active metal (e.g., Li, Zn) attached to the cathode, (iii) reducing the cathode pellet in butyl lithium, and (iv) improving cathode conductivity using conductive materials, such as lithium nitride and iron powders and by using an iron-rich FeS cathode material.

A lithium nitride addition improved cathode conductivity and low temperature discharge but it did not produce the desired OCV reduction. Cathode reduction using electrolyte-soluble butyl lithium lowered the OCV, but uniformity and extent of reduction were difficult to control.

Fig. 2. Continuous discharge performance of Li/FeS on three loads at room temperature. The continuous discharge performance of Zn/Ag₂O on 12.5 k Ω is included for purposes of comparison.

A small strip of lithium attached to the nickel grid cathode collector just before cell assembly proved to be the most practical and reproducible method overall. This technique uniformly reduced about 1% of the active material in the cathode along with extraneous impurities and produced stable OCV's at or near the reversible cell voltage. It also improved cathode performance and led to better high rate cell performance. The final cell design used the lithium strip reducer and an iron-rich iron-sulfide cathode material.

Typical cell discharge behavior is shown in Fig. 2. The cells deliver over 40 mAh on 10 k Ω and lower drain rates. The best cells gave over 45 mAh at similar drains. In comparison with a Zn-Ag₂O cell, the silver cell has about 100 mV higher discharge voltage and can deliver over 43 mAh capacity. The efficiency of utilization of the FeS cathode is about 60% at the lower current drains. Table I gives the results of accelerated storage. The capacity retention is excellent. The cells showed negligible loss of capacity at 12.5 k Ω load after 40 days at 60°C . None of the cells gained or lost weight during accelerated storage. The plastic compression seal proved to be reliable for this applica-

Table I. Capacity retention for Li/FeS cells after storage at 60°C for 40 days

tion. This period of 60°C storage corresponds to approximately 2 yr storage at room temperature.

Cells which performed well on continuous discharge at -10°C generally gave good overall performance. The LiClO_4 electrolyte gave the best performance followed by LiCF_3SO_3 and then LiAsF_6 . Cyclohexane addition to the electrolyte to lower viscosity and improve conductivity had little effect on overall performance. Cells with lower solute content and lower DME content gave better performance. Best performance on continuous discharge was obtained from cells having about 1.2M LiClO_4 in a 62 weight percent (w/o) PC/38 w/o DME solvent mixture with less than 60 ppm H_2O content. At -10°C , the best cells discharged on a 3.3 k Ω load for 6 min to 1.2V and over 280 min to the 1.1V cutoff. These results satisfied a minimum performance requirement for low temperature operation of electronic devices.

Of the cathode materials, only the synthesis 4 FeS could sustain the analog pulse beyond 40 mAh and also meet the room temperature backlight pulse regime at about 40 mAh (87% DOD). In both the analog and digital pulse tests, the best cell construction was an Li/Al alloy anode, synthesis 4 cathode, and 45 w/o PC/55 w/o DME/1.4M LiClO_4 electrolyte. Typical cell polarization and recovery curves for this system during analog pulse tests are shown in Fig. 3. The IR component of the cell polarization decreases slightly as the discharge proceeds through about 50% DOD. At this point, the total polarization and its ohmic component are at their lowest levels and so the pulse voltage is at its highest level. The lower polarization could result from an increase in surface area available for reaction as a result of the breaking up of FeS particles to produce smaller particles with higher total reaction area. The decrease in pulse polarization at mid-DOD is also associated with a slight increase in the quiescent load operating voltage (Fig. 2). This slight increase may be due to the formation of iron, a low resistance reaction product, in the cathode. The IR component then increases gradually until about 95% DOD where it begins to increase rapidly and becomes the dominant factor in cell failure on this test. Activation and concentration polarization are relatively small fractions of the total cell polarization towards the end of discharge.

At the end of discharge, the microporosity developed in the cathode during discharge is thought to cause the cathode to absorb electrolyte from the relative open-structure separator. This drying out of the separator likely accounts for the increased internal resistance and resultant cell fail-

ure before complete utilization of the active materials. The precipitation of the nonconductive Li_2S reaction product at the cathode would also block off the electrode and increase internal resistance.

An examination of the cells after discharge showed incidence of swelling. The amount of swelling generally increased with cell discharge. A full discharge resulted in about a 15% increase in cell height. Cell swelling has been isolated to at least a cathode phenomenon and is a complex event, affected by original pellet porosity and the discharge products, Fe and Li_2S . Lithium sulfide aggravates the problem because it is insoluble in the electrolyte and has a high molar volume (27.7 cm^3/mol).

Conclusions

A lithium-iron sulfide, propylene carbonate-dimethoxyethane, lithium perchlorate cell system has been identified which shows promise of equaling the performance of silver cells in selected applications. The use of alloy anodes improves pulse capability of lithium anodes in organic electrolytes. The cathode composition controls the overall efficiency of utilization and the energy density. Iron-rich FeS cathode compositions were shown to have excellent performance for various cell applications.

Calculation of the Free Energy of Formation of Ferrous Chloride Tetrahydrate

E. McCafferty*

Naval Research Laboratory, Washington, DC 20375

Under certain conditions, ferrous chloride tetrahydrate, $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ is a corrosion product on iron or steel in chloride environments. $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ has been identified as a corrosion product on plain carbon steel in hydrochloric acid solutions (1) and in hydrochloric acid vapors (2, 3). Although not a major corrosion product in the atmospheric corrosion or marine corrosion of iron, ferrous chloride salts can be found in localized regions within natural rust layers (4-7).

In the localized corrosion of iron or steel, Pourbaix has developed a generalized model of the thermodynamic conditions within pits, crevices, or stress corrosion cracks (8). According to Pourbaix's model, the internal electrolyte within such "occluded corrosion cells" (9) is a saturated ferrous chloride solution, in equilibrium with the solid corrosion products Fe_3O_4 and $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$. A number of experimental studies, mostly with stainless steels, have confirmed that occluded cell electrolytes become concentrated in metallic cations and in chloride ions (10-15). Recent thermodynamic calculations taking activity coefficients into account (16) have verified that at equilibrium, the internal electrolyte in the case of pure iron is saturated solution of ferrous chloride. The stable solid phase in equilibrium with saturated ferrous chloride solutions is the tetrahydrate $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ (17, 18); and its presence in scaled-up models of localized corrosion cells on iron has been confirmed experimentally (19, 20).

Despite the importance of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ in both the localized and general corrosion of iron and steel, thermodynamic data for the tetrahydrate are somewhat lacking. Standard compilations (21) list the enthalpy of formation ΔH_f° , but not the free energy of formation ΔG_f° of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$. The only published value for the free energy of formation of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ appears to be the value calculated by Susarev *et al.* (22).

The free energy of formation of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ has been calculated here in three ways: (i) from the equilibrium between the hydrate and its saturated solution, (ii) by estimation of the entropy of formation ΔS_f° , and (iii) by comparison of free energies of formation of a series of hydrates with values for their anhydrous salts. The average result of these calculations is $\Delta G_f^\circ [\text{FeCl}_2 \cdot 4\text{H}_2\text{O}_{(s)}] = -306.0$ kcal/mol. The value given previously by Susarev *et al.* is -304.3 kcal/mol (22).

Equilibrium Between $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ and Its Saturated Solutions

This method has been used by Susarev *et al.* (22), but we repeat their calculations using slightly different values for the properties of the saturated solution. Figure 1 illustrates a thermodynamic cycle for the formation of crystalline $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ through a saturated solution of ferrous chloride. In the reaction

* Electrochemical Society Active Member.

Fig. 1. Thermodynamic cycle for the formation of ferrous chloride tetrahydrate.

Table I. Properties of saturated ferrous chloride solutions

Quantity	Value	Source
Molality, m	5.09	Ref. (18)
γ_{\pm}	2.5	Extrapolated from
a_w	0.59	Ref. (22), (23)
$\Delta G_f^\circ (\text{Fe}^{++}_{(aq)})$	-18,850 cal/mol	NBS (21)
$\Delta G_f^\circ (\text{Cl}^{-}_{(aq)})$	-31,372 cal/mol	NBS (21)
$\Delta G_f^\circ (\text{H}_2\text{O}_{(l)})$	-56,687 cal/mol	NBS (21)

Table II. Calculated free energy of formation of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$

Method	ΔG_f° (kcal/mol)
Equilibrium between the crystalline hydrate and its saturated solution	-305.7
Estimation of the entropy term $T\Delta S_f^\circ$	-305.9
Comparisons between anhydrous salts and their hydrates	-306.3
	Avg: -306.0

if the reactants are each in their standard states (unit activity) at 298.15 K, then

$$\Delta G_1^\circ = 2.303 RT \log a_{\text{FeCl}_2} a_w^4 \quad [2]$$

where a_{FeCl_2} and a_w are the activities of FeCl_2 and water, respectively, in the saturated solution. For the 2-1 electrolyte FeCl_2 , $a_{\text{FeCl}_2} = 4(m\gamma_{\pm})^3$. Use of the values of m , γ_{\pm} , and a_w listed in Table I for saturated FeCl_2 solutions gives: $\Delta G_1^\circ = 4088$ cal/mol.

For the reaction

$$\Delta G_3^\circ = \Delta G_f^\circ [\text{FeCl}_2 \cdot 4\text{H}_2\text{O}_{(s)}] - \Delta G_f^\circ [\text{Fe}^{++}_{(aq)}] - 2\Delta G_f^\circ [\text{Cl}^{-}_{(aq)}] - 4\Delta G_f^\circ [\text{H}_2\text{O}_{(l)}] \quad [4]$$

Taking the standard free energies of formation for $\text{Fe}^{++}_{(aq)}$, $\text{Cl}^{-}_{(aq)}$, and $\text{H}_2\text{O}_{(l)}$ from the NBS tabulations (21) and using the relation $\Delta G_3^\circ = \Delta G_1^\circ + \Delta G_2^\circ$ gives the result: $\Delta G_f^\circ [\text{FeCl}_2 \cdot 4\text{H}_2\text{O}_{(s)}] = -305.7$ kcal/mol.

Estimation of the Entropy of Formation

The enthalpy of formation ΔH_f° of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ has been reported to be -370.3 kcal/mol (21). A second way of calculating ΔG_f° is by estimating the term $T\Delta S_f^\circ$ and then using the relation $\Delta G_f^\circ = \Delta H_f^\circ - T\Delta S_f^\circ$.

Both the free energy and enthalpy of formation have been tabulated for the hydrates of many divalent metal chlorides (21). For a given series of hydrates $\text{MCl}_2 \cdot n\text{H}_2\text{O}$, the term $T\Delta S_f^\circ/n$ decreases (in negative value) with increasing degree of hydration. That is, successive water

Fig. 2. Relationship between $T\Delta S_f^\circ/nH_2O$ and the radius of the metal cation for various series of hydrated divalent metal chlorides.

molecules produce progressively smaller contributions to the entropy change of hydrate formation. As noted by Ladd and Lee (24), the hydrate is stabilized by the interactions between the water dipole and metal cation. These interactions depend on the ion-dipole distance, which in turn is related to the radius of the metal cation. Figure 2 shows values for $T\Delta S_f^\circ/n$ as a function of the radius of the metal cation. The ionic radii are taken from Pauling (25)

Fig. 3. Relationship between free energies of formation of hydrated and anhydrous divalent metal chlorides.

or from the compilation of Parsons (26). Interpolating in Fig. 2 gives $T\Delta S_f^\circ/n$ for $FeCl_2 \cdot 4H_2O$ as -16.1 kcal/mol/mol H_2O , so that $\Delta G_f^\circ = -305.9$ kcal/mol. This value is in good agreement with the result calculated in the previous section (see Table II).

Comparisons Between Hydrated and Anhydrous Chlorides

A third method of estimating ΔG_f° for $FeCl_2 \cdot 4H_2O$ is by comparison of the free energies of formation of various anhydrous chlorides with the free energy values for their hydrates. Figure 3 shows the correlation for the divalent metal halides and their various hydrates. A similar correlation has been noted between the enthalpies of formation of various metal chlorides and their dihydrates (27). For the hydration reaction

the standard free energy change is given by

$$\Delta G_{\text{hydration}}^\circ = \Delta G_f^\circ [\text{hydrate}] - \Delta G_f^\circ [\text{anhydrous}] - n(-56.687) \quad [6]$$

Using ΔG_f° values from the NBS compilations (21), it can be shown that $\Delta G_{\text{hydration}}^\circ$ is approximately -1 to -4 kcal/mol H_2O for all the metal dichloride hydrates shown in Fig. 3, except for the hydrates of $MgCl_2$, which have higher $\Delta G_{\text{hydration}}^\circ$ values of -4 to -8 kcal/mol H_2O . By setting $\Delta G_{\text{hydration}}^\circ \cong n \cdot A$, Eq. [6] takes the form

$$\Delta G_f^\circ [\text{hydrate}] = \Delta G_f^\circ [\text{anhydrous}] - n(56.687 - A) \quad [7]$$

For all the metal cations shown in Fig. 3 (except for Mg^{2+} , which does not quite obey Eq. [7]), the three curves can be combined into a single curve having the form of Eq. [7] and given by the least squares fit

$$\Delta G_f^\circ [\text{hydrate}] = 1.009 \Delta G_f^\circ [\text{anhydrous}] - n(56.687 + 1.656) \quad [8]$$

Using the tabulated value (21) of $\Delta G_f^\circ (FeCl_2) = -72.26$ kcal/mol in Eq. [8] gives the result: $\Delta G_f^\circ [FeCl_2 \cdot 4H_2O_{(s)}] = -306.3$ kcal/mol.

Summary

The values of $\Delta G_f^\circ [FeCl_2 \cdot 4H_2O_{(s)}]$ calculated by the three different approaches are listed in Table II. The average value is -306.0 kcal/mol.

Inhibition of Localized Corrosion as Determined by a Galvanodynamic Method

Alfred Viehbeck* and David W. DeBerry*

SumX Corporation, Austin, Texas 78758

Most of the fundamental studies of organic adsorption inhibitors have been concerned with the effects of these compounds on the uniform corrosion of metals in the active state (1). There is only limited information on the effects of such compounds on the localized corrosion of passive metals. This communication describes the inhibition of pitting on Type 304L stainless steel by a surface active chelating agent (N-lauroylsarcosine or NLS) in aqueous solutions containing chloride ions (2). A galvanodynamic method was developed for study of this system and appears to have attractive features for the study of pitting corrosion in general.

Type 304L stainless-steel electrodes were formed from 0.15 cm thick sheet into a "flag" shape. The electrode "pole," which extended above the solution level, was insulated with Glyptal varnish to eliminate the metal/solution/gas interface. The 6.0 cm² exposed flag was polished to a mirror finish using 0.3 μm alumina and degreased with methanol. The primary test solution contained 0.1M NaCl and 0.2M sodium acetate adjusted to pH 5.1. Test solutions using water purified by a Milli-Q reagent water system or distilled from permanganate gave similar experimental results. Inhibited solutions were prepared from this stock solution by addition of 3.0 mM NLS.

Electrochemical experiments were performed at 23° ± 1°C in a three-compartment Pyrex cell fitted with a Pt counterelectrode and SCE reference electrode. All potentials are reported with respect to the SCE. Prior to each electrochemical run, the electrode was degreased, rinsed thoroughly with water, and placed in the deoxygenated test solution for 1h. Solutions were magnetically stirred and blanketed with purified nitrogen throughout the experiment. After the open-circuit stand, the electrode was polarized for 3 min to either -0.60V or -8 μA before initiating the potential or current scan, respectively.

A typical linear potential scan (LPS or "potentiodynamic" scan) for a Type 304L stainless-steel electrode in the uninhibited solution at a scan rate of 0.20 mV/s is shown by the dashed curve in Fig. 1. The breakdown potential (E_b) associated with the onset of pitting is signaled by the rapid increase in current occurring at +0.20V on the forward scan to more positive potentials. On the return scan (after reversal at 0.1 mA/cm²), the current hysteresis trace intersects the passive current trace at the so-called protection potential (E_{prot}) at -0.08V. Below this

potential any active pits are repassivated (3). This is shown by the observation that a second positive going scan following the return to potentials negative of E_{prot} results in a current response which closely follows the original scan. The LPS measurement method has received much study but is complicated by induction time and other effects which can cause the results to vary with scan rate and incidental experimental parameters.

The effect of NLS in solution on the LPS is shown by the solid curve in Fig. 1. The initial response on the forward scan is quite similar to that for the uninhibited case, suggesting that the surface passivation process is not affected by NLS. However, there is a substantial effect of NLS on the current response at higher potentials. The breakdown processes are suppressed, and small current spikes and plateaus appear which are probably due to the nucleation and subsequent repassivation of pits. Above +1.20V, the transpassive region begins, and finally a

Fig. 1. LPS curves for Type 304L SS electrode in 0.1M NaCl with 0.2M Na acetate solution (pH 5.1) and scan rate of 0.2 mV/s. Dashed curve is for uninhibited solution, and solid curve is for solution with 3.0 mM NLS.

* Electrochemical Society Active Member.

Key words: corrosion inhibition, linear current scan, N-lauroylsarcosine, pitting, 304 stainless steel.

Fig. 2. LCS curve for Type 304L SS electrode in test solution not containing NLS. Current scan rate: $0.5 \mu\text{A/s}$. Dashed line shows response on scan reversal.

sharp current rise is seen at $E_b = +1.39\text{V}$. The return scan gives an $E_{\text{prot}} = -0.12\text{V}$, which is slightly more active than the value observed in the absence of NLS. In general, these results indicate that NLS inhibits the breakdown of passivity and perhaps aids repassivation of incipient pits. However, once breakdown has occurred to a certain stage, pits can continue to propagate in the presence of NLS. Visual examination of the metal surfaces showed that electrodes polarized in inhibited solution had a few large pits ($0.1\text{-}1 \text{ mm}^2$), while those tested in the absence of NLS had many (>100) small pits ($<0.001 \text{ mm}^2$) uniformly distributed over the surface.

Although the linear current scan (LCS) method has not previously been used to study localized corrosion and its inhibition, we have found that it provides a rapid and accurate means of measuring important corrosion parameters. In the LCS method, a triangular current ramp is imposed on the electrode and the resulting potential is recorded. This approach provides direct control of the total charge passed and extent of pit propagation occurring in a given experiment. As pointed out by Hirozawa for other current-controlled methods, the LCS is "active" in nature and is not influenced by the induction-time effects introduced in potential-controlled measurements (4).

An LCS curve obtained for a Type 304L SS electrode subjected to a current scan rate of $0.5 \mu\text{A/s}$ in the uninhibited solution is shown in Fig. 2. On the forward (increasing positive current) scan, there is an initial rapid rise in the potential. The charge in this region is consumed by any active metal dissolution, adsorption, or passive film formation processes as well as the maintenance of the quasistationary film condition. The potential peak which follows is believed to be due to pit nucleation involving the most favorable surface sites. The peak potential and current density are a function of the kinetics of the passivity breakdown process. Further work on extracting kinetic information from LCS results is in progress.

The nearly constant potential obtained after the initial peak now represents E_b defined as the minimum potential for which pits will continue to nucleate and propagate with increasing current. The value of $+0.21\text{V}$ measured for E_b in this manner is in good agreement with that measured using the LPS method. When the current sweep di-

rection is reversed, a potential hysteresis curve is obtained. During this return scan (decreasing current), the current is used for continued pit propagation. If the current scan direction is again switched to increasing values, the potential response moves positive to reach the forward scan potential as illustrated by the dashed line in Fig. 2. This behavior is not an induction effect but is attributed to the additional driving force needed to nucleate new or repassivated pits as compared to that for propagation alone. This also indicates that the hysteresis observed on the decreasing current scan is due to the lower driving force requirements for pit propagation alone.

The effects of varying current scan rate (β) on the LCS response are shown in Fig. 3. As β is increased, several characteristics change, including the slope of the potential response in the passive region, the peak potential, and the current at which the peak potential occurs. However, the charge density at the peak maximum is not affected by β , even though the initial response appears to show β -dependent charging effects. Therefore, under any β , the charge density for passivity breakdown (Q_b) can be readily obtained; for the present system, $Q_b = 1.4 \text{ mC/cm}^2$. Note that E_b and the following portions of the potential curve are also independent of scan rate.

Extrapolating the potential response on the return scan to zero current yields a value for the LCS analog of the protection potential ($E_{\text{prot}} = -0.03\text{V}$) that is also independent of β . In addition, the effect of increasing the current limit is an increase in the slope of the return response. However, the value of E_{prot} is still unchanged for different scan limits, *i.e.*, different total charge passed. The LCS value for E_{prot} is somewhat more noble than the value found using the LPS method. The LCS method thus allows the rapid measurement of E_b , E_{prot} , and Q_b with minimal interference by induction time effects.

The response obtained for a LCS ($\beta = 1.0 \mu\text{A/s}$) on Type 304L SS in the presence of 3.0 mM NLS is shown in Fig. 4. Although the overall features of the trace are similar to those obtained in the absence of NLS, there are certain distinct differences. For instance, the initial peak maximum occurs at higher current density and more positive potential. These results indicate that the organic compound influences the interfacial processes in such a way that the electrode can sustain a higher charge density (Q_b)

Fig. 3. LCS curves for Type 304L SS electrode in test solution without NLS. $\beta = 0.5$ (a), 1.0 (b), and 5.0 (c) $\mu\text{A/s}$, respectively.

before localized breakdown of passivity takes place. The Q_b in this case is 2.6 mC/cm^2 .

A pronounced effect of NLS on the sustained pit nucleation and propagation potential is again observed. Although still substantially positive of the uninhibited value, the LCS measured E_b ($\sim +0.50\text{V}$) is not as positive as that measured by the slow LPS. This may be due to the pronounced effect of the inhibitor on the pit induction time. The LCS value is practically independent of scan rate. The return potential response has a lower slope with more "noise" but gives essentially the same value of E_{prot} as in the NLS-free solution. The presence of NLS appears to significantly increase the noise associated with the E_b plateau, perhaps indicating that it continues to interfere with pit nucleation and propagation even after the initial breakdown.

Fig. 4. Results of LCS for Type 304L SS electrode in test solution containing 3.0 mM NLS at $\beta = 1.0 \mu\text{A/s}$.

A mechanism for inhibition of uniform corrosion by N-lauroylsarcosine involves the formation of multiple "chelating" bonds to the bare metal surface (5). The present results suggest that the molecule may also be attached to the surface cations of the passive film through the amide nitrogen and carboxyl oxygen, forming an insoluble, passive film stabilizing surface compound. Preliminary capacitance (C_d) measurements (using the fast galvanostatic pulse method) show that the average C_d from -0.60 to 0.60V decreases from $18 \mu\text{F/cm}^2$ in the uninhibited solution to $1.5 \mu\text{F/cm}^2$ with 3.0 mM NLS in solution. The higher Q_b and more positive potentials required for maintaining localized attack may result from a strong tendency for surface complex formation at those sites on the surface which are most susceptible to pit formation. Work is continuing on the possibilities associated with using compounds such as NLS as probes of localized corrosion mechanisms.

Potentiodynamic Investigation of Copper in the Presence of Bromide Ions

Louis Brossard*

Institut de recherche d'Hydro-Québec, Varennes, Québec, Canada J0L 2P0

The anodic dissolution of copper in the presence of bromide ions has received little attention (1-3). It has been established that the valence of dissolution of copper is one (1), while the dissolution rate of bare metal is controlled by diffusion of ions in the solution as CuBr_2^- and CuBr_3^- (2).

At potential values larger than the reversible potential for the reaction

the formation of CuBr is observed on copper surface (2, 3). Two peaks of oxidation are present on the E-i curves, and the current of dissolution mainly results in the accumulation of copper bromide.

The aim of the present work is to establish the rate-determining step of the dissolution reaction in the region of the peaks in solutions having 0.05-1.2M NaBr. The influence of temperature (22°-64°C) is also investigated.

Experimental

The electrochemical cell, its accessories, and the test procedures have been described in previous papers (4, 5). In the present investigation, a copper wire electrode with a diameter of 0.06 cm and a total surface area of 0.4 cm^2 was used. The solution contained 0.05-1.2M NaBr, and the temperature was raised from 22° to 64°C. A potassium phthalate-based buffer was used to stabilize the pH at 4. The solution was carefully deaerated by nitrogen bubbling, which was discontinued just prior to the experiments.

The working electrodes were polarized from -450 to +400 mV_{SCE} by the linear potential sweep method. The scan rate, dE/dt was varied from 5 to 70 $\text{mV} \cdot \text{s}^{-1}$ in order to determine the influence of the scan rate on the peak currents.

All electrodes potential values are given in relation to the saturated calomel electrode except when otherwise specified.

Results

Figure 1 shows the potentiodynamic traces of copper at 0.2 and 0.9M NaBr. The scan rate is 12 $\text{mV} \cdot \text{s}^{-1}$, and the solution is quiescent. Two waves of oxidation are observed. The difference between the applied potential and the reversible potential, $E_{\text{Cu/CuBr}}$, of reaction [1] is given on the potential scale. The reversible potential of reaction [1] is given by (6, 7)

$$E_{\text{Cu/CuBr}} = -0.239 - 0.059 \log_{10}(\text{Br}^-) \quad [2]$$

where $E_{\text{Cu/CuBr}}$ is expressed in volts with respect to the saturated calomel electrode.

The difference between the peak potentials, E_{p1} and E_{p2} , and $E_{\text{Cu/CuBr}}$ is

$$E_{p1} - E_{\text{Cu/CuBr}} = 160 \pm 5 \text{ mV} \quad [3]$$

$$E_{p2} - E_{\text{Cu/CuBr}} = 385 \pm 5 \text{ mV} \quad [4]$$

Expressions [3] and [4] are practically unaffected by a change of Br^- ion concentration from 0.05 to 1.2M.

The main characteristics of the behavior of the copper anode in the region of the peaks are as follows. (i) The peak current of the first, i_{p1} , and the second wave, i_{p2} , depends on the intensity of the solution agitation (Fig. 2). (ii)

*Electrochemical Society Active Member.

Key words: bromide ions influence, copper dissolution kinetics, anodic dissolution.

The plot of i_{p1} and i_{p2} against the square root of the scan rate, on a stationary electrode in a quiescent solution, is a straight line (Fig. 3 and 4), with an ordinate at its origin equal to zero. The experimental relationships for solution of 0.2M NaBr are

$$i_{p1} = 0.23 \left(\frac{dE}{dt} \right)^{1/2} \quad [5]$$

$$i_{p2} = 0.28 \left(\frac{dE}{dt} \right)^{1/2} \quad [6]$$

where i_{p1} and i_{p2} are expressed in amperes per square centimeter and dE/dt in volts per second. (iii) The order of the reaction in relation to Br^- ion concentration, ξ , is close to one in the first peak region between 0.05 and 0.2M NaBr (Fig. 5). ξ is 0.5 in the first peak region, and found to be -0.6 in the second peak region above 0.2M. (iv) The anodic charge (Q_{ox}) obtained by the integration of the E-i curve in the peak region, e.g., from $E = E_{\text{Cu/CuBr}}$ to $E = E_{\text{Cu/CuBr}} + 500 \text{ mV}$, is practically unaffected by a change of Br^- ion concentration. For example, Q_{ox} is 490 mC cm^{-2} in 0.2M NaBr in comparison with 450 mC cm^{-2} in 0.9M NaBr (Fig. 1); the sweep rate is 12 mV s^{-1} . (v) The general shape of the E-i curve and its peak potentials remained unaffected by a change of the solution temperature (Fig. 6). However, the peak currents are higher as the solution temperature is increased. For example, i_{p1} is 16 mA cm^{-2} at 22°C and 32 mA cm^{-2} at 60°C.

Discussion

Below the equilibrium potential $E_{\text{Cu/CuBr}}$ a two-step reaction was considered (2) from which the dissolution process of the copper anode may be entirely explained.

The reaction is

and

Fig. 1. Potentiodynamic traces on a copper wire electrode in a quiescent solution of 0.2 and 0.9M NaBr. The electrode potential is given in relation to the reversible potential of $\text{Cu} + \text{Br}^- = \text{CuBr} + e$ (Eq. [2]). $dE/dt = 12 \text{ mV} \cdot \text{s}^{-1}$, $T = 22^\circ\text{C}$, $\text{pH} = 4$.

Fig. 2. Influence of the solution agitation on the potentiodynamic traces. where the subscripts i and s refer to concentrations at the copper-solution interface and the bulk solution, respectively.

The rate-determining step [8] is the diffusion transport of CuBr_2^- from the interface to the bulk solution. Step [7], the oxidation of copper to CuBr_2^- , is assumed to be in equilibrium.

The order of the reaction in relation to Br^- ion concentration is two, and the current of dissolution increases as the applied potential becomes larger.

This model is valid as long as the Br^- ion concentration at the copper-electrode interface, $(\text{Br}^-)_i$, and in the bulk solution, $(\text{Br}^-)_s$, is close together while the surface is free of corrosion products.

In the region of the peaks, the current results almost entirely in the accumulation of copper bromide on copper

Fig. 3. The anodic peak current of the first wave vs. the square root of the scan rate at three different NaBr concentrations. The solution is quiescent.

Fig. 4. The anodic peak current of the second wave vs. the square root of the scan rate. The solution is quiescent.

surface at sweep rate values close to or larger than $5 \text{ mV} \cdot \text{s}^{-1}$ (3). It is in agreement with the fact that the rate of dissolution of CuBr is $\sim 0.073 \times 10^{-8} \text{ mol cm}^{-2} \text{ s}^{-1}$ in a quiescent solution of 0.2M NaBr at 22°C , e.g., 0.071 mA cm^{-2} in comparison with an oxidation current having an average value of 7 mA cm^{-2} (Fig. 6).

Considering the formation of CuBr from reaction [1] and the large value of the peak currents (Fig. 3 and 4), the depletion of Br^- ions at the electrode surface, $(\text{Br})_s \ll (\text{Br})_i$, may be eventually considered. The diffusion-

Fig. 6. Influence of solution temperature on the potentiodynamic trace at 0.2M NaBr . The solution is quiescent, and $dE/dt = 5 \text{ mV} \cdot \text{s}^{-1}$.

Fig. 7. Dependence of the peak currents on the temperature in 0.2M NaBr solution. $dE/dt = 5 \text{ mV} \cdot \text{s}^{-1}$. ●: Experimental values of i_{p1} . ○: Experimental values of i_{p2} . □: Relative values calculated from Eq. [10].

controlled transport of Br^- ions from the bulk solution to the copper electrode is the rate-determining step in the oxidation reaction. Consequently, the current should reach a maximum in the E-i curves (8), i_p , and the plot of i_p against $(dE/dt)^{1/2}$ should be a straight line with an ordinate at its origin equal to zero. In addition, an order of reaction of one concerning i_p in relation to Br^- ion concentration may be predicted.

The characteristics marked (i), (ii), and (iii) deduced from Fig. 2, 3, and 5 suggest that the dissolution process in the region of the first peak is under the diffusion control of Br^- ions between 0.05 and 0.2M NaBr.

For a diffusion-controlled process, the peak current is related to the scan rate by the equation (8)

$$i_{p1} = 2.69 \times 10^5 n^{3/2} D^{1/2} \left(\frac{dE}{dt} \right)^{1/2} C_i \quad [9]$$

where i_{p1} is the peak current (in A cm^{-2}), D the diffusion coefficient ($\text{cm}^2 \text{ s}^{-1}$), (dE/dt) the scan rate ($\text{V} \cdot \text{s}^{-1}$), C_i the concentration of the electro-active species (mol cm^{-3}), and n the number of exchanged electrons. Considering Br^- ions as the diffusing species, its diffusion coefficient may be determined from the experimental relationship $i_{p1} - (dE/dt)^{1/2}$ and the values of n and C_{Br^-} . For 0.2M NaBr, n is 1 in the first peak region (1), $C_{\text{Br}^-} = 0.2 \times 10^{-3} \text{ mol cm}^{-3}$, and the slope of the $i_{p1} - (dE/dt)^{1/2}$ curve is $0.23 \text{ A cm}^{-2} \text{ V}^{-1/2} \text{ s}^{1/2}$ (Fig. 3). The substitution of these values in relation [9] gives $1.8 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ for D_{Br^-} , which is in agreement with those given in the literature for D_{Cl^-} and D_{I^-} (9).

The relative values of the peak current, corresponding to the curve for which ΔH^\ddagger is equal to $2.2 \text{ kcal mol}^{-1}$ in Fig. 7, were calculated considering that the change of the diffusion coefficient of Br^- ions in the solution with the temperature. From Eq. [9], the relative values of i_{p1} is given by

$$i_{p1} \propto D_{\text{Br}^-}^{1/2} \quad [10]$$

The values of D_{Br^-} at different solution temperature were calculated from the equation (10)

$$\frac{D\mu}{T} = \text{constant} \quad [11]$$

where μ is the viscosity of the solution given in Ref. (11). The relative values of i_{p1} are plotted against T^{-1} in Fig. 7. The slope of this curve gives a ΔH^\ddagger value equal to $2.2 \text{ cal} \cdot \text{mol}^{-1}$. The experimental value of ΔH^\ddagger is $3.6 \text{ kcal} \cdot \text{mol}^{-1}$ for the first peak and $2.1 \text{ kcal mol}^{-1}$ for the second peak. Therefore, the change of the peak current with temperature is attributed to the variation of D_{Br^-} .

Above 0.2M NaBr, the fractional value of ξ in the first peak region, characteristic (iii), suggests that the limitation of the current is not only due to the diffusion of ions in the solution. From the work of Kozin and co-workers (12, 13), it may tentatively be attributed to the presence of a corrosion product on the electrode surface, since the surface is partly covered by copper bromide at E_{p1} (2).

Concerning the second peak, it is strongly dependent on the first one, since the sum of Q_{ox} for the two waves is practically unaffected by a change of Br^- ion concentration (Fig. 1). This behavior is consistent with the fact that ξ is 0.5 in the first peak region and found to be -0.6 in the second peak region above 0.2M NaBr. In addition, n for the second peak may be higher than 1 (12). Therefore, the theoretical determination of i_{p2} from relation [9] is questionable. However, the experimental relationship $i_{p2} - (dE/dt)^{1/2}$, characteristic (ii), with an ordinate at its origin equal to zero, the dependence of i_{p2} on the intensity of the solution agitation (Fig. 2) and the value of ΔH^\ddagger for the second peak (Fig. 7) promote the idea that the rate-determining step of the dissolution in the second peak region is the diffusion of ions in the solution.

In summary, the two waves of oxidation observed on the potentiodynamic traces have their peak potential independent of Br^- ion concentration. The second peak is dependent on the first one since the sum of Q_{ox} for the two waves is practically unaffected by a change of Br^- ion concentration. The limitation of the dissolution current in the peak region is ascribed to the diffusion of ions in the solution. It is suggested that the species are Br^- ions in the first peak region between 0.5 and 0.2M NaBr.

NiO Solubility in Molten Li/K Carbonate under Molten Carbonate Fuel Cell Cathode Environments

Charles E. Baumgartner*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

The corrosion of molten carbonate fuel cell (MCFC) NiO cathodes during cell operation has been brought to attention recently (1-5) and is considered one of the major technical difficulties facing MCFC development at the present time. NiO, solubilized in the molten Li/K carbonate (62/38 mole ratio) at the cathode/carbonate interface, is diffusively transported through the carbonate reservoir towards the anode. At some location intermediate between the two electrodes, the local cell environment's oxygen partial pressure decreases below the level where NiO is stable and metallic nickel precipitates. Recent evidence obtained from cell tests has shown the extent of cathode degradation to be accelerated by increasing either the P_{CO_2} or the total $P(CO_2 + O_2)$ supplied to the cathode. This is important since commercial fuel cells are expected to operate with oxidant gases such as humidified 30% CO_2 /bal air at elevated pressures of between 6 and 10 atm. Estimations of the extent of cathode degradation occurring under these elevated pressures requires an understanding of how the NiO/carbonate equilibrium changes as a function of changing cathode gas environment. This note documents the measured equilibrium NiO solubility in Li/K carbonate melts under various humidified $CO_2/O_2/N_2$ gases containing a constant P_{CO_2}/P_{O_2} ratio of 2/1.

Experimental

Pellets of NiO, approximately 1.2 cm in diam, were pressed at 20,000 psi and air sintered for 24h at 1123 K. Equilibrium solubility measurements were made by placing one pellet in the bottom of a clean 7.5 cm tall \times 1.6 cm diam gold crucible along with 20 ± 1 g of premelted and ground high purity binary Li/K carbonate of eutectic composition 62 mole percent (m/o) $Li_2CO_3/38$ m/o K_2CO_3 (Apache Chemical Company, Seward, Illinois). The crucibles were placed in an $\alpha-Al_2O_3$ -lined box furnace whose cover was adapted for two thermocouples, a gas inlet, and a sampling tube. The cover gases utilized for this study, possessing P_{CO_2}/P_{O_2} ratios of 2/1 with a N_2 balance, were water saturated at 298 ± 1 K to give the following gas compositions

The samples were allowed to equilibrate at temperature for at least 150h. Beginning at that time, approximately 1g aliquots of molten carbonate were removed at 24h intervals by inserting an $\alpha-Al_2O_3$ pipette just below the melt's upper surface. These aliquots were transferred to clean gold crucibles where they cooled for subsequent nickel analysis by atomic absorption spectroscopy. The quoted solubilities represent a nickel analysis which did not vary more than $\pm 10\%$ relative to a mean over a 3 day period. The limit of $\pm 10\%$ represents the reproducibility obtained on identical samples and constitutes the cumulative deviation in the solubility and analytical techniques. In addition, a carbonate blank consisting of an identically prepared crucible containing carbonate only was occasionally carried through the procedure adjacent to the sample crucible to confirm that samples were not contaminated from the furnace environment.

Results and Discussion

The measured NiO solubility under the four gas environments is shown in Fig. 1. In each case, the solubility increased as a function of temperature once the equilibrium solubility level exceeded the background nickel concentration present in the nascent carbonates. Under experimental conditions where the equilibrium solubility remained below this level, the anolyte concentration did not decrease with time. It is suggested that this was due either to NiO supersaturation in the melt or to the homogeneous precipitation of a fine NiO suspension which was subsequently sampled along with the solubilized form. Samples were not left on test for times exceeding 500h to determine if the lower equilibrium values are slowly approached. In any event, the linear \ln solubility vs. inverse temperature relationship is clearly visible from the remaining data. As anticipated from the previously mentioned cell test experience, the highest solubility was recorded under the gas possessing the highest total $P(CO_2 + O_2)$. Measurements at temperatures exceeding 1143 K under the 5.8% $CO_2/2.9\% O_2$ containing gas were further complicated by carbonate dissociation shown previously to occur under similar conditions by Spedding and Mills (6). A significant increase in NiO dissolution occurred under these conditions; these data are not shown in Fig. 1.

Figure 2 shows a rearrangement of the data to illustrate the analyzed NiO concentration's dependency on the total gas ($CO_2 + O_2$) partial pressure at four different temperatures. (Some of the 923 K data were obtained by extrapolation due to the background nickel interference.) Each temperature's solubility is linear as a function of total $P(CO_2 + O_2)$ with the 923 K data, the operating tempera-

Fig. 2. Nickel oxide equilibrium solubility in Li/K carbonate at various temperatures as a function of CO₂ + O₂ pressure for gases with a P_{CO₂}/P_{O₂} ratio of 2/1.

ture of a MCFC, possessing a slope of 20.3×10^{-6} mole fraction NiO/atm (CO₂ + O₂) and a Y-intercept of 5.5×10^{-6} mole fraction NiO. From this linear relationship, the impact of MCFC system changes on NiO cathode solubility, and hence on the cathode corrosion rate, can be esti-

mated. For example, the calculated NiO equilibrium solubility under a rich oxidant (64.6% CO₂/32.3% O₂/3.1% H₂O) at 1 atm pressure with 25% oxidant electrochemical utilization is 20.3×10^{-6} mole fraction, and is equivalent to that calculated under a leaner gas (20% CO₂/10% O₂/3.1% H₂O/bal N₂) operated at 10 atm pressure and 75% oxidant utilization. Therefore, ignoring any electropotential influence on the cathode's solubility and assuming that the relevant transport properties are independent of gas pressure, cathodes operated under these two fuel cell conditions should exhibit similar corrosion rates.

The data presented in Fig. 2 also suggests that the NiO/carbonate equilibrium is not established simply by the CO₂ partial pressure as suggested previously (5, 7) since increasing the P_{CO₂} by a factor of 10 at constant temperature never resulted in more than a factor of 3.5 increase in solubilized nickel. This indicates that the solubilization mechanism is indeed complex and in need of further exploration.

Large Nickel Particle Powder Formed by Electrodeposition on a Metal Surface Partially Covered with a Polytetrafluoroethylene Layer

O. Teschke*

Instituto de Fisica, UNICAMP, 13.100 Campinas SP, Brazil

F. Galembek

Instituto de Quimica, UNICAMP, 13.100 Campinas SP, Brazil

Powdery metal deposits were obtained using electrolysis by Priestley (1) as early as 1803. Extensive studies on a large number of metals (Cu, Ni, Fe, Pb, Sn, Mn, Zn, Cd, Pd, W, Co) have been carried out since then. A detailed survey of this work was made by Ibl (2).

Kudra (3) first observed that the product of current density and the square root of the radius of electrodeposited particles is a constant. Theoretical work performed by this author leads to results compatible with this experimental observation. However, the poor adherence be-

*Electrochemical Society Active Member.

Key words: electrodeposition, coating, metal, film.

tween electrodeposited particles and the substrate was not explained. Atanasui and Calusaru (4) have also treated this problem on theoretical grounds. They proposed that the energy barrier for quantum mechanical tunneling is widened with decreasing concentration of the discharging species. However, the reason for the appearance of loosely connected outgrowths on a substrate has not been elucidated. Their loose connections are sufficiently strong to allow free flow of electrons and weak enough for the particles to fall off at the slightest disturbance. Powder particles are formed by nucleation and not by the extended growth of already existing irregularities. A

Fig. 1. Optical micrograph showing nickel particles formed by electrodeposition over a PTFE-covered nickel surface.

model of the mechanism of powder formation is not yet available, as far as we know.

This work describes a technique which was developed to form large particle powder. The technique consists of electrodeposition of nickel onto a metallic substrate covered by a thin polytetrafluoroethylene (PTFE) layer. Optical microscopy and scanning electron microscopy (SEM) observations were then performed to study the shape of the particles, which are loosely connected to the substrate.

Experimental

Stainless steel plates (5 cm × 2 cm × 1 mm) were initially nickel plated in a Watts solution at 30°C. The sample was rotated about its longer axis at a constant speed (20 rpm) in order to smooth out local electric field differences. All samples were prepared from the same stainless steel plate. The plate was initially washed in a detergent solution, mechanically scrubbed, and then cleaned in the usual sequence. A detailed description of the experimental condition is presented in Ref. (5).

The nickel plating solution consisted of the following compounds dissolved in distilled water: NiSO₄ · 6H₂O, 300 g/l, NiCl₂ · 6H₂O, 45 g/l, and H₃BO₃, 30 g/l. The resulting solution was stirred at 30°C in a Pyrex beaker. The counterelectrode was a nickel sheet.

A first nickel plating was given to the sheet for a total time of 12 min. The apparent current density was approx-

imately 10 mA/cm². After plating, the plates were washed with distilled water and dried.

PTFE T30 Teflon¹ dispersion was dialyzed against water to remove the stabilizing surfactant, and diluted to ca. 1% in distilled water. The dispersion was then allowed to settle within a long (ca. 60 cm) glass cylinder for 15 min, after which time the lower 10% of the cylinder contents was discarded. The dispersion was allowed to settle again, and after 1h the upper half of the cylinder contents was also discarded. To prevent excessive coagulation, 1% sodium laurylsulfate was added to the remaining dispersion, for storage. Prior to use, it was drained from a stock, the dispersed solid allowed to settle, and the liquid replaced by distilled water.

The previously plated metal sample was dipped into the Teflon dispersion, allowed to dry under air, and heated to 370°C. The electrode surface was then washed in an acidic solution (5% H₂SO₄ for 1 min) to remove the oxides formed, and another layer of nickel was electrolytically deposited on the electrode. The apparent current density was approximately 10 mA/cm², resulting in a much larger actual current density since only a few protrusions and pinholes are effective sites for the charge transfer reaction. During this second deposition, powder particles are formed over the PTFE layer. A photograph of the resulting surface is shown in Fig. 1. A cathode potential of 2V against a saturated calomel reference electrode was observed during the nickel deposition.

After the nickel electrodeposition, a thin nickel layer of about 150Å was evaporated over the samples for observation under a scanning electron microscope. SEM photographs giving more microscopic details are shown in Fig. 2. Pinholes at the surface of the PTFE film are shown in Fig. 2b. Typical pinhole diameters at the PTFE film are about 5 μm. Pinholes in the PTFE layer as well as cracks and protrusions in it are paths for electrons during the deposition, and metal is deposited around them. A SEM micrograph of a PTFE covered nickel surface before the particle formation shows a structure similar to that shown in the top portion of Fig. 2b. The PTFE shows a very irregular and spongy structure. The conductive metallic overlayer will not be deposited in most of the cavities. It is difficult then to determine which sites will effectively transfer electrons and result in particle growth.

Figures 1 and 2 show that the nickel deposit is made of round particles. Cross sections of the plates were obtained by cutting and polishing. Some of these are pre-

Fig. 2. Scanning electron micrographs of nickel particles formed by electrodeposition over a PTFE-covered nickel surface.

Fig. 3. Polished cross-sectional view of the nickel particles, PTFE layer, and nickel substrate.

sented in Fig. 3 and show common features: (i) nickel particles are obtained which have very little direct contact with the substrate metal, (ii) these particles take the approximate shape of half-spheres, (iii) their bases juxtapose to the PTFE layer, and (iv) metal tips connecting the substrate to the particles are not discernible, due either to small size or to damage during polishing.

Discussion and Conclusions

The shape of the particles reflects the influence of the PTFE layer. Protrusions and pinholes in the PTFE layer as well as cracks in it are paths for electrons during the deposition, and metal is deposited around them. After an initial growth, the layer is well away from the interface, and the deposition gives spherical particles. Since the PTFE layer imposes a fixed boundary to the particle growth, the deposits are half-spheres, as shown in Fig. 3. The particles have a diameter of 10-100 μm , but have a weak binding to the substrate since only tips of diameters around a few microns connect them to the substrate.

Figure 1 also shows that in some regions there is appreciable coalescence of the grown particles. The coales-

cence process following contact is characterized by the growth of the neck formed between the contacting powder particles (6).

In conclusion a technique was developed to form large particle powder. Nickel was deposited onto a metallic substrate covered by a thin PTFE layer. The deposit tends to form half-spherical particles with a weak binding to the substrate. The shape of the particles reflects the influence of the PTFE layer.

Comparison of the Activity of PdSn Colloidal Catalysts with the Activity of Pure Metals for HCHO Oxidation: Enhancement of the Activity by Ionic Tin

Jean Horkans

IBM, Thomas J. Watson Research Center, Yorktown Heights, New York 10598

The formation of a metallic conductor on an insulating substrate can often be accomplished most conveniently through the use of electroless deposition processes, which are initiated by a catalyst deposited on the insulator surface. The catalyst frequently is a PdSn mixed colloid, consisting of a metallic core of an alloy of Pd and Sn surrounded by a stabilizing layer of Sn(II) with the necessary counterions (mostly Cl^-) (1). It is assumed that the metallic Pd acts as the catalyst, whereas the ionic tin serves only to stabilize the colloid in solution. Indeed, excess ionic tin on the surface can be detrimental and is usually removed by following the activation step (the deposition of the colloid) by an acceleration step (2-5) (immersion in a solution that selectively dissolves ionic tin).

Earlier methods (6, 7) used to evaluate the activity of PdSn catalysts are not directly related to the role of the

Key words: electroless plating, organic voltammetry.

colloid in initiating electroless deposition. The work reported here examines PdSn colloids as catalysts for formaldehyde electro-oxidation. Of the two major partial electrode reactions occurring in electroless Cu plating, formaldehyde oxidation is the reaction that is kinetically limited and strongly influenced by the catalyst. The ionic tin in the colloid was found to be important to its function as a catalyst for the formaldehyde reaction.

The results suggest analogies to the changes in the catalytic activity of metal electrodes for the oxidation of organic molecules caused by the underpotential deposition (UPD) of less-noble adatoms (8-12). The first step in the oxidation of molecules like HCHO is thought (12) to be dissociative adsorption. During the oxidation of the carbon containing fragment, strongly bound intermediates (perhaps requiring several surface metal atoms) can form and can poison the reaction.

Motoo and Shibata (9) interpret their results in terms of this model. The enhancing UPD adatoms fall into two groups. In one group, the enhancement depends on the number of surface sites occupied by the adatom on the Pt electrode. The formation of the poison is blocked, since the required number of adjacent Pt sites is unavailable in the presence of the adatom. The second group of adatoms has a much larger effect on activity than the first. The activity is increased through a mechanism in which these adatoms adsorb oxygen containing species that participate in the oxidation reaction.

Other methods of depositing ionic species on metal electrodes also can result in increased activity of fuel cell catalysts (13, 14). The tin-covered surfaces of the present study were prepared by yet another method: deposition of a colloid. These catalysts show interesting parallels to the other adatom-covered metallic electrocatalysts.

Experimental

Formaldehyde oxidation was studied under conditions like those used during electroless Cu plating. The electrolyte was 0.4M Na₂SO₄, 0.03M HCHO, the pH adjusted to 11.7 with NaOH. A more detailed description of the experimental conditions is given elsewhere (15). The formaldehyde was used without further purification. No interference from the CH₃OH stabilizer was found (15). The temperature of the solution was maintained at 75°C. The reference was a mercury sulfate electrode (MSE), Hg/Hg₂SO₄, sat. K₂SO₄, in a separate compartment at room temperature.

The electrodes were evaporated metal films on glass substrates. An adhesion layer of 200Å of Nb was first deposited, followed by 2000Å of the desired metal. Some of the electrodes examined were prepared by depositing a colloid on the surface of the evaporated metal. The PdSn colloid was made by diluting with NaCl solution, a concentrate similar to that described in the patents of Zeblicky (16). Gold was chosen as the support material. It is known from electron microprobe analyses (7) that a 5 min immersion of a Au surface in the PdSn colloid typically results in coverages of ~ 1 µg/cm² of Pd and ~ 2-5 µg/cm² of tin. The SnCl₂ colloid was prepared according to the method suggested by Cohen and West (17) and consisted of 30 g/l SnCl₂ · 2H₂O with 10 ml/l of conc. HCl. It was aged for 2 days before use. Immersion of a metal surface in the SnCl₂ colloid deposits ~ 0.6 µg/cm² of tin (18).

Electrodes were maintained at the open-circuit potential while the solution was being deaerated with N₂. Tin salts have significant solubilities at pH 11.7 (19), and repeated cycling of the electrode potential results in changes in the curves as the colloid, or a component of the colloid, is removed from the surface. The first sweep is fairly reproducible, however, and only the first anodic sweep is reported here.

Results and Discussion

Representative curves for formaldehyde oxidation on Au, Pd, and PdSn-covered Au are shown in Fig. 1. The reaction occurs at a much less positive potential on the PdSn-covered surface than on either Au or Pd. The increased catalytic activity is due to one of the following: (i) an interaction between the Au electrode and the tin in the colloid, (ii) an interaction between the Au electrode and the Pd in the colloid, or (iii) an interaction between the Pd in the colloid and the surrounding tin. These possibilities can be narrowed by further experiments.

The interaction between Au and ionic tin is explored in Fig. 2. The interaction between Pd and ionic tin has also been investigated. Formaldehyde oxidation on Au and Pd surfaces covered by a SnCl₂ colloid (Fig. 2) occurs at less positive potentials than HCHO oxidation on Au and Pd (Fig. 1). In both cases, however, a more positive potential is required than on PdSn-covered Au. Thus, the interaction of Au with the tin salts cannot entirely account for the observations of Fig. 1.

In order to investigate the Au-Pd interaction, a 20Å thick film of Pd metal was evaporated on a Au electrode.

Fig. 1. Formaldehyde oxidation on clean Au (—), clean Pd (— · —), and Au covered with PdSn colloid (— —) in a pH 11.7 solution of 0.4M Na₂SO₄ and 0.03M HCHO. The temperature was 75°C. The sweep speed was 20 mV/s.

Fig. 2. Same as Fig. 1 for Au covered with a SnCl₂ colloid (—) and Pd covered with a SnCl₂ colloid (— —).

So thin a Pd film may not be continuous, but an island film would be an even better model than a continuous film for comparison with the PdSn-covered Au electrode. The results are given in Fig. 3, which shows that a thin Pd film does not shift HCHO oxidation on Au to less positive potentials. The interaction of the Pd in the colloid with the Au electrode therefore cannot explain the results of Fig. 1. It is thus evident that the ionic tin in the colloid plays a role in the high activity of the PdSn-covered Au electrode.

The effect of an accelerating step is shown in Fig. 4. The dashed curve was obtained on the PdSn-covered Au. The solid line was obtained on a Au surface that, after deposition of the PdSn colloid and rinsing, was immersed

Fig. 3. Same as Fig. 1 for a Au electrode (—) and for a Au electrode with 20Å of evaporated Pd (— —).

Fig. 4. Same as Fig. 1 for a PdSn-covered Au electrode before (—) and after (---) immersion in 1M NH_4HF_2 .

for 1 min in 1M NH_4HF_2 , a common accelerator, and then rinsed. This acceleration process is known (20) to remove from the surface approximately half of the tin but very little of the Pd. Removing tin shifts the curve to considerably more positive potentials.

Conclusions

The immersion of a metal in a SnCl_2 colloidal suspension will deposit the same order of magnitude of tin species as UPD, but the environment of the tin is very different. There is no orderly association of the tin atoms with the substrate atoms; the deposited material will exist in three-dimensional clumps; a variety of anions (mainly Cl^-) will be associated with the tin. The extent of charge transfer to the tin probably also differs between the colloid and UPD adatoms. Nonetheless, colloidal tin was found to be able greatly to enhance the catalytic activity of Pd and Au electrodes for HCHO oxidation.

The enhancement of the activity of Au and Pd by colloidal tin is probably by a mechanism similar to that discussed by Motoo and Shibata (9). The tin on the surface provides a site on which oxygen containing species can adsorb. These species can then participate in the oxidation of the adsorbed formaldehyde fragment.

Formaldehyde oxidation occurs at a much less positive potential on the PdSn-covered Au surface than on any of the other surfaces examined, including pure Pd and tin-covered Pd. The interaction causing the enhancement in activity seems to be between the Pd in the colloid and the tin in the colloid. One could ask, however, why the enhancement caused by the Pd-tin interaction in the colloid should be any greater than that caused by tin on a bulk Pd electrode. The answer probably lies in the small size of the Pd nuclei in the colloid, which is in the range of 10-50Å (21). The difference in surface energy between small particles and bulk metals may change the interaction with the tin. In addition, the Pd in the colloid is alloyed with a small amount of metallic Sn (1), and the environment of Pd at the center of the colloid is different

from that of Pd metal covered by a SnCl_2 colloid. Acceleration, by removing ionic tin from the PdSn colloid, shifts the formaldehyde-oxidation reaction to more positive potentials.

Distribution of Anions and Protons in Oxide Films Formed Anodically on Aluminum in a Phosphate Solution

H. Takahashi,* K. Fujimoto, H. Konno,* and M. Nagayama*

Analytical Chemistry Laboratory, Faculty of Engineering, Hokkaido University, Sapporo 060, Japan

ABSTRACT

Pure Al foil specimens were galvanostatically anodized in a neutral phosphate solution (pH = 7.0, 20°C), and the thickness and composition profile of the formed oxide films were examined as functions of the anode potential and current density (c.d.). Analysis of the films was made by chemical sectioning with a H₂SO₄ solution, combined with (i) electron microscopy, (ii) x-ray photoelectron spectroscopy, (iii) capacitance measurements, (iv) dc polarization measurements, and (v) solution analysis. The films were found to consist of two parts, an outer part containing PO₄³⁻ and OH⁻ ions, and an inner part consisting of pure alumina. The outer part dissolved in the H₂SO₄ solution at a rate faster than that of the inner part, and thus the two parts were clearly distinguished by following the time variations in the reciprocal of capacitance during the chemical sectioning. For films formed with a constant c.d., the thickness ratio of the two parts, $\delta_{\text{out}}/\delta_{\text{in}}$, and the phosphate concentration in the outer part do not change with the anode potential or the total film thickness. With increasing c.d., the two values tend to increase. The mechanism controlling the anion and proton distribution in the oxide film is discussed.

Anodic oxide films formed on aluminum contain an appreciable amount of anions brought from the anodizing solution. When anodizing in phosphate solutions, the incorporated anions locate in the outer part of the film, while an inner part next to the metal consists of stoichiometric oxide. This was first reported by Randall and Bernard (1), who used a radiotracer method combined with a film sectioning technique. Using SIMS, Wood and co-workers (2) obtained phosphorus profiles qualitatively similar to those reported by Randall. More recently, we applied XPS combined with chemical sectioning of the film and ascertained that phosphorus in the outer part exists in the form of PO₄³⁻ and that some protons are also incorporated in the outermost part of the oxide (3). Lanford *et al.* (4) measured hydrogen profiles for a variety of anodic oxide films using a nuclear reaction technique, and reported that protons exist only in the outermost part, at concentrations equivalent to about 1 mole percent (m/o) water in alumina.

The purpose of the present investigation was to obtain quantitative measurements of the phosphate and proton profiles of oxide films formed galvanostatically in a phosphate solution and also to examine the effects of the anode potential and current density (c.d.) for films formed in phosphate solution at conditions similar to those used here.

Experimental

Anodizing procedure.—Pure, 99.99% Al foil coupons (2 × 3 cm, tag shaped) were electropolished in a 4:1 mixture of glacial acetic acid and 60% perchloric acid at 10°–15°C by applying an anodic current of 100 mA/cm². The polished coupons were then immersed in a 20 g/l CrO₃–35 ml/l H₃PO₄ solution (90°C) for 20 min to remove oxide film formed during the electropolishing, washed with methanol, and dried. Anodizing was carried out in a 0.033M NH₄H₂PO₄–0.067M (NH₄)₂HPO₄ solution (pH = 7.0, 20°C, stirred), by applying a constant current, i_a , of 1 mA/cm² until the potential, E_a , reached desired values, mainly 50V

(vs. SCE). To examine the effect of c.d., i_a was changed in the range 0.05–10 mA/cm².

After anodizing, the amount of Al³⁺ in the formed oxide, W_o , was determined by subtracting the dissolved amount of Al³⁺, W_d , from the total amount of oxidized aluminum, W_T , estimated with Faraday's law. Here, the charge consumed by oxygen evolution was so small that it could be neglected (5).

Chemical sectioning of the films.—The anodized specimens were immersed for different times in a 2M H₂SO₄ solution stirred at 60°C to dissolve and section the films from the outside. During the sectioning, the following measurements were carried out.

Amount of dissolved Al³⁺ ions, W_d .—Solution samples taken at intervals were analyzed by the oxinate extraction method in which Al³⁺ oxinate were extracted into chloroform at a pH around 9.3 to avoid the interference from the phosphate (6).

Amount of dissolved PO₄³⁻ ions, W_p .—Solution samples were analyzed by the molybdenum blue method (7).

Capacitance of the remaining oxide, C_p .—Specimens were transferred to a 0.5M H₃BO₃–0.05M Na₂B₄O₇ solution (pH = 7.4, 20°C), and the measurements were conducted at 120 Hz using a Yokokawa-Hewlett Packard Model 4284A Capacitance Meter.

Voltage sustained by the remaining oxide, ΔE .—Measurements were made in the same borate solution as for C_p measurements, by applying a small anodic current, i_a , of 10 μ A/cm².

Remaining film thickness, δ .—This was measured from electron micrographs of the sections of films. Sliced samples were prepared by an ultrathin sectioning technique using a Porter-I ultramicrotome with a diamond knife (8). The samples were examined by a transmission electron microscope (Hitachi Model HU-12A); the acceleration voltage was 125 kV, and the magnification was checked with standard polyethylene latex particles.

Key words: aluminum, anodic oxide film, anion distribution, surface analysis

XPS spectra for the exposed film surfaces.—The instrument used was a Vacuum Generators ESCA 3 electron spectrometer. Specimens were irradiated by $MgK\alpha$ x-ray ($h\nu = 1253.6$ eV) in a vacuum of 10^{-7} Pa (10^{-10} torr range). The analyzer was set to give a resolution of 1.18 eV for FWHM of the Au 4f 7/2 peak. The spectrometer was calibrated with pure copper relative to the photoelectron peaks of Au 4f 7/2 (84.0 eV) and Cu 2p 3/2 (932.70 eV). The intensities of Al 2s, O 1s, and P 2p were obtained from the corresponding peak areas. For a given specimen, the measurements were made after removing a surface layer of about 0.5 nm by ion sputter etching. S 2p and C 1s spectra showed that all contaminating species brought from the chemical sectioning solution were completely removed by this procedure. Preferential sputtering was insignificant for all the elements in the oxide, and derivation of the film composition was made as in Ref. (9).

Results

Determination of the composition of 50V films formed at 1.0 mA/cm².—Figure 1 shows the time variations in the anode potential, E_a , and the amount of Al ions in the oxide, W_o , during anodizing at $i_a = 1.0$ mA/cm². The current efficiency for the oxide formation was 98%, and the 50V film had a W_o value of 9.9 $\mu\text{g}/\text{cm}^2$.

Dissolution behavior of oxide.—Figure 2 shows the time variations in the amount of dissolved Al^{3+} and PO_4^{3-} ions, W and W_p (as phosphorus), followed during the chemical sectioning. As can be seen from the W - t_d curve, the dissolution rate of the film up to 40 min is faster than that after 40 min, and the film is fully dissolved at 60 min; the exposed substrate metal dissolves faster than the oxide. The amount of dissolved Al^{3+} ions at 60 min agrees well with the value of W_o . The W_p - t_d curve shows that the dissolution of phosphate is complete at 40 min, where the amount of dissolved phosphate reaches a steady value, 0.32 $\mu\text{g}/\text{cm}^2$, as phosphorus. Thus, Fig. 2 implies that the film consists of two parts: an outer part containing phosphate and dissolving faster and an inner part without any phosphate and dissolving slower. The phosphate profile obtained from Fig. 2 will be discussed below with reference to Fig. 7. The average concentration of phosphate in the whole oxide was calculated to be 5.1 weight percent (w/o), assuming the chemical composition as $\text{Al}_x\text{O}_y(\text{PO}_4)_z$.

In Fig. 3, the reciprocal of the film capacitance, $1/C_p$, is plotted against the dissolution time, t_d ; $1/C_{p,0}$ is the value at $t_d = 0$. Assuming the dielectric constant of the oxide to be constant, $\epsilon = 9.8$,¹ the remaining film thickness, δ , corresponding to $1/C_p$, was calculated and is indicated on the

¹ The dielectric constant, $\epsilon = 9.8$, is higher than the generally accepted value (~ 8.4). Our value was obtained by substituting 66 nm and 0.131 $\mu\text{F}/\text{cm}^2$ for δ_0 and $C_{p,0}$ into $\epsilon = (\delta_0 \cdot C_{p,0}) / (8.86 \times 10^{-5})$. The $C_{p,0}$ value is influenced by the roughness of the surface. Assuming the roughness factor to be 1.2, the value for ϵ becomes 8.2.

Fig. 1. Changes in the anode potential, E_a , and the amount of Al^{3+} ions in the oxide, W_o , with anodizing time, t_a . Anodizing was carried out by applying a constant c.d. of 1.0 mA/cm² in 0.067M $\text{NH}_4\text{H}_2\text{PO}_4/0.033\text{M}$ $(\text{NH}_4)_2\text{HPO}_4$ solution ($\text{pH} = 7.0$; 20°C).

Fig. 2. Time variations in the amounts of dissolved Al^{3+} ions, W , and PO_4^{3-} ions, W_p (as phosphorus), during film sectioning in 2M H_2SO_4 solution at 60°C . The oxide film was formed by anodizing with $i_a = 1.0$ mA/cm² up to 50V (vs. SCE) in 0.067M $\text{NH}_4\text{H}_2\text{PO}_4/0.033\text{M}$ $(\text{NH}_4)_2\text{HPO}_4$ solution ($\text{pH} = 7.0$, 20°C).

right ordinate. The thinning rate slows down at 40 min and the film dissolution is complete at 60 min, in agreement with the result in Fig. 2. Here, the thickness of the outer part is proportional to $1/C_{p,0}$ minus $1/C_p^*$, and that of the inner part is proportional to $1/C_p^*$, the value at $t_d = 40$ min.

Electron micrographs of sections of films taken at different t_d 's (Fig. 4) clearly show the progress of the chemical sectioning. Figure 4 shows the metal substrate (M), and the oxide layer (O), and a thin layer of resin used to embed the sample. The micrographs show that the original film thickness, δ_0 , is about 66 nm, and the film thins almost uniformly until it is all dissolved at $t_d = 60$ min. This again coincides with the W - t_d and $1/C_p$ - t_d behavior.

Figure 5 shows how the dc polarization sustained by the remaining oxide, ΔE , decreases with t_d ; ΔE was measured by applying a small i_a , 10 $\mu\text{A}/\text{cm}^2$, in the borate solution. For every t_d , steady ΔE was attained within 10s, consuming only about 1×10^{-4} C. This very small charge again suggests the uniform dissolution of the oxide during the chemical sectioning. It should be noted here that for $t_d = 0$, the steady value of ΔE is 44V , smaller than the anodizing voltage of 50V because of the smaller value of i_a ($= 10$ $\mu\text{A}/\text{cm}^2$) compared to 1 mA/cm².

The time variations in the film thickness, δ , were estimated from the measured values of W , C_p , and ΔE using

Fig. 3. Time variations in the reciprocal capacitance, $1/C_p$, of film, and the remaining film thickness, δ , during film sectioning in 2M H_2SO_4 solution at 60°C . Anodizing conditions are the same as in Fig. 2.

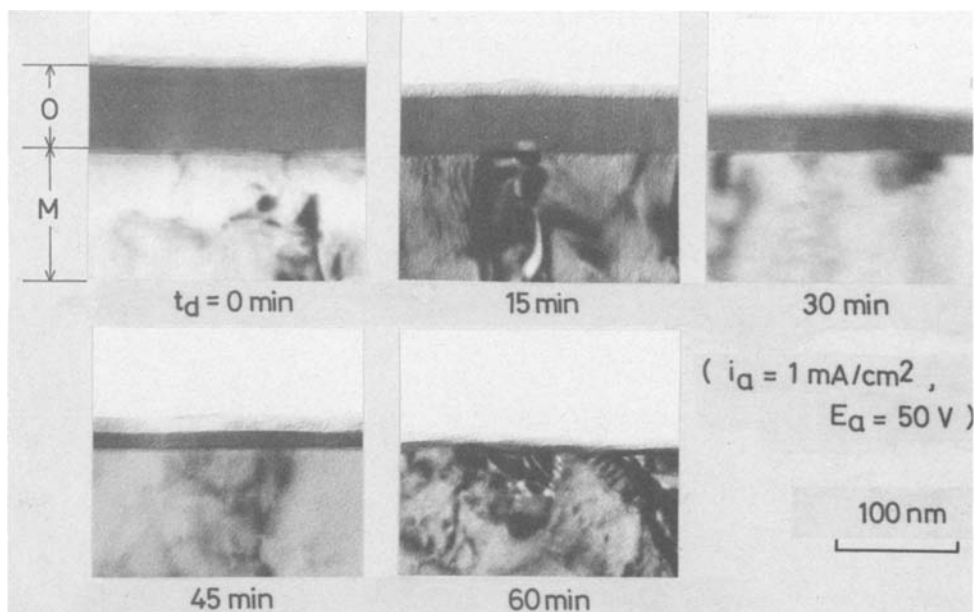

Fig. 4. Electron micrographs showing the progress of film thinning in 2M H_2SO_4 at 60°C. Anodizing conditions as in Fig. 2.

the following equation, and the results were compared with those from electron microscopy (Fig. 6)

$$\delta = 8.86 \times 10^{-8} \epsilon / C_p, \delta = (W_o - W) / \rho k, \text{ and } \delta = KE \quad [1]$$

In Fig. 6 the open circles are the data obtained from the C_p measurements with the dielectric constant of the oxide, $\epsilon = 9.8$. The small solid circles are from the amounts of dissolved Al^{3+} ions, W , assuming that the oxide density, ρ , is 2.95 and the weight fraction of Al^{3+} in the oxide, k , is 0.51. Error bars indicate the range of the data from electron microscopy. The open triangles indicate the data obtained from the ΔE measurements by assuming the thickness/voltage ratio, K , to be 1.5 nm/V. The ϵ , ρ , k , and K values used here are based on reported values, and the film thickness data estimated by the different methods are in good agreement. Thus, the total thickness of the 50V film is $\delta_o = 66$ nm, and the boundary between the outer and inner parts is around $\delta^* = 51$ nm inward from the surface of the oxide.

Phosphate profile from measurements of W and W_p .—From Fig. 6, it is possible to determine the depth position of the film, $x = (\delta_o - \delta)$, which will be exposed at a given dissolution time, t_d . By comparing the slopes of the W_p - t_d and W - t_d curves in Fig. 2 at various depths (or dissolution times), we obtained the P/Al mole ratio profile. The result is shown as the broken curve in Fig. 7. The P/Al mole ratio is almost 0.1 at the top of the film, it decreases steeply to about 0.03, and then stays constant down to a depth of nearly 50 nm. Beyond this depth phosphorus is not detected.

Fig. 5. Time variation in the steady value of dc polarization, ΔE , during film sectioning in 2M H_2SO_4 solution at 60°C. Anodizing condition as in Fig. 2.

Film composition estimated from XPS.—Typical XPS spectra taken for the outer and inner parts of the film are shown in Fig. 8. Phosphorus is detected in the outer part but not in the inner part. The peak positions of the spectra compared with those of standard samples suggest that Al and P exist in the form of Al^{3+} and PO_4^{3-} (or possibly HPO_4^{2-}). The composition profile of the film is shown by the solid curve in Fig. 7. The O/Al mole ratio is about 2 at the outer surface of the oxide, but it decreases with

Fig. 6. Time variation in the film thickness, δ , estimated by the measurements of C_p , W , ΔE and electron microscopy during film sectioning. Anodizing condition as in Fig. 2.

Fig. 7. Depth profiles of O/Al and P/Al mole ratio across oxide films formed by anodizing with 1 mA/cm² up to 50V (vs. SCE). Solid curves were obtained from XPS, and the dotted curve was obtained from the measurements of W and W_p .

Fig. 8. XPS spectra of Al 2s, P 2p, and O 1s orbitals for oxide films immersed in 2M H_2SO_4 solution at 60°C for different durations. Anodizing condition as in Fig. 2.

depth to reach about 1.7 within the first 10 nm, stays constant at this value until about $x = 50$ nm, and then decreases to 1.5, corresponding to the composition of a stoichiometric oxide. The 1.5 value appears to be maintained throughout the inner layer. The P/Al profile agrees quite well with that obtained by the W and W_p measurements, though the value of 0.028 for the outer part is slightly lower than the value estimated from the W and W_p measurements.

Effect of E_a and c.d. on the film composition.—The chemical sectioning behavior was observed for films formed by anodizing to various potentials, E_a , with $i_a = 1.0$ mA/cm² (see Fig. 1). Figure 9 shows W_p - t_d curves obtained for films with different anodizing potentials. All the W_p - t_d curves for films of different anodizing potentials coincide until W_p reaches steady values. The steady value of W_p indicates the total amount of phosphate incorporated in the films, and it increases with increasing anodizing potential. The time needed for complete dissolution of phosphate (broken vertical bars) also increases with E_a . The time required for the total dissolution of the film, obtained from the $1/C_p$ - t_d curves (Fig. 10), is shown by solid vertical bars. Except for the 14.9V film, the time required for complete dissolution of phosphate is considerably shorter than that required for whole film. For 14.9V film, the two bars nearly coincide, implying that there is no inner part free from phosphate. The coincidence of the inclined line segments, irrespective of E_a , suggests that for all the films the outer part, containing

Fig. 9. Time variation in the amount of dissolved phosphate, W_p (as phosphorus) during the sectioning of oxide films formed by anodizing with 1.0 mA/cm² up to different anode potentials.

Fig. 10. Time variation in the reciprocal capacitance, $1/C_p$, during the sectioning of oxide films formed by anodizing with 1.0 mA/cm² to different anode potentials.

phosphate, dissolves at one rate, and also that they have the same phosphate concentration in this part.

The $1/C_p$ - t_d curves obtained for films with different anodizing potentials are shown in Fig. 10. Break points distinguishing the outer and inner parts are seen in all the curves except in the 14.9V curve, in agreement with Fig. 9. Here again, $1/C_{p,0}$ is proportional to the total film thickness and $1/C_p^*$ is proportional to the thickness of the inner part. The amounts of Al^{3+} remaining in the oxide, $W_o - W$, are calculated by using the values of ϵ , ρ , and k described above and indicated on the right ordinate in Fig. 10.

In Fig. 11, the values of $1/C_{p,0}$ and $1/C_p^*$ are plotted as functions of E_a . The film thickness δ calculated as before is indicated on the right ordinate. The films formed below 20V consist of only a single phase similar to the outer part, and the films formed above 20V show almost constant δ_{out}/δ_{in} ratio (the ratio is 3.5 at 20V and 3.3 at 100V). Using the W_p - t_d curves (Fig. 9) and the corresponding W - t_d and δ - t_d relationships (Fig. 10), the P/Al profiles can be calculated as in Fig. 12. It is seen that, except for the 14.9V film, the outer part containing phosphate is clearly distinguishable from the inner part without phosphate incorporation. Here, the total film thickness is indicated by vertical bars on the abscissa, and the boundary between the two parts by broken, vertical lines. There is a high concentration of P at the top, and the P/Al ratio of about 0.03 is constant, irrespective of the thickness of the outer part for an $i_a = 1$ mA/cm².

The effect of c.d. on the phosphate profile was examined for 50V films formed at i_a of 0.1, 1, and 10 mA/cm², and is shown in Fig. 13. The phosphate concentration in the outer part increases with i_a . An increase in i_a causes a decrease in the thickness of the inner part. The thickness of the outer part is little affected by i_a . This is seen more clearly in Fig. 14, which shows the effect of i_a on $1/C_{p,0}$ and $1/C_p^*$. It is also recognized from Fig. 14 that the thinning rate of the outer part increases with increasing i_a , but that of the inner part is independent of i_a .

Fig. 11. Effect of anode potential, E_a , on $1/C_{p,0}$ (total film thickness, $\delta_{out} + \delta_{in}$) and $1/C_p^*$ (inner part thickness, δ_{in}) of oxide films formed by anodizing with 1.0 mA/cm².

Discussion

Mechanism controlling the composition profile.—It was shown above that phosphate is included only in the outer part of the oxide and its concentration increases as the anodizing c.d. is increased. This may be explained by the model for film growth shown in Fig. 15. When anodizing, oxide forms both at the metal/oxide and oxide/solution interfaces corresponding to the field-assisted transport of O^{2-} and Al^{3+} ions through the oxide. Here, Al^{3+} ions reaching the oxide/solution interface react with PO_4^{3-} as well as O^{2-} ions to form the outer phosphate incorporating part of the oxide, whereas O^{2-} ions arriving at the oxide/metal interface react with Al^{3+} ions to form the inner part consisting of pure alumina. The reason why phosphate is not included in the inner part is explained on the assumption that phosphate is almost immobile in the oxide because of its larger size. This assumption agrees with the fact that the phosphate concentration is almost constant throughout the outer part of the oxide except for the outermost part, where the concentration is considerably

Fig. 15. Schematic model showing the transport of ions across the oxide film during anodizing in a neutral phosphate solution.

higher. Thus phosphate can be used as a marker to estimate the transport number of Al^{3+} , $T_{\text{Al}^{3+}}$. Provided there is no dissolution of oxide during anodizing, $T_{\text{Al}^{3+}}$ would be equal to the thickness of the outer part divided by the total thickness of the oxide. As some dissolution is unavoidable, the exact determination of $T_{\text{Al}^{3+}}$ will be described later.

Using the XPS data shown in Fig. 7, the chemical composition of the outer part of the 50 V film can be determined. Assuming $\text{Al}_2\text{O}_x(\text{OH})_y(\text{PO}_4)_z$, the composition is $\text{Al}_2\text{O}_{2.92}(\text{OH})_{0.48}(\text{PO}_4)_{0.056}$. Alternatively, assuming $\text{Al}_2\text{O}_x(\text{PO}_4)_y \cdot z\text{H}_2\text{O}$, the composition becomes $\text{Al}_2\text{O}_{2.92}(\text{PO}_4)_{0.056} \cdot 0.26\text{H}_2\text{O}$. The XPS spectra for O 1s cannot predict which formula applies, because of the similarity in the binding energy of O 1s for OH^- and H_2O species (Fig. 8). It is, however, notable that both formulas allow a 0.4%–0.5% proton content in the outer part. This implies that OH^- ions rather than O^{2-} ions move in the outer part, but protons may move back from the boundary between the inner and outer parts, as suggested by Hoar and Mott (10).

Lanford *et al.* (4) have measured the proton profiles in barrier type oxide films with a nuclear reaction technique and reported only 0.17 w/o as H_2O (0.02 w/o as proton) in the outer surface. The cause of the discrepancy between this proton content and the one obtained in the present study is not clear, but the difference seems to depend upon the difference in anodizing conditions. Konno *et al.* (3) reported that the proton concentration in the outer part is almost zero after keeping the specimen at a constant anode potential after anodizing galvanostatically.

The high concentration of phosphate at the outermost part is considered to be either due to adsorption of phosphate during anodizing (1) or due to a thin film formed by the immersion of the specimen in the $\text{H}_3\text{PO}_4/\text{CrO}_3$ solution prior to the anodizing. In an XPS study to be published, we found a 5 nm hydrous oxide layer, which contains a high concentration of phosphate, is formed by the immersion of electropolished specimens in the $\text{H}_3\text{PO}_4/\text{CrO}_3$ solution (11). The hydrous oxide layer appears to play an important role in the formation of the oxide layer during the subsequent anodizing; the $\delta_{\text{out}}/\delta_{\text{in}}$ value is different between anodic oxide films on electropolished specimens and films on specimens electropolished and then immersed in the $\text{H}_3\text{PO}_4/\text{CrO}_3$ solution (11). The lack of inner layer for oxide films formed at less than 20 V may be related with the action of the pre-existing layer.

The effect of c.d. on the phosphate concentration in the outer part may be explained in the following manner. It is certain that any increase in the anodic c.d. is associated with the increase in the electric field at the oxide/solution and oxide/metal interfaces as well as that across the bulk oxide. The increase in the electric field in turn enhances the deprotonation of H_2PO_4^- and HPO_4^{2-} ions to form the more negatively charged species PO_4^{3-} , which has a higher coordinating ability toward Al^{3+} ions. Deprotonation of H_2O to form OH^- and O^{2-} is also facilitated,

and these ions will provide some competition with PO_4^{3-} ions in coordinating with Al^{3+} ions, but this does not alter the above interpretation. The increase in the phosphate concentration with increasing c.d. may be qualitatively explained in this manner.

Determination of the transport number of Al^{3+} ions.—As described above, $T_{\text{Al}^{3+}}$ is equal to the ratio of $\delta_{\text{out}}/(\delta_{\text{out}} + \delta_{\text{in}})$, if there is no dissolution during anodizing. However, some dissolution is unavoidable, and we used the following equation to estimate exact values of $T_{\text{Al}^{3+}}$

$$T_{\text{Al}^{3+}} = \frac{\delta_{\text{out}} + (\delta_{\text{out}} + \delta_{\text{in}})(1/\eta - 1)}{(\delta_{\text{out}} + \delta_{\text{in}})/\eta} = 1 - T_{\text{O}^{2-}}$$

where η is the current efficiency for the formation of oxide and $T_{\text{O}^{2-}}$ is the transport number of O^{2-} ions. Figure 16 shows the changes in $T_{\text{Al}^{3+}}$ (calculated) and η (experimental) with i_a . As is seen, $T_{\text{Al}^{3+}}$ gradually increases with increasing i_a from 0.73 at 0.05 mA/cm² to 0.81 at 10 mA/cm². As described above, an increase in i_a is always associated with an increase in electric field across the oxide, and hence it is reasonable that the transport of Al^{3+} ions, having smaller size and higher valency, is facilitated in preference to O^{2-} ions.

The method applied here is the same in principle as that reported by Randall and Bernard (1). They examined the effect of temperature and electrolyte concentration on $T_{\text{Al}^{3+}}$ and obtained the figures ranging from 0.72 to 0.84. The transport number of Al^{3+} obtained above is based on the immobility of the phosphate ions in the oxide. The possibility that the phosphate ions may be mobile has been pointed out by Davies *et al.* (12) and Pringle (13). They showed that smaller values for $T_{\text{Al}^{3+}}$ are obtained by using a xenon marker method, and the values do not change with the kind of inert gas markers. Thus, it is possible to explain the large value of $T_{\text{Al}^{3+}}$ obtained in the present study by the movement of phosphate inwards according to the electric field. However, it is notable that the transport number obtained by the marker method is dependent on the pre-existing films (14) and the acceleration voltage at the ion implantation of the marker (15).

Dissolution characteristics of the oxide.—As can be seen from Fig. 6 and 14, oxide films dissolve uniformly in the sulfuric acid solution, and the thinning rate of the outer part increases with i_a , while the thinning rate of the inner part does not change. It is likely that the dissolution rate is controlled by the amount of incorporated phosphate; the higher the concentration of phosphate, the faster the dissolution rate. Because the inner part does not contain any phosphate, this part dissolves at a slower rate, and it

Fig. 16. Changes in the current efficiency for oxide formation, η , and transport number of Al^{3+} , $T_{\text{Al}^{3+}}$, with c.d.

is not affected by the anodizing condition. A detailed description of the effect of phosphate incorporation on the dissolution behavior of oxide in acid solutions will be published separately. It could be that protons included in the outer part of the oxide play an important role in the dissolution, but this is not the case because plenty of protons are present in the film sectioning solution.

Conclusion

In the present study, the composition of barrier oxide films on aluminum anodically formed in a neutral phosphate solution was examined as a function of the anodizing condition. Techniques used were film sectioning in a H_2SO_4 solution combined with XPS, solution analysis, polarization measurements, and electron microscopy. The results are as follows.

1. During the sectioning in the H_2SO_4 solution, oxide films dissolve uniformly from the outside. The dissolution rate of the outer part is faster than that of the inner part.

2. The outer part of the oxide contains several percent of phosphate. Its concentration does not change throughout the outer part, except for the outermost part, where the concentration is quite high. A small amount of protons is included in the outer part. The inner part consists of pure alumina without any phosphate and protons.

3. For films formed by applying a constant current (i_a) up to different potentials (E_a), both the thickness of the outer part, δ_{out} , and that of the inner part, δ_{in} , increase in proportion to E_a , but there is no inner part at $E < 15\text{V}$. The phosphate concentration in the outer part is independent of E_a .

4. For 50V films formed with different i_a , δ_{in} decreases with i_a , but δ_{out} scarcely changes, and the phosphate concentration in the outer part increases with i_a . These findings are explained in terms of the enhancements of (i) Al^{3+} transport through the oxide and (ii) dissociation of protonated phosphate ions at the oxide/solution interface, due to the increase in the electric field.

Properties of ZnO-B₂O₃-SiO₂ Glasses for Surface Passivation

Yutaka Misawa

Hitachi Limited, Hitachi Research Laboratory, Hitachi, Ibaraki, Japan

ABSTRACT

Two ZnO-B₂O₃-SiO₂ glasses, glass A (ZnO: 65.4, B₂O₃: 24.5, SiO₂: 10.1 weight percent [w/o]) and glass B (ZnO: 63, B₂O₃: 29, SiO₂: 8 w/o), were prepared for the purpose of passivating high voltage silicon devices. Their physical and electrical properties were compared using DTA characteristics, SEM observations, x-ray diffraction patterns, thermal expansion coefficients, and surface charge densities, as a function of firing temperature. Reverse characteristics of semiconductor devices passivated with these glasses were also investigated. Differences in the variation of properties with firing temperature between the two glasses were found to originate mainly from differences in the variation of crystal morphology in the glasses as a function of firing temperature.

Surface passivation using glass powders with ZnO-B₂O₃-SiO₂ as the principal component results in good reliability for high voltage silicon power devices like thyristors, transistors, and diodes. Recently, higher breakdown voltage has been required for silicon power devices. One of the methods for obtaining higher breakdown voltages for glass passivated devices, without changing other electrical properties, is to control the surface charge density of the glass on the silicon so as to lower the surface electric fields of the devices. For instance, the negative surface charges deplete n-type silicon surface and lower the surface fields of the p⁺-n junction. However, the positive surface charges accumulate n-type silicon surface and are higher than the surface fields of the p⁺-n junction. We have already reported that surface charge density of ZnO-B₂O₃-SiO₂ glass/Si system could be controlled by changing glass composition (1). However, it is desirable that glasses for surface passivation have the following properties, except for surface charge density: (i) a thermal expansion coefficient nearly equal to that of silicon, (ii) low glass firing temperature, and (iii) no harmful effects on the p-n junction. The thermal expansion coefficient of ZnO-B₂O₃-SiO₂ glasses changes with glass composition (2). Furthermore, the surface charge density of the ZnO-B₂O₃-SiO₂ glass also changes with glass firing temperature (2, 3). Therefore, glasses for surface passivation of high voltage devices must be considered after considering both thermal and mechanical properties, except surface charge density.

In this paper, we describe various properties of two typical ZnO-B₂O₃-SiO₂ glasses with different negative surface charges which were selected as passivants for high voltage silicon devices from our previous work (1): glass A (ZnO: 65.4, B₂O₃: 24.5, SiO₂: 10.1 weight percent [w/o]) and glass B (ZnO: 63, B₂O₃: 29, SiO₂: 8 w/o), both as a function of firing temperature.

Experimental

Glass preparation.—The zinc oxide, boron oxide, and silicon oxide components were weighed and mixed in a revolving mixer. The purities of these materials were over 99.99%. The powder was fused at 1300°C in air and then poured into cold water. The glass frits that were produced were ground in a ball mill to give mean particle sizes of about 4 μm.

Measurements.—Thermal properties of the glasses were measured by differential thermal analysis (DTA) using 1g samples and a heating rate of 5°C/min. Characterization points such as softening point (*T_s*), crystallization starting point (*T_{cs}*), first crystallization point (*T_{c1}*) and second crystallization point (*T_{c2}*) were determined from the DTA curve, as mentioned later.

Cylindrical glass blocks (10 mm diam × 50 mm) were used for thermal expansion coefficient measurements which were made by a Type-8003SH dilatometer from RIGAKU DENKI. The samples were prepared by cutting and polishing the blocks after firing in platinum boats.

Key words: interfaces semiconductor, crystallization, charge.

Thermal expansion coefficients were computed from the expansion of samples between 50° and 350°C for a heating rate of 10°C/min.

The crystallized phase was observed by scanning electron microscopy (SEM) and x-ray diffraction techniques. Glasses, fired on silicon substrates, were used for these samples.

Surface charge density (*N_{FB}*) in the glass/silicon system was measured with metal-glass-silicon (MGS) capacitors. The MGS capacitors were prepared as follows. An electrophoretic method was used to deposit the glass powder on a phosphorus-doped (111) plane-oriented silicon substrate with a resistivity of 10 Ωcm. In this method, the colloidal suspension used consisted of isopropyl alcohol as a suspension medium, with a small amount of additive electrolyte, and glass powder whose size was controlled by decantation. Before glass deposition, about 2 μm of the silicon wafer surface was etched off. The deposited glass powder was then fired in oxygen. The glass film thickness was controlled to about 20 μm. Metal electrodes (2 mm diam) were formed on the glass film by evaporating aluminum. Deviation of the glass film thickness under the electrode for each sample was less than 3 μm. The capacitance of the MGS capacitors was measured with an MIS capacitance meter at a frequency of 1 MHz. Voltage was applied to the sample 0 – ±500V using a dc voltage source connected to the capacitance meter. Voltage shift, with hysteresis, of the C-V curve was several volts. This voltage corresponded to a surface charge density of 10¹⁰ cm⁻², which was very small and hence neglected.

The reverse characteristics of the p-n junction, passivated with glass, were investigated using samples like that shown in Fig. 1. Using a diffusion process, the samples were prepared on the (111)-plane-oriented n-type silicon substrates with a resistivity of 70-90 Ωcm. A deep moat was formed by chemical etching. The glass powder was deposited into the moat by the electrophoretic method and fired in oxygen. The electrodes were prepared by a vacuum evaporation of aluminum.

Results and Discussion

Thermal properties.—Figure 2 shows the DTA curves for glasses A and B. Table I lists thermal properties for glasses A and B. Their characteristic points as deter-

Fig. 1. Schematic of the glass-passivated devices

mined from DTA curve, as shown in Fig. 2. These glasses had two crystallization points. The first and second crystallization points for glass B were considerably higher than those for glass A, although their softening points and crystallization starting points were nearly equal. Furthermore, the peak height of the first crystallization point for glass A was smaller than that of the second, and vice versa for glass B.

Next, the phases of crystallization, which were expected to differ, were observed by SEM. Figure 3 shows several photomicrographs for glasses fired on silicon at different temperatures. Lumps of fine needle-like crystals, appearing like chestnut burrs, were observed in glass A. However, large needle-like crystals were observed in glass B. The crystals occurred on the surface only when the glass B firing temperature was 680°C. Crystallization was inside when the temperature was 700°C, and more crystals were observed for the sample fired at 720°C. That is, crystallization started from the surfaces such as condensation phase. In glass A, crystallization was observed

Fig. 2. Comparison of DTA curves for glasses A and B

all over, even when the firing temperature was 700°C as determined from SEM observations.

X-ray diffraction studies were used to identify the difference in crystallization between glasses A and B. The typical crystalline states are shown in Table I for glasses

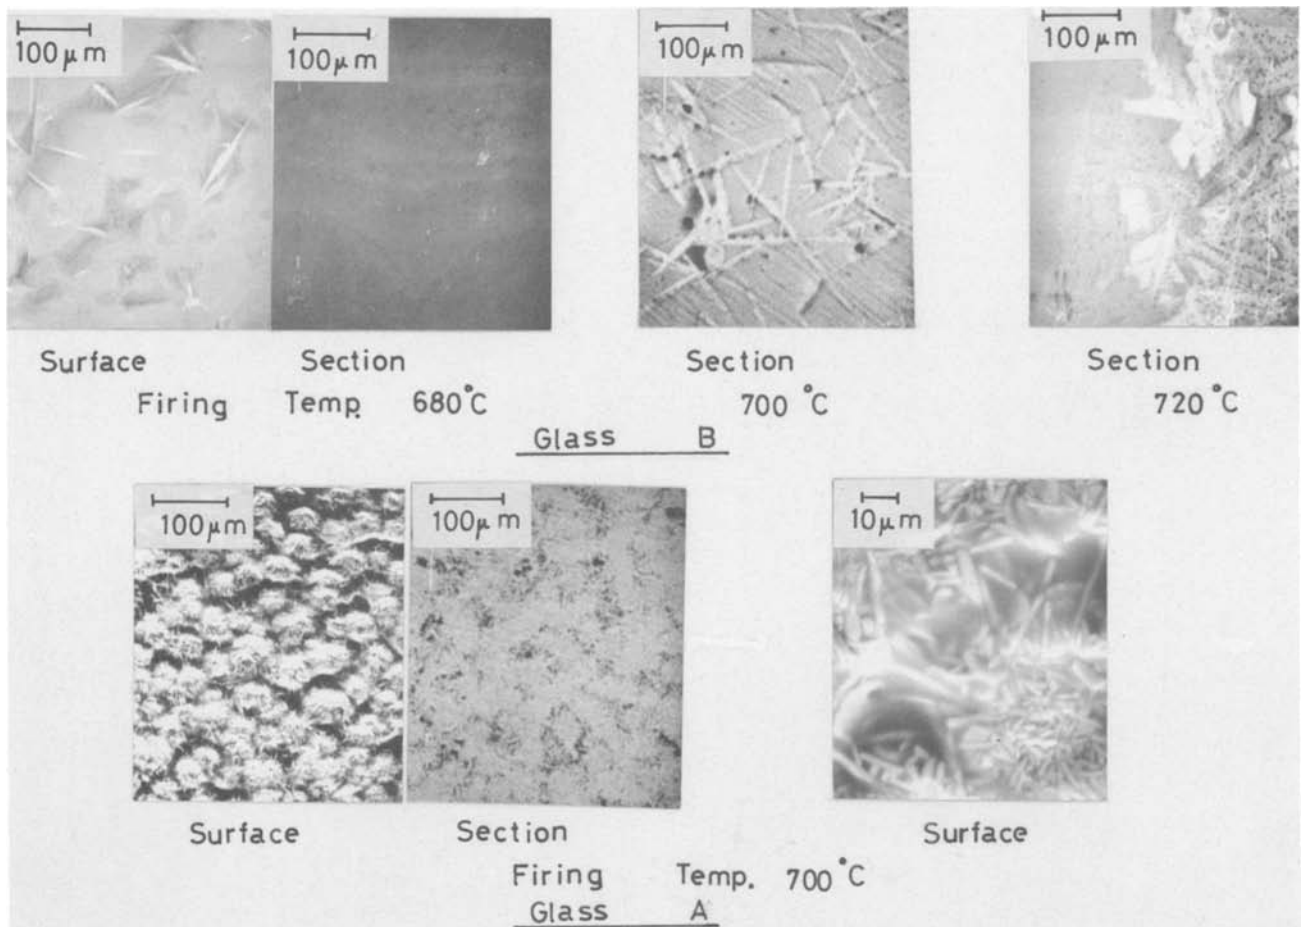

Fig. 3. Scanning electron micrographs of glasses fired on silicon at different temperatures

fired at different temperatures. Patterns were observed for samples fired above 680°C for glass A and above 720°C for glass B. The extent of crystallization for glass B was less than for glass A under the same firing conditions. For the latter, crystals were mainly $\alpha\text{ZnO} \cdot \text{B}_2\text{O}_3$ and $3\text{ZnO} \cdot \text{B}_2\text{O}_3$ when the firing temperature was 680°C. Above 700°C, the amount of $3\text{ZnO} \cdot \text{B}_2\text{O}_3$ crystals increased and $\alpha 5\text{ZnO} \cdot \text{B}_2\text{O}_3$ crystals appeared. However, for glass B when the firing temperature was low (720°C), only $3\text{ZnO} \cdot \text{B}_2\text{O}_3$ crystals were observed. At 740°C, $\beta 5\text{ZnO} \cdot \text{B}_2\text{O}_3$ crystals appeared. These results differ from other published work, in which $2\text{ZnO} \cdot \text{SiO}_2$ crystals appeared at low temperatures and $\alpha\text{ZnO} \cdot \text{B}_2\text{O}_3$ crystals at high temperatures (2).

Thermal expansion.—Figure 4 shows the relationship between the thermal expansion coefficient and glass firing temperature. The thermal expansion coefficient of glass A decreased rapidly between 680° and 700°C. However, that of glass B decreased gradually between 680° and 740°C. The thermal expansion coefficient of glasses in which crystallization was extensive, *i.e.*, firing temperature was more than 740°C, was nearly the same for glasses A and B. Changes in thermal expansion coefficient with firing temperature originated from the degree of crystallization. Consequently, these changes could be interpreted using the DTA results. The difference between crystallization starting point and first crystallization point was small in glass A, but large for glass B. Therefore, crystallization proceeded rapidly in the former and gradually in the latter. Furthermore, the extent of crystallization in the glasses could be attributed to the difference in crystallization rate, as mentioned above. However, the origin in the difference of crystal morphology between glasses A and B was not clear.

Surface charge density.—The relationships between glass composition, firing conditions, and surface charge density of glass/Si systems have been investigated previously (2, 3) and are considered only briefly here. Figure 5 shows the surface charge densities for glasses A and B fired on n-type silicon at various temperatures. Surface charges in both glasses were negative, indicating the direction of inversion on the n-type silicon, and became even more negative with increasing firing temperature. This tendency was the same as that for $\text{ZnO-B}_2\text{O}_3\text{-SiO}_2$ glasses with added PbO , SnO , and Sb_2O_3 (3). The surface charge density of glass B was larger in the negative direc-

Fig. 4. Thermal expansion coefficient of glasses A and B fired at various temperatures.

Fig. 5. Surface charge density of the samples made with glasses fired on n-type silicon at various temperatures.

tion than that of glass A, for which the B_2O_3 content was smaller. This result is in agreement with previous work (1).

Reverse characteristics of glass-passivated devices.—Figure 6 shows the relationship between breakdown voltage of glass-passivated devices and glass firing temperature. The glass film thickness was 20-40 μm . Breakdown voltage was defined as the voltage having a leak-

Fig. 6. Breakdown voltage of glass-passivated devices for glasses fired at various temperatures.

Fig. 7. Typical V-I characteristics of glass-passivated devices made with the glass B fired at various temperatures. Curves are shown for firing temperature equal to 700°C (curve 1), 720°C (curve 2), 740°C (curve 3), and 760°C (curve 4).

age current of 100 μ A. Breakdown voltage for glass B decreased remarkably with increasing firing temperature above 700°C. That is, high breakdown voltage could not be obtained at firing temperatures for which that thermal expansion coefficient was low. The breakdown voltage for glass A, however, scarcely varied between 680° and 720°C. The maximum breakdown voltage for glass A was equal to that for glass B. Thus, glass A was determined to be a suitable passivant of high voltage devices.

Figure 7 shows typical voltage-leakage current (V-I) characteristics for glass passivated devices made with glass B fired at various temperatures. V-I characteristics of devices with low breakdown voltages showed V-I characteristics of resistor above a critical voltage. However, the resistivity of the glass film measured using MGS capacitors made with glass fired on n-type silicon under the same conditions was by far lower than that of the glass-passivated devices. Consequently, it was believed that this low resistivity originated in the interface between the glass and silicon. Furthermore, the breakdown

voltage for glass B decreased when crystallization occurred at the glass-silicon interface. For glass A, the breakdown voltage did not decrease in spite of crystallization at the interface. The large crystallization seen in glass B caused poorer reverse characteristics of the semiconductor devices.

Conclusions

Two ZnO-B₂O₃-SiO₂ glasses, glass A (ZnO: 65.4, B₂O₃: 24.5, SiO₂: 10.1 w/o) and glass B (ZnO: 63, B₂O₃: 29, SiO₂: 8 w/o), were studied as a function of firing temperature. For glass A, crystallization proceeded rapidly with increasing firing temperature, and the crystals formed were fine needles. For glass B, the crystallization proceeded gradually, and the crystals formed were large. The leakage current of semiconductor devices passivated with the glasses having large crystals was large. Glass A was suitable as a passivant for high voltage devices. Crystal morphology in glass seemed to play the most important part in properties of ZnO-B₂O₃-SiO₂ glasses.

Plasma-Activated Deposition and Properties of Phosphosilicate Glass Film

Akira Takamatsu, Miyoko Shibata, Hideo Sakai, and Takeo Yoshimi

Hitachi, Limited, Musashi Works of Hitachi Limited, Kodaira-shi, Tokyo 187, Japan

ABSTRACT

Phosphosilicate glass film deposited by a plasma-activated reaction system (P-PSG) was studied. Fundamental characteristics of the P-PSG were investigated by systematically varying deposition parameters. In this plasma deposition method, the P-PSG having a high deposition rate (130 nm/min) and a high doped phosphorus concentration [about 10 weight percent (w/o) P] was deposited using the reaction gases SiH₄, PH₃, and N₂O. The P-PSG deposited by this method showed properties such as a strong film crack resistance during heat-treatments, a conformal step coverage, and a controllable compressive stress, compared with those of conventional PSG film deposited under atmospheric pressure (AP-PSG).

A plasma-activated silicon oxide film (P-SiO) (1-4) has been widely studied as an insulator for multilayer interconnects in semiconductor devices. The P-SiO gives good step coverage and a low dielectric constant. The P-SiO, however, has no gettering effect against contamination by alkali ions. In other words, it shows MOS instability after contamination. It is known that a phosphosilicate glass layer acts as a getter for Na⁺ ions and as a barrier to their entrance from the environment. Phosphosilicate glass layers deposited by chemical vapor deposition of silane plus phosphine under atmospheric pressure have been conventionally used as passivation films. However, the conventional PSG film deposited under atmospheric

pressure (AP-PSG) has undesirable step coverage and insufficient mechanical strength. The P-PSG was tried in order to improve step coverage, mechanical strength, and electrical properties. The deposition of the phosphosilicate glass film deposited by a plasma-activated reaction system (P-PSG) has been studied, without a detailed investigation of the film properties³.

In this report, the P-PSG was deposited using the reaction gases SiH₄, PH₃, and N₂O (5, 6). The reactor has parallel electrodes. The deposition parameters (substrate temperature, RF power, and reaction gas composition) were varied systematically. In this paper, fundamental characteristics of the P-PSG were investigated in detail. These properties were evaluated and compared to those of the AP-PSG. The purpose of our work was to determine the

Key words: insulation film, multilayer interconnects, step coverage.

optimum deposition conditions and to present the minute properties of the P-PSG.

Experimental

A basic reactor system for P-PSG deposition is shown in Fig. 1. The reaction chamber consisted of a quartz reaction tube 350 mm high and of 220 mm diam. A silicon wafer was placed on a susceptor, which was made of aluminum and heated by a resistance heater located under the susceptor. 4% SiH₄ and 1% PH₃, both in Ar gas, were introduced through the upper shower-type electrode, which was designed to improve the uniformity of gas flow at the surface of the wafer. Nitrous oxide (N₂O) was introduced through the top of the reaction chamber and then activated by the plasma discharge from an induction coil. The system was evacuated by a rotary pump. An RF power supply (13.56 MHz) was divided into two paths. One path went through the upper shower-type electrode, and the other path went to the induction coil wound around the reaction chamber. The distance between the shower-type electrode and the grounded susceptor was 25 mm.

Deposition parameters of the P-PSG were varied, as follows: deposition temperature was 200°-380°C; ratio of N₂O to SiH₄ + PH₃ from 5 to 80; mole percent (m/o) PH₃ in SiH₄ + PH₃ was from 0 to 25 m/o; pressure 0.8-2.0 torr; RF power 50-250W; total gas flow 50-900 ml/min. Each parameter was individually changed while all other variables were kept constant. The usual deposition condition was: deposition temperature = 380°C, RF power = 250W, pressure = 1 torr (133 Pa), PH₃ in SiH₄ + PH₃ = 8 m/o, ratio of N₂O to SiH₄ + PH₃ = 23, total gas flow = 190 ml/min.

Film thickness was measured mechanically with a Taylor-Hobson Talystep. Chemical etch rates were measured using the etchant BHF (buffered hydrofluoric acid), at 25°C. The refractive index was measured using an ellipsometer, at a wavelength of 632.8 nm. The phosphorus concentration was determined by fluorescent x-ray analysis (FXA). Infrared absorption spectra were taken with a Hitach EPI-G2 type spectrophotometer on wafers with 0.5 μm film thickness. The step coverage was evaluated by using a scanning electron microscope (SEM). The mechanical strength of the P-PSG was measured with a Vickers hardness tester. The defect density of the P-PSG was checked by a chemical etching method after heat-treatment. The breakdown voltage was measured by applying the P-PSG as a MOS structure. To determine Na⁺ contamination, ΔN_{FB} was calculated from the difference between flatband voltage, V_{FB}, before and after bias and temperature (BT) treatments. Dielectric constant was measured by using a capacitance meter at 1 MHz frequency.

Results and Discussion

Fundamental properties of the P-PSG were tracked as the following four deposition parameters which were systematically varied: (i) RF power, (ii) deposition tem-

Fig. 1. Schematic diagram of P-PSG deposition apparatus

Fig. 2. Properties of P-PSG as a function of RF power

perature, (iii) ratio of N₂O to SiH₄ + PH₃, and (iv) mole percent of PH₃ in SiH₄ + PH₃. The effects on deposition rate, phosphorus concentration, and etch rate are shown in Fig. 2-5.

RF power.—As shown in Fig. 2, RF power in the range 50-250W was selected. The deposition rate of the P-PSG gradually decreased with increasing RF power. The deposition rate was 130 nm/min under the usual condition (RF power = 250W). The phosphorus concentration was independent of RF power. The etch rate decreased lineally as RF power was increased.

Fig. 3. Properties of P-PSG as a function of deposition temperature

Fig. 4. Properties of P-PSG as a function of ratio of N_2O to $SiH_4 + PH_3$.

Deposition temperature.—The range of deposition temperatures studied was 200°–380°C (Fig. 3). With increasing deposition temperature, the deposition rate of the P-PSG increased slightly, while the phosphorus concentration decreased slightly. The etch rate decreased rapidly as the deposition temperature was increased.

Ratio of N_2O to $SiH_4 + PH_3$.—The ratio of N_2O to $SiH_4 + PH_3$ was varied in the range of 5–80, as shown in Fig. 4. The deposition rate and the phosphorus concentration decreased as the ratio of N_2O to $SiH_4 + PH_3$ was increased. The etch rate decreased only slightly as the ratio of N_2O to $SiH_4 + PH_3$ was increased. The decrease of etch rate

Fig. 5. Phosphorus concentration and deposition rate as a function of m/o PH_3 in $SiH_4 + PH_3$.

Fig. 6. Etch rate as a function of phosphorus concentration at various deposition temperatures.

corresponds to the decrease in phosphorus concentration (7).

Mole percent of PH_3 in $SiH_4 + PH_3$.—The mole percent of PH_3 in $SiH_4 + PH_3$ was varied in the range of 0–25 m/o, as shown in Fig. 5. The deposition rate of P-PSG appeared to decrease gradually as the mole percent of PH_3 in $SiH_4 + PH_3$ was increased. The phosphorus concentration of the P-PSG showed lower phosphorus concentration than that of the AP-PSG deposited using the same gas composition [PH_3 and $SiH_4 + PH_3$ (8, 9)]. However, the P-PSG having a high doped phosphorus concentration (more than 10 w/o) was also obtained when the ratio of the mole percent of PH_3 in $SiH_4 + PH_3$ was over 20 m/o.

Figure 6 shows how the chemical etch rates of P-PSG changed as a function of phosphorus concentration at various deposition temperatures. In general, the etch rate of the P-PSG increased with increasing phosphorus concentration, and, as the deposition temperature of the P-PSG was increased, the etch rate decreased. The etch rate of the P-PSG, which was deposited at 380°C, came close to that of the AP-PSG. It is considered that etch rates of the P-PSG are affected by some characteristics of the film such as bond strain in Si–O or P=O.

Pressure.—The total pressure during deposition was varied from 0.8 to 2 torr. The deposition rate of the P-PSG was independent of the pressure. The phosphorus concentration and the etch rate did not change appreciably with changes in pressure.

The refractive index of the P-SiO was 1.47. This value increased to 1.49 when the phosphorus concentration was over 10 w/o.

Infrared analysis.—The infrared absorption spectra of the P-PSG having various phosphorus concentrations are shown in Fig. 7. In the P-PSG, bands with wave numbers of 1330, 1090, 810, and 450 cm^{-1} were observed. These infrared spectra of the P-PSG are similar to those of the AP-PSG (10). As shown in detail in Fig. 8, absorption due to the P=O stretching at 1330 cm^{-1} increased as the phosphorus concentration in the P-PSG increased. The absorption due to Si–O stretching in the P-PSG was at a slightly higher wave number (1090 cm^{-1}) than that in the P-SiO (1070 cm^{-1}). These shifts were consistent with those of the AP-PSG (10, 11).

Other absorption bands of the P-PSG due to SiOH stretching (3650 cm^{-1}), H_2O (3350 cm^{-1}), and SiOH bending (950 cm^{-1}) (4, 11–13) were detected. These peaks

Fig. 7. Infrared absorption spectra of P-PSG. Film thickness: 0.5 μm .

were reduced with increasing deposition temperature and RF power.

Figure 8 shows absorbance for the P = O bond as a function of phosphorus concentration. The P-PSG which was deposited under low power or low deposition temperature showed low values in the P = O absorbance compared with those of the AP-PSG. The absorbance of the P-PSG deposited at 380°C and 250W RF power showed the same value as that of the AP-PSG at most phosphorus concentrations. This result shows that the

Fig. 8. Absorbance of P=O bond (1330 cm⁻¹) as a function of phosphorus concentration at various deposition temperatures.

P-PSG

AP-PSG

Fig. 9. Comparison of step coverage in P-PSG and AP-PSG

Fig. 10. Vickers hardness and density as a function of phosphorus concentration.

P-PSG deposited under low RF power or low deposition temperature includes phosphorus of lower states in the film which cannot be detected by infrared absorption.

Step coverage.—Cross-section views of the step coverage in the P-PSG and the AP-PSG are shown in Fig. 9. The step coverage over the steps of patterned aluminum was observed by SEM. The P-PSG produced a more conformal profile than that of the AP-PSG. This is one advantage of this plasma CVD process.

Mechanical strength.—The relationship of phosphorus concentration and Vickers hardness is shown in Fig. 10. Vickers hardness decreased rapidly with increasing phosphorus concentration. For example, in undoped film, the Vickers hardness is about 2000 kg/mm². However, in the P-PSG at 4 w/o P, it is about 1000 kg/mm². The density of

Fig. 11. Absolute value of the film stress in P-PSG as a function of phosphorus concentration.

Fig. 12. Defect density as a function of temperature during heat treatments.

the P-PSG is also shown in the Fig. 10. The density of the P-PSG increased slowly as phosphorus concentration increased. The density of the P-PSG was 2.23 g/cm³ at 4 w/o P.

The relationship between phosphorus concentration and film stress is shown in Fig. 11. The stress in the P-PSG was compressive, but that of the AP-PSG was tensile (14). The compressive stress in the P-PSG decreased as phosphorus concentration increased. The tensile stress in the AP-PSG decreased in a similar way.

The film crack resistance for heat-treatment of the P-PSG is shown in Fig. 12. The P-PSG deposited on aluminum was annealed in N₂ ambient, at temperatures from 400° to 470°C. The thickness of film was 0.8 μm. Defect densities of the P-PSG were approximately ten times less than those of the AP-PSG.

Electrical properties.—The electrical stability of the P-PSG is shown in Fig. 13. The value of ΔN_{FB} represents

Fig. 13. ΔN_{FB} as a function of phosphorus concentration at positive and negative bias stressing.

Table I. Characteristics of the P-PSG standard and the AP-PSG standard

Measurement	Film	P - PSG (4WT.% P)	AP - PSG (4WT.% P)
Reactor System		Plasma CVD	Atmos. CVD

Breakdown Voltage (V/cm)		3 - 8 x 10 ⁶	6 x 10 ⁶

the number of mobile ions such as Na⁺ contained within the film. In the P-PSG standard which did not undergo Na⁺ contamination treatment, ΔN_{FB} was approximately 5 × 10¹⁰/cm², and was constant with increasing phosphorus concentrations. However, after Na⁺ contamination treatment, ΔN_{FB} of the undoped film (P-SiO) was 5 × 10¹²/cm², which was two orders of magnitude greater than that of the P-PSG. This result implies that the P-PSG has a gettering effect for alkali ions, as does the AP-PSG, while undoped film does not have a barrier effect against them. The breakdown voltage of the P-PSG was about 300-800V at 1.0 μm film thickness. The dielectric constant of the P-PSG at 1 MHz was 4.0-4.3.

Conclusion

In this process, the P-PSG was deposited by using a plasma-activated reaction. Fundamental properties of the P-PSG were investigated by systematically varying deposition parameters and then comparing them to those of AP-PSG. In this deposition method, the P-PSG having

good uniformity, a high doped phosphorus concentration and a high deposition rate were achieved.

Some characteristics of the P-PSG are as follows.

1. The P-PSG had good step coverage.
2. The P-PSG showed the remarkable gettering effect for Na⁺ contaminations, while the P-SiO did not have this gettering effect.

3. The film crack resistance of the P-PSG during heat-treatments was improved, as compared to AP-PSG.

Other characteristics of the P-PSG are tabulated in Table I.

The optimum deposition condition for the P-PSG included high RF power and high deposition temperature. In order to obtain better insulation characteristics, features of the reaction system, such as the choice of reaction gases (SiH₄-PH₃-CO₂), and RF frequency (10-500 kHz), are being investigated.

As density of devices increases, an increasingly fine technology is necessary. At this point, it is expected that the P-PSG deposited by this plasma process will meet the challenge of the future VLSI technology.

Radial Etch Rate Nonuniformity in Reactive Ion Etching

A. G. Nagy

Motorola, Incorporated, SPS, Process Technology Laboratory, SRDL, Phoenix, Arizona 85008

ABSTRACT

A study was performed to determine some of the causes of the edge-to-center "bullseye" clearing pattern, in which the etch rate decreases monotonically from the wafer periphery to its center, observed when certain films are etched in a parallel-plate reactive ion etching system. It was found that gradients in local reactant concentrations, with a higher number density present near the edge of the substrate than over the center, are largely responsible for the observed nonuniformity. The concentration gradients appear to come about as a consequence of two reactant generation phenomena and one loss mechanism. The reactant generation phenomena are: (i) the "hot spot," which the edge of the wafer may represent to the plasma, causing enhanced reactant generation there, and (ii) differences in capacitive coupling from the RF generator to the plasma between the wafer's location on the cathode and the rest of the cathode. Stronger coupling surrounding the wafer leads to increased production of reactant around the wafer compared to the area directly above it. The reactant loss mechanism is controlled by the relative etch rates of the wafer *vs.* the cathode material, the using cathodes which etch at an appreciable rate in the plasma was found to promote improved uniformity. Ion bombardment was found to be uniform across the surface of the wafer, and, consequently, etch processes which are strongly bombardment dependent were found to be uniform.

Nonuniform clearing of films etched in plasma and reactive ion etching systems is a major problem in current integrated circuit patterning technology. In particular, when polysilicon, aluminum, or silicon nitride, as well as many other films, are etched in a parallel-plate system, they often display an edge-to-center "bullseye" clearing pattern in which the etch rate decreases monotonically from the periphery of the wafer to its center. This clearing pattern causes problems in selectivity and dimensional control. The present work was done to determine the relative importance of several possible causes of the bullseye effect.

Five possible causes were investigated: (i) local reactant concentration gradients near the wafer, (ii) temperature effects (possible thermal gradients across the wafer and their effect on etch rate), (iii) a possible gradient in the degree of ion bombardment across the wafer, (iv) the effects of the abrupt step represented by the edge of the wafer on the local discharge intensity and chemistry, and (v) the effect of the series capacitance represented by the wafer on the coupling of the RF to the plasma.

Apparatus

A plasma reactor, modified to give field-assisted etching in a pseudo-parallel-plate configuration (Fig. 1), was used in all of the experiments. The modifications are as follows: an aluminum plate ("dark shield" in Fig. 1), whose length (28.1 cm) is equal to the length of the cylindrical reactor, was welded to the inner wall of the chamber, effectively bisecting it. The discharge is confined to the upper half of the reactor. The chamber diameter (and dark shield width) is 34.2 cm. The reactor wall is grounded and serves as the anode. The 13.56 MHz signal is fed to another slightly smaller aluminum plate ($l = 24.2$ cm, $w = 26.1$ cm, $T = 3.18$ mm) which is separated from the dark shield by a 3.18 mm thick glass plate. This second aluminum plate serves as the cathode, giving an anode:cathode area ratio of 3.1:1.

Etch Conditions

The baseline process used in these experiments for etching undoped (615°C, 100 Pa SiH_4 ambient) polysilicon and silicon dioxide (grown in 1100°C steam ambient, atmospheric pressure) is as follows: the source gas is CF_4 , flow = 7 sccm, pressure = 13.3 Pa (0.10 torr), and RF power = 400W (0.62 W/cm²). This results in a nominal etch rate of 300 Å/min for both Si and SiO_2 . The 7.6 cm wafer was placed in the center position on the cathode in all etch runs. Where appropriate, these conditions were varied to determine their relative importance on the degree of nonuniformity.

Key words: plasma, etching, discharge, semiconductor.

Analytical Techniques

The etch rates of the samples were measured at nine equally spaced points across a diameter of the wafer using an IBM 7840 Film Thickness Analyzer. The etch rate at each point was obtained by dividing the etch depth by the etch time. The degree of etch nonuniformity was expressed as the ratio of average etch rate of the two outermost points to the etch rate of the slowest etching point on the wafer, usually the center. The average etch rate of the two next-to-outermost points was also divided by the slowest etching point to give an indication of the radial extent of the nonuniformity. For example, a typical value of nonuniformity is (1.16, 1.04), indicating a 16% and 4% faster etch rate compared to the central etch rate at the outermost and next-to-outermost radii, respectively.

Emission spectra were recorded to identify and monitor reactant species in the plasma. A Heath EV-700 monochromator was used to select the wavelength of interest, which was then detected by an RCA-IP28 photomultiplier.

Results and Discussion

Using the standard operating conditions, nonuniformity of undoped polysilicon films was found to be (1.16, 1.04) in the reactor described above when a quartz cover was placed over the aluminum cathode. The five possible causes of nonuniformity mentioned above were then investigated.

Fig. 1. Modification of the reactor for field assist etching showing the wafer platen, dark shield, and the gas flow pattern employed.

Fig. 2. Strip rate at the wafer edge and center as a function of wafer separation under conditions of constant molecular oxygen flow rate, pressure, and power. The edge strip rate is independent of separation; the center strip rate is linear in separation (1).

Local reactant concentration gradients.—Battey (1) found that reactant diffusion effects due to system geometry are the dominant cause of nonuniformity in photoresist stripping in a barrel-type system. The etch rate at the center of the wafers was found to be proportional to the spacing between the wafers on the boat, while that at the edges is independent of wafer spacing (Fig. 2). The ability of reactant species to diffuse to the center of the wafers is impaired when the separation between them is small, resulting in a larger concentration of reactant at the periphery of the wafers than at their centers, which brings about unequal etch rates.

A single wafer resting on the center of the cathode in the present system is analogous to etching in a barrel reactor at infinitely large wafer spacing, implying that local reactant diffusion effects in the vicinity of the wafer are minimal. This simple analogy predicts uniform etching in a parallel-plate system, for the lines in Fig. 2 meet when extrapolated to large wafer separations.

Experimentally, this is not the case. Table I shows results obtained when comparing etching of polysilicon with the wafer resting directly on the aluminum cathode (the unloaded case, as aluminum does not form a volatile fluoride) to that with various reactive covers placed over the cathode (loaded case). The results in Table I are plotted in Fig. 3.

The fact that polysilicon etches more nonuniformly in a parallel-plate system with a nonreactive cathode than with a reactive one implies that reactant concentration

Table I. Loaded case vs. unloaded case

Configuration	Etch rate at center (Å/min)	Nonuniformity
Aluminum cathode	315	1.34, 1.13
Quartz cathode cover (3.18 mm thick)	325	1.16, 1.04
Graphite cathode cover (3.18 mm thick)	168	1.17, 1.06
Silicon cathode cover (0.33 mm thick)	135	1.16, 1.04

CATHODE MATERIAL DEPENDENCE

Fig. 3. Etch rate vs. position for polysilicon etched on different cathode materials.

gradients are present in this configuration as well. This is not surprising; when a reactive cathode is used, atomic fluorine [the etchant species in CF_4 -plasma silicon etching (2-7)] is consumed at comparable rates over the entire cathode. When a nonreactive cathode is used, the only sink for fluorine atoms is the wafer itself; therefore, the concentration of reactant will be higher at the perimeter than at the center of the wafer. Gas phase diffusion is apparently not rapid enough to overcome reactant concentration gradients across the substrate surface, and the larger these gradients are, the more nonuniform the etch process becomes.

An attempt was made to measure the spatial variation of atomic fluorine concentration using optical spectroscopy while etching a rectangular silicon slab in the reactor. The experiment was done as follows: a strip of silicon 0.51 mm thick, 5.08 cm wide \times 24.2 cm long (the length of the cathode) was placed lengthwise on top of an aluminum plate the same size as the cathode. The assembly was placed on top of the cathode and pushed forward against the plexiglass reactor door to minimize any effect the front edge of the aluminum plate may have on the discharge. The detector for the spectrophotometer was positioned so that the fluorine concentration was monitored in five regions: over the plate about 7.5 cm on either side of the strip, over each of the two edges of the strip, and over the center of the strip. The regions were labeled 1 through 5 from the point to the left of the strip to the point to the right. The detector was about 1 cm above the surface of the plate in all cases. An edge-on view of the experimental configuration is shown in Fig. 4.

A small quantity of argon was added to the CF_4 , and the 7504Å argon line and the 7037Å fluorine line were monitored in accordance with the method described by Coburn and Chen (8).

Table II shows the relative fluorine concentrations observed, normalized to the point of lowest concentration. The fluorine concentration shows a clear dip over the silicon strip, consistent with the observed clearing pattern.

Thermal effects.—If the etch rate of polysilicon in CF_4 is temperature dependent, the existence of a positive thermal gradient from the center of the wafer outward could cause increasing etch rates toward the periphery.

Fig. 4. Experimental configuration to spectroscopically determine the spatial variation of fluorine concentration.

To investigate the possibility of such a temperature dependence, a 7.6 cm polysilicon wafer was first etched under standard conditions with the reactor cold, and then the etch rate was compared to that seen after running the reactor for a period of time sufficient to bring the cathode temperature up to approximately 100°C. No significant increase was seen, implying that, even if a severe thermal gradient exists across a wafer, this alone is not enough to cause significantly nonuniform etching. This conclusion is consistent with that drawn in a previous study (9).

Ion bombardment effects.—It is believed that while atomic fluorine is the principal etchant species in CF_4 plasma silicon etching, bombardment of the substrate by heavy ions (mainly CF_3^+) may result in the enhancement of the reaction rate of fluorine atoms with the silicon (2). Consequently, it was hypothesized that nonuniform ion bombardment across the surface of the wafer may result in nonuniform clearing patterns.

To explore this possibility, the following experiment was performed: a 10.2 cm wafer with 10,000Å of aluminum deposited upon 9000Å of silicon dioxide was patterned so that two concentric aluminum rings, each 1.27 cm wide, with 1.27 cm separating the two rings, remained on the wafer. The surface area of the outer ring was 35.2 cm², and the inner ring area was 11.8 cm². A fine wire was bonded to each of the rings with silver paint, and this wire was run out of the reactor through a feed through and connected through an RF choke to an external circuit (shown in Fig. 5) which allowed a dc bias to be applied to the ring.

It is known (10) that if an increasingly negative bias is applied to a probe in a glow discharge, a condition will be reached where only a steady flow of positive ions reaches the probe. This ion current is relatively independent of bias voltage. The rings were biased to this potential, and the ion current was measured. A difference in measured current density in the two rings would imply unequal positive ion flux across the wafer.

An average positive ion current density of 7.48×10^{-2} mA/cm² was measured at the inner ring under standard CF_4 plasma conditions vs. 7.53×10^{-2} mA/cm² for the outer ring, a difference of less than 1%.

As another test of ion bombardment uniformity, SiO_2 was etched in the present system under standard conditions. SiO_2 etching in fluorine chemistry is known to be an ion bombardment dominated process, that is, fluorine atoms will not etch SiO_2 at a significant rate unless the surface is simultaneously bombarded with ions or electrons (6). The etch rate of SiO_2 at the given conditions in a downstream tunnel-type reactor (in which no ion bombardment is possible) described in a previous paper (11) would be approximately 14 Å/min, calculated using the correlation presented in that paper.

Table II. Observed fluorine concentrations

Region	Experimental relative fluorine concentration
1	1.19
2	1.13
3	1.00
4	1.06
5	1.19

Fig. 5. DC bias circuit for measurement of ion bombardment to the wafer

Figure 6 shows that SiO_2 etching in the present system is indeed quite uniform. Since ion bombardment dominates SiO_2 etching in CF_4 , the uniform clearing pattern seen here supports the results obtained on ion bombardment uniformity described above. Uniform etching was also seen for undoped polysilicon in chlorine-rich chemistry [also known to be a bombardment-dominated process (12)] under standard conditions in the present system.

Based on these experimental results, it is concluded that ion bombardment is uniform in both CF_4 and CF_4/Cl_2 plasmas and thus cannot contribute to nonuniform etching.

Wafer edge effects.—The presence of any sharp edge or surface in a plasma environment will produce an intensified discharge at the region of discontinuity. The

SiO_2 ETCHING

Fig. 6. Etch rate vs. position for SiO_2 etched in CF_4 and CHF_3 on different cathode materials.

edge of the wafer may represent such a region, though proving this experimentally is difficult.

Elevating the wafer on a conductive disk will make the edge of the wafer appear as a larger step, without affecting the wafer's capacitive coupling to the generator. Etching a 7.6 cm polysilicon wafer placed on top of a 3.18 mm thick, 7.6 cm diam copper disk (quartz platen) resulted in a nonuniformity of (1.29, 1.08) compared to the (1.16, 1.04) nonuniformity obtained with the wafer resting directly on the quartz platen. This implies that edge effects apparently play a role in etch nonuniformity.

Effects of the series capacitance represented by the wafer on the local discharge intensity.—When a wafer rests on the cathode, it represents an additional series capacitance term in the circuit connecting the RF generator to the glow space (Fig. 7). Thus, the impedance of this "leg" of the circuit is greater than that of paths not including the wafer (the surrounding cathode). Consequently, the intensity of the discharge may be expected to be greater where the wafer does not rest (9), which would result in a concentration gradient leading to etch nonuniformity.

Two approaches were tried to test this effect. In one case, the wafer was decoupled from the generator, and in the other case (the inverse situation) the environment surrounding the wafer was decoupled. For the first case, the capacitive coupling of the generator through the wafer was made weaker by placing the etching wafer on top of a series of 7.6 cm diam, 3.18 mm thick glass disks. The wafer/disk assembly was surrounded by one or more 3.18 mm thick cathode-sized aluminum plates with 7.6 cm holes cut in their centers, the number of plates being equal to the number of disks. The purpose of the plates was to keep the surface level to hold edge effects to a minimum. For the inverse situation, copper disks were used in place of the glass disks, and the plates were made of glass instead of aluminum. The surface of the top glass plate was covered with aluminum foil to provide identical reactant loss mechanisms for the two configurations.

Decoupling the wafer was expected to increase the reactant concentration gradient between the wafer area and the surrounding cathode, leading to more nonuniform etching. Conversely, decoupling the surrounding cathode was expected to reduce the gradient, resulting in improved uniformity.

Fig. 7. Schematic representation of the capacitance coupling of the RF generator to the glow space.

While the increased concentration gradient produced by decoupling the wafer was expected to increase nonuniformity, this decoupling should not greatly alter the quantity of reactant available for the etch reaction. Therefore, the etch rate was not expected to change significantly during the wafer decoupling experiments. The effective "focusing" of the discharge obtained when surrounding the wafer with dielectric might be expected to slightly increase the etch rate, however. The results of the two experiments are given in Table III.

The results are in basic agreement with the expectations. It is difficult to determine if the observed changes in etch rate are significant, or if they are largely the result of experimental error. The trends are in the expected direction, however.

The capacitive impedance at 13.56 MHz of a wafer with 5000Å of undoped polysilicon deposited over 1000Å of silicon dioxide is approximately 3.2 Ω/cm², while that of 3.18 mm thick glass is about 8400 Ω/cm². The impedance rises by factors of about 2 with each successive elevation. Thus, it is not surprising that the nonuniformity changed dramatically after the first elevation in both experiments, and then remained relatively constant.

These results are not consistent with those of Mundt *et al.* (9), who were studying the bullseye effect while etching aluminum with CCl₄. They used a configuration similar to the second one described above, except that Teflon spacers were used instead of glass, and the wafer was allowed to rest directly on the lower electrode. The degree of nonuniformity decreased proportionately with the thickness of the Teflon spacer, and the clearing pattern even switched to one where etching proceeded from the center of the wafer outward to an increasing degree as the spacer thickness was increased above 0.86 mm.

The above results may, however, be partly explained by the fact that Teflon is known to release fluorine, a passivant to aluminum etching, under plasma conditions. As the Teflon thickness was increased, the quantity of fluorine released near the edge of the wafer rose because of the increase in available surface area. This should automatically slow down the rate of aluminum etching near the wafer periphery. Also, no attempt was made to keep the etching surface level, which may contribute to the differences between their results and those presented here.

Summary

The following conclusions may be drawn from the present study.

1. Ion bombardment across a wafer is uniform in the situation studied here. This suggests that ion-assisted processes, such as the etching of polysilicon in chlorine-containing plasmas, are preferred over more chemistry-dominated processes from the standpoint of uniformity.

2. The concentration of reactant is lower over the etching wafer than over the rest of the cathode. This concentration gradient comes about as a result of nonuniform local reactant production due to (i) the possibility that the edge of the wafer may represent a "hot spot" to the plasma, which would result in an intensified production of reactant species there, and (ii) differences between

Table III. Effects of series capacitance on local discharge intensity

Condition	Elevation (mm)	Etch rate at center (Å/min)	Nonuniformity
Polysilicon on bare Al cathode	0.00	315	1.34, 1.13
Wafer elevated on glass disks	3.18	326	1.51, 1.20
	6.35	330	1.54, 1.19
	9.53	331	1.52, 1.19
	12.70	297	1.59, 1.21
Wafer elevated on copper disks	3.18	346	1.12, 1.05
	8.73	414	1.14, 1.02
	14.29	364	1.13, 1.05

where the wafer lies on the cathode and the rest of the cathode, in capacitive coupling from the RF generator to the plasma. Uniformity may be improved or made worse by varying this capacitive coupling through the use of dielectric spacers either under or surrounding the wafer. It is apparently not possible to eliminate nonuniformity merely by decreasing the degree of capacitive coupling around the wafer without altering the discharge chemistry, flow patterns, system geometry, etc.

3. Reactant loss processes due to loading contribute to nonuniform etching. The local concentration gradient of reactant may be controlled by the choice of cathode material. Cathodes which do not form volatile species with the reactant promote increased etch rate nonuniformity.

Antimony Diffusion in Silicon: Effects of Ambient Gas and Time

ABSTRACT

A study of the effect of the furnace ambient composition (O_2 -Ar vs. O_2 - N_2) on the diffusion of antimony into silicon from a doped-glass source deposited by low pressure CVD was conducted. Two minima in sheet resistance were observed as a function of O_2 content for O_2 -Ar diffusions. Only one minimum was observed for O_2 - N_2 diffusions. Auger electron spectroscopy, Rutherford backscattering spectroscopy, secondary ion mass spectroscopy, and spreading resistance probe techniques were used to investigate the changes that occur at the doped-glass/silicon interface and in the doping profiles as a function of the diffusion ambient. The formation of a $Sb_xSi_yO_z$ thin film phase was observed and characterized. A model is proposed to account for the presence of two minima in sheet resistance (maxima in surface concentration) as a function of O_2 content in the diffusion ambient.

Doped silicate glasses are widely used in the semiconductor industry as diffusion sources. A large body of literature has been published on the mechanisms of dopant diffusion from the glass into silicon substrates. Barry and Olofsen (1-3) published a series of papers on the diffusion of phosphorus and boron from doped glasses. Wong and Ghezzi (4) and Ghezzi and Brown (5) reported on the diffusion of arsenic from doped glasses. A significant result of the recent work is that two spatially separated processes control the doping of silicon by the glass. The first of these is the flux of dopant through the glass/silicon interface. The second is the atomic motion of dopant through the silicon and the effect of crystal point defects upon this motion. These two processes will be discussed briefly in turn.

The role of the doped-glass/silicon interface in the diffusion has been studied in detail for the cases of boron, phosphorus, and arsenic. In all these cases, the authors found that for some diffusion ambients, a chemical reaction occurs at the doped-glass/silicon interface, resulting in the formation of a thin film phase which dramatically affects the motion of dopant into the substrate. Metallic arsenic was found at the interface for inert atmosphere diffusion from arsenic-doped glasses (6). A phase tentatively identified as SiB_6 was detected for the case of boron-doped glasses (7, 8), and a P_2O_5 -rich silicate phase was observed for phosphorus-doped glasses (9).

As an off-shoot of work on oxidation-induced stacking faults (OSIF), the phenomena of oxidation-enhanced diffusion (OED) and oxidation-retarded diffusion (ORD) have been reported in the literature. OED is well docu-

mented for phosphorus and boron (10-12). It has been proposed (11) that since boron and phosphorus diffuse via a partial interstitialcy mechanism, the enhanced diffusion in an oxidizing ambient is due to an increase in the concentration of Si self-interstitials. ORD has been observed for antimony diffusion by Mizuo and Higuchi (13). These authors propose that the concentration of vacancies decreases and the concentration of interstitials increases during oxidation. Antimony is proposed to diffuse via vacancies, and therefore its diffusion is retarded in an oxidizing atmosphere.

Both interface and substrate effects are directly related to the composition of the diffusion ambient. Diffusions are generally done in either nonoxidizing (N_2 or Ar) or oxidizing (N_2 - O_2 or Ar- O_2 mixtures) ambients. All of the previously reported work concerning diffusion of n-type dopants [P (14), As (15), Sb (16a)] from doped-glass sources is consistent in the following sense: a similar dependence of sheet resistance ρ_s upon O_2 concentration in the diffusion ambient is observed. High ρ_s is measured at both low and high O_2 contents in the diffusion ambient, with a ρ_s minimum at intermediate O_2 contents. As noted in Fig. 1, this behavior is independent of dopant, temperature, or diffusion time. An explanation for this common behavior based on interface effects has been advanced by Beyer (17) for the case of As-doped glasses. According to Beyer, under inert atmosphere conditions, a diffusion barrier is formed at the interface (in this case, metallic As) resulting in high sheet resistance. With the introduction of oxygen into the ambient, the barrier phase is oxidized, allowing the dopant to diffuse into the substrate and therefore lowering the sheet resistance. At high oxygen concentration, a competition results between oxidation and diffusion, creating an oxide at the interface which, in

Fig. 1. Sheet resistance vs. oxygen concentration for Sb, P, and As diffusion. (a): Ref. (14). (b): Ref. (16a). (c): Ref. (15).

turn, delays the arrival of the dopant to the substrate, *i. e.*, the sheet resistance increases.

Most of the work reported on diffusion from doped glasses concentrates on B, P, and As, while only recently some attention has been devoted to Sb-doped glasses (16a, 16b, 18). In this work, the effect of ambient composition and diffusion time on the doping of silicon with a stibino silicate glass is described. Experiments have been performed in both nonoxidizing (N_2 , Ar, or He) and oxidizing (Ar- O_2) ambients. The results demonstrate a dependence of sheet resistance on ambient composition which is different from those reported previously (Fig. 1). It will be shown that this behavior is a result of using Ar- O_2 mixtures for oxidizing ambients as opposed to the N_2 - O_2 mixtures used in most previous investigations. In order to understand the dependence of the Sb diffusion on the ambient, electrical measurements and standard analytical techniques including Rutherford backscattering spectroscopy (RBS), Auger electron spectroscopy (AES) and secondary ion mass spectroscopy (SIMS) were used to characterize both the Sb-doped glass and the Si substrate. A model is proposed to explain the experimental results.

Experimental Procedures

The diffusions were performed using antimony-doped glasses as sources. The glasses were deposited by low pressure chemical vapor deposition (LPCVD) at 360°C and 0.6 torr (19). Silane, oxygen, and trimethylantimony (a high vapor pressure liquid) were used as gas sources. The structure consisted of a p-type (100), 6-8.5 Ω -cm, 75 mm diam substrate, upon which a 700Å thick stibinosilicate glass was deposited with an antimony concentration of 20 weight percent (w/o) Sb (6.1 mole percent [m/o] Sb). A 700Å undoped SiO_2 layer was deposited on top of the doped glass to minimize dopant evaporation during diffusion. Anneals were carried out at 1250°C in Ar- O_2 mixtures. For each gas mixture, diffusion times of 0.5, 1, 2, 4, and 8h were used (Table I). Some diffusions were carried out in He or N_2 atmospheres.

The experimental apparatus consisted of a 30 in. hot-zone furnace equipped with a quartz diffusion tube. A mineral oil bubbler was adapted to the end cap to avoid atmospheric backstreaming during high temperature processing. Wafers were loaded in a quartz diffusion boat with 3/16 in. spacing and a 75-wafer capacity. Each run

Table I. Experimental conditions

Diffusion temperature	1250°C
Diffusion times	0.5, 1, 2, 4, 8h
Ar- O_2 gas composition	0%, 0.10%, 0.25%, 0.5%, 1%, 5%, 10%, 25%, 100% O_2
He- O_2 gas composition	0%, 1% O_2
N_2 - O_2 gas composition	0%, 1%, 5%, 10%, 25%, 100% O_2

consisted of three doped-glass-coated wafers placed at the center of the boat with the remainder of the boat filled with dummies. Bare silicon wafers were placed at both ends and at the center of the boat, such that the temperature uniformity and gas composition could be monitored through measurements of thickness of the oxide grown on these wafers during diffusion. For high oxygen concentrations, facility supplied oxygen and argon were used. For oxygen contents equal to or lower than 1% by volume, a 1% O_2 in Ar certified standard bottle¹ was used as a source and diluted as necessary.

Rotameters² were used for gas flow metering. After diffusion, the wafers were stripped in 48% HF, and the sheet resistance was measured in five places on the wafer with a four-point probe. Junctions were obtained by the bevel and stain technique. Sb concentration profiles within the Si substrate were derived from spreading resistance probe (SRP) measurements,³ using Irvin's curves (20).

AES was performed in a PEI⁴ thin film analyzer system which employs a stationary large-diameter primary electron beam. The concentration of the Sb in the doped glass is sufficiently high that AES depth profiles could be measured. However, in making those measurements, we have found that the shape of the Sb profiles could be affected by what is believed to be electric field-induced migration of the Sb, which occurs during the analysis. We have been able to minimize but not yet solve this problem and therefore have omitted AES Sb profiles in this paper. Some of the RBS and SIMS analyses were performed at commercial analytical facilities.⁵ SIMS profiles of the Sb in the glass were also found to be affected by the analytical measurement procedure and so they also are omitted.

Results and Discussion

Characterization of as-deposited SbSG.—Figure 2 is a random mode RBS spectrum of the as-deposited samples used in this study. From this spectrum, atomic densities can be calculated: antimony = 2.2×10^{21} cm^{-3} , oxygen = 3.7×10^{22} cm^{-3} , silicon in the cap = 1.8×10^{22} cm^{-3} , and silicon in the SbSG = 1.6×10^{22} cm^{-3} . This results in a stoichiometry of $SiO_{2.1}$ for the cap layer and $SiO_{2.3}Sb_{0.14}$ for the SbSG. From these results, it is calculated that the Sb makes up 20.8% by weight of the SbSG layer, in excellent agreement with the previously quoted value of 20% which was calculated from x-ray fluorescence data.⁶

Fig. 2. Random mode RBS spectrum of as-deposited structure.

Fig. 3. Channelled mode RBS spectrum of as-deposited structure.

The spectrum shown in Fig. 2 suggests slightly lower Si concentration in the SbSG layer (compared to the cap layer), but the two layers are not well resolved in this spectrum. Figure 3 is recorded with the incident beam channelled down the (100) axis of the substrate. The particle detector is located at an angle of 80° with respect to the surface normal in order to enhance depth resolution (21). Note that the SbSG and SiO_2 cap layers are well resolved in this spectrum, and the Sb concentration appears uniform with depth. With the better depth resolution of this spectrum, the difference in Si concentration between the SbSG and cap layers is more apparent.

Sheet resistance measurements.—In Fig. 4, ρ_s is plotted against percent O_2 by volume and as a function of diffusion time. While previously reported work (14-16) showed only one minimum in ρ_s as a function of O_2 content in the ambient, two minima are reported in this work. One minimum, which occurs at 0% O_2 (100% Ar) is always the lower

minimum and is independent of time. The second minimum is time dependent and shifts to lower O_2 concentrations for longer diffusion times. A replot of this data using an expanded scale shows the low O_2 portion in greater detail (Fig. 5).

To ascertain whether the appearance of two minima is an idiosyncrasy of Ar diffusions, a number of diffusions were performed in He-O_2 and $\text{N}_2\text{-O}_2$ mixtures. The minimum observed for inert Ar atmospheres was reproduced in 100% He atmospheres, while no minimum was observed for 100% N_2 diffusions. Figure 6 displays a comparison of the sheet resistance for wafers diffused in N_2 , Ar, and He atmospheres. It is apparent that the diffusions in N_2 give unique results. We discuss this further below.

Diffusion in N_2 ambient.—Data shown in Fig. 6 demonstrate that diffusions performed in N_2 give very different results from diffusions performed in Ar or He. While both Ar and He are inert gases, work by Raider *et al.* (22) on

Fig. 4. Sheet resistance as a function of oxygen content in the diffusion atmosphere and time.

the N_2 reaction at the Si-SiO₂ interface suggests that N_2 gas diffuses to the interface where it reacts to form an oxynitride. This suggests that in the case of diffusions performed in Ar or He, the phase formed at the interface is solely due to interaction between the doped glass and the substrate, while, in N_2 diffusion, interface interactions are modified by the presence of N_2 as a reactant.

AES was used to further investigate this possibility. Figure 7b is an AES survey spectrum representing the surface of a wafer which was diffused for 1h at 1250°C in 100% N_2 . The spectrum shows that the N_2 has reacted with the outer surface of the SiO₂ cap to form an oxynitride. Figure 8 is an AES depth profile of the same sample. It shows that the oxynitride formed at the surface of the SiO₂ cap is very thin. Further, N was also found distributed within the SbSG layer, reaching a maximum in concentration at the SbSG/substrate interface. This N peak near the interface is consistent with Raider's (22) observation from ESCA and etch-rate data of an oxynitride or mixed oxide and nitride at the oxide/substrate inter-

Fig. 5. Replot of the data in Fig. 4 emphasizing low oxygen concentrations.

Fig. 6. Sheet resistance for wafers diffused in Ar, He, and N_2 vs. time.

face. Although the concentration of N at the SbSG/substrate interface is small (note the expanded scale for the N_2 profile), it apparently affects the interface reactions. No HF insoluble interfacial films were observed for diffusions performed in N_2 . It is evident that N_2 should not be considered an inert ambient in the presence of SiO₂ at high temperatures.

Substrate dopant profiles.—Figure 9 displays concentration profiles obtained from SRP measurements for diffusions performed for 4h in 0%, 1%, 10%, and 100% oxygen ambients. These traces show the changes in dopant surface concentration (C_s) as a function of ambient composition. In Fig. 10a and 10b, C_s as obtained from SRP measurements is plotted against diffusion times for various ambient compositions. Figure 10a concentrates on oxygen-rich atmospheres with 0% O_2 plotted as a reference. No change in C_s with time is observed for 0% O_2 , indicating infinite-source-type behavior. This time independence is also found at 5% O_2 . Between 10% and 100% O_2 , a decrease in C_s is noted for increasing diffusion times. This is similar to Beyer's (17) observation for the case of arsenic-doped glasses diffused in a high O_2 ambient. Under these conditions, thermal oxide which grows at the doped-glass substrate interface slows down the arrival of dopant to the substrate and therefore decreases C_s . The shift of the second minimum in ρ_s to shorter times with

Fig. 8. AES depth profile of wafer diffused in nitrogen for 1h at 1250°C.

increasing O_2 concentration (Fig. 4) is also indicative of a thermal oxide barrier growing at the doped-glass/silicon interface. This can be inferred as follows: the thermal oxide thickness can be approximated by

$$d_{ox} = [X_0 B(t + \tau)]^{1/2}$$

where X_0 is the molar fraction of O_2 in the ambient, B is the parabolic rate constant (dependent on the O_2 concentration), t is the time, and τ is the time constant which corrects for the presence of an initial oxide (23). As X_0 in-

creases, the time required to form an oxide thick enough to significantly retard the diffusion must decrease.

Fig. 10. A(left): Surface concentrations (obtained from SRP measurements) vs. diffusion time and as a function of ambient composition ($O_2 \geq 5\%$). B(right): Same as Fig. 10A, but $O_2 \leq 1\%$.

Fig. 11. Junction depth vs. $t^{1/2}$ as a function of O_2 content in the diffusion ambient.

Figure 10b displays a plot of C_s vs. diffusion time for oxygen-poor ambients. Again, 0% O_2 is plotted as a reference. In Fig. 10b, the behavior is opposite to that in Fig. 10a in that C_s now increases as a function of diffusion time. This behavior is consistent with the formation and subsequent oxidation of a diffusion barrier at low O_2 contents. For longer diffusion time, *i.e.*, increased arrival of O_2 at the doped-glass/Si interface, the barrier is oxidized allowing for diffusion of dopant to the Si substrate and therefore increasing C_s . The above statements are supported by the behavior of x_j as a function of ambient and diffusion time, as plotted in Fig. 11. The shallower junctions obtained at low oxygen concentration are ascribed here to a barrier at the interface. Intermediate junction values at high O_2 /Ar ratios are consistent with a reduction of the dopant flux at the substrate surface due to thermal oxide formation.

Although the shallower junctions at high O_2 content (as compared to x_j in an inert atmosphere) could be attributed to ORD effects as reported by Tan and Gosele (24), the decrease in C_s with increasing oxidation time can by itself account for the decrease in junction depth. Take 8h

Fig. 12. Dopant concentration profiles for: (a) 1100°C, oxide side, (b) 1100°C, Si_3N_4 masked, (c) 1250°C, oxide side, and (d) 1250°C Si_3N_4 masked.

diffusions for 100% O_2 and inert atmosphere (100% Ar) as an example

	100% O_2	100% Ar	
x_j (μm)	7.0	7.5	(from Fig. 11)
C_s (cm^{-3})	6×10^{18}	3×10^{19}	(from Fig. 10a)

For simplicity, a ratio between junction depths as a function of C_s is obtained assuming infinite source behavior (erfc) and using Barry and Olofsen's formula (2). A similar ratio can be obtained for a finite source behavior (Gaussian) assumption.

$$x_j = 2 \sqrt{Dt} \operatorname{erfc}^{-1} \left(\frac{C_b}{C_s} \right)$$

and the ratio between x_j can be calculated from the ratio between erfc's

$$\left. \frac{x_j(O_2)}{x_j(Ar)} \right]_{\text{calc}} = 0.90 \quad \text{and} \quad \left. \frac{x_j(O_2)}{x_j(Ar)} \right]_{\text{exp}} = 0.93$$

Thus, the measured x_j difference between high oxygen and inert atmosphere diffusions could be attributed to the decrease in C_s .

Oxidation retarded diffusion.—Diffusions were conducted at 1100° and 1250°C to ascertain the presence of ORD in Sb diffusions into Si. The experimental procedure was similar to that reported by Mizuo and Higuchi (13), where Si substrates were predeposited with Sb, from a doped-glass source, and coated with Si_3N_4 , which was subsequently etched off from half of the wafer. The wafers were diffused in an O_2 atmosphere, and the junction depths in the Si_3N_4 covered and exposed areas were compared. Results plotted as concentration profiles are shown in Fig. 12. They indicate that, while ORD can be seen clearly for diffusions at 1100°C, it is not a significant effect for 1250°C diffusions.

HF insoluble film.—For O_2 concentrations less than 1% in Ar, a hydrophobic, HF insoluble film was present after diffusion. The film was more evident with decreasing oxygen content, and it became less apparent with increasing diffusion times. No film was observed after 8h diffusions.

Several analytical techniques were used to characterize this HF insoluble film. Figure 13 shows SIMS depth profiles of two samples. Both samples were diffused for 1h at 1250°C. One sample was diffused in a 100% Ar ambient, and the other in an Ar-1% O_2 ambient. Following the diffusions, both samples were etched in an HF solution. After etching, the sample diffused in 100% Ar exhibited a residual unetchable film, whereas the sample diffused in Ar-1% O_2 had the appearance of a clean Si surface.

Fig. 13. SIMS depth profile of substrates diffused in 100% Ar and 1% O_2 atmospheres (glass stripped in 48% HF).

Fig. 14. AES depth profiles of the HF insoluble films: (a) as deposited SbSG, (b) 100% He, 1h, 1250°C, HF stripped, (c) 1/4% O₂, 1h, 1250°C, HF stripped, and (d) 1/2% O₂, 1h, 1250°C, HF stripped.

The SIMS Sb profile of the sample diffused in 100% Ar shows a surface layer characterized by high Sb counts. Assuming a constant sputter rate, over the depth of the sputter crater, this layer has roughly the same thickness as the original SbSG layer. The profile of the sample diffused in Ar-1% O₂ does not show evidence of this layer. Finally, we note that these SIMS Sb profiles show that there is about a ten times greater surface concentration of Sb in the substrate of the sample diffused in 100% Ar, in agreement with SRP measurements described previously.

Figures 14b-14d show AES depth profiles of the HF insoluble films on samples diffused in 100% He, Ar-1/4% O₂, and Ar-1/2% O₂, respectively. For reference, Fig. 14a shows an AES depth profile of a 700Å SbSG layer which was not diffused. The Si LMM peak (92 eV) characteristic

Table II. Composition of HF insoluble film as determined from RBS measurements

	Cap	As Deposited SbSG	HF insoluble film
Si (cm ⁻³)	1.8×10^{22}	1.6×10^{22}	3.4×10^{22}
O (cm ⁻³)	3.7×10^{22}	3.7×10^{22}	8.2×10^{21}
Sb (cm ⁻³)	—	2.2×10^{21}	3.0×10^{20}
Stoichiometry	SiO _{2,1}	SiO ₂ Sb _{0,14}	SiO _{0,24} Sb _{0,0089}

of elemental Si is being monitored in these profiles, thus accounting for the low Si signal in Fig. 14a.

The AES depth profiles show that the HF insoluble film can be characterized basically as a silicon-oxygen compound which is very oxygen deficient compared to the original SbSG. Sb was not detectable in those residual films with AES, although it was detectable with SIMS. We shall show below that it is detectable with RBS also. The thickness of the HF insoluble film can be seen in Fig. 14b-14d to be inversely related to the concentration of O₂ in the diffusion ambient. Only very small partial pressures of O₂ are needed to prevent the appearance of the HF insoluble film. The AES profiles also show that the outer surface of the film is nearly pure Si, which may account for the failure of the film to etch in HF. The film/substrate interface is very broad compared to the SbSG/substrate interface (Fig. 14a). This suggests that the HF insoluble film is nonuniform in thickness and/or composition over the wafer surface.

Figure 15 shows an RBS spectrum of the HF insoluble film on the sample diffused in 100% He. This spectrum was recorded under conditions identical to those used to record the spectrum of the as-deposited sample (Fig. 2). From this spectrum, we can calculate the composition of the HF insoluble film. The results are summarized in Table II along with the previously calculated composition of the as-deposited sample. Once again, it can be seen that the HF insoluble film is both Sb and O deficient with respect to the as-deposited SbSG, while the Si concentration has more than doubled.

To summarize, the SIMS, AES, and RBS data have shown that the HF insoluble film can be characterized as being oxygen and antimony deficient with respect to the as-deposited SbSG. The AES data suggest that the surface of the film is rich in Si. The film is roughly the same thickness as the original SbSG layer for a 1h 1250°C diffusion in pure inert atmosphere, but it rapidly becomes thinner for small partial pressures of O₂ in the diffusion

Fig. 15. RBS spectrum of HF insoluble film for wafer diffused in 100% He atmosphere.

Fig. 16. Sheet resistance and surface concentration (C_s) as a function of O_2 concentration in the diffusion atmosphere.

ambient. For a 1h 1250°C diffusion in Ar-1% O_2 , no residual film could be detected.

Model

Both ρ_s and C_s are plotted against O_2 concentration in Fig. 16, where their inverse relationship becomes apparent.

In Fig. 17, a model is proposed to account for the presence of two maxima in C_s as a function of diffusion ambient composition (see Fig. 16). The C_s vs. percentage of O_2 curve can be separated into four parts: (i) inert atmosphere, (ii) low O_2 , (iii) medium O_2 , and (iv) high O_2 regions. The as-deposited structure consists of an undoped SiO_2 cap, a Sb-doped glass (2×10^{21} cm^{-3}), and a Si substrate with a background boron concentration of 2×10^{15} cm^{-3} . In the first segment (i), in inert atmosphere, a hydrophobic HF-insoluble film forms at the doped-glass/Si interface. Through various microchemical and electrical measurements we have shown that this film composition has the form $Sb_xSi_yO_z$ and acts as a high concentration source of Sb atoms. The idea of an infinite source is reinforced by the observation that C_s is independent of time for diffusions in inert atmospheres (see Fig. 10).

In the second segment of the curve (ii), at low O_2 concentrations the source film is thinner, making it a limited source, accounting for lower C_s values. The AES depth profiles (Fig. 14) demonstrate the progressively thinner layer for increasing concentrations of O_2 between 0% and about 1%. The interface film is postulated to act both as a source and a barrier to Sb diffusion from the stibinosilicate glass. For inert or low O_2 concentrations, the film forms rapidly at the interface and isolates the doped glass from the substrate (barrier action) so that the Sb diffusion into the substrate comes exclusively from the film (source action). For thick films (inert atmosphere diffusion), the source is infinite (Fig. 10a), while for thin films, the supply of Sb is limited and is not readily replenished by the glass.

In the third part of the curve (iii) an increase in C_s is observed for $1\% < \%O_2 \leq 25\%$. In this range, $Sb_xSi_yO_z$ is initially formed and supplies Sb to the substrate such that an initial rise in C_s occurs, analogous to a predeposition step. As opposed to the O_2 -poor part (ii), in the medium O_2 range this phase is rapidly oxidized. The initial dopant concentration at the substrate is now enhanced by both the Sb flux from the doped glass and also, as oxidation develops, by the pile-up effect. This effect which is caused by dopant redistribution between the growing oxide and silicon was first reported by Grove *et al.* (25) on his work on the oxidation of doped substrates.

As long as the diffusivity of Sb in SiO_2 (D) is greater than the parabolic oxidation rate constant (B), an increase in C_s with the oxygen concentration in the ambient will be observed. From Ghezzi and Brown (26) and at 1250°C, D (Sb in SiO_2) = $0.09 \mu/h^{1/2}$. From an extrapolation of Irene's data (26) to 1250°C, $B = 0.196 \mu/h^{1/2}$ for atmospheric pressure. Since Deal and Grove (23), report that B is proportional to the O_2 partial pressure in the ambient, the

Fig. 17. Schematic of proposed model

value of B can be calculated for any O_2 concentration. At 25% O_2 , $D = B$ such that up to 25% O_2 , the $D > B$ condition holds.

With increasing O_2 concentration in the diffusion ambient, as in part (iv), a competition between diffusion and oxidation becomes evident. As the O_2 concentration increases over 25%, D (Sb in SiO_2) $< B$, so that the thermal oxide growing at the doped oxide/substrate interfaces is now thick enough to slow down the arrival of Sb to that interface. This causes a decrease in C_s relative to C_s at intermediate O_2 concentrations. A similar argument for low C_s at high O_2 concentration has been proposed by Beyer (17) for the diffusion of As from doped-glass sources.

Summary

The effects of ambient and time on the diffusion of Sb into Si from a doped-glass source were studied. Two minima in C_s were found as a function of O_2 concentration in the diffusion ambient, when Ar- O_2 mixtures were used. From similar experiments using N_2 - O_2 mixtures it was determined that at high temperatures N_2 interacts with the doped-glass/silicon interface. This interaction affects the diffusion of Sb into silicon.

The formation of an interface film, $Sb_xSi_yO_z$, at low oxygen concentrations, for Ar- O_2 diffusion was identified. This film was characterized through AES, SIMS, and RBS analyses. A diffusion mechanism is proposed to account for the presence of two surface-concentration maxima as a function of O_2 content in the diffusion ambient. This mechanism is based on the formation of $Sb_xSi_yO_z$ at the doped-glass/silicon interface at low O_2 concentration and on pile-up effects at higher O_2 concentrations.

At present, we are performing additional RBS analyses on samples covering the entire range of oxygen concentrations in the ambient. These results and their implications with regard to the above model will be discussed in a subsequent paper.

Acknowledgments

The authors would like to thank Dr. Syd Wilson for his help in acquiring and interpreting the RBS data. Thanks are also due to Doris Travers and Karen Kobold for their contribution in running the LPCVD tubes and in the electrical characterization of the buried layers.

APPENDIX

Diffusion Coefficient

Assuming an erfc dopant-distribution profile (for oxygen concentrations of 0% and 5%), and from C_s and junction depth values obtained from SRP data, a diffusion coefficient for antimony in silicon at 1250°C was calculated. As can be seen in Table A-I the diffusion coefficient obtained in this work agrees fairly well with the reported literature values.

ABSTRACT

The defects caused by high temperature diffusion from a borosilicate glass source have been detected using deep level transient spectroscopy (DLTS). Energy levels at $E_c - 0.12$ eV, $E_c - 0.26$ eV, $E_c - 0.36$ eV, $E_c - 0.55$ eV, and $E_v + 0.23$ eV have been measured. It is shown that these levels are annealed out by subsequent processing steps such as phosphorus predeposition, thermal oxidations, and drive-in diffusion. An increase in carrier lifetime from 10 to 36 μ s was found to be associated with the decrease in the defect concentration.

The conventional diffusion processing steps have been known (1, 2) to cause process-induced defects in silicon. The energy levels within the silicon bandgap associated with these defects have been measured by Yau (1) and Sah (2). For the high temperature diffusion of boron and phosphorus at high surface concentrations obtained from BN and P₂O₅ sources, respectively, the energy levels were found to be $E_c - 0.08$, $E_c - 0.22$, $E_c - 0.264$, $E_c - 0.298$, and $E_c - 0.542$ eV. They showed that, unlike impurities, these defects could not be gettered either by surface oxide glasses or by a high concentration degenerate diffused layer but only by slow (0.42°C/min) cooling followed by a quench from the diffusion temperature to room temperature. In addition to the process-induced defects, the defects associated with radiation-induced damage (3-5) have been identified and some have been found to have the same energy levels as those indicated above.

Borosilicate glasses have been shown (6) to be preferable to boron nitride as a p-type planar diffusion source because the usual periodic reactivation cycles are not required (as it is for BN) due to the presence of boron in its activated state. No defect studies, however, have been done for a diffusion process for which borosilicate glasses have been used as a diffusion source. Neither have the effects of the subsequent processing steps that eventually lead to device fabrication been studied.

We report here, the results of a study of process-induced defects caused by diffusion from a borosilicate glass source and from subsequent processing steps using deep level transient spectroscopy (DLTS). Specifically, after boron predeposition diffusion from a borosilicate glass source, energy levels at $E_c - 0.12$, $E_c - 0.26$, $E_c - 0.36$, $E_c - 0.55$, and $E_v + 0.23$ eV were found within the Si bandgap. After the drive-in diffusion, however, deep levels are still present but their concentrations have been considerably reduced. Similar reductions in concentration were also found for subsequent processing steps such as POCl₃ predeposition diffusion and the final thermal oxidation. An increase in the carrier lifetime (as determined by the open-circuit voltage decay technique) from 10 μ s following the boron predeposition step to 36 μ s after the thermal oxidation step was also found, which correlates quite well with the decrease in defect concentration indicated above. The following describes our experimental techniques, results, and the conclusions that can be drawn from them.

Experimental Techniques

The starting material used was n-type silicon with a resistivity of 40 Ω -cm. Before any processing, it was chemically etched to 12 mil. Seven sets of samples (group 1-group 7) were obtained after each of the seven processing steps used for device fabrication. Group 1 samples were obtained after the boron predeposition step which consisted of diffusion from a borosilicate glass source at

1040°C for 60 min in a flowing nitrogen ambient. Since the diffusion was double-sided, the resulting structure was P⁺NP⁺. Group 2 samples went through a boron drive-in diffusion step at 1250°C for 25h in an oxygen and nitrogen ambient. The resulting structure was still P⁺NP⁺ and the junction depth was 1.56 mil (measured by angle lapping), while the surface boron concentration was 3.4×10^{18} cm⁻³. Next, phosphorus predeposition was done on one side (by masking the other side) from a POCl₃ source at 1100°C for 60 min. The result was a P⁺NP⁺N⁺ structure from which group 3 samples were obtained. This was followed by a drive-in diffusion at 1250°C for 7h in nitrogen ambient. The resulting structure was again P⁺NP⁺N⁺, and the junction depth of the P⁺N⁺ side was 0.9 mil. Group 4 samples were obtained from this lot. Group 5 samples were obtained after a gettering step at 1200°C for 60 min with borofilm on the P⁺ side (commercially available from Emulsitone). Group 6 samples, however, were obtained after a POCl₃ gettering heat-treatment at 1100°C for 60 min (on the N⁺ side). These samples did not go through a borofilm gettering step so that group 5 and group 6 samples could be compared with respect to the effectiveness of the two gettering processes. The final step resulting in group 7 samples was a wet thermal oxidation of both groups 5 and 6 samples at 1100°C for 9h. The structure for groups 4-7 samples was P⁺NP⁺N⁺. After processing, the samples from each group were back-side (N⁺ side) lapped to 9 mil. This removed the P⁺ region (in the case of groups 1 and 2 samples) or the P⁺N⁺ region (in the case of groups 3, 4, 5, 6, and 7 samples). A 10,000Å layer of Al was next deposited on the P⁺ side, while 10,000Å of Au-As alloy was deposited on the N-side. The samples were then sintered at 475°C for 10 min in nitrogen ambient to form ohmic contacts.

After packaging into a gold-plated T05 header, DLTS measurements were made using a system consisting of a 50 MHz capacitance bridge, PAR boxcar averager, and associated amplifiers (3, 7). The details of the DLTS measurement can be found elsewhere (7, 8). Briefly, the method consists of reverse biasing a p-n junction in such a way that the reverse bias can be momentarily reduced by a pulse. This results in a reduction in the width of the depletion layer during the pulse. Traps within the region where there is now no longer a depletion region capture charge carriers. After the pulse and as the depletion layer returns to equilibrium, the traps emit the captured charges by thermal stimulation giving rise to a decaying capacitance transient. The decay rate of the transient is related to the emission rate of the traps, which for electrons is given by

$$e_n = \sigma_n < V_n > N_D / g_1 \exp(-E_t / KT) \quad [1]$$

where σ_n is the capture cross section, $< V_n >$ the thermal velocity, N_D the carrier concentration, g_1 the degeneracy of the trap, and E_t the trap energy level with respect to the conduction band. By varying the temperature of the

Fig. 2. DLTS spectrum for a group 2 sample (after boron drive-in) showing reduced concentrations of deep levels.

sample from 77 to 300 K, for example, the trap emission rates are also varied. The trap emission rates can be measured by the DLTS apparatus in such a way that the output is maximum when a rate window set on the apparatus is equal to the capture rate of the trap. This gives rise to a DLTS spectrum, the peaks of which correspond to trap energy levels. The energy level of the trap, E_t , can be obtained from the experimental data using Eq. [1]. The trap concentration can be obtained from the magnitude of the DLTS peak and calibration of the measurement system, while the capture cross section can be obtained by a method already described by Lang (7).

Results

Figure 1 shows a complete DLTS run for a group 1 sample (after boron predeposition from a borosilicate glass source). Four majority carrier deep levels are present as the peaks show. By injecting holes into the N-region using a forward biasing pulse, a minority carrier trap was also detected. The energy levels, capture cross

sections, and trap concentrations were accurately obtained for peaks II, III, IV. The data for all the traps are shown in Table I. After the boron drive-in diffusion, the deep levels are still present, but have been severely reduced in concentration as Fig. 2 shows for group 2 samples. Similarly, after the POCl_3 predeposition (group 3), all the levels remain (Fig. 2) except for the level at $E_c - 0.55$ eV. The level at $E_c - 0.12$ eV appeared to have in-

creased at this point and is now the most dominant level. The same seems to be true after the final thermal oxidation step (group 7), as the DLTS spectrum in Fig. 4 shows.

Minority carrier lifetime values were obtained for samples from all groups using the open-circuit voltage decay technique (9). The effect of basewidth limitation of the lifetime was taken into consideration using the expression (9, 10)

$$\frac{1}{\tau_{\text{eff}}} = \frac{1}{\tau} + \frac{1/(W^2)}{2D} \quad [2]$$

where τ_{eff} is the measured lifetime, τ is the actual carrier lifetime, and $(W^2/2D)$ is the charge carrier transit time within the N region of the diode. W is the width of the N region, and D is the carrier diffusion coefficient. The resulting lifetime values are shown in Table II. An increase in lifetime with successive processing steps can be seen. This is in agreement with the reduction in deep level defect concentrations described above.

Discussion

The deep levels found after predeposition from the borosilicate glass source is due to the damage done by stresses caused by the high concentration of boron atoms at the surface ($2.5 \times 10^{20} \text{ cm}^{-3}$). These stresses result in the formation of defects other than those normally formed at these temperatures (such as simple vacancies). Other defects that may form at high boron concentrations are, for example, boron-vacancy pairs and divacancies. In fact, the results of ion bombardment and electron irradiation (3-5, 11, 12) show that some of the deep levels detected are identical to the energy levels for process-induced defects. For example, the level at $E_c - 0.26 \text{ eV}$ (this work) has been associated with the doubly negatively charged state of a divacancy (5). Another level usually found in electron-irradiated silicon is the level at $E_c - 0.17 \text{ eV}$ (close to our observed level at $E_c - 0.12 \text{ eV}$), which has been associated with oxygen-vacancy pairs (O-V). Other levels have been associated with hydrogenic dopant-vacancy pairs, such as Sb vacancy pair ($E_c - 0.39$

eV), arsenic-vacancy pair ($E_c - 0.42$ eV). Our measured level at $E_c - 0.36$ may be due to a defect of this type, possibly a boron-vacancy complex. A level at $E_c + 0.23$ eV has also been found in electron-irradiated silicon and has been suggested to be created by annealing above 225°C (12). Finally, the level at $E_c - 0.55$ eV is also found in electron-irradiated silicon and has been associated with a divacancy (12). Sah *et al.* has also shown that this level can be found in silicon whose surface has been mechanically lapped.

The fact that these defect levels are severely reduced by the subsequent processing steps is in conformity with the annealing properties of the defects discussed above. All of these defects (5) have been found to anneal out at temperatures of 700°C or higher. All the processing steps subsequent to the predeposition are at these high temperatures (~1000°C) which annealed out the defects created by the predeposition. The increase in the carrier lifetime with the processing steps is also in agreement with an annealing out of these defects.

Sah (2) indicated that a very slow cooling rate of about 0.42°C/min, from the diffusion temperature, is required for annealing out the defects. The cooling rate in our furnace was 1°C/min. The defects created by the predeposition were not annealed out by the predeposition cooling however, possibly due to a higher concentration of boron in our experiments. This, nonetheless, indicates that a much lower cooling rate is necessary to anneal out defects created by diffusion processes. Even if the defects are not annealed out during the cooldown from the boron predeposition, our results show that the subsequent processing steps will anneal them out.

Summary

It has been shown that high temperature diffusion from a borosilicate glass source results in high concentrations of deep levels. These levels, at $E_c - 0.12$, $E_c - 0.26$, $E_c - 0.55$, and $E_v + 0.23$, were found to be annealed out by the subse-

quent processing steps that lead to device fabrication. A corresponding increase in carrier lifetime with successive processing steps was observed. These defect levels were shown to be similar to those measured in ion- or electron-bombarded silicon, indicating that they may be due to stresses caused by the high boron concentration, resulting in the formation of complex defects.

Boron and Phosphorus Determination in Low Resistivity Solar-Grade Silicon

L. P. Hunt,* R. W. Francis,* and J. P. Dismukes*

Exxon Research and Engineering Company, Clinton, New Jersey 08801

ABSTRACT

A technique is developed to analyze boron and phosphorus concentrations in silicon by determining net carrier concentrations from Hall-effect measurements. The goal of the technique is to measure these impurities in purified metallurgical silicon (PMS) which is to be ultimately used for fabricating solar cells. Net carrier concentrations are measured on two wafers cut from a second-generation Czochralski ingot pulled from PMS. Boron and phosphorus concentrations in the PMS and the ingots are calculated from the net carrier concentrations by applying the segregation equations of the impurities. The accuracy of the boron measurements between 1 and 30 ppma is equivalent to that obtained on similar samples analyzed by multiple-pass float zoning. Phosphorus levels can be measured down to about 20% of that of the boron concentrations. Excellent precision of the Hall-effect technique is demonstrated. Sensitivity calculations show that net carrier concentration is the most critical parameter affecting the accuracy of the method. Overall, the technique is considered to be sufficient for making quality-control decisions with respect to boron and phosphorus levels in PMS and ingots grown from it.

The analytical technique described herein was developed to measure the concentrations of boron and phosphorus in a special grade of silicon for use in photovoltaic applications. This particular grade of silicon is, or has been, the focus of research and development programs (1, 9) with the common goal of increasing the purity of silicon that is metallurgically produced by the carbothermic reduction of silica in an arc furnace. The specific research and development programs involve some combination of the following procedures: (i) silicon of greater than 99% purity, produced from high purity raw materials and high purity arc-furnace operations, is upgraded by (ii) recrystallization from solution, (iii) slagging, (iv) acid leaching, and/or (v) gas blowing (10). This grade of silicon undergoes further purification via impurity segregation during certain forms of crystal growth which ultimately yield a material suitable for fabrication into solar cells.

A survey of Ref. (1-9) shows that PMS, before crystal growth, has the following general composition expressed in parts per million atomic (ppma): $1 < \text{Al} < 100$, $1 < \text{B} < 10$, $1 < \text{Fe} < 100$, $0.3 < \text{P} < 5$, and $\text{M} < 5$, where M stands for other transitional-series metals. Alkali and alkaline earth impurities are not considered to be significant since they vaporize from the silicon melt during crystal growth. The concentrations of Al, Fe, and transition metals can be measured by several analytical techniques such as atomic absorption or emission, x-ray fluorescence, and spark-source mass spectroscopy. However, none of the above techniques were found to provide reliable analyses for boron of about 1 ± 0.2 ppma or for phosphorus at somewhat lower concentrations.

The technique described below for determining boron and phosphorus is somewhat analogous to that used in the semiconductor industry for analyzing polysilicon produced by the Siemens process. The concentrations of boron and phosphorus in semiconductor polysilicon are calculated from resistivity measurements made on the one-pass and seven-pass sections of a multiple float-zone silicon rod (11). In the simplest float-zone case, one-pass resistivity is related to net carrier concentration [B]-[P], whereas the seven-pass resistivity is a measure of the boron concentration, [B], only. The concentration of the two impurities in polysilicon can be calculated by appropriately using (12) their segregation coefficients in the solution of two simultaneous equations involving net carrier concentration.

Purified metallurgical silicon is also subjected to crystal growth. Therefore, subsequent electrical measurements will allow calculation of the boron and phosphorus concentrations. A Czochralski (CZ) ingot that is grown from PMS is polycrystalline and can contain aluminum in

addition to boron and phosphorus. Therefore, a second-generation CZ ingot is grown from the first ingot. Since the second-generation ingot contains no measurable concentration of aluminum, Hall-effect measurement of the net carrier concentration is made on wafers cut from both the seed and tang ends of this second-generation ingot. Actual boron and phosphorus concentrations in both ingots and in the PMS can then be calculated from the net carrier concentrations. The calculations involve the positions along the ingot at which the net carrier concentrations were measured and the segregation coefficients of the two impurities.

The next section demonstrates the computational method for relating net carrier concentrations to those of boron and phosphorus. The theory and reason for Hall-effect measurements are also discussed.

Experimental

Hall-effect measurements.—Hall-effect measurements provide two valuable pieces of information for characterizing semiconductors that are not available from electrical resistivity measurements alone: majority carrier mobility and concentration. The latter equals the difference in the acceptor and donor concentrations and is relevant to this work provided the donors and acceptors are electrically active, *i.e.*, exist neither as neutral ion pairs nor as precipitated phases.

The principle of the technique (13) is to apply a magnetic field at right angles to a current flowing through a triple H-shaped sample of p- or n-type silicon. The generated electric field, E_H , is orthogonal and proportional to both the current density and the magnetic field. The Hall voltage associated with E_H is

$$V_H = \frac{RIB}{W} \quad [1]$$

where R is the Hall coefficient, I the current, B the magnetic field, and W the sample thickness. Calculation of the Hall coefficient from V_H and W permits the net majority carrier concentration to be calculated from

$$[\text{P}] = \frac{r_p}{Rq} \text{ or } [\text{n}] = -\frac{r_n}{Rq} \quad [2]$$

for p- or n-type samples, respectively. In the above equations, q is the electronic charge, and r is the Hall factor which depends on the band structure and the mechanism of carrier transport and scattering in a particular semiconductor. For silicon at room temperature, the p-type Hall factor is 0.71, while the n-type factor is 1.18, *i.e.*, $3\pi/8$ (14).

Under the assumption that all impurities are electrically active, the net carrier concentration determined from Eq.

*Electrochemical Society Active Member.

Key words: impurity, photovoltaic, solidification.

[1] and [2] equals the net ionized impurity concentration |B-P|. Sensitivity analysis indicates an experimental precision of within 5% in obtaining R in Eq. [1] and an accuracy in the determination of |B-P| from Eq. [2] of $\pm 10\%$. The latter stems primarily from a variation in the Hall factor with dopant density (15).

Computational procedure.—The translation of Hall-effect measurements into boron and phosphorus concentrations is more easily understood by first considering the mass flow of impurities from the PMS, through crystal growth, to the measured wafers. The mass flow of an impurity during crystal growth is determined by the segregation equation (16)

$$C = C_0 k_{\text{eff}} (1 - g)^{(k_{\text{eff}}-1)} \quad [3]$$

where g is the fraction of the melt solidified, C and C_0 are the impurity concentrations at points g and $g = 0$, respectively, and k_{eff} is the effective distribution coefficient of the impurity (17). It is convenient to rearrange Eq. [3] into a more general form involving relative concentrations

$$C/C_0 = k_{\text{eff}} (1 - g)^{(k_{\text{eff}}-1)} \quad [4]$$

The variation of C/C_0 for boron as a function of g is shown in Fig. 1 for $k_{\text{eff}} = 0.80$ (18).

The computational procedure being developed here also involves use of the average relative impurity concentration between two points, g_1 and g_2 , in an ingot. This is obtained by integrating Eq. [4]

$$\overline{C/C_0} = \frac{1}{g_2 - g_1} \int_{g_1}^{g_2} k_{\text{eff}} (1 - g)^{(k_{\text{eff}}-1)} dg \quad [5]$$

$$\overline{C/C_0} = \frac{1}{g_2 - g_1} [(1 - g_1)^{k_{\text{eff}}} - (1 - g_2)^{k_{\text{eff}}}] \quad [6]$$

The variation of $\overline{C/C_0}$ with g is also shown in Fig. 1 for boron.

The mass flow of impurities can be visualized with the aid of the mass flow diagram in Fig. 2. Purified metallurgical silicon is loaded into a Czochralski puller and polycrystalline ingot CZ1 is grown.¹ The seed and tang ends of the ingot are cropped at positions g_1 and g_2 , respectively. The cropped ingot becomes the melt for a second CZ growth in which ingot CZ2 is produced. Ingot CZ2 is cropped at positions g_3 and g_4 and then wafers are cut from the seed and tang ends. Wafers cut at positions g_{w1} and g_{w2} are used in the Hall-effect measurements. The growth and processing of the nominally 11 cm diam ingots used in this work were performed at Solar Power Corporation.

The following equations are developed considering the flow of boron from the initial PMS to the final wafers

¹Impurity segregation is no longer described by these equations when crystallite sizes are less than about 1 mm.

Fig. 1. Variation of boron concentration with fraction of the melt solidified.

Fig. 2. Mass flow diagram for impurities from PMS through wafers for Hall-effect analysis.

used for analysis. Similar equations apply to phosphorus, or to any other impurity.

The average boron concentration in PMS is the initial boron concentration in the melt for CZ1

$$\overline{B}_{\text{PMS}} = B^0_{\text{CZ1}} \quad [7]$$

The average boron concentration in CZ1, between points g_1 and g_2 , can be calculated from the initial melt concentration by using Eq. [6]

$$\overline{B}_{\text{CZ1}} = B^0_{\text{CZ1}} \cdot (\overline{B/B_0})_{\text{CZ1}} \quad [8]$$

Since cropped ingot CZ1 is used to charge the crucible for the second crystal growth step, then

$$B^0_{\text{CZ2}} = \overline{B}_{\text{CZ1}} \quad [9]$$

The average boron concentration in ingot CZ2, between points g_3 and g_4 , is calculated in the same way as was done for ingot CZ1

$$\overline{B}_{\text{CZ2}} = B^0_{\text{CZ2}} \cdot (\overline{B/B_0})_{\text{CZ2}} \quad [10]$$

Equations [7], [8], and [10] provide the average boron concentrations in PMS, CZ1, and CZ2. These are now related to the Hall-effect measurements on wafers w_1 and w_2 through the initial CZ2 melt concentration, B^0_{CZ2} . The boron concentration of a wafer, w , at point g_w is

$$B_w = B^0_{\text{CZ2}} \cdot (B/B_0)_w \quad [11]$$

It is now possible to set up two simultaneous equations in order to determine the concentrations of both boron and phosphorus. Since the Hall-effect technique measures net carrier concentration, n , then

$$B_{w1} - P_{w1} = n_{w1} \quad [12]$$

$$B_{w2} - P_{w2} = n_{w2} \quad [13]$$

By substituting Eq. [11] and its phosphorus equivalent into Eq. [12] and [13], one can calculate the concentration of both impurities in the initial CZ2 melt

$$B^0_{\text{CZ2}} \cdot (B/B_0)_{w1} - P^0_{\text{CZ2}} \cdot (P/P_0)_{w1} = n_{w1} \quad [14]$$

$$B^0_{\text{CZ2}} \cdot (B/B_0)_{w2} - P^0_{\text{CZ2}} \cdot (P/P_0)_{w2} = n_{w2} \quad [15]$$

In summary, the Hall-effect technique for determining the concentrations of boron and phosphorus consists of (i) measuring net carrier concentration of wafers from the seed and tang ends of a second-generation CZ ingot, (ii) solving Eq. [14] and [15] for the initial impurity concentrations in this ingot, and (iii) calculating the average impurity concentrations in the polysilicon, first-, and second-generation ingots from Eq. [7], [8], and [10].

The complete analysis for boron and phosphorus requires eight pieces of data: g_1 , g_2 , g_3 , g_4 , g_{w1} , g_{w2} , n_{w1} , and n_{w2} .

All the following calculations use $k_{\text{eff}} = 0.80$ for boron and $k_{\text{eff}} = 0.35$ for phosphorus (18).

Results

Accuracy.—Various grades of PMS were used for analysis. Their purity varied over a considerable range depending upon the quality of the raw materials used in their preparation, the conditions under which the arc furnace was operated, and the additional refining steps that were employed. Some of the materials were obtained from commercial vendors. One of the samples differed

substantially from the others: p-type semiconductor silicon was boron doped by adding a weighed amount of boron to the silicon in an attempt to provide a "standard."

Hall-effect measurements were compared to float-zone analyses performed at Hemlock Semiconductor Corporation. A third sequential CZ-growth step provided a 25 mm diam rod for float zoning. Resistivity data supplied by Hemlock Semiconductor were used to calculate average concentrations in a manner similar to that already outlined above. The resistivity values were converted to concentrations using the recently reported correlations by Thurber *et al.* (19). Their data show a maximum deviation of 68% at 0.07 Ω -cm from Irvin's curves (20). Deviations exceed 10% for resistivities between 0.004 and 0.7 Ω -cm.

Eight measurements must be made per Hall-effect analysis, as described earlier. The range of each measurement is presented in Table I.

A comparison of Hall-effect analyses with those from multiple-pass float zoning appear in Table II. The data are arranged according to increasing boron concentration. In the case of boron, Hall-determined concentrations generally agree well with those from float zoning when the errors of the analyses are considered. This agreement covers a range from about 1 to 30 ppma. It is important that the Hall technique provides accurate boron concentrations at the 1 ppma level since solar cell efficiency decreases significantly at concentrations exceeding this value. The actual weighed amount of boron added to the semiconductor silicon in sample 32 amounted to an average concentration in the ingot of 1.3 ppma. This value falls between the two analytically measured concentrations of 1.0 and 1.5 ppma.

Reasonable correspondence is found between the phosphorus concentrations using both analytical techniques. Lower concentrations, however, have a larger uncertainty associated with them. This is due to solving the simultaneous equations first for boron and then for phosphorus. In this procedure, errors propagate. "Less than" concentrations for the two methods result when calculations give a phosphorus that is slightly negative but close to zero when the error is considered. The data in Table II show that phosphorus can be determined down to about 10% to 30% of the boron concentration. Therefore, the

40	32 \pm 5	30 \pm 3	6 \pm 7	<6

* \bar{B}_{CZ2} = 1.3 ppma from actual weighed amounts of B and Si.

phosphorus concentration was set equal to 20% of the boron concentration when negative values were incurred.

Precision.—An indication of the precision of the Hall-effect technique was determined by growing three CZ1 ingots from the same batch of PMS. One additional CZ2 ingot was grown from each CZ1 ingot. Table III gives the results of the three Hall-effect analyses in terms of the average boron and phosphorus concentrations in PMS, CZ1, and CZ2. Precision is considered to be excellent.

Sensitivity.—Sensitivity calculations were carried out to determine the influence of the eight measured parameters on the derived boron and phosphorus concentrations. The effect on the calculated concentrations of making percentage changes in the parameters is indicated in Table IV. A 2% change in g values, which is considered to be the experimental error, results in \leq 1% change in boron and \leq 3% change in phosphorus. Therefore, errors in g values were not considered when calculating the errors given in Tables II and III.

The errors in Table III were determined by incorporating the estimated errors of the net carrier concentrations into the equations developed in the Experimental section. By adjusting the error in the net carrier concentrations, a value of $\pm 4\%$ was obtained that caused the boron concentration errors in Table III to agree with the spread in the absolute boron concentrations. Reported errors, then, are indicative of precision rather than accuracy.

Different values for the effective segregation coefficients of boron and phosphorus have been reported (18, 21-23). The sensitivity calculations in Table IV demonstrate that only a minor change in boron and phosphorus concentrations occur over the range of values of the segregation coefficient indicated.

Sensitivity calculations were performed for a given set of impurity conditions. Different errors are expected to occur in other circumstances.

Conclusions

Hall-effect analyses, performed on wafers cut from a second-generation CZ ingot pulled from PMS, provide an accurate measurement of boron and phosphorus concentrations, compared with those obtained from the multiple-pass float-zone method of analysis. Boron levels be-

$k_{eff}(P)^{**}$	+14	1.56	0.66

* 0.80 \rightarrow 0.82.

** 0.35 \rightarrow 0.40.

tween about 1 and 30 ppma were determined with an average error of approximately $\pm 20\%$. The lower limit of phosphorus measurement is about 20% of that for boron.

The precision of the Hall-effect technique, as determined by analyzing multiple samples prepared from the same batch of silicon, was excellent at the low-ppma level for both impurities.

Sensitivity calculations demonstrate that measurement of net carrier concentration is the most critical parameter affecting the analyses.

The Hall-effect method of analyzing boron and phosphorus in PMS via CZ ingots produced from it, is sufficient at a pilot-plant scale of production for characterizing the quality of these materials with respect to their suitability for fabricating solar cells. This presumes knowledge of concentrations of other impurities from different analytical techniques.

Acknowledgments

Appreciation is extended to E. Shipp for performing Hall-effect measurements, to R. Sylvain of Solar Power Corporation for overseeing growth and processing of ingots, and L. Tarhay of Hemlock Semiconductor Corporation for coordinating float-zone analyses.

Compositional Analysis of Silicon for Solar Cells

Lee P. Hunt*

Exxon Research and Engineering Company, Clinton, New Jersey 08801

ABSTRACT

A potential route to silicon for solar cells involves using an improved version of the carbothermic process to give an intermediate product capable of being upgraded by chemical and physical means to an acceptable end product. The compositional analysis of these intermediate and end products is discussed from the viewpoint of someone who must make research and development or business decisions based on information supplied by analysts. Methods are discussed for analyzing dopants (B and P), metals (Al, Fe, and others), and nonmetals (C, O, and SiC). Adequate methods are available, except when trying to measure the sub-ppm concentrations of metals present in the final silicon product. A plan is suggested for developing a quality assurance method for the time when the industry grows to the extent of requiring its own source of silicon rather than by-products from the semiconductor industry.

This paper deals with the compositional analysis of silicon from a user's point of view. The user is one who must make decisions based on analytical data concerning the purity of silicon. Such decisions must be made at various stages in a product's life. At the research and development stage, rapid analytical results from established techniques are needed so that decisions can be made to guide the research and development program. These techniques are hopefully available from outside analytical houses which have low cost and fast turnaround services. However, these two attributes usually do not go hand-in-

hand with the accurate and low level analyses needed for high purity silicon.

Since this review is concerned with silicon for solar cells, a product very young in its evolutionary cycle, most of the analytical techniques described are those readily available. Limitations of present capabilities are noted and suggestions are made for further development of techniques.

Silicon solar cells are typically fabricated from wafers cut from single or polycrystalline ingots. These ingots may be grown from semiconductor-grade silicon (SeG-Si) manufactured using the Siemens C process, which in-

*Electrochemical Society Active Member.

volves the high temperature hydrogen reduction of very pure trichlorosilane. This silicon compound, in turn, is prepared by the hydrochlorination of 98% pure metallurgical-grade silicon (MG-Si). Since the cost of solar cells must be considerably reduced in order to penetrate large-scale markets, much attention has been focused on upgrading MG-Si using lower cost metallurgical procedures (1-4) compared to higher cost chemical methods, such as the chlorosilane routes. This paper more particularly discusses the use of various analytical techniques for analyzing the composition of metallurgically processed silicon.

The compositional analysis of two grades of silicon are considered. Purified metallurgical silicon (PMS) is defined as the product of the carbothermic reduction of silica in an arc furnace under purer-than-normal conditions. This silicon can be upgraded by various chemical and physical techniques, e.g., acid leaching, slagging, directional solidification, etc., to produce a material of sufficient quality to be directionally solidified under conditions which provide for the effective segregation of impurities. The final ingot, called solar-grade silicon (SoG-Si), can be cut into wafers for solar cell fabrication. Table I shows typical impurity concentrations in PMS and SoG-Si based upon data reported in the literature.

The most important impurities in PMS and SoG-Si have been categorized for ease of discussion. Boron and phosphorus are the most common dopants, as well as the most difficult impurities to remove from silicon. This is because their segregation coefficients between liquid and solid silicon are very close to unity.

Of the metal impurities, aluminum and iron are treated separately because of their typically higher concentrations in PMS. This results from their common occurrence in raw materials as well as the construction materials used in metallurgical processing. Although aluminum is a dopant, its concentration in SoG-Si is lower than that of boron and phosphorus because it is easily removed both chemically and physically. In addition, only about 10% of the aluminum in silicon is electrically active. Even though the chemical methods of removing iron from silicon are not as numerous as those for aluminum, the concentration of iron can be reduced significantly during directional solidification because of iron's favorable segregation coefficient.

Other metal impurity concentrations in PMS can also be reduced to a great extent during directional solidification since their segregation coefficients are in the general range of 10^{-5} to 10^{-8} . The most important of these impurities are the lifetime killers such as Mo, Ti, V, and Zr. Fortunately, the most severe lifetime killers are the ones with the smallest segregation coefficients.

The remaining category of impurities is that of the non-metals. Included in this group is interstitial oxygen, and its various forms of precipitates, substitutional carbon, and silicon carbide as a second-phase material. Oxygen and carbon are important with respect to their influence on structural defects in crystalline SoG-Si. Silicon carbide particles can cause formation of twin planes during crystal growth and also can act as nucleation sites for impurities that lead to shunting of solar cells.

Boron and Phosphorus

Hall effect and float zone.—There are only two methods that appear to be reliable enough to provide accurate, precise analyses for boron and phosphorus at concentrations covering the range from sub-ppma to about 100 ppma. These are the float-zone, resistivity method that is traditionally used for evaluating semiconductor-grade polycrystalline silicon, and the Hall-effect technique (5).

The correlation between boron concentrations measured by these two methods is shown in Fig. 1. A least squares fit to the logarithm of the concentrations shows a slope of 0.94 and a Y-intercept of 0.04 for boron data covering a range of about 1 to 30 ppma. The square of the correlation coefficient indicates that 96% of the variation in the Hall boron concentration is explained by the re-

Table I. Concentrations of impurities reported in purified metallurgical silicon and SoG-Si

Impurity	Impurity concentration (ppmw)	
	PMS	SoG-Si
Al	50-500	0.005-0.05
B	0.1-10	0.1-10
C	50-100	0.5-1
Fe	50-100	<<1
Other metals	1-10	<<1
O	5-20	10-20
P	0.1-10	0.02-2
SiC	100-300	<1

gression equation. Although the Hall-effect method has not been tested in the sub-ppma range, it is projected to be an even more accurate method than the established float-zone technique (5).

Phosphorus is determined simultaneously with boron since the Hall effect measures the difference in net impurity concentration. Phosphorus was determined in the same silicon samples, as indicated above for boron, to ascertain the correlation between the Hall-effect and float-zone methods. Data are presented in Fig. 2 for fewer samples than for boron since phosphorus cannot be measured by either method to concentrations less than 20% of the boron concentration. The slope of the log-log plot is 1.08 with a Y-intercept of -0.21 . The square of the correlation coefficient is 0.94 for only five data points covering a phosphorus concentration range of about 0.1 to 20 ppma. As with boron, further work is required to establish that the method can be applied to even lower concentrations; prospects seem favorable.

Spark-source mass spectroscopy (SSMS).—SSMS provides a multielement analysis. However, its success strongly depends on the capability and skill of the analyst. Expertise developed within semiconductor companies for sparking directly to a solid silicon sample provides the greatest sensitivity (~ 0.01 ppma), provided that the equipment is dedicated to high-purity silicon. Even then, the difficulty in establishing accurate sensitivity factors to relate line intensities to concentrations results in analyses of boron and phosphorus that are lower than concentrations obtained by electrical resistivity measurements. A special method using silicon powder mixed with gallium has been reported (6). Another variation of this method, as performed by most commercial analytical laboratories, involves sparking dry graphite that contains the silicon sample previously dissolved in acid. This method has a sensitivity of about 0.01–0.5 ppma, depending upon the analyst, and also requires ultrapure acids and graphite.

Fig. 1. Correlation of boron analyses by Hall-effect and float-zone methods.

Fig. 2. Correlation of phosphorus analysis by Hall-effect and float-zone methods.

A comparison of the analysis of equivalent Czochralski wafers by the Hall-effect method and SSMS is shown in Fig. 3 for boron concentrations between 0.01 and 17 ppma. The SSMS concentrations are on the average about six times lower than equivalent Hall-effect concentrations. A comparison between two labs of equivalent silicon samples analyzed by SSMS for boron is provided in Fig. 4. The ratio of the concentrations reported by the two labs ranges from 0.07 to 3 for boron concentrations in the range of 0.4 to 8 ppma, as determined from resistivity measurements on single-crystal samples.

Similar comparisons are made for phosphorus analyses. The ratio of concentrations determined by the Hall-effect and SSMS methods are given in Fig. 5 for a relatively small range of phosphorus concentrations (1-6 ppma). The SSMS values are on the average three times lower than the Hall-effect concentrations, which agree with resistivity measurements. A comparison of determinations made by different labs on seven equivalent, phosphorus-doped samples gave a ratio of their concentrations that ranged from 0.5 to 20. These samples covered phosphorus levels from 1 to 30 ppma (Fig. 6).

SSMS has adequate sensitivity for measuring boron and phosphorus concentrations in silicon for solar cell applications. However, the method appears to have neither sufficient accuracy nor precision.

Emission spectroscopy (ES).—In the early stages of many research and development programs, emission spectroscopy has been used to analyze silicon because it is a widely available service that provides a fast multielement scan at reasonable cost. The method is capable of providing reliable data concerning order-of-magnitude changes in concentrations; it can be misleading for determination of smaller changes in impurity levels. ES data have been reported on the repeated analy-

Fig. 3. Ratio of boron concentrations measured by Hall-effect and SSMS.

Fig. 4. Ratio of boron concentrations measured at two laboratories using SSMS.

Fig. 6. Ratio of phosphorus concentrations measured at two laboratories using SSMS.

sis of a powdered MG-Si sample that was used as a standard by which to compare other ES analyses of purified MG-Si (7). The data, summarized in Fig. 7 for 37 analyses, show the concentration of boron to range from 23 to 240 ppma. The mean concentration of 96 ppma has a standard deviation of ± 61 ppma. This one-sigma value statistically implies that any given analysis has a 68% chance of falling within the range of 96 ± 61 ppma. For more exact work, the two-sigma standard deviation (95% probability) puts the mean boron concentration at 96 ± 121 ppma, indicating that any measured boron concentration has a greater than 100% error associated with it. For an impurity as important as boron, this error size is unacceptable. In addition, the lower limit of detection of about 3-30 ppma boron in silicon is not low enough for the 0.1-1 ppma upper concentration levels allowable for SoG-Si.

Fig. 7. Multiple ES analyses of boron in a standard MG-Si sample

Phosphorus cannot be determined by ES at concentrations less than about 1000 ppma. The values reported by most analytical labs involve use of a separate spectrophotometric measurement of the blue phosphomolybdate complex. Multiple analyses of the powdered MG-Si standard (7) using this method are summarized in Fig. 8. The mean is 42 ± 26 ppma for values that ranged from 2 to 140 ppma. This spectrophotometric method is neither sensitive nor accurate enough to be used for phosphorus determination in silicon intended for photovoltaic applications.

Other methods.—Boron determination in silicon down to 0.1 ppma has been reported using inductively coupled plasma emission spectroscopy (ICP-ES) (8). In order to reach this low level, silicon must be volatilized from the dissolved sample. This requires special chemical treatment to prevent boron loss from the sample along with the silicon. X-ray fluorescence spectrometry (XRFS) cannot be used to determine boron because of its low atomic number.

Preliminary analyses of silicon for phosphorus using ICP-ES showed a detection limit of about 0.1 ppma. However, sufficient data were not available to draw firm conclusions. Further work on this technique is warranted. XRFS, which can measure phosphorus concentrations down to about 10 ppma, is insufficient for solar silicon needs.

Aluminum, Iron, and Other Metals

As mentioned earlier, Al and Fe differ from the other metal impurities because of their much higher concentrations in PMS. Titanium is used below as a representative of the other lower concentration metal impurities.

The overall analytical picture for metal impurities is similar to that for B and P. Emission spectroscopy has a detection limit of about 10 ppmw and also has a large er-

Fig. 8. Multiple ES analyses of phosphorus in a standard MG-Si sample.

Fig. 9. Multiple ES analyses of aluminum in a standard MG-Si sample

ror associated with each analysis. Analyses of the MG-Si standard, described in the previous section, are shown in Fig. 9 for aluminum (7). Measured concentrations ranged from 1700 to 9100 ppmw with a mean and one standard deviation of 4300 ± 1900 ppmw. Equivalent data for iron were 8100 ± 2500 over a range of 5,000 to 15,000 ppmw (0.5%-1.5%); and for titanium, 440 ± 210 ppmw over a range of 40 to 1300 ppmw.

XRFS has not been investigated in as much detail, but the method is expected to give detection limits similar to that of ES.

Metal concentrations in various grades of silicon were analyzed using SSMS by two service laboratories. The results are summarized in Table II. The ratio of a concentration reported by Lab 1 to that reported by Lab 2 varied by as much as a factor of ten. In the case of titanium, Lab 1 provided a detection limit in the sub-ppmw range. However, it is pointed out that this sensitivity level was achieved under research and development-type conditions, as opposed to commercial-laboratory conditions, as indicated by equivalent Lab 2 data. In any case, titanium and other metal impurities were below the detection limit of SSMS performed at both laboratories. In summary, SSMS is adequate for indicating the general level of metal concentrations in PMS. It can also be used to check for possible metal contamination in SoG-Si, but cannot absolutely measure the very low level of metal concentrations that can affect solar cell efficiency (9).

The analyses in Table II show Al and Fe concentrations of 1-10 ppmw in wafers cut from ingots grown from MG-Si under different crystal-growth conditions. These concentrations are, at first glance, much higher than would be expected since segregation of Al and Fe is very effective during crystal growth. These concentrations have been confirmed using ICP-ES. Ward has reported up to almost 1 ppmw Fe as FeSi_2 precipitates in Czochralski wafers used in device production (10). The source of such iron is uncertain, as is also the case for aluminum. Since iron at the 1 ppmw level would severely degrade solar cell efficiency, the absence of degradation suggests that iron must be effectively removed in get-

Table II. Comparison of SSMS analyses from two laboratories

tering steps during solar cell processing. Further work is required to elucidate this problem.

ICP-ES has been used to determine metal concentrations at levels around the 0.1 ppmw level. The real capabilities of the technique remain to be established.

Nonmetals

Carbon and oxygen.—The same infrared technique used to measure C and O concentrations in SeG-Si can also be used for analyzing various grades of recrystallized PMS. A limitation exists for solar grades of silicon since silicon becomes opaque to infrared radiation when the boron concentration in it exceeds about 3–4 ppma.

Fourier transform infrared (FTIR) spectroscopy was used at room temperature to compare the C and O levels in PMS and SeG-Si recrystallized using Czochralski, Bridgman, and float zoning methods (11). Most of the data compared in Table III are averages from between 10 to 30 analyses of wafers cut from ingots; only limited data were available from Bridgman samples. When SeG-Si was the starting material, carbon levels were < 1 ppma. Oxygen concentrations were about 10 ppma in samples grown from crucibles, and < 1 ppma for float-zoned material. When PMS was the starting material, oxygen concentrations were again about 10 ppma because of the crucible, which contained the silicon during crystal growth. The complex topic of precipitated oxygen is purposely not dealt with in this paper. Carbon levels were about 15 ppma in once-crystallized ingots, and about 2 ppma in twice-crystallized Czochralski material, as would be predicted from carbon's segregation coefficient of 0.07. Carbon concentrations are higher in ingots from PMS than SeG-Si since PMS comes directly from a carbothermic reduction process.

Carbon cannot be determined in pure silicon using combustion techniques in the manner that they are usually practiced for other materials. These methods involve burning of a sample to form CO₂, which is measured in various ways in different equipment. Although the techniques are used to determine carbon in silicon alloys of lower silicon content, some unidentified problem, e.g., incomplete combustion, results in erratic results for high silicon alloys. Table IV summarizes data for carbon determinations carried out by five different laboratories using the Leco and Richard Steeps combustion methods (12). Analyses were performed on polycrystalline SeG-Si that had a supplier specification of < 0.3 ppma via FTIR. The combustion analyses indicated concentrations in excess of 100 ppma.

As a rule of thumb, the saturation solubility of carbon in silicon is about 10 ppma, and approximately an additional 10 ppma can be present under conditions of super-

saturation. Carbon concentrations in excess of about 20 ppma will precipitate as silicon carbide.

Silicon carbide.—Microscopic observation appears to be the only means to measure the content of SiC in silicon. Three methods have been used: counting of particles (i) on a filter paper through which a dissolved silicon sample has been passed, (ii) on a polished silicon surface, and (iii) within the volume of a silicon slab. Particle size and number are used to calculate SiC concentration.

1g samples of MG-Si and PMS were dissolved in boiling 3N NaOH and filtered through 0.6 μm paper (13). Silicon that had been fast cooled, after being tapped from an arc furnace, contained about 350 particles which showed a sharp size distribution centered around an average "diameter" of 4 μm. Nearly all particles were < 10 μm in size.

Polished samples of PMS and MG-Si, and of their directionally solidified ingots, were analyzed for SiC by microscopically counting the particles intersecting the surface (14). The method has a resolution of 0.5 μm and a sensitivity of 400 particles per 100 cm². Analyses of PMS and various sources of MG-Si showed SiC concentrations between 110 and 270 ppmw.

Infrared microscopy has a lower resolution (10 μm) than the optical method because of the limited depth of focus at higher magnification. However, the IR method allows the volume of samples to be surveyed, thereby eliminating the uncertainty that particles might not intersect a surface. This volume probe increases the sensitivity to five particles in a 500 μm thick, 100 cm² wafer. Twice-crystallized ingots grown by the Czochralski method contain no detectable SiC particles. Since SiC particles grow in size when silicon is molten, the 10 μm resolution of the IR microscope does not appear to be a limitation. As the size of any particles decrease, their number has to increase enormously to represent a significant weight fraction. Therefore, the concentration of SiC in once- or twice-crystallized Si is estimated to be << 1 ppmw. However, their effect on solar cell performance still needs to be explored.

Conclusions

The doping impurities boron and phosphorus can be simultaneously measured either by the float-zone/resistivity or the Czochralski/Hall-effect methods. Both methods give concentrations with adequate accuracy and precision. Other analytical methods have proved inadequate for determining either of these impurities. An exception is ICP-ES, which is sensitive enough for boron but which must be further investigated for phosphorus.

Metal impurities can be measured in PMS using either ES, XRFs, SSMS, or ICP-ES. All of the methods are semiquantitative in that they yield concentrations reliable within about a factor of two. This degree of reliability is good enough, however, to make adequate decisions concerning PMS quality for either research and development or production purposes.

Only SSMS, and perhaps ICP-ES, has adequate sensitivity to determine whether SoG-Si is pure enough with respect to metal impurities for use in manufacture of solar cells having acceptable efficiencies. If the SoG-Si is pure enough, neither method is sensitive enough to monitor such concentrations. However, the techniques can provide a means to test SoG-Si for inadvertent contamination.

The nonmetals, O, C, and SiC, can be measured by conventional methods. FTIR is adequate for determining both O and C. Laborious methods involving microscopic counting are sufficient for measuring the concentration of SiC, if necessary.

As the solar silicon industry grows, quality assurance of silicon could probably be met to a large extent by developing a strong capability of ICP-ES. With reasonable success, this method might be adequate for determining B and P concentrations in addition to metal concentrations, thereby simplifying the variety of techniques and associated equipment required. The Czochralski/Hall-effect

method appears to be the simplest and most reliable way to measure B and P concentrations in the mean time. Both C and O can be easily measured using FTIR. Various microscopic techniques would allow the determination of SiC, as well as the general defect structures that are always a problem in silicon.

ABSTRACT

The far-infrared (FIR) transmission properties and index of refraction of thick ($\sim 2000 \text{ \AA}$) vitreous germanium oxide films on single-crystal germanium have been measured before and after high temperature reaction with flowing ammonia gas. Significant shifts in the transmission spectra were observed as a function of both time at temperature and NH_3 flow rate. Correlation was observed with transmission minima reported in the literature for fine powders of germanium nitride and for thin ($<1000 \text{ \AA}$) layers of ion-implanted and annealed germanium/oxygen and germanium/nitrogen complexes. In addition, when the nitrided films were reoxidized at high pressure, structure was observed which corresponded to FIR transmission of hexagonal-phase GeO_2 powder specimens.

Insulating layers on semiconductor surfaces are an essential part of the current technology in planar devices and particularly in the metal-insulator-semiconductor structure often used to construct the basic unit (FET) of VLSI circuits. Oxides and nitrides of silicon can be formed directly on silicon single-crystal surfaces by thermal reaction with gases. However, other semiconductors of interest do not react as readily to form uniform layers of "native" insulators. Other means of formation, such as sputtering, evaporation, wet chemistry, etc., have been used, but these techniques generally lead to undesirable electrical properties at the interface between the in-

Key words: germanium, germanium insulator, germanium oxides, germanium nitrides, far-infrared transmission.

ulator and the substrate, even on silicon. Compared to silicon, electron and hole mobilities are more nearly the same, and higher in absolute value in germanium. Because of this, germanium has been suggested as an attractive candidate for low temperature CMOS elements (1). Recently, Hua *et al.* (2) have explored the possibility of forming nitrides on germanium by thermal reaction with ammonia/nitrogen mixtures. They observed that very thin films of oxynitride were formed with a 2.5:1 nitrogen-to-oxygen ratio. Further studies by Rosenberg (3) have indicated that an initial partial pressure of oxygen in the reaction chamber was a necessary condition for the reaction to occur between germanium and ammonia in a uniform manner over the surface. In those two stud-

ies, it was concluded that this procedure limited film thickness to the order of 100Å because of the barrier to oxygen and nitrogen diffusion presented by the uniform nitride (or oxynitride) layer that subsequently formed. In the studies reported here, a relatively thick (~2000Å) oxide layer on germanium was used as the starting point for high temperature reaction with ammonia gas. Displacement of the oxygen by nitrogen during the thermal reaction was monitored by means of infrared transmission in the 8-40 μm range. The extinguishing and developing of well-defined absorption maxima were compared to published data and to FIR transmission of pressed powder specimens of Ge₃N₄ and GeO/GeO₂.

Experimental

Specimens were prepared from a single wafer of (111) p-type germanium of 0.1 Ω-cm resistivity. The wafer was first given an organic contamination cleaning in hot trichloroethylene, hot acetone, hot methanol, hot deionized H₂O, 48% HF acid dip (30s), and final deionized H₂O rinse with zero-grade nitrogen blow dry. This was followed by a 30s etch in CP-4, another DI H₂O rinse, and nitrogen blow dry. Approximately 30% of the wafer was removed during the CP-4 etch leaving a surface that had a slight "orange peel" look and a final wafer thickness of 8.8 mil. Infrared transmission was then measured on the wafer in the 8-40 μm wavelength range via a Perkin Elmer Model 580 infrared spectrometer. At 8 μm, transmission was found to be on the order of 47%, which is approximately the value for germanium infrared optical components prepared commercially. The wafer was then scribed into several pieces and placed in a high pressure chamber used for oxide formation (4). An oxidation treatment of the specimens was performed in which the chamber was brought to 650°C at a pressure of 340 atm for 10 min with hydrocarbon-free, zero-grade oxygen. Upon removal from the pressure vessel, ellipsometry measurements (Rudolph Research Auto EL-II ellipsometer) disclosed, in general, that the layer formed had an index of refraction of 1.55-1.85 and a thickness on the order of 2200Å, with variations depending on the position of the particular piece in the pressure chamber. Previous studies of high pressure oxidation of germanium typically resulted in index of refraction values that were greater than the 1.6 usually reported in the literature (4). Individual pieces of the original specimen were then subjected to various schedules of temperature and time in flowing electronic grade H₂(5%)/N₂ and NH₃ gases in a silica-lined, 1 cm diam tube furnace. For those processings, the specimen was loaded into the center of the tube furnace on an alumina pallet. The system was then flushed for 0.5h at room temperature with zero-grade H₂/N₂ mixture supplied through clean fluorocarbon tubing. The outlet end of the furnace tube was sealed against ambient atmosphere backstreaming by connection, via fluorocarbon tubing, to a bubbler containing Dow 704 diffusion pump oil. For runs in which ammonia was used, an additional flush of NH₃ for 0.5h at about 250 sccm was used before commencing furnace heating. The volume of the furnace tube was approximately 50 cm³. The furnace was heated to the operating temperature at a rate of about 50C°/min, and cooled somewhat faster - about 100C°/min, by opening the halves of the split-tube furnace. Long-term cooling with the furnace closed (~3h) gave films that appeared identical to those that were rapidly cooled. In all cases, gas flow was maintained until the furnace tube temperature was <200°C.

After each run, the transmission and the index of refraction of the specimen were remeasured. Optical inspection of the surface was also performed with a Lietz Orthoplane metallurgical microscope equipped with a Nomarski interference contrast attachment.

Analyzed powders of GeO, GeO₂, and Ge₃N₄ were obtained from CERAC/PURE, Incorporated, and pressed with KBr into standard transmission disks in a metallurgical mounting press (at 20,000 psi) in a ratio of about 5 mg of specimen powder per gram of KBr. X-ray diffrac-

tion pattern measurements confirmed that the GeO₂ powder was predominately hexagonal crystalline in nature, and the Ge₃N₄ specimen was approximately a 20/80 ratio of the α/β-nitride. Infrared transmissions of the pressed powder specimens were normalized with a KBr blank disk in the reference beam. FIR transmission traces were made on the pressed powder specimens for comparison with the single-crystal germanium oxide and oxynitride films of this report.

Results

The transmissions of the cleaned and etched germanium wafer, and a piece of that same wafer after high pressure oxidation, are presented as traces 1 and 2 in Fig. 1. The structure between 25 and 40 μm is due to the Ge-Ge stretching vibrations. The spike at 15 μm is artificial and is caused by a filter change in the spectrometer. The relatively thin (~225 μm) specimen results in some surface to surface interference fringe resonances which are enhanced by the presence of the native oxide on the two specimen surfaces as shown in trace 2 of the figure. That trace is typical of the transmission measured on thick oxides formed by high pressure on (111) germanium. The index of refraction of this particular specimen was 1.70-1.81, as measured at various points on the surface. A broad shoulder from 9 to 11 μm (1100-950 cm⁻¹) and two minima at 11.5 μm (860 cm⁻¹) and 18 μm (570 cm⁻¹) are coincident with the structure reported in the literature for germania. The general shape of trace 2 corresponds well to that observed by Boal *et al.* (5) for thermally grown thick (~3800Å) silica films on single-crystal (111) silicon wafers, and the location of the two minima are coincident with those reported by Stein (6) for ion-implanted oxygen in single-crystal germanium (orientation unspecified) and by Murphy and Kirby for vitreous germania powder (7). This suggests that the GeO_x grown by high pressure oxidation are more nearly amorphous than crystalline at least on (111) surfaces.

When, as in Fig. 1, trace 3, the germanium oxide is exposed to flowing (180 sccm) NH₃ at 650°C, a finite broadening is observed to occur in the 860 cm⁻¹ minimum. The change in shape was observed after 0.5h and remained unchanged thereafter. Trace 3 of Fig. 1 shows the typical

Fig. 1. Nitridation of germanium oxide film. Traces (3), (4), (5), and (6): under condition of "high" ammonia flow. Reference traces: (1) bare germanium crystal after etching and, (2) same specimen as (1) after high pressure oxidation at 340 atm at 550°C for 10 min. Specimen no. GEN-30707c.

transmission waveform after 9.5h at 650°C. Essentially the same shape was obtained after 1h at 600°C with no further change for longer times at temperature. Upon increasing the temperature to 700°C, further change in the shape of the original oxide minimum centered at 860 cm^{-1} was observed, as shown in successive traces 4, 5, and 6 of Fig. 1. There, remnants of the broad, short wavelength shoulder and minimum of the characteristic oxide absorption band are still evident, but a definite shift is observed toward longer wavelength, with a new minimum evident in the vicinity of 720 cm^{-1} . It should be noted that the curves here have been offset along the ordinate axis for clarity. The actual transmissions at 8 μm (left-hand margin) of traces 1 through 4 were $\sim 46\%$, for trace 5, 39.5%, and for trace 6, 5.5%.

Noticeably different results were obtained when the experiment was repeated at a much lower ammonia flow rate of 3.5 sccm (about one chamber volume change every 14 min vs. about 4 changes per min in the first series). As shown in Fig. 2, a minimum of 730 cm^{-1} developed within the first hour and continued to increase with time at temperature. By 12h total time, a second well-defined minimum could be observed at 775 cm^{-1} , and, finally, by 20h, yet another minimum was observed at 910 cm^{-1} . Remnants of the 860 cm^{-1} oxide peak could still be detected after 29.5h at 700°C. In addition, no significant change was observed in the rather broad minimum at 570 cm^{-1} , which has been reported by others as being related to the germanium oxide absorption (7, 8). In comparison, treatment by $\text{H}_2(5\%)/\text{N}_2$ had no effect on the germania layers other than to enhance the rate of reduction/decomposition at temperatures above about 550°C. For example, at 600°C, repeated thermal treatments in H_2/N_2 at flows on the order of 100 sccm resulted only in a reduced depth of the transmission minimum at 860 cm^{-1} . Six hours in the H_2/N_2 mixture at 600°C was sufficient to completely remove the transmission minima at 860 and 570 cm^{-1} .

Trace 1 of Fig. 3 shows the specimen of Fig. 2 after a final (29.5h total) $\text{NH}_3/700^\circ\text{C}$ treatment in the low flow condition. Note that all of the minima mentioned above are still apparent in that trace as well. In trace 2 of Fig. 3, the results of a 15 min rinse in 25°C deionized H_2O is shown. The major change from the trace above is the further reduction of the oxide associated minimum at 860 cm^{-1} . When the same specimen was subsequently re-

Fig. 2. Nitridation of germanium oxide film under condition of "low" ammonia flow. Specimen no. GEN-30707e.

Fig. 3. Effect of high pressure reoxidation of ammonia-treated film. (1): After 1770 min in NH_3 at 700°C and 180 sccm flow. (2): Specimen as in trace (1), plus 15 min in 25°C deionized H_2O . (3): Specimen as in trace (2) plus 10 min of 650°C in oxygen, 340 atm. Specimen no. GEN-30707e.

exposed to oxygen at high pressure, the transmission measurements (trace 3, Fig. 3) disclosed that the oxide layer had regrown at the expense, at least in part, of the nitride or oxynitride. In addition, the dominant 860 cm^{-1} absorption is narrower, the subsidiary oxide associated minimum near 570 cm^{-1} had developed noticeable structure, and a new shorter wavelength minimum near 960 cm^{-1} can also be seen. Some of this structure has been subsequently observed in (100) specimens reacted with oxygen at high pressure for a longer time and is quite similar to hexagonal crystalline GeO_2 powders reported in the literature (7, 8).

Discussion

The nitrides of germanium appear to be polymorphic compositions of Ge_3N_4 . Ruddleston and Popper (9), in detailed powder x-ray diffraction studies, have essentially established that germanium nitrides are isomorphous with silicon nitrides. As with $\beta\text{-Si}_3\text{N}_4$, $\beta\text{-Ge}_3\text{N}_4$ is more readily formed from the reaction of the oxide with ammonia rather than by direct chemical combination of nitrogen with elemental germanium (9-12). Also, the α -phase of Ge_3N_4 appears, as with $\alpha\text{-Si}_3\text{N}_4$ (13), to form by condensation from the gaseous state whereas the β -phase develops within the condensed germanium oxide surface. This conclusion is supported in these studies as well. Microscopic examination of the surfaces after various temperature/time/flow treatments show the development of two distinctly different solids: one of hair-like fibers extending out of the plane of the surface, and the other a petal-like structure which develops and spreads in the plane of the oxide. In general, the fibrous material emanates from thermal etch pits; these are usually characteristic of preferential volatilization (14). Also, the number and length of the fibers are noticeably greater in the low NH_3 flow experiments, which is consistent with the concept that they grow by vapor deposition and are swept away at high flow conditions. Rosenberg (3) has also observed that a uniform film grows rapidly on the surface of germanium in an ammonia atmosphere followed by anisotropic vapor etching initiated at points on the surface where there were film discontinuities.

The initial reaction at 600°-650°C between NH_3 and the oxide is attributed to free or incompletely bonded germanium within the oxide layer. This conclusion would also explain the large variations in index observed on the oxidized layer before nitridation. Similar broadening was not observed when a N_2/H_2 mixture was used instead of NH_3 , indicating the necessity of having some atomic nitrogen present to promote the reaction. The inactivity of molecular nitrogen with germanium has been documented by others for conditions where relatively low temperatures are maintained - usually <700°C (12, 15). The 775 cm^{-1} minimum that develops in the sequence of Fig. 1 we attribute to the predominance of $\beta\text{-Ge}_3\text{N}_4$. Further evidence of this relationship was obtained by comparison with a transmission trace of commercially prepared $\beta\text{-Ge}_3\text{N}_4$ powder (trace 3 of Fig. 4) that was verified by x-ray diffraction to contain ~20% α -nitride. The minimum of the pressed powder specimen was also observed to be at 775 cm^{-1} . The reduction and shift of transmission observed in trace 6 of Fig. 1 corresponded to an extremely disturbed surface on the side of the specimen that was in contact with the alumina pallet on which the wafer was resting. We believe that buildup of α -phase nitride occurred in the stagnant space between the specimen and the pallet, resulting in the domination of 730 cm^{-1} α -nitride absorption, and that vaporization and redeposition of that phase contributed to increased surface scattering, thereby reducing the total transmission substantially over the span of the trace. The index of refraction for this specimen increased from 1.7-1.8 to 2.0-2.3 after the first 700°C treatment, and thereafter remained, on average, at 2.1. Index values could not be obtained on the "bottom" side due to decreased reflection. The final thickness of the layers were estimated by ellipsometry to be 1800 \AA , which is somewhat thinner than the original 2200 \AA oxide layer. This also supports the conclusion that

at high flow the α -phase is swept away by the gas. The specimen used to generate Fig. 2 was from the same wafer as that for Fig. 1 and had essentially the same transmission curve for the bare surface, high pressure-oxidized surface and the 650°C nitrided surface as given in Fig. 1. The Fig. 2 specimen was propped away from the pallet with a silica spacer so that NH_3 flow could proceed equally on both sides. After 4h (trace 2), distinct minima could be observed at 730 and 775 cm^{-1} , and they remained established throughout the subsequent treatment. In addition to these two and the remnant of the oxide (860 cm^{-1}) minimum, another is also observed at 910 cm^{-1} . The 910 cm^{-1} minimum was also observed in the transmission measurement of the $\beta\text{-Ge}_3\text{N}_4$ pressed powder (trace 3 of Fig. 4). Microscopic examination of both surfaces disclosed significantly more of the fibrous material on the surface of this specimen than on the specimen of Fig. 1. Reaction of germanium dioxide powder with flowing ammonia at 800°C shows only one minimum near 800 cm^{-1} , as reported by Elliott and Thompson (16). We conclude then that the 730 cm^{-1} minimum is associated with the α -phase nitride, and the 775 cm^{-1} minimum is associated with the β -phase. Similar two-phase growth (17) and transmission structure (16) has been observed for silicon nitride. Fine structure of this order of resolution has been observed for silicon nitride thin films (18), which had the same general form that we report here. More recently, high resolution transmission spectroscopy has demonstrated that still further substructure can be resolved (19). The index of refraction of the specimen of Fig. 2 was 1.65 after oxidation and 2.35 after 20h of NH_3 treatment. During the interim steps of nitridation, the ellipsometry values would not converge consistently to an index value, indicating possibly multiple layer or oxide/nitride phase mixing during the transition. The final thickness after 20h of nitridation was on the order of 2600 \AA .

When the specimens of Fig. 1 and 2 were reoxidized at the same conditions as in the original process (650°C/340 atm), decidedly different characteristics were observed in the subsequent transmission curves: compare Fig. 3, trace 3, with Fig. 1, trace 2. While the oxide had redeveloped at the expense of the nitride, the minimum at 860 cm^{-1} is noticeably narrower. In addition, structure is observed in the 570 cm^{-1} oxide minimum, and a new peak is observed at about 960 cm^{-1} . These general features are also observed in the pressed powder transmission of GeO_2 shown as trace 1 of Fig. 4 and in Ref. (7) for hexagonal GeO_2 . Oxidation of the nitrided layer appears to have a crystalline character rather than an amorphous one, as was observed for the bare surface germanium oxidation.

Conclusions

Thick films, with FIR structures characteristic of germanium nitride, have been produced on germanium crystal surfaces by reacting ammonia with thick germanium oxide layers. The development of specific and nonshifting FIR transmission structure suggests that definite changes in amounts of the phases occur rather than a continuous variation of solid solution Ge-O-N components. The relative amounts of α -like and β -like material remaining on the surface can be controlled to some extent by varying the flow of the ambient gas. Infrared transmission measurements can identify the presence of either (or both) phase on the crystal surface where the minimum at 775 cm^{-1} correlates with the β -phase and the 730 cm^{-1} minimum correlates with the α -phase.

When the nitrided layers are reoxidized at high pressure, the oxide formed at the expense of the nitrogen bearing layer has narrower transmission and fine structure, indicating that a crystalline oxide develops following the pattern established by the nitrided structure.

ABSTRACT

The amount of electrically active boron which is incorporated during the CVD of silicon using SiH₄ in H₂ at atmospheric pressure and B₂H₆ as dopant appears to be very sensitive to the input pressure of HCl and the presence of small amounts of water. Equilibrium gas-phase compositions have been calculated for this system using an iterative procedure. Assuming thermodynamic equilibrium between gas phase and solid phase, the experimentally observed dependences can be satisfactorily described. Based on these calculations also, an explanation can be given for the unexpected experimental results on boron autodoping.

Some years ago, a number of investigations were done on the kinetics (1-4) and thermodynamics (4-11) of the incorporation of dopant elements during growth of silicon from the vapor phase. Later on, Kühne (12) gave a theoretical consideration about the incorporation process. Recent papers of Reif (13) treat the respective role of kinetics and thermodynamics in doping processes with emphasis on transient effects.

Consideration of the equilibrium composition of the gas phase above the growing silicon layer turned out (10) to be useful in the interpretation of the observed dependence of the concentration of built-in phosphorus on the input partial pressure of the dopant compound. The implicit assumption made is that the growth rate is so low that the dopant compounds in the gas phase just above the growing layer are in thermodynamic equilibrium with the solid, such that the incorporation process is dominated by thermodynamics.

In this paper, an effort will be made to describe semi-quantitatively the incorporation of boron during the chemical vapor deposition (CVD) of silicon in the presence of hydrogen chloride and small amounts of water by considering the composition of the gas phase. Experimentally, a rather strong dependence has been observed by Bloem (14) in a region where the amount of boron which is incorporated does not depend on the silicon growth rate.

Key words: silicon, boron dope, CVD, gas-phase equilibrium, autodoping.

Calculation of the Equilibrium Composition

Use has been made of the computer program ECCVD-MAL (15), which calculates the equilibrium partial pressures of the various components by means of an iterative procedure. The B-H-Si, B-H-Si-Cl, B-H-Si-O, and B-H-Si-Cl-O systems contain 15, 30, 36, and 57 components, respectively. The thermodynamic data have been collected from Ref. (16). In each calculation, solid Si(s) has been assumed to be in equilibrium with the gas mixture, whereas always the presence of solid B(s) as a condensed phase has been taken as a possibility. Although boron silicides are known to exist (8, 17), unfortunately no reliable thermodynamic data concerning these compounds could be found. When oxygen is present SiO₂(s) has also been taken as a possible condensed phase, although it is known (18) that SiO₂(s) formation at 1400 K will only occur above 40 ppm of water, while at 1500 K more than 200 ppm is needed to precipitate solid SiO₂. Also, some of the B₂H₆O₂ compounds can be responsible for the formation of a condensed phase. The saturation

Table I. Saturation pressures at T = 1500 K for various B and O containing compounds

Compound	MP (K)	BP (K)	log P _{sat}	Ref.
B ₂ O ₃ (l)	723	2316	-4.633	(16)
BH ₃ O ₂ (s)	509	—	0.802	(16)
BH ₃ O ₃ (s)	444	573	5.906	(16)
B ₂ H ₄ O ₄ (s)	Unknown	—	6.117	(16)
B ₃ H ₃ O ₃ (s)	Unknown	—	3.958	(16)

pressures for these compounds, as far as they are known, are collected in Table I. From this table it can be seen that only $B_2O_3(l)$ can be envisaged as a likely additional condensed compound. Because of program limitations, only the condensed phases $Si(s)$, $B(s)$, and $SiO_2(s)$ were taken into account in the computer program. However, afterwards, a check was always done to see if one of the critical saturation values for the $B_xH_yO_z$ compounds had been surpassed.

Results and Discussion

For the sake of completeness and simplicity, first the equilibrium composition of the B-H-Si system and the B-H-Si-Cl system will be treated. Then the influence of H_2O will be investigated in the B-H-Si-O system and B-H-Si-Cl-O system, respectively.

B-H-Si system.—Figure 1 gives the calculated partial pressures of the various components in the equilibrium mixture consisting of the elements silicon, hydrogen, and boron (e.g., for an input gas which is a mixture of SiH_4 , H_2 , and B_2H_6) as a function of the input pressure of diborane ($P_{B_2H_6}^0$) at a temperature of 1500 K and for a total pressure of 1 atm. It can be seen from Fig. 1 that the slope of $\log P_{B_xH_y}$ vs. $\log P_{B_2H_6}^0$ equals p . It can also be seen from Fig. 1 that above $P_{B_2H_6}^0 = 10^{-5}$ atm the partial pressure of $B(g)$ attains the saturation pressure of $B(s)$, whereupon solid B is formed. This fixes the partial pressures of all B containing compounds.

Further, it is clear that BH_2 and BH_3 are the most abundant B containing compounds, also at high diborane input partial pressures. This is in contrast to the case of phosphorus dope, where at increasing phosphine input partial pressures the most abundant P containing compounds change from PH_2 and PH_3 to P_2 (10).

The simplest model of boron incorporation in the growing layer considers the incorporation of monatomic boron from the gas phase. According to this model, the B containing compounds with the highest partial pressures are thought to dissociate at high temperature into monatomic boron, which will adsorb at the Si surface and finally will be incorporated at a substitutional silicon site in the crystal. Thereupon B_{Si} dissociates into B_{-Si}^- and p (hole).

The foregoing can be summarized in the following equations

This, together with the condition

$$2P_{B_2H_6}^0 = \sum_{x,y} x P_{B_xH_y}$$

or, approximately (see Fig. 1)

$$2P_{B_2H_6}^0 = P_{BH_2} + P_{BH_3}$$

(and the assumption that the doped-silicon layer at the growth temperature behaves as an intrinsic semiconductor, i.e., $n = p = K_1^{1/2}$) leads to

$$[B_{-Si}^-] = \frac{K_{ad}K_{segr.}K_{ion}}{K_1^{1/2}} \cdot \frac{2P_{B_2H_6}^0}{\frac{P_{H_2}}{K_1} + \frac{P_{H_2}^{3/2}}{K_2}} \quad [1]$$

$[B_{-Si}^-]$ can be determined by means of resistivity measurements at room temperature, which essentially gives a hole concentration equal to $[B_{-Si}^-]_{high\ temp.}$ According to this equation, a plot of $\log [B_{-Si}^-]$ vs. $\log P_{B_2H_6}^0$ for $P_{B_2H_6}^0$ lower than 10^{-5} atm would yield a straight line with slope 1.

Fig. 1. Calculated equilibrium composition of the B-H-Si system as a function of the input partial pressure of diborane $P_{B_2H_6}^0$ ($P_{SiH_4}^0 = 10^{-3}$ atm, $P_{tot} = 1$ atm, $T = 1500$ K).

Above $P_{B_2H_6}^0 \approx 10^{-5}$ atm, the amount of B-containing compounds in the gas phase remains constant, and a constant amount of incorporated boron can be expected above this value.

B-H-Si-Cl system.—The calculated gas-phase composition of the B-H-Si-Cl system (e.g., for an input gas which is a mixture of $SiCl_4$, H_2 , and B_2H_6) is given in Fig. 2 as a function of the input pressure of diborane ($P_{B_2H_6}^0$) at a temperature of 1500 K and a total pressure of 1 atm. Here too, for low input partial pressures of diborane, a plot of $\log P_{B_xH_yCl_z}$ vs. $\log P_{B_2H_6}^0$ yields a straight line with slope p . The higher value of $P_{B_2H_6}^0$ ($\approx 10^{-4}$ atm), which is needed to condense $B(s)$ as compared with the B-H-Si system, can be ascribed to the fact that boron now also forms gaseous compounds with chlorine.

In a similar way as for the B-H-Si system, the incorporation of boron in the silicon matrix can be described by decomposition reactions for the most abundant B containing species which are present in the gas phase. (With respect to the B-H-Si system, only the new reactions are given)

Together with the condition

$$2P_{B_2H_6}^0 = P_{BH_2} + P_{BH_3} + P_{BCl} + P_{BCl_2} + P_{BCl_3} + P_{BHCl_2}$$

and the assumption that at the growth temperature $n = p = K_1^{1/2}$, it follows

$$[B^-_{Si}] = \frac{K_{ad}K_{segr}K_{ion}}{K_1^{1/2}} \times \frac{2P^{\circ}_{B_2H_6}}{\left(\frac{P_{H_2}}{K_1} + \frac{P_{H_2}^{3/2}}{K_2} + \frac{P_{HCl}}{K_3 P_{H_2}^{1/2}} + \frac{P_{HCl}^2}{K_4 \cdot P_{H_2}} + \frac{P_{HCl}^3}{K_5 \cdot P_{H_2}^{3/2}} + \frac{P_{HCl}^2}{K_6 \cdot P_{H_2}^{1/2}} \right)} \quad [2]$$

According to Eq. [2], a plot of $\log [B^-_{Si}]$ vs. $\log P^{\circ}_{B_2H_6}$ yields a straight line with slope 1 for low input pressures of diborane, as has been experimentally found by Rai-Choudhury [(8) and Fig. 3 thereafter]. It is obvious that at the input pressure of diborane where according to the calculations in Fig. 2 B(s) is present as a condensed phase, and in the experimental curve of Fig. 3, a deviation from linearity appears. On account of electron diffraction measurements, Rai-Choudhury argues (8) that this is due to the formation of $SiB_4(s)$. Although, however, this cannot be predicted from the calculations because of a lack of thermodynamic data for $SiB_4(s)$, this compound could be formed from a reaction between Si(s) and B(s), which gives a simple explanation for the fixed partial pressures of the boron compounds. The observed decrease of boron content in the silicon layer for diborane input pressures exceeding 10^{-4} atm (see Fig. 3) can be explained by assuming gas phase nucleation of B(s), which decreases the amount of B(g) for doping.

B-H-Si-O system.—From the calculation of the equilibrium composition of the B-H-Si-O system (e.g., the input gas is a mixture of SiH_4 , H_2 , B_2H_6 , and H_2O), it follows that BH_2 , BH_3 , BO , BHO , and BHO_2 are the most abundant B containing species. Again, a plot of $\log P_{B_2H_6}$ vs. $\log P^{\circ}_{B_2H_6}$ yields a straight line with slope p (Fig. 4).

The decomposition reactions, taking place at the growing silicon layer, are then (omitting the already cited reactions)

Together with the condition

$$2P^{\circ}_{B_2H_6} = P_{BH_2} + P_{BH_3} + P_{BO} + P_{BHO} + P_{BHO_2}$$

and the assumption that at the growth temperature $n = p = K_1^{1/2}$, it follows

$$[B^-_{Si}] = \frac{K_{ad}K_{segr}K_{ion}}{K_1^{1/2}} \times \frac{2P^{\circ}_{B_2H_6}}{\frac{P_{H_2}}{K_1} + \frac{P_{H_2}^{3/2}}{K_2} + \left(\frac{1}{K_7 \cdot P_{H_2}} + \frac{1}{K_8 \cdot P_{H_2}^{1/2}} \right) P_{H_2O} + \frac{1}{K_9 \cdot P_{H_2}^{3/2}} \cdot P_{H_2O}^2} \quad [3]$$

From Eq. [3], it follows that a plot of $\log [B^-_{Si}]$ vs. $\log P^{\circ}_{B_2H_6}$ gives a linear relationship with slope 1, as has been found experimentally for different values of $P^{\circ}_{H_2O}$ [(14) and Fig. 5 thereafter]. When the input pressure of H_2O is increased also, the partial pressures of the boron and oxygen containing compounds become larger, if solid SiO_2 is not present as a condensed phase (see Fig. 6). The effect of increasing water concentration is that the decomposition reactions (K_7 , K_8 , K_9) are hampered, so that the amount of incorporated boron decreases.

The experimentally determined dependency of $[B^-_{Si}]$ on $P^{\circ}_{H_2O}$ (14) (see Fig. 7) also in this case nicely follows the calculated partial pressure of monatomic boron and certainly not those of the B-O or B-O-H compounds, demonstrating that it is B - and not the B-O or B-O-H compounds - which is directly responsible for the amount of $[B^-]$ incorporated in the silicon matrix. Besides the direct visual relation between $[B^-]$ and P_B , a more indirect proof can be given by using Eq. [3], assuming that $P_{H_2O} = P^{\circ}_{H_2O}$, which is allowed because in all cases $P^{\circ}_{H_2O}$ is far in excess with respect to $P^{\circ}_{B_2H_6}$. (The use of $P^{\circ}_{H_2O}$ remains correct even if the reaction of water with silicon to SiO is taken into account, because the reactions are coupled via

After insertion of $P_{H_2} = 1$ atm and the appropriate thermodynamic data for $T = 1400$ K (16), Eq. [3] reads

$$[B^-_{Si}] = \frac{K_{ad}K_{segr}K_{ion}}{K_1^{1/2}} \times \frac{2P^{\circ}_{B_2H_6}}{(6.11 \times 10^7 + 1.77 \times 10^{15} \cdot P^{\circ}_{H_2O} + 6.32 \times 10^{18} \cdot (P^{\circ}_{H_2O})^2)} \quad [4]$$

For a fixed input pressure of diborane, a plot of $\log [B^-_{Si}]$ vs. $\log [6.11 \times 10^7 + 1.77 \times 10^{15} \cdot P^{\circ}_{H_2O} + 6.32 \times 10^{18} \cdot (P^{\circ}_{H_2O})^2]$ should give a linear relationship. The data from Fig. 7 can be taken to check this relationship, taking $P^{\circ}_{B_2H_6} = 10^{-9}$ atm. This has been done in Fig. 8, and, indeed, a good correspondence is obtained. The slope, 1.2, deviates somewhat from the expected value, 1.0. However, it is clear that the slope could be closer to unity than calculated with the least squares method if we look at the error in the experimental data (Fig. 7) and consider the uncertainty in the thermodynamic data for gaseous BHO (16) which K_p value according to the most recent data (16) is a factor 10^4 higher with respect to the earliest data (16). This could also be the reason for the discrepancy of the calculated ($P^{\circ}_{H_2O} \approx 3 \times 10^{-4}$ atm, see Eq. [4]) and experimental ($P^{\circ}_{H_2O} \approx 4 \times 10^{-5}$ atm, see Fig. 7) input pressure of H_2O for which BO and BHO , on the one hand, and BHO_2 , on the other, are equally important for the incorporation of elementary boron. As seen from Eq. [4], an increasing water-input pressure influences the position of the equilibria in such a way that the decomposition of B and O containing compounds at the surface is more difficult and $[B^-_{Si}]$ decreases. For low water-input pressures (where BO and BHO are the compounds which yield at decomposition the greatest part of monatomic gaseous boron), $[B^-_{Si}]$ is proportional to the reciprocal of $P^{\circ}_{H_2O}$ (see Fig. 7). For high water-input pressures (where BHO_2 is the compound which yields the greatest part of monatomic

gaseous boron), $[B^-_{Si}]$ is proportional to the reciprocal of the square of $P^{\circ}_{H_2O}$.

Finally, the incorporation of B and O containing species in solid silicon during growth cannot be excluded. However, as yet no experimental evidence is present to substantiate this point.

B-H-Si-Cl-O system.—Figure 9 shows the result of the calculation of the equilibrium composition of the gas phase, containing the elements silicon, hydrogen, boron, chlorine, and oxygen (e.g., the input gas is a mixture of SiH_4 , H_2 , B_2H_6 , HCl , and H_2O). Also in this case, a plot of $\log P_{B_2H_6}$ vs. $\log P^{\circ}_{B_2H_6}$, $\log P^{\circ}_{HCl}$, and $\log P^{\circ}_{H_2O}$ yields a straight line with slopes p , τ , and s , respectively. The most abundant B containing species are: BH_2 , BH_3 , BCl , BCl_2 , BCl_3 , $BHCl$, BO , BHO , BHO_2 , and $BClO$. With respect to the B-H-Si-Cl and B-H-Si-O systems, only one additional decomposition reaction has to be given

Together with the condition

$$2P^{\circ}_{B_2H_6} = P_{BH_2} + P_{BH_3} + P_{BCl} + P_{BCl_2} + P_{BCl_3} + P_{BHCl} + P_{BO} + P_{BHO} + P_{BHO_2} + P_{BClO}$$

and the assumption that $n = p = K_1^{1/2}$ this leads to

Fig. 2. Calculated equilibrium composition of the B-H-Si-Cl system as a function of $P_{B_2H_6}^0$ ($P_{SiCl_4}^0 = 7.9 \times 10^{-3}$ atm, $P_{tot} = 1$ atm, $T = 1500$ K).

$$[B^-_{Si}] = \frac{K_{ad}K_{segr}K_{ion}}{K_1^{1/2}} \times$$

$$2P_{B_2H_6}^0$$

$$\frac{P_{H_2}}{K_1} + \frac{P_{H_2}^{3/2}}{K_2} + \frac{P_{HCl}}{K_3 \cdot P_{H_2}^{1/2}} + \frac{P_{HCl}^2}{K_4 \cdot P_{H_2}} + \frac{P_{HCl}^3}{K_5 \cdot P_{H_2}^{3/2}} + \frac{P_{HCl}^2}{K_6 \cdot P_{H_2}^{1/2}} + \frac{P_{H_2O}}{K_7 \cdot P_{H_2}} + \frac{P_{H_2O}}{K_8 \cdot P_{H_2}^{1/2}} + \frac{P_{H_2O}^2}{K_9 \cdot P_{H_2}^{3/2}} + \frac{P_{H_2O} \cdot P_{HCl}}{K_{10} \cdot P_{H_2}^{3/2}} \quad [5]$$

Insertion of $P_{H_2} = 1$ atm and the needed thermodynamic data for $T = 1400$ K (16) in Eq. [5] gives

$$[B^-_{Si}] = \frac{K_{ad}K_{segr}K_{ion}}{K_1^{1/2}} \times$$

$$2P_{B_2H_6}^0$$

$$(6.11 \times 10^7 + 1.77 \times 10^{15} \cdot P_{H_2O} + 6.32 \times 10^{18} \cdot P_{H_2O}^2 + 5.40 \times 10^{18} \cdot P_{HCl} + 7.02 \times 10^{12} \cdot P_{HCl}^2 + 6.00 \times 10^{13} \cdot P_{HCl}^3 + 2.62 \times 10^{15} \cdot P_{H_2O} \cdot P_{HCl}) \quad [6]$$

Inspection of Fig. 10, which shows the calculated $[B^-_{Si}]$ curves as a function of the HCl input pressure for three different H_2O input pressures and a fixed B_2H_6 input pressure, shows that the influence of P_{HCl}^0 on $[B^-_{Si}]$ decreases if $P_{H_2O}^0$ increases, as has been experimentally observed by Bloem (14) (see Fig. 11). Because of the multiparameter problem in this case, and the large uncertainty of the actual concentrations, no real quantitative comparison is permitted. However, when both curves [the calculated (Fig. 10) and the experimental one (Fig. 11)] are compared, one again has to come to the conclusion that thermodynamics can describe the incorporation process rather well.

Enhanced growth rate of (heavily) doped polysilicon layers.—The above-given thermodynamic calculation can be extended to lower temperatures, which regime is normally used to grow polycrystalline silicon layers. It is known that when high partial pressures of diborane are used the growth rate is enhanced (19, 20) and the grain size increases (21). From the above-given thermodynamic analysis, it will follow that for these temperatures and concentrations of diborane, the saturation pressure of liquid B_2O_3 ($P_{sat}[B_2O_3(l)] = 10^{-11.5}$ atm at $800^\circ C$) is exceeded,

Fig. 3. Experimentally determined boron concentration as a function of $P_{B_2H_6}^0$ (8) for the B-H-Si-Cl system ($P_{SiCl_4}^0 = 7.9 \times 10^{-3}$ atm, $P_{tot} = 1$ atm, $T = 1500$ K). Experimental data from Ref. (8).

so it can be expected that a liquid layer of B_2O_3 (or droplets of liquid B_2O_3) is present on the growing silicon layer. If one assumes that in the carrier gas always enough residual O_2 (and/or H_2O) is present for the formation of B_2O_3 , then this liquid layer could be responsible for the enhanced growth rate with boron doping (19, 20) via a VLS mechanism, as well as for the reported enhanced grain size (21). The role of boron dope can also be the getting of oxygen, thus preventing the formation of solid SiO_2 .

Autodoping.—The calculations given above constitute another example to show that doping with n-type as well

as p-type impurities can be explained via the value of the free monatomic dopant vapor pressure in the gas phase (p_p, p_{As}, p_{Sb}, p_B) (22), and that equilibrium calculations give good predictions on the doping behavior.

Apart from the equilibrium considerations, there are also kinetic arguments to be fulfilled. One of these shows up as a function of growth rate as observed for phosphorus doping (3, 7). Another example is given by the effect of autodoping (23-25). Autodoping can be defined as the undesired dopant contribution from substrate wafers to the growing epitaxial layer (26). Apart from the direct solid-state diffusion of impurities, there is a considerable contribution to the autodoping via the gas phase.

It has been found that autodoping can be reduced considerably by a prebake and growth at reduced total pressures (26). The explanation given points to an easier desorption of impurities accompanied by an enhanced diffusion away from the surface at reduced pressures, leading to a smaller dopant partial pressure near the growing surface and thus to a lower effective segregation coefficient (23-25).

At higher temperatures, the direct solid-state diffusion of impurities from substrate to growing layer is increased.

B-H-Si-O system

Fig. 4. Calculated equilibrium composition of the B-H-Si-O system as a function of $P_{B_2H_6}^0$ ($P_{SiH_4}^0 = 10^{-3}$ atm, $P_{H_2O}^0 = 10^{-5}$ atm, $P_{tot} = 1$ atm, $T = 1400$ K).

The transport via the gas phase is reduced as the segregation coefficient decreases with increasing temperature for the n-type impurities. Desorption is also made easier at higher temperatures.

Fig. 5. Experimentally determined boron concentration as a function of $P_{B_2H_6}^0$ (14) for the B-H-Si-O system with $P_{H_2O}^0$ as a parameter ($P_{SiH_4}^0 = 10^{-3}$ atm, $P_{tot} = 1$ atm, $T = 1150^\circ\text{C}$). Experimental data from Ref. (14).

B-H-Si-O system

Fig. 6. Calculated equilibrium composition of the B-H-Si-O system as a function of $P_{H_2O}^0$ ($P_{SiH_4}^0 = 10^{-3}$ atm, $P_{B_2H_6}^0 = 10^{-9}$ atm, $P_{tot} = 1$ atm, $T = 1400$ K).

The beneficial effects on autodoping at reduced pressures only applies to n-type impurities (P, As, Sb). For boron doping, unexpectedly, an increase in autodoping is observed at reduced total pressures, whereas a change in temperature is hardly of influence (27).

The physical effects described above of desorption and ease of diffusion away from the substrate surface will equally apply to n-type and p-type dopants. For boron doping, however, the high reactivity of boron towards oxygen, i.e., the chemical influence of trace amounts of impurities such as water vapor, have to be considered additionally. In Fig. 6, it can be seen that small amounts of water which are normally present in reactors at atmospheric pressure (> 1 ppm) are already sufficient to take away a part or even most of the input concentration of B_2H_6 . This amount is converted into the inactive chemical species BHO, and thus the partial pressure of monatomic boron is effectively reduced. By reducing the total pressure in a clean system, the water vapor pressure will be reduced also. A reduction in water content shifts the gas-phase equilibria such that more free boron is available, leading to an increase in doping capabilities and increased autodoping as well.

As a function of temperature in the boron case there are two competing mechanisms (1) higher temperatures lead to easier desorption hence to a lower segregation coefficient (2). The influence of water vapor on the equilibria is reduced at higher temperatures, which increases the effective segregation coefficient. The balance thus depends on the impurity content of the system.

In this way, the differences in autodoping between n-type and p-type impurities can be explained qualitatively. A quantitative explanation needs a better knowledge of the impurity levels in the reactor.

Fig. 7. Experimentally determined boron concentration as a function of $P_{H_2O}^0$ (14) for the B-H-Si-O system. The diborane input concentration has been taken as a parameter. ($P_{SiH_4}^0 = 10^{-3}$ atm, $P_{tot} = 1$ atm, $T = 1150^\circ\text{C}$). The value $P_{H_2O}^0 = 1 \times 10^{-6}$ atm from Ref. (14) has been taken as 2×10^{-6} atm because in the carrier gas already 1 ppm H_2O is present (29). Experimental data from Ref. (14).

Fig. 8. Experimentally determined boron concentration for $P_{B_2H_6}^0 = 10^{-9}$ atm (see Fig. 7) as a function of the theoretical parameter $[6.11 \times 10^7 + 1.77 \times 10^{15} \cdot P_{H_2O}^0 + 6.32 \times 10^{18} \cdot (P_{H_2O}^0)^2]$ (see Eq. [4]). The data points are calculated from Ref. (14).

Water vapor thus appears to be undesirable when good quality epi is desired; however, it reduces the autodoping in the boron system. The same is true for the presence of HCl; autodoping therefore could be less a problem in growth via chlorosilanes compared to growth via silane (SiH_4). Undoubtedly, the surface coverage with foreign atoms will also influence the growth rate as a function of orientation of the substrate. In this respect, the pattern shift and pattern recognition will depend on small differences in surface contamination. Indications in this direction are available (28), but much study in this direction is still needed.

Conclusion

With the assumption that at the growing silicon surface equilibrium exists between the dopant compounds in the gas phase near the surface, calculation of the gas-phase composition yields valuable results that can be used for studying the equilibrium between the gas phase and the solid. This has been done for the interpretation of the quantity of boron which can be incorporated in silicon in the presence of small amounts of water during the growth of silicon by CVD from SiH_4 in H_2 at atmospheric pressure. The one-to-one correspondence which is obtained between equilibrium calculations and experimental results once more gives a firm indication that equilibrium calculations are quite valuable to obtain insight in the chemistry and physics of CVD processes. In addition, now an explanation can be given for the unusual behavior of boron autodoping at lower pressures.

ABSTRACT

The physical properties and oxidation behavior of silicon carbide thin films are reported. These films were RF sputtered from a composite target of stoichiometric proportion onto thermally oxidized silicon substrates. The refractive index of the carbide films, after annealing at 1100°C in hydrogen, was very close to the bulk value of 2.65. Structural and compositional properties were studied by Rutherford backscattering spectrometry, secondary ion mass spectrometry, and x-ray diffraction techniques. Thermal oxidation was carried out in wet and dry oxygen at 900°-1100°C for a period of up to 16h. Depending on the temperature and time period, the oxidation rate of silicon carbide was about 2-11 times slower than that of single-crystal (100) Si. The oxide layer grown out of the carbide films was determined to be silicon oxide. The average activation energy for wet and dry oxidation was calculated to be 50 and 43.5 kcal/mol, respectively. The patterning of the SiC films was investigated using CF_4/O_2 and NF_3 plasmas. "Bird's beak" profiles, obtained upon field oxidation of SiC/SiO₂/Si structures, were studied.

Silicon carbide has been used for various industrial applications. Among these are (i) for making electron devices (1, 2) because of its semiconducting properties and chemical inertness and stability at very high temperatures, and (ii) for surface coatings (3) due to its high wear resistance.

In this paper, however, thin films of silicon carbide are being investigated as an alternative or addition to silicon nitride in local oxidation technology (LOCOS) for Si VLSI fabrication. Like silicon nitride, silicon carbide is refractory and fairly resistant to oxidation in bulk form. In Table I, some of the appropriate physical properties of SiC, Si₃N₄, SiO₂, and Si are shown from Ref. (4-9).

As can be seen from Table I, a range of values has been published for the Young modulus of SiC, Si₃N₄, and Si. At best, the Young modulus for SiC is a factor of 5 higher than that of Si₃N₄. In that case, a more rigid SiC layer would result in reduced "bird's beak" formation.

A variety of methods for depositing SiC films have been reported, including RF sputtering (3, 10-12), chemical vapor deposition (1, 13-15), and reactive evaporation (16). In this work, RF sputtering from a composite SiC target was used for film deposition.

Ellipsometry, secondary ion mass spectrometry (SIMS), x-ray diffraction, and Rutherford backscattering spectrometry (RBS) were used to investigate the structural and physical properties of these thin films.

In order to apply SiC in the LOCOS technology, the oxidation behavior of carbide films needs to be studied in detail. Thermal oxidation properties of SiC films were investigated in both wet and dry oxygen. "Bird's beak" profiles were obtained from plasma-etched and oxidized SiC/SiO₂/Si structures and examined with cross-sectional scanning electron microscopy.

Experimental Procedure

A Veeco sputtering system was used for the carbide film deposition. A hot-pressed stoichiometric SiC composite target (99.7%) was used as cathode. The SiC films were RF sputtered onto thermally oxidized or unoxidized (100) silicon substrates in an argon pressure of 6×10^{-3} torr. The RF power ranged from 75 to 200W, and the substrate temperature was maintained at either 25° or 300°C. The background pressure before sputtering was usually less than 2.0×10^{-6} torr. Unless otherwise specified, after deposition, the SiC films were annealed at 1100°C in H₂ ambient for 30 min.

The SiC film deposition rate as a function of RF power is shown in Fig. 1. Film thickness was calculated from

*Electrochemical Society Active Member.

Key words: oxidation kinetics, activation energy, plasma etching, bird's beak.

SIMS and RBS profiles. Typical depositions were performed with an RF power of 200W (~ 5 W/cm²), resulting in a deposition rate of $\sim 125\text{\AA}/\text{min}$. The substrate temperature appears to have little effect on the deposition rate.

Thin Film Deposition

In order to study the refractive indexes of deposited SiC thin films for various annealing temperatures, the SiC films were first deposited on silicon substrates, and then annealed in a H₂ ambient for 30 min over the temperature range of 800°-1100°C. An automated ellipsometer (Rudolph Research) was used to determine the refractive index at a wavelength of 6328Å. The silicon substrate is assumed to have a refractive index of 3.86 and an absorption index of 0.018. Figure 2 illustrates the dependence of the refractive index of SiC films on the annealing temperature. The refractive index of as-sputtered SiC films is between 3.1 and 3.35. The refractive index of annealed films decreases as the annealing temperature increases.

Fig. 1. SiC deposition rate as a function of RF power

Table I. Physical properties of SiC, Si₃N₄, SiO₂, and Si

	Melting point (°C)	Refractive index	Heat of formation (kcal/g-mol)	Dielectric constant	Coefficient of thermal expansion ($\times 10^{-6}$ °C ⁻¹)	Young's modulus ($\times 10^6$ psi)
SiC	2700 (6)	2.65 (6)	-27 (6)	10.0 (4)	4.2 (4)	70 (6) 50 (9)
Si ₃ N ₄	1900 (6)	2.05 (5)	-179 (6)	7.5 (5)	2.8 (7)	55 (6) 13 (9)
SiO ₂	1600 (5)	1.46 (5)	-205 (6)	3.9 (5)	0.55 (6)	10.4 (6) 26 (6)
Si	1410 (6)	3.86 (8)	0 (6)	11.9 (5)	2.6 (5)	16 (9)

For an annealing temperature of 1100°C, the index reaches an average value close to the SiC bulk value of 2.65. The decrease in refractive index with increasing anneal temperature is believed to be related to the concomitant increase in the crystallinity of the SiC films (17).

RBS was performed to determine the Si/C ratio and contaminants present in the films. A 2 MeV ⁴He⁺ beam from a linear accelerator was used. The Si/C ratio computed from the data shown in Fig. 3 is very close to unity. Argon, which was used for film deposition, has been incorporated into the SiC layer and is estimated to be at ~ 2.2 atom percent.

SIMS analysis was performed with a Cameca IMS3-f ion microscope in order to study the major contaminants

Table II. Deposition conditions and related thin film properties

Sample	Background pressure (torr)	O/C ratio (from SIMS)	X-ray peaks	Oxidation resistance
MA-1-1	8.3×10^{-6}	0.6	SiO ₂	Lowest
MS-16	$< 2 \times 10^{-6}$	0.054	SiC	Highest
MA-4-1	3×10^{-6}	0.1	SiO ₂ , SiC	High

in annealed SiC films. Under the bombardment of a cesium primary beam with an impact energy of 17 eV, the relative intensities of various negative ion species—silicon (³⁰Si⁻), carbon (¹²C⁻), argon (⁴⁰Ar⁻), and oxygen (¹⁶O⁻)—were sampled as a function of depth. Figures 4a-4c show the SIMS data for three samples deposited under different conditions (see Table II), but annealed under essentially the same condition.

The SIMS data indicate a constant Si/C ratio with depth for all three samples. Oxygen was present in considerable amounts in the film of Fig. 4a, and to a lesser degree in the films of Fig. 4b and 4c. We found that minimizing the oxygen content in the carbide films results in increasing resistance to thermal oxidation. Under the same oxidation conditions (1000°C, wet O₂, 60 min), sample MA-1-1 (Fig. 4a) exhibited a 3400Å thick oxide, while samples MS-16 (Fig. 4b) and MA-4-1 (Fig. 4c) had oxides of 375 and 700Å, respectively.

X-ray diffraction was performed to investigate the crystallinity of the carbide films using a D-500 Siemens automated diffractometer. The x-ray spectra of Fig. 5a, 5b, and 5c are for the same samples as the SIMS profiles of Fig. 4a, 4b, and 4c. The peaks at 2θ angles of 35° and 70° correspond to SiC and Si, respectively. Since only one sil-

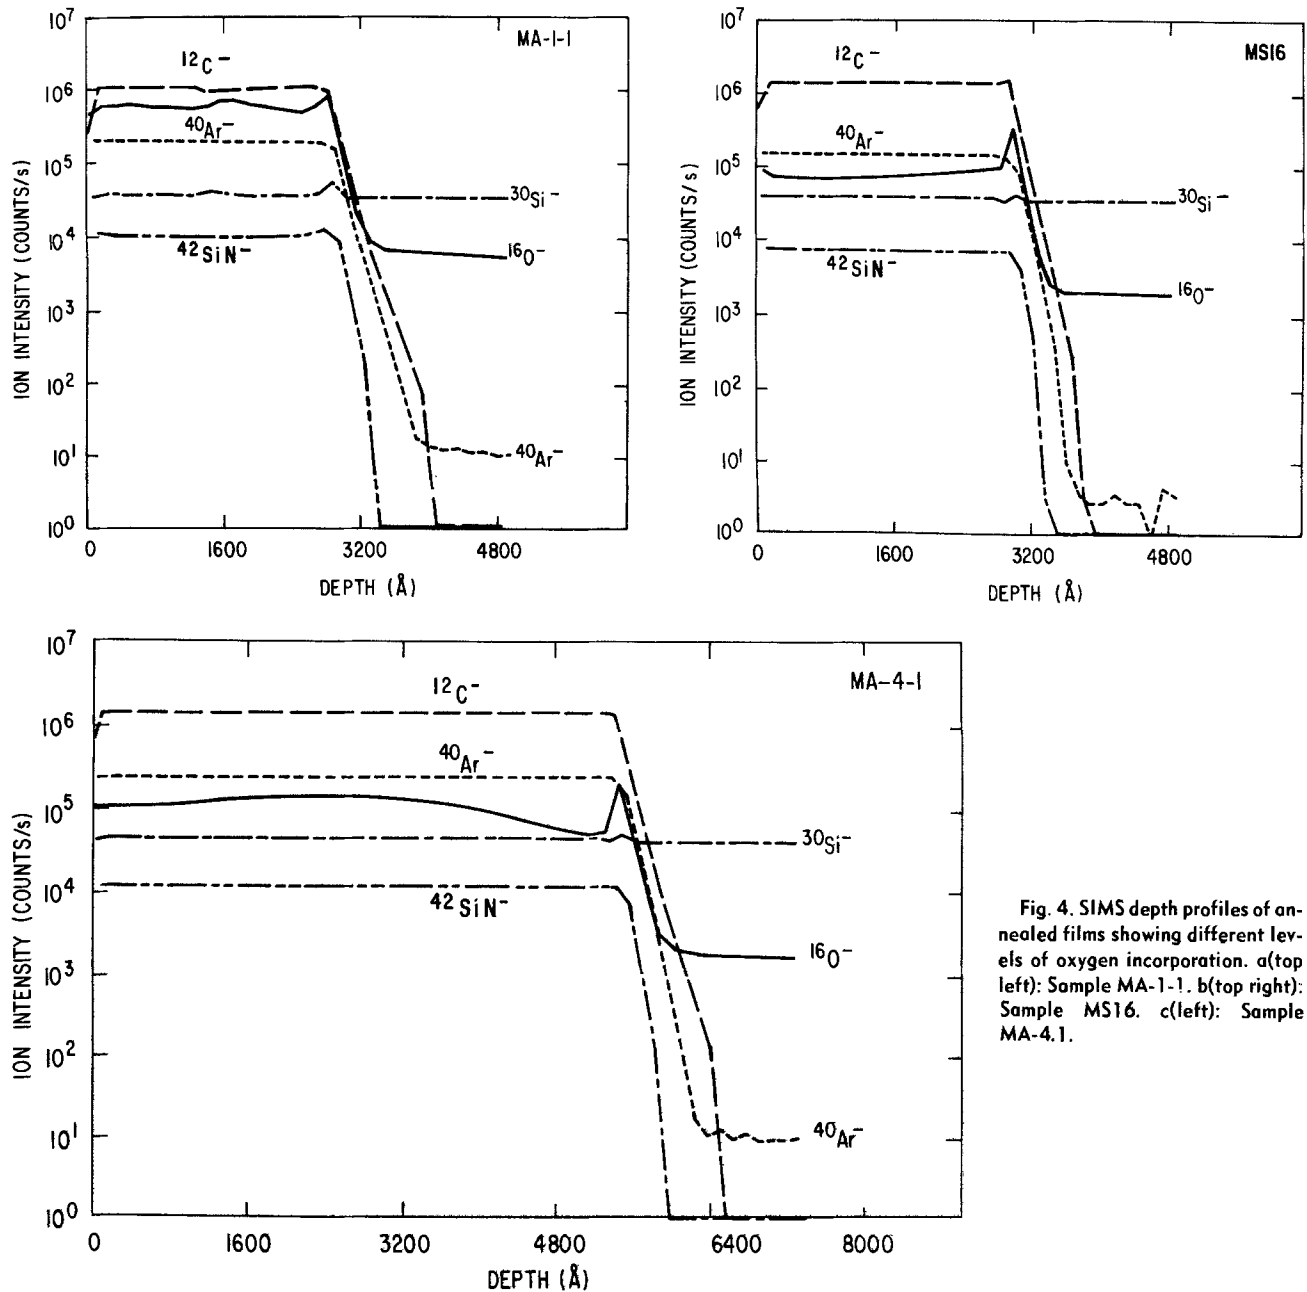

Fig. 4. SIMS depth profiles of annealed films showing different levels of oxygen incorporation. a(top left): Sample MA-1-1. b(top right): Sample MS16. c(left): Sample MA-4.1.

icon carbide peak was detected (corresponding to 2.51\AA), we could not determine the phase of our SiC films. The peak at 1.36\AA corresponds to the (400) peak of the Si substrate (18). The peaks at 2θ angles ranging from 15° to 25° are attributed to SiO_2 (19). For sample MA-1-1, shown in Fig. 4a as having the highest oxygen concentration, no SiC peak is observed in Fig. 5a. For sample MS-16, which exhibited the minimum O_2 contamination (as shown in Fig. 4b), the SiC peak is very strong and not accompanied by the SiO_2 lines (Fig. 5b). These data clearly show the strong effect of oxygen on the crystallinity of the silicon carbide films.

The relationship between deposition conditions (*i.e.*, background pressure) and thin film properties is summarized in Table II.

Oxidation Properties

It is known that the presence of water vapor in O_2 greatly accelerates the oxidation rate of Si and also enhances the oxidation rate of hot-pressed SiC (20). There have been many reports on the oxidation of SiC powder or crystal (20-23). However, to the best of our knowledge, no SiC thin film oxidation has been previously reported.

To study the oxidation resistance of SiC thin films, wet and dry thermal oxidation was conducted from 900° to

1100°C for periods of time of 15 min to 16h. Wet oxygen was prepared by bubbling the oxygen through deionized water at 95°C . The flow rate of oxygen was 1.9 l/min. The SiC thin films used for oxidation were prepared by RF sputtering for 45 min ($\sim 5500\text{\AA}$ thick) onto oxidized Si (100) wafers, followed by an anneal in H_2 at 1100°C for 30 min.

The oxide layer grown out of unannealed silicon carbide consisted only of silicon and oxygen, as shown by the SIMS depth profile in Fig. 6. Similar results were obtained in the case of films annealed prior to oxidation. The absence of carbon in oxide films grown out of bulk, single-crystal SiC was also reported by Suzuki *et al.* (21).

It has been found that the oxidation rate of as-sputtered SiC films is generally higher than that of annealed films (24). Figure 7 shows the effect of preoxidation annealing on wet oxidation of SiC films. The annealing temperature ranged from 800° to 1100°C and took place in H_2 for 30 min. As can be seen from the data in Fig. 7, the oxidation rate at lower temperatures ($T_{\text{ox}} = 950^\circ\text{C}$) is strongly influenced by preoxidation annealing. When the annealing temperature is increased by 100°C from 900° to 1000°C , a decrease in oxidation rate of a factor of 15 is achieved at $T_{\text{ox}} = 950^\circ\text{C}$. However, at higher oxidation temperatures (1050°C), the annealing process appar-

Fig. 5. X-ray diffraction spectra for the films shown in Fig. 4. a(top left): Sample MA-1-1. b(top right): Sample MS16. c(left): Sample MA-4-1.

ently takes place concurrently with the oxidation, resulting in a drastically reduced difference in oxidation rate. Figure 8 shows that a similar effect of preoxidation annealing on dry oxidation takes place.

The wet oxide thickness grown from annealed (1100°C) films as a function of time and temperature is shown in Fig. 9. The average oxidation rate of SiC crystal reported by Suzuki *et al.* (21) for $T_{ox} = 1000^{\circ}\text{C}$ is also shown for comparison. In general, the oxidation of our films agrees

well with the reported single-crystal oxidation data, except at long periods of time where our films do not follow the parabolic oxidation law.

Figure 10 shows the oxide thickness on silicon carbide as a function of dry oxidation time and temperature. The preoxidation annealing conditions were the same as in the case of wet oxidation. The dry oxidation also does not appear to obey the parabolic law for periods as long as 16h.

Fig. 6. SIMS depth profiles of oxidized silicon carbide films.

Fig. 7. Effect of pre-oxidation annealing on wet oxidation

Fig. 8. Effect of pre-oxidation annealing on dry oxidation

The Si (100)/SiC wet and dry oxidation rate ratio is shown in Fig. 11 and 12 as a function of oxidation time and temperature. For the same conditions, the ratio is higher for wet oxidation than for dry oxidation. It can also be seen that the ratio is highest at lower oxidation temperatures and decreases as time or temperature increases. It is expected that by continuing to decrease the temperature ($T_{ox} < 900^\circ\text{C}$), one can obtain further increases in oxidation rate ratio.

The wet and dry oxide thickness obtained at different temperatures are shown in Arrhenius plots in Fig. 13 and 14, respectively. Using the equation

$$X^n = Cte^{-E_a/kT}$$

for thermal oxidation kinetics, where X is the oxide thickness, C is a constant, and t and T are the oxidation time and temperature, respectively, one can calculate the value

Fig. 9. Silicon carbide wet oxidation thickness as a function of time and temperature. Dashed line is data of Suzuki *et al.* (21), showing average of Si- and C-face wet oxidation of SiC single crystal at 1000°C .

Fig. 10. Silicon carbide dry oxidation thickness as a function of time and temperature.

of the activation energy, E_a . For wet oxidation we obtained values of n of 1.15-1.34 and activation energies ranging from 49-52 kcal/mol. For the case of dry oxidation, the respective values were $n = 1.13-1.31$ and $E_a = 37-48$ kcal/mol. It is interesting to note that for both wet and dry oxidation similar values of n were obtained. The activation energies are also comparable in these cases. As shown in Table III, it is difficult to compare our results with those published in the literature on the oxidation of SiC crystals. The crystalline form and phase of the SiC have a strong effect on its oxidation properties. Comparing the data of Suzuki *et al.* (21), and Harris and Call (25), one can note that in the parabolic region ($n = 2$) they obtain the same activation energy (47-48 kcal/mol) for the C-face under wet and dry oxidation. This activation en-

Fig. 11. Silicon-silicon carbide wet oxidation rate ratio

Fig. 13. Activation energy for silicon carbide wet oxidation

ergy also roughly agrees with our results under both wet and dry conditions. However, for our thin film oxidation, we are essentially in the linear region with values of *n* closer to 1. This suggests that in our case the oxidation is limited more by the reaction rate than by the diffusion of various species.

Application to IC Processing

The use of SiC as an oxidation mask in the LOCOS process is being studied. The patterning of the SiC films was investigated using CF₄/O₂ and NF₃ plasmas. The etch rate

of unannealed films was generally higher than that of annealed films. For the latter, in a planar reactive ion etching system (Plasma Therm PK 1241) using NF₃, the etch rate was 320 Å/min at a pressure of 100 mtorr and a power of 200W. In a planar plasma system (Technics P.E. II), using CF₄/4% O₂, the etch rate was ~ 500 Å/min at a pressure of 300 mtorr and power of 300W. "Bird's beak" profiles were obtained upon field oxidation of the SiC/SiO₂/Si structures. A positive photoresist (Shipley AZ-1350J) was used for masking the SiC film during patterning. For example, Fig. 15 shows bird's beak profiles

Fig. 12. Silicon-silicon carbide dry oxidation rate ratio.

Table III. Comparison of oxidation kinetics for SiC bulk crystals and thin films

SiC form	Ambient	n^*	E_a (kcal/mol)	Temp. range	Ref.

resulting from a wet oxidation at 1000°C for 150 min for a structure consisting of a SiC layer of $\sim 4000\text{\AA}$ and a pad oxide of 280\AA . The resulting field oxide was $\sim 5000\text{\AA}$

while the SiC oxidized layer had a thickness of $800\text{-}900\text{\AA}$. The bird's beak figure of merit was measured to be $M = t_{\text{BB}}(10\%-90\%)/t_{\text{FOX}} \approx 0.5$. The bird's beak effect was observed to increase with pad oxide and field oxide thickness.

Fig. 14. Activation energy for silicon carbide dry oxidation

Fig. 15. "Bird's beak" profile obtained with the following parameters: $t_{\text{SiC}} = 4000\text{\AA}$, $t_{\text{SiO}_2(\text{pad})} = 280\text{\AA}$, and $t_{\text{SiO}_2(\text{field})} = 5000\text{\AA}$ (150 min, 1000°C).

Summary

The thermal oxidation of silicon carbide thin films has been shown to result in the growth of silicon oxide overlayer. The growth rate is sufficiently slow, such that LOCOS-type structures using SiC are feasible.

A Defect Etchant for $\langle 100 \rangle$ InGaAsP

J. A. Lourenco

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A defect revealing etching technique for n-InGaAsP grown on $\langle 100 \rangle$ InP by LPE is reported. A chemical solution used with illumination produces protrusions in thin quaternary layers, which correlate well with dislocation pits in underlying and overlying InP layers. Using the new etchant, an increase in defect density in the active layer over the defect density in the buffer layer has been detected in lattice matched ($\approx 0.04\%$) InGaAsP/InP LED structures.

The importance of the InGaAsP/InP material system, for its applications in fiber optics, is well established. In particular, heterostructures grown on InP by liquid phase epitaxy (LPE) are becoming increasingly important for fabrication of lasers, light emitting diodes, and photodiodes.

During LPE, defects from the substrate propagate through the various epitaxial layers when growth takes place. High quality single-crystal InP substrates are therefore used in order to minimize defects in the heterostructure. Nevertheless, the dislocation density in the epitaxial layers can be greater than in the substrate (1). Misfit dislocations can also arise at the interface between two layers, if interfacial stress is present (2).

It is well known that degradation of GaAlAs/GaAs devices is in large part due to defects in the heterostructure, particularly in the active layer (3, 4). In addition, it has been shown that dislocations cause deleterious effects in InGaAsP and InP photodiodes (5, 6). Study of lattice defects is therefore important in order to improve material and device quality.

Chemical etching is the simplest method for revealing dislocations and other defects in crystals. A number of papers have been published recently dealing with chemical, electrochemical, and photochemical etching of InP (7-11), InGaAs (12, 13), and InGaAsP grown on $\langle 111 \rangle$ B InP (14, 15). However, the $\langle 100 \rangle$ orientation is widely utilized for LED's, lasers, and other devices, but no chemical etchant that selectively reveals dislocations in $\langle 100 \rangle$ InGaAsP layers has yet been reported. The difficulty in finding a suitable chemical etchant for quaternary layers lies in their thickness, which rarely exceeds $2.0 \mu\text{m}$. A defect etchant for such layers will have to be extremely preferential and have a slow etching rate in order to reveal the defects with minimal material removal.

In this paper, a technique is presented which can reveal dislocations in $\langle 100 \rangle$ n-InGaAsP layers. A chemical etchant with a very low etch rate is used, which becomes very preferential when coupled with illumination. This allows for the formation of small protrusions in quaternary layers that exactly match dislocation pits in neighboring InP layers. Etching studies of n-type quaternary layers grown on Sn-doped InP are reported. Dislocation propagation through the epitaxial layers in InGaAsP/InP double heterostructures is also described.

Experimental

The material for etch investigations was InP and InGaAsP grown by liquid phase epitaxy from two-phase melts, using a conventional multiwell graphite boat (16). The substrate was $\langle 100 \rangle$ oriented S-doped (to $\sim 5 \times 10^{18} \text{cm}^{-3}$) InP, polished with a 1.0% bromine-methanol solution. On the substrate, a $\sim 4.0 \mu\text{m}$ thick Sn-doped InP

layer was grown, followed by an undoped or lightly Sn-doped InGaAsP layer ($\lambda = 1.3 \mu\text{m}$), approximately $1.2 \mu\text{m}$ thick. To prevent any thermal dissolution of the quaternary layer, due to disproportionate loss of phosphorus from the InGaAsP surface during the cooling period after epitaxy, an additional undoped InP layer was grown on the n-InGaAsP. This is an important step, because any thermal damage to the quaternary surface will be selectively attacked by the etchant and interfere with the results.

The different etching solutions used in this study are listed in Table I. After epitaxy, the protective InP layer was removed using a 1:1 HCl:H₃PO₄ solution (17) (solution A), exposing a quaternary surface which is free of any thermal or chemical damage. A sample was then cut from the LPE wafer and etched for 10 min using a solution of 100 ml of H₂O, 8g KOH, and 0.5g K₃Fe(CN)₆ (18) (solution B). The etching took place under illumination from a microscope lamp with a 15W tungsten filament bulb, placed directly over the sample. Under these conditions, the etch rate was approximately $1.5 \mu\text{m/h}$. Illumination was required to reveal etch features since solution B was not preferential without the light, even though there was no significant difference in the etch rate. After photoetching, the specimen was examined by optical interference microscopy and etch features could be observed. SEM analysis showed them as protrusions on the sample surface. Figure 1a is an optical micrograph of the etched surface, showing these protrusions. Using a solution of 100 ml of H₂O, 8g KOH, and 12g K₃Fe(CN)₆ (solution C), the rest of the quaternary layer was then removed, exposing the Sn-doped InP epitaxial layer surface.

For etching of InP, the Huber etch (19) (solution D) is usually taken as the most reliable in revealing material defects (20). However, preliminary experiments had shown that a 1:3 HNO₃:HBr solution (9) (solution E) was superior to it with respect to reproducibility and surface quality after etching. This was particularly true when etching p-InP. Therefore, solution E was the InP defect etchant of choice in this experiment. Thus, the Sn-doped InP surface was etched using this solution for approximately 10s, revealing etch pits. Figure 1b shows an optical micrograph of the etched sample, with every etch pit matching a protrusion on Fig. 1a, confirming that most of

Fig. 1. Interference contrast micrograph showing etch features: (a) n-type quaternary layer etched with solution B under illumination; and (b) underlying Sn-doped InP layer etched with solution E.

the features on the quaternary layer are dislocations propagating through the epitaxial layers.

Although in many samples the etch features on the quaternary layer matched closely the ones on the InP layer, quite often there was an increase in the defect density of the InGaAsP over the dislocation density of the InP. To determine if these extra features on the etched surface of the quaternary layer were real defects and not etching artifacts, several four-layer InGaAsP/InP LED structures (21), grown by LPE, were examined. They consisted of a Sn-doped InP buffer layer ($\sim 4 \mu\text{m}$ thick) on a S-doped <100> oriented InP substrate, followed by a $1.2 \mu\text{m}$ thick quaternary layer ($\lambda = 1.3 \mu\text{m}$ and lattice matched to InP to better than $\pm 0.06\%$), a $1.5 \mu\text{m}$ thick Zn-doped InP confining layer, and a Zn-doped quaternary cap layer. First, the quaternary cap was removed with solution C. This exposed the p-InP confining layer, which was etched for 10s using solution E. Figure 2a is an optical interference micrograph of the etched surface, showing the defects in the confining layer. This layer was then completely removed with solution A, exposing the smooth and damage-free top surface of the quaternary active layer.

When trying to defect etch this surface using the new photoetchant, as described above, a major problem arose: the illuminated solution reacted with the surface, changing its morphology and in effect destroying it. The same phenomenon was observed when trying to defect etch p-InGaAsP single layers. In the LED heterostructures studied, only the top ($\sim 0.2 \mu\text{m}$) of the active layer was p-type, as a result of acceptor diffusion from the confining layer. Most of the $\sim 1.2 \mu\text{m}$ thick active layer remained n-type quaternary material. Using solution C for approximately 20s, the top of the active layer was removed, and the remaining quaternary was all n-type.

Fig. 2. Interference contrast micrograph of defect etched layers of a InGaAsP/InP double heterostructure: (a) Zn-doped InP confining layer etched with solution E; (b) quaternary active layer etched with solution B under illumination; and (c) Sn-doped InP buffer layer etched with solution E.

When examined under an optical microscope, the new surface showed no signs of damage or preferential etching. Using solution B under illumination for 10 min, no deleterious surface reaction was observed. Figure 2b is an interference contrast micrograph of the etched n-portion of the active layer, showing etch features that exactly match the defects revealed on the confining layer.

When the active layer is totally removed and the underlying n-InP buffer layer is etched using solution E, dislocation pits are observed, most of which correspond exactly to the defects revealed in the upper layers. However, once again many of the defects present in the quaternary and confining layers are absent from the buffer. Figure 2c shows the surface of the n-InP layer after defect etching: all the etch pits in this micrograph have matching features in Fig. 2a and 2b, but many of the defects in Fig. 2a and 2b are missing in Fig. 2c.

The difference in defect density between the buffer and the quaternary layers becomes striking when dislocation-free material is used as the substrate. A few heterostructures grown on substrates with defect density of $<100 \text{ cm}^{-2}$ were investigated. No significant difference in defect density between the buffer layer and the substrate was detected, but a large increase in the number of defects in the quaternary layer was observed. These defects then propagated into the confining layer without significant change in number. The increase in defect density in

the heterostructures was observed throughout the whole wafer in every wafer studied, although it was different in different parts of the wafers and also from wafer to wafer. The additional defects ranged in value from 3×10^3 to 8×10^4 cm⁻², and it was usually lower in the center portion of the wafers.

Results and Discussion

A 100 ml solution of 8.0g potassium hydroxide and 0.5g potassium ferricyanide, coupled with illumination, etches <100> n-InGaAsP slowly and preferentially, allowing for the formation of protrusions on the quaternary surface. Because of deleterious reaction between the photoetchant and the Zn-doped surface, no results were obtained for p-type quaternary layers. The pattern of defects on the n-InGaAsP surface exactly matches the pattern of etch pits in InP layers grown on the quaternary layer. It also correlates well with the defect pattern of the InP layer on which the InGaAsP layer was grown.

A one-to-one correlation between the dislocations in epitaxial InP layers and in the substrate has been shown by other workers (1), and the present results agree with it. In this study, a one-to-one correlation between the defects in the quaternary active layer and in the InP confining layer has also been observed, but a substantial increase in defect density in the active layer over the defect density in the buffer layer has been detected in most samples. This increase in defect number, ranging from 3×10^3 to 8×10^4 cm⁻² in the samples studied, is not very important in heterostructures grown on substrates with high dislocation densities (greater than 10^4 cm⁻²). However, when the dislocation density of the substrates is low (less than 10^3 cm⁻²), lattice defects generated during crystal growth become very significant. With dislocation density in many substrates presently approaching zero, these additional defects will preclude achieving zero dislocation epitaxial material.

Generation of these lattice defects in the InGaAsP layer may be due to several factors, such as interfacial stress, less than perfect wipe-off of the epitaxial surface, or poor wetting by the quaternary melt. It may also be due to thermal dissociation of the InP surface during the time it takes to move the substrate from well to well in the graphite boat. However, the exact source of these additional defects has not yet been determined, and more work is needed to track it down and, if possible, eliminate it.

Characterization of Near-Surface Line Defects Formed during High-Temperature Annealing of Gold-Metallized III-V Compound Semiconductors (InP and GaAs)

S. Nakahara,* E. C. Felder, and H. Temkin*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We report a transmission electron microscope study on the new type of line defects which appeared near the {001} surface of Au-metallized InP and GaAs compound semiconductors as a result of high temperature annealing. The line direction of these defects was along the [110], and the nature of the strain field was similar to that of an edge dislocation having the Burgers vector of $a/2$ [110] type. Because the magnitude of the strain contrast was found to vary sensitively with the length of the defects, the possibility of these line defects being a dislocation has been ruled out. In addition, they lie at the bottom of rectangular pits created by a direct interfacial reaction with a Au overlayer, and the strain field was determined to originate from the elastic coherency present between the semiconductor and Au containing surface film.

There is an increasing interest in III-V compound semiconductor materials for a number of electronic applications. Various metallization schemes have been proposed for these semiconductors and used to obtain suitable electronic characteristics of a Schottky barrier or an ohmic contact. Gold, in combination with various dopants, is one of the elements which has been used extensively as a contact metal for this application. Heat-treatment of such a contact, necessary for obtaining low resistivity and strong mechanical bond, results in not only a lattice diffusion of Au into the semiconductor, but also a direct interaction with Au at the interface (1). Since such a metallization is often composed of more than one kind of metal, understanding of its interaction mechanism with the semiconductor may be difficult. Even a room-temperature interdiffusion within metallization layers alone was found to present quite a complex problem and involved an interfacial cracking accompanied by void formation, as recently observed in Au/Sn layers on GaAlAs LED's (2).

During the course of studying interactions between a Au metallization and III-V compound semiconductors (InP and GaAs), we have discovered a number of line defects lying along the [110] direction (but not along the $[1\bar{1}0]$) at the interface between a Au-metallization and the {001} surface of III-V compound semiconductors. We will show that the appearance of these line defects is connected with the early stages of reaction pit formation as a result of the preferential interaction of Au with the In or Ga component of InP or GaAs substrate. It will also be shown that these defects are not dislocations, but are rather lines of a strain center which is believed to have originated from an interaction of Au with the semiconductor. The contrast therefore arises from a coherency strain generated locally between the semiconductor substrate and a Au containing thin surface film.

Experimental

Metallizations (1000Å thick Au) were deposited on the chemically polished {001} face of InP or GaAs substrate by electron-beam deposition technique in a vacuum of better than 1×10^{-6} torr. The substrate was not intentionally cooled or heated during film deposition, but is believed to be close to room temperature. The metallized semiconductors were subsequently heat-treated at 420°C for 6 min in an atmosphere of forming gas (14% of H_2 in N_2). For a transmission electron microscope (TEM) observation, the heat-treated samples were cut into 3 mm square pieces, which were then mounted on a polished steel block while masking the metallized side with black wax. Some specimens were rinsed quickly in a KI solution (400g KI, 100g I_2 , and 400 ml H_2O) to remove an

*Electrochemical Society Active Member.

unreacted Au film prior to masking the metallized face with black wax. The 3 mm square pieces were polished mechanically down to about 200 μm with 600-grit slurry paste (Al_2O_3). After the mechanical thinning, the polished pieces were given an additional black wax around the circumferences, allowing only the center region to be exposed for the final chemical polishing in 5% Br-methanol solution. After the center region is perforated, the specimen was mounted on a holder for the subsequent TEM observation.

TEM micrographs were obtained with a JEM 200 electron microscope operated at 200 kV.

Results and Discussion

The interfacial region of Au-metallized (1000Å thick) and subsequently heat-treated {001} InP or GaAs substrates contained two characteristic features: rectangular surface pits elongated along the $\langle 110 \rangle$ direction and line defects lying parallel to the longer side of the pits. Since these features appear on both the Au-metallized InP and GaAs, we will illustrate only the InP case in the following discussion.

Fig. 1. Images of line defects taken with various two-beam conditions. a(top left): Reflection $g = (220)$, zone axis $Z = [001]$. b(top right): $g = (220)$, $Z = [001]$. c(bottom left): $g = (040)$, $Z = [001]$. d(bottom right): $g = (131)$, $Z = [114]$. Symbols LD and ED in b denote the line defect and its associated edge defect, respectively.

Fig. 2. A stereo-pair showing the images of line defects lying near the Au-metallized surface of InP $g = (2\bar{2}0)$.

The line defects were imaged using various two-beam conditions. Available reflections around the $\{001\}$ zone within the specimen tilt angle of $\pm 30^\circ$ were $\{220\}$, $\{400\}$, and $\{311\}$ type. Results of this contrast experiment are shown in Fig. 1. It is seen that the line defect (LD) images disappear for $\bar{g} = (2\bar{2}0)$, but their associated two edge (ED) images (see Fig. 1b) remain in-contrast for all reflections. To further understand these two image features, *i.e.*, those of line and edge parts, we took the stereomicrograph in the dynamical two-beam condition (see Fig. 2). The LD parts of the defects are seen to lie parallel to the Au-metallized surface but slightly below it. The associated edge defects ED are steeply extended from the two ends of LD toward the surface. To understand the nature of the ED parts, we imaged these defects in both the dynamical and kinematical conditions, while keeping the reflection that makes the LD part out of contrast. Figures 3a and 3b are taken in the dynamical [$g = (220)$] and kinematical conditions, respectively. One black arrow indicates the exact location of a line defect, and two white arrows the sites of the associated edge defects. As seen in Fig. 3b, the defect is actually located inside a reaction pit commonly observed at the interface of heat-treated Au/III-V semiconductors. The two edges are quite steep as compared with the long face of the elongated pit. Because of this steep angle of the edges, the thickness fringes associated with dynamical reflections always appear at these edge-face regions (see two white arrows in Fig. 1b), regardless of the type of reflections used.

From this contrast experiment, it can be inferred that these line defects, LD, have a strain field similar to a pure edge dislocation having the $[110]$ -type Burgers vector and lie at the bottom of reaction pits. As noted in Fig. 1, however, the size varies from one defect to another, and, therefore, these defects cannot be assigned to be dislocations, because dislocations should have a constant image width as long as they lie on the same depth of the crystal. It is also noted that in addition to the variable line widths these defects have variable lengths.

An interesting observation in TEM was that heating has caused the gradual disappearance of the LD images. Figure 4 illustrates these image features before and after beam heating inside a microscope. The beam heating was achieved by simply removing the second condenser aperture, thus exposing the specimen to an intense electron beam at the crossover for about 5 min. This exposure caused the black-white (BW) LD images to disappear slowly, leaving only the images of the two edges, and, in addition, to form the mottled background behind. A careful examination of this mottled background at high resolution revealed it to correspond to a continuous distribution of small islands which were formed on the surface by the local agglomeration of an unidentified surface film. When a specimen is not irradiated, the BW line defects have never disappeared. This observation indicates that the BW line defects are connected with surface straining at the bottom of the elongated pits, probably by an un-

known surface film. An intense electron irradiation breaks up this film into small islands, resulting in a relaxation of such a strained state. This leads to the formation of the mottled background, accompanied by the disappearance of the strong BW images. It can be therefore concluded that the relatively unstable strain region is present between a surface film and the substrate.

The nature of strain fields associated with these line defects can be determined using $\pm g$ reflections in combi-

Fig. 3. The images of line defects taken in the (a, top) dynamical [$g = (220)$] and (b, bottom) kinematical conditions. A black arrow marks the position of a line defect which is out of contrast and white arrows indicate the associated edge defects.

Fig. 4. The images of line defects (black arrows) taken (a, top) before and (b, bottom) after electron beam irradiation inside a microscope. $g = (220)$.

nation with bright- and dark-field images. This technique was previously demonstrated (3) to be useful in establishing the nature of strain fields for three-dimensional epitaxial islands of Ni grown on $\{001\}$ Cu. The bright-field images of the line defects taken with $\pm g$ reflections are shown in Fig. 5. Here, we found that the line defects exert a compressive stress on the surface of the semiconductor. This is schematically shown in Fig. 6. This strain state can be achieved equivalently by a local removal of rows of atoms from the surface of the semiconductor. It is conceivable that the preferential interaction of Au atoms with the In or Ga component can cause a similar stress state. This assumption is consistent with our observation (4) that interactions of Au with GaAs or InP result in the evolution of As or P gas. Gold presumably reacts preferentially with In or Ga (1), and rejects P or As, leading to the lattice collapse state (compressive state), as indicated by the strain fields associated with LD's.

The fact that the observed line defects are arranged along the $\langle 110 \rangle$ direction can be rationalized by the presence of atomic anisotropy in the $\{100\}$ plane. A close examination of stacking sequence along the $\{100\}$ plane indicates that the planes of P and In alternate along the $\langle 100 \rangle$ direction. In other words, similar to the $\{111\}$ planes, the $\{100\}$ planes are polar surfaces. This anisotropy results in the formation of elongated reaction pits previously observed (5) on Au-metallized GaAlAs surface. Chang *et al.* (5) discussed the formation of the reaction pits in terms of this anisotropy in the atomic arrangement in the $\{100\}$ faces. It appears, therefore, that the observed line defects are responsible for the early stages of pit formation and its subsequent growth. Although reactions of InP and GaAs with Au-metallization lead to the formation of pits, Pd metallization did not produce such pits. This

Fig. 5. The images of line defects taken with $\pm g$ reflections. a(top): $g = (220)$. b(bottom): $g = (220)$.

trend is found to be similar for the line defects; the line defects were not observed on Pd-metallized InP or GaAs. This structural difference can be rationalized (3) in terms of Pd's being capable of interacting equally with both the metal and metalloid components of the compound semiconductors, whereas Au can react strongly only with the metal component. For Au, this results in an ejection of P during heat-treatment, which leads to the lattice collapse state. Therefore, the presence of crystalline anisotropy

Fig. 6. A schematic illustration showing the stress state of a (001) InP substrate as a result of an interaction with Au. The vertical lines indicate the bending of the $(1\bar{1}0)$ lattice planes of InP.

Fig. 7. TEM micrograph showing the line defects (LD's) lying along the channels of thinned Au-metallization on InP.

will manifest itself in the unique morphology of pit structures, which is also followed by the LD structure.

It has been shown that the exact location of the LD's is at the bottom of pits. Although there is undoubtedly some surface film associated with such defects, the exact chemical composition could not be easily determined. But, we believe that the surface film is an alloy containing Au and In. In fact, we found regions where the part of unreacted Au still remains on the surface (see Fig. 7). A careful examination of such regions indicated that the unreacted part of Au film is actually split by channels in which the film is effectively thinner or almost absent. Furthermore, we found that the line defects lie inside these channels. A direct reaction of the semiconductor surface with Au is presumably responsible for the formation of the LD's.

In a device structure, the observed defects may play an important role in the spreading (6) of a Au-contact layer outside of a defined mask after heat-treatment, because

the surface diffusion of Au on the compound semiconductors can be quite high. In fact, it was recently shown (7) that the use of a passivation layer could minimize such a spreading. To determine the property of the unknown surface film, we have tested the effect of In film on the defect structure of InP, and found that under the same experimental condition In alone does not produce such a line defect. It is therefore most likely that the surface film associated with the line defects must have contained Au. In addition, the reaction pits should be present to stabilize such defects. It is concluded that Au primarily interacts with the In or Ga component via a surface (or interfacial) diffusion mechanism and forms the line defects. A continuous line defect formation leads to the creation of macroscopic reaction pits, where their intermetallic binary alloys (Au-In or Au-Ga) are accommodated.

We are currently conducting an experiment to provide an answer as to which plane the Au-metallized side is. An identification of In or P plane in the case of InP substrates should determine unambiguously the direction of line defects on the {001} plane, *i.e.*, [110] or [$\bar{1}\bar{1}0$]. This result will be reported shortly.

ABSTRACT

The oxygen content of silicon wafers has been determined by infrared absorption and photon activation analysis (PAA). We find a linear relationship between the absorption coefficient α_{ox} and the oxygen content (PAA). The conversion factor γ_{ox} is $3.0 \times 10^{17} \text{ cm}^{-2}$, in remarkable agreement with various recent investigations employing independent analytical methods.

The interstitial oxygen content of silicon crystals plays an important role in modern device technology due to its electrical behavior and its dominant influence on precipitation for internal gettering kinetics (1). Its amount is commonly determined spectroscopically by measuring Key words: interstitial oxygen in silicon, infrared absorption, photon activation analysis.

the well-known $9 \mu\text{m}$ band of the Si-O-Si vibration (2) (Fig. 1). The absorption coefficient α_{ox} derived from this IR transmittance curve is multiplied by a calibration factor γ_{ox} in order to get a concentration value.

Today, several calibration factors are used in the silicon industry. The first calibration factor employed, $\gamma_{ox} = 2.83 \times 10^{17} \text{ cm}^{-2}$, was found by Kaiser and Keck (3, 4). Other

Fig. 1. IR spectra of a 2 mm thick silicon slice polished on both sides taken in the range between 1400 and 900 cm^{-1} . a(left): CZ-Si containing interstitial oxygen and FZ-Si without detectable oxygen showing the pure lattice absorption of silicon. b(right): Interstitial oxygen band of the CZ-Si slice after subtracting the background absorption of the Si-lattice; the transmission minimum and maximum of the O_i band are marked.

calibration factors were determined by Baker (5, 6) and Graff (7) to be $\gamma_{\text{ox}} = 4.81 \times 10^{17} \text{ cm}^{-2}$ and $2.45 \times 10^{17} \text{ cm}^{-2}$, respectively.

The latter was used by measurement standard 50438 issued by DIN (Deutsches Institut für Normung) (8), and was taken over by ASTM (9) in 1981. Recently, a Japanese group (10) re-evaluated the calibration curve again and determined it to be

$$\gamma_{\text{ox}} = 3.05 \times 10^{17} \text{ cm}^{-2}$$

This value was already found in 1973 by Yatsurugi *et al.* (11). However, Yatsurugi's value got only little attention. A further confirmation for this new value has been published by a Chinese research group (12).

Although three consistent values are published for the calibration factor, some open questions still exist regarding the validity of its determination, such as for the precipitated oxygen which does not contribute to the 9 μm band.

Experimental

The samples were taken from silicon crystals produced with today's state-of-the-art oxygen-controlled CZ-growth technique. The crystals were boron doped with a specific resistivity greater than 15 $\Omega \text{ cm}$, (100) oriented with a diameter of 100 mm. Samples were taken from eight crystals with different oxygen content ranging from 4 to $11 \times 10^{17} \text{ cm}^{-3}$ (DIN calibration). From each ingot, three adjacent pieces were cut with 10 and 2 mm thickness. The 2 mm slices were used for IR measurement, the 10 mm slug for photon activation analysis. The IR samples were polished on both sides with diamond slurry. Cylindrically shaped samples were drilled from the center and regions far enough from the edge for the PAA; the PAA samples were bright-etched and chemically cleaned.

Redissolution experiments carried out between 1250° and 1300°C (13) showed that the material investigated did not contain any measurable precipitated oxygen already introduced during the pulling process. However, for high oxygen samples (O_i greater than $10 \times 10^{17} \text{ atom/cm}^3$, DIN calibration), we know from diffusion length measurements (14) that small amounts of oxygen can be precipi-

Fig. 2. Typical radial oxygen distribution of the silicon slices used in the experiment.

tated if the diffusion length is smaller than 400 μm . The material we used had always diffusion lengths greater than 400 μm , indicating that only negligible amounts of oxygen may not be built-in on interstitial sites (14, 15). The homogeneity of the radial oxygen distribution was checked by scanning an IR spot over the diameter. Figure 2 shows a typical result.

IR analysis.—The IR analyses were carried out using two different pieces of equipment: a Fourier transform spectrometer (FTS 14 Digilab), and a dispersive spectrometer (PE 580 B).

For determining the interstitial oxygen content, the IR transmittance between 1400 and 900 cm^{-1} was recorded (Fig. 1). Due to the superposed multiple phonon excitations of the silicon host lattice, all sample spectra have been subtracted from an oxygen-free reference spectrum. For calculating the oxygen absorption coefficient α_{ox} , Eq. [1] has been applied, taking into account multiple reflection contributions (6, 16)

$$\alpha_{\text{ox}} = -\frac{1}{d} \ln \left[\frac{-B + \sqrt{B^2 + 4AT}}{2A} \right] \quad [1]$$

The abbreviations A , B , T , and d are explained in the Appendix. The diameter of the IR spot employed was 8 mm. Thus, the IR signal averages the oxygen data in a sample volume which is comparable to that used in PAA.

Photon activation analysis combined with inert gas fusion.—The absolute oxygen content in silicon is analyzed by activation with high energy photons (17, 18) generated by bombardment of a tungsten target with 30 MeV electrons. This means that the maximum of intensity of the Bremsstrahlung is in the range of about 20 MeV. This energy range delivers a giant resonance for the nuclear reaction

which the analysis is based on. During the irradiation, the sample rotates to get a homogeneously activated sample. The entire homogeneously activated sample volume is then used in the analysis. After irradiation, the samples are etched with nitric acid/hydrofluoric acid (1:1) in order to remove activated surface oxide and to eliminate blank value problems. The inert gas fusion is performed in a graphite crucible with iron as metallic bath. The sample is completely dissolved at 2000°C, under helium gas flux. The sample collection efficiency is about 100%. The molten silicon reacts preferentially with graphite, whereas oxygen reacts with carbon to yield carbon monoxide. The oxidation of the generated CO to CO_2 is caused by Schütze reagent I_2O_5 . Carbon dioxide is absorbed on ascarite.

The determination of the activated oxygen is based on the annihilation radiation, generated by β^+ -radiation of ^{15}O , which reacts with an electron under emission of two gamma rays of 511 keV

Table I. List of values of oxygen contents (PAA) and IR absorption coefficients

Series	Oxygen content (10^{17} at. cm^{-3}) (PAA)	IR absorption coefficient (cm^{-1})	
		PE 580 B	FTS 14
A: A_1	6.37 ± 0.76	1.90	1.93

H_r		4.57	4.59
H_m		4.63	

$$\beta^+ + e^- = 2\gamma$$

$$E_\gamma = 511 \text{ keV}$$

For measuring the 511 keV line, it is necessary to take the gas fusion process, in order to avoid an interference of the 511 keV line by the Compton effect of ^{28}Al , which comes from the following nuclear reaction

Fig. 3. Plot of the oxygen concentrations determined by the photon activation analysis (PAA) vs. the absorption coefficient of the IR active oxygen band at 1106 cm^{-1} . A least mean squares fit yields a conversion factor $\gamma_{\text{ox}} = 3.0 \times 10^{17} \text{ cm}^{-2}$.

The 511 keV γ -line is measured with two NaI (TI) detectors in coincidence in order to determine oxygen decay curve and content. The calibration of the analysis method described above is done by a standard; in case of oxygen Al_2O_3 is taken. Al_2O_3 is measured without chemical separation on a second detector design.

Results

Table I compares the oxygen concentrations obtained by photon activation analysis (PAA) with the absorption coefficients determined by IR spectroscopy. For each class of oxygen concentration, eight individual photon activation analyses were carried out.

The accuracy of the oxygen determination by PAA is typically better than $\pm 15\%$. The detection limit of this method is $5 \times 10^{15} \text{ cm}^{-3}$. However, the accuracy of the IR data is better than $\pm 2\%$.

In Fig. 3, the data listed in Table I are plotted. A least mean squares fit yields a straight line with a slope of $3.0 \times 10^{17} \text{ cm}^{-2}$. The standard deviation amounts to $\pm 0.2 \times 10^{17} \text{ cm}^{-2}$. This gives the following calibration factor for the IR absorption method

$$\gamma_{\text{ox}} = [3.0 \pm 0.2] \times 10^{17} \text{ cm}^{-2}$$

Discussion

The calibration factor of $3.0 \times 10^{17} \text{ cm}^{-2}$ is close to the values recently published by Li *et al.* (12), Iizuka *et al.* (10), and Yatsurugi *et al.* (11). Also, our calibration factor is close to the value of $2.83 \times 10^{17} \text{ cm}^{-2}$, which was the first to be published by Kaiser *et al.* (3). All these factors

Fig. 4. Calibration curves for the oxygen concentration published by different authors.

quoted were obtained by different analytical methods. Li *et al.* used charged particle activation and helium carrier gas fusion-gas chromatography (12). Yatsurugi *et al.* used charged particle activation (11). Kaiser *et al.* used vacuum fusion gas analysis (3). T. Iizuka *et al.* used charged particle activation (10). In this work, we used photon activation combined with inert gas fusion.

When compared with the calibration factors employed in ASTM and DIN standards (Fig. 4), a calibration factor of $3 \times 10^{17} \text{ cm}^{-2}$ appears to be reasonable. It gains additional importance and credibility in that a variety of recent investigations yields practically the same value. Therefore, a new discussion about the calibration factors used in the actual standards is deemed necessary.

The Growth and Characterization of HgTe Epitaxial Layers Made by Organometallic Epitaxy

I. Bhat* and S. K. Ghandhi**

Department of Electrical, Computer, and Systems Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

Mercury telluride layers have been grown on cadmium telluride substrates, by the reaction of diethyltelluride and mercury. Typical growth rates, at 415°C, are 3.3 $\mu\text{m/h}$. Resulting films had an apparent Hall mobility of $1 \times 10^5 \text{ cm}^2/\text{V}\cdot\text{s}$ at liquid nitrogen temperature, and an effective electron concentration of $2 \times 10^{19}/\text{cm}^3$. The growth and electrical characteristics of these films are described in this paper.

Mercury telluride is a semimetallic compound which has been investigated because of its unique material properties and also because it is the major component of the mixed II-VI compounds, $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$. Conventionally, these compounds are grown in closed systems. Vapor transport systems, with elemental sources, have also been used (1), but require multiple zone furnaces and are relatively complex in their operation. The growth of HgTe by organometallic chemical vapor deposition (OMCVD),

using elemental mercury and diethyltelluride, offers the alternative of a relatively simple open-flow system. Here, high growth rates at low temperatures can be achieved with comparable crystal morphology.

Kuech *et al.* (2) used a hotwall system to grow HgTe on CdTe substrates, by using elemental mercury and dimethyltelluride. However, the growth rate reported was very low (0.3-0.6 $\mu\text{m/h}$) and no electrical characteristics of the layer were given. Irvine *et al.* (3) used diethyltelluride and elemental mercury to grow HgTe at 410°C. Again, no details of the technique were provided, and no detailed study of the growth characteristics was attempted.

**Electrochemical Society Active Member.

Key words: MOCVD, OMVPE, HgTe, epitaxy, organometallic.

In this work, we report on the growth of HgTe on (100)-oriented CdTe substrates, and over a wide range of deposition temperatures and reactant partial pressures. It is shown that the 77 K mobility of these layers is higher than that presented in earlier work.

Experimental

Epitaxial growth of HgTe was carried out at atmospheric pressure in a quartz horizontal reactor tube, using palladium-purified hydrogen over heated mercury.¹ Diethyltelluride (DETe)² vapor was introduced by bubbling hydrogen through DETe bubbler, which was held at 15°C.

The main reactor tube was 51 mm diam, and used a RF-heated graphite susceptor, located 6 cm from the inlet. The mercury vapor source was provided by passing hydrogen over a heated chamber containing mercury. In addition, the tube wall in front of the susceptor was heated to prevent mercury condensation.

Substrates used for epitaxial deposition were (100)-oriented undoped CdTe wafers.³ Several wafers of (100) 3° → (110) orientation have also been used for our work. Substrates were purchased in polished form. These were first cleaned in organic solvents, after which 20 μm of the surface was etched off in a 2% Br-methanol solution to result in a highly polished, shiny surface.

After loading the substrates, the system was thoroughly purged with nitrogen followed by hydrogen. The hydrogen flow through the Hg line was set at 8-10 cm³/min, and the flow through all other flowmeters adjusted to their appropriate values. The RF was turned on followed by the tube heater. The Hg heater was turned on when the susceptor temperature reached about 250°C. This sequence of steps was necessary to prevent any condensation of Hg on the substrates prior to growth. At all times during the growth run, the susceptor temperature was kept higher than Hg temperature. This prevents mercury droplets, which are not saturated with tellurium, from etching the substrate and causing etch pits in the grown layer. Once the substrate temperature reached the growth temperature, hydrogen through the Hg line was increased to the desired value, the DETe bubbler was turned on. The total gas flow used was 0.67 l/min in all these experiments.

The RF heater was shut down at the end of the deposition run, which lasted 1-2h. Next, the hydrogen flow through DETe bubbler was turned off, followed by the tube heater and the Hg heater. The total flow through the system was increased to 4 l/min to allow a faster cool-down of the system. Once the susceptor reached 150°C, the hydrogen flow through the mercury was turned off, and the system was purged with nitrogen prior to removing the substrates from the reactor.

The thickness of the deposited layer was measured gravimetrically. In some cases, this was verified by scribing the substrates, and then observing with the aid of a scanning electron microscope. No separate etching was found necessary to delineate the interface. Good correlation was obtained between these techniques.

Electrical measurements were made by the van der Pauw technique, after deposits from the edge and the back side were etched off. Ohmic contacts were made to the substrate using silver epoxy. No thermal alloying cycle was found necessary to ensure a good ohmic contact to these samples.

Results and Discussion

Initial HgTe growth attempts were made over a wide range of reactor conditions in order to establish the conditions for growing good epitaxial layers. Next, a few growth runs were carried out under the following conditions. (i) for a fixed partial pressure of Hg, DETe, and total flow, the susceptor temperature was varied from 395° to 440°C. (ii) The hydrogen flow through the DETe bubbler was varied from 64 to 190 ml/min, (corresponding to

the DETe partial pressure of 0.7×10^{-3} to 2×10^{-3} atm). Other parameters, such as a mercury partial pressure, total flow through the system, and substrate temperature, were fixed during these experiments. (iii) The susceptor temperature, total flow through the system, and DETe partial pressure were kept fixed, while the Hg partial pressure was varied from 0.03 to 0.1 atm.

In all the above experiments, the Hg reservoir temperature was held at 300°C, and the tube in front of the susceptor was heated to 250°C.

Layer morphology.—The surface of all the grown HgTe layers shows a series of steps, all running parallel to one of the (011) directions. The direction of this pattern was independent of the position or the orientation of the sample in the reactor. The step features were more prominent on the layers grown on (100) 3° → (110)-oriented substrates, than on (100) substrates. Other workers (3) have also reported similar types of surface features for HgTe layers grown on (100) 2° → (110) CdTe substrates. Figure 1 shows the surface morphology for a typical layer grown during the course of this work.

In all our work, we observed that the layer morphology was strongly dependent on the substrate quality, with samples cut from some substrates providing consistently better morphology than those cut from other substrates. This is indicative of the immature state-of-the-art of bulk CdTe substrate technology.

Effect of temperature.—The substrate temperature is the main parameter affecting the growth rate, and control of this temperature to within $\pm 1^\circ\text{C}$ is very important for obtaining reproducible results. The growth rate of the HgTe layer was measured as a function of the substrate temperature over the range 395°-440°C, while maintaining all the other parameters constant. The gas flows chosen for these experiments were a total hydrogen flow of 0.67 l/min, a DETe flow of 1.3 ml/min, and a Hg flow of 38 ml/min, corresponding to partial pressures of 2×10^{-3} and 5.7×10^{-2} atm, respectively (flow rate of the pure reactants are given here). Figure 2 shows the variation of the growth rate with temperature, and exhibits an activation energy for the deposition process of 30 kcal/mol over the entire range. Little or no growth was observed below about 400°C. In a pyrolysis study (3) of DETe, it was noted that the partial dissociation enthalpy of the C-M bond is about 25 kcal/mol, which agrees reasonably well with the activation energy obtained by direct measurement of the deposition process. Hence, the growth of HgTe is probably limited by the stability of the DETe molecule.

Effect of mercury partial pressure.—The growth rate at any specific temperature was found to be independent of

Fig. 1. Surface morphology for a HgTe layer. $T: 415^\circ\text{C}$. Growth rate: 3.3 μm/h. $p_{\text{Hg}}: 0.055 \text{ atm}$. $P_{\text{DETe}}: 2 \times 10^{-3} \text{ atm}$.

Growth Rate
($\mu\text{m/hr}$)

Fig. 2. Growth rate of HgTe layers vs. $10^3/T$. $p_{\text{DETe}}: 2 \times 10^{-3}$ atm. $p_{\text{Hg}} = 0.05$ atm. Total flow: 0.67 l/min.

the mercury partial pressure, within experimental error. This is expected because p_{Hg} is 20 to 40 times higher than p_{DETe} , so that the DETe flow will be the rate limiter in the transport process. The minimum Hg pressure is determined by the equilibrium partial pressure of Hg at the growth temperature and is approximately 0.01 atm at 415°C (4, 5). A somewhat higher mercury pressure (by a factor of 2-4) was used to prevent decomposition of the growing layers.

Effect of DETe flow.—Experiments were conducted to determine the effect of DETe flow rate on the growth rate of HgTe. These were carried out with a hydrogen flow rate of 64-190 ml/min through DETe bubbler, with 78 ml/min of hydrogen over the mercury reservoir. This corresponds to 0.4-1.3 ml/min of pure DETe and 38 ml/min of pure mercury flow. The total hydrogen flow was 0.67 l/min. For these experiments, the susceptor temperature was kept at 415°C, the reactor tube at 250°C, and the mercury reservoir at 300°C.

Figure 3 shows a sublinear behavior in the growth rate with DETe flow. A Langmuir-Hinshelwood model (6) can be invoked to explain this behavior. We note that the deposition process is kinetically controlled for the following reasons: first, the growth rate of HgTe varies with the growth temperature (with an activation energy of 30 kcal/mol); second, the growth rate observed at 415°C is

growth rate
($\mu\text{m/hr}$)

Fig. 3. Growth rate vs. p_{DETe} . $T: 415^\circ\text{C}$. $p_{\text{Hg}}: 0.05$ atm. Total flow: 0.67 l/min.

approximately one tenth of what would be expected if the process were mass-transport limited; finally, the growth rate depends on the substrate orientation.

We propose that the growth of HgTe occurs by the simultaneous noncompetitive adsorption of $(\text{C}_2\text{H}_5)_2\text{Te}$ or $(\text{C}_2\text{H}_5)_2\text{Te}$ and Hg atoms, followed by a surface catalyzed reaction. The growth rate R for this model is given by

$$R = K_1 \theta_{\text{DETe}} \theta_{\text{Hg}}$$

where K_1 is a rate constant, and θ_{DETe} and θ_{Hg} are the surface coverages of DETe and Hg, respectively. The surface coverage can be related to the respective gas phase partial pressure by

$$\theta_{\text{DETe}} = \frac{\beta_{\text{DETe}} p_{\text{DETe}}}{(1 + \beta_{\text{DETe}} p_{\text{DETe}})}$$

Here, p_{DETe} is the DETe gas phase partial pressure and β_{DETe} is the ratio of the rate constant for adsorption of DETe to the rate constant for desorption. In addition

$$\theta_{\text{Hg}} = \frac{\beta_{\text{Hg}} p_{\text{Hg}}}{(1 + \beta_{\text{Hg}} p_{\text{Hg}})}$$

where all the terms have their usual meanings. Hence

$$R = \frac{K_1 \beta_{\text{DETe}} p_{\text{DETe}} \beta_{\text{Hg}} p_{\text{Hg}}}{(1 + \beta_{\text{DETe}} p_{\text{DETe}})(1 + \beta_{\text{Hg}} p_{\text{Hg}})}$$

Since elemental mercury is used, at vapor pressures in excess of the equilibrium value, it is reasonable to assume that $\beta_{\text{Hg}} p_{\text{Hg}} \gg 1$. Then

$$R = \frac{K_1 \beta_{\text{DETe}} p_{\text{DETe}}}{(1 + \beta_{\text{DETe}} p_{\text{DETe}})}$$

so that the predicted growth rate is sublinear in p_{DETe} and independent of p_{Hg} .

The actual reaction mechanisms are, in all probability, more complex than those proposed here. However, in the absence of detailed experimental data, it serves no useful purpose to present them now.

Electrical characteristics.—Hall and resistivity measurements were made at 77 and 300 K by means of the van der Pauw method, with a magnetic field strength of 2.3 kG. All the layers were n-type at liquid nitrogen temperature with an apparent carrier concentration in the range of $1-4 \times 10^{16} \text{ cm}^{-3}$. No significant changes in the carrier concentration or resistivity at room temperature were observed on different HgTe layers grown under various growth conditions. This is expected of a semi-metal like HgTe, in which the intrinsic carrier concentra-

Fig. 4. Apparent mobility and carrier concentration at 77 K vs. T . $p_{\text{DETe}}: 2 \times 10^{-3}$ atm. $p_{\text{Hg}}: 0.05$ atm. Total flow: 0.67 l/min. \circ : Mobility. \square : Carrier concentration.

tion at room temperature is approximately $4 \times 10^{17} \text{ cm}^{-3}$ (7). Hence, the external impurities or the defects do not play a dominant role in controlling its electrical properties at room temperature.

Even though single-carrier analysis of Hall mobility data cannot be applied to find the net carrier concentration in HgTe, this measurement gives a qualitative measure of the relative values of holes and electrons. Figure 4 shows the apparent mobility and carrier concentration (8) at 77 K as a function of the growth temperature. We note that the carrier concentration decreases as the growth temperature is increased. This can be explained as follows: for a constant Hg pressure, we can expect a higher Hg vacancy concentration in the layers as the growth temperature is increased. Since Hg vacancies are believed to behave like acceptors (9), the material becomes more p-type, thus indicating a lower net electron concentration. Measurements made on samples grown at 415°C over a range of Hg pressures (3×10^{-2} to 8×10^{-2} atm) show an increase in electron concentration from 2.2×10^{16} to $3 \times 10^{16} \text{ cm}^{-3}$ and lend support to this argument.

The outdiffusion of impurities from the substrate also plays a role in determining the electrical characteristics of the layers. In fact, it is possible that their diffusion rate in HgTe at the growth temperature can even be higher than the growth rate (10). Residual impurities on the substrate surface after chemical etching can also alter the electrical characteristics of the layer.

Conclusion

HgTe layers have been grown onto CdTe substrates by OMCVD using elemental mercury and diethyltelluride. The growth characteristics have been studied at different growth temperatures and at various reactant partial pressures. The activation energy for the deposition process has been found to be 30 kcal/mol, which is in fair agreement with the partial dissociation enthalpy of the M-C

bond of diethyltelluride. The electrical characteristics of the layers are comparable to those of the best bulk HgTe. In conclusion, this work establishes the feasibility of obtaining device-quality HgTe layers by OMCVD techniques. It is planned to extend this work to the growth of the ternary alloy $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$.

Controlled Film Formation during CCl_4 Plasma Etching

S. E. Bernacki*¹ and B. B. Kosicki²

Sperry Research Center, Sudbury, Massachusetts 01776

ABSTRACT

Carbon tetrachloride plasma etching can be performed in a regime in which a film-like product is simultaneously formed on vertical surfaces but inhibited from forming on horizontal surfaces. If the photoresist profile is properly tailored, this process is capable of etching polysilicon or layered refractory metal (tantalum, molybdenum) silicided polysilicon films with virtually no change in linewidth from the developed photoresist image. We discuss the influence of the masking profile on the etched film profile and present conditions necessary for controlled film formation.

Dry etching is replacing wet chemical etching in selected semiconductor device fabrication steps because of its ability to accurately etch images into underlying films with either vertical or controllably sloped sidewalls. Vertical sidewalls are essential to achieve the degree of linewidth control necessary for the successful operation of MOS transistors on the micron scale. Regardless of which technology is used (plasma etching, reactive ion etching) the origin of the anisotropic etching behavior ultimately lies in directional ion bombardment normal to the substrate surface arising from applied electric fields. Even though this is the root cause of anisotropy, however, other chemical effects can heavily influence the degree of anisotropy actually realized.

In this paper we will investigate one of these chemical effects: that of polymerization or spontaneous deposition of material onto surfaces exposed to the plasma. Gener-

ally, polymerization is regarded as something to be avoided in as much as it may coat chamber and work surfaces and lead to cross contamination or erratic etching behavior. In some instances, however, this phenomenon has been exploited by intentionally coating chamber walls with material that forms volatile products upon ion bombardment, thereby eliminating the redeposition of nonvolatile sputtered material from the chamber walls. Another use of polymerization can be seen in the reactive ion etching of silicon dioxide down to a silicon surface, reducing its etch rate and thereby enhancing the silicon dioxide to silicon etch rate ratio.

We will describe a third use of intentional polymerization, where the operating point is chosen such that the determining factor in the competitive balance between etching and deposition is the local angle between the substrate surface and the ion bombardment direction.

Experimental Procedure

The samples used in this study consisted of LPCVD polysilicon layers 0.3 to 0.5 μm thick, deposited at 615°C onto oxidized, 3 in. diam <100> 20-50 $\Omega\text{-cm}$, p-type silicon

Fig. 1. Cross-sectional diagram of plasma etching chamber

wafers. The polysilicon was doped either by arsenic ion implantation or POCl₃ sourced phosphorus diffusion to resistivities of 10⁻³ to 10⁻² Ω-cm. Within this range, etch rate decreased very slightly with increasing resistivity. The underlying oxide thickness varied between 25 and 500 nm and had no effect on the results. Shipley 3000 positive photoresist of initial thickness 1.2 μm was used throughout, with exposures performed with a Canon PLA 521. Intentional sloping of the photoresist sidewall was obtained by simply postbaking vertical sidewalled resist patterns at temperatures between 110° and 140°C for various lengths of time.

The etching apparatus consisted of the rectangular parallel plate etching chamber diagrammed in Fig. 1. The etching samples rest on the lower grounded electrode with the top electrode excited by a 13.56 MHz RF generator through an appropriate matching network. Both electrodes are rectangular with dimensions of 35 × 53 cm with a 1 cm spacing, giving an enclosed volume of 1.85 liters. The gas feed is via a series of holes spaced 1 in apart along the entire centerline of the long axis of the lower electrode, and the pumping ports are below the outer edge of the lower electrode, as shown. The top electrode is covered by a 1 cm thick quartz plate, and the bottom electrode is anodized aluminum. All other chamber surfaces are aluminum. The entire chamber volume of 12.4 liters is pumped by a 100 cfm Roots blower. The rotary piston roughing pump is charged with Halovac® fluid which is continuously filtered during use. The etching gas was carbon tetrachloride, controlled by a mass flowmeter from a liquid source heated to 36°-40°C. All experiments were carried out at 23°C, with no temperature rise noted throughout the short etching times used (typically a few minutes). Temperatures were measured by means of a thermocouple imbedded in the lower electrode.

Results and Discussion

Table I lists vertical etching rates of common semiconductor materials under chamber conditions of 13 Pa pressure, 35 sccm CCl₄ throughput, and 1000W RF power applied to the top electrode. Estimation of exact power density or volume is difficult because of unknown dissipation in the tuning network and other leakage paths, but the dark space between the plasma and the grounded substrate electrode was approximately 1 mm. With this etch rate ratio of 20 to 1 for doped polysilicon to silicon dioxide, we have been able to routinely define 0.5 μm thick polysilicon gates over 25 nm thermal silicon dioxide without difficulty on 3 in. wafers.

When doped-polysilicon samples masked by photoresist with vertical sidewalls are etched under these con-

ditions, vertical walled polysilicon profiles are easily produced (1). The reason for this behavior can be seen in Fig. 2, which shows that a sidewall film has been formed along the polysilicon edge during etch. The film in this photograph has been partially dislodged by a 1 min dip in a 130°C sulfuric acid solution. The observation of this sidewall film is direct evidence of the surface inhibitor mechanism, which has been cited as the predominant cause of vertical walled behavior at comparatively high chamber pressures and low ion bombardment energies (2). This phenomenon is also more likely to occur in chlorinated gas systems rather than fluorinated because of the increased susceptibility of chlorine containing plasmas to form polymerized films (3).

The etching system lends itself to several interesting and difficult etching applications. One of these is the patterning of layered films of metal silicides on doped polysilicon to produce low resistivity MOS gate electrodes. Most attempts to etch these films have resulted in either poor etching results or complicated multistep etching procedures because of the generally different vertical and horizontal etching rates of the composite layers. Even

Fig. 3. SEM of the edge of an etched film consisting of 1500Å molybdenum silicide on top of 2000Å phosphorus-doped polysilicon. Both the masking photoresist and the sidewall film have been removed in this photograph.

though the vertical etching rates are different here also (see Table I), the presence of this sidewall film results in zero horizontal etching of all layers, allowing smooth, continuous vertical walled profiles to be produced, as can be seen in Fig. 3, which shows an etched film of molybdenum silicide on doped polysilicon.

Another property of this etching system is the ability to severely overetch samples with no observable undercut or sidewall attack, due to the masking nature of this film after it has been formed. A small overetch is generally needed to allow for nonuniformity in most dry etching schemes, but in some cases substantial overetch becomes necessary, for example, to clear filamentary residues where the polysilicon film conformally crosses over steps in the substrate. Such a situation is depicted in Fig. 4, showing etched polysilicon lines crossing over $0.5\ \mu\text{m}$ oxide steps in the substrate with the resist still in place. In Fig. 4a, the sample has been etched just to completion, that is, just to clearing on horizontal surfaces. Note the silicon residues along both sides of the oxide step, which is merely a consequence of the strictly anisotropic etching behavior of this system and the large vertical thickness of poly at this step. The top surface exhibits the characteristic roughness of partially etched polysilicon. Figure 4b has been subjected to a 100% overetch, which was just sufficient to clear the poly filaments. The etched polysilicon sidewall, being coated by polymer, faithfully replicates the photoresist image with no discernible undercut in spite of the necessary overetch. Further study of this etching system has produced evidence revealing the presence of a similar sidewall film upon the photoresist mask itself, in addition to the etched layer. Such a film is shown in Fig. 5, where it has been partially mechanically peeled away from the resist mask. Other photographs show that this film is, in fact, continuous across the resist-polysilicon boundary, and indicates that this is just an extension of the sidewall film previously detected on the polysilicon alone (Fig. 2).

In order to systematically study the properties of these films, a better method of sample preparation was needed rather than the chemical soaking or mechanical displacement shown in the previous samples, which are time consuming and disturb the film. An encapsulation technique devised for this purpose is illustrated in Fig. 6.

Fig. 5. SEM of a polymer film mechanically peeled away from a photoresist sidewall masking a doped polysilicon layer after etching.

After an original resist pattern is used to mask a polysilicon plasma etching operation, the entire sample is coated with an additional layer of thick resist, referred to as encapsulating resist in the figure. The sample is then cleaved, exposing a cross-sectional face of the entire structure. We then make use of the differential etch rate in an oxygen plasma to recess the resist face with respect to all other materials, including the sidewall film, which is held in place by both resists. A key feature is that the film is rigidly constrained in its original configuration, in contrast to earlier preparation methods which relied on mechanical or chemical methods to dislodge the film for

Fig. 4. Etched polysilicon patterns crossing over $0.5\ \mu\text{m}$ substrate steps. A(left): etched just to completion. B(right): etched to completion plus 100% overetch.

Fig. 6. Diagram of encapsulation technique developed to study sidewall film formation.

observation, losing the information conveyed by its original position. From the above description, it is clear that this technique will reveal the sidewall film only on the photoresist and not on the underlying polysilicon line, as the poly will not be recessed by the oxygen plasma. However, as already noted, the film is continuous across the resist-polysilicon boundary, and in every sample which exhibited a polymer film on the resist we have been able to observe the film on the polysilicon. That is, our observations are that the existence of the film on the resist implies existence on the poly.

Figure 7 shows an SEM of a sample prepared as above clearly showing the film along the resist sidewalls. The film does not form on the top surface; presumably, it is prevented from doing so by normal ion bombardment. Also, the film does not cover the entire sidewall, but disappears near the top of the resist as soon as the vertical wall starts rounding off to the top surface. The film is uniform and appears to be 300Å thick on vertical walled samples such as these. Auger analysis of the film reveals mostly carbon and chlorine, suggesting that it is a decomposition product of the CCl₄ feed gas similar to "glow polymer" depositions reported elsewhere in similar RF discharge environments (4).

Fig. 7. SEM of a 0.8 μm wide line etched into a 0.5 μm doped-polysilicon layer prepared by the encapsulation technique in Fig. 6.

There are instances, however, where under these same plasma etching conditions samples exhibit sloped polysilicon walls and a reduction in linewidth dependent on overetch time, implying that the sidewalls were in fact being etched and that the protective film was not forming. Sloping photoresist sidewalls such as those obtained by negative E-beam exposure or resulting from poor mask sample contact during optical contact printing are always associated with such behavior, although the reverse is not always true. That is, vertical polysilicon sidewalls may be associated with either sloping or vertical photoresist sidewalls. This observation, coupled with the disappearance of the film as soon as the sidewall starts to round off at the top surface of the encapsulated samples, as noted above, suggests that this parameter, *i. e.*, "degree to which sidewall is perpendicular to wafer," plays an important role in polymer formation.

Fig. 8. SEM cross sections of resist-polysilicon profiles where no sidewall film and lateral etching are observed.

Fig. 9. Anisotropic etching model used to describe profiles such as seen in Fig. 8.

Fig. 10. Measured sidewall angle tangent ratios plotted against initial photoresist angle. Also indicated are the resist-poly etch rate ratio and the region of sidewall film formation.

To study the relationship between photoresist sidewall slope, polymer film formation, and polysilicon sidewall slope, a series of measurements were made of etching profiles resulting from controlled slope resist patterns created by overbaking vertical-walled patterns. Profile angles were taken from SEM cross sections such as shown in Fig. 8, and sidewall film presence was detected by the encapsulation technique described earlier.

When the masking photoresist has sidewalls possessing large angles, as defined in Fig. 6, the resulting etch profiles closely fit those predicted by a simple, purely anisotropic etching model, which assumes that all points of an exposed surface are etched at constant etch rate R in the vertical direction. Figure 9 applies the model to the current situation of a photoresist mask with sidewall angle θ_{resist} . As a consequence of the resists being etched vertically with rate R_R , the point P in the figure moves to the left at rate $R_R \tan \theta_R$. The movement of point P , the effective mask edge, combines with the etch rate of the polysilicon R_P to produce a sidewall angle θ_{poly} satisfying the relation $R_R \tan \theta_R = R_P \tan \theta_P$. Therefore, $\tan \theta_{\text{poly}} / \tan \theta_{\text{resist}} = R_R / R_P$, independent of θ . Incidentally, this is mathematically equivalent to previous anisotropic models (5), where the normal etch rate of a surface depends on the cosine of the angle between the surface and the vertical. This formulation, however, emphasizes the simplifying assumption of constant vertical etch rate of all surfaces.

When we apply our encapsulation technique to samples in which the photoresist exhibits a large slope, we find

no evidence of sidewall film formation on the masking resist. Conversely, when samples with small or zero angles are etched, we observe vertical polysilicon sidewalls, no change in poly linewidth even upon overetching as much as 300%, and the clear presence of sidewall film as revealed by the encapsulation method.

Figure 10 presents the data from a set of samples as a plot of the sidewall angle tangent ratio vs. θ_R , the original resist angle. Also indicated in the figure is the unpatterned etch rate ratio of the two films, 0.47, obtained from independent runs. For initial $\theta_R > 30^\circ$, the tangent ratio is constant and agrees quite well with the etch rate ratio, as predicted above. As the resist angle decreases below 30° , however, the polysilicon angle no longer decreases in accordance with the model, but rather drops abruptly to zero at about 10° resist angle.

Also shown in the figure are the results of SEM observations of the encapsulated wafer indicating either the presence of the film for $\theta_{\text{resist}} < 15^\circ$ or the absence of the film for $\theta_{\text{resist}} > 25^\circ$. The indeterminate region between 15° and 25° signifies that the film was present in some instances and absent in others, reflecting the sensitivity of this operating region to minor fluctuations in etching parameters.

The results shown in Fig. 10 suggest a relationship between the formation of a polymer film and a deviation from the simple anisotropic etching model, namely, that the film, once formed, can act as an etching mask to prevent any lateral etching. Note that the terms "anisotropic" and "vertical walled" are not the same and cannot be used interchangeably. This can be seen in the discussion involving Fig. 9, where, even though strict anisotropy is assumed, sloping polysilicon sidewalls will occur and are expected if the photoresist is sloped. In the absence of polymer film formation, vertical polysilicon sidewalls will result only with vertical resist sidewalls, whereas in the presence of film formation, vertical polysilicon walls can result even with a finite resist sidewall slope. That is, we can say this film enhances the ability to produce vertical-walled structures by interfering with the sideways etching mechanisms under certain conditions without affecting the intrinsic anisotropy of the etching system.

The question of whether the polymerization phenomenon is related to the intrinsic anisotropy of the system, although an interesting one, will not be addressed in this paper.

The reason for the angular dependence of film formation lies in the flux of positive ion bombardment normal to the substrate surface. For small sidewall angles, the flux onto the sidewall is either zero for $\theta = 0$ or very small, proportional to $\sin \theta$ allowing the polymer film to form under proper conditions. As θ increases, the surface is increasingly exposed to the clearing effect of the ion bombardment, until θ_{crit} , when a rough balance exists between protective film removal and formation. This is not a simple, sharp boundary, however; rather, there exists a blurred transition where both competing effects can occur simultaneously, as is evident from the data. For $\theta > \theta_{\text{crit}}$, the polymer film is completely prevented from forming and etching of the substrate material proceeds. In summary, Fig. 11 illustrates the three distinct etching profiles determined solely by photoresist sidewall angle which may result under identical plasma etching conditions. Clearly, for maximum polysilicon linewidth control the sidewall angle θ should be less than θ_{crit} and prefera-

Fig. 11. Illustration of the three different results which can occur under identical plasma etching conditions as a result of photoresist sidewall angle.

bly zero to assure polymer formation and vertical-walled polysilicon patterns. This is hard, if not impossible, to achieve with projection aligners, which makes this of great potential importance.

The quantity θ_{crit} , therefore, is an observable or a measurable quantity which can provide information about the internal state of the plasma environment and the degree of balance between deposition and etching. Since the degree of deposition is dependent upon (among other parameters) concentration of polymerizing species and the tendency of film removal (and hence etching) is dependent upon ion bombardment flux and energy, one can actually manipulate the θ_{crit} of a system by varying these parameters. For example, the θ_{crit} of our system can be driven towards 90° by increasing the gas flow to 84 sccm, the pressure to 17 Pa, and reducing the power to 800W. Figure 12 shows a sample etched under these conditions resulting in vertical polysilicon sidewalls even for extremely sloping resist sidewalls. However, the figure also shows a disadvantage of pushing the critical angle too high: a high probability of residue in the etched areas. This is to be expected, of course, since by the above parameter variations we have altered the balance point of the system towards spontaneous deposition everywhere.

Conclusions

This paper demonstrates that during plasma etching the original photoresist profile can exert a dominating influence on the lateral etching mechanism through the intermediary phenomenon of selective polymerization on photoresist and etched polysilicon sidewalls. When such is the case, the condition of near vertical photoresist sidewall results in reliable film formation, no observable pattern erosion, and greatest linewidth control. The concept of θ_{crit} is introduced as a measure of the balance point of the competing reactions of etching and film deposition which exists in the plasma environment, and indicates the latitude of photoresist sidewall slope which can be tolerated before any lateral etching takes place.

Porosity-Controlled Nickel Electrode Film by Vacuum Deposition

M. Bica de Moraes, D. M. Soares, and O. Teschke*

Grupo de Hidrogênio, Instituto de Física, UNICAMP, Campinas, 13.100 São Paulo, Brazil

ABSTRACT

We report, for the hydrogen evolution reaction, the electrochemical properties of porous nickel films prepared by vacuum deposition in argon atmosphere. The argon pressure in the deposition chamber determines the film structure. A correlation between electrolytic activity and film structure was observed.

Porous electrodes have been extensively used in electrochemical reactions (1, 2). The advantage of a porous surface structure is a many-fold increase per unit of cross-sectional area of the active surface area. Even though the apparent current density increases considerably, the actual current density is lower than that encountered in conventional plane electrodes, thus leading to a lesser overvoltage. The high specific electrode surface area makes the module more compact both in volume and weight. The catalytic properties of these electrodes can be understood in terms of their macroporosity and microporosity. The macroporosity is the space between crystallite agglomerates and it is a function of their arrangement. It can be observed under an optical microscope and it can be considered as having a definite cross-sectional and geometric perimeter. Microporosity is the very fine porosity existing within or on the surface of the crystallites. It

is characterized by different crystallite diameters which determines the number of adsorbed atoms located in different positions. Recently, nickel deposits with different structural characteristics were obtained by vacuum deposition under different condensation and annealing conditions (3). Electrocatalytic characteristics of nickel electrodes are altered by changes in their crystalline structure (4, 5).

One method of preparation of high porosity nickel films is by evaporation in an atmosphere of inactive gases at low pressures. This technique has been used for the preparation of black metal surfaces for infrared absorption (6) and for the preparation of fine metal particles (7, 8).

This paper describes a method developed for making porous nickel electrodes with controlled porosity by vacuum evaporation. The macroporosity and microporosity were modified by changing the argon pressure during deposition. A correlation between electrocatalytic activity and the electrode surface structure is observed.

Key words: thin films, vacuum deposition, nickel electrode.

Table I. Argon pressures during each deposition

Electrode	First deposition pressure (torr)	Second deposition pressure (torr)
1	0.1	—
2	0.1	0.37
3	0.1	0.75
4	0.1	1.1

Experimental

The electrodes were prepared in an ordinary high vacuum evaporation unit by deposition of nickel films onto metal screens in argon gas at low pressures. Nickel was evaporated inside the vacuum chamber by means of a tungsten wire basket heater. When evaporation was carried out in an argon pressure not lower than ≈ 0.05 torr, a film of porous structure (black nickel) was formed onto the metal screen. Argon gas (purity better than 99.99%) was admitted to the chamber by means of a variable leak valve. Evaporations were made with high purity nickel (99.96%), while the wire basket heating current was provided by an ac power supply. In order to attain, for a given argon pressure in the chamber, good reproducibility on the thickness and porosity of the nickel films, the

Fig. 1. Micrograph of a nickel electroplated electrode surface

Fig. 2. Morphologies of black nickel catalyst films deposited at various argon pressures P . a(top left): single-layer film, $P = 0.1$ torr. b(top right): two-layer film, $P = 0.1$ torr (first layer) and $P = 0.37$ torr (second layer). c(bottom left): two-layer film, $P = 0.1$ torr (first layer) and $P = 0.75$ torr (second layer). d(bottom right): two-layer film, $P = 0.1$ torr (first layer) and $P = 1.1$ torr (second layer).

same weight of nickel (0.1g) was evaporated in each deposition. The low residual background pressure in the chamber ($\sim 2 \times 10^{-6}$ torr) before evaporation assured a very small degree of contamination of the films.

The metal screens that supported the nickel electrocatalysts were 25 cm² squares cut from the same stainless steel 40 mesh screens. The screens were cleaned, degreased, and nickel electroplated prior to the electrocatalyst vacuum deposition. One of screens was deposited with a single black nickel layer, while all the others were deposited with two successive layers at two different argon pressures, as shown in Table I.

One of the inherent difficulties with black nickel films is their poor adhesion to the substrate (3). However, we found that treatment of the samples by a hot KOH solution improves adhesion to a large extent. After vacuum deposition, the screens were immersed in a 10% KOH solution at room temperature. The temperature of the solution was then slowly raised. The screens remained in the solution for about 20 min, when the temperature reached 70°C. Black nickel films treated in this way showed not only improved mechanical adhesion, but also withstood corrosion by the alkaline electrolyte in a very satisfactory way. All the screens listed in Table I underwent the KOH fixing treatment described above. When two layers were deposited on the same screen, the fixing treatment was repeated after each deposition.

Results and Discussions

The morphologies of the film surfaces were studied by means of scanning electron microscopy (SEM). SEM micrographs of regions of several electrode surfaces are shown in Fig. 1 and Fig. 2a to 2d. Figure 1 shows the surface of an electrode before receiving the vacuum-deposited nickel overlayer. Its crystallite structure is characteristic of electrolytic nickel depositions made with a Watts solution at 80°C and a current density of 10 mA/cm². We may also observe that there is no significant microporosity in this sample. The surface of an electrode with a vacuum-deposited black nickel film at an argon pressure of 0.1 torr (electrode no. 1) is shown in Fig. 2a. The photograph shows that the macrostructure of the electrode film was enhanced by the formation of larger crystallite conglomerates, resulting in a larger macroporosity. We may also observe that the crystallites' microstructure is now substantial. The surface structure of the electrode no. 2 is shown in Fig. 2b. The first deposition essentially increased the macrostructure area, while the second one gave a finer structure to the crystallites, increasing substantially their microareas. The micrograph of Fig. 2c exhibits the surface of electrode no. 3. Void electrode spaces are estimated by comparing the light color region in the photograph with the gray and the black ones, which correspond, respectively, to the upper, intermediate, and bottom levels of the deposited structure. The surface structure of electrode no. 4 is shown in Fig. 2d. The second deposition produces a fusion of a few crystallite conglomerates resulting in a decrease in the macroporosity.

In order to relate the film structure to its catalytic activity, the films were tested for the hydrogen evolution reaction (HER). Electrochemical studies of the catalysts were performed in an electrolysis test cell by measuring the voltage drop between the working electrode and the reference electrode. The working electrodes consisted of 10 cm² disks cut from each one of the prepared square screens. The reference electrode was Hg/HgO, and Luggin capillary tubing was used to make the electrical connections between the reference electrode and the electrolysis cell components. The counterelectrode was a 10 cm² platinum disk. In all electrochemical measurements, KOH 30% at 80°C was used as an electrolyte. The temperature was thermostatically controlled. The electrochemical activity of the electrodes was measured by a current interrupter technique, which is described elsewhere (9).

A satisfactory reproducibility of the electrochemical measurements was obtained after pretreatment of the electrodes at 1 A/cm² during 30 min. The set of Tafel plots

Fig. 3. Tafel diagrams for the hydrogen evolution reaction for various nickel-deposited electrodes. \blacktriangle , \triangle , \bullet , and \circ correspond to electrode films whose surface morphologies are shown in the micrographs of Fig. 2a, 2b, 2c, and 2d, respectively.

for the hydrogen evolution reaction is plotted in Fig. 3. Each plot corresponds to one of the electrodes whose surfaces are shown in Fig. 2a through 2d.

A correlation between electrolytic activity and film structure is observed by means of the plots of the electrode voltage against the reference electrode as a function of the argon pressure at which the uppermost nickel film layer is deposited. These plots are given in Fig. 4. They were obtained from the plots of Fig. 3 by taking the electrode current density as a parameter. The plots show that there is a minimum of the electrovoltage for an argon deposition pressure of the uppermost layer of approximately 0.7 torr. The different overvoltage presented by each electrode is related to their different structural characteristics.

The hydrogen in the interior surface is produced, and a steady current will be supported only if an efficient gas

Fig. 4. Electrode polarization voltage E as function of the argon deposition pressure for the uppermost nickel film layer for various current densities.

and ion transport from the surface to the bulk electrolyte through the pore structure takes place. The minimum overvoltage for the various electrodes was obtained by the maximum macroporosity film showing that mass transport plays an important role in electrode overvoltage. From Fig. 3, we observe that for the maximum measured current density the transport-limited current density plateau was not yet reached.

Conclusions

We have shown that vacuum-deposited black nickel films can be successfully used as electrocatalysts for the hydrogen evolution reactions with high current densities. The deposition of the catalytic film on the nickel-electroplated electrodes was found to cause a reduction on their overvoltage, and to depend on the argon pressure at which the uppermost film layer was deposited. An optimum nickel film structure for which the overvoltage reduction is a maximum was found to exist.

Characterization of Implanted Nitride for VLSI Applications

M. J. Kim* and M. Ghezzi*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

A silicon nitride layer formed by nitrogen implantation was characterized for VLSI application. Molecular nitrogen was implanted in an energy range of 5 to 60 keV for forming various nitride layers during subsequent annealing at 1000°C in nitrogen. The nitride layers formed were characterized before and after furnace annealing with differential IR, SIMS, and ellipsometry to find a useful implantation condition for a local oxidation mask. The initial IR peak of the implanted nitrogen was 815 cm⁻¹ for the entire implantation energy range. While the position shifted to a higher wave number for the high energy implants after annealing, the low energy implants peak remained very close to 830 cm⁻¹, which is comparable to the LPCVD nitride peak. This finding suggests that the composition of the low energy nitrides is nearly stoichiometric. Annealing shifted the concentration profile toward the surface and increased the peak nitrogen concentration. The nitride profile peaked at the surface or disappeared below 10 keV. The masking properties of these nitrides were tested by growing 5300Å oxide in steam at 1000°C. The nitrides with dosages of 5×10^{16} N₂⁺/cm² ions formed an effective oxidation mask for implantation energy below 40 keV. Under the experimented conditions, the nitride formed with 10 keV appeared to be an effective oxidation masking with adequate etching selectivity to SiO₂, reducing the "bird's beak" size to one fourth of the conventional LOCOS.

LPCVD nitride has been used extensively for local oxidation (LOCOS) (1) for VLSI processes. The nitride is generally used in combination with a thin buffer oxide between the silicon and the nitride to prevent the silicon from cracking due to thermal stresses. The buffer oxide acts as a conduct for the oxidants, extending the field oxidation beyond the edges of the active areas. In order to improve the LOCOS and isolation processes, many studies (2-6) have been made. The adjustment of the relative thicknesses of nitride and buffer oxide was attempted, to reduce the lateral oxide extension (3). Stress analysis (7, 8) was done, to suppress the edge lifting of the nitride that enhances the lateral penetration of the oxidant. More recently, the sidewall mask isolation (SWAMI) (9-11) process was developed in which a nitride layer made of nitride, oxide, and silicon is conformally deposited on active areas with nearly vertical sidewalls. Unmasked RIE etching of the nitride layer leaves nitride sidewall protection along the mesa perimeter, which blocks the penetration of the oxidant into the buffer oxide (12). A relatively sharp oxide edge was obtained by means of a progressive nitride edge lifting on the sidewall and planar surfaces during oxidation. This process was done by controlling the silicon etch depth, with added cost and process complexity.

Another method used to prevent channeling of the oxidant through the buffer oxide is sealed interface localized oxidation (SILO) (13, 14) where a thin silicon nitride layer is formed directly on silicon to seal the interface. One type of SILO nitride is formed by a direct thermal reaction of silicon under ammonia plasma (15). The most important factor is preservation of the original silicon from contamination and defect generation. In this regard, nitrogen implantation appears to be the better method because it is cleaner and generates a more gradual transition between silicon and silicon nitride. Etch pitting along the nitride mask was not observed for the implanted nitride (12). Oxidation inhibition in nitrogen-implanted silicon has been studied for the N₂⁺ energies between 40 and 200 keV and doses between 10¹⁵ and 4×10^{16} N₂⁺/cm² (16). The characterization of the implanted film has also been performed for a high energy range, from 48 to 150 keV (17-20).

The purpose of this study was to characterize an implanted-nitrogen layer formed at low energy and to optimize the implant conditions for application to LOCOS. For film characterization differential Fourier transform infrared (FTIR) and secondary ion mass spectroscopy (SIMS) analyses were extensively used before and after the nitridization annealing. The FTIR spectrum produces useful information about the structural changes in the nitride layers. The concentration profiles made by SIMS help us to understand the real nitrogen distribution after

Key words: semiconductor, dielectric isolation, ion implantation, LOCOS, annealing.

each process step. We observed that nitrides formed by implantation at an energy below 40 keV effectively mask 5300Å steam oxidation. The low energy nitride is also selectively etchable for exposing the active area for subsequent device processing. Among the low energy nitrides, both optimum and practical process conditions could be found through extensive analysis and property characterization.

Experimental Procedure

The substrates used for the experiment were <100> n-type silicon wafers with an average resistivity of 5 Ω -cm. The interstitial oxygen content of the Czochralski-grown wafer was analyzed by infrared (IR) spectroscopy, according to the ASTM F121-80 method. The oxygen content was determined to be about 1.7×10^{18} atom/cm³.

To form a nitrogen-implantation mask, the wafers were oxidized in steam at 1000°C to grow 0.3 μ m of SiO₂. The oxide was patterned to form three different regions: test structures, uniform oxide cover, and bare silicon. Instead of 0.3 μ m SiO₂, a resist pattern was also used as an implantation mask for some of the wafers. The test structure contained a variety of 1-9 μ m² windows, which made it possible to test whether such small patterns can be resolved during oxidation. By virtue of the masking properties of oxide and resist, only the openings in the test patterns and the exposed silicon were nitrogen doped; the nitrogen implant was blocked elsewhere. Molecular nitrogen ions (N₂⁺) at an energy range of between 5 and 60 keV were implanted with doses between 1×10^{16} and 5×10^{16} N₂⁺ ion/cm². The temperature of the wafers was kept near room temperature (20° ± 2°C) during implantation. The nitrogen concentration profile was measured with a Cameca IMS 3-ion microscope using Se⁺ primary ions. In order to maximize the detection sensitivity, the ⁴²SiN⁺ species was profiled. Differential FTIR was used for IR spectroscopy in the energy range of 400-4000 cm⁻¹. After the initial nitrogen profile was made and IR spectroscopic analysis completed, the wafers were annealed in dry nitrogen at 1000°C for 1h. Postannealing analyses using SIMS and IR were also performed to compare the property changes.

Field oxidation was then carried out under conditions similar to those for conventional LOCOS. Thus, nitrogen-implanted LOCOS was performed in steam at 1000°C for selective growth of 5380Å oxide. Wafers with different

doses and ion energies were examined with a scanning electron microscope (SEM). The thicknesses of nitrides and field oxides were also measured with an ellipsometer at a wavelength of 0.6328 μ m. The step height between the nitride and local oxide was measured with a mechanical surface profilometer (Dektak). The masking nitride was etched away in hot phosphoric acid at 180°C to check the etch selectivity of the Si₃N₄ vs. the SiO₂.

Results and Discussion

FTIR analysis.—Figure 1 shows the IR spectra of areas implanted with a dose of 5×10^{16} N₂⁺/cm². The implantation energies were 5, 10, 20, 30, 40, 50, and 60 keV, as specified.

In order to obtain an accurate measurement of the Si-N bonds, a differential intensity spectrum was plotted for each sample. That is, the IR absorptions from the nitrogen-implanted and unimplanted areas were first obtained; then the latter was subtracted from the former to find the contribution of nitrogen. The large peaks, near 815 cm⁻¹, are associated with Si-N bond vibration caused by nitrogen interstitials. The small peaks at 1115 and 620 cm⁻¹ for the oxidized specimens were contributed by the uncompensated oxygen and silicon of the reference area. Assuming that 0.18 μ m of silicon was consumed for the oxidation and that the original wafer thickness was 343 μ m, a fraction of each element, equivalent to 0.18/343, is responsible for the uncompensated peaks. The resist-masked wafers (NC2-1, 2, and 3) do not have these minor peaks, but only a broad low-energy peak near 490 cm⁻¹, which can be linked with the inherent nitride bonds in a pure nitride spectrum.

The measured absorbances are effective absorbances; we assume that the reflective loss variations to implant energy are small. The peak absorption intensities in Fig. 1 are different from each other. The peak absorbance increases with ion implantation energy, although the dose is fixed. The intensity decrease at low energy may be caused by a larger loss of nitrogen near the surface for low energy implants and by a larger fraction of inactive nitrogen atoms in the high concentration region. The native oxide of the implanted wafer was measured to be about 20Å. Since the projected range is lower for lower energy, the number of nitrogen ions captured by the native oxide is correspondingly higher. In our case, the doped native oxide had been etched away together with

Fig. 1. IR absorbance spectrums of implanted nitrogen at specified energies. The major peak is centered at 820 cm⁻¹. The resist-masked NC2-1, 2, and 3 have better nitride spectra, with absence of the false peak near 420 cm⁻¹.

Fig. 2. Effect of N_2^+ fluence on the IR intensity for 50 keV implantation. The intensity is proportional to the fluence.

the masking oxide on the reference area, carrying away its share of N_2 atoms. However, the major cause of the peak intensity reduction may be linked to inactive excess nitrogen atoms, such as nitrogen bubbles, in the high concentration layer implanted at low energy, which cannot contribute to the IR absorption. According to a TEM analysis of a nitrogen-implanted silicon layer (21), nitrogen bubbles actually were observed. The measured absorbances for 5, 10, 15, 30, 40, 50, and 60 keV wafers are 0.026, 0.030, 0.044, 0.048, 0.051, 0.055, and 0.056, respectively. All the peaks are consistently positioned at 815 cm^{-1} .

Figure 2 shows the change of the nitrogen peak intensity with the ion dose. With the energy fixed at 50 keV, NC2-8 with a dose of $1 \times 10^{16} \text{ N}_2^+/\text{cm}^2$ is compared to NC2-6 with a dose of $5 \times 10^{16} \text{ N}_2^+/\text{cm}^2$. The NC2-8 peak intensity is 0.012, approximately one-fifth of the NC2-6

peak intensity, which indicates that the inactive nitrogen loss is very small at 50 keV. This finding agrees with the results shown in Fig. 1: while the intensity losses decrease from 15% to 30 keV to 7% at 40 keV, there is little change from 50 to 60 keV. Because the implantation energy must be minimized without a significant loss of nitrogen ions, it was concluded that there is no need to increase the implantation energy above 50 keV.

Figure 3 shows an IR spectrum of the nitride layers after annealing in nitrogen at 1000°C for 1 h. There is little loss of nitrogen intensity, except for the 5 keV specimen having an extremely shallow layer. However, there are two significant changes in peak position and peak width. While the high energy peaks are broadening, the low energy peaks are being sharpened. The most significant phenomenon is that the peak position is dependent on

Fig. 3. IR spectrum after nitridation annealing for 1h at 1000°C . The amount of peak shift increases with energy.

the implantation energy. The peak positions of 5, 10, 20, 30, and 60 keV specimens are 840, 845, 855, 865, and 875, respectively. While the peak for the 5 keV wafer was shifted by 25 cm^{-1} from the original 815 cm^{-1} , the peak for the 60 keV wafer was shifted by 50 cm^{-1} .

In order to compare the properties of the implanted nitride with those of a pure nitride, an IR spectrum of a deposited nitride was made. An LPCVD furnace was used for the nitride deposition at 825°C from SiH_2Cl_2 and NH_3 . The measured thickness was 877\AA . The peak position of the Si-N absorbance of the LPCVD nitride was 833 cm^{-1} . The low-energy peak, near 490 , was attributed to single-phonon absorption (19) in regions of damaged or strained silicon adjacent to and in the nitride layer. Since the peak position was closely related to the stoichiometric ratio of the compound (6), the nitride layers made with an implantation energy lower than 10 keV approached a N/Si ratio of $4/3$.

Nitrogen redistribution.—The absolute nitrogen density was measured by SIMS profile, as implanted and after annealing at 1000°C . The initial distribution of the implanted nitrogen was close to the standard Gaussian distribution, except for the appearance of a shoulder at a concentration level of about $10^{19}/\text{cm}^3$. This shoulder is associated with the deeper penetration of monatomic nitrogen generated from the dissociation of molecular nitrogen ions. The profile was calibrated by using the as-implanted sample (6). By comparing the intensity counts of the sample with the intensity counts of the known peak concentration, the actual nitrogen concentration profile could be obtained.

Figure 4 shows the nitrogen concentration profile for six different implantation energies of molecular nitrogen ions. The total dose of these profiles is fixed at $5 \times 10^{16} \text{ N}_2^+/\text{cm}^2$. A progressive reduction of penetration depth with lower implantation energy was observed, as expected. However, this result does not necessarily mean that all of the atoms are incorporated in the silicon layer. The appearance of the shoulder at the $10^{19}/\text{cm}^3$ level is particularly significant for the higher energy profile. Under these conditions, the collision impact is expected to

be higher, with a larger proportion of monatomic nitrogen atoms being generated. The larger the number of dissociated N_2^+ molecules, the more pronounced is the shoulder.

The projected range, R_p , for 50 keV implantation is about 696\AA . Thus, the nitrogen fluence required to make stoichiometric Si_3N_4 is approximately $2.1 \times 10^{17} \text{ N}_2^+/\text{cm}^2$ from a relation of $F = C \cdot R_p \cdot d$, where F is the dose (N_2^+/cm^2) of molecular nitrogen, C is number of nitrogen ions per molecule, and d is molecular density. Compared to the atomic oxygen fluence required for buried oxide isolation (6), the theoretical fluence for implanted nitride is lower by a factor of 6. Moreover, the experimental dose is even smaller, as will be seen in the annealed profiles.

After annealing, the concentration profile moves to the left of the initial curve. (Indeed, each of the annealed curves shown in Fig. 8 and 9 moved toward the surface.) This is opposite to a normal thermal redistribution, where the profile widens and moves to the right. We explain this singularity as follows. The peak of energy deposition in the crystal, because of the atomic collisions associated with ion implantation, takes place to the left of the concentration peak (6). Hence, the profile of vacancies and defects created by implantation damage also lies to the left of the nitrogen concentration peak (6). These defects attract nitrogen to the left, to form silicon nitride during the high temperature annealing process.

The nitrogen migration not only shifts the peak position, but also increases the nitrogen concentration at the peak. This is a natural consequence of the accumulation of nitrogen in a narrower layer while preserving the area density. The nitrogen migration toward the vacancy peak creates an effective oxidation mask, even with a nitrogen fluence of $5 \times 10^{16} \text{ N}_2^+/\text{cm}^2$ and with low implantation energy. Several unique features can be noted in the curves of Fig. 5 and 6. In addition to the concentration profile shift to the left after annealing, the shape of the profile changes. The increase in peak nitrogen concentration after annealing was linked with the implantation-induced defects, as explained above. The shoulder associated with the monatomic nitrogen tends to disappear during annealing. This is particularly significant for the 60 keV case. Since the diffusivity of the nitrogen atoms is much

Fig. 4. SIMS profile of nitrogen implanted at specified energies for $5 \times 10^{16} \text{ N}_2^+/\text{cm}^2$.

Fig. 5. Concentration profile shift toward the surface by annealing. The monatomic nitrogen "shoulder" disappears with annealing.

higher than that of molecular nitrogen ions, the nitrogen atoms can migrate to the peak at a much faster rate. This assumption is supported by the fact that all of the lower parts of the annealed curves are shifted much more than the upper parts. All the annealed curves with energy above 20 keV show that the concentration peak is located well below the surface, which means that a complete extension of nitride to the surface is lacking. The remaining silicon layer on the surface will interfere with the selective etching of nitride on the active area. The annealed samples implanted at 5 and 10 keV, which do not have the concentration peak below the surface, are more useful for the practical applications of nitrogen-implanted LOCOS. All of the annealed curves are plotted together in Fig. 7. As the implantation energy decreases, the peak concentration increases in a way similar to the as-implanted. The peak plateau of the 10 keV curve exactly matches the surface of the wafer. The 5 keV profile shows neither peak nor plateau, which indicates that a large amount of nitro-

gen is lost by outdiffusion during annealing. This loss is apparent for curve 1 in Fig. 7, where the 5 keV profile after annealing did not reach the concentration peak of the as-implanted. This loss is also confirmed by the IR intensity reduction shown in Fig. 3. However, for 10 keV, the plateau of curve 2 is perpendicular to the surface and the IR intensity loss is negligible. Therefore, the 10 keV implantation appears to be superior for forming the densest nitride at the surface, for only the annealing conditions described.

Practice of nitrogen-implanted LOCOS.—The nitrogen-implanted nitrides were tested for the effectiveness of oxidation masking during a field oxidation in steam. All the wafers were selectively implanted with molecular nitrogen ions in the 5-60 keV energy range. They were then annealed in N_2 for 1h at 1000°C to form nitride patterns. Annealing in another inert ambient such as argon or helium would be as effective. These nitride patterns were used as an oxidation mask during a steam oxidation at 1000°C for

Fig. 6. Concentration profile changes of the 5, 10, and 20 keV nitrogen-implanted samples after annealing. The peak of the 20 keV sample remains under the surface, that of 10 keV coincides with the surface, and that of 5 keV disappears.

Fig. 7. Nitride profile after annealing. All the peak concentrations increase except the nitride made from implantation at 5 keV.

2h, which produced an oxide 5380Å thick over bare silicon.

The most effective method of evaluating the masking capability of the nitrides was found to be the step height measurement. Figure 8 shows the step heights measured between the nitrides and field oxides. A large step of about 3030Å was generated up to 40 keV, but the step height rapidly declined above 40 keV. The observed step

height for the 50 keV wafer was 2800Å, and that for the 60 keV wafer was only 1600Å. In order to show the effect of nitrogen fluence, the step height produced by 1×10^{16} N₂⁺/cm² at 50 keV is also presented in Fig. 8. In this case, the step was only 620Å, indicating no masking capability. The measured layer thicknesses in the regions implanted at 50 keV nitride with 5×10^{16} N₂⁺/cm² dosage, 60 keV nitride with 5×10^{16} N₂⁺/cm² dosage, and 50 keV nitride with

Fig. 8. Field oxide step height as a function of nitrogen implantation energy, measured from the masking nitrides. The nitrides with implantation higher than 50 keV are not capable of masking 5300Å steam oxidation at 1000°C.

1×10^{16} N_2^+ /cm² dosage were, respectively, 1290, 2100, and 4950 Å after the local oxidation. The thick nitrides after annealing are not true nitrides, but are matrices of silicon and nitride. During LOCOS, the silicon crystals are apparently oxidized, and the oxidizing agents are channeled through the partial oxides. Thus, the low concentrated, thick nitrides do not have masking capability against the oxidation. The lower the energy is, the higher the nitrogen concentration and the more effective the mask, as shown in Fig. 8. However, a 5×10^{16} N_2^+ /cm² dose implantation at 5 keV required 9h, with a medium-current implanter (Extrion Model 200 CF4), and a low energy one is not economical. The slight deviation from the horizontal level of the step height for 5 and 10 keV in Fig. 8 comes from the thinner nitrides produced at these energies.

Figure 9 shows SIMS profiles of nitride (SiN^+) and silicon (Si^{++}) of the regions with 5×10^{16} N_2^+ /cm² dosage at 40 keV and 1×10^{16} N_2^+ /cm² dosage at 60 keV after the field oxidation. The dense nitride is retained after the field oxidation with a formation of oxide on its top. Since the step height shown in Fig. 8 does not change much up to 40 keV, it seems that the surface oxidation apparently pushes the nitride inward, leaving some trace of nitride at the surface. The 60 keV profile also supports the result shown in Fig. 8. The oxynitride profile step approximately coincides with the measured dielectric thickness.

A selective nitride etching experiment was performed after utilizing the masking properties. All of the locally oxidized wafers were submerged in hot phosphoric acid at 180°C, after the hydrofluoric acid (HF) dip, to remove the surface oxide. While the thin nitrides could be selectively etched away, the thicker nitrides were not completely etched away and left hazy surfaces. The thicker nitrides could easily be etched away with 10% buffered HF. This fact indicates that they are oxide and nitride mixtures with compositions closer to oxide when the implantation energy is high. This experiment also suggests that the thinner nitride is superior for etching selectivity and desirable for the nitrogen-implanted LOCOS (NILO) process.

Figure 10 shows a comparison of a conventional LOCOS cross section with one made by this method. In the case of Fig. 10a, there is a 300 Å buffer SiO_2 layer between the 800 Å LPCVD nitride and the silicon substrate. The buffer oxide is thermally grown to protect the silicon surface from cracking due to thermal stresses caused by the nitride. The buffer oxide layer becomes a route for the

oxidant to diffuse underneath the nitride, thus extending the oxidation within the perimeter of the active area. The extended oxidation can exert enough force to lift the nitride edges, resulting in an accelerated oxidant channeling. The parasitic lateral oxidation channel, known as a "bird's beak," in this case is 0.75 μ m long. Since it is nearly constant, as shown in Fig. 10b, it limits scaling to 1 or <1 μ m VLSI circuits. Conversely, in the case of nitrogen implantation, no native oxide exists. Since the nitride is formed by a direct reaction with silicon, the interface is completely sealed. Initially, the oxidation takes place only vertically. As the oxidation proceeds isotropically at the nitride edges, the silicon is oxidized laterally, but at a much slower rate. In Fig. 10c, the lateral extension of oxide is about 0.2 μ m, which is about a four-fold reduction from the conventional LOCOS result, previously reported.

Conclusions

The relevant features of the NILO process are summarized as follows. For a fixed fluence, the intensity of Si-N bond absorption significantly increases with the nitrogen-implanted energy up to 50 keV. The Si-N absorption peak is centered at 815 cm^{-1} for all the implanted layers in the energy range between 5 and 60 keV. At higher implantation energy (~ 50 keV), the absorption intensity is proportional to the fluence of nitrogen implantation. The peak position of the IR spectrum after annealing shifts to a higher wave number as the nitrogen implantation energy increases. The IR peaks for the low energy implanted wafers are close to those for LPCVD-deposited nitrides. The annealing always shifts the nitrogen profile toward the surface, and the annealed peak concentration is higher than the as-implanted, except at 5 keV implantation. The nitride profile peaks are located below the surface for all the implantation energies above 20 keV. The peak plateau for 10 keV coincides with the surface, whereas the 5 keV peak disappears after the 1000°C annealing. The nitrides made with an implantation dose of 5×10^{16} N_2^+ /cm² and energy less than 40 keV effectively mask 5380 Å steam oxidation at 1000°C. The nitrides with energy higher than 40 keV and lower dosage are converted to oxynitrides during the NILO process. The low energy nitrides can be selectively etched in hot phosphoric acid, whereas the high energy oxynitride is more readily etched in hydrofluoric acid. Experimentally, the nitride formed with 10 keV implantation appears to be the most practical and effective NILO mask. The lateral

Fig. 9. SIMS profiles of the nitride and silicon in the implanted regions after the field oxidation. The dense nitride with 5×10^{16} N_2^+ /cm² dosage at 40 keV survives, whereas the nitride with 1×10^{16} N_2^+ /cm² dosage at 40 keV is completely converted to oxynitride.
